The Journal of Machine Learning Research
Print-Archive Edition
Volume 18 (papers from 2017)
Issues 1–73

The Journal of Machine Learning Research (JMLR) is an open access journal. All articles published in JMLR are freely available via electronic distribution. This Print-Archive Edition is published annually as a means of archiving the contents of the journal in perpetuity. The contents of this edition are articles published electronically in JMLR in 2017.

JMLR is abstracted in ACM Computing Reviews, INSPEC, and Psychological Abstracts/PsycINFO.

JMLR is a publication of Journal of Machine Learning Research, Inc. For further information regarding JMLR, including open access to articles, visit http://www.jmlr.org/.

JMLR Print-Archive Edition is a publication of Microtome Publishing under agreement with Journal of Machine Learning Research, Inc. For further information regarding the Print-Archive Edition, including subscription and distribution information and background on open-access print archiving, visit Microtome Publishing at http://www.mtome.com/.

Collection copyright © 2017 The Journal of Machine Learning Research, Inc. and Microtome Publishing.
Individual articles copyright © 2017 by their respective authors and distributed under a Creative Commons Attribution 4.0 International License.

ISSN 1532-4435 (print)
ISSN 1533-7928 (online)

JMLR Editorial Board

Editor-in-Chief
Bernhard Schölkopf, MPI for Intelligent Systems, Germany

Editor-in-Chief
Kevin Murphy, Google Research, USA

Managing Editor
Aron Culotta, Illinois Institute of Technology, USA

Production Editor
Charles Sutton, University of Edinburgh, UK

JMLR Web Master
Chiyuan Zhang, Massachusetts Institute of Technology, USA

JMLR Action Editors
Ryan Adams, Princeton University, USA. **Shivani Agarwal**, University of Pennsylvania, USA. **Edoardo M. Airoldi**, Harvard University, USA. **Anima Anandkumar**, California Institute of Technology, USA. **Peter Auer**, University of Leoben, Austria. **David Barber**, University College London, UK. **Samy Bengio**, Google Research, USA. **Yoshua Bengio**, Université de Montréal, Canada. **Jeff Bilmes**, University of Washington, USA. **Karsten Borgwardt**, ETH Zurich, Switzerland. **Léon Bottou**, Facebook AI Research. **François Caron**, University of Oxford, United Kingdom. **Miguel A. Carreira-Perpinan**, University of California, Merced, USA. **Alexander Clark**, King's College London, UK. **Corinna Cortes**, Google Research, USA. **Koby Crammer**, Technion, Israel. **Sanjoy Dasgupta**, University of California, San Diego, USA. **Inderjit S. Dhillon**, University of Texas, Austin, USA. **Jennifer Dy**, Northeastern University, USA. **Gal Elidan**, Hebrew University, Israel. **Charles Elkan**, University of California at San Diego, USA. **Barbara Engelhardt**, Princeton University, USA. **Rob Fergus**, New York University, USA. **Kenji Fukumizu**, The Institute of Statistical Mathematics, Japan **Amir Globerson**, Tel Aviv University, Israel **Moises Goldszmidt**, Microsoft Research, USA. **Russ Greiner**, University of Alberta, Canada. **Arthur Gretton**, University College London, UK. **Maya Gupta**, Google Research, USA. **Isabelle Guyon**, ClopiNet, USA. **Moritz Hardt**, Google Research, USA. **Thomas Hofmann**, ETH Zurich, Switzerland **Bert Huang**, Virginia Tech, USA. **Aapo Hyvärinen**, University of Helsinki, Finland **Alex Ihler**, University of California, Irvine, USA. **Tommi Jaakkola**, Massachusetts Institute of Technology, USA. **Samuel Kaski**, Aalto University, Finland **Sathiya Keerthi**, Microsoft Research, USA. **Emtiyaz Khan**, RIKEN Center for Advanced Intelligence, Japan **George Konidaris**, Duke University, USA. **Andreas Krause**, ETH Zurich, Switzerland **Sanjiv Kumar**, Google Research, USA. **Christoph Lampert**, Institute of Science and Technology, Austria **Daniel Lee**, University of Pennsylvania, USA. **Qiang Liu**, Dartmouth College, USA. **Gábor Lugosi**, Pompeu Fabra University, Spain **Michael Mahoney**, University of California at Berkeley, USA. **Shie Mannor**, Technion, Israel **Jon McAuliffe**, University of California at Berkeley, USA. **Robert E. McCulloch**, University of Chicago, USA. **Chris Meek**, Microsoft Research, USA. **Qiaozhu Mei**, University of Michigan, USA. **Vahab Mirrokni**, Google Research, USA. **Mehryar Mohri**, New York University, USA. **Joris Mooij**, University of Amsterdam, Netherlands **Boaz Nadler**, Weizmann Institute of Science, Israel. **Long Nguyen**, University of Michigan, USA. **Sebastian Nowozin**, Microsoft Research, Cambridge, UK **Una-May O'Reilly**, Massachusetts Institute of Technology, USA. **Manfred**

Opper, Technical University of Berlin, Germany **Laurent Orseau**, Google Deepmind, USA. **Luis Ortiz**, University of Michigan - Dearborn, USA. **Jie Peng**, University of California, Davis, USA. **Jan Peters**, Technische Universitaet Darmstadt, Germany **Avi Pfeffer**, Charles River Analytics, USA. **Joelle Pineau**, McGill University, Canada. **Massimiliano Pontil**, Istituto Italiano di Tecnologia (Italy), University College London (UK) **Luc de Raedt**, Katholieke Universiteit Leuven, Belgium **Alexander Rakhlin**, University of Pennsylvania, USA. **Ben Recht**, University of California, Berkeley, USA. **Lorenzo Rosasco**, Massachusetts Institute of Technology, USA. **Saharon Rosset**, Tel Aviv University, Israel **Ruslan Salakhutdinov**, University of Toronto, Canada. **Sujay Sanghavi**, University of Texas, Austin, USA. **Mark Schmidt**, University of British Columbia, Canada. **Marc Schoenauer**, INRIA Saclay, France **John Shawe-Taylor**, University College London, UK **Xiaotong Shen**, University of Minnesota, USA. **David Sontag**, New York University, USA. **Peter Spirtes**, Carnegie Mellon University, USA. **Nathan Srebro**, Toyota Technical Institute at Chicago, USA. **Ingo Steinwart**, University of Stuttgart, Germany **Amos Storkey**, University of Edinburgh, UK **Csaba Szepesvari**, University of Alberta, Canada. **Olivier Teytaud**, INRIA Saclay, France **Ivan Titov**, University of Amsterdam, Netherlands **Ryan Tibshirani**, Carnegie Mellon University **Ryota Tomioka**, Microsoft Research Cambridge, UK **Koji Tsuda**, National Institute of Advanced Industrial Science and Technology, Japan **Zhuowen Tu**, University of California at San Diego, USA. **Nicolas Vayatis**, ENS Cachan, France **S V N Vishwanathan**, Purdue University, USA. **Manfred Warmuth**, University of California at Santa Cruz, USA. **Kilian Weinberger**, Cornell University, USA. **David Wipf**, Microsoft Research Asia, China **Daniela Witten**, University of Washington. **Stefan Wrobel**, Fraunhofer IAIS and University of Bonn, Germany **Eric Xing**, Carnegie Mellon University, USA. **Tong Zhang**, Baidu Inc, China **Zhihua Zhang**, Peking University, China **Hui Zou**, University of Minnesota, USA.

JMLR MLOSS Editors

Alexandre Gramfort, INRIA, Université Paris-Saclay, France **Antti Honkela**, University of Helsinki, Finland **Balázs Kégl**, CNRS / Université Paris-Saclay, France **Cheng Soon Ong**, Australian National University, Australia

Journal of Machine Learning Research

Volume 18 (papers from 2017)
Volume year 2018

Part A

18(1):1–29 **Averaged Collapsed Variational Bayes Inference**
Katsuhiko Ishiguro, Issei Sato, Naonori Ueda

18(2):1–45 **Scalable Influence Maximization for Multiple Products in Continuous-Time Diffusion Networks**
Nan Du, Yingyu Liang, Maria-Florina Balcan, Manuel Gomez-Rodriguez, Hongyuan Zha, Le Song

18(3):1–35 **Local algorithms for interactive clustering**
Pranjal Awasthi, Maria Florina Balcan, Konstantin Voevodski

18(4):1–5 **SnapVX: A Network-Based Convex Optimization Solver**
David Hallac, Christopher Wong, Steven Diamond, Abhijit Sharang, Rok Sosič, Stephen Boyd, Jure Leskovec

18(5):1–30 **Communication-efficient Sparse Regression**
Jason D. Lee, Qiang Liu, Yuekai Sun, Jonathan E. Taylor

18(6):1–36 **Improving Variational Methods via Pairwise Linear Response Identities**
Jack Raymond, Federico Ricci-Tersenghi

18(7):1–37 **Distributed Sequence Memory of Multidimensional Inputs in Recurrent Networks**
Adam S. Charles, Dong Yin, Christopher J. Rozell

18(8):1–35 **Persistence Images: A Stable Vector Representation of Persistent Homology**
Henry Adams, Tegan Emerson, Michael Kirby, Rachel Neville, Chris Peterson, Patrick Shipman, Sofya Chepushtanova, Eric Hanson, Francis Motta, Lori Ziegelmeier

18(9):1–57 **Spectral Clustering Based on Local PCA**
Ery Arias-Castro, Gilad Lerman, Teng Zhang

18(10):1–33 **On Perturbed Proximal Gradient Algorithms**
Yves F. Atchadé, Gersende Fort, Eric Moulines

18(11):1–39 **Differential Privacy for Bayesian Inference through Posterior Sampling**
Christos Dimitrakakis, Blaine Nelson, Zuhe Zhang, Aikaterini Mitrokotsa, Benjamin I. P. Rubinstein

18(12):1–5 **Refinery: An Open Source Topic Modeling Web Platform**
Daeil Kim, Benjamin F. Swanson, Michael C. Hughes, Erik B. Sudderth

18(13):1–43 **Using Conceptors to Manage Neural Long-Term Memories for Temporal Patterns**
Herbert Jaeger

18(14):1–45 **Automatic Differentiation Variational Inference**
Alp Kucukelbir, Dustin Tran, Rajesh Ranganath, Andrew Gelman, David M. Blei

18(15):1–35 **Empirical Evaluation of Resampling Procedures for Optimising SVM Hyperparameters**
Jacques Wainer, Gavin Cawley

18(16):1–49 **A Unified Formulation and Fast Accelerated Proximal Gradient Method for Classification**
Naoki Ito, Akiko Takeda, Kim-Chuan Toh

18(17):1–5 **Imbalanced-learn: A Python Toolbox to Tackle the Curse of Imbalanced Datasets in Machine Learning**
Guillaume Lemaître, Fernando Nogueira, Christos K. Aridas

18(18):1–65 **Information-Geometric Optimization Algorithms: A Unifying Picture via Invariance Principles**
Yann Ollivier, Ludovic Arnold, Anne Auger, Nikolaus Hansen

18(19):1–53 **Breaking the Curse of Dimensionality with Convex Neural Networks**
Francis Bach

18(20):1–32 **Memory Efficient Kernel Approximation**
Si Si, Cho-Jui Hsieh, Inderjit S. Dhillon

18(21):1–38 **On the Equivalence between Kernel Quadrature Rules and Random Feature Expansions**
Francis Bach

18(22):1–40 **Analyzing Tensor Power Method Dynamics in Overcomplete Regime**
Animashree Anandkumar, Rong Ge, Majid Janzamin

18(23):1–5 **JSAT: Java Statistical Analysis Tool, a Library for Machine Learning**
Edward Raff

18(24):1–29 **Identifying a Minimal Class of Models for High–dimensional Data**
Daniel Nevo, Ya'acov Ritov

18(25):1–5 **Auto-WEKA 2.0: Automatic model selection and hyperparameter optimization in WEKA**
Lars Kotthoff, Chris Thornton, Holger H. Hoos, Frank Hutter, Kevin Leyton-Brown

18(26):1–5 **POMDPs.jl: A Framework for Sequential Decision Making under Uncertainty**
Maxim Egorov, Zachary N. Sunberg, Edward Balaban, Tim A. Wheeler, Jayesh K. Gupta, Mykel J. Kochenderfer

18(27):1–32 **Generalized Pólya Urn for Time-Varying Pitman-Yor Processes**
François Caron, Willie Neiswanger, Frank Wood, Arnaud Doucet, Manuel Davy

18(28):1–39 **Particle Gibbs Split-Merge Sampling for Bayesian Inference in Mixture Models**
Alexandre Bouchard-Côté, Arnaud Doucet, Andrew Roth

18(29):1–53 **Certifiably Optimal Low Rank Factor Analysis**
Dimitris Bertsimas, Martin S. Copenhaver, Rahul Mazumder

18(30):1–52 **Group Sparse Optimization via lp,q Regularization**
Yaohua Hu, Chong Li, Kaiwen Meng, Jing Qin, Xiaoqi Yang

18(31):1–32 **Preference-based Teaching**
Ziyuan Gao, Christoph Ries, Hans U. Simon, Sandra Zilles

18(32):1–40 **Nonparametric Risk Bounds for Time-Series Forecasting**
Daniel J. McDonald, Cosma Rohilla Shalizi, Mark Schervish

18(33):1–39 **Online Bayesian Passive-Aggressive Learning**
Tianlin Shi, Jun Zhu

18(34):1–41 **Asymptotic Analysis of Objectives Based on Fisher Information in Active Learning**
Jamshid Sourati, Murat Akcakaya, Todd K. Leen, Deniz Erdogmus, Jennifer G. Dy

18(35):1–39 **A Spectral Algorithm for Inference in Hidden semi-Markov Models**
Igor Melnyk, Arindam Banerjee

18(36):1–30 **Simplifying Probabilistic Expressions in Causal Inference**
Santtu Tikka, Juha Karvanen

18(37):1–22 **Nearly optimal classification for semimetrics**
Lee-Ad Gottlieb, Aryeh Kontorovich, Pinhas Nisnevitch

18(38):1–39 **Bridging Supervised Learning and Test-Based Co-optimization**
Elena Popovici

18(39):1–5 **GFA: Exploratory Analysis of Multiple Data Sources with Group Factor Analysis**
Eemeli Leppäaho, Muhammad Ammad-ud-din, Samuel Kaski

18(40):1–6 **GPflow: A Gaussian Process Library using TensorFlow**
Alexander G. de G. Matthews, Mark van der Wilk, Tom Nickson, Keisuke Fujii, Alexis Boukouvalas, Pablo León-Villagrá, Zoubin Ghahramani, James Hensman

18(41):1–49 **COEVOLVE: A Joint Point Process Model for Information Diffusion and Network Evolution**
Mehrdad Farajtabar, Yichen Wang, Manuel Gomez-Rodriguez, Shuang Li, Hongyuan Zha, Le Song

18(42):1–60 **Learning Local Dependence In Ordered Data**
Guo Yu, Jacob Bien

18(43):1–29 **Bayesian Learning of Dynamic Multilayer Networks**
Daniele Durante, Nabanita Mukherjee, Rebecca C. Steorts

18(44):1–29 **Time-Accuracy Tradeoffs in Kernel Prediction: Controlling Prediction Quality**
Samory Kpotufe, Nakul Verma

18(45):1–21 **Asymptotic behavior of Support Vector Machine for spiked population model**
Hanwen Huang

18(46):1–22 **Distributed Semi-supervised Learning with Kernel Ridge Regression**
Xiangyu Chang, Shao-Bo Lin, Ding-Xuan Zhou

18(47):1–43 **On Markov chain Monte Carlo methods for tall data**
Rémi Bardenet, Arnaud Doucet, Chris Holmes

18(48):1–33 **Explaining the Success of AdaBoost and Random Forests as Interpolating Classifiers**
Abraham J. Wyner, Matthew Olson, Justin Bleich, David Mease

18(49):1–47 **Clustering from General Pairwise Observations with Applications to Time-varying Graphs**
Shiau Hong Lim, Yudong Chen, Huan Xu

18(50):1–41 **Uniform Hypergraph Partitioning: Provable Tensor Methods and Sampling Techniques**
Debarghya Ghoshdastidar, Ambedkar Dukkipati

18(51):1–24 **Reconstructing Undirected Graphs from Eigenspaces**
Yohann De Castro, Thibault Espinasse, Paul Rochet

18(52):1–11 **An Optimal Algorithm for Bandit and Zero-Order Convex Optimization with Two-Point Feedback**
Ohad Shamir

18(53):1–31 **Perishability of Data: Dynamic Pricing under Varying-Coefficient Models**
Adel Javanmard

18(54):1–24 **Two New Approaches to Compressed Sensing Exhibiting Both Robust Sparse Recovery and the Grouping Effect**
Mehmet Eren Ahsen, Niharika Challapalli, Mathukumalli Vidyasagar

18(55):1–35 **On the Consistency of Ordinal Regression Methods**
Fabian Pedregosa, Francis Bach, Alexandre Gramfort

18(56):1–26 **Statistical Inference with Unnormalized Discrete Models and Localized Homogeneous Divergences**
Takashi Takenouchi, Takafumi Kanamori

18(57):1–59 **Density Estimation in Infinite Dimensional Exponential Families**
Bharath Sriperumbudur, Kenji Fukumizu, Arthur Gretton, Aapo Hyvärinen, Revant Kumar

18(58):1–52 **Lens Depth Function and k-Relative Neighborhood Graph: Versatile Tools for Ordinal Data Analysis**
Matthäus Kleindessner, Ulrike von Luxburg

18(59):1–39 **Joint Label Inference in Networks**
Deepayan Chakrabarti, Stanislav Funiak, Jonathan Chang, Sofus A. Macskassy

18(60):1–45 **Achieving Optimal Misclassification Proportion in Stochastic Block Models**
Chao Gao, Zongming Ma, Anderson Y. Zhang, Harrison H. Zhou

18(61):1–33 **On the Propagation of Low-Rate Measurement Error to Subgraph Counts in Large Networks**
Prakash Balachandran, Eric D. Kolaczyk, Weston D. Viles

18(62):1–58 **Dense Distributions from Sparse Samples: Improved Gibbs Sampling Parameter Estimators for LDA**
Yannis Papanikolaou, James R. Foulds, Timothy N. Rubin, Grigorios Tsoumakas

18(63):1–29 **Fundamental Conditions for Low-CP-Rank Tensor Completion**
Morteza Ashraphijuo, Xiaodong Wang

18(64):1–34 **Parallel Symmetric Class Expression Learning**
An C. Tran, Jens Dietrich, Hans W. Guesgen, Stephen Marsland

18(65):1–35 **Learning Partial Policies to Speedup MDP Tree Search via Reduction to I.I.D. Learning**
Jervis Pinto, Alan Fern

18(66):1–42 **Hierarchically Compositional Kernels for Scalable Nonparametric Learning**
Jie Chen, Haim Avron, Vikas Sindhwani

18(67):1–29 **Sharp Oracle Inequalities for Square Root Regularization**
Benjamin Stucky, Sara van de Geer

18(68):1–43 **Soft Margin Support Vector Classification as Buffered Probability Minimization**
Matthew Norton, Alexander Mafusalov, Stan Uryasev

18(69):1–29 **Variational Particle Approximations**
Ardavan Saeedi, Tejas D. Kulkarni, Vikash K. Mansinghka, Samuel J. Gershman

18(70):1–37 **A Bayesian Framework for Learning Rule Sets for Interpretable Classification**
Tong Wang, Cynthia Rudin, Finale Doshi-Velez, Yimin Liu, Erica Klampfl, Perry MacNeille

18(71):1–46 **A Robust-Equitable Measure for Feature Ranking and Selection**
A. Adam Ding, Jennifer G. Dy, Yi Li, Yale Chang

18(72):1–32 **Multiscale Strategies for Computing Optimal Transport**
Samuel Gerber, Mauro Maggioni

18(73):1–46 **Non-parametric Policy Search with Limited Information Loss**
Herke van Hoof, Gerhard Neumann, Jan Peters

Part B

18(74):1–40 **Tests of Mutual or Serial Independence of Random Vectors with Applications**
Martin Bilodeau, Aurélien Guetsop Nangue

18(75):1–34 **Recovering PCA and Sparse PCA via Hybrid-(l1,l2) Sparse Sampling of Data Elements**
Abhisek Kundu, Petros Drineas, Malik Magdon-Ismail

18(76):1–61 **Quantifying the Informativeness of Similarity Measurements**
Austin J. Brockmeier, Tingting Mu, Sophia Ananiadou, John Y. Goulermas

18(77):1–36 **Time for a Change: a Tutorial for Comparing Multiple Classifiers Through Bayesian Analysis**
Alessio Benavoli, Giorgio Corani, Janez Demšar, Marco Zaffalon

18(78):1–44 **Relational Reinforcement Learning for Planning with Exogenous Effects**
David Martínez, Guillem Alenyà, Tony Ribeiro, Katsumi Inoue, Carme Torras

18(79):1–31 **Bayesian Tensor Regression**
Rajarshi Guhaniyogi, Shaan Qamar, David B. Dunson

18(80):1–50 **Robust Discriminative Clustering with Sparse Regularizers**
Nicolas Flammarion, Balamurugan Palaniappan, Francis Bach

18(81):1–36 **Making Decision Trees Feasible in Ultrahigh Feature and Label Dimensions**
Weiwei Liu, Ivor W. Tsang

18(82):1–37 **Learning Scalable Deep Kernels with Recurrent Structure**
Maruan Al-Shedivat, Andrew Gordon Wilson, Yunus Saatchi, Zhiting Hu, Eric P. Xing

18(83):1–52 **Convolutional Neural Networks Analyzed via Convolutional Sparse Coding**
Vardan Papyan, Yaniv Romano, Michael Elad

18(84):1–42 **Stochastic Primal-Dual Coordinate Method for Regularized Empirical Risk Minimization**
Yuchen Zhang, Lin Xiao

18(85):1–21 **Angle-based Multicategory Distance-weighted SVM**
Hui Sun, Bruce A. Craig, Lingsong Zhang

18(86):1–47 **Minimax Estimation of Kernel Mean Embeddings**
Ilya Tolstikhin, Bharath K. Sriperumbudur, Krikamol Muandet

18(87):1–28 **The Impact of Random Models on Clustering Similarity**
Alexander J. Gates, Yong-Yeol Ahn

18(88):1–35 **Hierarchical Clustering via Spreading Metrics**
Aurko Roy, Sebastian Pokutta

18(89):1–5 **The MADP Toolbox: An Open Source Library for Planning and Learning in (Multi-)Agent Systems**
Frans A. Oliehoek, Matthijs T. J. Spaan, Bas Terwijn, Philipp Robbel, João V. Messias

18(90):1–50 **A survey of Algorithms and Analysis for Adaptive Online Learning**
H. Brendan McMahan

18(91):1–35 **A distributed block coordinate descent method for training l1 regularized linear classifiers**
Dhruv Mahajan, S. Sathiya Keerthi, S. Sundararajan

18(92):1–31 **Distributed Learning with Regularized Least Squares**
Shao-Bo Lin, Xin Guo, Ding-Xuan Zhou

18(93):1–67 **Identifying Unreliable and Adversarial Workers in Crowdsourced Labeling Tasks**
Srikanth Jagabathula, Lakshminarayanan Subramanian, Ashwin Venkataraman

18(94):1–38 **An Easy-to-hard Learning Paradigm for Multiple Classes and Multiple Labels**
Weiwei Liu, Ivor W. Tsang, Klaus-Robert Müller

18(95):1–32 **Fisher Consistency for Prior Probability Shift**
Dirk Tasche

18(96):1–5 **openXBOW – Introducing the Passau Open-Source Crossmodal Bag-of-Words Toolkit**
Maximilian Schmitt, Björn Schuller

18(97):1–47 **Optimal Rates for Multi-pass Stochastic Gradient Methods**
Junhong Lin, Lorenzo Rosasco

18(98):1–29 **Rank Determination for Low-Rank Data Completion**
Morteza Ashraphijuo, Xiaodong Wang, Vaneet Aggarwal

18(99):1–32 **Bayesian Network Learning via Topological Order**
Young Woong Park, Diego Klabjan

18(100):1–37 **Stability of Controllers for Gaussian Process Dynamics**
Julia Vinogradska, Bastian Bischoff, Duy Nguyen-Tuong, Jan Peters

18(101):1–51 **Harder, Better, Faster, Stronger Convergence Rates for Least-Squares Regression**
Aymeric Dieuleveut, Nicolas Flammarion, Francis Bach

18(102):1–28 **Confidence Sets with Expected Sizes for Multiclass Classification**
Christophe Denis, Mohamed Hebiri

18(103):1–50 **Online Learning to Rank with Top-k Feedback**
Sougata Chaudhuri, Ambuj Tewari

18(104):1–72 **A Unifying Framework for Gaussian Process Pseudo-Point Approximations using Power Expectation Propagation**
Thang D. Bui, Josiah Yan, Richard E. Turner

18(105):1–23 **Accelerating Stochastic Composition Optimization**
Mengdi Wang, Ji Liu, Ethan X. Fang

18(106):1–37 **Distributed Bayesian Learning with Stochastic Natural Gradient Expectation Propagation and the Posterior Server**
Leonard Hasenclever, Stefan Webb, Thibaut Lienart, Sebastian Vollmer, Balaji Lakshminarayanan, Charles Blundell, Yee Whye Teh

18(107):1–28 **Optimal Dictionary for Least Squares Representation**
Mohammed Rayyan Sheriff, Debasish Chatterjee

18(108):1–37 **Computational Limits of A Distributed Algorithm for Smoothing Spline**
Zuofeng Shang, Guang Cheng

18(109):1–67 **Hinge-Loss Markov Random Fields and Probabilistic Soft Logic**
Stephen H. Bach, Matthias Broecheler, Bert Huang, Lise Getoor

18(110):1–49 **Clustering with Hidden Markov Model on Variable Blocks**
Lin Lin, Jia Li

18(111):1–55 **Approximation Vector Machines for Large-scale Online Learning**
Trung Le, Tu Dinh Nguyen, Vu Nguyen, Dinh Phung

18(112):1–29 **Efficient Sampling from Time-Varying Log-Concave Distributions**
Hariharan Narayanan, Alexander Rakhlin

18(113):1–24 **Document Neural Autoregressive Distribution Estimation**
Stanislas Lauly, Yin Zheng, Alexandre Allauzen, Hugo Larochelle

18(114):1–26 **Target Curricula via Selection of Minimum Feature Sets: a Case Study in Boolean Networks**
Shannon Fenn, Pablo Moscato

18(115):1–52 **A General Distributed Dual Coordinate Optimization Framework for Regularized Loss Minimization**
Shun Zheng, Jialei Wang, Fen Xia, Wei Xu, Tong Zhang

18(116):1–40 **Second-Order Stochastic Optimization for Machine Learning in Linear Time**
Naman Agarwal, Brian Bullins, Elad Hazan

18(117):1–49 **Regularized Estimation and Testing for High-Dimensional Multi-Block Vector-Autoregressive Models**
Jiahe Lin, George Michailidis

18(118):1–25 **Learning Theory of Distributed Regression with Bias Corrected Regularization Kernel Network**
Zheng-Chu Guo, Lei Shi, Qiang Wu

18(119):1–59 **Probabilistic Line Searches for Stochastic Optimization**
Maren Mahsereci, Philipp Hennig

18(120):1–49 **Learning Instrumental Variables with Structural and Non-Gaussianity Assumptions**
Ricardo Silva, Shohei Shimizu

18(121):1–34 **Classification of Time Sequences using Graphs of Temporal Constraints**
Mathieu Guillame-Bert, Artur Dubrawski

18(122):1–43 **Distributed Stochastic Variance Reduced Gradient Methods by Sampling Extra Data with Replacement**
Jason D. Lee, Qihang Lin, Tengyu Ma, Tianbao Yang

18(123):1–41 **Kernel Partial Least Squares for Stationary Data**
Marco Singer, Tatyana Krivobokova, Axel Munk

18(124):1–40 **Robust and Scalable Bayes via a Median of Subset Posterior Measures**
Stanislav Minsker, Sanvesh Srivastava, Lizhen Lin, David B. Dunson

18(125):1–53 **Statistical and Computational Guarantees for the Baum-Welch Algorithm**
Fanny Yang, Sivaraman Balakrishnan, Martin J. Wainwright

18(126):1–45 **Online but Accurate Inference for Latent Variable Models with Local Gibbs Sampling**
Christophe Dupuy, Francis Bach

18(127):1–45 **Poisson Random Fields for Dynamic Feature Models**
Valerio Perrone, Paul A. Jenkins, Dario Spanò, Yee Whye Teh

18(128):1–33 **Gap Safe Screening Rules for Sparsity Enforcing Penalties**
Eugene Ndiaye, Olivier Fercoq, Alexandre Gramfort, Joseph Salmon

18(129):1–31 **Minimax Filter: Learning to Preserve Privacy from Inference Attacks**
Jihun Hamm

18(130):1–38 **Knowledge Graph Completion via Complex Tensor Factorization**

Abstract

This paper presents the Averaged CVB (ACVB) inference and offers convergence-guaranteed and practically useful fast Collapsed Variational Bayes (CVB) inferences. CVB inferences yield more precise inferences of Bayesian probabilistic models than Variational Bayes (VB) inferences. However, their convergence aspect is fairly unknown and has not been scrutinized. To make CVB more useful, we study their convergence behaviors in a empirical and practical approach. We develop a convergence-guaranteed algorithm for any CVB-based inference called ACVB, which enables automatic convergence detection and frees non-expert practitioners from the difficult and costly manual monitoring of inference processes. In experiments, ACVB inferences are comparable to or better than those of existing inference methods and deterministic, fast, and provide easier convergence detection. These features are especially convenient for practitioners who want precise Bayesian inference with assured convergence.

Keywords: nonparametric Bayes, collapsed variational Bayes inference, averaged CVB

1. Introduction

Bayesian probabilistic models are powerful because they are capable of expressing complex structures underlying data using various latent variables by formulating the inherent uncertainty of the data generation and collection process as stochastic perturbations. To fully utilize such Bayesian probabilistic models, we rely on Bayesian inferences that compute the posterior distributions of the model given the data. Bayesian inferences infer the shapes of the posterior distribution, in contrast to the point estimate inferences such as Maximum Likelihood (ML) inferences and Maximum a Posterior (MAP) inference that approximate a complicated parameter distribution by a single parameter (set).

Two Bayesian inference algorithms are frequently used for Bayesian probabilistic models: the Gibbs sampler and variational Bayes (cf. Bishop, 2006; Murphy, 2012). The former guarantees asymptotic convergence to the true posteriors of random variables given infinitely many stochastic samples. Variational Bayes (VB) solutions (cf. Attias, 2000; Blei et al., 2016) often enjoy faster convergence with deterministic iterative computations and massively parallel computation thanks to the factorization. The VB approaches also allow easy and automatic detection of convergence. However, VB yields only local optimal solutions due to its use of approximated posteriors.

We can improve these inference methods by developing collapsed estimators, which integrate some parameters out from inferences. Collapsed Gibbs samplers are one of the best inference solutions since they achieve faster convergence and better estimation than the original Gibbs samplers. Recently, collapsed variational Bayes (CVB) solutions have been intensively studied, especially for topic models such as latent Dirichlet allocation (LDA) (Teh et al., 2007; Asuncion et al., 2009; Sato and Nakagawa, 2012) and HDP-LDA (Sato et al., 2012). The seminal paper by Teh and others examined a 2nd-order Taylor approximation of variational expectation (Teh et al., 2007). A simpler 0th-order approximated CVB (CVB0) solution has also been developed as an optimal solution in the sense of minimized α-divergence (Sato and Nakagawa, 2012). These papers report that CVB and CVB0 yield better inference results than VB solutions and even slightly better than exact collapsed Gibbs in data modeling (Kurihara et al., 2007; Teh et al., 2007; Asuncion et al., 2009), link prediction, and neighborhood search (Sato et al., 2012).

In this paper, we are interested in the convergence issue of CVB inferences. The convergence behavior of CVB inferences remains difficult to analyze theoretically, but basically there is no guarantee of convergence for general CVB inferences. Interestingly, this problem has not discussed in the literature with one exception (Foulds et al., 2013), where the authors studied the convergence of CVB on LDA. Unfortunately, their proposal is an online stochastic approximation of MAP which is only valid for LDA. The convergence issue of CVB inference is, however, a more general and problematic issue for practitioners who are unfamiliar with, but still want to tackle state-of-the-art machine learning techniques to various models, not limited to LDA. Since there is no theoretically sound way of determining and detecting convergence of CVB inferences, users must manually determine the convergence of the CVB inferences: a daunting task for non-experts. In that sense, CVB is less attractive than naive VB and EM algorithms, whose convergences are guaranteed and easy to detect automatically. These reasons motivate us to study the convergence behaviors of CVB inferences. Even though the problem remains difficult in theory, we take an empirical and a practical approach to it. We first monitor the naive variational lower bound and the pseudo leave-one-out (LOO) training log likelihood, and then empirically show that the latter may serve as convergence metrics. Next, we develop a simple and effective technique that assures CVB convergence for general Bayesian probabilistic models. Our proposed annealing technique, called **Averaged CVB (ACVB)**, guarantees CVB convergence and allows automatic convergence detection. ACVB has two advantages. First, ACVB posterior updates offer assured convergence due to a simple annealing mechanism. Second, fixed points of the CVB algorithm are equivalent to the converged solution of ACVB, if the original CVB algorithm has fixed points. Our formulation is applicable to any model and is equally valid for CVB as well as CVB0. A convergence-guaranteed ACVB will be the preferred choice for practitioners who want to apply state-of-the-art inference to their problems. In Table 1, we summarize the existing CVB works and this paper, based on applied models and the convergence issue.

We validate our proposed idea on two popular Bayesian probabilistic models. As a simpler model family, we choose LDA (Blei et al., 2003), which is a finite mixture model for a typical Bag-of-Words document data where an observation is governed by a single latent variable. As a more complex model family, we choose the Infinite Relational Model (IRM, Kemp et al., 2006), which

Table 1: CVB-related studies summary: in terms of applied models and convergence

is an infinite mixture model for a relational (network) data where an observation link is governed by two latent variables.

In experiments using several real-world relational datasets, we observe that the Averaged CVB0 (ACVB0) inferences offer good data modeling performances, outperform naive VB inferences in many cases, and often show significantly better performances than the 2nd-order CVB and its averaged version. We also observe that ACVB0 typically converges quickly in terms of CPU time, compared to the 2nd-order CVBs and ACVBs. The ACVB0 achieves competitive results with the 0-th order CVB0 inference, which is known to be one of the best Bayesian inference methods. In addition, the ACVB0 guarantees the convergence of the algorithm while the CVB0 does not. Based on these findings, we conclude that ACVB0 inference is convenient and appealing for practitioners because it shows good modeling performance, assures automatic convergence and has relatively fast computation.

The contributions of this paper are summarized as follows:

1. We empirically study the convergence behaviors of CVB inferences and propose a simple but effective annealing technique called Averaged Collapsed Variational Bayes (ACVB) inference that assures the convergence of CVB inferences for all models.

2. We confirm that CVB0 with the above averaging technique (ACVB0) inference offers competitive modeling performances compared to the CVB0 inference, which is one of the best Bayesian inference solutions. We report that the ACVB0 and CVB0 solutions i) outperform naive VBs in most cases, ii) are often significantly better than the 2nd-order counterparts, and iii) are in general computationally faster than the 2nd-order ACVB and CVB solutions.

The rest of this paper is organized as follows. In the 2nd section, we first introduce Bayesian probabilistic models used in experimental validation. Then we briefly review the variational Bayes and the collapsed variational Bayes inferences. Then we present the convergence issue of the CVB inferences using two sections. In section 3, we first empirically show that we can monitor the convergence of the CVB inference by a handy measurement: the pseudo leave-one-out log-likelihood. In section 4, we propose a simple but effective variant of the CVB, the averaged collapsed variational Bayes (ACVB) inference that ensure the convergence of the inference process. The 5th section is devoted to experimental evaluations, and the final section concludes the paper.

2. Background

2.1 Generative Models

In experimental validations, we chose two types of different Bayesian probabilistic models. In this section we first briefly explain them.

2.1.1 LDA

Latent Dirichlet allocation(LDA) (Blei et al., 2003) is a popular Bayesian probabilistic model for topic modeling of Bag-of-Words (BoW) style document data collections. In this paper, we employ LDA as a representative of a model family where an observed word (sample) is governed by a single latent variable.

Assume the observed BoW data collection consists of D documents, where each $d(\in \{1, 2, \ldots, D\})$-th document has N_d tokens. A token may choose a value (word) from the set of unique words whose cardinality is V. Then a probabilistic generative process of LDA is written as follows:

$$\boldsymbol{\beta}_k \mid \boldsymbol{\beta}_0 \sim \text{Dirichlet}(\boldsymbol{\beta}_0), \tag{1}$$

$$\boldsymbol{\theta}_d \mid \boldsymbol{\alpha} \sim \text{Dirichlet}(\boldsymbol{\alpha}), \tag{2}$$

$$z_{d,i} \mid \boldsymbol{\theta}_d \sim \text{Discrete}(\boldsymbol{\theta}_d), \tag{3}$$

$$x_{d,i} \mid \boldsymbol{\beta}_k, z_{d,i} \sim \text{Discrete}\left(\boldsymbol{\beta}_{z_{d,i}}\right). \tag{4}$$

Topic models including LDA are characterized by the notion of topics. A topic is represented as a V-dimensional vector whose v-th attribute indicates the mixing ratio of a v-th word, $\boldsymbol{\beta}_k$, in Equation (1). We assume the number of topics is given as a hyperparameter, and denote the number of topics by K and thus $k \in \{1, 2, \ldots, K\}$. A document is formulated as a mixture of topics. The mixing proportion of the K topics for $d \in \{1, 2, \ldots, D\}$th document is $\boldsymbol{\theta}_d$, in Equation (2).

$z_{d,i}$ in Equation (3) denotes a topic assignment of the dth document's ith observed word. Because $\boldsymbol{\theta}$ is a K-dimensional vector, $z_{d,i} = k \in \{1, 2, \ldots, K\}$. Throughout our paper, we interchangeably choose the 1-of-K representation of Z, where $z_{d,i} = k$ is equivalently represented by $z_{d,i,k} = 1, z_{d,i,l\neq k} = 0$. We generate the observed i-th observation (token) of the d-th document from a V-dimensional Discrete distribution, as in Equation (4). $x_{d,i} = v$ means the i-th token is the v-th symbol (word) out of V vocabularies.

2.1.2 IRM

As a slightly complex model family, we also employ the Infinite Relational Model (Kemp et al., 2006), which is an infinite mixture model for a relational (network) data where an observation link is governed by two latent variables: the cluster assignments of the from-node and the to-node.

IRM is an application of the Dirichlet Process Mixture (DPM) (Sethuraman, 1994; Ferguson, 1973; Blackwell and MacQueen, 1973) for relational data. First, assume a binary two-place relation on the two sets (domains) of objects, namely, $D_1 \times D_2 \to \{0, 1\}$, where $D_1 = \{1, \ldots, i, \ldots, N_1\}$ and $D_2 = \{1, \ldots, j, \ldots, N_2\}$. IRM divides the set of objects into multiple clusters based on the observed relational data matrix of $\boldsymbol{X} = \{x_{i,j} \in \{0, 1\}\}$. Data entry $x_{i,j} \in \{0, 1\}$ denotes the existence of a relation between a row (the first domain) object $i \in \{1, 2, \ldots, N_1\}$ and a column (the second domain) object $j \in \{1, 2, \ldots, N_2\}$. In an online purchase record case, the first domain corresponds to a user list, and object i denotes specific user i. The second domain corresponds to a product item list, and object j denotes specific item j. Data entry $x_{i,j}$ represents the relation between user i and item j: the purchase record.

For such data, we define an IRM as follows:

$$\theta_{k,l}|a_{k,l}, b_{k,l} \sim \text{Beta}\left(a_{k,l}, b_{k,l}\right), \tag{5}$$

$$z_{1,i}|\alpha_1 \sim \text{CRP}\left(\alpha_1\right), \tag{6}$$

$$z_{2,j}|\alpha_2 \sim \text{CRP}\left(\alpha_2\right), \tag{7}$$

$$x_{i,j}|\boldsymbol{Z}_1, \boldsymbol{Z}_2, \{\theta\} \sim \text{Bernoulli}\left(\theta_{z_{1,i}, z_{2,j}}\right). \tag{8}$$

In Equation (5), $\theta_{k,l}$ is the strength of the relation between cluster k in the first domain and cluster l in the second domain. $z_{1,i}$ in Equation (6) and $z_{2,j}$ in Equation (7) denote cluster assignments in the first and the second domains, respectively. Each domain has its own CRP prior, therefore two domains may have different numbers of clusters. We generate observed relational data $x_{i,j}$ following Equation (8), conditioned by cluster assignments $\boldsymbol{Z}_1 = \{z_{1,i}\}_{i=1}^{N_1}$, $\boldsymbol{Z}_2 = \{z_{2,j}\}_{j=1}^{N_2}$ and strengths θ. A typical example of IRM is shown in Figure 1. The IRM infers the appropriate cluster assignment of objects $\boldsymbol{Z}_1 = \{z_{1,i}\}$ and $\boldsymbol{Z}_2 = \{z_{2,j}\}$, given observation relation matrix $\boldsymbol{X} = \{x_{i,j}\}$. We can interpret the clustering as the permutation of object indices to discover the "block" structure (Figure 1 (b)).

As a special case, we can build an IRM for a binary two-place relation between the same domain objects $D \times D \to \{0, 1\}$. The probabilistic generative model of the *single-domain* IRM is described as follows:

$$\theta_{k,l}|a_{k,l}, b_{k,l} \sim \text{Beta}\left(a_{k,l}, b_{k,l}\right), \tag{9}$$

$$z_i|\alpha \sim \text{CRP}\left(\alpha\right), \tag{10}$$

$$x_{i,j}|\boldsymbol{Z}, \{\theta\} \sim \text{Bernoulli}\left(\theta_{z_i, z_j}\right). \tag{11}$$

The generative model clearly shows the difference of a *multi-domain* IRM (Eqs. (5-8)) and *a single-domain* IRM (Eqs. (9-11)). In the latter, there are only N objects in domain D, and they serve as either from-nodes or to-nodes in the network. Object indices i and j point to the same domain. On the other hand, a multi-domain IRM distinguishes the first domain object i from the second domain object j.

Konishi et al. (2014) first introduced CVB algorithms for the single-domain IRM. However, it is not applicable when the number of from-nodes and to-nodes are different. Further, its use is inappropriate if the relations are directional. Thus, the single-domain model has limited applicability,

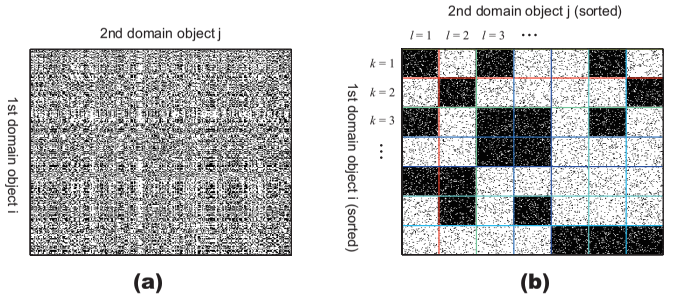

Figure 1: Example of Infinite Relational Models (IRM): (a) input observation $\boldsymbol{X}$. (b) a visualization of inferred clusters $\boldsymbol{Z}$.

unlike the multi-domain IRM. Even though we focus on the multi-domain IRM, all discussions are also valid for a single-domain IRM.

Lastly, we assume two-place relations throughout this paper, but extension that covers higher-order relations is straightforward.

2.2 Variational Bayes (VB) Inference

It is beneficial to quickly derive a VB solution for comparison with a collapsed VB inference. For the VB inference of LDA and IRM, we maximize the VB lower bound, which is defined as:

$$\mathscr{L} = \int q\left(\boldsymbol{Z}, \boldsymbol{\Phi}\right) \log \frac{p\left(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Phi}\right)}{q\left(\boldsymbol{Z}, \boldsymbol{\phi}\right)} d\boldsymbol{Z} d\boldsymbol{\Phi}, \tag{12}$$

where $\boldsymbol{Z}$ denotes all of the hidden variables (assume $\boldsymbol{Z} = \{\boldsymbol{Z}_1, \boldsymbol{Z}_2\}$ for the IRM case), $\boldsymbol{\Phi}$ denotes all of the associated parameters (e.g., $\boldsymbol{\alpha}_d$ and $\boldsymbol{\beta}_k$ in LDA, $\boldsymbol{\theta}_{k,l}$ in IRM), $\boldsymbol{X}$ denotes all of the observations, and $q(\cdot)$s are *variational* posteriors that approximate the true posteriors. The form of the variational posteriors are chosen to make the inference algorithm efficient. For example, all variational posteriors are assumed to be independent from each other when the mean-field approximation is employed. The lower bound is derived from the following re-formulation of the marginal log likelihood (model evidence) $p\left(\boldsymbol{X}\right)$ by Jensen's inequality (Bishop, 2006; Murphy, 2012):

$$\begin{aligned}
\log p\left(\boldsymbol{X}\right) &= \log \int p\left(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Phi}\right) d\boldsymbol{Z} d\boldsymbol{\Phi} \\
&= \log \int q\left(\boldsymbol{Z}, \boldsymbol{\Phi}\right) \frac{p\left(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Phi}\right)}{q\left(\boldsymbol{Z}, \boldsymbol{\Phi}\right)} d\boldsymbol{Z} d\boldsymbol{\Phi} \\
&\geq \int q\left(\boldsymbol{Z}, \boldsymbol{\Phi}\right) \log \frac{p\left(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Phi}\right)}{q\left(\boldsymbol{Z}, \boldsymbol{\Phi}\right)} d\boldsymbol{Z} d\boldsymbol{\Phi} = \mathscr{L}.
\end{aligned}$$

Thus maximizing the lower bound by identifying good variational posteriors q is reasonable in the sense that it is an approximation of the marginal log likelihood. Maximizing the VB lower bound

is also equivalent to minimizing the Kullback-Leibler divergence between true posteriors p^* and variational posteriors q:

$$\log p(\boldsymbol{X}) = \mathscr{L} - \int q(\mathbf{Z}, \boldsymbol{\Phi}) \log \frac{p(\mathbf{Z}, \boldsymbol{\Phi} \mid \boldsymbol{X})}{q(\mathbf{Z}, \boldsymbol{\Phi})} d\mathbf{Z} d\boldsymbol{\Phi} = \mathscr{L} + \mathrm{KL}(q \mid p^*) .$$

We can readily obtain a general update rule of variational posterior $q(\mathbf{Z})$ and $q(\boldsymbol{\Phi})$ (Bishop, 2006; Murphy, 2012). For example, we have the following update rule for the variational posterior of the ith hidden variable:

$$q(z_i) \propto \exp\left(\mathbb{E}_{q(\mathbf{Z}^{\setminus i}), q(\Phi)}[\log p(\boldsymbol{X}, \mathbf{Z}, \boldsymbol{\Phi})]\right), \tag{13}$$

where $\mathbf{Z}^{\setminus i}$ denotes all of the hidden variables excluding the ith hidden variable. Note that the variational posterior of a hidden variable is dependent on the current values of $q(\Phi)$, i.e., the variational posteriors of all of the associated parameters. The resulting update rules boil down to simple updates of the sufficient statistics of the distributions for hidden variables and parameters for LDA and IRM.

2.3 Collapsed Variational Bayes (CVB) Inference

The general idea of CVB inferences for hierarchical probabilistic models (Kurihara et al., 2007; Teh et al., 2007, 2008; Asuncion et al., 2009; Sato and Nakagawa, 2012; Sato et al., 2012) assumes the variational posteriors of the hidden variables of the model where the *parameters are marginalized out beforehand*. In Equation (12), since parameters $\boldsymbol{\Phi}$ are not marginalized (collapsed) out, we need to compute their variational posteriors as well. The variational posteriors of the parameters impact the inference results and may increase the risk of being trapped at a bad local optimal point.

CVB inference first marginalizes out the parameters in an exact way (as in a collapsed Gibbs sampler). After that, the remaining hidden variables are assumed to be independent from each other. This brings two advantages to CVB. First, the effects of the marginalized parameters are correctly evaluated in CVB while VB approximates them. This means that the variational posteriors computed by CVB will approximate the true posteriors better than those of VB. Second, we can reduce the number of unknown quantities to be inferred because the parameters are already marginalized. This makes the inference faster, more stable, and decreases the risk of being trapped in local optimal solutions. Mathematically, it has been proven that the lower bound of CVB is always tighter than that of the original VB (Teh et al., 2007). This means CVB is always a better approximation of the true posterior than VB.

The following is the formal definition of the CVB lower bound:

$$\mathscr{L}[\mathbf{Z}] = \int q(\mathbf{Z}) \log \frac{p(\boldsymbol{X}, \mathbf{Z})}{q(\mathbf{Z})} d\mathbf{Z}. \tag{14}$$

This is the same formulation as Equation (12) except for the absense of marginalized parameters. Therefore, a general solution is derived in the same manner as in the VB case:

$$q(z_i) \propto \exp\left(\mathbb{E}_{q(\mathbf{Z}^{\setminus i})}[\log p(\boldsymbol{X}, \mathbf{Z})]\right). \tag{15}$$

The CVB inference procedure resembles collapsed Gibbs samplers. We remove one object from the model, recompute the posterior of the object cluster assignment, and return it to the model.

One difference is that CVB computes the soft cluster assignments of $\boldsymbol{Z}$ while the collapsed Gibbs sampler computes hard assignments for each process. We repeat this process on all objects. This one sweep of updates corresponds to one iteration of CVB inference.

One problem is that it is difficult to conduct precise update computations for CVB unlike the original VB, even for such relatively simple Bayesian probabilistic models as LDA and IRM. More specifically, taking expectations over $q(\mathbf{Z}^{\setminus i})$ require intractable discrete combinatorial computations. To remedy this issue, CVB inference approximates these expectations by Taylor expansion. If we denote the expectation of predicate x as $a = \mathbb{E}[x]$, we have:

$$f(x) \approx f(a) + f'(a)(x-a) + \frac{1}{2} f''(a)(x-a)^2 . \tag{16}$$

Taking the expectations of both sides of Equation (16) yields the following equation:

$$\begin{aligned} \mathbb{E}[f(x)] &\approx \mathbb{E}[f(a)] + \mathbb{E}[f'(a)(x-a)] + \frac{1}{2}\mathbb{E}[f''(a)(x-a)^2] \\ &= f(a) + \frac{1}{2}\mathbb{E}[f''(a)(x-a)^2] \\ &= f(\mathbb{E}[x]) + \frac{1}{2} f''(\mathbb{E}[x])\, \mathbb{V}[x] . \end{aligned} \tag{17}$$

The 0th-order term is constant. The 1st-order term is canceled because $x-a$ becomes zero by taking the expectation. $\mathbb{V}$ denotes the posterior variance.

There are two types of approximations in CVB studies. The original **CVB** (Teh et al., 2007) employs 2nd-order Taylor approximation and considers the variance, as in Equation (17). (Asuncion et al., 2009) revealed that the 0th-order Taylor approximation performs quite well in practice for LDA. This is called the **CVB0** solution, which approximates the posterior expectation by

$$\mathbb{E}[f(x)] \approx f(\mathbb{E}[x]). \tag{18}$$

Obviously, the CVB0 solution is simpler than that of the 2nd-order approximation. However it is often superior to the 2nd-order CVB in terms of the perplexity of the learned model (Asuncion et al., 2009; Sato and Nakagawa, 2012; Sato et al., 2012). This may seem counter-intuitive since a 0th-order approximation does not approximate anything. To answer this question, we note that a 0th-order approximation CVB0 is in fact a 1st-order approximation: "CVB1". Recall that in Equation (17) the 1st-order term vanished. This indicates that the 0th-order expansion is equal to the 1st-order expansion. Moreover, it is reasonable that the 1st-order approximation works well in general cases and indeed may outperform higher-order approximations due to uncertainties within the data and imperfections in inference algorithms.

3. Convergence Issue of CVB

3.1 Our Interest: No Assurance for CVB Convergence

It is theoretically guaranteed that each iteration of VB monotonically increases the variational lower bound (Equation (12)) (Attias, 2000; Bishop, 2006). This means VB inference monotonically improves the approximated posterior, and eventually converges to its local optimal solutions. Thus, VB inference yields easy detection of convergence by monitoring the lower bound, and the algorithm automatically halts when it reaches a local optimal point.

Unfortunately, no theoretical guarantee of CVB convergence has been provided so far, probably because we cannot correctly evaluate the posterior expectations over $\boldsymbol{Z}$. What we try to find in CVB solutions is a stationary point of a *Taylor-approximated* CVB lower bound; we are not sure that the procedure actually monotonically improves the *true* lower bound. Moreover, it is unknown whether if the CVB update algorithm has a (algorithmic) fixed point. We are not sure whether the algorithm will even stop after infinitely many iterations. Convergence analysis of CVB inference remains an important open problem in the machine learning field. However, the problem has not been well discussed in the literature though many researchers reported that CVB inference yields better posterior estimations in various cases.

Instead of tackling this problem directly, we study two aspects of CVB convergence in this paper. First we empirically study the convergence behaviors of CVB by monitoring a couple of quantities: a naive VB lower bound and the pseudo leave-one-out log likelihood. We show that the latter is potentially useful for CVB convergence detection. We also propose yet another way to deal with CVB convergence, based on a simple annealing technique. We explain the first aspect in this section and the annealing technique in the next section.

3.2 Assessing Candidate Quantities for CVB Convergence Detection

We cannot correctly compute the true CVB lower bound in Equation (14). Therefore, our first approach is to find some quantities that can serve as proxies of it.

For that purpose, we examine two quantities. The first candidate is an approximation of the naive VB lower bound in Equation (12). The VB lower bound is always a lower bound of the true CVB lower bound. Given the variational posterior of hidden variables $q(\boldsymbol{Z})$, we use this posterior as a proxy of $q(\boldsymbol{Z})$ of the naive VB inference. Computing the variational posteriors of marginalized parameters yields an evaluation of the naive VB lower bound (Equation 12). Of course, this is not equal to the "true" VB lower bound computed by the naive VB inference, but it may be useful for detecting convergence in CVB inferences.

The second one is the pseudo Leave-one-out (LOO) log likelihood of the training data set. The CVB solutions (and the Gibbs sampler) compute the predictive distribution of an object, say, $z_{1,i}$, in a LOO manner. Therefore, we might be able to detect the convergence of CVB inference by watching these predictive distributions. To simplify the explanation, consider a simple model where sample x_i is associated with hidden variable z_i through some probabilistic distributions. A pseudo LOO log likelihood is an approximation of the entire log likelihood (Besag, 1975):

$$\log p\left(\boldsymbol{X} \mid \boldsymbol{Z}\right) \cong \sum_i \log p\left(x_i | \boldsymbol{X}^{\backslash i}, \boldsymbol{Z}\right). \tag{19}$$

We can decompose the above log likelihood as the following simpler sum over samples i:

$$\sum_i \log \sum_k p\left(x_i, z_i = k \mid \boldsymbol{X}^{\backslash i}, \boldsymbol{Z}^{\backslash i}\right). \tag{20}$$

We can easily confirm that $\sum_k p\left(x_i, z_i = k \mid \boldsymbol{X}^{\backslash i}, \boldsymbol{Z}^{\backslash i}\right)$ is in fact a normalization term of a typical collapsed Gibbs posterior by decomposing joint distributions between x_i and z_i. One merit of pseudo LOO log likelihood is its computation cost. It requires no additional cost to compute this quantity during the collapsed Gibbs, since we inevitably compute this normalizer to conduct sampling. Importantly this also holds for the CVB inference; solving Equation (15) typically results in a softened

version of the collapsed Gibbs solution, requiring the same normalizing term. Thus computing the pseudo LOO log likelihood incurs no extra computation cost for CVB inference.

For example, in the case of IRM, we compute the sum of the r.h.s. of Equation (23) (in the appendix) over all the possible values of $z_{1,i} = k \in \{1, 2, \ldots, K\}$ when we update the variational posterior of $q(z_{1,i})$. Let us denote this sum as $C_{1,i}$, which corresponds to $\sum_k p\left(x_i, z_i = k \mid \boldsymbol{X}^{\backslash i}, \boldsymbol{Z}^{\backslash i}\right)$ in Equation (20). In the same manner, we collect $C_{2,j}$ in the second domain updates as the counterpart of C_1. The total log sum $C = \sum_i \log C_{1,i} + \sum_j \log C_{2,j}$ then serves as a "pseudo" log likelihood of the training dataset for CVB.

For LDA and IRM, we synthesize small and large artificial data to test the two quantities. We generated two synthetic Bag-of-Words datasets for LDA. The sizes of these datasets were $D = 500, V = 1000, K = 10$ (smaller **synth 1** data), and $D = 1500, V = 5000, K = 40$ (larger **synth 2** data). Similarly, we generated two synthetic relation datasets for IRM. The sizes and the true numbers of the clusters of these datasets were $N_1 = 100, N_2 = 200, K_1 = 4, K_2 = 5$ (smaller **synth 1** data), and $N_1 = 1,000, N_2 = 1,500, K_1 = 7, K_2 = 6$ (larger **synth 2** data).

Figures 2 and 3 respectively present the evolutions of these two quantities in CVB and CVB0. The hyperparameters are set in the same procedure of the experimental validations (see the Experiment section).

We first notice that the behaviors of the naive VB lower bound (the solid lines) are different in LDA and IRM. This is not desirable behavior as a cue of convergence detection. In the case of LDA (upper panels in the figures), the VB lower bounds first rise to maximum values, and converge at the lower levels. In the case of IRM (lower panels in the figures), on the other hand, the VB lower bound steadily increases and converges at its highest values. It is not surprising that the naive VB lower bound exhibits such strange behaviors. Recall that CVB inference does not directly increase the VB lower bound, which is a looser bound than that of CVB. We also note that the computation load of the lower bound is much heavier than the CVB updates. Thus there is no strong reason to adopt the naive VB lower bound as a convergence monitoring quantity of CVBs.

In contrast, the pseudo LOO training log likelihood (dashed lines) shows similar behaviors in all cases; monotonically increases its value over the iterations (seemingly) and converges at the maximum values. This behavior is preferable as a cue of the convergence than the case of the lower bound. It is also remarkable that pseudo LOO training log likelihood incurs no extra computation loads over the original CVB updates. Since the property of the quantity more or less resembles the model evidence, the pseudo LOO log likelihood is a good choice for convergence detection.

Based on these results, it is preferable to monitor the pseudo LOO log likelihood to asses the convergence of the CVB inferences. However, we stress that there is no theoretical guarantee that the convergence of the pseudo LOO log likelihood is somehow related to the convergence of the CVB inference.

4. Averaged CVB: Convergence Technique for General CVB

In this section, we propose a more direct and convergence-guaranteed technique for general CVB inferences called Averaged CVB (ACVB) and prove that it reaches the fixed point of the original CVB algorithm, if it exists.

Generally it is fruitful to offer an easy convergence detection algorithm for CVB (not restricted to LDA and IRM). For many practitioners, manually determine the convergence of the inference algorithms is difficult. This might be one reason why EM-based algorithms are preferred by prac-

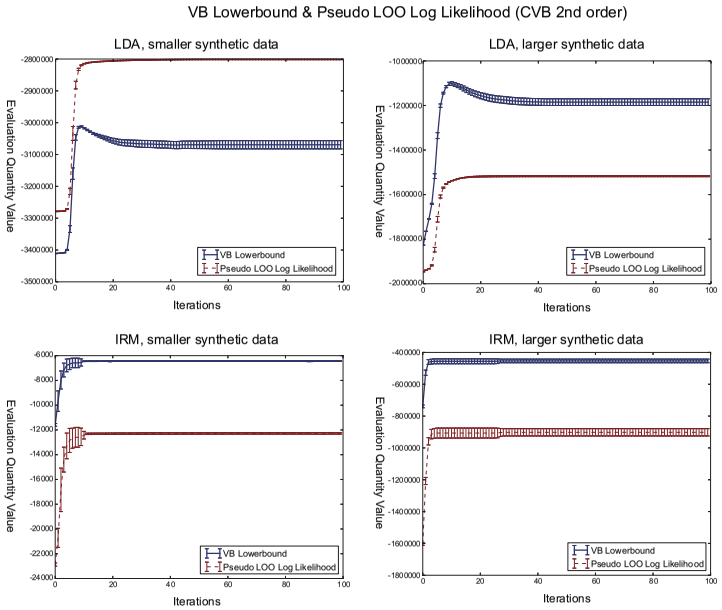

Figure 2: Evolution of two quantities over CVB iterations. Solid lines indicate the evolution of naive VB lower bound. Dashed lines indicate the evolution of pseudo LOO log likelihood on training data. Error bars denote the standard deviations. Upper panels: LDA results on two synthetic data. Lower panels: IRM results on two synthetics data.

titioners: they are convergence guaranteed and the convergence is easy to detect. A convergence-guaranteed ACVB motivates users to use CVB inference, which is more precise than naive VB in theory, with automatic computation termination at a guaranteed convergence.

To the best of our knowledge, a paper by Foulds et al. (Foulds et al., 2013) is the only work that proposes convergence-assured CVB inference. This model, which is based on the Robbins and Monro stochastic approximation (Robbins and Monro, 1951), is only valid for LDA-CVB0. More precisely, the solution presented in the paper is a MAP solution, leveraging the fact that the MAP solution closely resembles the CVB0 solution in the case of LDA. They changed the CVB0 update by ignoring the subtraction of a topic assignment probability vector from sufficient statistics and manually adjusting the Dirichlet parameters, which makes the CVB0 update is equal to the MAP update in LDA. However, this approach is not valid for IRM because the MAP and CVB0 solutions are different. On the contrary, the ACVB is valid for any probabilistic models and indeed for both CVB and CVB0.

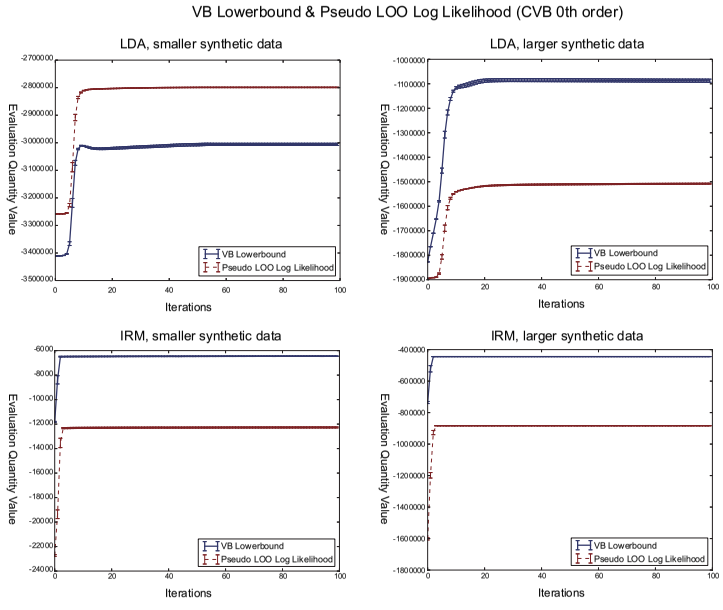

Figure 3: Evolution of two quantities over CVB0 iterations. Solid lines indicate the evolution of naive VB lower bound. Dashed lines indicate the evolution of pseudo LOO log likelihood on training data. Error bars denote the standard deviations. Upper panels: LDA results on two synthetic data. Lower panels: IRM results on two synthetics data.

4.1 Procedure of ACVB

This technique is based on monitoring the changes of $q(\mathbf{Z})$. The rationale is simple: it is reasonable to monitor $q(\mathbf{Z})$ since the CVB solutions are trying to obtain the stationary point of the Taylor-approximated lower bound with respect to $q(\mathbf{Z})$, even though we don't know whether the stationary point exists, as explained before.

Our solution is a simple annealing technique called Averaged CVB (ACVB) which assures the convergence of CVB solutionDfwe s. We emphasize that the ACVB discussion is not limited to LDA and IRM; this technique is applicable to CVB inference on any model. Also, ACVB is equally valid for CVB (2nd order) and CVB0.

After a certain number of iterations for "burn-in", we gradually decrease the portion of the variational posterior changes:

$$\bar{q}^{(s+1)} = \left(1 - \frac{1}{s+1}\right)\bar{q}^{(s)} + \frac{1}{s+1}q^{(s+1)}, \quad \text{or} \quad \bar{q}^{(S)} = \frac{1}{S}\sum_{s=1}^{S} q^{(s)}, \text{“} \tag{21}$$

where s denotes the iterations after completion of the "burn-in" period, $\bar{q}^{(s)}$ denotes the "annealed" variational posterior at the sth iteration, $q^{(s)}$ denotes the variational posterior by CVB inference at the sth iteration, and S is the total number of iterations. After the "burn-in" period, we monitor the ratio of changes of $\bar{q}$ and detect the convergence when the ratio falls below a predefined threshold. As the final result, we use $\bar{q}^{(s)}$, not $q^{(s)}$. During the burn-in period, we monitor the changes of q, which in most cases quickly converges before entering the annealing process.

Hereafter, we respectively denote the (naive) CVB solution and the CVB0 solution, both for ACVB, as **ACVB** and **ACVB0** solutions.

4.2 Properties of ACVB

Concerning the convergence of ACVB, there are three points to note. The first is rather evident but makes ACVB useful for practical CVB inference. ACVB assure convergence, and we can easily detect it by taking the difference of $\bar{q}$ in successive iterations.

Lemma 1 *Averaged variational posterior $\bar{q}^{(s)}$ is convergence-assured: $\forall \epsilon > 0$, $\exists S_0$, s.t. $\forall S > S_0 \Rightarrow \frac{1}{N}\sum_{i=1}^{N}\left|\bar{q}_i^{(S)} - \bar{q}_i^{(S-1)}\right| < \epsilon$.*

Proof Since

$$\frac{1}{S}\sum_{s=1}^{S} q^{(s)} = \left(1 - \frac{1}{S}\right)\frac{1}{S-1}\sum_{s=1}^{S-1} q^{(s)} + \frac{1}{S}q^{(S)},$$

we have

$$\begin{aligned}\left|\frac{1}{S}\sum_{s=1}^{S} q^{(s)} - \frac{1}{S-1}\sum_{s=1}^{S-1} q^{(s)}\right| &= \left|-\frac{1}{S}\frac{1}{S-1}\sum_{s=1}^{S-1} q^{(s)} + \frac{1}{S}q^{(S)}\right| \\ &\leq \frac{1}{S}\frac{1}{S-1}\sum_{s=1}^{S-1}|q^{(s)}| + \frac{1}{S}|q^{(S)}| \\ &\leq \frac{1}{S}\frac{1}{S-1}(S-1) + \frac{1}{S} = \frac{2}{S}.\end{aligned}$$

Thus,

$$\frac{1}{N}\sum_{i=1}^{N}\left|\frac{1}{S}\sum_{s=1}^{S} q_i^{(s)} - \frac{1}{S-1}\sum_{s=1}^{S-1} q_i^{(s)}\right| \leq \frac{2}{S}.$$

If we set $S_0 = \frac{2}{\epsilon}$, then $\forall S > S_0$,

$$\frac{1}{N}\sum_{i=1}^{N}\left|\frac{1}{S}\sum_{s=1}^{S} q_i^{(s)} - \frac{1}{S-1}\sum_{s=1}^{S-1} q_i^{(s)}\right| \leq \frac{2}{S} < \frac{2}{S_0} = \epsilon.$$

This means

$$\frac{1}{N}\sum_{i=1}^{N}\left|\bar{q}_i^{(S)} - \bar{q}_i^{(S-1)}\right| < \epsilon.$$

■

Thus, we can automatically stop the ACVB inference by a stopping rule based on the difference of the ACVB posteriors.

The second point is also noteworthy and validates the use of ACVB in Bayesian inference. We can prove that converged $\bar{q}$ is asymptotically equivalent to the fixed point of the CVB update algorithm, if it exists (note that it is unclear whether the original CVB update algorithm has a fixed point in theory).

Lemma 2 *If variational posterior $q^{(s)}$ converges to a fixed point of the CVB update algorithm, then averaged variational posterior $\bar{q}^{(s)}$ also converges to the fixed point of the CVB algorithm.*

Proof Let q^* be a fixed point of the CVB update algorithm. With this assumption,

$$\lim_{s\to\infty} q^{(s)} = q^* \Leftrightarrow \forall \epsilon > 0, \exists s_0 \text{ s.t. } \forall s > s_0 \Rightarrow |q^{(s)} - q^*| < \epsilon/2.$$

Here, we define

$$\left|\sum_{s=1}^{s_0}(q^{(s)} - q^*)\right| = M > 0,$$

and thus,

$$\lim_{s\to\infty}\frac{M}{s} = 0 \Leftrightarrow \forall \epsilon > 0, \exists s_0' \text{ s.t. } \forall s > s_0' \Rightarrow \frac{M}{s} < \epsilon/2.$$

When $S_0 = \max\{s_0, s_0'\}$, we have

$$\begin{aligned}\forall S > S_0, |\bar{q}^{(S)} - q^*| &= \left|\sum_{s=1}^{S}\frac{1}{S}(q^{(s)} - q^*)\right| \\ &< \frac{M}{S} + \sum_{s=S_0+1}^{S}\left|\frac{1}{S}(q^{(s)} - q^*)\right| \\ &\leq \epsilon/2 + \left|\frac{S - S_0}{S}\right|\epsilon/2 \leq \epsilon/2 + \epsilon/2 = \epsilon.\end{aligned}$$

Therefore,

$$\lim_{s\to\infty}\bar{q}^{(s)} = q^*.$$

■

Note that the literature fails to resolve whether the CVB algorithm (based on Taylor approximation) has an algorithmic fixed point. However, ACVB remains useful because it assures the convergence of the inference process and will find the true solution if CVB has a fixed point. No solutions to the convergence problem of CVB have ever been published, to the best of our knowledge.

As the third point, we note on the required iteration, S, for the convergence of ACVB. The following lemma provides -an insight to set up the maximum number of iterations.

Lemma 3 *The maximum distance between the averaged variational posteriors of consecutive steps is upperbounded by a term proportional to* $\frac{1}{s}$ *where* s *is the number of iterations.*

Proof Consider the averaged variational posterior concerning one hidden variable, z_i. Also consider that $\bar{q}(z_i)$ is a real-valued vector on a simplex (say, on a K dimensional simplex). From the definition, we see:

$$\left\|\bar{q}^{(s+1)}(z_i) - \bar{q}^{(s)}(z_i)\right\| = \frac{1}{s+1}\left\|\bar{q}^{(s)}(z_i) - \bar{q}^{(s+1)}(z_i)\right\| .$$

The maximum L2 distance between two simplex vectors is $\sqrt{2}$. Therefore:

$$\left\|\bar{q}^{(s+1)}(z_i) - \bar{q}^{(s)}(z_i)\right\| = \frac{1}{s+1}\left\|\bar{q}^{(s)}(z_i) - \bar{q}^{(s+1)}(z_i)\right\| \leq \frac{\sqrt{2}}{s+1} .$$

■

Using this lemma, we roughly expect the number of maximum iterations to satisfy a certain threshold of the averaged CVB posterior differences. For example, we have $\left\|\bar{q}^{(s+1)}(z_i) - \bar{q}^{(s)}(z_i)\right\| < 1.4 \times 10^{-3}$ with $s = 1000$ iterations, and $\left\|\bar{q}^{(s+1)}(z_i) - \bar{q}^{(s)}(z_i)\right\| < 1.0 \times 10^{-4}$ with $s = 14000$ iterations. We can use these s as the number of maximum iterations for running the program. In practice we typically need much fewer iterations to achieve the designed threshold.

5. Experiments

This section presents our experimental validations. In summary, we obtained the following results.

1. For almost all the datasets, CVB and ACVB inferences achieved better modeling performance than the naive VB, in both LDA and IRM.
2. CVB0 and ACVB0 inferences often performed significantly better than their 2nd-order counterparts.
3. The computations of the CVB0 and ACVB0 inferences are generally faster than the other VB-based methods.

5.1 Procedure

We compared the performance of the proposed averaged CVB solutions (**ACVB**, **ACVB0**) with naive variational Bayes (**VB**) and CVB solutions (**CVB**, **CVB0**), which are the baseline deterministic inferences. As a reference, we also include comparisons with the collapsed Gibbs samplers (**Gibbs**) with a small number of iterations.

Initialization and hyperparameter choices are important for a fair comparison of inference methods. We employ hyperparameter updates for all solutions: fixed point iterations for VB, CVB, CVB0, ACVB, and ACVB0 and hyper-prior sampling for Gibbs. For LDA, we fixed the initial hyperparameter values based on knowledge from the existing (many) LDA works, especially relying on the result of (Asuncion et al., 2009). For IRM, we tested several initial hyperparameter values and report the results computed using the best hyperparameter setting. All of the hidden variables were initialized in a completely random manner with the uniform distribution to assign soft values

Dataset	D	V	N
20 news group	10,000	13,178	1,046,101
Enron	10,000	15,258	937,113

Table 2: Dataset sizes used in our LDA experiments.

of $p(z_i = k)$. In the case of Gibbs, we performed hard assignments of $z_i = k$ to the most weighted cluster. For the VB, CVB, CVB0, ACVB, and ACVB0 solutions, we normalized the assigned weights. For the LDA experiments, we set the number of topics as $K \in \{50, 100, 200\}$. For the IRM experiments, all of the inferences except Gibbs require a number of truncated clusters a priori. To assess the effect of the truncation level, our experiments examined $K_1 = K_2 = K \in \{20, 40, 60\}$. In practice, we just need to prepare a sufficiently large K to handle data complexity.

We compared the performance of the inference methods by test data perplexity for LDA and by the averaged test data marginal log likelihood for IRM. Given an observation dataset, we excluded roughly 10% of the observations from the inference as held-out test data. After the inference was finished, we computed the perplexity or the marginal log likelihoods of the test data. The test data were randomly sampled for each run. The perplexity and the log likelihood were computed for 20 runs with different initialization and hyperparameter settings.

In the experiments, we set the maximum numbers of inference iterations and iterated the inferences until we reached that maximum. Then we reported the final values of the perplexities (for LDA) or the averaged log likelihood (for IRM) as well the evolutions of these values versus the CPU times.

For the reference Gibbs sampler on LDA, we iterated the sampling procedure $1,000$ times and discarded the first 100 iterations as the burn-in period. For the reference Gibbs sampler on IRM, we iterated the sampling procedure $3,000$ times and discarded the first $1,500$ iterations as the burn-in period.

5.2 Datasets

For our experiments, we prepared several real-world datasets that allowed us to assess the inference performance at several scales and densities.

For the LDA experiments we employed two popular real-world datasets and converted them to the BoW format.

The first dataset is the **20 news group** corpus (Asuncion et al., 2009; Sato and Nakagawa, 2012), including randomly chosen $D = 10,000$ documents with a vocabulary size $V = 13,178$. The second dataset is the **Enron** email corpus (McCallum et al., 2005) including randomly chosen $D = 10,000$ documents with a vocabulary size of $V = 15,258$. Stop words were eliminated. Note the reference materials for detailed information of these datasets. The data sizes and densities are summarized in Table 5.2.

For the IRM experiments, we collected small and large real-world datasets. We explain them more closely since the IRM and the relational data analysis are probably less common than the LDA and the topic model researches for many readers.

The first real-world relational dataset is the Enron e-mail dataset (Klimt and Yang, 2004), which has been used in many studies (Tang et al., 2008; Fu et al., 2009; Ishiguro et al., 2010, 2012). We

Dataset	N_1	N_2	# of "1" entries	Density
Enron Jun.	151	151	257	1.13%
Enron Aug.	151	151	439	1.93%
Enron Oct.	151	151	707	3.10%
Enron Dec.	151	151	377	1.66%
Lastfm UserXUser	1,892	1,892	21,512	0.60%
Lastfm ArtistXTag	6,099	1,088	23,253	0.35%

Table 3: Dataset sizes used in our IRM experiments.

extracted monthly e-mail transactions for 2001. The dataset contains $N = N_1 = N_2 = 151$ company members of Enron. $x_{i,j} = 1(0)$ if there is (not) an e-mail sent from member i to member j. Out of twelve months, we selected the transactions of June (**Enron Jun.**), August (**Enron Aug.**), October (**Enron Oct.**), and December (**Enron Dec.**).

The second real-world relational dataset is the Lastfm dataset[1], which contains several records for the Last.fm music service, including lists of most listened-to musicians, tag assignments for artists, and friend relations among users. We employed the friend relations among $N = N_1 = N_2 = 1892$ users (**Lastfm UserXUser**). $x_{i,j} = 1(0)$ if there is (not) a friend relation from user i to user j. This dataset has ten times more objects and 100 times more matrix entries than the Enron dataset. We also employed the artist-tag relations between $17,632$ artists and $11,946$ tags. Since the relation matrix is too large for Gibbs and naive VB inference, we truncated the number of artists and tags. The original observations were the co-occurrence counts of (artist name, tag) pairs. We binarized the observations as to whether the (artist name, tag) pair counts exceeded; we ignore singletons of (artist name, tag). If the counts exceeded 1, then the observation entries were set to 1; otherwise, they were set to 0. Then all the rows (artists) and columns (tags) that have no "1" entries were removed. The resulting binary matrix consisted of $N_1 = 6,099$ artists and $N_2 = 1,088$ tags (**Lastfm ArtistXTag**). $x_{i,j} = 1(0)$ if artist i is (not) assigned tag word j more than once.

The data sizes and densities are summarized in Table 5.2.

5.3 Results

We start by presenting the numerical performances of the inferences. For LDA, we present the perplexities after 150 iterations in Table 5.3. For IRM, we present the averaged test data log likelihood after 200 iterations in Table 5.3. The results of the best setup are presented for each solution. In addition, we conducted statistical significance tests using t-tests.

First, we review the results of the deterministic (VB-based) inference methods on LDA. CVB0 and ACVB0 inferences always outperformed the naive VB, CVB, and ACVB for LDA[2]. These results are in good accordance with existing CVB researches. The 2nd-order CVB and ACVB inferences often performed worse than the naive VB. (Asuncion et al., 2009) reported that the superiority of CVB inference over naive VB gradually diminishes as the number of topics K increases to roughly more than 100. Our results are probably related to this report.

1. Provided by HetRec2011. http://ir.ii.uam.es/hetrec2011/
2. We note that all of the ACVB0 results on LDA are significantly better than the other VB-based methods, although CVB0 is significantly better than ACVB0 in almost cases.

Table 4: Test perplexity on LDA (10% test data) after 150 iterations. Smaller values are better. Boldface indicates the best method within deterministic methods and is significantly better than method(s) marked with $*$ (by t-test, $p = 0.05$). Numbers of Gibbs sampler are computed after $1,000$ iterations. Upper panel: $K = 50$, middle panel: $K = 100$, lower panel: $K = 200$.

CVB0 significantly outperformed ACVB0 in most cases, given the same number of inference iterations. However, ACVB0 provides an easy convergence detection scheme with some theoretical supports, while CVB0 has no such mechanism[3]. In that sense there is no strong reason to choose CVB0 instead of the convergence-guaranteed ACVB0.

Second, we examine the IRM results. For IRM, the CVB and ACVB inferences are significantly better than naive VB in many cases. The ACVB0 inference especially often significantly outperformed the other VB-based methods when K is small. One possible reason is that the averaged posteriors are smoothed versions of the original CVB posteriors. This smoothing may work well for sparse relational data, where inferred solutions tens to be peaky. This result serves as a good reason to adopt ACVB(0) inference: ACVB not only assures the termination of inference algorithm, but also provides better inference solutions than the original CVB in IRM cases.

Third and finally, we compared the performance of the ACVBs and the Collapsed Gibbs sampler. Interestingly, $1,000$ iterations of collapsed Gibbs on LDA performed significantly better than ACVBs, and $3,000$ iterations of the collapsed on IRM did not work as well as expected. We believe this basically depends on the complexity of the model. LDA is a simple probabilistic model. Thus $1,000$ iterations of the collapsed Gibbs are adequate for obtaining good posterior computations. However, IRM is a relatively more complex model than IRM, especially because of the existence of two hidden variables (z_1, z_2) for one observation. This indicates that the (A)CVB inference algorithms on IRM are more likely to be trapped at bad local optima, whereas the collapsed Gibbs sampler yielded stable but not good solutions regardless of the initial Ks. As reported in (Albers et al., 2013), the collapsed Gibbs for IRM requires millions of iterations to obtain better results.

3. although we empirically observed that the pseudo LOO log likelihood may serve as a convergence detector.

Table 5: Marginal test data log likelihood per test data entry (10% test data) on IRM after 200 iterations. Larger values are better. Boldface indicates the best method within deterministic methods and is significantly better than method(s) marked with $*$ (by t-test, $p = 0.05$). Numbers of the Gibbs sampler are computed after 3,000 iterations. Upper panel: $K = 20$, middle panel: $K = 40$, lower panel: $K = 60$.

Thus it is perfectly possible that a collapsed Gibbs outperformed all the VB-based techniques, given more sophisticated sampling techniques and many more iterations.

Our results demonstrate one point of contention. The ACVB and CVB inferences are significantly better than naive VB inference for almost all the IRM cases. This apparently conflicts with a former IRM-CVB study (Konishi et al., 2014) for single-domain IRMs. They reported that CVB inference is inferior to VB for sparse relational data. However, in our experiments, VB never outperformed ACVB or CVB. Our speculation is that this is due to the model structure of the multi-domain IRM (the focus of this paper) and the single-domain IRM in Konishi et al. (2014). In the observation process of a multi-domain IRM (Equation 8), two hidden variables from two independent domains interact (i.e., $z_{1,i}$ and $z_{2,j}$), whereas two from the same domain do not (e.g., $z_{1,i}$ and $z_{1,i'}$). On the

other hand, in the case of a single-domain IRM (Equation 11), two hidden variables from the same (and the sole) domain interact (i.e. z_i and z_j). Given that LDA has no such variable interactions, we believe the multi-domain IRM is one step closer to LDA than the single-domain IRM in terms of interaction complication. Therefore, perhaps the behaviors of the (A)CVB and VB inferences in the multi-domain IRM resembles the LDA cases: CVB is superior to VB.

Figures 4 and 5 present examples of the clustering attained for the **Synth2** and **Lastfm UserXUser** data in $K = 60$. All of the object indices in the figures are sorted so that the objects are grouped into blocks. The horizontal and vertical color lines respectively indicate the borders of the object clusters for first domain k and second domain l. We show the MAP assignments and assign an object to the cluster with the highest posterior probability.

Finally, we show a few plots of performance measures over CPU time. Figure 6 illustrates the time evolution of the test data perplexity of LDA on different data sets. Figure 7 illustrates the time evolution of the test data likelihood of IRM on different data sets. We refrain from presenting the CPU time evolutions of our naive implementations of the collapsed Gibbs samplers, since there is a number of very efficient sampling methods for LDA (Li et al., 2014).

We observe that the ACVB0 and CVB0 inferences generally proceed faster than the other inference methods. Combined with assured convergence and the good numerical performances, we conclude that the ACVB0 solution is a good inference choice for practical usages.

6. Conclusion

In this paper, we proposed an Averaged Collapsed Variational Bayes (ACVB) inference, which is a convergence-guaranteed and useful deterministic inference algorithm that is expected to replace naive VB in practical applications.

We studied the convergence aspect of CVB inference in two ways to address its open problem. We started by examining two possible convergence metric candidates for CVB solutions. Next, we proposed a simple and effective annealing technique, Averaged CVB (ACVB), to assure the convergence of CVB solutions. ACVB posterior updates offer assured convergence due to their simple annealing mechanism. Moreover, the fixed point of the original CVB update algorithm is equivalent to the converged solution of ACVB, if the CVB algorithm has a fixed point (an issue unresolved in the literature). ACVB is applicable to any model and is equally valid for CVB and CVB0.

In experiments using several real-world relational data sets, we concluded that the Averaged CVB0 (ACVB0) inference offers the following impressive performances. It outperforms naive VB inference in many cases and often shows significantly better performances than 2nd-order CVB and its averaged version. ACVB0 typically converges faster than the 2nd-order CVB and ACVB. ACVB0 achieves competitive results with 0-th order CVB0 inference, which is one of the best Bayesian inference methods. In addition, ACVB0 guarantees the convergence of the algorithm while CVB0 does not. Based on these findings we conclude that ACVB0 is an appealing Bayesian inference method for practitioners, who needs precise posterior inferences with guaranteed computational convergences.

For future work, we will enhance the inference speed, especially for relatively slower IRMs. One candidate is to stochastically approximate the sample size as in SGD. Recently, (Foulds et al., 2013) proposed such an approximation for LDA. Another approach parallelizes the inference procedure (Hansen et al., 2011; Albers et al., 2013); they examined the parallelization of collapsed

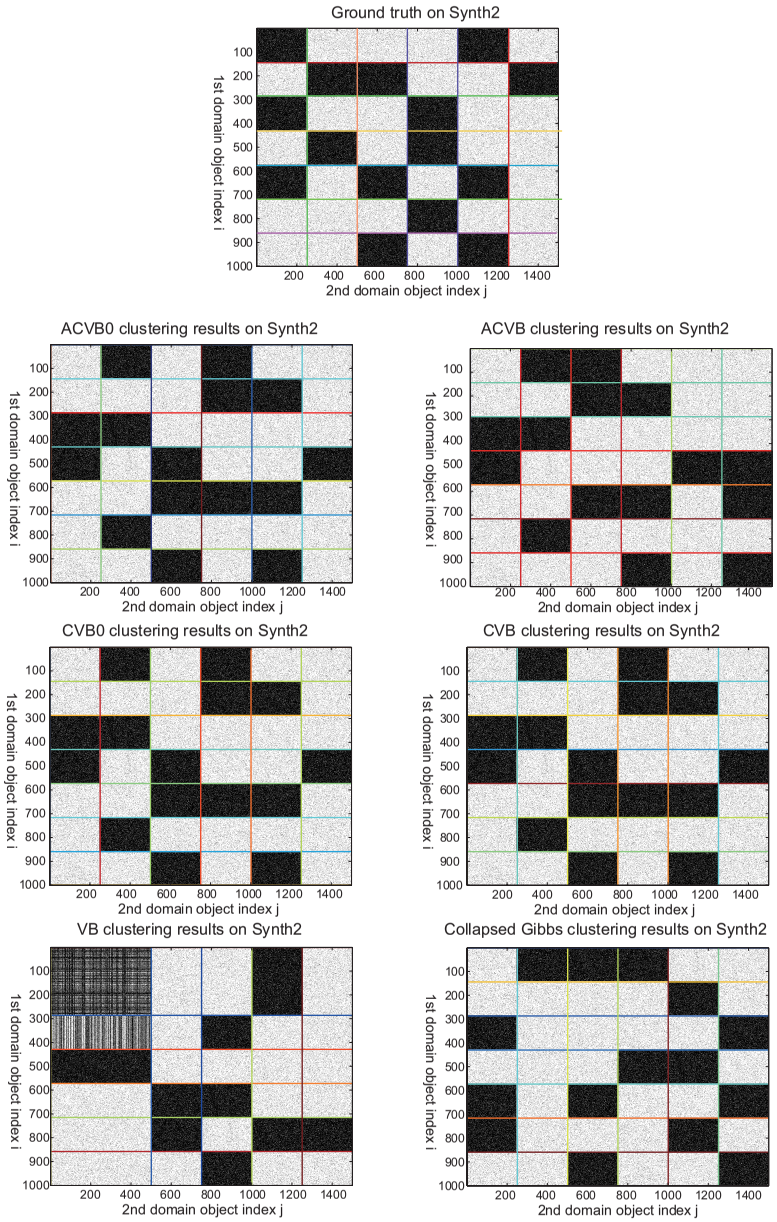

Figure 4: MAP clustering assignments for **Synth2** dataset. All object indices are sorted.

Horizontal axis denotes CPU times [sec], and vertical axis denotes average test data marginal log likelihoods per relation entry. Presented Gibbs results are those of sampled assignments, not of averaged posteriors.

Gibbs samplers for IRM. It is also important to explore efficient CVB algorithms for more advanced models such as MMSB and its variants (Airoldi et al., 2008; Miller et al., 2009; Griffiths and Ghahramani, 2011). Aside from the representation of multiple cluster assignments, few studies have addressed other issues. For example, (Fu et al., 2009; Ishiguro et al., 2010) focused on the dynamics of network evolution in the context of stochastic blockmodels (MMSB and IRM). Subset IRM (Ishiguro et al., 2012) is another extension of IRM that automatically filters out nodes from the clustering if they are not very informative for grouping. Applying CVB to these models might make it easier for practitioners to examine the depth of various relational data.

Appendix A. CVB inference algorithm for multi-domain IRM

The IRM model in this paper is a multi-domain model where observation $x_{i,j}$ is governed by row latent variable $z_{1,i}$ and column latent variable $z_{2,j}$. Since we distinguish the row and the column objects, there are $N_1 + N_2$ latent variables.

The CVB inference of IRM was first studied in (Konishi et al., 2014). However, their paper focused on a single-domain model, where the observation matrix is a $N \times N$ square matrix and the cluster assignment is only defined on N objects without distinguishing rows and columns. Its CVB scheme is slightly different from the multi-domain IRM, which is our focus in this paper. For readers' convenience, we briefly describe the CVB posteriors for multi-domain IRMs. Since we do not fully explain the actual update rules, readers are referred to (Konishi et al., 2014) to obtain them.

The CVB inference procedure resembles collapsed Gibbs sampling more than ordinary VB inference. We take one object from the model, recompute the posterior of the object cluster assignment, and put it back in the model. One difference is that CVB computes the soft cluster assignments of $\boldsymbol{Z} = \{\boldsymbol{Z}_1, \boldsymbol{Z}_2\}$, while the Gibbs sampler computes hard assignments for each process. We repeat this process on all the objects, and one iteration(sweep) of CVB inference completes.

Next we derive the update rule of the hidden cluster assignment of the first domain $z_{1,i}$. First, we modify the representation of the CVB lower bound. The integral is replaced by the summation because $\boldsymbol{Z}$ is discrete:

$$\begin{aligned}\mathscr{L}\left[z_{1,i}, \boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2\right] &= \sum_{z_{1,i}} \sum_{\boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2} \left[q(z_{1,i})\, q\left(\boldsymbol{Z}_1^{\setminus(1,i)}\right) q(\boldsymbol{Z}_2) \log \frac{p\left(\boldsymbol{X}^{(1,i)}, \boldsymbol{X}^{\setminus(1,i)}, z_{1,i}, \boldsymbol{Z}_1^{\setminus(1,i)} \boldsymbol{Z}_2\right)}{q(z_{1,i})\, q\left(\boldsymbol{Z}_1^{\setminus(1,i)}\right) q(\boldsymbol{Z}_2)} \right] \\ &= \sum_{z_{1,i}} \mathbb{E}_{\boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2} \Big[q(z_{1,i}) \Big\{ \log p\left(\boldsymbol{X}^{(1,i)} | \boldsymbol{X}^{\setminus(1,i)}, z_{1,i}, \boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2\right) \\ &\qquad + \log p\left(z_{1,i} | \boldsymbol{Z}_1^{\setminus(1,i)}\right) - \log q(z_{1,i}) \\ &\qquad + (\text{Terms that are not related to } z_{1,i}) \Big\} \Big]. \end{aligned} \tag{22}$$

$\boldsymbol{X}^{(1,i)} = \{x_{i,\cdot}\}$ denotes the set of all the observations concerning object i of the first domain. The remaining observations, the hidden variables excluding $z_{1,i}$, and the statistics computed on these data, are denoted by $\setminus(1,i)$. $\mathbb{E}_x[y]$ indicates the expectations of y on the variational posterior of x.

Taking the derivative of Equation (22) w.r.t. $q(z_{1,i})$ and equating it to zero, we have the following update rule for $q(z_{1,i})$:

$$q(z_{1,i}) \propto \exp\left\{ \mathbb{E}_{\boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2}\left[\log p\left(\boldsymbol{X}^{(1,i)} | \boldsymbol{X}^{\setminus(1,i)}, z_{1,i}, \boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2\right)\right] + \mathbb{E}_{\boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2}\left[\log p\left(z_{1,i} | \boldsymbol{Z}_1^{\setminus(1,i)}\right)\right] \right\}. \tag{23}$$

To evaluate the above equation, we first need to compute the arguments of the expectations. We employ finite truncation of the Stick breaking process (Sethuraman, 1994) as a prior of $\boldsymbol{Z}$. With straightforward computations we have the following (cf. (Konishi et al., 2014)):

$$p\left(z_{1,i} = k | \boldsymbol{Z}_1^{\setminus(1,i)}\right) = \frac{m_{1,k}^{\setminus(1,i)} + 1}{m_{1,k}^{\setminus(1,i)} + M_{1,k}^{\setminus(1,i)} + \alpha_1 + 1} \prod_{k'=1}^{k-1} \frac{M_{1,k'}^{\setminus(1,i)} + \alpha_1}{m_{1,k'}^{\setminus(1,i)} + M_{1,k'}^{\setminus(1,i)} + \alpha_1 + 1}. \tag{24}$$

$$\begin{aligned} &p\left(\boldsymbol{X}^{(1,i)} | z_{1,i} = k, \boldsymbol{Z}_1^{\setminus(1,i)}, \boldsymbol{Z}_2, \boldsymbol{X}^{\setminus(1,i)}\right) \\ &= \prod_{l=1}^{K_2} \frac{\Gamma\left(a_{k,l} + b_{k,l} + n_{k,l}^{\setminus(1,i)} + N_{k,l}^{\setminus(1,i)}\right)}{\Gamma\left(a_{k,l} + n_{k,l}^{\setminus(1,i)}\right)\Gamma\left(b_{k,l} + N_{k,l}^{\setminus(1,i)}\right)} \frac{\Gamma\left(a_{k,l} + n_{k,l}^{\setminus(1,i)} + n_{k,l}^{+(1,i)}\right)\Gamma\left(b_{k,l} + N_{k,l}^{\setminus(1,i)} + N_{k,l}^{+(1,i)}\right)}{\Gamma\left(a_{k,l} + b_{k,l} + n_{k,l}^{\setminus(1,i)} + N_{k,l}^{\setminus(1,i)} + n_{k,l}^{+(1,i)} + N_{k,l}^{+(1,i)}\right)}. \end{aligned} \tag{25}$$

In the above, we introduced the following sufficient statistics:

$$m_{1,k} = \sum_{i=1}^{N_1} \mathbb{I}(z_{1,i} = k) = \sum_{i=1}^{N_1} z_{1,i,k}, \quad m_{1,k}^{\setminus(1,i)} = m_{1,k} - \mathbb{I}(z_{1,i} = k), \tag{26}$$

$$M_{1,k} = \sum_{i=1}^{N_1} \mathbb{I}(z_{1,i} > k) = \sum_{k'=k+1}^{K_1} m_{1,k'}, \quad M_{1,k}^{\setminus(1,i)} = M_{1,k} - \mathbb{I}(z_{1,i} > k), \tag{27}$$

$$n_{k,l} = \sum_{i=1}^{N_1} \sum_{j=1}^{N_2} z_{1,i,k} z_{2,j,l} x_{i,j}, \quad n_{k,l}^{\setminus(1,i)} = n_{k,l} - \sum_{j=1}^{N_2} z_{1,i,k} z_{2,j,l} x_{i,j}, \tag{28}$$

$$N_{k,l} = \sum_{i=1}^{N_1} \sum_{j=1}^{N_2} z_{1,i,k} z_{2,j,l} (1 - x_{i,j}), \quad N_{k,l}^{\setminus(1,i)} = N_{k,l} - \sum_{j=1}^{N_2} z_{1,i,k} z_{2,j,l} (1 - x_{i,j}) \tag{29}$$

$$n_{k,l}^{+(1,i)} = \sum_{j=1}^{N_2} z_{2,j,l} x_{i,j}, \quad N_{k,l}^{+(1,i)} = \sum_{j=1}^{N_2} z_{2,j,l} (1 - x_{i,j}). \tag{30}$$

The final step is to compute intractable expectations with a help of Taylor-expansion approximation. Since this step is completely identical with (Konishi et al., 2014) thus we refrain from presenting details.

Appendix B. Numerical Performance after Convergence

In the experiment section, we examined the performances of several inference solutions fixing the number of inference iterations. Based on the evolutions in Figure 6, we think the LDA inferences have already almost reached the converged status with 150 iterations. However, the results of IRM (Figure 7) indicate that the inference may take some additional time until convergence. Then it is natural to ask that how the performances of the inferences change when we keep the algorithm iterates until convergence (on IRM).

We need to decide which parameter/statistics to be monitored to detect convergence. For the VB solution, we monitored the VB lower bound. For the CVB and CVB0 solutions, we monitored the pseudo LOO log likelihood of the training data set in Sec. 3. For the ACVB and ACVB0 solutions, we used the annealed posteriors. We determined the solution convergence from the relative changes

Abstract

A typical viral marketing model identifies influential users in a social network to maximize a single product adoption assuming unlimited user attention, campaign budgets, and time. In reality, multiple products need campaigns, users have limited attention, convincing users incurs costs, and advertisers have limited budgets and expect the adoptions to be maximized soon. Facing these user, monetary, and timing constraints, we formulate the problem as a submodular maximization task in a continuous-time diffusion model under the intersection of one matroid and multiple knapsack constraints. We propose a randomized algorithm estimating the user influence[1] in a network ($|\mathcal{V}|$ nodes, $|\mathcal{E}|$ edges) to an accuracy of ϵ with $n = \mathcal{O}(1/\epsilon^2)$ randomizations and $\tilde{\mathcal{O}}(n|\mathcal{E}| + n|\mathcal{V}|)$ computations. By exploiting the influence estimation algorithm as a subroutine, we develop an adaptive threshold greedy algorithm achieving an approximation factor $k_a/(2 + 2k)$ of the optimal when k_a out of the k knapsack constraints are active. Extensive experiments on networks of millions of nodes demonstrate that the proposed algorithms achieve the state-of-the-art in terms of effectiveness and scalability.

Keywords: Influence Maximization, Influence Estimation, Continuous-time Diffusion Model, Matroid, Knapsack

1. Introduction

Online social networks play an important role in the promotion of new products, the spread of news, the success of political campaigns, and the diffusion of technological innovations. In these contexts, the influence maximization problem (or viral marketing problem) typically has the following flavor: identify a set of influential users in a social network, who, when convinced to adopt a product, shall influence other users in the network and trigger a large cascade of adoptions. This problem has been studied extensively in the literature from both the modeling and the algorithmic aspects (Richardson and Domingos, 2002; Kempe et al., 2003; Leskovec et al., 2007; Chen et al., 2009, 2010a,b, 2011, 2012; Ienco et al., 2010; Goyal et al., 2011a,b; Gomez-Rodriguez and Schölkopf, 2012), where it has been typically assumed that the host (*e.g.*, the owner of an online social platform) faces a single product, endless user attention, unlimited budgets and unbounded time. However, in reality, the host often encounters a much more constrained scenario:

- **Multiple-Item Constraints:** multiple products can spread simultaneously among the same set of social entities. These products may have different characteristics, such as their revenues and speed of spread.
- **Timing Constraints:** the advertisers expect the influence to occur within a certain time window, and different products may have different timing requirements.
- **User Constraints:** users of the social network, each of which can be a potential source, would like to be exposed to only a small number of ads. Furthermore, users may be grouped by their geographical locations, and advertisers may have a target population they want to reach.
- **Product Constraints:** seeking initial adopters entails a cost to the advertiser, who needs to pay to the host and often has a limited amount of money.

For example, Facebook (*i.e.*, the host) needs to allocate ads for various products with different characteristics, *e.g.*, clothes, books, or cosmetics. While some products, such as clothes, aim at influencing within a short time window, some others, such as books, may allow for longer periods. Moreover, Facebook limits the number of ads in each user's sidebar (typically it shows less than five) and, as a consequence, it cannot assign all ads to a few highly influential users. Finally, each advertiser has a limited budget to pay for ads on Facebook and thus each ad can only be displayed to some subset of users. In our work, we incorporate these myriads of practical and important requirements into consideration in the influence maximization problem.

We account for the multi-product and timing constraints by applying product-specific continuous-time diffusion models. Here, we opt for continuous-time diffusion models instead of discrete-time models, which have been mostly used in previous work (Kempe et al., 2003; Chen et al., 2009, 2010a,b, 2011, 2012; Borgs et al., 2012). This is because artificially discretizing the time axis into bins introduces additional errors. One can adjust the additional tuning parameters, like the bin size, to balance the tradeoff between the error and the computational cost, but the parameters are not easy to choose optimally. Extensive experimental comparisons on both synthetic and real-world data have shown that discrete-time models provide less accurate influence estimation than their continuous-time counterparts (Gomez-Rodriguez et al., 2011; Gomez-Rodriguez and Schölkopf, 2012; Gomez-Rodriguez et al., 2013; Du et al., 2013a,b).

However, maximizing influence based on continuous-time diffusion models also entails additional challenges. First, evaluating the objective function of the influence maximization

1. Partial results in the paper on influence estimation have been published in a conference paper: Nan Du, Le Song, Manuel Gomez-Rodriguez, and Hongyuan Zha. Scalable influence estimation in continuous time diffusion networks. In Advances in Neural Information Processing Systems 26, 2013.

problem (*i.e.*, the influence estimation problem) in this setting is a difficult graphical model inference problem, *i.e.*, computing the marginal density of continuous variables in loopy graphical models. The exact answer can be computed only for very special cases. For example, Gomez-Rodriguez and Schölkopf (2012) have shown that the problem can be solved exactly when the transmission functions are exponential densities, by using continuous time Markov processes theory. However, the computational complexity of such approach, in general, scales exponentially with the size and density of the network. Moreover, extending the approach to deal with arbitrary transmission functions would require additional nontrivial approximations which would increase even more the computational complexity. Second, it is unclear how to scale up influence estimation and maximization algorithms based on continuous-time diffusion models to millions of nodes. Especially in the maximization case, the influence estimation procedure needs to be called many times for different subsets of selected nodes. *Thus, our first goal is to design a scalable algorithm which can perform influence estimation in the regime of networks with millions of nodes.*

We account for the user and product constraints by restricting the feasible domain over which the maximization is performed. We first show that the overall influence function of multiple products is a submodular function and then realize that the user and product constraints correspond to constraints over the ground set of this submodular function. To the best of our knowledge, previous work has not considered both user and product constraints simultaneously over general unknown different diffusion networks with non-uniform costs. In particular, (Datta et al., 2010) first tried to model both the product and user constraints only with uniform costs and infinite time window, which essentially reduces to a special case of our formulations. Similarly, (Lu et al., 2013) considered the allocation problem of multiple products which may have competitions within the infinite time window. Besides, they all assume that multiple products spread within the same network. In contrast, our formulations generally allow products to have different diffusion networks, which can be unknown in practice. Soma et al. (2014) studied the influence maximization problem for one product subject to one knapsack constraint over a known bipartite graph between marketing channels and potential customers; Ienco et al. (2010) and Sun et al. (2011) considered user constraints but disregarded product constraints during the initial assignment; and, Narayanam and Nanavati (2012) studied the cross-sell phenomenon (the selling of the first product raises the chance of selling the second) and included monetary constraints for all the products. However, no user constraints were considered, and the cost of each user was still uniform for each product. *Thus, our second goal is to design an efficient submodular maximization algorithm which can take into account both user and product constraints simultaneously.*

Overall, this article includes the following major contributions:

- Unlike prior work that considers an a priori described simplistic discrete-time diffusion model, we first **learn** the diffusion networks from data by using continuous-time diffusion models. This allows us to address the timing constraints in a principled way.

- We provide a novel formulation of the influence estimation problem in the continuous-time diffusion model from the perspective of probabilistic graphical models, which allows heterogeneous diffusion dynamics over the edges.

- We propose an efficient randomized algorithm for continuous-time influence estimation, which can scale up to millions of nodes and estimate the influence of each node to an accuracy of ϵ using $n = \mathcal{O}(1/\epsilon^2)$ randomizations.

- We formulate the influence maximization problem with the aforementioned constraints as a submodular maximization under the intersection of matroid constraints and knapsack constraints. The submodular function we use is based on the actual diffusion model learned from the data for the time window constraint. This novel formulation provides us a firm theoretical foundation for designing greedy algorithms with theoretical guarantees.

- We develop an efficient adaptive-threshold greedy algorithm which is linear in the number of products and proportional to $\widetilde{\mathcal{O}}(|\mathcal{V}| + |\mathcal{E}^*|)$, where $|\mathcal{V}|$ is the number of nodes (users) and $|\mathcal{E}^*|$ is the number of edges in the largest diffusion network. We then prove that this algorithm is guaranteed to find a solution with an overall influence of at least $\frac{k_a}{2+2k}$ of the optimal value, when k_a out of the k knapsack constraints are active. This improves over the best known approximation factor achieved by polynomial time algorithms in the combinatorial optimization literature. Moreover, whenever advertising each product to each user entails the same cost, the constraints reduce to an intersection of matroids, and we obtain an approximation factor of $1/3$, which is optimal for such optimization.

- We evaluate our algorithms over large synthetic and real-world datasets and show that our proposed methods significantly improve over previous state-of-the-arts in terms of both the accuracy of the estimated influence and the quality of the selected nodes in maximizing the influence over independently hold-out real testing data.

In the remainder of the paper, we will first tackle the influence estimation problem in section 2. We then formulate different realistic constraints for the influence maximization in section 3 and present the adaptive-thresholding greedy algorithm with its theoretical analysis in section 4; we investigate the performance of the proposed algorithms in both synthetic and real-world datasets in section 5; and finally we conclude in section 6.

2. Influence Estimation

We start by revisiting the continuous-time diffusion model by Gomez-Rodriguez et al. (2011) and then explicitly formulate the influence estimation problem from the perspective of probabilistic graphical models. Because the efficient inference of the influence value for each node is highly non-trivial, we further develop a scalable influence estimation algorithm which is able to handle networks of millions of nodes. The influence estimation procedure will be a key building block for our later influence maximization algorithm.

2.1 Continuous-Time Diffusion Networks

The continuous-time diffusion model associates each edge with a transmission function, that is, a density over the transmission time along the edge, in contrast to previous discrete-time models which associate each edge with a fixed infection probability (Kempe et al., 2003).

Moreover, it also differs from discrete-time models in the sense that events in a cascade are not generated iteratively in rounds, but event timings are sampled directly from the transmission function in the continuous-time model.

Continuous-Time Independent Cascade Model. Given a *directed* contact network, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, we use the independent cascade model for modeling a diffusion process (Kempe et al., 2003; Gomez-Rodriguez et al., 2011). The process begins with a set of infected source nodes, $\mathcal{A}$, initially adopting certain contagion (idea, meme or product) at time zero. The contagion is transmitted from the sources along their out-going edges to their direct neighbors. Each transmission through an edge entails *random* waiting times, τ, drawn from different independent pairwise waiting time distributions(one per edge). Then, the infected neighbors transmit the contagion to their respective neighbors, and the process continues. We assume that an infected node remains infected for the entire diffusion process. Thus, if a node i is infected by multiple neighbors, only the neighbor that first infects node i will be the *true* parent. As a result, although the contact network can be an arbitrary directed network, each diffusion process induces a Directed Acyclic Graph (DAG).

Heterogeneous Transmission Functions. Formally, the pairwise transmission function $f_{ji}(t_i|t_j)$ for a directed edge $j \to i$ is the conditional density of node i getting infected at time t_i given that node j was infected at time t_j. We assume it is shift invariant: $f_{ji}(t_i|t_j) = f_{ji}(\tau_{ji})$, where $\tau_{ji} := t_i - t_j$, and causal: $f_{ji}(\tau_{ji}) = 0$ if $\tau_{ji} < 0$. Both parametric transmission functions, such as the exponential and Rayleigh function (Gomez-Rodriguez et al., 2011), and nonparametric functions (Du et al., 2012) can be used and estimated from cascade data.

Shortest-Path Property. The independent cascade model has a useful property we will use later: given a sample of transmission times of all edges, the time t_i taken to infect a node i is the length of the shortest path in $\mathcal{G}$ from the sources to node i, where the edge weights correspond to the associated transmission times.

2.2 Probabilistic Graphical Model for Continuous-Time Diffusion Networks

The continuous-time independent cascade model is essentially a directed graphical model for a set of *dependent* random variables, that is, the infection times t_i of the nodes, where the conditional independence structure is supported on the contact network $\mathcal{G}$. Although the original contact graph $\mathcal{G}$ can contain directed loops, each diffusion process (or a cascade) induces a directed acyclic graph (DAG). For those cascades consistent with a particular DAG, we can model the joint density of t_i using a directed graphical model:

$$p\left(\{t_i\}_{i\in\mathcal{V}}\right) = \prod_{i\in\mathcal{V}} p\left(t_i|\{t_j\}_{j\in\pi_i}\right), \tag{1}$$

where each π_i denotes the collection of parents of node i in the induced DAG, and each term $p(t_i|\{t_j\}_{j\in\pi_i})$ corresponds to a conditional density of t_i given the infection times of the parents of node i. This is true because given the infection times of node i's parents, t_i is independent of other infection times, satisfying the local Markov property of a directed graphical model. We note that the independent cascade model only specifies explicitly the pairwise transmission function of each directed edge, but does not directly define the conditional density $p(t_i|\{t_j\}_{j\in\pi_i})$.

However, these conditional densities can be derived from the pairwise transmission functions based on the Independent-Infection property:

$$p\left(t_i|\{t_j\}_{j\in\pi_i}\right) = \sum\nolimits_{j\in\pi_i} f_{ji}(t_i|t_j) \prod\nolimits_{l\in\pi_i, l\neq j} S(t_i|t_l), \tag{2}$$

which is the sum of the likelihoods that node i is infected by each parent node j. More precisely, each term in the summation can be interpreted as the likelihood $f_{ji}(t_i|t_j)$ of node i being infected at t_i by node j multiplied by the probability $S(t_i|t_l)$ that it has survived from the infection of each other parent node $l \neq j$ until time t_i.

Perhaps surprisingly, the factorization in Equation (1) is the same factorization that can be used for an arbitrary induced DAG consistent with the contact network $\mathcal{G}$. In this case, we only need to replace the definition of π_i (the parent of node i in the DAG) to the set of neighbors of node i with an edge pointing to node i in $\mathcal{G}$. This is not immediately obvious from Equation (1), since the contact network $\mathcal{G}$ can contain directed loops which seems to be in conflict with the conditional independence semantics of directed graphical models. The reason why it is possible to do so is as follows: any fixed set of infection times, $t_1, \ldots, t_d$, induces an ordering of the infection times. If $t_i \leq t_j$ for an edge $j \to i$ in $\mathcal{G}$, $h_{ji}(t_i|t_j) = 0$, and the corresponding term in Equation (2) is zeroed out, making the conditional density consistent with the semantics of directed graphical models.

Instead of directly modeling the infection times t_i, we can focus on the set of mutually *independent* random transmission times $\tau_{ji} = t_i - t_j$. Interestingly, by switching from a node-centric view to an edge-centric view, we obtain a fully factorized joint density of the set of transmission times

$$p\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}\right) = \prod\nolimits_{(j,i)\in\mathcal{E}} f_{ji}(\tau_{ji}), \tag{3}$$

Based on the Shortest-Path property of the independent cascade model, each variable t_i can be viewed as a transformation from the collection of variables $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$. More specifically, let $\mathcal{Q}_i$ be the collection of directed paths in $\mathcal{G}$ from the source nodes to node i, where each path $q \in \mathcal{Q}_i$ contains a sequence of directed edges (j, l). Assuming all source nodes are infected at time zero, then we obtain variable t_i via

$$t_i = g_i\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}|\mathcal{A}\right) = \min_{q\in\mathcal{Q}_i} \sum\nolimits_{(j,l)\in q} \tau_{jl}, \tag{4}$$

where the transformation $g_i(\cdot|\mathcal{A})$ is the value of the shortest-path minimization. As a special case, we can now compute the probability of node i infected before T using a set of independent variables:

$$\Pr\{t_i \leq T|\mathcal{A}\} = \Pr\left\{g_i\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}|\mathcal{A}\right) \leq T\right\}. \tag{5}$$

The significance of the relation is that it allows us to transform a problem involving a sequence of dependent variables $\{t_i\}_{i\in\mathcal{V}}$ to one with independent variables $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$. Furthermore, the two perspectives are connected via the shortest path algorithm in weighted directed graph, a standard well-studied operation in graph analysis.

2.3 Influence Estimation Problem in Continuous-Time Diffusion Networks

Intuitively, given a time window, the wider the spread of infection, the more influential the set of sources. We adopt the definition of influence as the expected number of infected nodes given a set of source nodes and a time window, as in previous work (Gomez-Rodriguez and Schölkopf, 2012). More formally, consider a set of source nodes $\mathcal{A} \subseteq \mathcal{V}, |\mathcal{A}| \leq C$ which get infected at time zero. Then, given a time window T, a node i is infected within the time window if $t_i \leq T$. The expected number of infected nodes (or the influence) given the set of transmission functions $\{f_{ji}\}_{(j,i)\in\mathcal{E}}$ can be computed as

$$\sigma(\mathcal{A}, T) = \mathbb{E}\left[\sum_{i\in\mathcal{V}} \mathbb{I}\left\{t_i \leq T|\mathcal{A}\right\}\right] = \sum_{i\in\mathcal{V}} \Pr\left\{t_i \leq T|\mathcal{A}\right\}, \tag{6}$$

where $\mathbb{I}\{\cdot\}$ is the indicator function and the expectation is taken over the the set of *dependent* variables $\{t_i\}_{i\in\mathcal{V}}$. By construction, $\sigma(\mathcal{A}, T)$ is a non-negative, monotonic nondecreasing submodular function in the set of source nodes shown by Gomez-Rodriguez and Schölkopf (2012).

Essentially, the influence estimation problem in Equation (6) is an inference problem for graphical models, where the probability of event $t_i \leq T$ given sources in $\mathcal{A}$ can be obtained by summing out the possible configuration of other variables $\{t_j\}_{j\neq i}$. That is

$$\Pr\{t_i \leq T|\mathcal{A}\} = \int_0^\infty \cdots \int_{t_i=0}^{T} \cdots \int_0^\infty \left(\prod\nolimits_{j\in\mathcal{V}} p\left(t_j|\{t_l\}_{l\in\pi_j}\right)\right)\left(\prod\nolimits_{j\in\mathcal{V}} dt_j\right), \tag{7}$$

which is, in general, a very challenging problem. First, the corresponding directed graphical models can contain nodes with high in-degree and high out-degree. For example, in Twitter, a user can follow dozens of other users, and another user can have hundreds of "followers". The tree-width corresponding to this directed graphical model can be very high, and we need to perform integration for functions involving many continuous variables. Second, the integral in general can not be evaluated analytically for heterogeneous transmission functions, which means that we need to resort to numerical integration by discretizing the domain $[0, \infty)$. If we use N levels of discretization for each variable, we would need to enumerate $\mathcal{O}(N^{|\pi_i|})$ entries, exponential in the number of parents.

Only in very special cases, can one derive the closed-form equation for computing $\Pr\{t_i \leq T|\mathcal{A}\}$. For instance, Gomez-Rodriguez and Schölkopf (2012) proposed an approach for exponential transmission functions, where the special properties of exponential density are used to map the problem into a continuous time Markov process problem, and the computation can be carried out via a matrix exponential. However, without further heuristic approximation, the computational complexity of the algorithm is exponential in the size and density of the network. The intrinsic complexity of the problem entails the utilization of approximation algorithms, such as mean field algorithms or message passing algorithms. We will design an efficient randomized (or sampling) algorithm in the next section.

2.4 Efficient Influence Estimation in Continuous-Time Diffusion Networks

Our first key observation is that we can transform the influence estimation problem in Equation (6) into a problem with *independent* variables. With the relation in Equation (5),

we can derive the influence function as

$$\begin{aligned}\sigma(\mathcal{A}, T) =& \sum\nolimits_{i\in\mathcal{V}} \Pr\left\{g_i\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}|\mathcal{A}\right) \leq T\right\} \\ =& \mathbb{E}\left[\sum\nolimits_{i\in\mathcal{V}} \mathbb{I}\left\{g_i\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}|\mathcal{A}\right) \leq T\right\}\right],\end{aligned} \tag{8}$$

where the expectation is with respect to the set of independent variables $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$. This equivalent formulation suggests a naive sampling (NS) algorithm for approximating $\sigma(\mathcal{A}, T)$: draw n samples of $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$, run a shortest path algorithm for each sample, and finally average the results (see Appendix A for more details). However, this naive sampling approach has a computational complexity of $O(nC|\mathcal{V}||\mathcal{E}| + nC|\mathcal{V}|^2 \log|\mathcal{V}|)$ due to the repeated calling of the shortest path algorithm. This is quadratic to the network size, and hence not scalable to millions of nodes.

Our second key observation is that for each sample $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$, we are only interested in the neighborhood size of the source nodes, *i.e.*, the summation $\sum_{i\in\mathcal{V}} \mathbb{I}\{\cdot\}$ in Equation (8), rather than in the individual shortest paths. Fortunately, the neighborhood size estimation problem has been studied in the theoretical computer science literature. Here, we adapt a very efficient randomized algorithm by Cohen (1997) to our influence estimation problem. This randomized algorithm has a computational complexity of $O(|\mathcal{E}|\log|\mathcal{V}| + |\mathcal{V}|\log^2|\mathcal{V}|)$ and it estimates the neighborhood sizes for *all* possible single source node locations. Since it needs to run once for each sample of $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$, we obtain an overall influence estimation algorithm with $O(n|\mathcal{E}|\log|\mathcal{V}| + n|\mathcal{V}|\log^2|\mathcal{V}|)$ computation, nearly linear in network size. Next we will revisit Cohen's algorithm for neighborhood estimation.

2.4.1 Randomized Algorithm for Single-Source Neighborhood-Size Estimation

Given a fixed set of edge transmission times $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$ and a source node s, infected at time zero, the neighborhood $\mathcal{N}(s, T)$ of a source node s given a time window T is the set of nodes within distance T from s, *i.e.*,

$$\mathcal{N}(s, T) = \left\{i \mid g_i\left(\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}\right) \leq T,\ i \in \mathcal{V}\right\}. \tag{9}$$

Instead of estimating $\mathcal{N}(s, T)$ directly, the algorithm will assign an exponentially distributed random label r_i to each network node i. Then, it makes use of the fact that the minimum of a set of exponential random variables $\{r_i\}_{i\in\mathcal{N}(s,T)}$ is still an exponential random variable, but with its parameter being equal to the total number of variables, that is, if each $r_i \sim \exp(-r_i)$, then the smallest label within distance T from source s, $r_* := \min_{i\in\mathcal{N}(s,T)} r_i$, will distribute as $r_* \sim \exp\{-|\mathcal{N}(s, T)|r_*\}$. Suppose we randomize over the labeling m times and obtain m such least labels, $\{r_*^u\}_{u=1}^m$. Then the neighborhood size can be estimated as

$$|\mathcal{N}(s, T)| \approx \frac{m-1}{\sum_{u=1}^m r_*^u}. \tag{10}$$

which is shown by Cohen (1997) to be an unbiased estimator of $|\mathcal{N}(s, T)|$. This is an elegant relation since it allows us to transform the counting problem in (9) to a problem of finding the minimum random label r_*. The key question is whether we can compute the least label r_* efficiently, given random labels $\{r_i\}_{i\in\mathcal{V}}$ and any source node s.

Cohen (1997) designed a modified Dijkstra's algorithm (Algorithm 3) to construct a data structure $r_*(s)$, called least label list, for each node s to support such query. Essentially, the algorithm starts with the node i with the smallest label r_i, and then it traverses in breadth-first search fashion along the reverse direction of the graph edges to find all reachable nodes. For each reachable node s, the distance d_* between i and s, and r_i are added to the end of $r_*(s)$. Then the algorithm moves to the node i' with the second smallest label $r_{i'}$, and similarly find all reachable nodes. For each reachable node s, the algorithm will compare the current distance d_* between i' and s with the last recorded distance in $r_*(s)$. If the current distance is smaller, then the current d_* and $r_{i'}$ are added to the end of $r_*(s)$. Then the algorithm move to the node with the third smallest label and so on. The algorithm is summarized in Algorithm 3 in Appendix B.

Algorithm 3 returns a list $r_*(s)$ per node $s \in \mathcal{V}$, which contains information about distance to the smallest reachable labels from s. In particular, each list contains pairs of distance and random labels, (d, r), and these pairs are ordered as

$$\infty > d_{(1)} > d_{(2)} > \ldots > d_{(|r_*(s)|)} = 0 \tag{11}$$

$$r_{(1)} < r_{(2)} < \ldots < r_{(|r_*(s)|)}, \tag{12}$$

where $\{\cdot\}_{(l)}$ denotes the l-th element in the list. (see Appendix B for an example).

If we want to query the smallest reachable random label r_* for a given source s and a time T, we only need to perform a binary search on the list for node s:

$$r_* = r_{(l)}, \text{ where } d_{(l-1)} > T \geq d_{(l)}. \tag{13}$$

Finally, to estimate $|\mathcal{N}(s,T)|$, we generate m *i.i.d.* collections of random labels, run Algorithm 3 on each collection, and obtain m values $\{r_*^u\}_{u=1}^m$, which we use in Equation (10) to estimate $|\mathcal{N}(i,T)|$.

The computational complexity of Algorithm 3 is $O(|\mathcal{E}|\log|\mathcal{V}| + |\mathcal{V}|\log^2|\mathcal{V}|)$, with expected size of each $r_*(s)$ being $O(\log|\mathcal{V}|)$. Then the expected time for querying r_* is $O(\log\log|\mathcal{V}|)$ using binary search. Since we need to generate m set of random labels and run Algorithm 3 m times, the overall computational complexity for estimating the single-source neighborhood size for all $s \in \mathcal{V}$ is $O(m|\mathcal{E}|\log|\mathcal{V}| + m|\mathcal{V}|\log^2|\mathcal{V}| + m|\mathcal{V}|\log\log|\mathcal{V}|)$. For large-scale network, and when $m \ll \min\{|\mathcal{V}|, |\mathcal{E}|\}$, this randomized algorithm can be much more efficient than approaches based on directly calculating the shortest paths.

2.4.2 Constructing Estimation for Multiple-Source Neighborhood Size

When we have a set of sources, $\mathcal{A}$, its neighborhood is the union of the neighborhoods of its constituent sources

$$\mathcal{N}(\mathcal{A},T) = \bigcup\nolimits_{i\in\mathcal{A}} \mathcal{N}(i,T). \tag{14}$$

This is true because each source independently infects its downstream nodes. Furthermore, to calculate the least label list r_* corresponding to $\mathcal{N}(\mathcal{A},T)$, we can simply reuse the least label list $r_*(i)$ of each individual source $i \in \mathcal{A}$. More formally,

$$r_* = \min\nolimits_{i\in\mathcal{A}} \ \min\nolimits_{j\in\mathcal{N}(i,T)} r_j, \tag{15}$$

where the inner minimization can be carried out by querying $r_*(i)$. Similarly, after we obtain m samples of r_*, we can estimate $|\mathcal{N}(\mathcal{A},T)|$ using Equation (10). Importantly, very little additional work is needed when we want to calculate r_* for a set of sources $\mathcal{A}$, and we can reuse work done for a single source. This is very different from a naive sampling approach where the sampling process needs to be done completely anew if we increase the source set. In contrast, using the randomized algorithm, only an additional constant-time minimization over $|\mathcal{A}|$ numbers is needed.

2.4.3 Overall Algorithm

So far, we have achieved efficient neighborhood size estimation of $|\mathcal{N}(\mathcal{A},T)|$ with respect to a given set of transmission times $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$. Next, we will estimate the influence by averaging over multiple sets of samples for $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$. More specifically, the relation from (8)

$$\sigma(\mathcal{A},T) = \mathbb{E}_{\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}}[|\mathcal{N}(\mathcal{A},T)|] = \mathbb{E}_{\{\tau_{ji}\}}\mathbb{E}_{\{r^1,\ldots,r^m\}|\{\tau_{ji}\}}\left[\frac{m-1}{\sum_{u=1}^m r_*^u}\right], \tag{16}$$

suggests the following overall algorithm :

Continuous-Time Influence Estimation (ConTinEst):

1. Sample n sets of random transmission times $\{\tau_{ij}^l\}_{(j,i)\in\mathcal{E}} \sim \prod_{(j,i)\in\mathcal{E}} f_{ji}(\tau_{ji})$.
2. Given a set of $\{\tau_{ij}^l\}_{(j,i)\in\mathcal{E}}$, sample m sets of random labels $\{r_i^u\}_{i\in\mathcal{V}} \sim \prod_{i\in\mathcal{V}} \exp(-r_i)$.
3. Estimate $\sigma(\mathcal{A},T)$ by sample averages $\sigma(\mathcal{A},T) \approx \frac{1}{n}\sum_{l=1}^n \left((m-1)/\sum_{u_l=1}^m r_*^{u_l}\right)$.

What is even more important is that the number of random labels, m, does not need to be very large. Since the estimator for $|\mathcal{N}(A,T)|$ is unbiased (Cohen, 1997), essentially the outer-loop of averaging over n samples of random transmission times further reduces the variance of the estimator in a rate of $\mathcal{O}(1/n)$. In practice, we can use a very small m (*e.g.*, 5 or 10) and still achieve good results, which is also confirmed by our later experiments. Compared to (Chen et al., 2009), the novel application of Cohen's algorithm arises for estimating influence for multiple sources, which drastically reduces the computation by cleverly using the least-label list from single source. Moreover, we have the following theoretical guarantee (see Appendix C for the proof).

Theorem 1 *Draw the following number of samples for the set of random transmission times*

$$n \geq \frac{C\Lambda}{\epsilon^2}\log\left(\frac{2|\mathcal{V}|}{\alpha}\right) \tag{17}$$

where $\Lambda := \max_{\mathcal{A}:|\mathcal{A}|\leq C} 2\sigma(\mathcal{A},T)^2/(m-2) + 2Var(|\mathcal{N}(\mathcal{A},T)|)(m-1)/(m-2) + 2a\epsilon/3$ *and* $|\mathcal{N}(\mathcal{A},T)| \leq |\mathcal{V}|$*, and for each set of random transmission times, draw* m *sets of random labels. Then* $|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \leq \epsilon$ *uniformly for all* $\mathcal{A}$ *with* $|\mathcal{A}| \leq C$*, with probability at least* $1-\alpha$*.*

The theorem indicates that the minimum number of samples, n, needed to achieve certain accuracy is related to the actual size of the influence $\sigma(\mathcal{A}, T)$, and the variance of the neighborhood size $|\mathcal{N}(\mathcal{A}, T)|$ over the random draw of samples. The number of random labels, m, drawn in the inner loop of the algorithm will monotonically decrease the dependency of n on $\sigma(\mathcal{A}, T)$. It suffices to draw a small number of random labels, as long as the value of $\sigma(\mathcal{A}, T)^2/(m-2)$ matches that of $Var(|\mathcal{N}(\mathcal{A}, T)|)$. Another implication is that influence at larger time window T is harder to estimate, since $\sigma(\mathcal{A}, T)$ will generally be larger and hence require more random samples.

3. Constraints of Practical Importance

By treating our proposed influence estimation algorithm ConTinEst as a building block, we can now tackle the influence maximization problem under various constraints of practical importance. Here, since ConTinEst can estimate the influence value of any source set with respect to any given time window T, the **Timing Constraints** can thus be naturally satisfied. Therefore, in the following sections, we mainly focus on modeling the **Multiple-Item Constraints**, the **User Constraints** and the **Product Constraints**.

3.1 Multiple-Item Constraints

Multiple products can spread simultaneously across the same set of social entities over different diffusion channels. Since these products may have different characteristics, such as the revenue and the speed of spread, and thus may follow different diffusion dynamics, we will use multiple diffusion networks for different types of products.

Suppose we have a set of products $\mathcal{L}$ that propagate on the same set of nodes $\mathcal{V}$. The diffusion network for product i is denoted as $\mathcal{G}_i = (\mathcal{V}, \mathcal{E}_i)$. For each product $i \in \mathcal{L}$, we search for a set of source nodes $\mathcal{R}_i \subseteq \mathcal{V}$ to which we can assign the product i to start its campaign. We can represent the selection of $\mathcal{R}_i$'s using an assignment matrix $A \in \{0,1\}^{|\mathcal{L}|\times|\mathcal{V}|}$ as follows: $A_{ij} = 1$ if $j \in \mathcal{R}_i$ and $A_{ij} = 0$ otherwise. Based on this representation, we define a new ground set $\mathcal{Z} = \mathcal{L} \times \mathcal{V}$ of size $N = |\mathcal{L}| \times |\mathcal{V}|$. Each element of $\mathcal{Z}$ corresponds to the index (i, j) of an entry in the assignment matrix A, and selecting element $z = (i, j)$ means assigning product i to user j (see Figure 1 for an illustration). We also denote $\mathcal{Z}_{*j} = \mathcal{L} \times \{j\}$ and $\mathcal{Z}_{i*} = \{i\} \times \mathcal{V}$ as the j-th column and i-th row of matrix A, respectively. Then, under the above mentioned additional requirements, we would like to find a set of assignments $\mathcal{S} \subseteq \mathcal{Z}$ so as to maximize the following **overall influence**

$$f(S) = \sum_{i\in\mathcal{L}} a_i \sigma_i(\mathcal{R}_i, T_i), \tag{18}$$

where $\sigma_i(\mathcal{R}_i, T_i)$ denote the influence of product i for a given time T_i, $\{a_i > 0\}$ is a set of weights reflecting the different benefits of the products and $\mathcal{R}_i = \{j \in \mathcal{V} : (i, j) \in S\}$. We now show that the overall influence function $f(S)$ in Equation (18) is submodular over the ground set $\mathcal{Z}$.

Lemma 2 *Under the continuous-time independent cascade model, the overall influence $f(S)$ is a normalized monotone submodular function of S.*

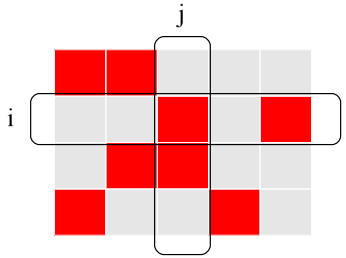

Figure 1: Illustration of the assignment matrix A associated with partition matroid $\mathcal{M}_1$ and group knapsack constraints. If product i is assigned to user j, then $A_{ij} = 1$ (colored in red). The ground set $\mathcal{Z}$ is the set of indices of the entries in A, and selecting an element $(i, j) \in \mathcal{Z}$ means assigning product i to user j. The user constraint means that there are at most u_j elements selected in the j-th column; the product constraint means that the total cost of the elements selected in the i-th row is at most B_i.

Proof By definition, $f(\emptyset) = 0$ and $f(S)$ is monotone. By Theorem 4 in Gomez-Rodriguez and Schölkopf (2012), the component influence function $\sigma_i(\mathcal{R}_i, T_i)$ for product i is submodular in $\mathcal{R}_i \subseteq \mathcal{V}$. Since non-negative linear combinations of submodular functions are still submodular, $f_i(S) := a_i\sigma_i(\mathcal{R}_i, T_i)$ is also submodular in $S \subseteq \mathcal{Z} = \mathcal{L}\times\mathcal{V}$, and $f(S) = \sum_{i\in\mathcal{L}} f_i(S)$ is submodular. ■

3.2 User Constraints

Each social network user can be a potential source and would like to be exposed only to a small number of ads. Furthermore, users may be grouped according to their geographical locations, and advertisers may have a target population they want to reach. Here, we will incorporate these constraints using the matroids which are combinatorial structures that generalize the notion of linear independence in matrices (Schrijver, 2003; Fujishige, 2005). Formulating our constrained influence maximization task with matroids allows us to design a greedy algorithm with provable guarantees.

Formally, suppose that each user j can be assigned to at most u_j products. A matroid can be defined as follows:

Definition 3 *A matroid is a pair, $\mathcal{M} = (\mathcal{Z}, \mathcal{I})$, defined over a finite set (the ground set) $\mathcal{Z}$ and a family of sets (the independent sets) $\mathcal{I}$, that satisfies three axioms:*

1. *Non-emptiness: The empty set $\emptyset \in \mathcal{I}$.*
2. *Heredity: If $Y \in \mathcal{I}$ and $X \subseteq Y$, then $X \in \mathcal{I}$.*
3. *Exchange: If $X \in \mathcal{I}, Y \in \mathcal{I}$ and $|Y| > |X|$, then there exists $z \in Y \setminus X$ such that $X \cup \{z\} \in \mathcal{I}$.*

An important type of matroid is the partition matroid where the ground set $\mathcal{Z}$ is partitioned into disjoint subsets $\mathcal{Z}_1, \mathcal{Z}_2, \ldots, \mathcal{Z}_t$ for some t and

$$\mathcal{I} = \{S \mid S \subseteq \mathcal{Z} \text{ and } |S \cap \mathcal{Z}_i| \leq u_i, \forall i = 1, \ldots, t\}$$

for some given parameters $u_1, \ldots, u_t$. The user constraints can then be formulated as

> Partition matroid $\mathcal{M}_1$: partition the ground set $\mathcal{Z}$ into $\mathcal{Z}_{*j} = \mathcal{L} \times \{j\}$ each of which corresponds to a column of A. Then $\mathcal{M}_1 = \{\mathcal{Z}, \mathcal{I}_1\}$ is
>
> $$\mathcal{I}_1 = \{S | S \subseteq \mathcal{Z} \text{ and } |S \cap \mathcal{Z}_{*j}| \leq u_j, \forall j\}.$$

3.3 Product Constraints

Seeking initial adopters entails a cost to the advertiser, which needs to be paid to the host, while the advertisers of each product have a limited amount of money. Here, we will incorporate these requirements using knapsack constraints which we describe below.

Formally, suppose that each product i has a budget B_i, and assigning item i to user j costs $c_{ij} > 0$. Next, we introduce the following notation to describe product constraints over the ground set $\mathcal{Z}$. For an element $z = (i, j) \in \mathcal{Z}$, define its cost as $c(z) := c_{ij}$. Abusing the notation slightly, we denote the cost of a subset $S \subseteq \mathcal{Z}$ as $c(S) := \sum_{z \in S} c(z)$. Then, in a feasible solution $S \subseteq \mathcal{Z}$, the cost of assigning product i, $c(S \cap \mathcal{Z}_{i*})$, should not be larger than its budget B_i.

Now, without loss of generality, we can assume $B_i = 1$ (by normalizing c_{ij} with B_i), and also $c_{ij} \in (0, 1]$ (by throwing away any element (i, j) with $c_{ij} > 1$), and define

> Group-knapsack: partition the ground set into $\mathcal{Z}_{i*} = \{i\} \times \mathcal{V}$ each of which corresponds to one row of A. Then a feasible solution $S \subseteq \mathcal{Z}$ satisfies
>
> $$c(S \cap \mathcal{Z}_{i*}) \leq 1, \forall i.$$

Importantly, these knapsack constraints have very specific structure: they are on different groups of a partition $\{\mathcal{Z}_{i*}\}$ of the ground set and the submodular function $f(S) = \sum_i a_i \sigma_i(\mathcal{R}_i, T_i)$ is defined over the partition. In consequence, such structures allow us to design an efficient algorithm with improved guarantees over the known results.

3.4 Overall Problem Formulation

Based on the above discussion of various constraints in viral marketing and our design choices for tackling them, we can think of the influence maximization problem as a special case of the following constrained submodular maximization problem with $P = 1$ matroid constraints and $k = |\mathcal{L}|$ knapsack constraints,

$$\begin{aligned} \max_{S \subseteq \mathcal{Z}} \quad & f(S) \\ \text{subject to} \quad & c(S \cap \mathcal{Z}_{i*}) \leq 1, \quad 1 \leq i \leq k, \\ & S \in \bigcap_{p=1}^{P} \mathcal{I}_p, \end{aligned} \tag{19}$$

where, for simplicity, we will denote all the feasible solutions $S \subseteq \mathcal{Z}$ as $\mathcal{F}$. This formulation in general includes the following cases of practical importance :

Uniform User-Cost. An important case of influence maximization, which we denote as the Uniform Cost, is that for each product i, all users have the same cost c_{i*}, *i.e.*, $c_{ij} = c_{i*}$. Equivalently, each product i can be assigned to at most $b_i := \lfloor B_i / c_{i*} \rfloor$ users. Then the product constraints are simplified to

> Partition matroid $\mathcal{M}_2$: for the product constraints with uniform cost, define a matroid $\mathcal{M}_2 = \{\mathcal{Z}, \mathcal{I}_2\}$ where
>
> $$\mathcal{I}_2 = \{S | S \subseteq \mathcal{Z} \text{ and } |S \cap \mathcal{Z}_{i*}| \leq b_i, \forall i\}.$$

In this case, the influence maximization problem defined by Equation (19) becomes the problem with $P = 2$ matroid constraints and no knapsack constraints ($k = 0$). In addition, if we assume only one product needs campaign, the formulation of Equation (19) further reduces to the classic influence maximization problem with the simple cardinality constraint.

User Group Constraint. Our formulation in Equation (19) essentially allows for general matroids which can model more sophisticated real-world constraints, and the proposed formulation, algorithms, and analysis can still hold. For instance, suppose there is a hierarchical community structure on the users, *i.e.*, a tree $\mathcal{T}$ where leaves are the users and the internal nodes are communities consisting of all users underneath, such as customers in different countries around the world. In consequence of marketing strategies, on each community $C \in \mathcal{T}$, there are at most u_C slots for assigning the products. Such constraints are readily modeled by the Laminar Matroid, which generalizes the partition matroid by allowing the set $\{\mathcal{Z}_i\}$ to be a laminar family (*i.e.*, for any $\mathcal{Z}_i \neq \mathcal{Z}_j$, either $\mathcal{Z}_i \subseteq \mathcal{Z}_j$, or $\mathcal{Z}_j \subseteq \mathcal{Z}_i$, or $\mathcal{Z}_i \cap \mathcal{Z}_j = \emptyset$). It can be shown that the community constraints can be captured by the matroid $\mathcal{M} = (\mathcal{Z}, \mathcal{I})$ where $\mathcal{I} = \{S \subseteq \mathcal{Z} : |S \cap C| \leq u_C, \forall C \in \mathcal{T}\}$. In the next section, we first present our algorithm, then provide the analysis for the uniform cost case and finally leverage such analysis for the general case.

4. Influence Maximization

In this section, we first develop a simple, practical and intuitive adaptive-thresholding greedy algorithm to solve the continuous-time influence maximization problem with the aforementioned constraints. Then, we provide a detailed theoretical analysis of its performance.

4.1 Overall Algorithm

There exist algorithms for submodular maximization under multiple knapsack constraints achieving a $1 - \frac{1}{e}$ approximation factor by (Sviridenko, 2004). Thus, one may be tempted to convert the matroid constraint in the problem defined by Equation (19) to $|\mathcal{V}|$ knapsack constraints, so that the problem becomes a submodular maximization problem under $|\mathcal{L}| + |\mathcal{V}|$ knapsack constraints. However, this naive approach is not practical for large-scale scenarios because the running time of such algorithms is exponential in the number of knapsack constraints. Instead, if we opt for algorithms for submodular maximization under k knapsack constraints and P matroids constraints, the best approximation factor achieved by polynomial time algorithms is $\frac{1}{P+2k+1}$ (Badanidiyuru and Vondrák, 2014). However,

Algorithm 1: Density Threshold Enumeration

Input: parameter δ; objective f or its approximation $\widehat{f}$; assignment cost $c(z), z \in \mathcal{Z}$

Set $d = \max\{f(\{z\}) : z \in \mathcal{Z}\}$;

for $\rho \in \left\{\frac{2d}{P+2k+1}, (1+\delta)\frac{2d}{P+2k+1}, \ldots, \frac{2|\mathcal{Z}|d}{P+2k+1}\right\}$ **do**

  Call Algorithm 2 to get S_ρ;

Output: $\operatorname{argmax}_{S_\rho} f(S_\rho)$

this is not good enough yet, since in our problem $k = |\mathcal{L}|$ can be large, though $P = 1$ is small.

Here, we will design an algorithm that achieves a better approximation factor by exploiting the following key observation about the structure of the problem defined by Equation (19): the knapsack constraints are over different groups $\mathcal{Z}_{i*}$ of the whole ground set, and the objective function is a sum of submodular functions over these different groups.

The details of the algorithm, called BudgetMax, are described in Algorithm 1. BudgetMax enumerates different values of a so-called density threshold ρ, runs a subroutine to find a solution for each ρ, which quantifies the cost-effectiveness of assigning a particular product to a specific user, and finally outputs the solution with the maximum objective value. Intuitively, the algorithm restricts the search space to be the set of most cost-effective allocations. The details of the subroutine to find a solution for a fixed density threshold ρ are described in Algorithm 2. Inspired by the lazy evaluation heuristic (Leskovec et al., 2007), the algorithm maintains a working set G and a marginal gain threshold w_t, which geometrically decreases by a factor of $1+\delta$ until it is sufficiently small to be set to zero. At each w_t, the subroutine selects each new element z that satisfies the following properties:

1. It is feasible and the density ratio (the ratio between the marginal gain and the cost) is above the current density threshold;

2. Its marginal gain
$$f(z|G) := f(G \cup \{z\}) - f(G)$$
is above the current marginal gain threshold.

The term "density" comes from the knapsack problem, where the marginal gain is the mass and the cost is the volume. A large density means gaining a lot without paying much. In short, the algorithm considers only high-quality assignments and repeatedly selects feasible ones with marginal gain ranging from large to small.

Remark 1. The traditional lazy evaluation heuristic also keeps a threshold, however, it only uses the threshold to speed up selecting the element with maximum marginal gain. Instead, Algorithm 2 can add multiple elements z from the ground set at each threshold according to the descending order of their marginal gains, and thus reduces the number of rounds from the size of the solution to the number of thresholds $\mathcal{O}(\frac{1}{\delta}\log\frac{N}{\delta})$. This allows us to trade off between the runtime and the approximation ratio (refer to our theoretical guarantees in section 4.2).

Algorithm 2: Adaptive Threshold Greedy for Fixed Density

Input: parameters ρ, δ; objective f or its approximation $\widehat{f}$; assignment cost $c(z), z \in \mathcal{Z}$;set of feasible solutions $\mathcal{F}$; and d from Algorithm 1.

Set $d_\rho = \max\{f(\{z\}) : z \in \mathcal{Z}, f(\{z\}) \geq c(z)\rho\}$;

Set $w_t = \frac{d_\rho}{(1+\delta)^t}$ for $t = 0, \ldots, L = \operatorname{argmin}_i\left[w_i \leq \frac{\delta d}{N}\right]$ and $w_{L+1} = 0$;

Set $G = \emptyset$;

for $t = 0, 1, \ldots, L, L+1$ **do**

  for $z \notin G$ *with* $G \cup \{z\} \in \mathcal{F}$ *and* $f(z|G) \geq c(z)\rho$ **do**

    if $f(z|G) \geq w_t$ **then**

      Set $G \leftarrow G \cup \{z\}$;

Output: $S_\rho = G$

Remark 2. Evaluating the influence of the assigned products f is expensive. Therefore, we will use the randomized algorithm in Section 2.4.3 to compute an estimation $\widehat{f}(\cdot)$ of the quantity $f(\cdot)$.

4.2 Theoretical Guarantees

Although our algorithm is quite intuitive, it is highly non-trivial to obtain the theoretical guarantees. For clarity, we first analyze the simpler case with uniform cost, which then provides the base for analyzing the general case.

4.2.1 Uniform Cost

As shown at the end of Section 3.4, the influence maximization, in this case, corresponds to the problem defined by Equation (19) with $P = 2$ and no knapsack constraints. Thus, we can simply run Algorithm 2 with $\rho = 0$ to obtain a solution G, which is roughly a $\frac{1}{P+1}$-approximation.

Intuition. The algorithm greedily selects feasible elements with sufficiently large marginal gain. However, it is unclear whether our algorithm will find *good* solutions and whether it will be *robust* to noise. Regarding the former, one might wonder whether the algorithm will select just a few elements while many elements in the optimal solution O will become infeasible and will not be selected, in which case the greedy solution G is a poor approximation. Regarding the latter, we only use the estimation $\widehat{f}$ of the influence f (*i.e.*, $|\widehat{f}(S) - f(S)| \leq \epsilon$ for any $S \subseteq \mathcal{Z}$), which introduces additional error to the function value. A crucial question, which has not been addressed before (Badanidiyuru and Vondrák, 2014), is whether the adaptive threshold greedy algorithm is robust to such perturbations.

Fortunately, it turns out that the algorithm will provably select sufficiently many elements of high quality. First, the elements selected in the optimal solution O but not selected in G can be partitioned into $|G|$ groups, each of which is associated with an element in G. Thus, the number of elements in the groups associated with the first t elements in G, by the property of the intersection of matroids, are bounded by Pt. See Figure 2 for an illustration. Second, the marginal gain of each element in G is at least as large as that of any

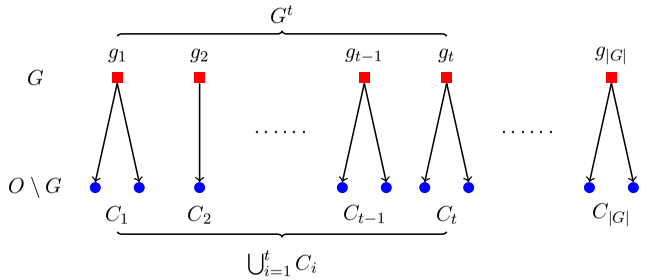

Figure 2: Notation for analyzing Algorithm 2. The elements in the greedy solution G are arranged according to the order in which Algorithm 2 selects them in Step 3. The elements in the optimal solution O but not in the greedy solution G are partitioned into groups $\{C_t\}_{1\leq t\leq |G|}$, where C_t are those elements in $O \setminus G$ that are still feasible before selecting g_t but are infeasible after selecting g_t.

element in the group associated with it (up to some small error). This means that even if the submodular function evaluation is inexact, the quality of the elements in the greedy solution is still good. The two claims together show that the marginal gain of $O \setminus G$ is not much larger than the gain of G, and thus G is a good approximation for the problem.

Formally, suppose we use an inexact evaluation of the influence f such that $|\widehat{f}(S) - f(S)| \leq \epsilon$ for any $S \subseteq \mathcal{Z}$, let product $i \in \mathcal{L}$ spread according to a diffusion network $\mathcal{G}_i = (\mathcal{V}, \mathcal{E}_i)$, and $i^* = \operatorname{argmax}_{i\in\mathcal{L}} |\mathcal{E}_i|$. Then, we have:

Theorem 4 *Suppose $\widehat{f}$ is evaluated up to error $\epsilon = \delta/16$ with* ConTinEst. *For influence maximization with uniform cost, Algorithm 2 (with $\rho = 0$) outputs a solution G with $f(G) \geq \frac{1-2\delta}{3} f(O)$ in expected time $\widetilde{\mathcal{O}}\left(\frac{|\mathcal{E}_{i^*}|+|\mathcal{V}|}{\delta^2} + \frac{|\mathcal{L}||\mathcal{V}|}{\delta^3}\right)$.*

The parameter δ introduces a tradeoff between the approximation guarantee and the runtime: larger δ decreases the approximation ratio but results in fewer influence evaluations. Moreover, the runtime has a linear dependence on the network size and the number of products to propagate (ignoring some small logarithmic terms) and, as a consequence, the algorithm is scalable to large networks.

Analysis. Suppose $G = \{g_1, \ldots, g_{|G|}\}$ in the order of selection, and let $G^t = \{g_1, \ldots, g_t\}$. Let C_t denote all those elements in $O \setminus G$ that satisfy the following: they are still feasible before selecting the t-th element g_t but are infeasible after selecting g_t. Equivalently, C_t are all those elements $j \in O \setminus G$ such that (1) $j \cup G^{t-1}$ does not violate the matroid constraints but (2) $j \cup G^t$ violates the matroid constraints. In other words, we can think of C_t as the optimal elements "blocked" by g_t. Then, we proceed as follows.

By the property of the intersection of matroids, the size of the prefix $\bigcup_{i=1}^t C_t$ is bounded by Pt. As a consequence of this property, for any $Q \subseteq \mathcal{Z}$, the sizes of any two maximal independent subsets T_1 and T_2 of Q can only differ by a multiplicative factor at most P. This can be realized with the following argument. First, note that any element $z \in T_1 \setminus T_2$, $\{z\} \cup T_2$ violates at least one of the matroid constraints since T_2 is maximal. Then, let $\{V_i\}_{1\leq i\leq P}$ denote all elements in $T_1 \setminus T_2$ that violate the i-th matroid, and partition $T_1 \cap T_2$ arbitrarily among these V_i's so that they cover T_1. In this construction, the size of each V_i must be at most $|T_2|$, since otherwise by the Exchange axiom, there would exist $z \in V_i \setminus T_2$ that can be added to T_2, without violating the i-th matroid, leading to a contradiction. Therefore, $|T_1|$ is at most P times $|T_2|$.

Next, we apply the above property as follows. Let Q be the union of G^t and $\bigcup_{i=1}^t C_t$. On one hand, G^t is a maximal independent subset of Q, since no element in $\bigcup_{i=1}^t C_t$ can be added to G^t without violating the matroid constraints. On the other hand, $\bigcup_{i=1}^t C_t$ is an independent subset of Q, since it is part of the optimal solution. Therefore, $\bigcup_{i=1}^t C_t$ has size at most P times $|G^t|$, which is Pt. Note that the properties of matroids are crucial for this analysis, which justifies our formulation using matroids. In summary, we have

Claim 1 $\sum_{i=1}^t |C_i| \leq Pt$, *for* $t = 1, \ldots, |G|$.

Now, we consider the marginal gain of each element in C_t associated with g_t. First, suppose g_t is selected at the threshold $\tau_t > 0$. Then, any $j \in C_t$ has marginal gain bounded by $(1+\delta)\tau_t + 2\epsilon$, since otherwise j would have been selected at a larger threshold before τ_t by the greedy criterion. Second, suppose g_t is selected at the threshold $w_{L+1} = 0$. Then, any $j \in C_t$ has marginal gain approximately bounded by $\frac{\delta}{N} d$. Since the greedy algorithm must pick g_1 with $\widehat{f}(g_1) = d$ and $d \leq f(g_1) + \epsilon$, any $j \in C_t$ has marginal gain bounded by $\frac{\delta}{N} f(G) + \mathcal{O}(\epsilon)$. Putting everything together we have:

Claim 2 *Suppose g_t is selected at the threshold τ_t. Then $f(j|G^{t-1}) \leq (1+\delta)\tau_t + 4\epsilon + \frac{\delta}{N} f(G)$ for any $j \in C_t$.*

Since the evaluation of the marginal gain of g_t should be at least τ_t, this claims essentially indicates that the marginal gain of j is approximately bounded by that of g_t.

Since there are not many elements in C_t (Claim 1) and the marginal gain of each of its elements is not much larger than that of g_t (Claim 2), we can conclude that the marginal gain of $O \setminus G = \bigcup_{i=1}^{|G|} C_t$ is not much larger than that of G, which is just $f(G)$.

Claim 3 *The marginal gain of $O \setminus G$ satisfies*

$$\sum_{j\in O\setminus G} f(j|G) \leq [(1+\delta)P + \delta] f(G) + (6 + 2\delta)\epsilon P|G|.$$

Finally, since by submodularity, $f(O) \leq f(O \cup G) \leq f(G) + \sum_{j\in O\setminus G} f(j|G)$, Claim 3 shows that $f(G)$ is close to $f(O)$ up to a multiplicative factor roughly $(1+P)$ and additive factor $\mathcal{O}(\epsilon P|G|)$. Given that $f(G) > |G|$, it leads to roughly a 1/3-approximation for our influence maximization problem by setting $\epsilon = \delta/16$ when evaluating $\widehat{f}$ with ConTinEst. Combining the above analysis and the runtime of the influence estimation algorithm, we have our final guarantee in Theorem 4. Appendix D.1 presents the complete proofs.

4.2.2 General Case

In this section, we consider the general case, in which users may have different associated costs. Recall that this case corresponds to the problem defined by Equation (19) with $P = 1$ matroid constraints and $k = |\mathcal{L}|$ group-knapsack constraints. Here, we will show that there is a step in Algorithm 1 which outputs a solution S_ρ that is a good approximation.

Intuition. The key idea behind Algorithm 1 and Algorithm 2 is simple: spend the budgets *efficiently* and spend them *as much as possible*. By spending them efficiently, we mean to only select those elements whose density ratio between the marginal gain and the cost is above the threshold ρ. That is, we assign product i to user j only if the assignment leads to large marginal gain without paying too much. By spending the budgets as much as possible, we mean to stop assigning product i only if its budget is almost exhausted or no more assignments are possible without violating the matroid constraints. Here we make use of the special structure of the knapsack constraints on the budgets: each constraint is only related to the assignment of the corresponding product and its budget, so that when the budget of one product is exhausted, it does not affect the assignment of the other products. In the language of submodular optimization, the knapsack constraints are on a partition $\mathcal{Z}_{i*}$ of the ground set and the objective function is a sum of submodular functions over the partition.

However, there seems to be a hidden contradiction between spending the budgets efficiently and spending them as much as possible. On one hand, efficiency means the density ratio should be large, so the threshold ρ should be large; on the other hand, if ρ is large, there are just a few elements that can be considered, and thus the budget might not be exhausted. After all, if we set ρ to be even larger than the maximum possible value, then no element is considered and no gain is achieved. In the other extreme, if we set $\rho = 0$ and consider all the elements, then a few elements with large costs may be selected, exhausting all the budgets and leading to a poor solution.

Fortunately, there exists a suitable threshold ρ that achieves a good tradeoff between the two and leads to a good approximation. On one hand, the threshold is sufficiently small, so that the optimal elements we abandon (*i.e.*, those with low-density ratio) have a total gain at most a fraction of the optimum; on the other hand, it is also sufficiently large, so that the elements selected are of high quality (*i.e.*, of high-density ratio), and we achieve sufficient gain even if the budgets of some items are exhausted.

Theorem 5 *Suppose $\widehat{f}$ is evaluated up to error $\epsilon = \delta/16$ with* ConTinEst. *In Algorithm 1, there exists a ρ such that*

$$f(S_\rho) \geq \frac{\max\{k_a, 1\}}{(2|\mathcal{L}|+2)(1+3\delta)} f(O)$$

where k_a is the number of active knapsack constraints:

$$k_a = |\{i : S_\rho \cup \{z\} \notin \mathcal{F}, \forall z \in \mathcal{Z}_{i*}\}|.$$

The expected running time is $\widetilde{\mathcal{O}}\left(\frac{|\mathcal{E}_{i^*}|+|\mathcal{V}|}{\delta^2} + \frac{|\mathcal{L}||\mathcal{V}|}{\delta^4}\right)$.

Importantly, the approximation factor improves over the best known guarantee $\frac{1}{P+2k+1} = \frac{1}{2|\mathcal{L}|+2}$ for efficiently maximizing submodular functions over P matroids and k general knapsack constraints. Moreover, since the runtime has a linear dependence on the network size, the algorithm easily scales to large networks. As in the uniform cost case, the parameter δ introduces a tradeoff between the approximation and the runtime.

Analysis. The analysis follows the intuition. Pick $\rho = \frac{2f(O)}{P+2k+1}$, where O is the optimal solution, and define

$$O_- := \{z \in O \setminus S_\rho : f(z|S_\rho) < c(z)\rho + 2\epsilon\},$$
$$O_+ := \{z \in O \setminus S_\rho : z \notin O_-\}.$$

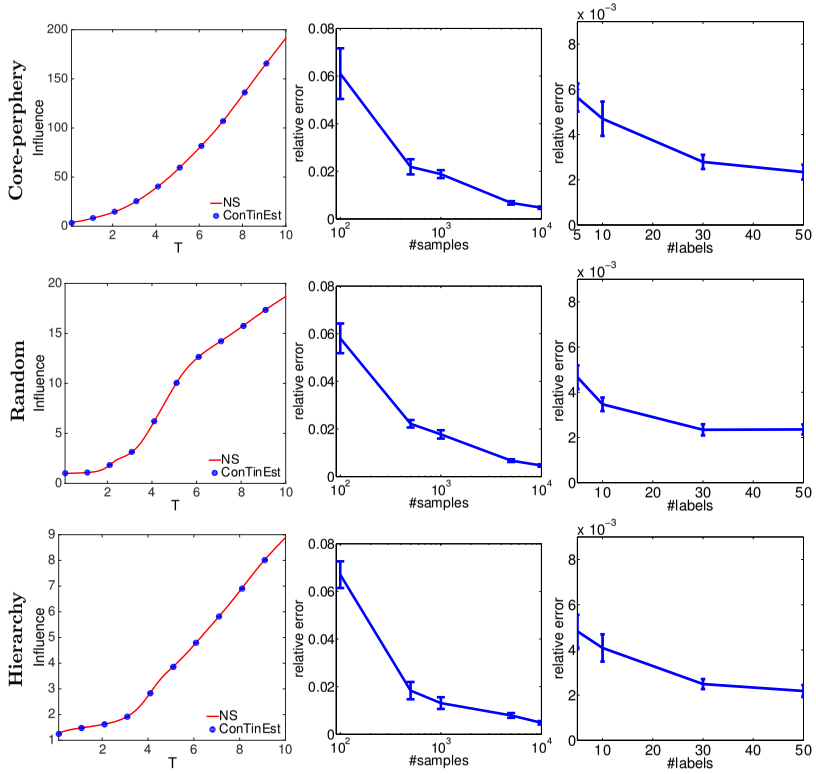
Note that, by submodularity, O_- is a superset of the elements in the optimal solution that we abandon due to the density threshold and, by construction, its marginal gain is small:

$$f(O_-|S_\rho) \leq \rho c(O_-) + \mathcal{O}(\epsilon|S_\rho|) \leq k\rho + \mathcal{O}(\epsilon|S_\rho|),$$

where the small additive term $\mathcal{O}(\epsilon|S_\rho|)$ is due to inexact function evaluations. Next, we proceed as follows.

First, if no knapsack constraints are active, then the algorithm runs as if there were no knapsack constraints (but only on elements with density ratio above ρ). Therefore, we can apply the same argument as in the case of uniform cost (refer to the analysis up to Claim 3 in Section 4.2.1); the only caveat is that we apply the argument to O_+ instead of $O \setminus S_\rho$. Formally, similar to Claim 3, the marginal gain of O_+ satisfies

$$f(O_+|S_\rho) \leq [(1+\delta)P + \delta] f(S_\rho) + \mathcal{O}(\epsilon P|S_\rho|),$$



where the small additive term $\mathcal{O}(\epsilon P|S_\rho|)$ is due to inexact function evaluations. Using that $f(O) \leq f(S_\rho) + f(O_-|S_\rho) + f(O_+|S_\rho)$, we can conclude that S_ρ is roughly a $\frac{1}{P+2k+1}$-approximation.

Second, suppose $k_a > 0$ knapsack constraints are active and the algorithm discovers that the budget of product i is exhausted when trying to add element z to the set $G_i = G \cap \mathcal{Z}_{i*}$ of selected elements at that time. Since $c(G_i \cup \{z\}) > 1$ and each of these elements has density above ρ, the gain of $G_i \cup \{z\}$ is above ρ. However, only G_i is included in our final solution, so we need to show that the marginal gain of z is not large compared to that of G_i. To do so, we first realize that the algorithm greedily selects elements with marginal gain above a decreasing threshold w_t. Then, since z is the last element selected and G_i is nonempty (otherwise adding z will not exhaust the budget), the marginal gain of z must be bounded by roughly that of G_i, which is at least roughly $\frac{1}{2}\rho$. Since this holds for all active knapsack constraints, then the solution has value at least $\frac{k_a}{2}\rho$, which is an $\frac{k_a}{P+2k+1}$-approximation.

Finally, combining both cases, and setting $k = |\mathcal{L}|$ and $P = 1$ as in our problem, we have our final guarantee in Theorem 5. Appendix D.2 presents the complete proofs.

5. Experiments on Synthetic and Real Data

In this section, we first evaluate the accuracy of the estimated influence given by ConTinEst and then investigate the performance of influence maximization on synthetic and real networks by incorporating ConTinEst into the framework of BudgetMax. We show that our approach significantly outperforms the state-of-the-art methods in terms of both speed and solution quality.

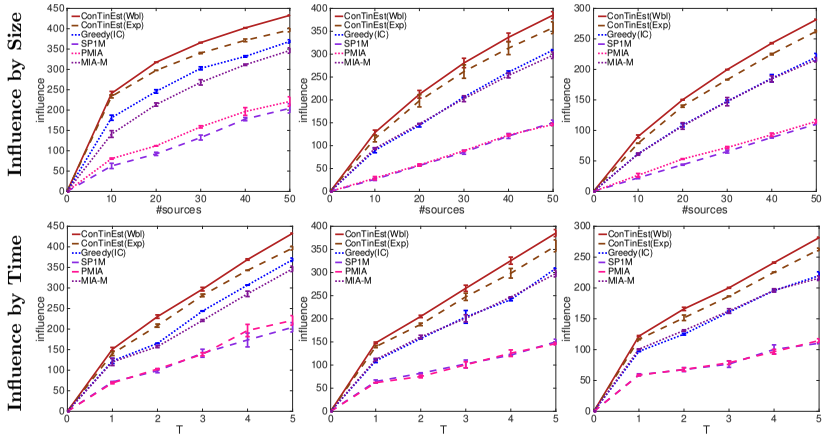
(a) Influence vs. time (b) Influence vs. #samples (c) Error vs. #labels

Figure 3: Influence estimation for core-periphery, random, and hierarchical networks with 1,024 nodes and 2,048 edges. Column (a) shows estimated influence by NS (near ground truth), and ConTinEst for increasing time window T; Column (b) shows ConTinEst's relative error against number of samples with 5 random labels and $T = 10$; Column (c) reports ConTinEst's relative error against the number of random labels with 10,000 random samples and $T = 10$.

5.1 Experiments on Synthetic Data

We generate three types of Kronecker networks (Leskovec et al., 2010) which are synthetic networks generated by a recursive Kronecker product of a base 2-by-2 parameter matrix with itself to generate self-similar graphs. By tuning the base parameter matrix, we are able to generate the Kronecker networks which can mimic different structural properties of many real networks. In the following, we consider networks of three different types of structures: (*i*) core-periphery networks (parameter matrix: [0.9 0.5; 0.5 0.3]), which mimic the information diffusion traces in real-world networks (Gomez-Rodriguez et al., 2011), (*ii*) random networks ([0.5 0.5; 0.5 0.5]), typically used in physics and graph theory (Easley and Kleinberg, 2010) and (*iii*) hierarchical networks ([0.9 0.1; 0.1 0.9]) (Clauset et al., 2008). Next, we assign a pairwise transmission function for every directed edge in each type of network and set its parameters at random. In our experiments, we use the Weibull distribution from (Aalen et al., 2008),

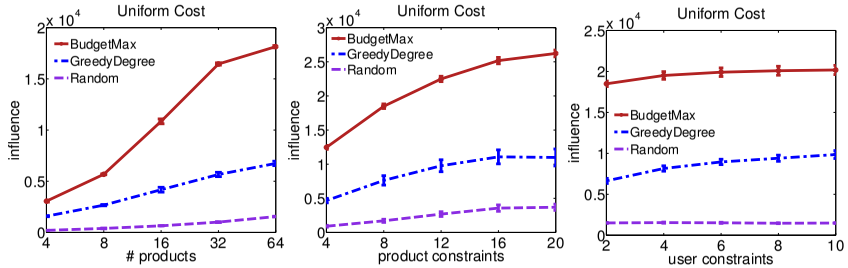
$$f(t;\alpha,\beta) = \frac{\beta}{\alpha}\left(\frac{t}{\alpha}\right)^{\beta-1} e^{-(t/\alpha)^{\beta}}, t \geq 0, \tag{20}$$



where $\alpha > 0$ is a scale parameter and $\beta > 0$ is a shape parameter. The Weibull distribution (Wbl) has often been used to model lifetime events in survival analysis, providing more flexibility than an exponential distribution. We choose α and β from 0 to 10 uniformly at random for each edge in order to have heterogeneous temporal dynamics. Finally, for each type of Kronecker network, we generate 10 sample networks, each of which has different α and β chosen for every edge.

5.1.1 Influence Estimation

To the best of our knowledge, there is no analytical solution to the influence estimation given Weibull transmission function. Therefore, we compare ConTinEst with the Naive Sampling (NS) approach by considering the highest degree node in a network as the source, and draw 1,000,000 samples for NS to obtain near ground truth. In Figure 3, Column (a) compares ConTinEst with the ground truth provided by NS at different time window T, from 0.1 to 10 in networks of different structures. For ConTinEst, we generate up to 10,000 random samples (or sets of random waiting times), and 5 random labels in the inner loop. In all three networks, estimation provided by ConTinEst fits the ground truth accurately, and the relative error decreases quickly as we increase the number of samples and labels (Column (b) and Column (c)). For 10,000 random samples with 5 random labels, the relative error is smaller than 0.01.



5.1.2 Influence Maximization with Uniform Cost

In this section, we first evaluate the effectiveness of ConTinEst to the classic influence maximization problem where we have only one product to assign with the simple cardinality constraint on the users. We compare to other influence maximization methods developed based on discrete-time diffusion models: traditional greedy by (Kempe et al., 2003), with discrete-time Linear Threshold Model (LT) and Independent Cascade Model (IC) diffusion models, and the heuristic methods SP1M, PMIA and MIA-M by (Chen et al., 2009, 2010a, 2012). For Influmax, since it only supports exponential pairwise transmission functions,

(a) Core-periphery (b) Random (c) Hierarchy

Figure 4: Influence $\sigma(\mathcal{A}, T)$ achieved by varying number of sources $|\mathcal{A}|$ and observation window T on the networks of different structures with 1,024 nodes, 2,048 edges and heterogeneous Weibull transmission functions. Top row: influence against #sources by $T = 5$; Bottom row: influence against the time window T using 50 sources.

(a) By products (b) By product constraints (c) By user constraints

Figure 5: Over the 64 product-specific diffusion networks, each of which has 1,048,576 nodes, the estimated influence (a) for increasing the number of products by fixing the product-constraint at 8 and user-constraint at 2; (b) for increasing product-constraint by user-constraint at 2; and (c) for increasing user-constraint by fixing product-constraint at 8. For all experiments, we have $T = 5$ time window.

we fit an exponential distribution per edge by NetRate (Gomez-Rodriguez et al., 2011). Furthermore, Influmax is not scalable. When the average network density (defined as the average degree per node) of the synthetic networks is ~ 2.0, the run time for Influmax

is more than 24 hours. In consequence, we present the results of ConTinEst using fitted exponential distributions (Exp). For the discrete-time IC model, we learn the infection probability within time window T using Netrapalli's method (Netrapalli and Sanghavi, 2012). The learned pairwise infection probabilities are also served for SP1M and PMIA, which approximately calculate the influence based on the IC model. For the discrete-time LT model, we set the weight of each incoming edge to a node u to the inverse of its in-degree, as in previous work (Kempe et al., 2003), and choose each node's threshold uniformly at random. The top row of Figure 4 compares the expected number of infected nodes against the source set size for different methods. ConTinEst outperforms the rest, and the competitive advantage becomes more dramatic the larger the source set grows. The bottom row of Figure 4 shows the expected number of infected nodes against the time window for 50 selected sources. Again, ConTinEst performs the best for all three types of networks.

Next, using ConTinEst as a subroutine for influence estimation, we evaluate the performance of BudgetMax with the uniform-cost constraints on the users. In our experiments we consider up to 64 products, each of which diffuses over one of the above three different types of Kronecker networks with $\sim$ one million nodes. Further, we randomly select a subset of 512 nodes $\mathcal{V}_S \subseteq \mathcal{V}$ as our candidate target users, who will receive the given products, and evaluate the potential influence of an allocation over the underlying one-million-node networks. For BudgetMax, we set the adaptive threshold δ to 0.01 and the cost per user and product to 1. For ConTinEst, we use 2,048 samples with 5 random labels on each of the product-specific diffusion networks. We repeat our experiments 10 times and report the average performance.

We compare BudgetMax with a nodes' degree-based heuristic, which we refer to as GreedyDegree, where the degree is treated as a natural measure of influence, and a baseline method, which assigns the products to the target nodes randomly. We opt for the nodes' degree-based heuristic since, in practice, large-degree nodes, such as users with millions of followers in Twitter, are often the targeted users who will receive a considerable payment if he (she) agrees to post the adoption of some products (or ads) from merchants. GreedyDegree proceeds as follows. It first sorts the list of all pairs of products i and nodes $j \in \mathcal{V}_S$ in descending order of node-j's degree in the diffusion network associated to product i. Then, starting from the beginning of the list, it considers each pair one by one: if the addition of the current pair to the existing solution does not violate the predefined matroid constraints, it is added to the solution, and otherwise, it is skipped. This process continues until the end of the list is reached. In other words, we greedily assign products to nodes with the largest degree. Due to the large size of the underlying diffusion networks, we do not apply other more expensive node centrality measures such as the clustering coefficient and betweenness.

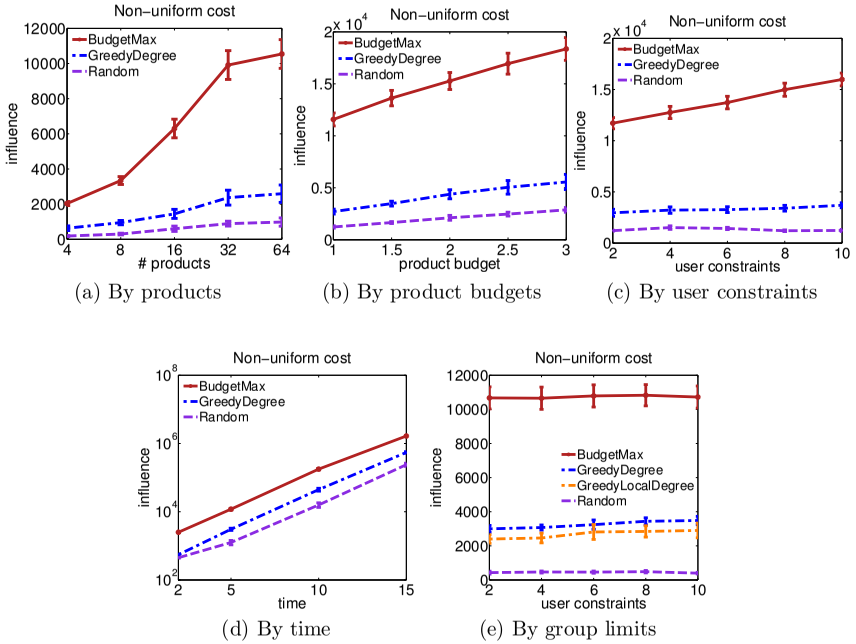


Figure 5 summarizes the results. Panel (a) shows the achieved influence against number of products, fixing the budget per product to 8 and the budget per user to 2. As the number of products increases, on the one hand, more and more nodes become assigned, so the total influence will increase. Yet, on the other hand, the competition among products for a few existing *influential* nodes also increases. GreedyDegree achieves a modest performance, since high degree nodes may have many overlapping children. In contrast, BudgetMax, by taking the submodularity of the problem, the network structure and the diffusion dynamics of the edges into consideration, achieves a superior performance, especially as the number

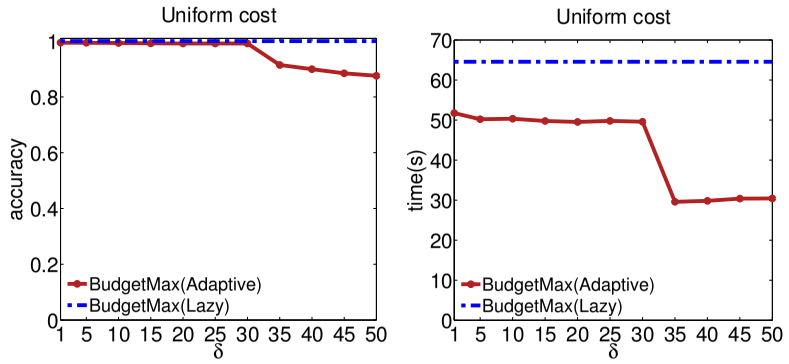
of product (*i.e.*, the competition) increases. Panel (b) shows the achieved influence against the budget per product, considering 64 products and fixing the budget per user to 2. We find that, as the budget per product increases, the performance of GreedyDegree tends to flatten and the competitive advantage of BudgetMax becomes more dramatic. Finally, Panel (c) shows the achieved influence against the budget per user, considering 64 products and fixing the budget per product to 8. We find that, as the budget per user increases, the influence only increases slowly. This is due to the fixed budget per product, which prevents additional new nodes to be assigned. This meets our intuition: by making a fixed number of people watching more ads per day, we can hardly boost the popularity of the product. Additionally, even though the same node can be assigned to more products, there is hardly ever a node that is the *perfect* source from which all products can efficiently spread.

5.1.3 Influence Maximization with Non-Uniform Cost

In this section, we evaluate the performance of BudgetMax under non-uniform cost constraints, using again ConTinEst as a subroutine for influence estimation. Our designing of user-cost aim to mimic a real scenario, where advertisers pay much more money to celebrities with millions of social network followers than to normal citizens. To do so, we let $c_i \propto d_i^{1/n}$ where c_i is the cost, d_i is the degree, and $n \geq 1$ controls the increasing speed of cost with respect to the degree. In our experiments, we use $n = 3$ and normalize c_i to be within $(0, 1]$. Moreover, we set the product-budget to a base value from 1 to 10 and add a random adjustment drawn from a uniform distribution $U(0, 1)$.



We compare our method to two modified versions of the above mentioned nodes' degree-based heuristic GreedyDegree and to the same baseline method. In the first modified version of the heuristic, which we still refer to as GreedyDegree, takes both the degree and the corresponding cost into consideration. In particular, it sorts the list of all pairs of products i and nodes $j \in \mathcal{V}_S$ in descending order of degree-cost ratio d_j/c_j in the diffusion network associated to product i, instead of simply the node-j's degree, and then proceeds similarly as before. In the second modified version of the heuristic, which we refer as GreedyLocalDegree, we use the same degree-cost ratio but allow the target users to be partitioned into distinct groups (or communities) and pick the most cost-effective pairs within each group locally instead. Figure 6 compares the performance of our method with the competing methods against four factors: (a) the number of products, (b) the budget per product, (c) the budget per user and (d) the time window T, while fixing the other factors. In all cases, BudgetMax significantly outperforms the other methods, and the achieved influence increases monotonically with respect to the factor value, as one may have expected. In addition, in Figure 6(e), we study the effect of the Laminar matroid combined with group knapsack constraints, which is the most general type of constraint we handle in this paper (refer to Section 3.4). The selected target users are further partitioned into K groups randomly, each of which has, $Q_i, i = 1 \dots K$, limit which constrains the maximum allocations allowed in each group. In practical scenarios, each group might correspond to a geographical community or organization. In our experiment, we divide the users into 8 equal-size groups and set $Q_i = 16, i = 1 \dots K$ to indicate that we want a balanced allocation in each group. Figure 6(e) shows the achieved influence against the budget per user for $K = 8$ equally-sized groups and $Q_i = 16, i = 1 \dots K$. In contrast to Figure 6(b), the total

(a) By products (b) By product budgets (c) By user constraints

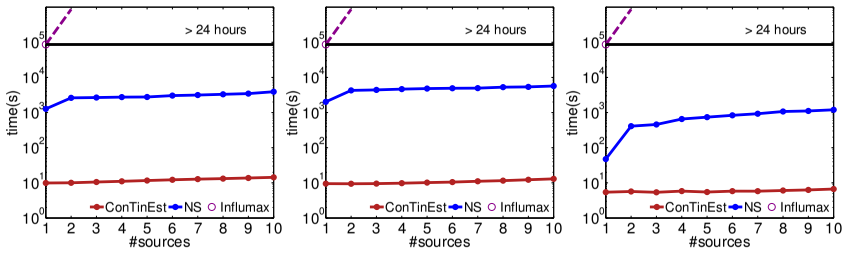
(d) By time (e) By group limits

Figure 6: Over the 64 product-specific diffusion networks, each of which has a total 1,048,576 nodes, the estimated influence (a) for increasing the number of products by fixing the product-budget at 1.0 and user-constraint at 2; (b) for increasing product-budget by fixing user-constraint at 2; (c) for increasing user-constraint by fixing product-budget at 1.0; (d) for different time window T; and (e) for increasing user-constraint with group-limit 16 by fixing product-budget at 1.0.

(a) δ vs. accuracy (b) δ vs. time

Figure 7: The relative accuracy and the run-time for different threshold parameter δ.

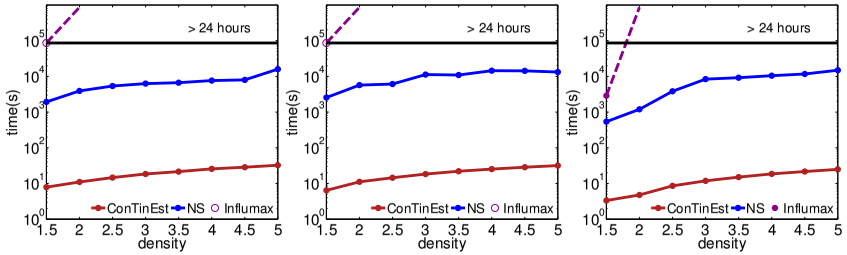
estimated influence does not increase significantly with respect to the budget (*i.e.*, number of slots) per user. This is due to the fixed budget per group, which prevents additional new nodes to be assigned, even though the number of available slots per user increases.



5.1.4 Effects of Adaptive Thresholding

In Figure 7, we investigate the impact that the threshold value δ has on the accuracy and runtime of our adaptive thresholding algorithm and compare it with the lazy evaluation method. Note that the performance and runtime of lazy evaluation do not change with respect to δ because it does not depend on it. Panel (a) shows the achieved influence against the threshold δ. As expected, the larger the δ value, the lower the accuracy. However, our method is relatively robust to the particular choice of δ since its performance is always over a 90-percent relative accuracy even for large δ. Panel (b) shows the runtime against the threshold δ. In this case, the larger the δ value, the lower the runtime. In other words, Figure 7 verifies the intuition that δ is able to trade off the solution quality of the allocation with the runtime time.

5.1.5 Scalability



In this section, we start with evaluating the scalability of the proposed algorithms on the classic influence maximization problem where we only have one product with the cardinality constraint on the users.

We compare it to the state-of-the-art method Influmax (Gomez-Rodriguez and Schölkopf, 2012) and the Naive Sampling (NS) method in terms of runtime for the continuous-time influence estimation and maximization. For ConTinEst, we draw 10,000 samples in the outer loop, each having 5 random labels in the inner loop. We plug ConTinEst as a subroutine into the classic greedy algorithm by (Nemhauser et al., 1978). For NS, we also draw 10,000 samples. The first two experiments are carried out in a single 2.4GHz processor.

(a) Core-Periphery (b) Random (c) Hierarchy

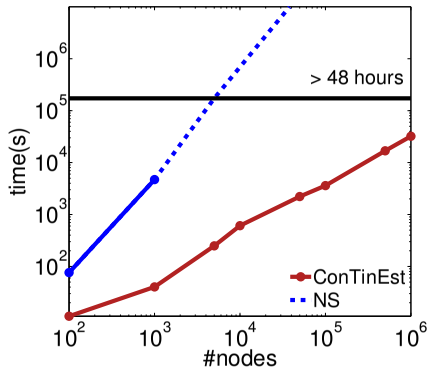
Figure 8: Runtime of selecting increasing number of sources on Kronecker networks of 128 nodes and 320 edges with $T = 10$.

(a) Core-Periphery (b) Random (c) Hierarchy

Figure 9: Runtime of selecting 10 sources in networks of 128 nodes with increasing density by $T = 10$.

Figure 8 compares the performance of increasingly selecting sources (from 1 to 10) on small Kronecker networks. When the number of selected sources is 1, different algorithms essentially spend time estimating the influence for each node. ConTinEst outperforms other methods by order of magnitude and for the number of sources larger than 1, it can efficiently reuse computations for estimating influence for individual nodes. Dashed lines mean that a method did not finish in 24 hours, and the estimated run time is plotted.

Next, we compare the run time for selecting 10 sources with increasing densities (or the number of edges) in Figure 9. Again, Influmax and NS are order of magnitude slower due to their respective exponential and quadratic computational complexity in network density. In contrast, the run time of ConTinEst only increases slightly with the increasing density since its computational complexity is linear in the number of edges. We evaluate the speed on large core-periphery networks, ranging from 100 to 1,000,000 nodes with density 1.5 in Figure 10. We report the parallel run time only for ConTinEst and NS (both are implemented by MPI running on 192 cores of 2.4Ghz) since Influmax is not scalable. In contrast to NS, the performance of ConTinEst increases linearly with the network size and can easily scale up to one million nodes.



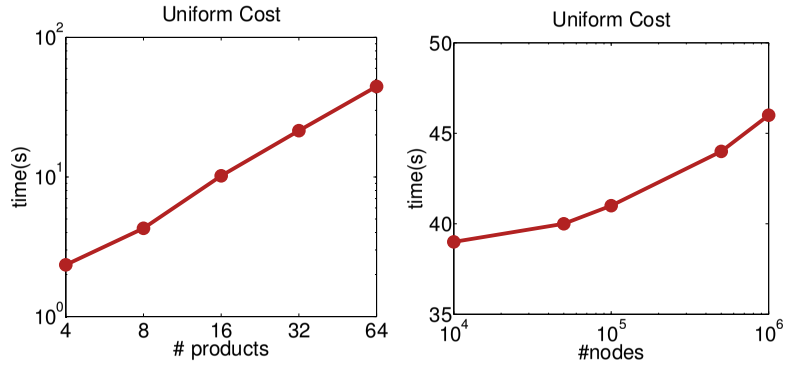


Figure 10: For core-periphery networks by $T = 10$, runtime of selecting 10 sources with increasing network size from 100 to 1,000,000 by fixing 1.5 network density.

(a) Speed by products (b) Speed by nodes

Figure 11: Over the 64 product-specific diffusion networks, each of which has 1,048,576 nodes, the runtime (a) of allocating increasing number of products and (b) of allocating 64 products to 512 users on networks of varying size. or all experiments, we have $T = 5$ time window and fix product-constraint at 8 and user-constraint at 2.

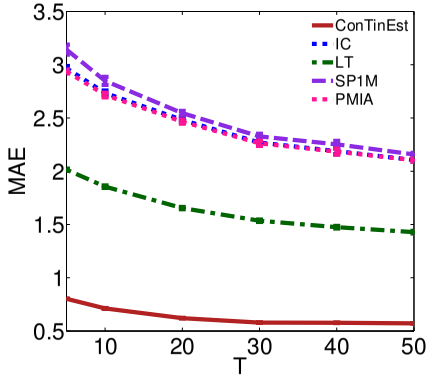

Figure 12: In MemeTracker dataset, comparison of the accuracy of the estimated influence in terms of mean absolute error.

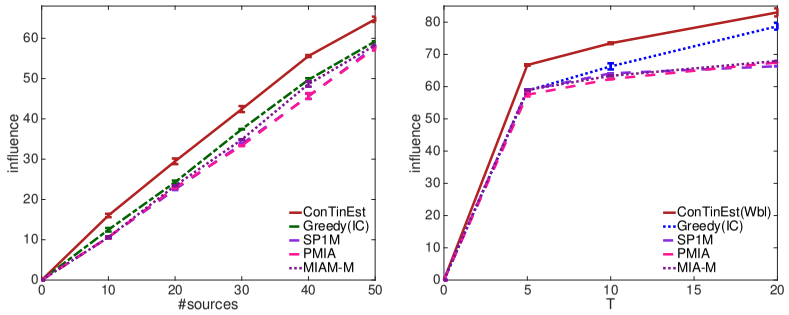


Finally, we investigate the performance of BudgetMax in terms of runtime when using ConTinEst as subroutine to estimate the influence. We can precompute the data structures and store the samples needed to estimate the influence function in advance. Therefore, we focus only on the runtime for the constrained influence maximization algorithm. BudgetMax runs on 64 cores of 2.4Ghz by using OpenMP to accelerate the first round of the optimization. We report the allocation time for increasing number of products in Figure 11(a), which clearly shows a linear time complexity with respect to the size of the ground set. Figure 11(b) evaluates the runtime of allocation by varying the size of the network from 16,384 to 1,048,576 nodes.

5.2 Experiments on Real Data

In this section, we first quantify how well our proposed algorithm can estimate the true influence in the real-world dataset. Then, we evaluate the solution quality of the selected sources for influence maximization under different constraints. We have used the public MemeTracker datasets (Leskovec et al., 2009), which contains more than 172 million news articles and blog posts from 1 million mainstream media sites and blogs.

5.2.1 Influence Estimation

We first trace the flow of information from one site to another by using the hyperlinks among articles and posts as in the work of Gomez-Rodriguez et al. (2011); Du et al. (2012). In detail, we extracted 10,967 hyperlink cascades among top 600 media sites. We then evaluate the accuracy of ConTinEst as follows. First, we repeatedly split all cascades into a 80% training set and a 20% test set at random for five times. On each training set, we learn one continuous-time model, which we use for ConTinEst, and a discrete-time model, which we use for the competitive methods: IC, SP1M, PMIA and MIAM-M. For the continuous-time

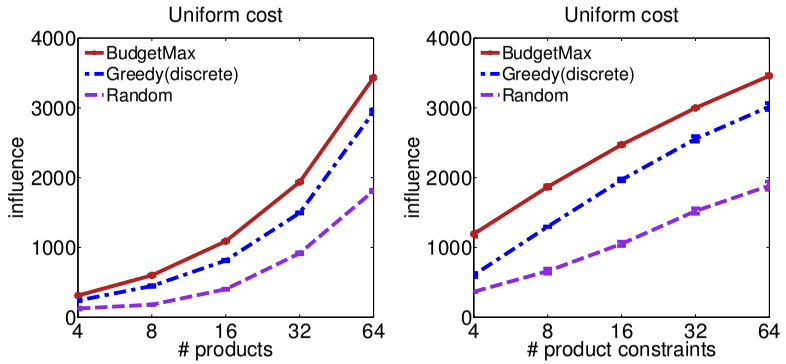
(a) Influence vs. #sources (b) Influence vs. time

Figure 13: In MemeTracker dataset, (a) comparison of the influence of the selected nodes by fixing the observation window $T = 5$ and varying the number sources, and (b) comparison of the influence of the selected nodes by fixing the number of sources to 50 and varying the time window.

model, we opt for NetRate (Gomez-Rodriguez et al., 2011) with exponential transmission functions (fixing the shape parameter of the Weibull family to be one) to learn the diffusion networks by maximizing the likelihood of the observed cascades. For the discrete-time model, we learn the infection probabilities using the method by Netrapalli and Sanghavi (2012).

Second, let $\mathcal{C}(u)$ be the set of all cascades where u was the source node. By counting the total number of distinct nodes infected before T in $\mathcal{C}(u)$, we can quantify the real influence of node u up to time T. Thus, we can evaluate the quality of the influence estimation by computing the average (across nodes) Mean Absolute Error (MAE) between the real and the estimated influence on the test set, which we show in Figure 12. Clearly, ConTinEst performs the best statistically. Since the length of real cascades empirically conforms to a power-law distribution, where most cascades are very short (2-4 nodes), the gap of the estimation error is not too large. However, we emphasize that such accuracy improvement is critical for maximizing long-term influence since the estimation error for individuals will accumulate along the spreading paths. Hence, any consistent improvement in influence estimation can lead to significant improvement to the overall influence estimation and maximization task, which is further confirmed in the following sections.

5.2.2 Influence Maximization with Uniform Cost



We first apply ConTinEst to the continuous-time influence maximization task with the simple cardinality constraint on the users. We evaluate the influence of the selected nodes in the same spirit as influence estimation: the true influence is calculated as the total number of distinct nodes infected before T based on $\mathcal{C}(u)$ of the selected nodes. Figure 13 shows that the selected sources given by ConTinEst achieve the best performance as we vary the number of selected sources and the observation time window.

Next, we evaluate the performance of BudgetMax on cascades from Memetracker traced from quotes which are short textual phrases spreading through the websites. Because all published documents containing a particular quote are time-stamped, a cascade induced by the same quote is a collection of times when the media site first mentioned it. In detail, we use the public dataset released by Gomez-Rodriguez et al. (2013), which splits the original Memetracker dataset into groups, each associated to a topic or real-world event. Each group consists of cascades built from quotes which were mentioned in posts containing particular keywords. We considered 64 groups, with at least 100,000 cascades, which play the role of products. Therein, we distinguish well-known topics, such as "Apple" and "Occupy Wall-Street", or real-world events, such as the Fukushima nuclear disaster in 2013 and the marriage between Kate Middleton and Prince William in 2011.

We then evaluate the accuracy of BudgetMax in the following way. First, we evenly split each group into a training and a test set and then learn one continuous-time model and a discrete-time model per group using the training sets. As previously, for the continuous-time model, we opt for NetRate (Gomez-Rodriguez et al., 2011) with exponential transmission functions, and for the discrete-time model, we learn the infection probabilities using the method by Netrapalli and Sanghavi (2012), where the step-length is set to one. Second, we run BudgetMax using both the continuous-time model and the discrete-time model. We refer to BudgetMax with the discrete-time model as the Greedy(discrete) method. Since we do have no ground-truth information about cost of each node, we focus our experiments using a uniform cost. Third, once we have found an allocation over the learned networks, we evaluate the performance of the two methods using the cascades in the test set as follows: given a group-node pair (i, j), let $\mathcal{C}(j)$ denote the set of cascades induced by group i that contains node j. Then, we take the average number of nodes coming after j for all the cascades in $\mathcal{C}(j)$ as a proxy of the average influence induced by assigning group i to node j. Finally, the influence of an allocation is just the sum of the average influence of each group-node pair in the solution. In our experiments, we randomly select 128 nodes as our target users.

Figure 14 summarizes the achieved influence against four factors: (a) the number of products, (b) the budget per product, (c) the budget per user and (d) the time window T, while fixing the other factors. In comparison with the Greedy(IC) and a random allocation, BudgetMax finds an allocation that indeed induces the largest diffusion in the test data, with an average 20-percent improvement overall.

In the end, Figure 15 investigates qualitatively the actual allocations of groups (topics or real-world events; in red) and sites (in black). Here, we find examples that intuitively one could expect: "japantoday.com" is assigned to Fukushima Nuclear disaster or "finance.yahoo.com" is assigned to "Occupy Wall-street". Moreover, because we consider several topics and real-world events with different underlying diffusion networks, the selected nodes are not only very popular media sites such as nytimes.com or cnn.com but also several modest sites (Bakshy et al., 2011), often specialized or local, such as freep.com or localnews8.com.

(a) By products (b) By product constraints

(c) By user constraints (d) By time

Figure 14: Over the inferred 64 product-specific diffusion networks, the true influence estimated from separated testing data (a) for increasing the number of products by fixing the product-constraint at 8 and user-constraint at 2; (b) for increasing product-constraint by fixing user-constraint at 2; (c) for increasing user-constraint by fixing product-constraint at 8; (d) for different time window T.

6. Conclusion

We have studied the influence estimation and maximization problems in the continuous-time diffusion model. We first propose a randomized influence estimation algorithm ConTinEst, which can scale up to networks of millions of nodes while significantly improves over previous state of the art methods in terms of the accuracy of the estimated influence. Once we have a subroutine for efficient influence estimation in large networks, we then tackle the problem of maximizing the influence of multiple types of products (or information) in

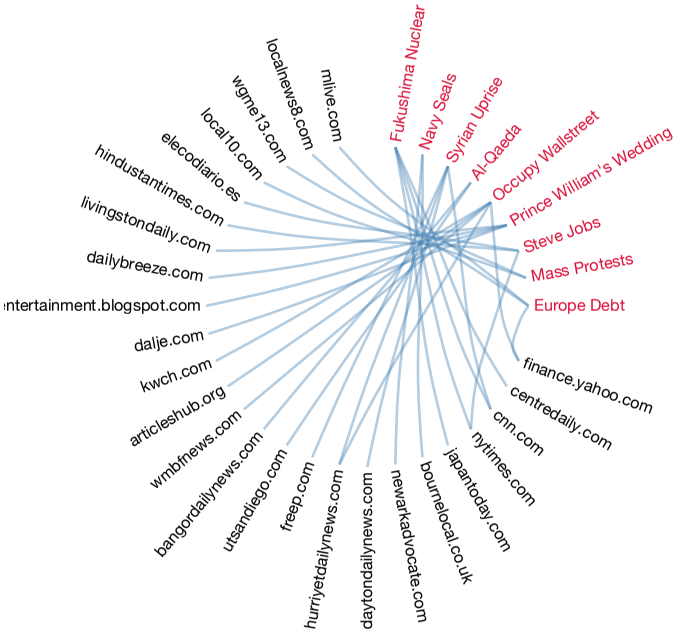


Figure 15: The allocation of memes to media sites.

realistic continuous-time diffusion networks subject to various practical constraints: different products can have different diffusion structures; only influence within a given time window is considered; each user can only be recommended a small number of products; and each product has a limited campaign budget, and assigning it to users incurs costs. We provide a novel formulation as a submodular maximization under an intersection of matroid constraints and group-knapsack constraints, and then design an efficient adaptive threshold greedy algorithm with provable approximation guarantees, which we call BudgetMax. Experimental results show that the proposed algorithm performs remarkably better than other scalable alternatives in both synthetic and real-world datasets. There are also a few interesting open problems. For example, when the influence is estimated using ConTinEst, its error is a random variable. How does this affect the submodularity of the influence function? Is there an influence maximization algorithm that has better tolerance to the random error? These questions are left for future work.

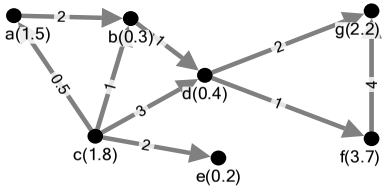
Appendix A. Naive Sampling Algorithm



The graphical model perspective described in Section 2.2 suggests a naive sampling (NS) algorithm for approximating $\sigma(\mathcal{A}, T)$:

1. Draw n samples, $\left\{\left\{\tau_{ji}^l\right\}_{(j,i)\in\mathcal{E}}\right\}_{l=1}^n$, *i.i.d.* from the waiting time product distribution $\prod_{(j,i)\in\mathcal{E}} f_{ji}(\tau_{ji})$;
2. For each sample $\left\{\tau_{ji}^l\right\}_{(j,i)\in\mathcal{E}}$ and for each node i, find the shortest path from source nodes to node i; count the number of nodes with $g_i\left(\left\{\tau_{ji}^l\right\}_{(j,i)\in\mathcal{E}}\right) \leq T$;
3. Average the counts across n samples.

Although the naive sampling algorithm can handle arbitrary transmission function, it is not scalable to networks with millions of nodes. We need to compute the shortest path for each node and each sample, which results in a computational complexity of $O(n|\mathcal{E}| + n|\mathcal{V}|\log|\mathcal{V}|)$ for a single source node. The problem is even more pressing in the influence maximization problem, where we need to estimate the influence of source nodes at different location and with increasing number of source nodes. To do this, the algorithm needs to be repeated, adding a multiplicative factor of $C|\mathcal{V}|$ to the computational complexity (C is the number of nodes to select). Then, the algorithm becomes quadratic in the network size. When the network size is in the order of thousands and millions, typical in modern social network analysis, the naive sampling algorithm become prohibitively expensive. Additionally, we may need to draw thousands of samples (n is large), further making the algorithm impractical for large-scale problems.

Appendix B. Least Label List

The notation "argsort$((r_1, \ldots, r_{|\mathcal{V}|}), \text{ascend})$" in line 2 of Algorithm 3 means that we sort the collection of random labels in ascending order and return the argument of the sort as an ordered list.

- Node labeling : $e(0.2) < b(0.3) < d(0.4) < a(1.5) < c(1.8) < g(2.2) < f(3.7)$
- Neighborhoods: $\mathcal{N}(c, 2) = \{a, b, c, e\}$; $\mathcal{N}(c, 3) = \{a, b, c, d, e, f\}$;
- Least-label list: $r_*(c) : (2, 0.2), (1, 0.3), (0.5, 1.5), (0, 1.8)$
- Query: $r_*(c, 0.8) = r(a) = 1.5$

Figure 16: Graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, edge weights $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$, and node labeling $\{r_i\}_{i\in\mathcal{V}}$ with the associated output from Algorithm 3.

Algorithm 3: Least Label List

Input: a reversed directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with edge weights $\{\tau_{ji}\}_{(j,i)\in\mathcal{E}}$, a node labeling $\{r_i\}_{i\in\mathcal{V}}$

Output: A list $r_*(s)$ for each $s \in \mathcal{V}$

```
for each s ∈ V do d_s ← ∞, r_*(s) ← ∅;
for i in argsort((r_1, ..., r_|V|), ascend) do
    empty heap H ← ∅;
    set all nodes except i as unvisited;
    push (0, i) into heap H;
    while H ≠ ∅ do
        pop (d_*, s) with the minimum d_* from H;
        add (d_*, r_i) to the end of list r_*(s);
        d_s ← d*;
        for each unvisited out-neighbor j of s do
            set j as visited;
            if (d, j) in heap H then
                Pop (d, j) from heap H;
                Push (min {d, d_* + τ_js}, j) into heap H;
            else if d_* + τ_js < d_j then
                Push (d_* + τ_js, j) into heap H;
```

Figure 16 shows an example of the Least-Label-List. The nodes from a to g are assigned to exponentially distributed labels with mean one shown in each parentheses. Given a query distance 0.8 for node c, we can binary-search its Least-label-list $r_*(c)$ to find that node a belongs to this range with the smallest label $r(a) = 1.5$.

Appendix C. Theorem 1

Theorem 1 *Sample the following number of sets of random transmission times*

$$n \geqslant \frac{C\Lambda}{\epsilon^2}\log\left(\frac{2|\mathcal{V}|}{\alpha}\right)$$

where $\Lambda := \max_{\mathcal{A}:|\mathcal{A}|\leq C} 2\sigma(\mathcal{A},T)^2/(m-2) + 2Var(|\mathcal{N}(\mathcal{A},T)|)(m-1)/(m-2) + 2a\epsilon/3$, $|\mathcal{N}(\mathcal{A},T)| \leqslant a$, *and for each set of random transmission times, sample* m *set of random labels. Then we can guarantee that*

$$|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \leqslant \epsilon$$

simultaneously for all $\mathcal{A}$ *with* $|\mathcal{A}| \leqslant C$, *with probability at least* $1-\alpha$.

Proof Let $S_\tau := |\mathcal{N}(\mathcal{A},T)|$ for a fixed set of $\{\tau_{ji}\}$ and then $\sigma(\mathcal{A},T) = \mathbb{E}_\tau[S_\tau]$. The randomized algorithm with m randomizations produces an unbiased estimator $\widehat{S}_\tau = (m-1)/(\sum_{u=1}^m r_*^u)$ for S_τ, *i.e.*, $\mathbb{E}_{r|\tau}[\widehat{S}_\tau] = S_\tau$, with variance $\mathbb{E}_{r|\tau}[(\widehat{S}_\tau - S_\tau)^2] = S_\tau^2/(m-2)$ (Cohen, 1997).

Then $\widehat{S}_\tau$ is also an unbiased estimator for $\sigma(\mathcal{A},T)$, since $\mathbb{E}_{\tau,r}[\widehat{S}_\tau] = \mathbb{E}_\tau\mathbb{E}_{r|\tau}[\widehat{S}_\tau] = \mathbb{E}_\tau[S_\tau] = \sigma(\mathcal{A},T)$. Its variance is

$$\begin{aligned}
Var(\widehat{S}_\tau) &:= \mathbb{E}_{\tau,r}[(\widehat{S}_\tau - \sigma(\mathcal{A},T))^2] = \mathbb{E}_{\tau,r}[(\widehat{S}_\tau - S_\tau + S_\tau - \sigma(\mathcal{A},T))^2] \\
&= \mathbb{E}_{\tau,r}[(\widehat{S}_\tau - S_\tau)^2] + 2\,\mathbb{E}_{\tau,r}[(\widehat{S}_\tau - S_\tau)(S_\tau - \sigma(\mathcal{A},T))] + \mathbb{E}_{\tau,r}[(S_\tau - \sigma(\mathcal{A},T))^2] \\
&= \mathbb{E}_\tau[S_\tau^2/(m-2)] + 0 + Var(S_\tau) \\
&= \sigma(\mathcal{A},T)^2/(m-2) + Var(S_\tau)(m-1)/(m-2)
\end{aligned}$$

Then using Bernstein's inequality, we have, for our final estimator $\widehat{\sigma}(\mathcal{A},T) = \frac{1}{n}\sum_{l=1}^n \widehat{S}_{\tau^l}$, that

$$\Pr\{|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \geqslant \epsilon\} \leqslant 2\exp\left(-\frac{n\epsilon^2}{2Var(\widehat{S}_\tau) + 2a\epsilon/3}\right) \tag{21}$$

where $\widehat{S}_\tau < a \leqslant |\mathcal{V}|$.

Setting the right hand side of relation (21) to α, we have that, with probability $1-\alpha$, sampling the following number sets of random transmission times

$$\begin{aligned}
n &\geqslant \frac{2Var(\widehat{S}_\tau) + 2a\epsilon/3}{\epsilon^2}\log\left(\frac{2}{\alpha}\right) \\
&= \frac{2\sigma(\mathcal{A},T)^2/(m-2) + 2Var(S_\tau)(m-1)/(m-2) + 2a\epsilon/3}{\epsilon^2}\log\left(\frac{2}{\alpha}\right)
\end{aligned}$$

we can guarantee that our estimator to have error $|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \leqslant \epsilon$.

If we want to insure that $|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \leqslant \epsilon$ simultaneously hold for all $\mathcal{A}$ such that $|\mathcal{A}| \leqslant C \ll |\mathcal{V}|$, we can first use union bound with relation (21). In this case, we have that, with probability $1-\alpha$, sampling the following number sets of random transmission times

$$n \geqslant \frac{C\Lambda}{\epsilon^2}\log\left(\frac{2|\mathcal{V}|}{\alpha}\right)$$

we can guarantee that our estimator to have error $|\widehat{\sigma}(\mathcal{A},T) - \sigma(\mathcal{A},T)| \leqslant \epsilon$ for all $\mathcal{A}$ with $|\mathcal{A}| \leqslant C$. Note that we have define the constant $\Lambda := \max_{\mathcal{A}:|\mathcal{A}|\leq C} 2\sigma(\mathcal{A},T)^2/(m-2) + 2Var(S_\tau)(m-1)/(m-2) + 2a\epsilon/3$. ■

Appendix D. Complete Proofs for Section 4

D.1 Uniform Cost

In this section, we first prove a theorem for the general problem defined by Equation (19), considering a normalized monotonic submodular function $f(S)$ and general P (Theorem 7) and $k = 0$, and then obtain the guarantee for our influence maximization problem (Theorem 4).

Suppose $G = \{g_1, \ldots, g_{|G|}\}$ in the order of selection, and let $G^t = \{g_1, \ldots, g_t\}$. Let C_t denote all those elements in $O \setminus G$ that satisfy the following: they are still feasible before selecting the t-th element g_t but are infeasible after selecting g_t. Formally,

$$C_t = \left\{ z \in O \setminus G : \{z\} \cup G^{t-1} \in \mathcal{F}, \{z\} \cup G^t \notin \mathcal{F} \right\}.$$

In the following, we will prove three claims and then use them to prove the Theorems 7 and 4. Recall that for any $i \in \mathcal{Z}$ and $S \subseteq \mathcal{Z}$, the marginal gain of z with respect to S is denoted as

$$f(z|S) := f(S \cup \{z\}) - f(S)$$

and its approximation is denoted by

$$\widehat{f}(z|S) = \widehat{f}(S \cup \{z\}) - \widehat{f}(S).$$

Also, when $|f(S) - \widehat{f}(S)| \leq \epsilon$ for any $S \subseteq \mathcal{Z}$, we have

$$|\widehat{f}(z|S) - f(z|S)| \leq 2\epsilon$$

for any $z \in \mathcal{Z}$ and $S \subseteq \mathcal{Z}$.

Claim 1. *$\sum_{i=1}^{t} |C_i| \leq Pt$, for $t = 1, \ldots, |G|$.*

Proof We first show the following property about matroids: for any $Q \subseteq \mathcal{Z}$, the sizes of any two maximal independent subsets T_1 and T_2 of Q can only differ by a multiplicative factor at most P. Here, T is a maximal independent subset of Q if and only if:

- $T \subseteq Q$;
- $T \in \mathcal{F} = \bigcap_{i=1}^{P} \mathcal{I}_p$;
- $T \cup \{z\} \notin \mathcal{F}$ for any $z \in Q \setminus T$.

To prove the property, note that for any element $z \in T_1 \setminus T_2$, $\{z\} \cup T_2$ violates at least one of the matroid constraints since T_2 is maximal. Let $\{V_i\}_{1 \leq i \leq P}$ denote all elements in $T_1 \setminus T_2$ that violate the i-th matroid, and then partition $T_1 \cap T_2$ using these V_i's so that they cover T_1. Note that the size of each V_i must be at most that of T_2, since otherwise by the Exchange axiom, there would exist $z \in V_i \setminus T_2$ that can be added to T_2 without violating the i-th matroid, leading to a contradiction. Therefore, $|T_1|$ is at most P times $|T_2|$.

Now we apply the property to prove the claim. Let Q be the union of G^t and $\bigcup_{i=1}^{t} C_t$. On one hand, G^t is a maximal independent subset of Q, since no element in $\bigcup_{i=1}^{t} C_t$ can be added to G^t without violating the matroid constraints. On the other hand, $\bigcup_{i=1}^{t} C_t$ is an independent subset of Q, since it is part of the optimal solution. Therefore, $\bigcup_{i=1}^{t} C_t$ has size at most P times $|G^t|$, which is Pt. ■

Claim 2. *Suppose g_t is selected at the threshold τ_t. Then, $f(j|G^{t-1}) \leq (1+\delta)\tau_t + 4\epsilon + \frac{\delta}{N} f(G), \forall j \in C_t$.*

Proof First, consider $\tau_t > w_{L+1} = 0$. Since g_t is selected at the threshold τ_t, we have that $\widehat{f}(g_t|G^{t-1}) \geq \tau_t$ and thus $f(g_t|G^{t-1}) \geq \tau_t - 2\epsilon$. Any $j \in C_t$ could have been selected at an earlier stage, since adding j to G^{t-1} would not have violated the constraint. However, since $j \notin G^{t-1}$, that means that $\widehat{f}(j|G^{t-1}) \leq (1+\delta)\tau_t$. Then,

$$f(j|G^{t-1}) \leq (1+\delta)\tau_t + 2\epsilon.$$

Second, consider $\tau_t = w_{L+1} = 0$. For each $j \in C_t$, we have $\widehat{f}(j|G) < \frac{\delta}{N} d$. Since the greedy algorithm must pick g_1 with $\widehat{f}(g_1) = d$ and $d \leq f(g_1) + \epsilon$, then

$$f(j|G) < \frac{\delta}{N} f(G) + 4\epsilon.$$

The claim follows by combining the two cases. ■

Claim 3. *The marginal gain of $O \setminus G$ satisfies*

$$\sum_{j \in O \setminus G} f(j|G) \leq [(1+\delta)P + \delta] f(G) + (6 + 2\delta)\epsilon P |G|.$$

Proof Combining Claim 1 and Claim 2, we have:

$$\begin{aligned}\sum_{j \in O \setminus G} f(j|G) = \sum_{t=1}^{|G|} \sum_{j \in C_t} f(j|G) &\leq (1+\delta) \sum_{t=1}^{|G|} |C_t|\tau_t + \delta f(G) + 4\epsilon \sum_{t=1}^{|G|} |C_t| \\ &\leq (1+\delta) \sum_{t=1}^{|G|} |C_t|\tau_t + \delta f(G) + 4\epsilon P |G|.\end{aligned}$$

Further, $\sum_{t=1}^{|G|} |C_t|\tau_t \leq P \sum_{t=1}^{|G|} \tau_t$ by Claim 1 and a technical lemma (Lemma 6). Finally, the claim follows from the fact that $f(G) = \sum_t f(g_t|G^{t-1}) \geq \sum_t (\tau_t - 2\epsilon)$. ■

Lemma 6 *If $\sum_{i=1}^{t} \sigma_{i-1} \leq t$ for $t = 1, \ldots, K$ and $\rho_{i-1} \geq \rho_i$ for $i = 1, \ldots, K-1$ with $\rho_i, \sigma_i \geq 0$, then $\sum_{i=1}^{K} \rho_i \sigma_i \leq \sum_{i=1}^{K} \rho_{i-1}$.*

Proof Consider the linear program

$$\begin{aligned} V \quad = \quad & \max_{\sigma} \sum_{i=1}^{K} \rho_i \sigma_i \\ & \text{s.t.} \quad \sum_{i=1}^{t} \sigma_{i-1} \leq t, \quad t = 1, \ldots, K, \\ & \qquad \sigma_i \geq 0, \quad i = 1, \ldots, K-1 \end{aligned}$$

with dual

$$\begin{aligned} W \quad = \quad & \min_{u} \sum_{i=1}^{K} t u_{t-1} \\ & \text{s.t.} \quad \sum_{t=i}^{K-1} u_t \geq \rho_i, \quad i = 0, \ldots, K-1, \\ & \qquad u_t \geq 0, \quad t = 0, \ldots, K-1. \end{aligned}$$

As $\rho_i \geq \rho_{i+1}$, the solution $u_i = \rho_i - \rho_{i+1}, i = 0, \ldots, K-1$ (where $\rho_K = 0$) is dual feasible with value $\sum_{t=1}^{K} t(\rho_{t-1} - \rho_t) = \sum_{i=1}^{K} \rho_{i-1}$. By weak linear programming duality, $\sum_{i=1}^{K} \rho_i \sigma_i \leq V \leq W \leq \sum_{i=1}^{K} \rho_{i-1}$. ■

Theorem 7 *Suppose we use Algorithm 2 to solve the problem defined by Equation (19) with $k = 0$, using $\rho = 0$ and $\widehat{f}$ to estimate the function f, where $|\widehat{f}(S) - f(S)| \leq \epsilon$ for all $S \subseteq \mathcal{Z}$. It holds that the algorithm returns a greedy solution G with*

$$f(G) \geq \frac{1}{(1+2\delta)(P+1)} f(O) - \frac{4P|G|}{P + c_f}\epsilon$$

where O is the optimal solution, using $\mathcal{O}(\frac{N}{\delta}\log\frac{N}{\delta})$ evaluations of $\widehat{f}$.

Proof By submodularity and Claim 3, we have:

$$f(O) \leq f(O \cup G) \leq f(G) + \sum_{j \in O \setminus G} f(j|G) \leq (1+\delta)(P+1)f(G) + (6+2\delta)\epsilon P|G|,$$

which leads to the bound in the theorem.

Since there are $\mathcal{O}(\frac{1}{\delta}\log\frac{N}{\delta})$ thresholds, and there are $\mathcal{O}(N)$ evaluations at each threshold, the number of evaluations is bounded by $\mathcal{O}(\frac{N}{\delta}\log\frac{N}{\delta})$. ■

Theorem 7 essentially shows $f(G)$ is close to $f(O)$ up to a factor roughly $(1+P)$, which then leads to the following guarantee for our influence maximization problem. Suppose product $i \in \mathcal{L}$ spreads according to diffusion network $\mathcal{G}_i = (\mathcal{V}, \mathcal{E}_i)$, and let $i^* = \text{argmax}_{i \in \mathcal{L}} |\mathcal{E}_i|$.

Theorem 4. *In the influence maximization problem with uniform cost, Algorithm 2 (with $\rho = 0$) is able to output a solution G that satisfies $f(G) \geq \frac{1-2\delta}{3} f(O)$ in expected time $\widetilde{\mathcal{O}}\left(\frac{|\mathcal{E}_{i^*}|+|\mathcal{V}|}{\delta^2} + \frac{|\mathcal{L}||\mathcal{V}|}{\delta^3}\right)$.*

Proof In the influence maximization problem, the number of matroids is $P = 2$. Also note that $|G| \leq f(G) \leq f(O)$, which leads to $4|G|\epsilon \leq 4\epsilon f(O)$. The approximation guarantee then follows from setting $\epsilon \leq \delta/16$ when using ConTinEst (Du et al., 2013a) to estimate the influence.

The runtime is bounded as follows. In Algorithm 2, we need to estimate the marginal gain of adding one more product to the current solution. In ConTinEst (Du et al., 2013a), building the initial data structure takes time

$$\mathcal{O}\left((|\mathcal{E}_{i^*}|\log|\mathcal{V}| + |\mathcal{V}|\log^2|\mathcal{V}|)\frac{1}{\delta^2}\log\frac{|\mathcal{V}|}{\delta}\right)$$

and afterwards each function evaluation takes time

$$\mathcal{O}\left(\frac{1}{\delta^2}\log\frac{|\mathcal{V}|}{\delta}\log\log|\mathcal{V}|\right).$$

As there are $\mathcal{O}\left(\frac{N}{\delta}\log\frac{N}{\delta}\right)$ evaluations where $N = |\mathcal{L}||\mathcal{V}|$, the runtime of our algorithm follows. ■

D.2 General case

As in the previous section, we first prove that a theorem for the problem defined by Equation (19) with general normalized monotonic submodular function $f(S)$ and general P (Theorem 8), and then obtain the guarantee for our influence maximization problem (Theorem 5).

Theorem 8 *Suppose Algorithm 1 uses $\widehat{f}$ to estimate the function f which satisfies $|\widehat{f}(S) - f(S)| \leq \epsilon$ for all $S \subseteq \mathcal{Z}$. Then, there exists a ρ such that*

$$f(S_\rho) \geq \frac{\max\{1, |A_\rho|\}}{(P+2k+1)(1+2\delta)} f(O) - 8\epsilon|S_\rho|$$

where A_ρ is the set of active knapsack constraints:

$$A_\rho = \{i : S_\rho \cup \{z\} \notin \mathcal{F}, \forall z \in \mathcal{Z}_{i*}\}.$$

Proof Consider the optimal solution O and set $\rho^* = \frac{2}{P+2k+1} f(O)$. By submodularity, we have $d \leq f(O) \leq |\mathcal{Z}|d$, so $\rho \in \left[\frac{2d}{P+2k+1}, \frac{2|\mathcal{Z}|d}{P+2k+1}\right]$, and there is a run of Algorithm 2 with ρ such that $\rho^* \in [\rho, (1+\delta)\rho]$. In the following we consider this run.

Case 1 Suppose $|A_\rho| = 0$. The key observation in this case is that since no knapsack constraints are active, the algorithm runs as if there were only matroid constraints. Then, the argument for matroid constraints can be applied. More precisely, let

$$O_+ := \{z \in O \setminus S_\rho : f(z|S_\rho) \geq c(z)\rho + 2\epsilon\}$$

$$O_- := \{z \in O \setminus S_\rho : z \notin O_+\}.$$

Note that all elements in O_+ are feasible. Following the argument of Claim 3 in Theorem 7, we have:

$$f(O_+|S_\rho) \leq ((1+\delta)P + \delta) f(S_\rho) + (4+2\delta)\epsilon P|S_\rho|. \tag{22}$$

Also, by definition, the marginal gain of O_- is:

$$f(O_-|S_\rho) \leq k\rho + 2\epsilon|O_-| \leq k\rho + 2\epsilon P|S_\rho|, \tag{23}$$

where the last inequality follows from the fact that S_ρ is a maximal independent subset, O_- is an independent subset of $O \cup S_\rho$, and the sizes of any two maximal independent subsets in the intersection of P matroids can differ by a factor of at most P. Plugging (22)(23) into $f(O) \leq f(O_+|S_\rho) + f(O_-|S_\rho) + f(S_\rho)$, we obtain the bound

$$f(S_\rho) \geq \frac{f(O)}{(P+2k+1)(1+\delta)} - \frac{(6+2\delta)\epsilon P|S_\rho|}{(P+1)(1+\delta)}.$$

Case 2 Suppose $|A_\rho| > 0$. For any $i \in A_\rho$ (*i.e.*, the i-th knapsack constraint is active), consider the step when i is added to A_ρ. Let $G_i = G \cap \mathcal{Z}_{i*}$, and we have $c(G_i) + c(z) > 1$.

Since every element g we include in G_i satisfies $\widehat{f}(g|G) \geq c(g)\rho$ with respect to the solution G_i when g is added. Then $f(g|G) = f_i(g|G_i) \geq c(g)\rho - 2\epsilon$, and we have:

$$f_i(G_i \cup \{z\}) \geq \rho[c(G_i) + c(z)] - 2\epsilon(|G_i| + 1) > \rho - 2\epsilon(|G_i| + 1). \tag{24}$$

Note that G_i is non-empty since otherwise the knapsack constraint will not be active. Any element in G_i is selected before or at w_t, so $f_i(G_i) \geq w_t - 2\epsilon$. Also, note that z is not selected in previous thresholds before w_t, so $f_i(\{z\}\,|G_i) \leq (1+\delta)w_t + 2\epsilon$ and thus,

$$f_i(\{z\}\,|G_i) \leq (1+\delta)f_i(G_i) + 2\epsilon(2+\delta). \tag{25}$$

Combining Eqs. 24 and 25 into $f_i(G_i \cup \{z\}) = f_i(G_i) + f_i(\{z\}\,|G_i)$ leads to

$$\begin{aligned} f_i(G_i) \geq \frac{\rho}{(2+\delta)} - \frac{2\epsilon(|G_i|+3+\delta)}{(2+\delta)} &\geq \frac{1}{2(1+2\delta)}\rho^* - \frac{2\epsilon(|G_i|+3+\delta)}{(2+\delta)} \\ &\geq \frac{f(O)}{(P+2k+1)(1+2\delta)} - 5\epsilon|G_i|. \end{aligned}$$

Summing up over all $i \in A_\rho$ leads to the desired bound. ■

Suppose item $i \in \mathcal{L}$ spreads according to the diffusion network $\mathcal{G}_i = (\mathcal{V}, \mathcal{E}_i)$. Let $i^* = \text{argmax}_{i\in\mathcal{L}} |\mathcal{E}_i|$. By setting $\epsilon = \delta/16$ in Theorem 8, we have:

Theorem 5. *In Algorithm 1, there exists a ρ such that*

$$f(S_\rho) \geq \frac{\max\{k_a, 1\}}{(2|\mathcal{L}|+2)(1+3\delta)} f(O)$$

where k_a is the number of active knapsack constraints. The expected runtime to obtain the solution is $\widetilde{\mathcal{O}}\left(\frac{|\mathcal{E}_{i^*}|+|\mathcal{V}|}{\delta^2} + \frac{|\mathcal{L}||\mathcal{V}|}{\delta^4}\right)$.

Abstract

We study the design of interactive clustering algorithms. The user supervision that we consider is in the form of cluster split/merge requests; such feedback is easy for users to provide because it only requires a high-level understanding of the clusters. Our algorithms start with any initial clustering and only make local changes in each step; both are desirable properties in many applications. Local changes are desirable because in practice edits of other parts of the clustering are considered churn - changes that are perceived as quality-neutral or quality-negative. We show that in this framework we can still design provably correct algorithms given that our data satisfies natural separability properties. We also show that our framework works well in practice.

1. Introduction

Clustering is usually studied in an unsupervised learning scenario where the goal is to partition the data given pairwise similarity information. Designing provably-good clustering algorithms is challenging because given a similarity function there may be many possible clusterings of the data. Traditional approaches resolve this ambiguity by making assumptions on the data-generation process. For example, there is a large body of work on clustering data that is generated by a mixture of Gaussians (Achlioptas and McSherry, 2005; Kannan et al., 2005; Dasgupta, 1999; Arora and Kannan, 2001; Brubaker and Vempala, 2008; Kalai et al., 2010; Moitra and Valiant, 2010; Belkin and Sinha, 2010), and finding clusters with certain density (Rinaldo and Wasserman, 2010; Chaudhuri and Dasgupta, 2010). But instead of making such assumptions and trying to set the corresponding hyperparameters, we can use limited user (expert) supervision to help the algorithm reach the correct answer.

Interactive clustering algorithms have been facilitated by the availability of cheap crowd-sourcing tools in recent years, which enable collection of relevant user input. In certain applications such as search and document classification, where users are willing to help a clustering algorithm arrive at their own desired answer with a small amount of additional feedback, interactive clustering algorithms are very useful. The works of Balcan and Blum (2008) and Awasthi and Zadeh (2010) provide some initial theoretical results in this new and exciting research area, but their models are not very practical.

We observe that in many practical settings we already start with a fairly good clustering computed with semi-automated techniques. For example, consider a massive online news portal that maintains a large collection of news articles. Suppose that the news articles are clustered on the "back-end," and are used to serve several "front-end" applications such as recommendations and article profiles. For such a system, we do not have the freedom to compute arbitrary clusterings and present them to the user, which has been suggested in prior interactive clustering work (Balcan and Blum, 2008; Awasthi and Zadeh, 2010). But it is still feasible to get specific feedback on the current proposed clustering and *locally* edit this clustering. In particular, we may only want to change the "bad" part of the clustering that is revealed by the feedback without changing the rest of the clustering. Our intuition for only considering *local* edits is that in practice changes to other parts of the clustering are considered *churn* - changes that are perceived as quality-neutral or quality-negative. This observation is especially true for large clustering systems that serve many users, which operate on the assumption that if some of the data is broken, it will be pointed out by a user. For such applications it is undesirable to change what the user is not complaining about. Motivated by these observations, in this paper we study the problem of designing *local* algorithms for interactive clustering.

We propose a theoretical interactive clustering model and provide strong experimental evidence supporting its utility in practice. In our model we start with some initial clustering of the data. The algorithm then interacts with the user in stages. In each stage the user provides limited feedback on the proposed clustering in the form of *split* and *merge* requests. The algorithm then makes a *local* edit to the clustering that is consistent with user feedback. Such edits are aimed at improving the problematic part of the clustering pointed out by the user. The goal of the algorithm is to quickly converge (using as few requests as possible) to a clustering that the user is happy with - we call this clustering the target (ground truth) clustering.

In our model the user may request a certain cluster to be *split* if it is *overclustered* (intersects two or more clusters in the target clustering). The user may also request to *merge* two given clusters if they are *underclustered* (both intersect the same target cluster). Note that the user does not tell the algorithm how to perform the split or the merge; such input is unrealistic because it requires a manual analysis of the data points in the corresponding clusters. We also restrict the algorithm to only make *local* changes at each step - in response we may change only the cluster assignments of the points in the corresponding clusters. If the user requests to split a cluster C_i, we may change only the cluster assignments of the points in C_i, and if the user requests to merge C_i and C_j, we may only reassign the points in C_i and C_j.

The split and merge requests in our model are a natural form of feedback. It is easy for users to spot over/underclustering errors and request the corresponding splits/merges (without having to provide any additional information about how to perform the edit). For our model to be practically applicable, we also need to account for noise in the user requests. In particular, if the user requests a merge, only a fraction or a constant number of the points in the two clusters may belong to the same target cluster. Our model (see Section 2) allows for such noisy user responses.

We study the complexity of algorithms in this framework (the number of edits requests needed to find the target clustering) as a function of the error of the initial clustering. We define clustering error in terms of *underclustering* error δ_u and *overclustering* error δ_o (see Section 2). Given that the initial error is often fairly small [1], we would like to develop algorithms whose complexity depends

1. Given 2 different k-clusterings, δ_u and δ_o is at most k^2.

polynomially on δ_u, δ_o and only logarithmically on n, the number of data points. We show that this is indeed possible given that the target clustering satisfies a natural *stability* property (see Section 2). In addition, we develop provably correct algorithms for the well-known correlation-clustering objective (Bansal et al., 2004), which considers pairs of points that are clustered inconsistently with respect to the target clustering (see Section 2).

1.1 Our Results

Our local interactive clustering model is summarized in Section 2.4. This model is then instantiated with specific split/merge algorithms in Section 3 and Section 4. In Section 3 we study the η-merge model. Here we assume that the user may request to split a cluster C_i only if C_i contains points from several ground-truth clusters. The user may request to merge C_i and C_j only if an η-fraction of the points in each C_i and C_j are from the same ground-truth cluster. Note that these restrictions are on the user requests, and not the clustering we are editing. In particular, there may be pairs of clusters C_i and C_j where a smaller fraction of the points are from the same target cluster. But we assume that the user will not request to merge C_i and C_j in such cases because there is not enough evidence to request this merge. Instead, we assume that the user will ask for a split of C_i and/or C_j first, or ask for another merge involving C_i or C_j (where there is more evidence that they need to be merged). This is a realistic restriction because we assume that the merge requests come from high-level observations about the clusters, for example from observing the cluster profiles/summaries.

For this model for $\eta > 0.5$, given an initial clustering with overclustering error δ_o and underclustering error δ_u, we present interactive clustering algorithms that require δ_o split requests and $2(\delta_u + k)\log_{\frac{1}{1-\eta}} n$ merge requests to find the target clustering, where n is the number of points in the data set. For $\eta > 2/3$, given an initial clustering with correlation-clustering error δ_{cc}, we present algorithms that require at most δ_{cc} edit requests to find the target clustering.

In Section 4 we relax the condition on the merges and allow the user to request a merge even if C_i and C_j only have a single point from the same target cluster. We call this the *unrestricted-merge* model. Here the requirement on the accuracy of the user response is much weaker and we need to make further assumptions about the nature of the requests. In particular, we assume that each merge request is chosen uniformly at random from the set of possible merge requests. Under this assumption we present algorithms that with probability at least $1 - \epsilon$ require δ_o split requests and $O(\log \frac{k}{\epsilon}\delta_u^2)$ merge requests to find the target clustering.

Our interactive clustering algorithms take either global or local pairwise similarity data as input. Our most general algorithms use the global average-linkage tree T_{glob} to compute local clustering edits. This tree is constructed from all the data points in the clustering, but it is too large to be directly pruned by users. Still, we can use this global tree to compute accurate local clustering edits. Our split algorithm finds the node in T_{glob} where the corresponding points are first split in two. It is more challenging to design a correct merge procedure, given that we allow "impure" merges, where the clusters in the merge request intersect more than one ground-truth cluster. To perform such merges, in the η-merge model we design an algorithm to extract the "pure" subsets of the two clusters, which must only contain points from the same target cluster. Our algorithm searches for the deepest node in T_{glob} that has enough points from both clusters. In the unrestricted-merge model, we develop another merge algorithm that either merges the two clusters or merges them and splits them. This algorithm always makes progress if the requested merge is "impure," and makes progress on average if it is "pure" (both clusters are subset of the same target cluster).

When the data satisfies stronger assumptions, we present more efficient split and merge algorithms that do not require global pairwise similarity information. These procedures compute the edit by only considering the similarities between the points in the user request.

In Section 5 we demonstrate the effectiveness of our algorithms on real data. We show that for the purposes of splitting known overclustering instances, our split algorithm performs better than well-known algorithms in unsupervised split/merge clustering literature, such as spectral clustering and k-means. We also test our entire interactive clustering framework on the 20 Newsgroup data set, which is known to very challenging for unsupervised (Telgarsky and Dasgupta, 2012; Heller and Ghahramani, 2005; Dasgupta and Hsu, 2008; Dai et al., 2010; Boulis and Ostendorf, 2004; Zhong, 2005) and semi-supervised clustering methods (Basu et al., 2002, 2004). We find that in many scenarios our framework is able find the target Newsgroup clustering after a limited number of edit requests.

1.2 Related work

In this section we give an overview of the related work in the literature.

Interactive Clustering: Interactive clustering models in previous works (Balcan and Blum, 2008; Awasthi and Zadeh, 2010) were inspired by an analogous model for learning under feedback (Angluin, 1998). In this model, the algorithm can propose a hypothesis to the user (in this case, a clustering of the data) and get some feedback regarding the correctness of the current hypothesis. As in our model, the feedback in Balcan and Blum (2008); Awasthi and Zadeh (2010) is in the form of split and merge requests. The goal is to design efficient algorithms that require few user requests. A major limitation in the models of Balcan and Blum (2008) and Awasthi and Zadeh (2010) is that the algorithm is able to choose any arbitrary clustering as the starting point, and can make arbitrary changes to the clustering in each step. Hence these algorithms may propose a series of "bad" clusterings to the user to quickly prune the search space and reach the target clustering. Our interactive clustering model is in the context of an initial clustering; we are restricted to only making local changes to this clustering to correct the errors pointed out by the user. This model is well-motivated by several applications, including the Google application described in Section 5.1.

Active Clustering: Other active clustering frameworks have been proposed, where *active* either refers to selecting which pairwise similarities to consider (not studied here), or requesting user supervision with respect to the ground-truth clustering. For the former problem, Erikkson et al. (2011) study minimizing the number of pairwise similarities needed for an algorithm to compute an accurate clustering. They propose an adaptive algorithm that selects which pairwise similarities to consider. The assumption on the similarity function that they study, which they call *tight clustering condition*, is equivalent to the *strict separation* property studied here. Krishnamurthy et al. (2012) propose a different framework to adaptively select which pairwise similarities to consider. They also study an assumption on the similarity function, which is a generalization of the *strict separation* property that considers the expected pairwise similarities. Their framework recursively splits clusters; they propose a spectral-clustering algorithm to perform the split. They also suggest using the k-means algorithm to perform the split (albeit with no provable guarantees). In our experimental section we compare our proposed split procedures with a similar spectral clustering algorithm and the k-means algorithm (see Section 5.1).

For the latter semi-supervised clustering problem, Nie et al. (2012) develop a clustering algorithm that iteratively extends class labels. It may be used with an empty set of initial labels (unsu-

pervised setting), or with a non-empty set of initial labels (semi-supervised setting). The algorithm minimizes an estimate of Bayes error with respect to the unlabeled instances.

Basu et al. (2002) study the same semi-supervised clustering problem in the context of the k-means objective. Their algorithm has access to the class labels of some seed fraction f of the points in the data set. They propose two variations of a supervised k-means algorithm: one which only uses the known labels to compute the initial clustering (termed *Seeded K-Means*), and another that also enforces that the known labels do not change while the centers/clusters are updated (termed *Constrained K-Means*). They perform experiments on the same 20 Newsgroups data sets that we consider in Section 5.2. The experiments of Basu et al. (2002) show that even though the supervision improves accuracy, even for $f > 0.5$ the output clustering still has many mistakes. They also show that the accuracy depends on how difficult the data set is w.r.t. the separability of the ground-truth clusters, and show improved accuracy on an easier instance (termed *Different-3 Newsgroups*) when compared to a harder one (termed *Same-3 Newsgroups*). In a related work, Basu et al. (2004) study the same problem but with supervision in the form of pairwise *must-link* and *cannot-link* constraints. They propose another supervised k-means algorithm and perform experiments on the same 20 Newsgroups data sets. They are still unable to come close to recovering the ground-truth for a difficult Newsgroups data set (termed *News-sim3*), but have more success with an easier Newsgroup data set (termed *News-diff3*). Ashtiani et al. (2016) also study the k-means objective with supervision in the form of pairwise *must-link* and *cannot-link* constraints, which are modeled as oracle queries. For center-based clustering instances (specified by a Voroni decomposition around a set of centers) that satisfy a separability condition with respect to the cluster centers, they propose an accurate algorithm that requires a limited number of queries; they do not provide any experimental results.

In our experimental section we give a comparison of our results on the 20 Newsgroups data sets with those of Basu et al. (2002) and Basu et al. (2004) (see Section 5.2.4). Our comparison considers the amount of required supervision and accuracy of the final clustering output. We show that only our framework is able to fully recover the ground-truth clustering, albeit we can do this consistently only with some restrictions on the requested merges. On the other hand, Basu et al. (2002) and Basu et al. (2004) do not come close to finding the ground-truth for the harder Newsgroups data sets even when they use a large amount of supervision.

We also note that the supervision considered by Nie et al. (2012), Basu et al. (2002), Basu et al. (2004) and Ashtiani et al. (2016) is harder for the user to provide. Such supervision requires an understanding of the individual data points on the part of the user. The user must study the individual data points to provide instance class labels as in Nie et al. (2012) and Basu et al. (2002), or study pairwise relationships between individual data points to provide must-link and cannot-link constraints as in Basu et al. (2004) and Ashtiani et al. (2016). The supervision in the form of cluster split/merge requests that we consider here is a more realistic form of interaction - it only requires the user to understand the high-level properties of the clusters.

Split/Merge Techniques: Several unsupervised split/merge frameworks have also been proposed (Ding and He, 2002; Lee et al., 2012; Chaudhuri et al., 1992). They focus on designing split/merge algorithms but do not consider any user feedback. Ding and He (2002) propose to use a spectral clustering algorithm to perform the splits. To perform merges, they only consider returning the union of the points in the two clusters. In our experiments, we compare the effectiveness of our split procedures with splits given by spectral clustering (see Section 5.1). With respect to merges, our merge algorithms for $\eta = 1$ are equivalent to the merge proposed by Ding and He (2002), but

in our framework merges may only be initiated by user requests, while Ding and He (2002) propose automatically selecting the next clusters to merge using the max-min-cut criterion (without any user supervision), which they show works well in practice. However, the experiments of Ding and He (2002) also assume that we know the target number of clusters, while our model does not make such assumptions.

Lee et al. (2012) propose a different unsupervised split/merge framework based on optimizing Bayes error. They propose spectral clustering and k-means for computing the splits, which we compare with in our experimental section (see Section 5.1). To perform merges, they again only consider returning the union of the two clusters; the next two clusters to merge are selected by optimizing Bayes error. Unlike Ding and He (2002), they do not assume that we know the number of target clusters. They show good experimental results for video segmentation, but their unsupervised approach may not work for challenging data sets like 20 Newsgroups, where it may not be possible to find the ground truth without user feedback. Chaudhuri et al. (1992) propose another unsupervised split/merge framework for image-segmentation applications. Their split procedure is application-specific because it considers gray-scale values (we cannot compare with it), while their merge is based on edge density.

Data Separability Properties: The data separability (stability) property that we consider in this work is a natural generalization of the "stable marriage" property (see Definition 2), which has been studied in a variety of previous works (Balcan et al., 2008; Bryant and Berry, 2001). It is the weakest among the stability properties that have been studied recently such as *strict separation* and *strict threshold separation* (Balcan et al., 2008; Erikkson et al., 2011; Ackerman et al., 2012; Ackerman and Dasgupta, 2014; Balcan et al., 2014). This property is also known to hold for real-world data. In particular, Voevodski et al. (2012) observed that this property holds for protein sequence data, where similarities are computed with sequence alignment and ground truth clusters correspond to evolutionary-related proteins. Other stronger separability properties have also been considered in the literature (Awasthi and Balcan, 2015).

2. Notation and Preliminaries

Given a data set X of n points we define $\mathcal{C} = \{C_1, C_2, \ldots C_k\}$ to be a k-clustering of X where the C_i's represent the individual clusters. Given two clusterings $\mathcal{C}$ and $\mathcal{C}'$, we next define several notions of clustering error, which are used in our theoretical analysis.

2.1 Clustering Error

Given two clusterings $\mathcal{C}$ and $\mathcal{C}'$, we define the distance between a cluster $C_i \in \mathcal{C}$ and the clustering $\mathcal{C}'$ as:

$$\text{dist}(C_i, \mathcal{C}') = |\{C'_j \in \mathcal{C}' : C'_j \cap C_i \neq \emptyset\}| - 1.$$

This distance is the number of *additional* clusters in $\mathcal{C}'$ that contain points from C_i; it evaluates to 0 when all points in C_i are contained in a single cluster in $\mathcal{C}'$. Naturally, we can then define the distance between $\mathcal{C}$ and $\mathcal{C}'$ as:

$$\text{dist}(\mathcal{C}, \mathcal{C}') = \sum_{C_i \in \mathcal{C}} \text{dist}(C_i, \mathcal{C}').$$

Notice that this notion of clustering distance is asymmetric: $\text{dist}(\mathcal{C},\mathcal{C}') \neq \text{dist}(\mathcal{C}',\mathcal{C})$. Also note that $\text{dist}(\mathcal{C},\mathcal{C}') = 0$ if and only if $\mathcal{C}$ refines $\mathcal{C}'$. Observe that if $\mathcal{C}$ is the ground-truth clustering, and $\mathcal{C}'$ is a proposed clustering, then $\text{dist}(\mathcal{C},\mathcal{C}')$ can be considered an *underclustering error*, and $\text{dist}(\mathcal{C}',\mathcal{C})$ an *overclustering error*.

An underclustering error is an instance of several clusters in a proposed clustering containing points from the same ground-truth cluster; this ground-truth cluster is said to be *underclustered*. Conversely, an overclustering error is an instance of points from several ground-truth clusters contained in the same cluster in a proposed clustering; this proposed cluster is said to be *overclustered*. In the following sections we use $\mathcal{C}^* = \{C_1^*, C_2^*, \ldots C_k^*\}$ to refer to the ground-truth clustering, and use $\mathcal{C}$ to refer to a proposed clustering. We use δ_u to refer to the underclustering error of a proposed clustering, and δ_o to refer to the overclustering error. In other words, we have $\delta_u = \text{dist}(\mathcal{C}^*,\mathcal{C})$ and $\delta_o = \text{dist}(\mathcal{C},\mathcal{C}^*)$. We use δ to denote the sum of the two errors: $\delta = \delta_u + \delta_o$. We call δ the *under/overclustering error*, and use $\delta(\mathcal{C},\mathcal{C}^*)$ to refer to the error of $\mathcal{C}$ with respect to $\mathcal{C}^*$.

We observe that the *under/overclustering error* $\delta(\mathcal{C},\mathcal{C}^*)$ may also be restated in terms of the *bipartite cluster-intersection graph* of Xiang et al. (2012). This bipartite graph $G = (\mathcal{C},\mathcal{C}^*,E)$ describes the relationships between the clusters of $\mathcal{C}$ and $\mathcal{C}^*$, with nodes on one side corresponding to the clusters of $\mathcal{C}$ and nodes on the other side corresponding to the clusters of $\mathcal{C}^*$. The set of (unweighted) edges E corresponds to the intersections between the two sets of clusters: there is an edge if the corresponding clusters intersect on at least one data point (Xiang et al., 2012). Then we can express the *under/overclustering error* $\delta(\mathcal{C},\mathcal{C}^*)$ using vol(G), the sum of the degrees of the nodes of G:

$$\delta(\mathcal{C},\mathcal{C}^*) = \text{vol}(G) - |\mathcal{C}| - |\mathcal{C}^*|.$$

In addition to the *under/overclustering* error defined above, in parts of our analysis we define the distance between two clusterings using the *correlation-clustering* objective function. Given a proposed clustering $\mathcal{C}$, and a ground-truth clustering $\mathcal{C}^*$, we define the correlation-clustering error δ_{cc} as the number of (ordered) pairs of points that are clustered *inconsistently* with $\mathcal{C}^*$:

$$\delta_{cc} = |\{(u,v) \in X \times X : c(u,v) \neq c^*(u,v)\}|,$$

where $c(u,v) = 1$ if u and v are in the same cluster in $\mathcal{C}$, and 0 otherwise; $c^*(u,v) = 1$ if u and v are in the same cluster in $\mathcal{C}^*$, and 0 otherwise. In our analysis we also call each such pair of points a *pairwise correlation-clustering error*.

Note that as before we may divide the correlation-clustering error δ_{cc} into overclustering component δ_{cco} and underclustering component δ_{ccu}:

$$\delta_{cco} = |\{(u,v) \in X \times X : c(u,v) = 1 \text{ and } c^*(u,v) = 0\}|,$$
$$\delta_{ccu} = |\{(u,v) \in X \times X : c(u,v) = 0 \text{ and } c^*(u,v) = 1\}|.$$

Observe that by definition $\delta_{cc} = \delta_{cco} + \delta_{ccu}$.

2.2 Definitions

Our interactive clustering model concerns computing *local* clustering edits, which only change the part of the clustering that the user is complaining about. This intuition is captured by the following definition.

Definition 1 (Local algorithm) *We say that an interactive clustering algorithm is* local *if in each iteration only the cluster assignments of the points involved in the edit request may be changed. If the user requests to split C_i, the algorithm may only reassign the points in C_i. If the user requests to merge C_i and C_j, the algorithm may only reassign the points in $C_i \cup C_j$.*

We next define the properties of a clustering that we study in this work, which describe how separable the ground-truth clusters are.

Definition 2 (Stability) *Given a clustering $\mathcal{C} = \{C_1, C_2, \cdots C_k\}$ over a domain X and a similarly function $S : X \times X \mapsto \Re$, we say that $\mathcal{C}$ satisfies stability with respect to S if for all $i \neq j$, and for all $A \subset C_i$ and $A' \subseteq C_j$, $S(A, C_i \setminus A) > S(A, A')$, where for any two sets A, A', $S(A, A') = E_{x \in A, y \in A'} S(x, y)$.*

In addition to the *stability* property, we also study the stronger *strict separation* and *strict threshold separation* properties, which were first introduced in Balcan et al. (2008). They are defined below. Clearly, we can verify that *strict separation* and *strict threshold separation* imply *stability*.

Definition 3 (Strict separation) *Given a clustering $C = \{C_1, C_2, \cdots C_k\}$ over a domain X and a similarly function $S : X \times X \mapsto \Re$, we say that C satisfies strict separation with respect to S if for all $i \neq j$, $x, y \in C_i$ and $z \in C_j$, $S(x, y) > S(x, z)$.*

Definition 4 (Strict threshold separation) *Given a clustering $C = \{C_1, C_2, \cdots C_k\}$ over a domain X and a similarly function $S : X \times X \mapsto \Re$, we say that C satisfies strict threshold separation with respect to S if there exists a threshold t such that, for all i, $x, y \in C_i$, $S(x, y) > t$, and, for all $i \neq j$, $x \in C_i, y \in C_j$, $S(x, y) \leq t$.*

We model the user as an oracle that provides edit requests. In order for our algorithms to make progress, the oracle requests must be somewhat consistent with the target clustering, which is captured by the following definitions.

Definition 5 (η-merge model) *The oracle may request to split a cluster C_i only if C_i contains points from more than one target cluster. The oracle may request to merge two clusters C_i and C_j only if at least an η-fraction of the points in each C_i and C_j belong to the same target cluster.*

Definition 6 (unrestricted-merge model) *The oracle may request to split a cluster C_i only if C_i contains points from more than one target cluster. The oracle may request to merge two clusters C_i and C_j only if C_i and C_j both intersect the same target cluster.*

Note that the assumptions about the split requests are the same in both models. With respect to the merges, in the η-merge model the oracle may request to merge two clusters if both have a *constant fraction* of points from the same target cluster. In the unrestricted-merge model, the oracle may request to merge two clusters even if both only have *some* points from the same target cluster. In each model, we will refer to the split/merge requests that satisfy these definitions as *valid* edit requests.

Also note that in the η-merge model the restrictions on valid merge requests are with respect to the oracle requests, and not the clustering we are editing. In particular, there may be pairs of clusters C_i and C_j where a smaller fraction of the points are from the same target cluster. But we assume that the oracle will not request to merge C_i and C_j in such cases. Instead, we assume that the oracle will ask for a split of C_i and/or C_j first, or ask for a different (valid) merge involving C_i or C_j.

2.3 Generalized clustering error

We observe that the clustering errors defined in the previous section may be generalized by abstracting their common properties. We define the following properties of what we call *natural* clustering error, which is any integer-valued error that decreases when we locally improve the proposed clustering.

Definition 7 *We say that a clustering error is* natural *if it satisfies the following properties:*

- *If there exists a cluster C_i that contains points from C_j^* and some other ground-truth cluster(s), then splitting this cluster into two clusters $C_{i,1} = C_i \cap C_j^*$ and $C_{i,2} = C_i - C_{i,1}$ must decrease the error.*
- *If there exist two clusters that contain only points from the same target cluster, then merging them into one cluster must decrease the error.*
- *The error is integer-valued.*

We expect a lot of definitions of clustering error to satisfy the above criteria (especially the first two properties), in addition to other domain-specific criteria. Clearly, the under/overclustering error $\delta = \delta_u + \delta_o$ and the correlation-clustering error δ_{cc} are also *natural* clustering errors (Claim 8). Given a *natural* clustering error γ, a proposed clustering $\mathcal{C}$ and the target clustering $\mathcal{C}^*$, we will use $\gamma(\mathcal{C}, \mathcal{C}^*)$ to denote the magnitude of the error of $\mathcal{C}$ with respect to $\mathcal{C}^*$. We can also prove that the under/overclustering error defined in the previous section is the lower-bound on any *natural* clustering error (Theorem 9).

Claim 8 *The under/overclustering error and the correlation clustering error satisfy Definition 7 and hence are natural clustering errors.*

Theorem 9 *For any* natural *clustering error γ, any proposed clustering $\mathcal{C}$, and any target clustering $\mathcal{C}^*$, $\gamma(\mathcal{C}, \mathcal{C}^*) \geq \delta(\mathcal{C}, \mathcal{C}^*)$.*

Proof Given any proposed clustering $\mathcal{C}$, and any target clustering $\mathcal{C}^*$, we may transform $\mathcal{C}$ into $\mathcal{C}^*$ via the following sequence of edits. First, we split all overclustering instances using the following iterative procedure: while there exists a cluster C_i that contains points from C_j^* and some other ground-truth cluster(s), we split it into two clusters $C_{i,1} = C_i \cap C_j^*$ and $C_{i,2} = C_i - C_{i,1}$. Note that this iterative split procedure will require exactly δ_o split edits, where δ_o is the initial overclustering error. Then, when we are left with only "pure" clusters (each intersects exactly one target cluster), we merge all underclustering instances using the following iterative procedure: while there exist two clusters C_i and C_j that contain only points from the same target cluster, merge C_i and C_j. Note that this iterative merge procedure will require exactly δ_u merge edits, where δ_u is the initial underclustering error. Let us use γ to refer to any *natural* clustering error of $\mathcal{C}$ with respect to $\mathcal{C}^*$. By the first property of *natural* clustering error, each split must have decreased γ by at least one. By the second property, each merge must have decreased γ by at least one as well. Given that we performed exactly $\delta = \delta_o + \delta_u$ edits, it follows that initially $\gamma(\mathcal{C}, \mathcal{C}^*)$ must have been at least δ. ■

For additional discussion about comparing clusterings see Meilă (2007). Note that several criteria discussed in Meilă (2007) satisfy our first two properties (given that we replace "must decrease the error" with "must increase the similarity" in Definition 7). In addition, the Rand criteria and the Mirkin criteria discussed in Meilă (2007) are closely related to the correlation clustering error defined here (all three measures are a function of the number of pairs of points that are clustered incorrectly).

2.4 Local interactive clustering

We now give a general overview of our local interactive clustering model. This model is then instantiated by specific split/merge algorithms in Section 3 and Section 4 (depending on the assumptions about the oracle requests and the separability of the data).

Our approach is outlined in Figure 1 - we iteratively keep on making the local edits requested by the oracle. Note that the oracle does not provide the algorithm with any additional information about how to execute the split/merge. The description in Figure 1 also assumes that the requests come one at a time. Batch requests can be handled as well by queuing them in arbitrary order and then executing them one at a time (as long as the clusters in the request have not changed).

Given that the oracle requests must be somewhat consistent with the target clustering (see our assumptions about the validity of such requests in Section 2.2), and that our algorithms must therefore make progress with respect to finding the target clustering (see our analysis in Section 3 and Section 4), we expect the loop to terminate when we reach the target clustering.

Also note that the description in Figure 1 does not say anything about the sequence of oracle requests. The algorithms for the η-merge model in Section 3 are consistent with this description; they make no additional assumptions about this sequence. However, the algorithms in the unrestricted-merge model in Section 4 do make an additional assumption that each merge request is drawn uniformly at random from the set of valid merge requests.

Figure 1: Local interactive clustering model

while (there exists split/merge request from oracle)

- perform corresponding local clustering edit

3. The η-merge model

In this section we describe and analyze our split/merge algorithms in the η-merge model. As a preprocessing step for all our split/merge algorithms, we first run the hierarchical average-linkage algorithm on all the points in the data set to compute the global average-linkage tree, which we denote by T_{glob}. The leaf nodes in this tree contain the individual points, and the root node contains all the points. The tree is computed in a bottom-up fashion: starting with the leafs in each iteration the two most similar nodes are merged, where the similarity between two nodes N_1 and N_2 is the average similarity between the points in N_1 and the points in N_2.

We assign a label "impure" to each cluster in the initial clustering; these labels are used by the merge procedure but are not visible to the user. Given a split or merge request from the oracle, a local clustering edit is computed from the global tree T_{glob} as described in Figure 2 and Figure 3.

To implement Step 1 in Figure 2, we start at the root of T_{glob} and "follow" the points in C_i down one of the branches until we find a node that splits them. In order to implement Step 2 in Figure 3, it suffices to perform a post-order traversal of T_{glob} and return the first node that has "enough" points from both clusters.

Figure 2: Split procedure

Algorithm: SPLIT PROCEDURE

Input: Cluster C_i, global average-linkage tree T_{glob}.

1. Search T_{glob} to find the node N at which the set of points in C_i are first split in two.
2. Let N_1 and N_2 be the children of N. Set $C_{i,1} = N_1 \cap C_i$, $C_{i,2} = N_2 \cap C_i$.
3. Delete C_i and replace it with $C_{i,1}$ and $C_{i,2}$. Mark the two new clusters as "impure".

The split procedure is fairly intuitive: if the average-linkage tree is consistent with the target clustering, it suffices to find the node in the tree where the corresponding points are first split in two. It is more challenging to develop a correct merge procedure: note that Step 2 in Figure 3 is only correct if $\eta > 0.5$, which ensures that if two nodes in the tree have more than an η-fraction of the points from C_i and C_j, one must be an ancestor of the other. If the average-linkage tree is consistent with the ground-truth, then clearly the node equivalent to the corresponding target cluster (that C_i and C_j both intersect) will have enough points from C_i and C_j; therefore the node that we find in Step 2 must be this node or one of its descendants. In addition, because our merge procedure may replace two clusters with three, we require pure/impure labels for the merge requests to terminate: "pure" clusters may only have other points added to them, and retain this label throughout the execution of the algorithm.

Figure 3: Merge procedure

Algorithm: MERGE PROCEDURE

Input: Clusters C_i and C_j, global average-linkage tree T_{glob}.

1. If C_i is marked as "pure" set $\eta_1 = 1$ else set $\eta_1 = \eta$. Similarly set η_2 for C_j.
2. Search T_{glob} for a node of maximal depth N that contains *enough* points from C_i and C_j: $|N \cap C_i| \geq \eta_1 |C_i|$ and $|N \cap C_j| \geq \eta_2 |C_j|$.
3. Replace C_i by $C_i \setminus N$, replace C_j by $C_j \setminus N$.
4. Add a new cluster containing $N \cap (C_i \cup C_j)$, mark it as "pure".

We now state the performance guarantee for these split and merge algorithms.

Theorem 10 *Suppose the target clustering satisfies stability, and the initial clustering has overclustering error δ_o and underclustering error δ_u. In the η-merge model, for any $\eta > 0.5$, the algorithms in Figure 2 and Figure 3 require at most δ_o split requests and $2(\delta_u + k) \log_{\frac{1}{1-\eta}} n$ merge requests to find the target clustering.*

In order to prove the theorem, we must do some preliminary analysis. First, we observe that if the target clustering satisfies stability, then every node of the average-linkage tree must be *laminar* (consistent) with respect to the target clustering. Informally, each node in a hierarchical clustering tree T is said to be *laminar* (consistent) with respect to the clustering $\mathcal{C}$ if for each cluster $C_i \in \mathcal{C}$, the points in C_i are first grouped together in T before they are grouped with points from any other cluster $C_{j \neq i}$. We formally state and prove these observations next.

Definition 11 (Laminar) *A node N is laminar with respect to a clustering $\mathcal{C}$ if for each cluster $C_i \in \mathcal{C}$ we have either $N \cap C_i = \emptyset$, $N \subseteq C_i$, or $C_i \subset N$.*

Lemma 12 *Suppose the ground-truth clustering $\mathcal{C}^*$ over a domain X satisfies stability with respect to a similarity function S. Let T be the average-linkage tree for X constructed with S. Then every node in T is laminar w.r.t. $\mathcal{C}^*$.*

Proof The proof of this statement can be found in Balcan et al. (2008). The intuition is that if there is a node in T that is not laminar w.r.t. C^*, then the average-linkage algorithm, at some step, must have merged $A \subseteq C_i^*$, with $B \subset C_j^*$ for some $i \neq j$. However, this will contradict the stability property for the sets A and/or B. ■

It follows that the split computed by the algorithm in Figure 2 must also be consistent with the target clustering; we call such splits *clean*.

Definition 13 (Clean split) *A partition (split) of a cluster C_i into clusters $C_{i,1}$ and $C_{i,2}$ is said to be* clean *if $C_{i,1}$ and $C_{i,2}$ are non-empty, and for each ground-truth cluster C_j^* such that $C_j^* \cap C_i \neq \emptyset$, either $C_j^* \cap C_i = C_j^* \cap C_{i,1}$ or $C_j^* \cap C_i = C_j^* \cap C_{i,2}$.*

We now prove the following properties regarding the correctness of the split/merge procedures; these properties are then used in the proof of Theorem 10.

Lemma 14 *If the ground-truth clustering satisfies stability and $\eta > 0.5$ then,*

- ***a.*** *The split procedure in Figure 2 always produces a clean split.*
- ***b.*** *The new cluster added by the merge procedure in Figure 3 must be "pure", i.e., it must contain points from a single ground-truth cluster.*

Proof a. For purposes of contradiction, suppose the returned split is not clean: $C_{i,1}$ and $C_{i,2}$ contain points from the same ground-truth cluster C_j^*. It must be the case that C_i contains points from several ground-truth clusters, which implies that w.l.o.g. $C_{i,1}$ contains points from some other ground-truth cluster $C_{l \neq j}^*$. This implies that N_1 is not laminar w.r.t. $\mathcal{C}^*$, which contradicts Lemma 12. **b.** By our assumption, at least $\eta |C_i|$ points from C_i and $\eta |C_j|$ points from C_j are from the same ground-truth cluster C_l^*. Clearly, the node N' in T_{glob} that is equivalent to C_l^* (which contains all the points in C_l^* and no other points) must contain *enough* points from C_i and C_j, and only ascendants and

descendants of N' may contain more than an $\eta > 1/2$ fraction of points from both clusters. Therefore, the node N that we find in Step 2 in Figure 3 must be N' or one of its descendants, and will only contain points from C_l^*. ■

We also prove an additional property of the split algorithm - it always makes progress with respect to reducing overclustering error. This property is then used in the proof of Theorem 10.

Lemma 15 *If the ground-truth clustering satisfies stability, then the split algorithm in Figure 2 must reduce overclustering error by exactly 1.*

Proof Suppose we execute Split(C_1), and call the resulting clusters C_2 and C_3. Call δ_1 the overclustering error before the split, and δ_2 the overclustering error after the split. Let's use k_1 to refer to the number of ground-truth clusters that intersect C_1, and define k_2 and k_3 in the same manner. Due to the *clean split* property, no ground-truth cluster can intersect both C_2 and C_3, therefore it must be the case that $k_2 + k_3 = k_1$. Also, clearly $k_2, k_3 > 0$. Therefore we have:

$$\begin{aligned} \delta_2 &= \delta_1 - (k_1 - 1) + (k_2 - 1) + (k_3 - 1) \\ &= \delta_1 - k_1 + (k_2 + k_3) - 1 \\ &= \delta_1 - 1. \end{aligned}$$

■

Using Lemma 14 and Lemma 15, we can now prove the bounds on the number of split and merge requests stated in Theorem 10.

Proof [Proof of Theorem 10] We first give a bound on the number of splits. Lemma 15 shows that each split reduces the overclustering error by exactly 1. It is easy to verify that merges cannot increase overclustering error. Therefore the total number of splits may be at most δ_o.

We next give the argument about the number of *impure* and *pure* merges. We call a merge *pure* if both clusters have the label "pure", and call it *impure* otherwise. We first argue that we cannot have too many impure merges before each cluster in C is marked pure. Consider the clustering $P = \{C_i \cap C_j^* \mid C_i \text{ is marked "impure" and } C_i \cap C_j^* \neq \emptyset\}$. Clearly, at the start $|P| = \delta_u + k$. A merge does not increase the number of clusters in P, and the splits do not change P at all (because of the *clean split* property). Moreover, each impure merge *depletes* some $P_i \in P$ by moving at least $\eta|P_i|$ of its points to a pure cluster. Clearly, we can then have at most $\log_{1/(1-\eta)} n$ merges depleting each P_i. Since each impure merge must deplete some P_i, it must be the case that we can have at most $(\delta_u + k)\log_{1/(1-\eta)} n$ impure merges in total.

Notice that a pure cluster can only be created by an impure merge, and there can be at most one pure cluster created by each impure merge. Clearly, a pure merge removes exactly one pure cluster. Therefore the number of pure merges may be at most the total number of pure clusters that are created, which is at most the total number of impure merges. Therefore the total number of merges must be less than $2(\delta_u + k)\log_{1/(1-\eta)} n$. ■

We can also restate the run-time bound in Theorem 10 in terms of any *natural* clustering error γ. The following corollary follows from Theorem 10 and Theorem 9.

Corollary 16 *Suppose the target clustering satisfies stability, and the initial clustering has clustering error γ, where γ is any* natural *clustering error as defined in Definition 7. In the η-merge model, for any $\eta > 0.5$, the algorithms in Figure 2 and Figure 3 require at most $O((\gamma + k)\log_{\frac{1}{1-\eta}} n)$ edit requests to find the target clustering.*

3.1 Algorithms for correlation-clustering error

To efficiently find the target clustering with respect to the correlation clustering error, we propose a different merge procedure, which is described in Figure 4.

Figure 4: Merge procedure for the *correlation-clustering* objective

Algorithm: MERGE PROCEDURE

Input: Clusters C_i and C_j, global average-linkage tree T_{glob}

Search T_{glob} for a node of maximal depth N that contains *enough* points from C_i and C_j: $|N \cap C_i| \geq \eta|C_i|$ and $|N \cap C_j| \geq \eta|C_j|$
if $|C_i| \geq |C_j|$ **then**
  Replace C_i by $C_i \cup (N \cap C_j)$
  Replace C_j by $C_j \setminus N$
else
  Replace C_i by $C_i \setminus N$
  replace C_j by $C_j \cup (N \cap C_i)$
end if

Here instead of creating a new "pure" cluster, we add the corresponding points to the larger of the two clusters in the merge request. Notice that this algorithm is much simpler than the merge algorithm in Figure 3, and does not require pure/impure labels. Using this merge procedure and the split procedure presented earlier gives the following performance guarantee.

Theorem 17 *Suppose the target clustering satisfies stability, and the initial clustering has correlation-clustering error δ_{cc}. In the η-merge model, for any $\eta > 2/3$, using the split and merge procedures in Figures 2 and 4 requires at most δ_{cc} edit requests to find the target clustering.*

Proof Recall that we may express the correlation clustering error δ_{cc} as a summation of overclustering error δ_{cco} and underclustering error δ_{ccu} (see Section 2.1). Consider the contributions of individual points to δ_{cco} and δ_{ccu}, which are defined as:

$$\delta_{cco}(u) = |\{v \in X : c(u,v) = 1 \text{ and } c^*(u,v) = 0\}|,$$
$$\delta_{ccu}(u) = |\{v \in X : c(u,v) = 0 \text{ and } c^*(u,v) = 1\}|.$$

We first argue that a split of a cluster C_i must reduce δ_{cc}. Given that the split is *clean*, it is easy to verify that the outcome may not increase $\delta_{ccu}(u)$ for any $u \in C_i$. We can also verify that for each $u \in C_i$, $\delta_{cco}(u)$ must decrease by at least 1. This completes the argument, given that for all other points $w \notin C_i$, $\delta_{cco}(w)$ and $\delta_{ccu}(w)$ remain unchanged.

We now argue that if $\eta > 2/3$, each merge of C_i and C_j must reduce δ_{cc}. Without loss of generality, suppose that $|C_i| \geq |C_j|$, and let us use P to refer to the "pure" subset of C_j that is

moved to C_i. We observe that the outcome must remove at least δ_1 *pairwise correlation-clustering errors* (see Section 2.1), where δ_1 satisfies $\delta_1 \geq 2|P|(\eta|C_i|)$. Similarly, we observe that the outcome may add at most δ_2 pairwise correlation-clustering errors, where δ_2 satisfies:

$$\delta_2 \leq 2|P|((1-\eta)|C_i|) + 2|P|((1-\eta)|C_j|) \leq 4|P|((1-\eta)|C_i|).$$

It follows that for $\eta > 2/3$, δ_1 must exceed δ_2; therefore the number of pairwise correlation-clustering errors must decrease, giving a lower correlation-clustering error. ■

Observe that the runtime bound in Theorem 17 is tight up to a constant: in some instances any *local* algorithm requires at least $\delta_{cc}/2$ edits to find the target clustering. To verify this, suppose the target clustering is composed of n singleton clusters, and the initial clustering contains $n/2$ clusters of size 2. In this instance, the initial correlation clustering error $\delta_{cc} = n$, and the oracle must issue at least $n/2$ split requests before we reach the target clustering (one for each of the $n/2$ initial clusters).

3.2 Algorithms under stronger assumptions

When the data satisfies stronger separability properties we may simplify the presented algorithms and/or obtain better performance guarantees. In particular, if the data satisfies the *strict separation* property (see Definition 3), we may change the split and merge algorithms to use the local average-linkage tree, which is constructed from only the points in the edit request. In addition, if the data satisfies *strict threshold separation* (see Definition 4), we may remove the restriction on η and use a different merge procedure that is correct for any $\eta > 0$.

Theorem 18 *Suppose the target clustering satisfies strict separation, and the initial clustering has overclustering error δ_o and underclustering error δ_u. In the η-merge model, for any $\eta > 0.5$, the algorithms in Figure 5 and Figure 6 require at most δ_o split requests and $2(\delta_u + k)\log_{\frac{1}{1-\eta}} n$ merge requests to find the target clustering.*

Proof Let us use $\mathcal{L}^*$ to refer to the ground-truth clustering of the points in the split/merge request. If the target clustering satisfies strict separation, it is easy to verify that every node in the local average-linkage tree T_{loc} must be laminar (consistent) w.r.t. $\mathcal{L}^*$. We can then use this observation to prove the equivalent of Lemma 14 for strict separation for the split procedure in Figure 5 and the merge procedure in Figure 6. Similarly, we can prove the equivalent of Lemma 15 for strict separation for the split procedure in Figure 5. The analysis in Theorem 10 remains unchanged. ■

Theorem 19 *Suppose the target clustering satisfies strict threshold separation, and the initial clustering has overclustering error δ_o and underclustering error δ_u. In the η-merge model, for any $\eta > 0$, the algorithms in Figure 5 and Figure 7 require at most δ_o split requests and $2(\delta_u + k)\log_{\frac{1}{1-\eta}} n$ merge requests to find the target clustering.*

Proof If the target clustering satisfies strict threshold separation, we can verify that for any $\eta > 0$, the split procedure in Figure 5 and the merge procedure in Figure 7 still have the properties stated in Lemma 14 and Lemma 15. The analysis in Theorem 10 remains unchanged.

To verify that the split procedure always produces a clean split, again let us use $\mathcal{L}^*$ to refer to the ground-truth clustering of the points in the split request. If the target clustering satisfies strict threshold separation, we can again verify that every node in the local average-linkage tree T_{loc} must be laminar (consistent) w.r.t. $\mathcal{L}^*$. It follows that the split procedure always produces a clean split and must reduce overclustering error by exactly 1. Note that clearly this argument does not depend on the setting of η.

We now verify that the new cluster added by the merge procedure in Figure 7 must be "pure" (must contain points from a single target cluster). Observe that due to the strict threshold separation property, in the graph G in Figure 7, all pairs of points from the same target cluster must be connected before any pairs of points from different target clusters. It follows that the first component that contains at least an η-fraction of points from C_i and C_j must be "pure". Note that this argument applies for any $\eta > 0$. ■

Figure 5: Split procedure under stronger assumptions

Algorithm: SPLIT PROCEDURE

Input: Cluster C_i, local average-linkage tree T_{loc}.

1. Let $C_{i,1}$ and $C_{i,2}$ be the children of the root in T_{loc}.
2. Delete C_i and replace it with $C_{i,1}$ and $C_{i,2}$. Mark the two new clusters as "impure".

Figure 6: Merge procedure under strict separation

Algorithm: MERGE PROCEDURE

Input: Clusters C_i and C_j, local average-linkage tree T_{loc}.

1. If C_i is marked as "pure" set $\eta_1 = 1$ else set $\eta_1 = \eta$. Similarly set η_2 for C_j.
2. Search T_{loc} for a node of maximal depth N that contains *enough* points from C_i and C_j: $|N \cap C_i| \geq \eta_1|C_i|$ and $|N \cap C_j| \geq \eta_2|C_j|$.
3. Replace C_i by $C_i \setminus N$, replace C_j by $C_j \setminus N$.
4. Add a new cluster containing $N \cap (C_i \cup C_j)$, mark it as "pure".

As in Corollary 16, we may also restate the run-time bounds in Theorem 18 and Theorem 19 in terms of any natural clustering error γ. The following corollaries follow from Theorem 18, Theorem 19 and Theorem 9.

Corollary 20 *Suppose the target clustering satisfies strict separation, and the initial clustering has clustering error γ, where γ is any* natural *clustering error as defined in Definition 7. In the η-merge model, for any $\eta > 0.5$, the algorithms in Figure 5 and Figure 6 require at most $O((\gamma+k)\log_{\frac{1}{1-\eta}} n)$ edit requests to find the target clustering.*

Figure 7: Merge procedure under strict threshold separation

Algorithm: MERGE PROCEDURE

Input: Clusters C_i and C_j.

1. If C_i is marked as "pure" set $\eta_1 = 1$ else set $\eta_1 = \eta$. Similarly set η_2 for C_j.
2. Let $G = (V, E)$ be a graph where $V = C_i \cup C_j$ and $E = \emptyset$. Set $N = \emptyset$.
3. While true:
   Connect the next-closest pair of points in G;
   Let $\hat{C}_1, \hat{C}_2, \ldots, \hat{C}_m$ be the connected components of G;
   if there exists $\hat{C}_l$ such that $|\hat{C}_l \cap C_i| \geq \eta |C_i|$ and $|\hat{C}_l \cap C_j| \geq \eta |C_j|$ **then**
      $N = \hat{C}_l$;
      break;
   end if
4. Replace C_i by $C_i \setminus N$, replace C_j by $C_j \setminus N$.
5. Add a new cluster containing N, mark it as "pure".

Corollary 21 *Suppose the target clustering satisfies strict threshold separation, and the initial clustering has clustering error γ, where γ is any* natural *clustering error as defined in Definition 7. In the η-merge model, for any $\eta > 0$, the algorithms in Figure 5 and Figure 7 require at most $O((\gamma + k) \log_{\frac{1}{1-\eta}} n)$ edit requests to find the target clustering.*

4. The unrestricted-merge model

In this section we further relax the assumptions about the nature of the oracle requests. As before, the oracle may request to split a cluster if it contains points from two or more target clusters. For merges, now the oracle may request to merge C_i and C_j if both clusters contain only a single point from the same ground-truth cluster. We note that this is a minimal set of assumptions for a local algorithm to make progress, otherwise the oracle may request irrelevant splits or merges that prevent the algorithm from finding the target clustering. For this model we propose the merge algorithm described in Figure 8. The split algorithm remains the same as in Figure 2.

To provably find the ground-truth clustering in this setting we require that each merge request must be chosen uniformly at random from the set of *valid* merge requests. This assumption is consistent with the observation in Awasthi and Zadeh (2010) that in the unrestricted-merge model with arbitrary request sequences, even very simple clustering instances require a prohibitively large number of requests. We do not make additional assumptions about the nature of the split requests; in each iteration any *valid* split may be proposed by the oracle. In this setting our algorithms have the following performance guarantee.

Theorem 22 *Suppose the target clustering satisfies stability, and the initial clustering has overclustering error δ_o and underclustering error δ_u. In the unrestricted-merge model, assuming that each*

Figure 8: Merge procedure for the unrestricted-merge model

Algorithm: MERGE PROCEDURE

Input: Clusters C_i and C_j, global average-linkage tree T_{avg}.

1. Let C'_i, C'_j = Split($C_i \cup C_j$), where the split is performed as in Figure 2.
2. Delete C_i and C_j.
3. If the sets C'_i and C'_j are the same as C_i and C_j, then add $C_i \cup C_j$, otherwise add C'_i and C'_j.

merge request is chosen uniformly at random from the set of valid merge requests, with probability at least $1 - \epsilon$, the algorithms in Figure 2 and Figure 8 require δ_o split requests and $O(\log \frac{k}{\epsilon} \delta_u^2)$ merge requests to find the target clustering.

Theorem 22 is proved in the following lemmas. We first state a lemma regarding the correctness of the Algorithm in Figure 8. We argue that if the algorithm merges C_i and C_j, it must be the case that both C_i and C_j only contain points from the same ground-truth cluster.

Lemma 23 *If the algorithm in Figure 8 merges C_i and C_j in Step 3, it must be the case that $C_i \subset C_l^*$ and $C_j \subset C_l^*$ for some ground-truth cluster C_l^*.*

Proof We prove the contrapositive. Suppose C_i and C_j both contain points from C_l^*, and in addition $C_i \cup C_j$ contains points from some other ground-truth cluster. Let us define $S_1 = C_l^* \cap C_i$ and $S_2 = C_l^* \cap C_j$. Because the clusters C'_i, C'_j result from a *clean* split, it follows that $S_1, S_2 \subset C'_i$ or $S_1, S_2 \subset C'_j$. Without loss of generality, assume $S_1, S_2 \subset C'_i$. Then clearly $C'_i \neq C_i$ and $C'_i \neq C_j$, so C_i and C_j are not merged. ■

The δ_o bound on the number of split requests follows from the observation that each split reduces the overclustering error by exactly 1 (see Lemma 15), and the fact that the merge procedure does not increase overclustering error (see Lemma 24).

Lemma 24 *The merge algorithm in Figure 8 does not increase overclustering error.*

Proof Suppose $C_i \cup C_j$ intersects several ground-truth clusters, and hence we obtain two new clusters C'_i, C'_j. Let us call δ_1 the overclustering error before the merge, and δ_2 the overclustering error after the merge. Let's use k_1 to refer to the number of ground-truth clusters that intersect C_i, k_2 to refer to the number of ground-truth clusters that intersect C_j, and define k'_1 and k'_2 in the same manner. The new clusters C'_i and C'_j result from a "clean" split, therefore no ground-truth cluster may intersect both of them. It follows that $k'_1 + k'_2 < k_1 + k_2$. Therefore we now have:

$$\begin{aligned} \delta_2 &= \delta_1 - (k_1 - 1) - (k_2 - 1) + (k'_1 - 1) + (k'_2 - 1) \\ &= \delta_1 - (k_1 + k_2) + (k'_1 + k'_2) < \delta_1. \end{aligned}$$

If C_i and C_j are both subset of the same ground-truth cluster, then clearly the merge operation has no effect on the overclustering error. ■

Finally, Lemma 25 and Lemma 26 bound the number of impure and pure merges. Here we call a proposed merge *pure* if both clusters are subset of the same ground-truth cluster, and *impure* otherwise.

Lemma 25 *The merge algorithm in Figure 8 requires at most δ_u impure merge requests.*

Proof We argue that the result of each impure merge request must reduce the underclustering error δ_u by at least 1. Recall from Section 2.1 that we may express δ_u as a summation of underclustering error with respect to each target cluster. Suppose the oracle requests to merge C_i and C_j, and C_i' and C_j' are the resulting clusters. Clearly, the local edit has no effect on the underclustering error with respect to target clusters that do not intersect C_i or C_j. In addition, because the new clusters C_i' and C_j' result from a *clean* split, for target clusters that intersect exactly one of C_i, C_j, the underclustering error must stay the same. For target clusters that intersect both C_i and C_j, the underclustering error must decrease by exactly one; the number of such target clusters is at least one. ■

Lemma 26 *Assuming that each merge request is chosen uniformly at random from the set of valid merge requests, the probability that the algorithm in Figure 8 requires more than $O(\log \frac{k}{\epsilon}\delta_u^2)$ pure merge requests is less than ϵ.*

Proof We first consider the pure merge requests involving points from some ground-truth cluster C_i^*, the total number of pure merge requests (involving any ground-truth cluster) can then be bounded with a union-bound. To facilitate our argument, let us assign an identifier to each cluster containing points from C_i^* in the following manner:

1. Maintain a *cluster-id* variable, which is initialized to 1. To assign a "new" identifier to a cluster, set its identifier to *cluster-id*, and increment *cluster-id*.
2. In the initial clustering, assign a *new* identifier to each cluster containing points from C_i^*.
3. When we split a cluster containing points from C_i^*, assign its identifier to the newly-formed cluster containing points from C_i^*.
4. When we merge two clusters that are not both subset of the same target cluster, if one of the clusters contains points from C_i^*, assign its identifier to the newly-formed cluster containing points from C_i^*. If both clusters contain points from C_i^*, assign a *new* identifier to the newly-formed cluster containing points from C_i^*.
5. When we merge two clusters C_1 and C_2, and both contain only points from C_i^*, if the outcome is one new cluster, assign it a *new* identifier. If the outcome is two new clusters, assign them the identifiers of C_1 and C_2.

Observe that when clusters containing points from C_i^* are assigned identifiers in this manner, the maximum value of *cluster-id* is bounded by $O(\delta_i)$, where δ_i denotes the underclustering error

of the initial clustering with respect to C_i^*: $\delta_i = \mathrm{dist}(C_i^*, C)$. To verify this, consider that we assign exactly $\delta_i + 1$ new identifiers in Step 2, and each time we assign a new identifier in Steps 4 and 5, δ_i decreases by one.

We say that a *pure* merge request involving points from C_i^* is *original* if the user has never asked us to merge clusters with the given identifiers, otherwise we say that this merge request is *repeated*. Given that the maximum value of *cluster-id* is bounded by $O(\delta_i)$, the total number of *original* merge requests must be $O(\delta_i^2)$.

We now argue that if a merge request is not original, we can lower bound the probability that it will result in the merging of the two clusters. For a repeated merge request $M_i = \mathrm{Merge}(C_1, C_2)$, let X_i be a random variable defined as follows:

$$X_i = \begin{cases} 1 & \text{if neither } C_1 \text{ nor } C_2 \text{ have been involved in a pure merge request since} \\ & \text{the last time a merge of clusters with these identifiers was proposed.} \\ 0 & \text{otherwise.} \end{cases}$$

Clearly, when $X_i = 1$ it must be the case that C_1 and C_2 are merged. Assuming that each merge request is chosen uniformly at random from the set of valid merge requests, we observe that $\Pr[X_i = 1] > \frac{1}{2\delta_i+1}$. To verify this, observe that in each merge request the probability that the user requests to merge C_1 and C_2 is $\frac{1}{m}$, and the probability that the user requests a pure merge involving C_1 or C_2 and some other cluster is less than $\frac{2\delta_i}{m}$, where m is the total number of valid merge requests; we can then bound the probability that the former happens before the latter.

We can then use a Chernoff bound to argue that after $t = O(\log \frac{k}{\epsilon}\delta_i^2)$ *repeated* merge requests, the probability that $\sum_{i=1}^{t} X_i < \delta_i$ (which must be true if we need more *repeated* merge requests) is less than ϵ/k. Therefore, the probability that we need more than $O(\log \frac{k}{\epsilon}\delta_i^2)$ *repeated* merge requests is less than ϵ/k.

By the union-bound, the probability that we need more than $O(\log \frac{k}{\epsilon}\delta_i^2)$ *repeated* merge requests for *any* ground-truth cluster C_i^* is less than $k \cdot \epsilon/k = \epsilon$. Therefore with probability at least $1-\epsilon$ for all ground-truth clusters we need $\sum_i O(\log \frac{k}{\epsilon}\delta_i^2) = O(\log \frac{k}{\epsilon}\sum_i \delta_i^2) = O(\log \frac{k}{\epsilon}\delta_u^2)$ *repeated* merge requests, where δ_u is the underclustering error of the initial clustering. Also recall that for all ground-truth clusters we need $\sum_i O(\delta_i^2) = O(\delta_u^2)$ *original* merge requests. Adding the two terms together, it follows that with probability at least $1-\epsilon$ we need a total of $O(\log \frac{k}{\epsilon}\delta_u^2)$ pure merge requests. ■

As in the previous section, we also restate the run-time bound in Theorem 22 in terms of any *natural* clustering error γ. The following corollary follows from Theorem 22 and Theorem 9.

Corollary 27 *Suppose the target clustering satisfies stability, and the initial clustering has clustering error γ, where γ is any* natural *clustering error as defined in Definition 7. In the unrestricted-merge model, assuming that each merge request is chosen uniformly at random from the set of valid merge requests, with probability at least $1-\epsilon$, the algorithms in Figure 2 and Figure 8 require $O(\log \frac{k}{\epsilon}\gamma^2)$ edit requests to find the target clustering.*

4.1 Algorithms under stronger assumptions

As in Section 3.2, if the data satisfies *strict separation*, then instead of the split procedure in Figure 2 we can use the procedure in Figure 5, which uses the local average-linkage tree (constructed from

only the points in the user request). Similarly, we can modify the merge procedure in Figure 8 to perform the split as in Figure 5. We can then prove the equivalent of Theorem 22 and Corollary 27 for strict separation for these split/merge algorithms.

5. Experimental Results

We perform two sets of experiments. We first test our proposed split algorithm on the clustering of business listings maintained by Google. We then test the proposed model in its entirety on the 20 Newsgroups data set.

5.1 Clustering business listings

Google maintains a large collection of data records representing businesses, which as of 2013 contained more than 100 millions records. These records are initially clustered using a similarity function. Each cluster is expected to contain records about the same distinct business. Clusters are then summarized; these summaries are served to users online via various front-end applications. Users report bugs such as "you are displaying the name of one business, but the address of another" (caused by overclustering), or "a particular business is shown multiple times" (caused by underclustering). The clusters involved in these requests are often quite large and usually contain records about several businesses. Therefore this setting closely matches our interactive clustering model - users provide high-level feedback requesting cluster merges/splits, where the corresponding data points intersect several ground-truth clusters.

Here we evaluate the effectiveness of our proposed split algorithm in such cases. Correctness of a split is evaluated with respect to the ground-truth labels, which are obtained through manual inspection of the listings in the cluster. For example, from manual inspection it is very easy to see that two Starbucks records with different addresses are in fact different businesses (have different ground-truth labels) even if, say, they have the same corporate phone number. But this observation is not necessarily captured by the noisy similarity function, causing the listings to incorrectly cluster together.

We consider two criteria to determine whether a split is correct or not, and show experimental results for both. We first consider a binary split correct if the two resulting sub-clusters are "clean" according to Definition 13. Note that a clean split is sufficient and necessary for reducing the under/overclustering error in our model. To compute the splits, we use the algorithm in Figure 5, which we refer to as *Clean-Split*. This algorithm is easier to implement and run than the algorithm in Figure 2 because it only requires local pairwise similarities (for the listings in the cluster). But this algorithm is still provably correct under stronger assumptions on the data (see Theorem 18 and Theorem 19), which we believe are still satisfied in this application.

We compare performance with two well-known split algorithms from split/merge clustering literature: the optimal 2-median clustering (*2-Median*), and a "sweep" of the second-smallest eigenvector of the corresponding graph Laplacian matrix. With respect to the spectral split algorithm, let $\{v_1, \ldots, v_n\}$ be the order of the vertices when sorted by their eigenvector entries. We compute the partition $\{v_1, \ldots, v_i\}$ and $\{v_{i+1}, \ldots, v_n\}$ such that its conductance is smallest (*Spectral-Balanced*), and a partition such that the similarity between v_i and v_{i+1} is smallest (*Spectral-Gap*).

We compare the split algorithms on overclustering instances that were discovered during a manual clustering quality evaluation. We consider 20 such instances to ensure that our results are consistent, given that there may be differences in the difficulty of each instance. We have anonymized

Table 1: Number of correct (clean) splits on the Google business listings data sets.

Clean-Split	2-Median	Spectral-Gap	Spectral-Balanced
19	13	12	3

these data-sets and made them publicly available. [2] The results are presented in Table 1. We observe that the *Clean-Split* algorithm works best, giving a correct split in 19 out of the 20 cases. The well-known *Spectral-Balanced* technique usually does not give correct splits in this application. The balance constraint causes it to put records about the same business on both sides of the partition (especially when all the "clean" splits are not well-balanced), which increases clustering error. As expected, the *Spectral-Gap* technique improves on this limitation (because it does not have a balance constraint), but the result is often still incorrect. The *2-Median* algorithm performs fairly well, but it is still a limited approach in this application: the optimal centers may correspond to listings about the same business, and even if they represent distinct businesses, the resulting split is still sometimes incorrect.

In addition to using the clean-split criterion, we also evaluate the computed splits using the correlation-clustering (cc) error. We find that using this criterion *Clean-Split* and *2-Median* compute the best splits, while the other two algorithms perform significantly worse. The results for *Clean-Split* and *2-Median* are presented in Table 2 - we see that *Clean-Split* is more reliable because it fails to reduce the cc-error only once, compared to 4 such failures for *2-Median*. Table 2 also reinforces our theoretical understanding of the effectiveness of our split algorithm. We know that a clean split is sufficient to reduce the cc-error, but it is not necessary. Our experiments illustrate these observations: *Clean-Split* makes progress in reducing the cc-error in 19 out of 20 cases (when the resulting split is clean), while we have also confirmed that *2-Median* sometimes still reduces the cc-error even when the resulting split is not clean.

5.2 Clustering Newsgroup documents

In order to test our entire interactive clustering model, we perform experiments on the 20 Newsgroups data set.[3] The points in the data set are posts to twenty different online forums (called newsgroups). We sample these data to generate 5 data sets of manageable size (containing 276-301 points), which are labeled A through E in the figures. Each data set contains some documents from every newsgroup. The purpose of these 5 data sets is to check the consistency of our results, given that there may be considerable variation in how separable the ground-truth clusters are in each case. For each data set, the ground-truth is determined by the newsgroups that the documents belong to.

Each Newsgroup document is represented by a term frequency - inverse document frequency (tf-idf) vector (Salton and Buckley, 1988). We use cosine similarity to compare these vectors, which gives a similarity score in $[0, 1]$. We compute an initial clustering by using the following procedure to perturb the ground-truth: for each document we keep its ground-truth cluster assignment with probability 0.5, and otherwise reassign it to one of the other clusters, which is chosen uniformly at random. This procedure generates initial clusterings with overclustering error of about 100, underclustering error of about 100, and correlation-clustering error of about 5000.

2. The anonymized Google business listings data sets are available here.
3. http://people.csail.mit.edu/jrennie/20Newsgroups/

Table 2: Change in correlation-clustering error for splits on the Google business listings data sets. A negative value corresponds to a decrease in error.

Data Set	Clean-Split	2-Median
1	-14	-14
2	-5	-5
3	-11	-11
4	-117	-117
5	-42	+90
6	-4	-4
7	-12	-30
8	-27	-27
9	-6	-6
10	-6	-6
11	+6	-8
12	-10	+14
13	-6	-6
14	-12	-22
15	-6	-6
16	-10	+14
17	-11	-27
18	-10	-10
19	-11	-5
20	-10	-10

To simulate user feedback, we compute the set of all valid split and merge requests. Consistent with our model, a split of a cluster is considered valid if it contains points from 2 or more ground-truth clusters, and a merge is considered valid if at least an η- fraction of the points in each cluster are from the same ground-truth cluster. We then choose one of the valid splits/merges uniformly at random, and ask the algorithm to compute the corresponding split/merge. We continue to iterate until we find the ground-truth clustering or reach a limit on the number of edit requests (set to 20000).

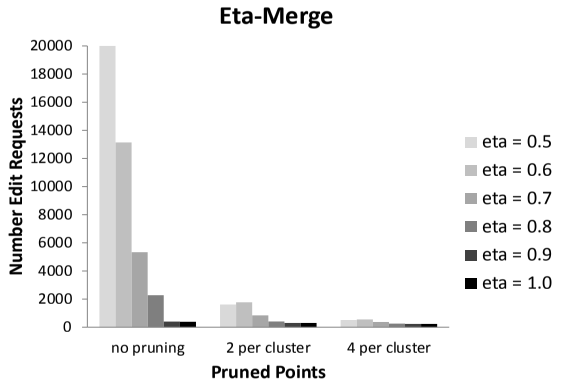
The Newsgroup data is know to be very challenging for unsupervised (Telgarsky and Dasgupta, 2012; Heller and Ghahramani, 2005) and semi-supervised clustering algorithms (Basu et al., 2002, 2004). In particular, on harder Newsgroup clustering instances Basu et al. (2002) and Basu et al. (2004) report that they are unable to come close to finding the ground-truth clustering even with considerable supervision.

To study how our algorithms perform on easier clustering instances, we also slightly prune our data sets. Our heuristic iteratively finds and removes the outlier in each target cluster, where the outlier is the point with minimum sum-similarity to the other points in the target cluster. For each

data set, we perform experiments with the original (unpruned) data set, a pruned data set with 2 points removed per target cluster, and a pruned data set with 4 points removed per target cluster, which prunes 40 and 80 points, respectively. Our pruning heuristic generates clustering instances where the ground-truth clusters are more separable, similar to the Different-3 data set of Basu et al. (2002) and the News-diff3 data set of Basu et al. (2004).

5.2.1 EXPERIMENTS IN THE η-MERGE MODEL

We first experiment with algorithms in the η-merge model. Here we use the algorithm in Figure 2 to perform the splits, and the algorithm in Figure 3 to perform the merges. We show the results for data set A in Figure 9; the complete experimental results are in Appendix B. We find that for larger settings of η, the amount of supervision (number of split/merge requests needed to find the target clustering) is quite low and consistent with our theoretical analysis. The results are better for pruned data sets, where we get very good performance regardless of the setting of η. The results for the algorithms in Figure 2 and Figure 4 (for the correlation-clustering objective) are very favorable as well.



5.2.2 EXPERIMENTS IN THE UNRESTRICTED-MERGE MODEL

We also experiment with algorithms in the unrestricted merge model. Here we use the same algorithm to perform the splits, and use the algorithm in Figure 8 to perform the merges. We show the results on data set A in Figure 10; the complete experimental results are in Appendix B. We find that again for larger settings of η the amount of supervision is quite low and consistent with our theoretic analysis (we only show results for $\eta \geq 0.5$), and performance improves further for pruned data sets. Our investigations show that for unpruned data sets and smaller settings of η, we are still able to quickly achieve very small clustering error (results not shown), but the algorithms are unable to converge to the ground-truth clustering due to inconsistencies in the average-linkage tree. We can address some of these inconsistencies by constructing the tree in a more robust way, which indeed gives improved performance (see Appendix C).

5.2.3 EXPERIMENTS WITH SMALL INITIAL ERROR

We also consider a setting where the initial clustering is already very accurate. In order to simulate this scenario, when we compute the initial clustering, for each document we keep its ground-truth cluster assignment with probability 0.95, and otherwise reassign it to one of the other clusters, which is chosen uniformly at random. This procedure usually gives us initial clusterings with over-clustering and underclustering error between 5 and 20, and correlation-clustering error between 500 and 1000. Note that this setting also closely matches the scenario where the initial clustering is computed using a good clustering algorithm, which is quite realistic in some applications.

As expected, in this setting our interactive algorithms perform much better, especially on pruned data sets. Figure 11 displays the results; we can see that in these scenarios it often takes less than one hundred edit requests to find the target clustering in both models.

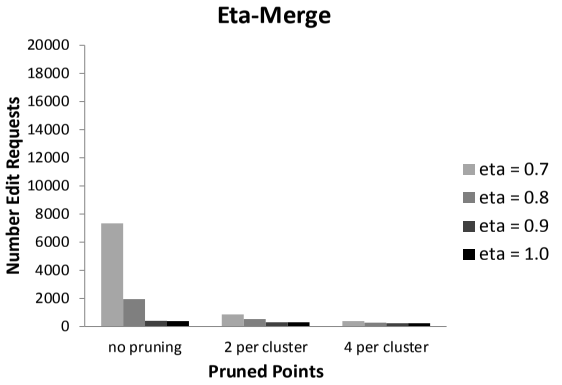


Figure 9: Experimental results in the η-merge model for data set A. The second chart corresponds to algorithms for correlation clustering error.

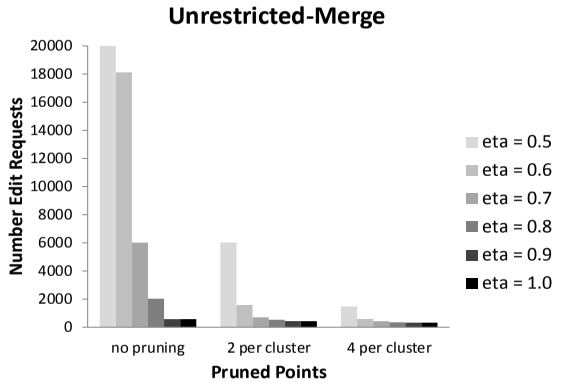

Figure 10: Experimental results in the unrestricted merge model for data set A.

5.2.4 COMPARISON WITH OTHER SEMI-SUPERVISED CLUSTERING MODELS

In this section we give a performance comparison on the 20 Newsgroups data sets with the semi-supervised clustering models of Basu et al. (2002) and Basu et al. (2004). The accuracy of the output clustering is stated in terms of *normalized mutual information* (NMI) (see Strehl et al., 2000).

Table 3 shows a comparison on a harder Newsgroup clustering instance; table 4 shows a comparison on an easier instance. The performance of our approach is with respect to the η-merge model, using the algorithm in Figure 2 to perform the splits, and the algorithm in Figure 3 to perform the merges; we focus on a single setting of $\eta = 0.7$. To compare the amount of supervision used by each model, consider that n instance class labels in the framework of Basu et al. (2002) are equivalent to $n(n-1)/2$ pairwise labels in the framework of Basu et al. (2004). Let us also oversimplify and assume that the cost of a pairwise label in the framework of Basu et al. (2004) is the same as the cost of one/split merge request in our framework. Also, we can adjust for differences in data set size by assuming that the proportion of supervision does not change. In particular, 1500 instance class labels on a data set of 3000 documents correspond to 150 instance class labels on a data set of 301 documents. These 150 instance class labels are then equivalent to 150 * 149 / 2 = 11175 pairwise labels. Similarly, 1500 instance class labels on a data set of 3000 documents correspond to 138 instance class labels on a data set of 276 documents, which are then equivalent to 138 * 137 / 2 = 9453 pairwise labels.

Then for a harder clustering instance we observe that we need less supervision than Basu et al. (2002) and roughly 7.5 times more supervision than Basu et al. (2004) to achieve a completely correct clustering (NMI = 1.0) as opposed to a clustering that is only half-correct (NMI = 0.44, 0.55). For an easier clustering instance, we observe that we need roughly 2.7 times less supervision than

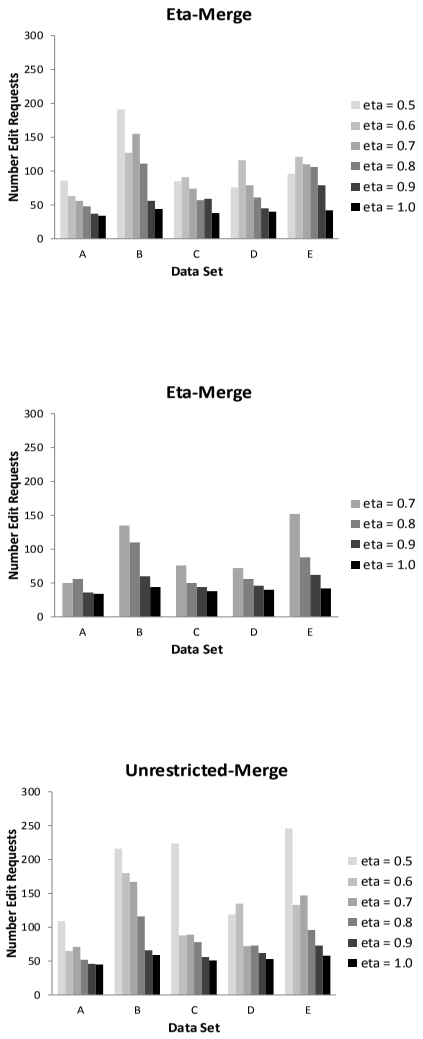

Figure 11: Experimental results for initial clusterings with small error. Results presented for pruned data sets (4 points per cluster). The second chart corresponds to algorithms for correlation clustering error.

Basu et al. (2002), and 3.9 times more supervision than Basu et al. (2004) to achieve a completely correct clustering (NMI = 1.0) as opposed to a mostly-correct clustering (NMI = 0.88).

These are favorable comparisons for our model - we are able to compute more accurate clusterings while using a comparable amount of supervision. We also note that for Basu et al. (2002) and Basu et al. (2004), additional supervision does not improve accuracy - the stated performance is the best accuracy they can achieve. Our framework is the only approach that has demonstrated a complete recovery of the ground truth on the Newsgroup data.

Table 3: Framework comparison on harder Newsgroup clustering instance.

Framework	Data Set Name	Data Set Size	Amount of Supervision	Output Accuracy
Basu et al. (2002)	Same-3	3000	1500 labeled data points	NMI = 0.44
Basu et al. (2004)	News-sim3	300	1000 pairwise constraints	NMI = 0.55
Interactive clustering	Data Set E	301	7573 split/merge requests	NMI = 1.0

Table 4: Framework comparison on easier Newsgroup clustering instance.

Framework	Data Set Name	Data Set Size	Amount of Supervision	Output Accuracy
Basu et al. (2002)	Different-3	3000	1500 labeled data points	NMI = 0.88
Basu et al. (2004)	News-diff3	300	1000 pairwise constraints	NMI = 0.88
Interactive clustering	Data Set D	276	3548 split/merge requests	NMI = 1.0

6. Discussion

In this work we motivated and studied a new framework and algorithms for interactive clustering. Our framework models practical constraints on the algorithms: we start with an initial clustering that we cannot modify arbitrarily, and are only allowed to make local edits consistent with user requests. In this setting, we develop several simple, yet effective algorithms under different assumptions about the nature of the edit requests and the structure of the data. We present theoretical analysis that shows that our algorithms converge to the target clustering after a limited number of edit requests. We also present experimental evidence that shows that our algorithms work well in practice.

Several directions come out of this work. It would be interesting to relax the condition on η in the η-merge model, and the assumption about the request sequences in the unrestricted-merge model. It is also important to study additional properties of an interactive clustering algorithm. In particular, it is often desirable that the algorithm never increase the error of the current clustering. Our algorithms in Figures 2, 4 and 8 have this property, but the algorithm in Figure 3 does not.

Other user feedback models have also been proposed (see Appendix A for how they relate to the split/merge feedback considered here). It is valuable to further study the practical applicability of each kind of feedback and understand under what conditions they are equivalent.

Appendix A. Other feedback models

Besides the cluster split/merge feedback considered here, two other kinds of feedback have also been studied in the literature: *cluster-assignment* feedback (Basu et al., 2002; Nie et al., 2012) and *must-link/cannot-link* feedback (Basu et al., 2004; Ashtiani et al., 2016). The former reveals the ground-truth cluster assignment of a single data point; the latter reveals whether or not a pair of points are in the same ground-truth cluster.

Claim 28 *Cluster-assignment feedback and must-link/cannot link feedback can be converted to cluster split/merge feedback in the unrestricted-merge model.*

Proof We first observe that cluster-assignment feedback can be converted to must-link/cannot-link feedback as follows. For every two known cluster assignments for points x and y s.t. x and y belong to the same ground-truth cluster, output a must-link feedback for (x, y). For every two known cluster assignments for points x and y s.t. x and y belong to different ground-truth clusters, output a cannot-link feedback for (x, y).

We next observe that must-link/cannot-link feedback can be converted to cluster split/merge feedback in the unrestricted merge model as follows. For every must-link feedback for points x and y, if x and y belong to different clusters in the proposed clustering, request to merge these two clusters. For every cannot-link feedback for points x and y, if x and y belong to the same cluster in the proposed clustering, request to split this cluster. Observe that by definition, the output split/merge requests satisfy the assumptions of the unrestricted-merge model. ■

However, the conversion in Claim 28 is sometimes vacuous: cluster split/merge feedback is only output when the cluster-assignment or must-link/cannot-link feedback disagrees with the current clustering. Still, it is reasonable to assume that while the proposed clustering is not equivalent to the ground truth, a constant fraction of such feedback will disagree with the proposed clustering.

Appendix B. Complete experimental results

The following figures show the complete experimental results for all the algorithms. Figure 12 shows the results in the η-merge model. Figure 13 shows the results in the η-merge model for the algorithms in Figure 2 and Figure 4 (for the correlation-clustering objective). Figure 14 shows the results in the unrestricted-merge model.

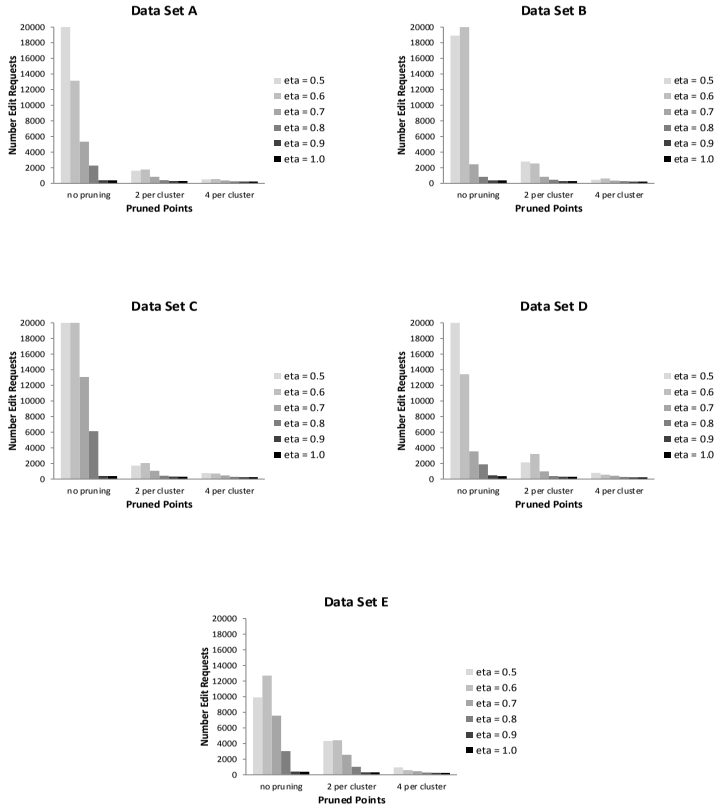

Figure 12: Experimental results in the η-merge model.

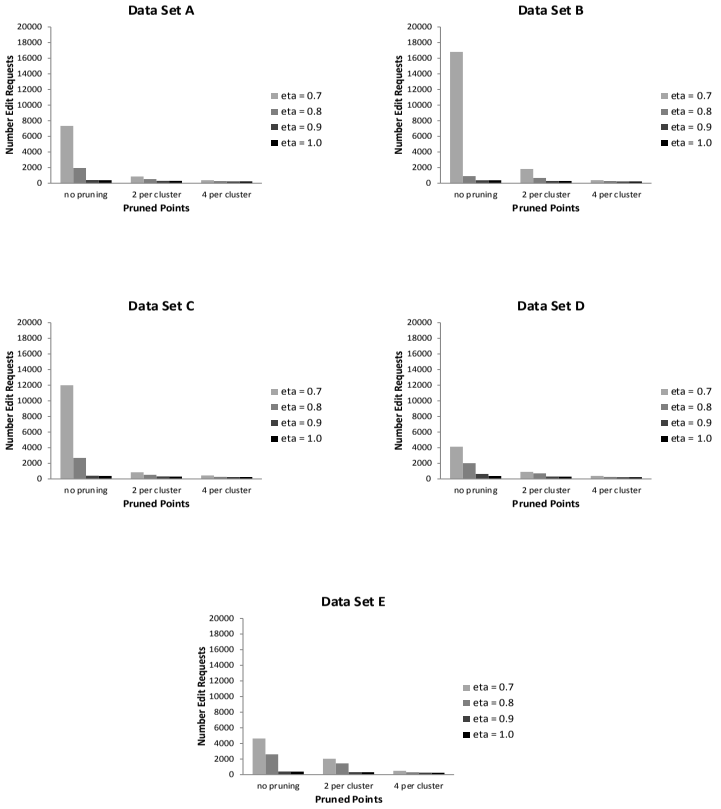

Figure 13: Experimental results in the η-merge model for algorithms for correlation-clustering objective.

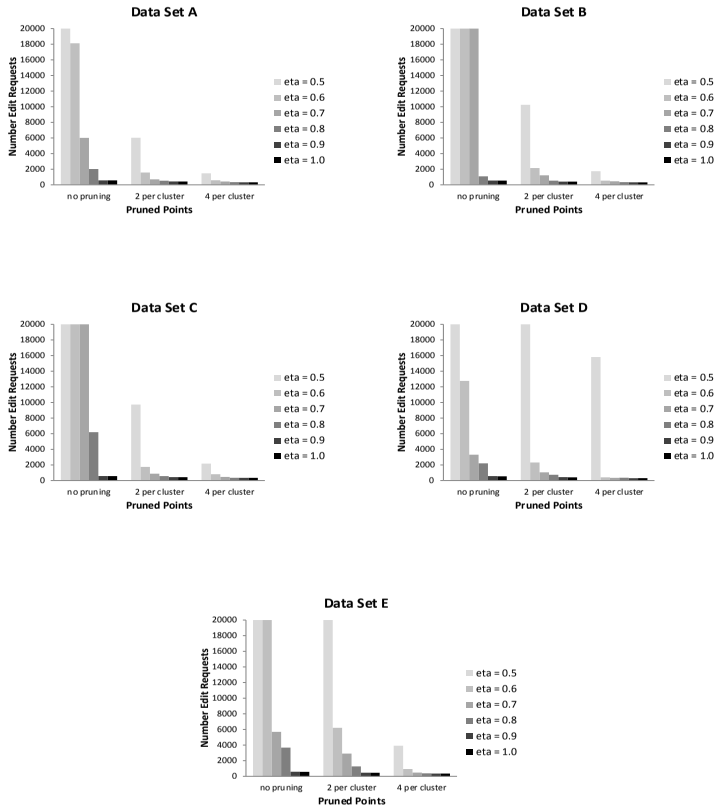

Figure 14: Experimental results in the unrestricted-merge model.

Appendix C. Experiments with robust average-linkage tree

When we investigate instances where our algorithms are unable to find the target clustering, we observe that there are outlier points that are attached near the root of the average-linkage tree, which are incorrectly split off and re-merged by the algorithm without making any progress towards finding the target clustering.

We can address these outliers by constructing the average-linkage tree in a more robust way: first find groups ("blobs") of similar points of some minimum size, compute an average-linkage tree for each group, and then combine these trees using average-linkage. The tree constructed in such fashion may then be used by our algorithms.

We tried this approach, using Algorithm 2 from Balcan and Gupta (2010) to compute the blobs. We find that using the robust average-linkage tree gives better performance for the unpruned data sets, but gives no gains for the pruned data sets, as expected. Figure 15 displays the comparison in the unrestricted merge model for the five unpruned data sets. For the pruned data sets, we expect the robust tree to be very similar to the standard tree, which explains why there is little difference in performance (results not shown).

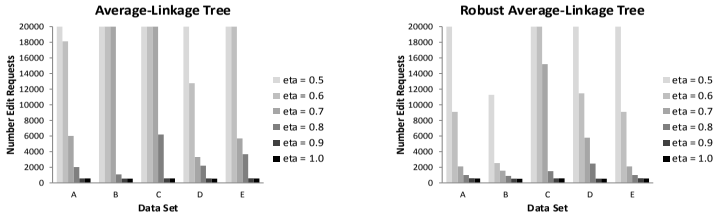

Figure 15: Experimental results in the unrestricted-merge model using a standard versus robust average-linkage tree. Results presented for unpruned data sets.

Abstract

SnapVX is a high-performance solver for convex optimization problems defined on networks. For problems of this form, SnapVX provides a fast and scalable solution with guaranteed global convergence. It combines the capabilities of two open source software packages: Snap.py and CVXPY. Snap.py is a large scale graph processing library, and CVXPY provides a general modeling framework for small-scale subproblems. SnapVX offers a customizable yet easy-to-use Python interface with "out-of-the-box" functionality. Based on the Alternating Direction Method of Multipliers (ADMM), it is able to efficiently store, analyze, parallelize, and solve large optimization problems from a variety of different applications. Documentation, examples, and more can be found on the SnapVX website at `http://snap.stanford.edu/snapvx`.

Keywords: convex optimization, network analytics, graphs, data mining, ADMM

1. Introduction

Convex optimization is a widely used approach of modeling and solving problems in many different fields, as it offers well-established methods for finding globally optimal solutions. Numerous general-purpose optimization software packages exist (Sturm, 1999; Byrd et al., 2006; Mosek, 2010; Diamond and Boyd, 2016), but they typically rely on algorithms that are difficult to scale, so many modern machine learning problems cannot be solved by these common, yet general, approaches. Instead, solving large scale examples often requires developing problem-specific solution methods, which can be very fast but require significant optimization expertise to build. Furthermore, they are limited in scope, as they must be fine-tuned to only one particular type of problem and thus are hard to generalize.

In this paper, we build on the observation that many large convex optimization examples follow a common form in that they can often be split up into a series of subproblems using a network (graph) structure. Nodes are subproblems, representing anything from timestamps in a time-series data set to users in a social network. The edges then define the coupling, or relationships between the different nodes, and the combination of nodes and edges yields the original convex optimization problem. This representation can refer to problems defined on actual networks, such as social or transportation systems, or questions classically modeled in other ways, such as control theory or time-series analysis.

Here, we present SnapVX, a solver that is both scalable and general on optimization problems defined over networks. It combines the graph capabilities of Snap.py (Leskovec and Sosič, 2016) with the general modeling framework from CVXPY (Diamond and Boyd, 2016). We show how SnapVX works, present syntax and supported features, scale it to large problems, and describe how it can be used to solve convex optimization problems from a variety of different fields. The full version of our solver, which is released under the BSD Open-Source License, can be found at the project website, `http://snap.stanford.edu/snapvx`. In addition to the source code, the download contains installation instructions, unit tests, documentation, and several examples to help users get started.

2. SnapVX General Form

Consider an optimization problem on an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with vertex set $\mathcal{V}$ and edge set $\mathcal{E}$, of the form:

$$\underset{x}{\text{minimize}} \quad \sum_{i \in \mathcal{V}} f_i(x_i) + \sum_{(j,k) \in \mathcal{E}} g_{jk}(x_j, x_k). \tag{1}$$

Variable x_i is associated with node i, for $i = 1, \ldots, |\mathcal{V}|$ (the size of x_i can vary at each node). In problem (1), f_i is the cost function at node i, and g_{jk} is the cost associated with edge (j, k). Constraints are represented by extended (infinite) values of f_i and g_{jk}. Note that nodes and edges can also have local, private optimization variables (which can also vary in size). These remain confined to a single node or edge, though, whereas the x_i's are shared between different parts of the network. We consider only convex objectives and constraints for f_i and g_{jk}, so the entire problem is a convex optimization problem.

To solve problem (1), SnapVX uses a splitting algorithm based on the Alternating Direction Method of Multipliers (ADMM) (Boyd et al., 2011). With ADMM, each individual component of the graph solves its own subproblem, iteratively passing small messages over the network and eventually converging to an optimal solution. See the SnapVX developer documentation for more details on the underlying derivation. By splitting up the problem into a series of subproblems, SnapVX is able to solve much larger convex optimization examples than standard solvers, which solve the whole problem at once. ADMM also keeps the optimality benefits that general solvers enjoy: not only are we guaranteed to obtain an optimal solution, but we also are given a certificate of optimality in the form of primal and dual residuals; see (Parikh and Boyd, 2014).

SnapVX stores the network using a Snap.py graph structure. This allows fast traversal and easy manipulation, as well as efficient storage. On top of the standard graph, each node/edge is given convex objectives and constraints using CVXPY syntax. To find a global solution, SnapVX automatically splits up the problem and solves each subproblem using CVXPY, iteratively handling the ADMM message passing behind the scenes. Though wrapped in a Python layer, CVXPY uses ECOS and CVXOPT (two high-performance numerical optimization packages) as its primary underlying solvers (Andersen et al., 2014; Domahidi et al., 2013), so the Python overhead is not significant and allows for easier interpretability and improved user interface. To parallelize the solver, a worker pool coordinates

updates for the separate subproblems using Python's multiprocessing library. SnapVX is built to run on a single machine, parallelizing across multiple cores and allowing "out-of-the-box" functionality on machines ranging from standard laptops to large-memory servers.

3. Syntax and Supported Features

We now present usage of SnapVX on a simple example. Complete documentation and more examples are available on the SnapVX website. Consider two nodes with an edge between them. We solve for a problem where each node has an unknown variable $x_i \in \mathbb{R}^1$. The first node's objective is to minimize x_1^2 subject to $x_1 \leq 0$, the second's is to minimize $|x_2 + 3|$, and the edge objective penalizes the square norm difference between the two variables, $\|x_1 - x_2\|_2^2$. The following code specifies the optimization problem and solves it:

```
from snapvx import *
gvx = TGraphVX() #Create a new graph
x1 = Variable(1, name='x1') #Create a variable for node 1
gvx.AddNode(1, Objective=square(x1), Constraints=[x1 <= 0]) #Add new node
x2 = Variable(1, name='x2') #Repeat for node 2
gvx.AddNode(2, abs(x2 + 3), [])
gvx.AddEdge(1, 2, Objective=square(norm(x1 - x2)), Constraints=[]) #Add edge between nodes
gvx.Solve() #Solve the problem
gvx.PrintSolution() #Print the solution on a node-by-node basis
```

As SnapVX is meant to be a general-purpose solver, it has many customizable options to help easily and efficiently solve a wide range of convex optimization problems. These include ADMM iteration limits, verbose mode (to list intermediate steps at each iteration), and defining customized convergence thresholds. Two key features are highlighted below:

- **Bulk Loading -** Often, the objectives and constraints at each node or edge will share a common form. For example, all the nodes could be trying to minimize $\|x - a_i\|_2$ for different values of a_i. Rather than requiring users to manually input each of these values, SnapVX allows for "bulk loading" of data. The functions *AddNodeObjectives* and *AddEdgeObjectives* allow the user to specify the general form of the objectives and an external file with separate data, and SnapVX fills in the details. This functionality makes practical and significantly speeds up the loading of very large data sets.
- **ADMM ρ-update -** The convergence time of ADMM depends on the value of the penalty parameter ρ (Nishihara et al., 2015), as it affects the tradeoff between primal and dual convergence, both of which need to be obtained for the overall problem to be solved. SnapVX users are not only able to select the value of ρ (it defaults to $\rho = 1$), but can also define a function to update ρ after each iteration based on the primal and dual residual values (He et al., 2000; Fougner and Boyd, 2015).

4. Scalability

One of the biggest benefits of SnapVX is that it allows us to solve large problems very efficiently. It does so by automatically parallelizing the ADMM updates across multiple cores of a single machine using Python's multiprocessing class. Note that SnapVX is meant to be run on a single machine, rather than in a distributed computing environment. Convergence time depends on the problem complexity, but we empirically observe that it scales

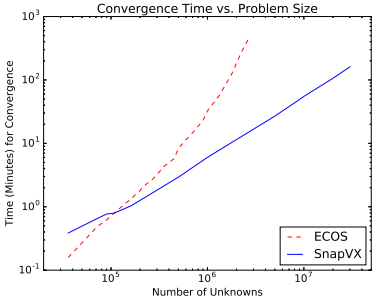

Figure 1: Timing comparison of SnapVX and a general-purpose solver.

# of Unknowns	SnapVX Solution Time (Minutes)
100,000	0.79
500,000	2.95
1 million	6.06
5 million	27.30
10 million	55.42
20 million	106.33
30 million	161.95

Table 1: SnapVX convergence time for several different problem sizes.

approximately linearly with problem size. We compare SnapVX and a general solver for a problem on a 3-regular graph. Each node solves for an unknown variable in $\mathbb{R}^{9000}$, where the node objectives are sum-of-Huber penalties (Huber, 1964) and edges have network lasso penalties (Hallac et al., 2015). By varying the number of nodes, we can span a wide range of problem sizes. The time required for SnapVX to converge, on a 40-core CPU where the entire problem can fit into memory, is shown in Table 1. Figure 1 displays a comparison to a general-purpose solver (ECOS, via CVXPY) in log-log scale.

5. Applications

SnapVX was created to allow users without significant optimization expertise to solve large network-based convex optimization problems by taking advantage of the powerful and scalable ADMM algorithm. Common examples from many different fields can be formulated in a SnapVX-friendly manner. Our software has been used to solve real-world machine learning problems ranging from housing price prediction (Hallac et al., 2015) to ride-sharing analysis (Ghosh et al., 2016) to high-dimensional regression (Yamada et al., 2016), often significantly outperforming other commonly used approaches. Examples in the SnapVX download package and on the project website — including financial modeling, network inference, image processing, PageRank, and time-series analysis — guide users towards applying the software to a variety of applications. Both user and developer documentation help new users get started and, if they are interested, contribute to the code base. A robust set of unit tests ensures that the software has been properly downloaded and that the code is functioning as expected. Overall, our open-source software provides an easy-to-use ADMM solver that can scale to large problems and apply to a wide variety of examples. With an active user base and rising interest from a range of scientific and engineering fields, we hope that SnapVX can become a useful tool for convex optimization problems, both in research and industry.

Abstract

We devise a communication-efficient approach to distributed sparse regression in the high-dimensional setting. The key idea is to average "debiased" or "desparsified" lasso estimators. We show the approach converges at the same rate as the lasso as long as the dataset is not split across too many machines, and consistently estimates the support under weaker conditions than the lasso. On the computational side, we propose a new parallel and computationally-efficient algorithm to compute the approximate inverse covariance required in the debiasing approach, when the dataset is split across samples. We further extend the approach to generalized linear models.

Keywords: Distributed Sparse Regression, Averaging, Debiasing, lasso, high-dimensional statistics

1. Introduction

Explosive growth in the size of modern datasets has fueled interest in distributed statistical learning. For examples, we refer to Boyd et al. (2011); Dekel et al. (2012); Duchi et al. (2012); Zhang et al. (2013) and the references therein. The problem arises, for example, when working with datasets that are too large to fit on a single machine and must be distributed across multiple machines. The main bottleneck in the distributed setting is usually communication between machines/processors, so the overarching goal of algorithm design is to minimize communication costs.

In distributed statistical learning, the simplest and most popular approach is *averaging*: each machine forms a local estimator $\hat{\theta}_k$ with the portion of the data stored locally, and a "master" averages the local estimators to produce an aggregate estimator: $\bar{\theta} = \frac{1}{m}\sum_{k=1}^{m} \hat{\theta}_k$. Averaging was first studied by Mcdonald et al. (2009) for multinomial regression. They derive non-asymptotic error bounds on the estimation error that show averaging reduces the variance of the local estimators, but has no effect on the bias (from the centralized solution). In follow-up work, Zinkevich et al. (2010) studied a variant of averaging where each machine computes a local estimator with stochastic gradient descent (SGD) on a random subset of the dataset. They show, among other things, that their estimator converges to the centralized estimator.

More recently, Zhang et al. (2013) studied averaged empirical risk minimization (ERM). They show that the mean squared error (MSE) of the averaged ERM decays like $O\big(N^{-\frac{1}{2}} + \frac{m}{N}\big)$, where m is the number of machines and N is the total number of samples. Thus, so long as $m \lesssim \sqrt{N}$, the averaged ERM matches the $N^{-\frac{1}{2}}$ convergence rate of the centralized ERM. Even more recently, Rosenblatt and Nadler (2014) studied the optimality of averaged ERM in two asymptotic settings: $N \to \infty$, m, p fixed and $p, n \to \infty$, $\frac{p}{n} \to \mu_l \in (0, 1)$, where $n = \frac{N}{m}$ is the number of samples per machine. They show that in the $n \to \infty$, p fixed setting, the averaged ERM is first-order equivalent to the centralized ERM. However, when $p, n \to \infty$, the averaged ERM is suboptimal (versus the centralized ERM).

We develop a divide and conquer approach to statistical learning. In the high-dimensional setting, regularization is essential. The key idea is to average *debiased* or *desparsified* regularized M-estimators. Under suitable conditions, it is possible to show that the local debiased estimators are asymptotically normal. thus the averaged estimator delivers the same statistical performance as the computationally infeasible centralized M-estimator.

Formally, we show that the error of the averaged estimator decomposes into a $\widetilde{O}_P\big(\frac{1}{\sqrt{N}}\big)$ asymptotically normal term and a remainder term. As long as $m \lesssim \frac{\sqrt{N}}{s \log p}$, where s is the sparsity of the unknown regression coefficients, the reminder term is asymptotically negligible. Thus the averaged estimator converges at the same rate as a centralized estimator. Further, the averaged estimator is model selection consistent under a weak minimum signal strength condition. In the following section, we review the theoretical properties of the lasso and debiased lasso and describe our contributions more formally.

2. A divide-and-conquer approach to sparse regression

To keep things simple, we focus on sparse linear regression. Consider the sparse linear model

$$y = X\beta^* + \epsilon,$$

where the rows of $X \in \mathbf{R}^{n \times p}$ are predictors, and the components of $y \in \mathbf{R}^n$ are the responses. To keep things simple, we assume

(A1) the predictors $x \in \mathbf{R}^p$ are independent σ_x-subgaussian random vectors with whose covariance Σ has smallest eigenvalue $\sigma_p(\Sigma) > \lambda_{\min}$ and largest eigenvalue $\sigma_1(\Sigma) < \lambda_{\max}$;

(A2) the regression coefficients $\beta^* \in \mathbf{R}^p$ are s-sparse, i.e. all but s components of β^* are zero;

(A3) the components of the noise ϵ are independent, mean zero σ_y-subgaussian random variables.

Given the predictors and responses, the lasso estimates β^* by

$$\hat{\beta} := \arg\min_{\beta \in \mathbf{R}^p} \frac{1}{2n} \|y - X\beta\|_2^2 + \lambda \|\beta\|_1.$$

There is a well-developed theory of the lasso that says, under suitable assumptions on X, the lasso estimator $\hat{\beta}$ is nearly minimax optimal(e.g. see Hastie et al. (2015), Chapter 11 for an overview). More precisely, under some conditions on $\frac{1}{n} X^T X$, the MSE of the lasso estimator is roughly $\frac{s \log p}{n}$, which is the minimax rate.

2.1 Background on the lasso and debiasing

However, the lasso estimator is also biased[1]. Since averaging only reduces variance, not bias, we gain (almost) nothing by averaging the biased lasso estimators. That is, it is possible to show if we naively averaged local lasso estimators, the MSE of the averaged estimator is of the same order as that of the local estimators. The key to overcoming the bias of the averaged lasso estimator is to "debias" the lasso estimators before averaging.

The *debiased lasso estimator* by Javanmard and Montanari (2013a) is

$$\hat{\beta}^d := \hat{\beta} + \frac{1}{n} \hat{\Theta} X^T (y - X\hat{\beta}), \tag{1}$$

where $\hat{\beta}$ is the lasso estimator and $\hat{\Theta} \in \mathbf{R}^{p \times p}$ is an approximate inverse to $\hat{\Sigma} = \frac{1}{n} X^T X$. Intuitively, the debiased lasso estimator trades bias for variance. The trade-off is obvious when $\hat{\Sigma}$ is non-singular: setting $\hat{\Theta} = \hat{\Sigma}^{-1}$ gives the ordinary least squares (OLS) estimator $(X^T X)^{-1} X^T y$.

Another way to interpret the debiased lasso estimator is a corrected estimator that compensates for the bias incurred by shrinkage. By the optimality conditions of the lasso, the correction term $\frac{1}{n} X^T (y - X\hat{\beta})$ is a subgradient of $\lambda \|\cdot\|_1$ at $\hat{\beta}$. By adding a term proportional to the subgradient of the regularizer, the debiased lasso estimator compensates for the bias incurred by regularization. The debiased lasso estimator has previously been used to perform inference on the regression coefficients in high-dimensional regression models. We refer to the papers by Javanmard and Montanari (2013a); van de Geer et al. (2013); Zhang and Zhang (2014); Belloni et al. (2011) for details.

The choice of $\hat{\Theta}$ in the correction term is crucial to the performance of the debiased estimator. Javanmard and Montanari (2013a) suggest forming $\hat{\Theta}$ row by row: the j-th row of $\hat{\Theta}$ is the optimum of

$$\begin{aligned} \underset{\theta \in \mathbf{R}^p}{\text{minimize}} \quad & \theta^T \hat{\Sigma} \theta \\ \text{subject to} \quad & \|\hat{\Sigma}\theta - e_j\|_\infty \leq \delta. \end{aligned} \tag{2}$$

1. We refer to Section 2.2 in Javanmard and Montanari (2013a) for a more formal discussion of the bias of the lasso estimator.

The parameter δ should large enough to keep the problem feasible, but as small as possible to keep the bias (of the debiased lasso estimator) small. As we shall see, when the rows of X are subgaussian, setting $\delta \sim \left(\frac{\log p}{n}\right)^{\frac{1}{2}}$ is usually large enough to keep (2) feasible.

Definition 1 (Generalized coherence) *Given $X \in \mathbf{R}^{n \times p}$, let $\hat{\Sigma} = \frac{1}{n} X^T X$. The* generalized coherence *between $\hat{\Sigma}$ and $\Theta \in \mathbf{R}^{p \times p}$ is*

$$\mathrm{GC}(\hat{\Sigma}, \Theta) = \max_{j \in [p]} \|\hat{\Sigma}\Theta_j^T - e_j\|_\infty.$$

The preceding definition is a generalization of the usual notion of coherence as it appears in the compressed sensing literature. Assume the columns of X are normalized so that $\|x_j\|_2 = 1$, and $\Theta = I$. The diagonal entries of $\hat{\Sigma}\Theta - I$ vanish. Thus $\mathrm{GC}(\hat{\Sigma}, \Theta)$ is the largest off diagonal entry of $\hat{\Sigma}$, which is the largest inner product between columns of X: $\frac{1}{n} \max_{i \neq j} \left| e_i^T X^T X e_j \right|$. We recognize the preceding quantity as the coherence of X.

Lemma 2 (Javanmard and Montanari (2013a)) *Under (A1), when $16 \kappa \sigma_x^4 n > \log p$, the event*

$$\mathcal{E}_{\mathrm{GC}}(\hat{\Sigma}) := \left\{ \mathrm{GC}(\hat{\Sigma}, \Sigma^{-1}) \leq \frac{8}{\sqrt{c_1}} \sqrt{\kappa} \sigma_x^2 \left(\frac{\log p}{n} \right)^{\frac{1}{2}} \right\}$$

occurs with probability at least $1 - 2p^{-2}$ for some $c_1 > 0$, where $\kappa := \frac{\lambda_{\max}(\Sigma)}{\lambda_{\min}(\Sigma)}$ is the condition number of Σ.

As we shall see, the bias of the debiased lasso estimate is of higher order than its variance under suitable conditions on $\hat{\Sigma}$. In particular, we require $\hat{\Sigma}$ to satisfy the *restricted eigenvalue (RE) condition.*

Definition 3 (RE condition) *For any $\mathcal{S} \subset [p]$, let*

$$\mathcal{C}(\mathcal{S}) := \{\Delta \in \mathbf{R}^p \mid \|\Delta_{\mathcal{S}^c}\|_1 \leq 3 \|\Delta_{\mathcal{S}}\|_1\}.$$

We say $\hat{\Sigma}$ satisfies the RE condition on the cone $\mathcal{C}(\mathcal{S})$ when

$$\Delta^T \hat{\Sigma} \Delta \geq \mu_l \|\Delta_{\mathcal{S}}\|_2^2$$

for some $\mu_l > 0$ and any $\Delta \in \mathcal{C}(\mathcal{S})$.

The RE condition requires $\hat{\Sigma}$ to be positive definite on $\mathcal{C}(\mathcal{S})$. When the rows of $X \in \mathbf{R}^{n \times p}$ are *i.i.d.* Gaussian random vectors, Raskutti et al. (2010) show there are constants $\mu_1, \mu_2 > 0$ such that

$$\frac{1}{n} \|X\Delta\|_2^2 \geq \mu_1 \|\Delta\|_2^2 - \mu_2 \frac{\log p}{n} \|\Delta\|_1^2 \text{ for any } \Delta \in \mathbf{R}^p$$

with probability at least $1 - c_2 \exp(-c_2 n)$. Their result implies the RE condition holds on $\mathcal{C}(\mathcal{S})$ (for any $\mathcal{S} \subset [p]$) as long as $n \gtrsim |S| \log p$, even when there are dependencies among the predictors. Their result was extended to subgaussian designs by Rudelson and Zhou (2013), also allowing for dependencies among the covariates. We state their result verbatim.

Lemma 4 (Rudelson and Zhou (2013)) *Under (A1), if* $n > 4000\tilde{s}\sigma_x^2 \log(\frac{Cp}{\tilde{s}})$ *and* $p > \tilde{s}$, *where* $\tilde{s} := s + 25920\kappa s = C's$, *the event*

$$\mathcal{E}_{\mathrm{RE}}(X) = \left\{\Delta^T\hat{\Sigma}\Delta \geq \frac{1}{2}\lambda_{\min}(\Sigma)\|\Delta_S\|_2^2 \text{ for any } \Delta \in \mathcal{C}(S)\right\}$$

occurs with probability at least $1 - 2e^{-\frac{n}{4000\sigma_x^4}}$, *where* C *and* C' *are universal constants.*

Proof The lemma is a consequence of Rudelson and Zhou (2013), Theorem 6. In their notation, we set $\delta = \frac{1}{\sqrt{2}}$, $k_0 = 3$ and bound $\max_{j\in[p]} \|Ae_j\|_2^2$ and $K(s_0, k_0, \Sigma^{\frac{1}{2}})$ by $\lambda_{\max}(\Sigma)$ and $\lambda_{\min}(\Sigma)^{-\frac{1}{2}}$. ■

When the RE condition holds, the lasso and debiased lasso estimators are consistent for a suitable choice of the regularization parameter λ. The parameter λ should be large enough to dominate the "empirical process" part of the problem: $\frac{1}{n}\left\|X^T y\right\|_\infty$, but as small as possible to reduce the bias incurred by regularization. As we shall see, setting $\lambda \sim \sigma_y(\frac{\log p}{n})^{\frac{1}{2}}$ is a good choice.

Lemma 5 *Under (A3),*

$$\frac{1}{n}\|X^T\epsilon\|_\infty \leq \max_{j\in[p]}(\hat{\Sigma}_{j,j})^{\frac{1}{2}}\sigma_y\Big(\frac{3\log p}{c_2 n}\Big)^{\frac{1}{2}}$$

with probability at least $1 - ep^{-2}$ *for any (non-random)* $X \in \mathbf{R}^{n\times p}$.

When $\hat{\Sigma}$ satisfies the RE condition and λ is large enough, Negahban et al. (2012) show that the lasso is consistent.

Lemma 6 (Negahban et al. (2012)) *If in addition to (A2) and (A3),*

1. $\hat{\Sigma}$ *satisfies the RE condition on* $\mathcal{C}(\mathrm{supp}(\beta^*))$ *with constant* μ_l
2. $\frac{1}{n}\|X^T\epsilon\|_\infty \leq \lambda$,

$$\|\hat{\beta} - \beta^*\|_1 \leq \frac{3}{\mu_l}s\lambda \text{ and } \|\hat{\beta} - \beta^*\|_2 \leq \frac{3}{\mu_l}\sqrt{s}\lambda.$$

When the lasso estimator is consistent, the debiased lasso estimator is also consistent. Further, it is possible to show that the bias of the debiased estimator is of higher order than its variance. Similar results by Javanmard and Montanari (2013a); van de Geer et al. (2013); Zhang and Zhang (2014); Belloni et al. (2011) are the key step in showing the asymptotic normality of the (components of) the debiased lasso estimator. The result we state is essentially Javanmard and Montanari (2013a), Theorem 2.3.

Lemma 7 *If in addition to (A2) and (A3),*

1. $\hat{\Sigma}$ *satisfies the RE condition on* $\mathcal{C}(\mathrm{supp}(\beta^*))$ *with constant* μ_l
2. $\frac{1}{n}\|X^T\epsilon\|_\infty \leq \lambda$,
3. $(\hat{\Sigma}, \hat{\Theta})$ *has generalized incoherence* δ,

the debiased lasso estimator has the form

$$\hat{\beta}^d = \beta^* + \frac{1}{n}\hat{\Theta}X^T\epsilon + \hat{\Delta},$$

where $\|\hat{\Delta}\|_\infty \leq \frac{3\delta}{\mu_l}s\lambda$.

Lemma 7, together with Lemmas 5 and 2, shows that the bias of the debiased lasso estimator is of higher order than its variance. In particular, setting λ and δ to be the order of the upper bounds on $\inf_{\Theta\in\mathbf{R}^{p\times p}} \mathrm{GC}(\hat{\Sigma}, \Theta)$ and $\frac{1}{n}\|X^T\epsilon\|_\infty$ given by Lemmas 5 and 2 gives a bias term $\|\hat{\Delta}\|_\infty$ that is $O_P(\frac{s\log p}{n})$. By comparison, the variance term $\frac{1}{n}\|\hat{\Theta}X^T\epsilon\|_\infty$ is the maximum of p subgaussian random variables with mean zero and variances of $O(1)$, which is $O\big((\frac{\log p}{n})^{\frac{1}{2}}\big)$. Thus the bias term is of higher order than the variance term as long as $n \gtrsim s^2\log p$.

Corollary 8 *If in addition to the conditions of Lemma 6,*

1. $(\hat{\Sigma}, \hat{\Theta})$ *has generalized incoherence* $\delta'(\frac{\log p}{n})^{\frac{1}{2}}$,
2. $\lambda = \max_{j\in[p]}(\hat{\Sigma}_{j,j})^{\frac{1}{2}}\sigma_y\big(\frac{3\log p}{c_2 n}\big)^{\frac{1}{2}}$,

$$\|\hat{\Delta}\|_\infty \leq \frac{3\sqrt{3}}{\sqrt{c_2}}\frac{\delta'\max_{j\in[p]}(\hat{\Sigma}_{j,j})^{\frac{1}{2}}}{\mu_l}\sigma_y\frac{s\log p}{n}.$$

The rest of the paper is organized as follows. In the subsequent section, we describe a divide-and-conquer approach to sparse regression and derive its theoretical properties. We show that

1. the averaged estimator converges at the same rate as the communication-intensive centralized lasso estimator. In particular, a thresholded version of the averaged estimator attains the same estimation rate as the centralized lasso estimator $\|\bar{\beta}^{ht} - \beta^*\|_2 \lesssim (\frac{s\log p}{N})^{\frac{1}{2}}$, and only requires one round of communication.
2. a thresholded version of the averaged estimator is model selection consistent as long as the minimum signal strength is at least $(\frac{\log p}{N})^{\frac{1}{2}}$. We remark that the model selection consistency result does not require X to obey an irrepresentability condition, which the centralized lasso does require.

Although the divide-and-conquer approach is communication efficient, it is costly in terms of floating point operations. The parallel runtime of debiasing is roughly equivalent to the cost of evaluating p lasso estimators, due to computation of $\hat{\Theta}$. In the rest of this section, we describe a more sophisticated approach to debiasing: each machine debiases $\frac{p}{m}$, instead of all p, regression coefficients. Thus the parallel runtime of the more sophisticated approach is roughly m times smaller than that of a naive approach.

In Section 4, we further refine the approach to reduce the sample complexity from $n \gtrsim ms^2\log p$ to $n \gtrsim ms\log p$. In Section 6, we show via simulation experiments that

the averaged debiased estimator outperforms averaging local lasso estimates, and performs as well as the centralized lasso. Section 5 generalizes our approach from least-squares to generalized linear models such as logistic regression.

Finally in Section 7, we show the optimality of our estimator in terms of the amount of communication, and rounds of communication using recent work on communication lower bounds. We also provide a comparison of the average debiased estimator and the centralized lasso estimator. The parallel runtime of the averaging debiased estimator is only larger than the centralized lasso by a constant multiplicative factor.

2.2 Averaging debiased lassos

Recall the problem setup: we are given N samples of the form (x_i, y_i) distributed across m machines:

$$X = \begin{bmatrix} X_1 \\ \vdots \\ X_m \end{bmatrix}, \quad y = \begin{bmatrix} y_1 \\ \vdots \\ y_m \end{bmatrix}.$$

The k-th machine has local predictors $X_k \in \mathbf{R}^{n_k \times p}$ and responses $y_k \in \mathbf{R}^{n_k}$. To keep things simple, we assume the data is evenly distributed, i.e. $n_1 = \cdots = n_k = n = \frac{N}{m}$. The *averaged debiased lasso* estimator (for lack of a better name) is

$$\bar{\beta} = \frac{1}{m}\sum_{k=1}^{m} \hat{\beta}_k^d = \frac{1}{m}\sum_{k=1}^{m} \big(\hat{\beta}_k + \hat{\Theta}_k X_k^T (y_k - X_k \hat{\beta}_k)\big), \tag{3}$$

We begin by studying the error of the $\bar{\beta}$ in the ℓ_∞ norm.

Lemma 9 *Suppose the local sparse regression problem on each machine satisfies the conditions of Corollary 8, that is when $m \le p$,*

1. $\{\hat{\Sigma}_k\}_{k\in[m]}$ *satisfy the RE condition on* $\mathcal{C}(\mathrm{supp}(\beta^*))$ *with constant* μ_l,
2. $\{(\hat{\Sigma}_k, \hat{\Theta}_k)\}_{k\in[m]}$ *have generalized incoherence* $c_{\mathrm{GC}}\big(\frac{\log p}{n}\big)^{\frac{1}{2}}$,
3. $\lambda_1 = \cdots = \lambda_m = c_\Sigma \sigma_y \big(\frac{3\log p}{c_2 n}\big)^{\frac{1}{2}}$.

Then

$$\|\bar{\beta} - \beta^*\|_\infty \le c\sigma_y \Big(\Big(\frac{c_\Omega \log p}{N}\Big)^{\frac{1}{2}} + \frac{c_{\mathrm{GC}} c_\Sigma}{\mu_l}\sigma_y \frac{s\log p}{n}\Big)$$

with probability at least $1 - ep^{-1}$, *where* $c > 0$ *is a universal constant,* $c_\Omega := \max_{j\in[p],k\in[m]}((\hat{\Theta}_k \hat{\Sigma}_k \hat{\Theta}_k^T)_{j,j})$ *and* $c_\Sigma := \max_{j\in[p],k\in[m]}((\hat{\Sigma}_k)_{j,j})^{\frac{1}{2}}$.

Lemma 10 hints at the performance of the averaged debiased lasso. In particular, we note the first term is $O\big(\big(\frac{\log p}{N}\big)^{\frac{1}{2}}\big)$, which matches the convergence rate of the centralized estimator. When n is large enough, $\frac{s\log p}{n}$ is negligible compared to $\big(\frac{\log p}{N}\big)^{\frac{1}{2}}$, and the error is $O\big(\big(\frac{\log p}{N}\big)^{\frac{1}{2}}\big)$.

Next, we show the conditions of Lemma 10 occur with high probability when the rows of X are independent subgaussian random vectors.

Lemma 10 *Under (A1), (A2), and (A3), when $m < p$, $p > \tilde{s}$,*

1. $n > \max\big\{4000\tilde{s}\sigma_x^2 \log(\frac{Cp}{\tilde{s}}),\ 8000\sigma_x^4 \log p,\ \frac{3}{c_1}\max\{\sigma_x^2, \sigma_x\}\log p\big\}$,
2. $\lambda_1 = \cdots = \lambda_m = \max_{j\in[p],k\in[m]}((\hat{\Sigma}_k)_{j,j})^{\frac{1}{2}}\sigma_y\big(\frac{3\log p}{c_2 n}\big)^{\frac{1}{2}}$,
3. $\delta_1 = \cdots = \delta_m = \frac{8}{\sqrt{c_1}}\sqrt{\kappa}\sigma_x^2\big(\frac{\log p}{n}\big)^{\frac{1}{2}}$ *and form* $\{\hat{\Theta}_k\}_{k\in[m]}$ *by* (2),

$$\|\bar{\beta} - \beta^*\|_\infty \le c\Big(\sigma_y\Big(\frac{\max_{j\in[p]}\Sigma^{-1}_{j,j}\log p}{N}\Big)^{\frac{1}{2}} + \frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s\log p}{n}\Big)$$

with probability at least $1 - (8+e)p^{-1}$ *for some universal constant* $c > 0$.

The averaged debiased lasso has one serious drawback versus the lasso: $\bar{\beta}$ is usually dense. The density of $\bar{\beta}$ detracts from the intrepretability of the coefficients and makes the estimation error large in the ℓ_2 and ℓ_1 norms. To remedy both problems, we threshold the averaged debiased lasso:

$$\mathrm{HT}_t(\bar{\beta}) \leftarrow \bar{\beta}_j \cdot \mathbf{1}_{\{|\bar{\beta}_j| \ge t\}},$$
$$\mathrm{ST}_t(\bar{\beta}) \leftarrow \mathrm{sign}(\bar{\beta}_j)\cdot\max\{|\bar{\beta}_j| - t,\, 0\}.$$

As we shall see, both hard and soft-thresholding give sparse aggregates that are close to β^* in ℓ_2 norm.

Lemma 11 *As long as $t > \|\bar{\beta} - \beta^*\|_\infty$, $\bar{\beta}^{ht} := \mathrm{HT}_t(\bar{\beta})$ satisfies*

1. $\|\bar{\beta}^{ht} - \beta^*\|_\infty \le 2t$,
2. $\|\bar{\beta}^{ht} - \beta^*\|_2 \le 2\sqrt{2s}t$,
3. $\|\bar{\beta}^{ht} - \beta^*\|_1 \le 2\sqrt{2}st$.

The analogous result also holds for $\bar{\beta}^{st} := \mathrm{ST}_t(\bar{\beta})$.

Proof By the triangle inequality,

$$\begin{aligned}\|\bar{\beta}^{ht} - \beta^*\|_\infty &\le \|\bar{\beta}^{ht} - \bar{\beta}\|_\infty + \|\bar{\beta} - \beta^*\|_\infty \\ &\le t + \big\|\bar{\beta} - \beta^*\big\|_\infty \\ &\le 2t.\end{aligned}$$

Since $t > \big\|\bar{\beta} - \beta^*\big\|_\infty$, $\bar{\beta}_j^{ht} = 0$ whenever $\beta_j^* = 0$. Thus $\bar{\beta}^{ht}$ is s-sparse and $\bar{\beta}^{ht} - \beta^*$ is $2s$-sparse. By the equivalence between the ℓ_∞ and ℓ_2, ℓ_1 norms,

$$\|\bar{\beta}^{ht} - \beta^*\|_2 \le 2\sqrt{2s}t,$$
$$\|\bar{\beta}^{ht} - \beta^*\|_1 \le 2\sqrt{2}st.$$

The argument for $\bar{\beta}^{st}$ is similar. ■

By combining Lemma 11 with Lemma 10, we show that $\bar{\beta}^{ht}$ converges at the same rates as the centralized lasso.

Theorem 12 *Under the conditions of Lemma 10, hard-thresholding $\bar{\beta}$ at $\sigma_y\Big(\frac{4\max_{j\in[p]}\Sigma^{-1}_{j,j}\log p}{c_2 N}\Big)^{\frac{1}{2}} + \frac{48\sqrt{6}}{\sqrt{c_1 c_2}}\frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s\log p}{n}$ gives*

1. $\|\bar{\beta}^{ht}-\beta^*\|_\infty \lesssim_P \sigma_y\Big(\frac{\max_{j\in[p]}\Sigma^{-1}_{j,j}\log p}{N}\Big)^{\frac{1}{2}} + \frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s\log p}{n}$,
2. $\|\bar{\beta}^{ht}-\beta^*\|_2 \lesssim_P \sigma_y\Big(\frac{\max_{j\in[p]}\Sigma^{-1}_{j,j}s\log p}{N}\Big)^{\frac{1}{2}} + \frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s^{\frac{3}{2}}\log p}{n}$,
3. $\|\bar{\beta}^{ht}-\beta^*\|_1 \lesssim_P \sigma_y\Big(\frac{\max_{j\in[p]}\Sigma^{-1}_{j,j}s^2\log p}{N}\Big)^{\frac{1}{2}} + \frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s^2\log p}{n}$.

Remark 13 *By Theorem 12, when $m \lesssim \frac{n}{s^2\log p}$, the variance term is dominant and the convergence rates given by the theorem simplify:*

1. $\|\bar{\beta}^{ht}-\beta^*\|_\infty \lesssim_P \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$,
2. $\|\bar{\beta}^{ht}-\beta^*\|_2 \lesssim_P \big(\frac{s\log p}{N}\big)^{\frac{1}{2}}$,
3. $\|\bar{\beta}^{ht}-\beta^*\|_1 \lesssim_P \big(\frac{s^2\log p}{N}\big)^{\frac{1}{2}}$.

The convergence rates for the centralized lasso estimator $\hat{\beta}$ are identical (modulo constants):

1. $\|\hat{\beta}-\beta^*\|_\infty \lesssim_P \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$,
2. $\|\hat{\beta}-\beta^*\|_2 \lesssim_P \big(\frac{s\log p}{N}\big)^{\frac{1}{2}}$,
3. $\|\hat{\beta}-\beta^*\|_1 \lesssim_P \big(\frac{s^2\log p}{N}\big)^{\frac{1}{2}}$.

The estimator $\bar{\beta}^{ht}$ matches the convergence rates of the centralized lasso in ℓ_1, ℓ_2, and ℓ_∞ norms. Furthermore, $\bar{\beta}^{ht}$ can be evaluated in a communication-efficient manner by a one-shot averaging approach.

Corollary 14 *Under the conditions of Lemma 10, further assume*

1. $m \lesssim \frac{n}{s^2\log p}$,
2. *β-min:* $|\beta^*_j| \gtrsim \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$ *for any* $j \in \mathrm{supp}(\beta^*)$.

Then $\mathrm{supp}(\bar{\beta}^{ht}) = \mathrm{supp}(\beta^*)$.

Proof As long as we threshold at $t > \|\bar{\beta}^{ht}-\beta^*\|_\infty$, $\mathrm{supp}(\bar{\beta}^{ht}) \subset \mathrm{supp}(\beta^*)$. That is, all the zero components of β^* are correctly estimated. Further, as long as the non-zero components of β^* have magnitude at least $2t$, they are not set to zero by thresholding at t. By Theorem 12, there is such a $t \sim \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$. ■

3. A distributed approach to debiasing

The averaged estimator we studied has the form

$$\bar{\beta} = \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k + \hat{\Theta}_k X_k^T(y - X_k\hat{\beta}_k).$$

The estimator requires each machine to form $\hat{\Theta}_k$ by the solution of (2). Since the dual of (2) is an ℓ_1-regularized quadratic program:

$$\underset{\gamma\in\mathbf{R}^p}{\text{minimize}}\ \frac{1}{2}\gamma^T\hat{\Sigma}_k\gamma - \hat{\Sigma}_k\gamma + \delta\|\gamma\|_1, \tag{4}$$

forming $\hat{\Theta}_k$ is (roughly speaking) p times as expensive as solving the local lasso problem, making it the most expensive step (in terms of floating point operations) of evaluating the averaged estimator. To trim the cost of the debiasing step, we consider an estimator that forms only a single $\hat{\Theta}$:

$$\tilde{\beta} = \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k + \frac{1}{N}\hat{\Theta}\sum_{k=1}^m X_k^T(y - X_k\hat{\beta}_k). \tag{5}$$

To evaluate (5),

1. each machine sends $\hat{\beta}_k$ and $\frac{1}{n}X_k^T(y - X_k\hat{\beta}_k)$ to a central server,
2. the central server forms $\frac{1}{m}\sum_{k=1}^m \hat{\beta}_k$ and $\frac{1}{N}\sum_{k=1}^m X_k^T(y - X_k\hat{\beta}_k)$ and sends the averages to all the machines,
3. each machine, given the averages, forms $\frac{p}{m}$ rows of $\hat{\Theta}$ and debiases $\frac{p}{m}$ coefficients:

$$\tilde{\beta}_j = \frac{1}{m}\sum_{k=1}^m \hat{\beta}_j + \hat{\Theta}_{j,\cdot}\Big(\frac{1}{N}\sum_{k=1}^m X_k^T(y - X_k\hat{\beta}_k)\Big),$$

where $\hat{\Theta}_{j,\cdot} \in \mathbf{R}^p$ is a row vector.

As we shall see, each machine can perform debiasing with only the data stored locally. Thus, forming the estimator (5) requires two rounds of communication.

The question that remains is how to form $\hat{\Theta}_{j,\cdot}$. We consider an estimator proposed by van de Geer et al. (2013): nodewise regression on the predictors. For some $j \in [p]$ that machine k is debiasing, the machine solves

$$\hat{\gamma}_j := \underset{\gamma\in\mathbf{R}^{p-1}}{\arg\min}\frac{1}{2n}\|X_{k,j} - X_{k,-j}\gamma\|_2^2 + \lambda_j\|\gamma\|_1,\ j \in [p],$$

where $X_{k,-j} \in \mathbf{R}^{n\times(p-1)}$ is X_k less its j-th column $X_{k,j}$. Implicitly, we are forming

$$\hat{C} := \begin{bmatrix} 1 & -\hat{\gamma}_{1,2} & \dots & -\hat{\gamma}_{1,p} \\ -\hat{\gamma}_{2,1} & 1 & \dots & -\hat{\gamma}_{2,p} \\ \vdots & \vdots & \ddots & \vdots \\ -\hat{\gamma}_{p,1} & -\hat{\gamma}_{p,2} & \dots & -\hat{\gamma}_{p,p} \end{bmatrix},$$

where the components of $\hat{\gamma}_j$ are indexed by $k \in \{1, \ldots, j-1, j+1, \ldots, p\}$. We scale the rows of $\hat{C}$ by $\mathbf{diag}\Big(\big[\hat{\tau}_1, \ldots, \hat{\tau}_p\big]\Big)$, where

$$\hat{\tau}_j = \big(\frac{1}{n}\|X_j - X_{-j}\hat{\gamma}_j\|_2^2 + \lambda_j\|\hat{\gamma}_j\|_1\big)^{\frac{1}{2}},$$

to form $\hat{\Theta} = \hat{T}^{-2}\hat{C}$. Each row of $\hat{\Theta}$ is given by

$$\hat{\Theta}_{j,\cdot} = -\frac{1}{\hat{\tau}_j^2}\begin{bmatrix}\hat{\gamma}_{j,1} & \ldots & \hat{\gamma}_{j,j-1} & 1 & \hat{\gamma}_{j,j+1} & \ldots & \hat{\gamma}_{j,p}\end{bmatrix}. \tag{6}$$

Since $\hat{\gamma}_j$ and $\hat{\tau}_j$ only depend on X_k, they can be formed without any communication.

Before we justify the choice of $\hat{\Theta}$ theoretically, we mention that it is an approximate "inverse" of $\hat{\Sigma}$ (in a component-wise sense). By the optimality conditions of nodewise regression,

$$\begin{aligned}\hat{\tau}_j^2 &= \frac{1}{n}\|X_j - X_{-j}\hat{\gamma}_j\|_2^2 + \lambda_j\|\hat{\gamma}_j\|_1 \\ &= \frac{1}{n}\|X_j - X_{-j}\hat{\gamma}_j\|_2^2 + \frac{1}{n}(X_j - X_{-j}\hat{\gamma}_j)^T X_{-j}^T\hat{\gamma}_j \\ &= \frac{1}{n}X_j(X_j - X_{-j}\hat{\gamma}).\end{aligned}$$

Recalling the defintition of $\hat{\Theta}$, we have

$$\frac{1}{n}\hat{\Theta}_{j,\cdot}X^T X_j = \frac{1}{\hat{\tau}_j^2}\frac{1}{n}(X_j - \hat{\gamma}_j^T X_{-j})^T X_j = \lambda_j \text{ and}$$
$$\frac{1}{n}\|\hat{\Theta}_{j,\cdot}X^T X_{-j}\|_\infty = \frac{1}{\hat{\tau}_j^2}\Big\|\frac{1}{n}(X_j - \hat{\gamma}_j^T X_{-j})^T X_{-j}\Big\|_\infty \leq \frac{\lambda_j}{\hat{\tau}_j^2}$$

for any $j \in [p]$. Thus

$$\max_{j\in[p]}\|\hat{\Theta}_{j,\cdot}\hat{\Sigma} - e_j\|_\infty \leq \frac{\lambda_j}{\hat{\tau}_j^2}. \tag{7}$$

van de Geer et al. (2013) show that when the rows of X are *i.i.d.* subgaussian random vectors and the precision matrix Σ^{-1} is sparse, $\hat{\Theta}_{j,\cdot}$ converges to Σ_j^{-1} at the usual convergence rate of the lasso. For completeness, we restate their result.

We consider a sequence of regression problems indexed by the sample size N, dimension p, sparsity s_0 that satisfies (A1), (A2), and (A3). As N grows to infinity, both $p = p(N)$ and $s = s(N)$ may also grow as a function of N. To keep notation manageable, we drop the index N. We further assume

(A4) the covariance of the predictors (rows of X) has smallest eigenvalue $\lambda_{\min}(\Sigma) \sim \Omega(1)$ and largest diagonal entry $\max_{j\in[p]}\Sigma_{j,j} \sim O(1)$,

(A5) the rows of Σ^{-1} are sparse: $\max_{j\in[p]}\frac{s_j^2\log p}{n} \sim o(1)$, where s_j is the sparsity of Σ_j^{-1}.

Lemma 15 (van de Geer et al. (2013), Theorem 2.4) *Under (A1)–(A5),* (6) *with suitable parameters* $\lambda_j \sim \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$ *satisfies*

$$\|\hat{\Theta}_{j,\cdot} - \Sigma_j^{-1}\|_1 \lesssim_P \left(\frac{s_j^2\log p}{n}\right)^{\frac{1}{2}} \text{ for any } j \in [p].$$

We show that the averaged estimator (5) matches the convergence rate of the centralized lasso.

Theorem 16 *Under (A1)–(A5),* (5)*, where* $\hat{\Theta}$ *is given by* (6)*, with suitable parameters* $\lambda_j, \lambda_k \sim \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$*,* $j \in [p]$*,* $k \in [m]$ *satisfies*

$$\|\bar{\beta} - \beta^*\|_\infty \lesssim_P \Big(\frac{\log p}{N}\Big)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n},$$

where $s_{\max} := \max\{s_0, s_1, \ldots, s_p\}$.

Proof See the appendix. ■

By combining the Lemma 11 with Theorem 16, we can show that $\tilde{\beta}^{ht} := \mathrm{HT}(\tilde{\beta}, t)$ for an appropriate threshold t converges to β^* at the same rates as the centralized lasso.

Theorem 17 *Under the conditions of Theorem 16, hard-thresholding* $\tilde{\beta}$ *at* $t \sim \big(\frac{\log p}{N}\big)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n}$ *gives*

1. $\|\tilde{\beta}^{ht} - \beta^*\|_\infty \lesssim_P \big(\frac{\log p}{N}\big)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n}$,
2. $\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim_P \big(\frac{s_0\log p}{N}\big)^{\frac{1}{2}} + \frac{\sqrt{s_0}s_{\max}\log p}{n}$,
3. $\|\tilde{\beta}^{ht} - \beta^*\|_1 \lesssim_P \big(\frac{s_0^2\log p}{N}\big)^{\frac{1}{2}} + \frac{s_0 s_{\max}\log p}{n}$.

Theorem 17 shows that for $m \lesssim \frac{n}{s_{\max}^2\log p}$, the variance term is dominant, so the convergence rates simplify:

1. $\|\tilde{\beta}^{ht} - \beta^*\|_\infty \lesssim_P \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$,
2. $\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim_P \big(\frac{s_{\max}\log p}{N}\big)^{\frac{1}{2}}$,
3. $\|\tilde{\beta}^{ht} - \beta^*\|_1 \lesssim_P \big(\frac{s_{\max}^2\log p}{N}\big)^{\frac{1}{2}}$.

Thus, estimator $\tilde{\beta}^{ht}$ shares the advantages of $\bar{\beta}^{ht}$ over the centralized lasso (cf. Remark 13). It also achieves computational gains over $\bar{\beta}^{ht}$ by amortizing the cost of debiasing across m machines.

4. A sharper estimation result

It is possible to obtain a sharper estimation result by forgoing the ℓ_∞ norm convergence rate. By sharper, we mean the sample complexity of the averaged estimator from $m \lesssim \frac{n}{s_0^2 \log p}$ to $m \lesssim \frac{n}{s_0 \log p}$.

The sharper estimation result depends on a result by Javanmard and Montanari (2013b), which we combine with Lemma 15 and restate for completeness. Before stating the results, we define the (∞, l) norm of a point $x \in \mathbf{R}^p$ as

$$\|x\|_{(\infty,l)} := \max_{\mathcal{A} \subset [p], |\mathcal{A}| \geq l} \frac{\|x_{\mathcal{A}}\|_2}{\sqrt{l}}.$$

When $l = 1$, the (∞, l) norm of x is its ℓ_∞ norm. When $l = p$, the (∞, l) norm is the ℓ_2 norm (rescaled by $\frac{1}{\sqrt{p}}$). Thus the (∞, l) norm interpolates between the ℓ_2 and ℓ_∞ norms. Javanmard and Montanari (2013b), Theorem 2.3 shows that the bias of the debiased lasso is of order $\frac{\sqrt{s_0} \log p}{n}$.

Lemma 18 *Under the conditions of Theorem 16,*

$$\|\hat{\Delta}_k\|_{(\infty, c' s_0)} \lesssim_P \frac{c\sqrt{s_0} \log p}{n} \text{ for any } k \in [m] \text{ for any } c' > 0,$$

where c is a constant that depends only on c' and Σ.

By Lemma 18, the estimator (5) is consistent in the (∞, s_0) norm. The argument is similar to the proof of Theorem 16.

Theorem 19 *Under the conditions of Theorem 16,*

$$\|\bar{\beta} - \beta^*\|_{(\infty, c' s_0)} \sim O_P\Big(\Big(\frac{\log p}{N}\Big)^{\frac{1}{2}} + \frac{\sqrt{s_0} \log p}{n}\Big).$$

Theorem 20 *Under the conditions of Theorem 16, hard-thresholding $\tilde{\beta}$ at $t = |\tilde{\beta}|_{(\hat{s}_0)}$ for some $\hat{s}_0 \sim s_0$, i.e. setting all but the largest $\hat{s}_0$ debiased coefficients to zero, gives*

1. $\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim_P \big(\frac{s_0 \log p}{N}\big)^{\frac{1}{2}} + \frac{s_0 \log p}{n}$,
2. $\|\bar{\beta}^{ht} - \beta^*\|_1 \lesssim_P \big(\frac{s_0^2 \log p}{N}\big)^{\frac{1}{2}} + \frac{s_0^{3/2} \log p}{n}$.

By Theorem 20, when $m \lesssim \frac{N}{s_0 \log p}$, the variance term is dominant and the convergence rates given by the theorem simplify to the convergence rates of the (centralized) lasso estimator:

1. $\|\bar{\beta}^{ht} - \beta^*\|_2 \lesssim_P \big(\frac{s_0 \log p}{N}\big)^{\frac{1}{2}}$,
2. $\|\bar{\beta}^{ht} - \beta^*\|_1 \lesssim_P \big(\frac{s_0^2 \log p}{N}\big)^{\frac{1}{2}}$.

Thus, by forgoing estimation error in the ℓ_∞ norm, it is possible to reduce the sample complexity of the averaged estimator to $m \lesssim \frac{s_0 \log p}{N}$. When $m = 1$, we recover the sample complexity of the centralized lasso estimator.

5. Averaging debiased ℓ_1 regularized M-estimators

The distributed approach to debiasing extends readily to ℓ_1 regularized M-estimators. As before, we are given N pairs (x_i, y_i) stored on m machines. Let $\rho(y_i, a)$ be a loss function function, which is convex in a, and $\dot{\rho}$, $\ddot{\rho}$ be its derivatives with respect to a. That is

$$\dot{\rho}(y, a) = \frac{d}{da}\rho(y, a), \quad \ddot{\rho}(y, a) = \frac{d^2}{da^2}\rho(y, a).$$

We define $\ell_k(\beta) = \frac{1}{n}\sum_{i=1}^n \rho(y_i, x_i^T \beta)$, where the sum is only over the pairs on machine k. The averaged estimator is

$$\bar{\beta} := \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k + \hat{\Theta}\Big(\frac{1}{m}\sum_{k=1}^m \nabla \ell_k(\hat{\beta}_k)\Big), \tag{8}$$

where $\hat{\beta}_k$ is the local ℓ_1 regularized M-estimator: $\hat{\beta}_k := \arg\min_{\beta \in \mathbf{R}^p} \ell_k(\beta) + \lambda_k \|\beta\|_1$. As before, we form $\hat{\Theta}$ by nodewise regression on the weighted design matrix $X_{\hat{\beta}_k} := W_{\hat{\beta}_k} X_k$, where $W_{\hat{\beta}_k}$ is diagonal and its diagonal entries are

$$\big(W_{\hat{\beta}_k}\big)_{i,i} := \ddot{\rho}(y_i, x_i^T \hat{\beta}_k)^{\frac{1}{2}}.$$

That is, for some $j \in [p]$ that machine k is debiasing, the machine solves

$$\hat{\gamma}_j := \arg\min_{\gamma \in \mathbf{R}^{p-1}} \frac{1}{2n}\|X_{\hat{\beta}_k, j} - X_{\hat{\beta}_k, -j}\gamma\|_2^2 + \lambda_j \|\gamma\|_1, \; j \in [p],$$

and forms

$$\hat{\Theta}_{j,\cdot} = -\frac{1}{\hat{\tau}_j^2}\begin{bmatrix}\hat{\gamma}_{j,1} & \dots & \hat{\gamma}_{j,j-1} & 1 & \hat{\gamma}_{j,j+1} & \dots & \hat{\gamma}_{j,p}\end{bmatrix},$$

where

$$\hat{\tau}_j = \big(\frac{1}{n}\|X_{\hat{\beta}_k, j} - X_{\hat{\beta}_k, -j}\hat{\gamma}_j\|_2^2 + \lambda_j \|\hat{\gamma}_j\|_1\big)^{\frac{1}{2}}.$$

We assume

(B1) the pairs $\{(x_i, y_i)\}_{i \in [N]}$ are *i.i.d.*; the predictors are bounded:

$$\max_{i \in [N]} \|x_i\|_\infty \lesssim 1;$$

the projection of $X_{\beta^*, j}$ on $\mathcal{R}(X_{\beta^*, -j})$ in the $\mathbf{E}\left[\nabla^2 \ell_k(\beta^*)\right]$ inner product is bounded: $\|X_{\beta^*, -j}\gamma_{\beta^*, j}\|_\infty \lesssim 1$ for any $j \in [p]$, where

$$\gamma_{\beta^*, j} := \arg\min_{\gamma \in \mathbf{R}^{p-1}} \mathbf{E}\left[\|X_{\beta^*, j} - X_{\beta^*, -j}\gamma\|_2^2\right].$$

(B2) the rows of $\mathbf{E}\left[\nabla^2 \ell_k(\beta^*)\right]^{-1}$ are sparse: $\max_{j \in [p]} \frac{s_j^2 \log p}{n} \sim o(1)$, where s_j is the sparsity of $\left(\mathbf{E}\left[\nabla^2 \ell_k(\beta^*)\right]^{-1}\right)_{j,\cdot}$.

(B3) the smallest eigenvalue of $\mathbf{E}\left[\nabla^2 \ell_k(\beta^*)\right]$ is bounded away from zero and its entries are bounded.

(B4) for any β such that $\|\beta - \beta^*\|_1 \le \delta$ for some $\delta > 0$, the diagonal entries of W_β stays away from zero, and

$$|\ddot{\rho}(y, x^T\beta) - \ddot{\rho}(y, x^T\beta^*)| \le |x^T(\beta - \beta^*)|.$$

(B5) we have $\frac{1}{n}\|X_k(\hat{\beta}_k - \beta^*)\|_2^2 \lesssim_P s_0\lambda_k^2$ and $\|\hat{\beta}_k - \beta^*\|_1 \lesssim_P s_0\lambda_k$.

(B6) the derivatives $\dot{\rho}(y, a)$, $\ddot{\rho}(y, a)$ is locally Lipschitz:

$$\max_{i\in[N]} \sup_{|a,a'-x_i^T\beta^*|\le\delta} \sup_y \frac{|\ddot{\rho}(y,a)-\ddot{\rho}(y,a')|}{|a-a'|} \le K \text{ for some } \delta > 0.$$

Further,

$$\max_{i\in[N]} \sup_y |\dot{\rho}(y, x_i^T\beta)| \sim O(1),$$
$$\max_{i\in[N]} \sup_{|a-x_i^T\beta^*|\le\delta} \sup_y |\ddot{\rho}(y, a)| \sim O(1).$$

(B7) the diagonal entries of

$$\mathbf{E}\big[\nabla^2\ell_k(\beta^*)\big]^{-1}\mathbf{E}\big[\nabla\ell_k(\beta^*)\nabla\ell_k(\beta^*)^T\big]\mathbf{E}\big[\nabla^2\ell_k(\beta^*)\big]^{-1}$$

are bounded.

The preceding assumptions deserve elaboration. Assumptions (B1), (B4), (B6), and (B7) are standard in the literature on high-dimensional regression. They ensure the various intermediate quantities, such as $\rho(y, x^T\beta)$ and its derivaties, remain bounded. Assumption (B2) is perhaps the most restrictive. The assumption serves to ensure that the debiasing step is effective in reducing the bias of the regularized estimator. It may be relaxed (at the cost of additional technicalities) to the rows of $\mathbf{E}\big[\nabla^2\ell_k(\beta^*)\big]^{-1}$ admit a s_j-sparse approximation. We refer to Bühlmann and Van De Geer (2011) for the details. Assumption (B3) is a quantitative version of the usual rank condition in regression. It ensures the regression coefficients are identifiable in the limit. Assumption (B5) is not necessary; it is implied by the other assumptions. We refer to Bühlmann and Van De Geer (2011), Chapter 6 for the details. Here we state it as an assumption to simplify the exposition.

We are ready to state our main results concerning the averaged estimator(8). It shows the averaged estimator achieves the convergence rate of the centralized ℓ_1-regularized M-estimator.

Theorem 21 *Under (B1)–(B7),* (8) *with suitable parameters* $\lambda_j, \lambda_k \sim \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$, $j \in [p]$, $k \in [m]$ *satisfies*

$$\|\bar{\beta} - \beta^*\|_\infty \lesssim_P \Big(\frac{\log p}{N}\Big)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n}, \tag{9}$$

where $s_{\max} := \max\{s_0, s_1, \ldots, s_p\}$.

Proof The averaged estimator is given by

$$\bar{\beta} - \beta^* = \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k - \hat{\Theta}\nabla\ell_k(\hat{\beta}_k)(\hat{\beta}_k - \beta^*) - \beta^*.$$

By the smoothness of ρ,

$$\dot{\rho}(y_i, x_i^T\hat{\beta}_k) = \dot{\rho}(y_i, x_i^T\beta^*) + \ddot{\rho}(y_i, \tilde{a}_i)x_i^T(\hat{\beta}_k - \beta^*),$$

where $\tilde{a}_i$ is a point between $x_i^T\hat{\beta}_k$ and $x_i^T\beta^*$. Thus

$$\begin{aligned}\bar{\beta} - \beta^* &= \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k - \hat{\Theta}(\nabla\ell_k(\beta^*) + Q_k(\hat{\beta}_k - \beta^*)) - \beta^* \\ &= -\hat{\Theta}\big(\tfrac{1}{m}\textstyle\sum_{k=1}^m \nabla\ell_k(\beta^*)\big) + \frac{1}{m}\sum_{k=1}^m \big(I - \hat{\Theta}Q_k\big)(\hat{\beta}_k - \beta^*).\end{aligned}$$

where $Q_k = \frac{1}{n}\sum_{i=1}^n \ddot{\rho}(y_i, \tilde{a}_i)x_i x_i^T$, where the sum is over the data points on machine k. Taking norms, we obtain

$$\|\bar{\beta} - \beta^*\|_\infty \le \big\|\hat{\Theta}\big(\tfrac{1}{m}\textstyle\sum_{k=1}^m \nabla\ell_k(\beta^*)\big)\big\|_\infty + \frac{1}{m}\sum_{k=1}^m \big\|\big(I - \hat{\Theta}Q_k\big)(\hat{\beta}_k - \beta^*)\big\|_\infty.$$

It is possible to show that $\big\|\hat{\Theta}\big(\frac{1}{m}\sum_{k=1}^m \nabla\ell_k(\beta^*)\big)\big\|_\infty \lesssim_P \big(\frac{\log p}{N}\big)^{\frac{1}{2}}$, which corresponds to the first term in (9). We refer to Bühlmann and Van De Geer (2011), Chapter 6 for the details.

We turn our attention to the second term. By the triangle inequality,

$$\begin{aligned}&\|(I - \hat{\Theta}Q_k)(\hat{\beta}_k - \beta^*)\|_\infty \\ &\quad\le \big\|\big(I - \hat{\Theta}\nabla^2\ell_k(\hat{\beta}_k)\big)(\hat{\beta}_k - \beta^*)\big\|_\infty + \big\|\hat{\Theta}(\nabla^2\ell_k(\hat{\beta}_k) - Q_k)(\hat{\beta}_k - \beta^*)\big\|_\infty \\ &\quad\le \max_{j\in[p]}\big\|e_j^T - \hat{\Theta}_{j,\cdot}\nabla^2\ell_k(\hat{\beta}_k)\big\|_\infty\|\hat{\beta}_k - \beta^*\|_1 \\ &\qquad + \frac{1}{n}\sum_{i=1}^n \|\hat{\Theta}x_i\|_\infty|\ddot{\rho}(y_i, x_i^T\hat{\beta}_k) - \ddot{\rho}(y_i, \tilde{a}_i)x_i^T(\hat{\beta}_k - \beta^*)|.\end{aligned}$$

We proceed term by term. By (7),

$$\max_{j\in[p]}\big\|e_j^T - \hat{\Theta}_{j,\cdot}\nabla^2\ell_k(\hat{\beta}_k)\big\|_\infty \le \frac{\lambda_j}{\hat{\tau}_j^2} \lesssim \frac{1}{\hat{\tau}_j^2}\Big(\frac{\log p}{n}\Big)^{\frac{1}{2}}.$$

By van de Geer et al. (2013), Theorem 3.2,

$$|\hat{\tau}_j^2 - \tau_j^2| \lesssim_P \Big(\frac{\max\{s_0, s_j\}\log p}{n}\Big)^{\frac{1}{2}}$$

Thus $\max_{j\in[p]}\big\|e_j^T - \hat{\Theta}_{j,\cdot}\nabla^2\ell_k(\hat{\beta}_k)\big\|_\infty \lesssim_P \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$ and, by (B5),

$$\max_{j\in[p]}\big\|e_j^T - \hat{\Theta}_{j,\cdot}\nabla^2\ell_k(\hat{\beta}_k)\big\|_\infty\|\hat{\beta}_k - \beta^*\|_1 \lesssim_P \frac{s_{\max}\log p}{n}.$$

We turn our attention to the second term. We have $\|\hat{\Theta}x_i\|_\infty \lesssim_P 1$ because

$$\begin{aligned}\|\hat{\Theta}x_i\|_\infty &\le \max_{j\in[p]} \|\hat{\Theta}_{j,\cdot} X_k^T\|_\infty \lesssim \max_{j\in[p]} \|\hat{\Theta}_{j,\cdot} X_{k,\beta^*}^T\|_\infty \\ &\le \max_{j\in[p]} \frac{1}{\hat{\tau}_j^2} \|(X_{k,\beta^*})_j - (X_{k,\beta^*})_{-j}\hat{\gamma}_j\|_\infty.\end{aligned}$$

Again, by van de Geer et al. (2013), Theorem 3.2,

$$\begin{aligned}&\lesssim_P \max_{j\in[p]} \frac{1}{\tau_j^2} \|(X_{k,\beta^*})_j - (X_{k,\beta^*})_{-j}\hat{\gamma}_j\|_\infty \\ &\lesssim_P \max_{j\in[p]} \frac{1}{\tau_j^2} \|(X_{k,\beta^*})_j - (X_{k,\beta^*})_{-j}\gamma_j\|_\infty \\ &\quad + \frac{1}{\tau_j^2} \|(X_{k,\beta^*})_j\|_\infty \|(\hat{\gamma}_j - \gamma_j)\|_1.\end{aligned}$$

which, by (B1) and van de Geer et al. (2013), Theorem 3.2,

$$\lesssim_P 1 + \frac{s_j \log p}{n}.$$

Thus

$$\begin{aligned}&\frac{1}{n}\sum_{i=1}^n \|\hat{\Theta}x_i\|_\infty \left|\ddot{\rho}(y_i, x_i^T\hat{\beta}_k) - \ddot{\rho}(y_i, \tilde{a}_i) x_i^T(\hat{\beta}_k - \beta^*)\right| \\ &\lesssim_P \frac{1}{n}\sum_{i=1}^n \left|\ddot{\rho}(y_i, x_i^T\hat{\beta}_k) - \ddot{\rho}(y_i, \tilde{a}_i) x_i^T(\hat{\beta}_k - \beta^*)\right|,\end{aligned}$$

which, by (B5) and (B6), is at most

$$\lesssim \frac{1}{n}\|X_k(\hat{\beta}_k - \beta^*)\|_2^2 \lesssim_P \frac{s_0 \log p}{n}.$$

We put the pieces together to deduce $\frac{1}{m}\sum_{k=1}^m \left\|(I - \hat{\Theta}Q_k)(\hat{\beta}_k - \beta^*)\right\|_\infty \lesssim_P \frac{s_{\max}\log p}{n}$. ■

By combining the Lemma 11 with Theorem 16, we can show that $\tilde{\beta}^{ht} := \mathrm{HT}(\tilde{\beta}, t)$ for an appropriate threshold t converges to β^* at the same rates as the centralized ℓ_1-regularized M-estimator.

Theorem 22 *Under the conditions of Theorem 21, hard-thresholding $\tilde{\beta}$ at $t \sim \left(\frac{\log p}{N}\right)^{\frac{1}{2}} + \frac{\max_{j\in[p]} s_j \log p}{n}$ gives*

1. $\|\tilde{\beta}^{ht} - \beta^*\|_\infty \lesssim_P \left(\frac{\log p}{N}\right)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n}$,
2. $\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim_P \left(\frac{s_0 \log p}{N}\right)^{\frac{1}{2}} + \frac{\sqrt{s_0} s_{\max}\log p}{n}$,
3. $\|\tilde{\beta}^{ht} - \beta^*\|_1 \lesssim_P \left(\frac{s_0^2 \log p}{N}\right)^{\frac{1}{2}} + \frac{s_0 \max_{j\in[p]} s_j \log p}{n}$.

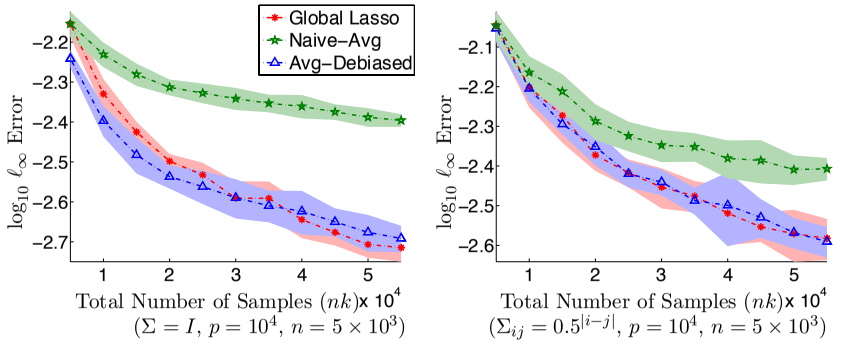

Figure 1: The estimation error (in ℓ_∞ norm) of the averaged debiased lasso estimator versus that of the centralized lasso when the predictors are Gaussian. In both settings, the estimation error of the averaged debiased estimator is comparable to that of the centralized lasso, while that of the naive averaged lasso is much worse.

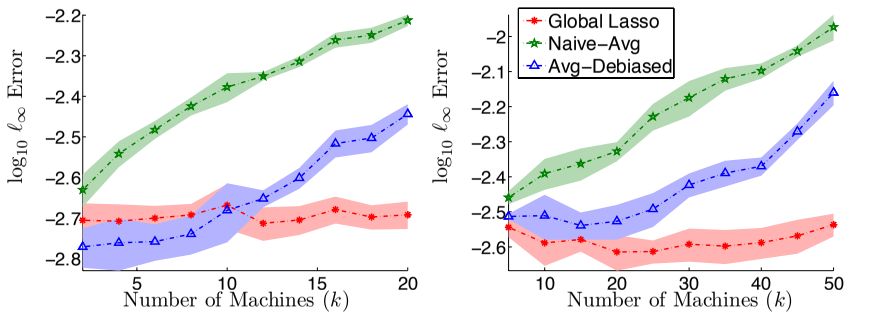


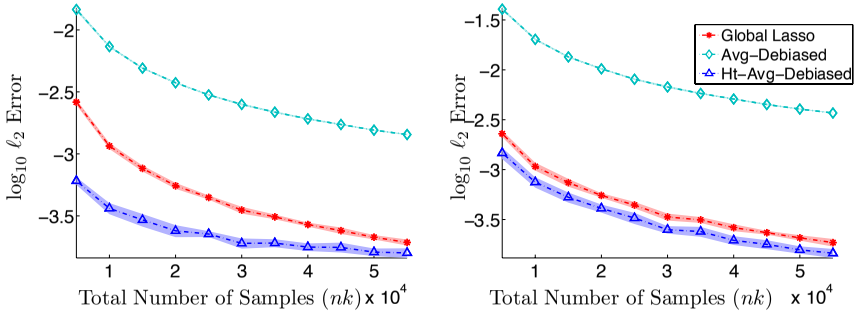
Assuming $s_0 \sim s_{\max}$, Theorem 22 shows when $m \lesssim \frac{n}{s_0^2 \log p}$, the variance term is dominant, so the convergence rates simplify to

1. $\|\tilde{\beta}^{ht} - \beta^*\|_\infty \lesssim_P \left(\frac{\log p}{N}\right)^{\frac{1}{2}}$,
2. $\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim_P \left(\frac{s_0 \log p}{N}\right)^{\frac{1}{2}}$,
3. $\|\tilde{\beta}^{ht} - \beta^*\|_1 \lesssim_P \left(\frac{s_0^2 \log p}{N}\right)^{\frac{1}{2}}$.

6. Simulations

We validate our theoretical results with simulations. First, we study the estimation error of the averaged debiased lasso in ℓ_∞ norm. To focus on the effect of averaging, we grow the number of machines m linearly with the (total) sample size N. In other words, we fix the sample size per machine n and grow the total sample size N by adding machines. The tuning parameters were set to their oracle values stated in the Theorem 12. Figure 1 compares the estimation error (in ℓ_∞ norm) of the averaged debiased lasso estimator with that of the centralized lasso. We see the estimation error of the averaged debiased lasso estimator is comparable to that of the centralized lasso, while that of the naive averaged lasso is much worse.

We conduct a second set of simulations to study the effect of the number of machines on the estimation effort of the averaged estimator. To focus on the effect of the number of



($\Sigma = I$, $p = 10^4$, $nk = 2 \times 10^5$) ($\Sigma_{ij} = 0.5^{|i-j|}$, $p = 10^4$, $nk = 2 \times 10^5$)

Figure 2: The estimation error (in ℓ_∞ norm) of the averaged estimator as the number of machines k vary. When the number of machines is small, the error is comparable to that of the centralized lasso. However, when the number of machines exceeds a certain threshold, the bias term (which grows linearly in k) is dominant, and the performance of the averaged estimator degrades.

machines k, we fix the (total) sample size N and vary the number of machines the samples are distributed across. The tuning parameters were again set to the oracle values stated in the Theorem 12. Figure 2 shows how the estimation error (in ℓ_∞ norm) of the averaged estimator grows as the number of machines grows. When the number of machines is small, the estimation error of the averaged estimator is comparable to that of the centralized lasso. However, when the number of machines exceeds a certain threshold, the estimation error grows with the number of machines. This transition occurs when $\frac{s \log p}{n} \gtrsim \left(\frac{\log p}{N}\right)^{\frac{1}{2}}$, or equivalently, when $k \gtrsim \left(\frac{N}{s^2 \log p}\right)^{\frac{1}{2}}$. The preceding observation is consistent with the prediction of Lemma 10: when the number of machines exceeds a certain threshold, the bias term of order $\frac{s \log p}{n}$ becomes dominant. Since $\frac{s \log p}{n} \propto k$, we expect the error to grow linearly with k, which agrees with the trends in Figure 2.

We conduct a third set of simulations to study the effect of thresholding on the estimation error in ℓ_2 norm. The tuning parameters were set to the oracle values stated in the Theorem 12. Figure 3 compares the estimation error incurred by the averaged estimator with and without thresholding versus that of the centralized lasso. Since the averaged estimator is usually dense, its estimation error (in ℓ_2 norm) is large compared to that of the centralized lasso. However, after thresholding, the averaged estimator performs comparably versus the centralized lasso. This demonstrates the importance of the thresholding step to achieve low ℓ_2 error.

In practice, it is possible to set the tuning parameter δ by the bisection method in the accompanying code to Javanmard and Montanari (2013a); via bisection, they search for the smallest δ such that the optimization program in (2) is feasible. The lasso tuning parameter λ is set by first estimating the noise variance using the residuals and then using the formula

($\Sigma = I$, $p = 10^4$, $n = 5 \times 10^3$) ($\Sigma_{ij} = 0.5^{|i-j|}$, $p = 10^4$, $n = 5 \times 10^3$)

Figure 3: The estimation error (in ℓ_2 norm) of the averaged estimator with and without thresholding versus that of the centralized lasso when the predictors are Gaussian. In both settings, thresholding reduces the estimation error by order(s) of magnitude. Although the estimation error of the averaged estimator is large compared to that of the centralized lasso, the thresholded averaged estimator performs comparably, or even better than, the centralized lasso.

$\lambda = \sigma\sqrt{2 \log p}$. The parameter λ can be chosen independently of σ, if we replace the lasso with the sqrt-lasso Belloni et al. (2011); all of the same theoretical guarantees still apply, since the sqrt-lasso has the same consistency guarantees. For generalized linear models, the oracle choice of λ depends on known quantities Negahban et al. (2012).

7. Summary and discussion

We devised a communication-efficient approach to distributed sparse regression in the high-dimensional setting. The key idea is first "debiasing" local lasso estimators, and then averaging the debiased estimators. We show that as long as the data is not split across too many machines, the averaged estimator achieves the convergence rate of the centralized lasso estimator. In the appendix, we show that by foregoing consistency in the ℓ_∞ norm, it is possible to further reduce the sample complexity of the averaged estimator to that of the centralized lasso estimator. Further, the distributed approach to debiasing extends readily to other ℓ_1 regularized M-estimators. In concurrent work, the approach of averaging debiased M-estimators was proposed by Battey et al. (2015) for high-dimensional inference.

7.1 Communication and Computational complexity

In recent years, there has a been a flurry of work on establishing communication lower bounds for mean estimation in the Gaussian distribution. In other words, they establish the minimum communication C needed to obtain ℓ_2^2 risk R , where $\|\hat{\beta} - \beta^*\|_2^2 \leq R$ (Duchi et al., 2014; Garg et al., 2014). These results are not directly applicable to sparse linear

regression, since they do not impose sparsity on the mean. In Braverman et al. (2015), the authors established that to obtain risk $R \leq \frac{s \log p}{N}$ at least $\Omega\big(\frac{m \min(n,p)}{\log p}\big)$ bits of communication is required. Our approach communicates $\tilde{O}(mp)$ bits to achieve risk of $\frac{s \log p}{N}$, so is communication-optimal when $p \lesssim n$. To our knowledge, lowest known communication complexity for solving the lasso is at least $mp \frac{\sigma_{\max}(\Sigma)}{\sigma_{\min}(\Sigma)} \log \frac{1}{\epsilon}$, for any desired accuracy $\epsilon \gtrsim \sqrt{\frac{s \log p}{n}}$ (Agarwal et al., 2012). This communication cost is larger than our algorithm by a multiplicative factor of $\frac{\sigma_{\max}(\Sigma)}{\sigma_{\min}(\Sigma)} \log \frac{1}{\epsilon}$, which is substantially larger when the problem is poorly conditioned.

In light of the fact that our approach is essentially optimal in terms of communication cost, we turn to the computational complexity of our method. The most intensive step of our approach is the computation of $\hat{\Theta}$. To compute one row of $\hat{\Theta}$ requires solving an optimization problem whose cost is equivalent to a lasso in dimension p with n samples. For the purpose of comparison, let us assume that the lasso solver performs T iterations. Thus the complexity of solving a lasso in dimension p with n samples is $O(npT)$. In the simple approach of Section 2 where each machine computes its own $\hat{\Theta}$, the parallel runtime is $O(np^2T)$. However using the approach of Section 3, each machine is only computing p/m rows of $\hat{\Theta}$. This brings down the parallel runtime to $O(\frac{np^2T}{m})$. In comparison, the cost of solving the lasso using a state-of-art optimization method such as Agarwal et al. (2012) has parallel runtime $O(npT)$, so our computational cost is larger by a factor of $O(\frac{p}{m})$. It is reasonable to think of $\frac{p}{m}$ as a constant, since as the number of variables p increases the dataset sizes increases and we will be forced to use a larger cluster size m due to memory constraints on a single machine. Although our computational complexity is larger in the distributed setting, the dominant factor is often bottlenecked by the communication and latency limitations, rather than local computation.

Appendix A. Proofs of Lemmas

Proof [Proof of Lemma 2] Let $z_i = \Sigma^{-\frac{1}{2}} x_i$. The generalized coherence between X and Σ^{-1} is given by

$$|||\Sigma^{-1}\hat{\Sigma} - I|||_\infty = |||\frac{1}{n}\sum_{i=1}^n (\Sigma^{-\frac{1}{2}} z_i)(\Sigma^{\frac{1}{2}} z_i)^T - I|||_\infty,$$

where $|||X|||_\infty$ is the maximum entry of a X. Each entry of $\frac{1}{n}\sum_{i=1}^n (\Sigma^{-\frac{1}{2}} z_i)(\Sigma^{\frac{1}{2}} z_i)^T - I$ is a sum of independent subexponential random variables. Their subexponential norms are bounded by

$$\|(\Sigma^{-\frac{1}{2}} z_i)_j (\Sigma^{\frac{1}{2}} z_i)_k - \mathbf{1}\{j=k\}\|_{\psi_1} \leq 2\|(\Sigma^{-\frac{1}{2}} z_i)_j (\Sigma^{\frac{1}{2}} z_i)_k\|_{\psi_1},$$

where $\|X\|_{\psi_1}$ and $\|Y\|_{\psi_2}$ are the sub-exponential and sub-Gaussian norms of the random variables X and Y. Recall for any two subgaussian random variables X, Y, we have

$$\|XY\|_{\psi_1} \leq 2\|X\|_{\psi_2}\|Y\|_{\psi_2}.$$

Thus

$$\|(\Sigma^{-\frac{1}{2}} z_i)_j (\Sigma^{\frac{1}{2}} z_i)_k - \delta_{j,k}\|_{\psi_1} \leq 4\|(\Sigma^{-\frac{1}{2}} z_i)_j\|_{\psi_2}\|(\Sigma^{\frac{1}{2}} z_i)_k\|_{\psi_2} \leq 4\sqrt{\kappa}\sigma_x^2,$$

where $\sigma_x = \|z_i\|_{\psi_2}$. By a Bernstein-type inequality,

$$\mathbf{Pr}\Big(\frac{1}{n}\sum_{i=1}^n (\Sigma^{-\frac{1}{2}} z_i)_j (\Sigma^{\frac{1}{2}} z_i)_k - \delta_{j,k} \geq t\Big) \leq 2e^{-c_1 \min\{\frac{nt^2}{\tilde{\sigma}_x^4}, \frac{nt}{\tilde{\sigma}_x^2}\}},$$

where $c_1 > 0$ is a universal constant and $\tilde{\sigma}_x^2 := 4\sqrt{\kappa}\sigma_x^2$. Since $\tilde{\sigma}_x^4 n > \log p$, we set $t = \frac{2\tilde{\sigma}_x^2}{\sqrt{c_1}}\big(\frac{\log p}{n}\big)^{\frac{1}{2}}$ to obtain

$$\mathbf{Pr}\Big(\frac{1}{n}\sum_{i=1}^n (\Sigma^{-\frac{1}{2}} z_i)_j (\Sigma^{\frac{1}{2}} z_i)_k - \delta_{j,k} \geq \frac{2\tilde{\sigma}_x^2}{\sqrt{c_1}}\Big(\frac{\log p}{n}\Big)^{\frac{1}{2}}\Big) \leq 2p^{-4}.$$

We obtain the stated result by taking a union bound over the p^2 entries of $\frac{1}{n}\sum_{i=1}^n (\Sigma^{-\frac{1}{2}} z_i)(\Sigma^{\frac{1}{2}} z_i)^T - I$. ■

Proof [Proof of Lemma 5] By Vershynin (2010), Proposition 5.10,

$$\mathbf{Pr}\Big(\frac{1}{n}|x_j^T\epsilon| > t\Big) \leq e\exp\Big(-\frac{c_2 n^2 t^2}{\sigma_y^2\|x_j^T\|_2^2}\Big) \leq e\exp\Big(-\frac{c_2 n^2 t^2}{\sigma_y^2 \max_{j\in[p]}\hat{\Sigma}_{j,j}}\Big).$$

We take a union bound over the p components of $\frac{1}{n}X^T\epsilon$ to obtain

$$\mathbf{Pr}\Big(\frac{1}{n}\|X^T\epsilon\|_\infty > t\Big) \leq e\exp\Big(-\frac{c_2 n^2 t^2}{\sigma_y^2 \max_{j\in[p]}\hat{\Sigma}_{j,j}} + \log p\Big).$$

We set $t = \max_{j\in[p]}\hat{\Sigma}_{j,j}^{\frac{1}{2}}\sigma_y\big(\frac{3\log p}{c_2 n}\big)^{\frac{1}{2}}$ to obtain the desired conclusion. ■

Proof [Proof of Lemma 7] We start by substituting the linear model into (1):

$$\hat{\beta}^d = \hat{\beta} + \frac{1}{n}\hat{\Theta}X^T(y - X\hat{\beta}) = \beta^* + \hat{\Theta}\hat{\Sigma}(\beta^* - \hat{\beta}) + \frac{1}{n}\hat{\Theta}X^T\epsilon.$$

By adding and subtracting $\hat{\Delta} = \beta^* - \hat{\beta}$, we obtain

$$\hat{\beta}^d = \beta^* + \frac{1}{n}\hat{\Theta}X^T(y - X\hat{\beta}) = \beta^* + (\hat{\Theta}\hat{\Sigma} - I)(\beta^* - \hat{\beta}) + \frac{1}{n}\hat{\Theta}X^T\epsilon.$$

We obtain the expression of $\hat{\beta}^d$ by setting $\hat{\Delta}$.

To show $\|\hat{\Delta}\|_\infty \leq \frac{3\delta}{\mu}s\lambda$, we apply Hölder's inequality to each component of $\hat{\Delta}$ to obtain

$$|(\hat{\Theta}\hat{\Sigma} - I)(\beta^* - \hat{\beta})| \leq \max_j \|\hat{\Sigma}m_j^T - e_j\|_\infty\|\hat{\beta} - \beta^*\|_1 \leq \delta\|\hat{\beta} - \beta^*\|_1, \tag{10}$$

where δ is the generalized incoherence between X and $\hat{\Theta}$. By Lemma 6, $\|\hat{\beta} - \beta^*\|_1 \leq \frac{3}{\mu}s\lambda$. We combine the bound on $\|\hat{\beta} - \beta^*\|_1$ with (10) to obtain the stated bound on $\|\hat{\Delta}\|_\infty$. ■

Proof [Proof of Lemma 10] By Lemma 7,

$$\bar{\beta} - \beta^* = \frac{1}{N}\sum_{k=1}^{m} \hat{\Theta}_k X_k^T \epsilon_k + \frac{1}{m}\sum_{k=1}^{m} \hat{\Delta}_k.$$

We take norms to obtain

$$\|\bar{\beta} - \beta^*\|_\infty \leq \Big\|\frac{1}{N}\sum_{k=1}^{m} \hat{\Theta}_k X_k^T \epsilon_k\Big\|_\infty + \frac{1}{m}\sum_{k=1}^{m} \|\hat{\Delta}_k\|_\infty.$$

We focus on bounding the first term. Let $a_j^T := e_j^T \begin{bmatrix}\hat{\Theta}_1 X_1^T & \dots & \hat{\Theta}_m X_m^T\end{bmatrix}$. By Vershynin (2010), Proposition 5.10,

$$\mathbf{Pr}\Big(|\frac{1}{N} a_j^T \epsilon| > t\Big) \leq e\exp\Big(-\frac{c_2 N^2 t^2}{\|a_j\|_2^2 \sigma_y^2}\Big)$$

for some universal constant $c_2 > 0$. Further,

$$\|a_j\|_2^2 = \sum_{k=1}^{m} \|X_k \hat{\Theta}_k^T e_j\|_2^2 = n\sum_{k=1}^{m} \big(\hat{\Theta}_k \hat{\Sigma}_k \hat{\Theta}_k^T\big)_{j,j} \leq c_\Omega N,$$

where $c_\Omega := \max_{j\in[p],k\in[m]} \big(\hat{\Theta}_k \hat{\Sigma}_k \hat{\Theta}_k^T\big)_{j,j}$. By a union bound over $j \in [p]$,

$$\mathbf{Pr}\Big(\max_{j\in[p]} |\frac{1}{N} a_j^T \epsilon| > t\Big) \leq e\exp\Big(-\frac{c_2 N t^2}{c_\Omega \sigma_y^2} + \log p\Big).$$

We set $t = \sigma_y\big(\frac{2c_\Omega \log p}{c_2 N}\big)^{\frac{1}{2}}$ to deduce

$$\mathbf{Pr}\Big(\max_{j\in[p]} |\tfrac{1}{N} a_j^T \epsilon| \geq \sigma_y\big(\tfrac{2c_\Omega \log p}{c_2 N}\big)^{\frac{1}{2}}\Big) \leq ep^{-1}.$$

We turn our attention to bounding the second term. By Lemma 5 and a union bound over $j \in [p]$, when we set

$$\lambda_1 = \dots = \lambda_m = \lambda := \max_{j\in[p],k\in[m]} \big((\hat{\Sigma}_k)_{j,j}\big)^{\frac{1}{2}} \sigma_y\Big(\frac{3\log p}{c_2 n}\Big)^{\frac{1}{2}},$$

we have $\frac{1}{n}\|X_k^T \epsilon\|_\infty \leq \lambda$ for any $k \in [m]$ with probability at least $1 - \frac{em}{p^2} \geq 1 - ep^{-1}$. By Lemma 7, when

1. $\{\hat{\Sigma}_k\}_{k\in[m]}$ satisfy the RE condition on $\mathcal{C}(\mathrm{supp}(\beta^*))$ with constant μ_l,
2. $\{(\hat{\Sigma}_k, \hat{\Theta}_k)\}_{k\in[m]}$ have generalized incoherence $c_{\mathrm{GC}}\big(\frac{\log p}{n}\big)^{\frac{1}{2}}$,

the second term is at most $\frac{3\sqrt{3}}{\sqrt{c_2}} \frac{c_{\mathrm{GC}} c_\Sigma}{\mu_l} \sigma_y \frac{s\log p}{n}$. We put the pieces together to obtain

$$\|\bar{\beta} - \beta^*\|_\infty \leq \sigma_y\Big(\frac{2c_\Omega \log p}{c_2 N}\Big)^{\frac{1}{2}} + \frac{3\sqrt{3}}{\sqrt{c_2}} \frac{c_{\mathrm{GC}} c_\Sigma}{\mu_l} \sigma_y \frac{s\log p}{n},$$

■

Proof [Proof of Lemma 10] We start with the conclusion of Lemma 10:

$$\|\bar{\beta} - \beta^*\|_\infty \leq \sigma_y\Big(\frac{2c_\Omega \log p}{c_2 N}\Big)^{\frac{1}{2}} + \frac{3\sqrt{3}}{\sqrt{c_2}} \frac{c_{\mathrm{GC}} c_\Sigma}{\mu_l} \sigma_y \frac{s\log p}{n}.$$

First, we show that the two constants $c_\Omega = \max_{j\in[p],\, k\in[m]} (\hat{\Theta}_k \hat{\Sigma}_k \hat{\Theta}_k^T)_{j,j}$ and $c_\Sigma := \max_{j\in[p],k\in[m]} ((\hat{\Sigma}_k)_{j,j})^{\frac{1}{2}}$ are bounded with high probability.

Lemma 23 *Under (A1),*

$$\mathbf{Pr}\big(\max_{j\in[p]} \Sigma_j^{-1}\hat{\Sigma}\Sigma_j^{-1} > 2\max_{j\in[p]} \Sigma_{j,j}^{-1}\big) \leq 2pe^{-c_1 \min\{\frac{n}{\sigma_x^2}, \frac{n}{\sigma_x}\}}$$

for some universal constant $c_1 > 0$.

Proof [Proof of Lemma 23] We express

$$\Sigma_{j,\cdot}^{-1}\hat{\Sigma}\Sigma_{j,\cdot}^{-1} = \Sigma_{j,\cdot}^{-1}\hat{\Sigma}\Sigma_{j,\cdot}^{-1} - \Sigma_{j,j}^{-1} + \Sigma_{j,j}^{-1} = \frac{1}{n}\sum_{i=1}^{n} (x_i^T \Sigma_{\cdot,j}^{-1})^2 - \Sigma_{j,j}^{-1} + \Sigma_{j,j}^{-1}.$$

Since the subgaussian norm of $z_i = \Sigma^{-\frac{1}{2}} x_i$ is σ_x, $x_i^T \Sigma_{\cdot,j}^{-1}$ is also subgaussian with subgaussian norm bounded by

$$\|x_i^T \Sigma_{\cdot,j}^{-1}\|_{\psi_2} \leq \|z_i\|_{\psi_2} \|\Sigma_{\cdot,j}^{-\frac{1}{2}}\|_2 \leq \sigma_x (\Sigma_{j,j}^{-1})^{\frac{1}{2}}.$$

We recognize $\frac{1}{n}\sum_{i=1}^{n} (x_i^T \Sigma_{\cdot,j}^{-1})^2 - \Sigma_{j,j}^{-1}$ as a sum of *i.i.d.* subexponential random variables with subexponential norm bounded by

$$\|(x_i^T \Sigma_{\cdot,j}^{-1})^2 - \Sigma_{j,j}^{-1}\|_{\psi_1} \leq 2\|(x_i^T \Sigma_{\cdot,j}^{-1})^2\|_{\psi_1} \leq 4\|x_i^T \Sigma_{\cdot,j}^{-1}\|_{\psi_2}^2 \leq 4\sigma_x^2 \Sigma_{j,j}^{-1}.$$

By Vershynin (2010), Proposition 5.16, we have

$$\mathbf{Pr}\Big(\frac{1}{n}\sum_{i=1}^{n} (x_i^T \Sigma_{\cdot,j}^{-1})^2 - \Sigma_{j,j}^{-1} > t\Big) \leq 2e^{-c_1 \min\{\frac{nt^2}{16\sigma_x^2 (\Sigma_{j,j}^{-1})^2}, \frac{nt}{4\sigma_x \Sigma_{j,j}^{-1}}\}}$$

for some absolute constant $c_1 > 0$. For $t = \Sigma_{j,j}^{-1}$, the bound simplifies to

$$\mathbf{Pr}\Big(\frac{1}{n}\sum_{i=1}^{n} (x_i^T \Sigma_{\cdot,j}^{-1})^2 - \Sigma_{j,j}^{-1} > \Sigma_{j,j}^{-1}\Big) \leq 2e^{-c_1 \min\{\frac{n}{16\sigma_x^2}, \frac{n}{4\sigma_x}\}}.$$

We take a union bound over $j \in [p]$ to obtain the stated result. ■

Since we form $\{\hat{\Theta}_k\}_{k\in[m]}$ by (2),

$$(\hat{\Theta}_k \hat{\Sigma}_k \hat{\Theta}_k^T)_{j,j} \leq \max_{j\in[p]} (\Sigma^{-1}\hat{\Sigma}_k\Sigma^{-1}))_{j,j}.$$

Lemma 23 implies

$$\max_{j\in[p]} (\Sigma^{-1}\hat{\Sigma}_k\Sigma^{-1}))_{j,j} \leq 2\max_{j\in[p]} \Sigma_{j,j}^{-1} \text{ for each } k \in [m]$$

with probability at least $1 - 2pe^{-c_1 \min\{\frac{n}{\sigma_x^2}, \frac{n}{\sigma_x}\}}$.

Lemma 24 *Under (A1),*

$$\mathbf{Pr}(\max_{j\in[p]}(\hat{\Sigma}_{j,j})^{\frac{1}{2}} > \sqrt{2}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}) \leq 2pe^{-c_1\min\{\frac{n}{16\sigma_x^2},\frac{n}{4\sigma_x}\}}$$

for some universal constant $c_1 > 0$.

We put the pieces together to obtain the stated result:

1. By Lemma 23 (and a union bound over $k \in [m]$),

$$\mathbf{Pr}(c_\Omega \geq 2\max_j \Sigma^{-1}_{j,j}) \leq 2mpe^{-c_1\min\{\frac{n}{\sigma_x^2},\frac{n}{\sigma_x}\}}.$$

Since $m \leq p$, when $n > \frac{3}{c_1}\max\{\sigma_x^2, \sigma_x\}\log p$,

$$\mathbf{Pr}\big(c_\Omega < 2\max_j \Sigma^{-1}_{j,j}\big) \geq 1 - 2p^{-1}.$$

2. By Lemma 24 (and a union bound over $k \in [m]$),

$$\mathbf{Pr}(c_\Sigma < \sqrt{2}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}) \geq 1 - 2mpe^{-c_1\min\{\frac{n}{16\sigma_x^2},\frac{n}{4\sigma_x}\}}.$$

When $n > \frac{3}{c_1}\max\{\sigma_x^2, \sigma_x\}\log p$, the right side is again at most $2p^{-1}$.

3. By Lemma 4, as long as

$$n > \max\{4000\tilde{s}\sigma_x^2\log(\tfrac{Cp}{\tilde{s}}),\ 8000\sigma_x^4\log p\},$$

$\hat{\Sigma}_1, \ldots, \hat{\Sigma}_m$ all satisfy the RE condition with probability at least

$$1 - 2me^{-\frac{n}{4000\sigma_x^4}} \geq 1 - 2p^{-1}.$$

4. By Lemma 2,

$$\mathbf{Pr}\big(\cap_{k\in[m]}\mathcal{E}_{\mathrm{GC}}(\hat{\Sigma}_k)\big) \geq 1 - 2p^{-2}.$$

Since $m < p$, the probability is at least $1 - 2p^{-1}$.

We apply the bounds $c_\Omega \leq 2\max_{j\in[p]}\Sigma^{-1}_{j,j}$, $c_\Sigma \leq \sqrt{2}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}$, $c_{\mathrm{GC}} = \frac{8}{\sqrt{c_1}}\sqrt{\kappa}\sigma_x^2$, and $\mu_l = \frac{1}{2}\lambda_{\min}(\Sigma)$ to obtain

$$\|\bar{\beta} - \beta^*\|_\infty \leq \sigma_y\left(\frac{4\max_{j\in[p]}\Sigma^{-1}_{j,j}\log p}{c_2 N}\right)^{\frac{1}{2}} + \frac{48\sqrt{6}}{\sqrt{c_1 c_2}}\frac{\sqrt{\kappa}\max_{j\in[p]}(\Sigma_{j,j})^{\frac{1}{2}}}{\lambda_{\min}(\Sigma)}\sigma_x^2\sigma_y\frac{s\log p}{n}.$$

■

Proof [Proof of Lemma 24] We follow a similar argument as the proof of Lemma 23:

$$\hat{\Sigma}_{k;j,j} = \hat{\Sigma}_{j,j} = \hat{\Sigma}_{j,j} - \Sigma_{j,j} + \Sigma_{j,j} = \frac{1}{n}\sum_{i=1}^n x_{i,j}^2 - \Sigma_{j,j} + \Sigma_{j,j}.$$

Since the $z_i = \Sigma^{-\frac{1}{2}}x_i$ is subgaussian with subgaussian norm σ_x, $x_{i,j}$ is also subgaussian with subgaussian norm bounded by

$$\|x_{i,j}\|_{\psi_2} \leq \|\Sigma^{\frac{1}{2}}_{j,\cdot}z_i\|_{\psi_2} \leq \sigma_x(\Sigma_{j,j})^{\frac{1}{2}}.$$

We recognize $\hat{\Sigma}_{j,j} - \Sigma_{j,j} = \frac{1}{n}\sum_{i=1}^n x_{i,j}^2 - \Sigma_{j,j}$ as a sum of *i.i.d.* subexponential random variables with subexponential norm bounded by

$$\|\hat{\Sigma}_{j,j} - \Sigma_{j,j}\|_{\psi_1} \leq 2\|x_{i,j}^2\|_{\psi_1} \leq 4\|x_{i,j}\|_{\psi_2}^2 \leq 4\sigma_x^2\Sigma_{j,j}.$$

By Vershynin (2010), Proposition 5.16, we have

$$\mathbf{Pr}(|\hat{\Sigma}_{j,j} - \Sigma_{j,j}| > t) \leq 2e^{-c_1\min\{\frac{nt^2}{16\sigma_x^2\Sigma_{j,j}^2},\frac{nt}{\sigma_x\Sigma_{j,j}}\}}$$

for some absolute constant $c_1 > 0$. For $t = \Sigma_{j,j}$, the bound simplifies to

$$\mathbf{Pr}(|\hat{\Sigma}_{j,j} - \Sigma_{j,j}| > \Sigma_{j,j}) \leq 2e^{-c_1\min\{\frac{n}{16\sigma_x^2},\frac{n}{4\sigma_x}\}}.$$

We take a union bound over $j \in [p]$ to obtain the stated result. ■

Proof [Proof of Theorem 16] We start by substituting the linear model into (5):

$$\begin{aligned}\tilde{\beta} &= \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k - \hat{\Theta}\hat{\Sigma}_k(\hat{\beta}_k - \beta^*) + \frac{1}{n}\hat{\Theta}X_k^T\epsilon_k \\ &= \frac{1}{m}\sum_{k=1}^m \hat{\beta}_k - \hat{\Theta}\hat{\Sigma}_k(\hat{\beta}_k - \beta^*) + \frac{1}{N}\hat{\Theta}X^T\epsilon.\end{aligned}$$

Subtracting β^* and taking norms, we obtain

$$\|\tilde{\beta} - \beta^*\|_\infty \leq \frac{1}{m}\sum_{k=1}^m \|(I - \hat{\Theta}\hat{\Sigma}_k)(\hat{\beta}_k - \beta^*)\|_\infty + \big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_\infty. \tag{11}$$

By Vershynin (2010), Proposition 5.16, and Lemma (23), it is possible to show that

$$\big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_\infty \lesssim_P \left(\frac{\log p}{N}\right)^{\frac{1}{2}}.$$

We turn our attention to the first term in (11). It's straightforward to see each term in the sum is bounded by

$$\begin{aligned}&\|(I - \hat{\Theta}\hat{\Sigma}_k)(\hat{\beta}_k - \beta^*)\|_\infty \\ &\quad\leq \|(I - \Sigma^{-1}\hat{\Sigma}_k)(\hat{\beta}_k - \beta^*)\|_\infty + \|(\Sigma^{-1} - \hat{\Theta})\hat{\Sigma}_k(\hat{\beta}_k - \beta^*)\|_\infty \\ &\quad\leq \max_{j\in[p]}\|e_j^T - \Sigma_j^{-1}\hat{\Sigma}_k\|_\infty\|\hat{\beta}_k - \beta^*\|_1 + \|\Sigma_j^{-1} - \hat{\Theta}_{j,\cdot}\|_1\|\hat{\Sigma}_k(\hat{\beta}_k - \beta^*)\|_\infty.\end{aligned}$$

We put the pieces together to deduce each term is $O\big(\frac{s_{\max}\log p}{n}\big)$:

1. By Lemmas 4, 6, 24, $\|\hat{\beta}_k - \beta^*\|_1 \lesssim_P \sqrt{s_0}\lambda_k$.
2. By Lemma 15, $\|\Sigma_j^{-1} - \hat{\Theta}_{j,\cdot}\|_1 \lesssim_P s_j\big(\frac{\log p}{n}\big)^{\frac{1}{2}}$.
3. By the triangle inequality,

$$\|\hat{\Sigma}_k(\hat{\beta}_k - \beta^*)\|_\infty \leq \Big\|\frac{1}{n}X_k^T(y_k - X_k\hat{\beta}_k)\Big\|_\infty + \Big\|\frac{1}{n}X_k^T\epsilon_k\Big\|_\infty.$$

   By the optimality conditions of the (local) lasso estimators, the first term is λ_k, and it is possible to show, by Lemma 23 and Vershynin (2010), Proposition 5.16, that the second term is $O_P\big(\big(\frac{\log p}{n}\big)^{\frac{1}{2}}\big)$.

Since $\lambda_k \asymp \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$, by a union bound over $k \in [m]$, we obtain

$$\|\bar{\beta} - \beta^*\|_\infty \sim O_P\Big(\Big(\frac{\log p}{N}\Big)^{\frac{1}{2}} + \frac{s_{\max}\log p}{n}\Big),$$

where $s_{\max} := \max\{s_0, s_1, \ldots, s_p\}$. ■

Proof [Proof of Lemma 18] The result is essentially Javanmard and Montanari (2013b), Theorem 2.3 with $\hat{\Omega} = \hat{\Theta}$ given by (6). Lemma 15 shows that

$$\max_{j\in[p]} \|\hat{\Theta}_{j,\cdot} - \Sigma_j^{-1}\|_1 \lesssim_P s_j\big(\tfrac{\log p}{n}\big)^{\frac{1}{2}},$$

Since $\frac{\max_{j\in[p]} s_j^2 \log p}{n} \sim o(1)$, $\hat{\Theta}$ satisfies the conditions of Javanmard and Montanari (2013b), Theorem 2.3:

$$\|\hat{\Delta}_k\|_{(\infty,c's_0)} \lesssim_P \frac{c\sqrt{s_0}\log p}{n} \text{ for any } k \in [m],$$

The bound is uniform in $k \in [m]$ by a union bound for suitable parameters $\lambda_k \sim \big(\frac{\log p}{n}\big)^{\frac{1}{2}}$. ■

Proof [Proof of Theorem 19] We start by substituting the linear model into (5):

$$\tilde{\beta} = \frac{1}{m}\sum_{k=1}^m \hat{\Delta}_k + \frac{1}{N}\hat{\Theta}X^T\epsilon.$$

Subtracting β^* and taking norms, we obtain

$$\|\tilde{\beta} - \beta^*\|_{(\infty,c's_0)} \leq \frac{1}{m}\sum_{k=1}^m \|\hat{\Delta}_k\|_{(\infty,c's_0)} + \big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_{(\infty,c's_0)}. \tag{12}$$

By Lemma 18, the first (bias) term is of order $\frac{c\sqrt{s_0}\log p}{n}$. We focus on showing the second (variance) term is of order $\big(\frac{\log p}{N}\big)^{\frac{1}{2}}$. Since the (∞, l) norm is non-increasing in l,

$$\big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_{(\infty,c's_0)} \leq \big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_\infty.$$

By Vershynin (2010), Proposition 5.16 and Lemma 23, it is possible to show that

$$\big\|\frac{1}{N}\hat{\Theta}X^T\epsilon\big\|_\infty \sim O_P\Big(\Big(\frac{\log p}{N}\Big)^{\frac{1}{2}}\Big).$$

Thus the second term in (12) is of order $\big(\frac{\log p}{N}\big)^{\frac{1}{2}}$. We put all the pieces together to obtain the stated conclusion. ■

Proof [Proof of Theorem 20] Since $\tilde{\beta}^{ht} - \beta^*$ is $2s_0$-sparse,

$$\|\tilde{\beta}^{ht} - \beta^*\|_2^2 \lesssim s_0\|\tilde{\beta}^{ht} - \beta^*\|_{(\infty,c's_0)}^2$$

or, equivalently,

$$\|\tilde{\beta}^{ht} - \beta^*\|_2 \lesssim \sqrt{s_0}\|\tilde{\beta}^{ht} - \beta^*\|_{(\infty,c's_0)}.$$

By the triangle inequality,

$$\begin{aligned}\|\tilde{\beta}^{ht} - \beta^*\|_{(\infty,c's_0)} &\leq \|\tilde{\beta}^{ht} - \tilde{\beta}\|_{(\infty,c's_0)} + \|\tilde{\beta} - \beta^*\|_{(\infty,c's_0)} \\ &\leq 2\|\tilde{\beta} - \beta^*\|_{(\infty,c's_0)},\end{aligned}$$

where the second inequality is by the fact that thresholding at $t = |\tilde{\beta}|_{(c's_0)}$ minimizes $\|\beta - \beta^*\|_{(\infty,c's_0)}$ over $c's_0$-sparse points β. Thus

$$\|\tilde{\beta}^{ht} - \beta^*\|_2 = O_P\Big(\Big(\frac{s_0\log p}{N}\Big)^{\frac{1}{2}} + \frac{s_0\log p}{n}\Big).$$

To complete the proof, we observe that the estimation error bound of $\tilde{\beta}^{ht}$ in the ℓ_1 norm follows by the fact that $\tilde{\beta}^{ht} - \beta^*$ is $2s_0$-sparse. ■

Abstract

Inference methods are often formulated as variational approximations: these approximations allow easy evaluation of statistics by marginalization or linear response, but these estimates can be inconsistent. We show that by introducing constraints on covariance, one can ensure consistency of linear response with the variational parameters, and in so doing inference of marginal probability distributions is improved. For the Bethe approximation and its generalizations, improvements are achieved with simple choices of the constraints. The approximations are presented as variational frameworks; iterative procedures related to message passing are provided for finding the minima.

Keywords: variational inference, graphical models, message passing algorithms, statistical physics, linear response

1. Introduction

Given a probability distribution $p(x)$, estimation of marginal probability distributions such as $p(x_i)$ and $p(x_i; x_j)$ is one of the most important inference tasks addressed in graphical models, alongside estimation of the maximum probability state and the log partition function (see Wainwright and Jordan, 2008; Mezard and Montanari, 2009; MacKay, 2004). The challenge is addressed in many research fields by a variety of methods. In Boltzmann machine learning and probabilistic independent component analysis the expectation-maximization algorithm requires such estimates (see Wainwright and Jordan, 2008; Miskin and MacKay, 2000). In heuristic optimization, a branch and bound search (or decimation procedure) over a high dimensional space can be made more efficient, by branching on x_i (or some small set of variables) in an informed manner using approximate probabilities (see Montanari et al., 2007). In channel coding we wish to determine the likely state of a bit sent over a noisy channel, which can be inferred with a measure of certainty from the marginal probability (see Richardson and Urbanke, 2008). In statistical physics, marginal probability distributions provide insight into phase transitions and thermodynamic phases (see Parisi, 1987).

Approximation of marginal probability distributions (called marginals henceforth) with high accuracy is NP-hard even in the case of Ising spins (binary variables) with pairwise interactions (see Dagum and Luby, 1993; Long and Servedio, 2010), but in practice, many schemes might be applied successfully. Approximate inference of marginal distributions is often performed by Markov chain Monte Carlo (MCMC) procedures (see Andrieu et al., 2003). These methods are a workhorse of inference, but have some disadvantages: the estimates are achieved with an accuracy that decays only slowly with time resources (exploiting the central limit theorem), the result is stochastic, and takes a non-parametric form. For these reasons variational approximations are often preferred, the price being a (difficult to quantify) bias in the approximations (see Wainwright and Jordan, 2008; Mezard and Montanari, 2009; MacKay, 2004).

In a basic variational approximation an intractable probability distribution $p(x)$ is approximated by a tractable one $q(x)$, the parameters of q are determined by minimizing the Kullback Leibler (KL) divergence $D_{KL}[p||q]$. The challenge of marginalization is thus replaced by two linked challenges: appropriate construction of q, and minimization of a KL-divergence. An example of a tractable distribution is a factorized one: $q(x) = \prod_i q(x_i)$, which leads to a mean-field variational approximation; KL-divergence could then typically be minimized by an iteration of fixed point equations (see Wainwright and Jordan, 2008; Mezard and Montanari, 2009). It is common for the estimates obtained by variational approximations to be over-confident, the uncertainty in some variables is reduced since the structure of the approximation q discounts some sources of variance.

A given variational framework may be minimized by several algorithms, and it is interesting that many famous heuristic algorithms developed independently of variational frameworks have been shown to be particular solutions to variational approximations. Most notably loopy belief propagation has been shown to be one method to solve the Bethe variational approximation, and expectation propagation was shown to be one method to solve the expectation consistent variational approximation. This connection to variational frameworks has allowed interesting insight into algorithm construction, proofs of solution existence and convergence (see Yedidia et al., 2005; Wainwright and Jordan, 2008; Yuille, 2002).

We have so far identified one mechanism by which to estimate marginals: we can directly marginalize our approximation $q(x)$, which is tractable by construction. These same estimates (when not extremal) can be found as first derivatives of the variational function (in the above description, the KL-divergence), as we later show. Second order derivatives of the KL-divergence are also possible and can give covariance estimates. These covariance estimates are called linear responses, since they measure the response of some expectation (the first derivative estimate) to an infinitesimal linear perturbation (the second derivative). Linear response and marginalization estimates are tractable for variational approximations; and for some statistics, we can use either method to obtain an estimate for the same quantity.

We will consider variational approximations applied to a model of N discrete variables x_i defined by probability [1]

$$p(x) = \frac{1}{Z} \prod_{a=1}^{M} \psi_a(x_a) \,, \tag{1}$$

where ψ_a are the potentials (also called factors) and are non-negative functions of the variables indexed by subset a, $x_a = \{x_i : i \in a\}$, Z is the partition function. Probabilities of this kind can be represented as a factor graph (see Wainwright and Jordan, 2008; Mezard and Montanari, 2009), as shown in Figure 1. Our aim is to demonstrate a mechanism whereby existing variational schemes can be leveraged for improved inference of marginals.

This paper considers a new self-consistent approximation to improve variational methods, with an emphasis on the Bethe approximation and its generalizations (called region-based, or cluster-variational, approximations). We propose the addition of constraints requiring the consistency of estimates obtained via direct marginalization and linear response. We minimize the variational function subject to an agreement of these estimates and show that the resulting unique estimate is an improvement on the two estimates that are obtained without the constraints.

1.1 Literature Review

The linear response has been leveraged to improve estimates of marginals in a variety of problems, the idea originating in statistical physics (see Parisi, 1987; Opper and Winther, 2003; Welling and Teh, 2004).

Physics approaches often aim to improve understanding of phase transitions for problem classes in the limit of a large number of variables (see Parisi, 1987), rather than in development of algorithmic approaches to solve particular finite instances. An early application of linear response was the self-consistent Ornstein-Zernike approximation (SCOZA), proposed by Høye and Stell (1977), which was later applied by Dickman and Stell (1996) to simple graphical models. The SCOZA has been applied to disordered models where marginals are not homogeneous, for example to the random field Ising model in Kierlik, Rosinberg, and Tarjus (1999), but in the service of estimating globally averaged and disorder averages quantities, and never in such a way as to understand particular single variable or pairwise marginals, which is the question we address.

Opper and Winther (2001) proposed the adaptive-TAP approach as an extension of the standard Thouless-Anderson-Palmer mean-field method; in the original formulation of this method, a self-consistency relation between the linear response and magnetizations of a mean-field approximation were reconciled to arrive at a more advanced mean-field theory. Opper and Winther (2005) and Winther and Opper (2005) later reinterpreted this method as a special case of expectation consistent approximate inference, that made a connection between moment-matching algorithms such as expectation propagation and variational frameworks, as well as expanding the range of applications. Expansions of the expectation consistent approximation to mitigate for errors on higher order cumulants have

1. For brevity in expressions we will use the notation x both for a random variable and its realization, relying on context for the distinction.

shown promise in Opper, Paquet, and Winther (2013) and Paquet, Winther, and Opper (2009), but at this point come with few theoretical guarantees.

In the context of machine learning, other related approaches for improving mean-field estimation have been successfully demonstrated in Kappen and Rodriguez (1998) and Giordano, Broderick, and Jordan (2015). Mean-field variational Bayes is an important application of variational approximations, but the absence of an accurate understanding of covariance in the model parameters had been a weakness. Recently it was shown by Giordano, Broderick, and Jordan (2015) that linear response could be used to more accurately estimate these quantities.

The Bethe variational approximation is also an important approximation in the context of sparse graphical models, for which loopy belief propagation (LBP) is the most famous algorithm. Linear response has also been used to improve this approximation, examples include Montanari and Rizzo (2005) and Mooij, Wemmenhove, Kappen, and Rizzo (2007). A large part of this development has been through loop-correction algorithms since the failure of the approximation is known to be related to loops in the graphical model representation. There also exist elegant loop correction methods not relying on the linear response: libDAI is a code repository that has collected some of the methods together (see Mooij, 2010), we developed our methods based on this library, in particular, the implementation of Heskes, Albers, and Kappen (2003). An expansion about the loop free approximation was developed by Chertkov and Chernyak (2006), but is cumbersome when many loops are present.

Several papers related to an extension of the Bethe approximation were published by Yasuda and Tanaka (2013), Raymond and Ricci-Tersenghi (2013b),Raymond and Ricci-Tersenghi (2013a) and Yasuda (2013). The idea was very similar to that of adaptive-TAP, to minimize the variational function subject to the constraint of statistical consistency. When applied to the mean-field approximation it was realized these methods were equivalent to adaptive-TAP, but in the context of Bethe and region-based free energies improved performance was identified. In Raymond and Ricci-Tersenghi (2013b) and Huang and Kabashima (2013) linear response frameworks were also leveraged in the reverse direction to solve the inverse-Ising problem (inferring parameters from statistics).

These variational frameworks were applied initially to Bethe and mean-field approximations on pairwise binary state models, in Yasuda (2013) an extension to general discrete states was provided, whereas Raymond and Ricci-Tersenghi (2013b) applied the technique to region-based variational frameworks and a broader range of constraint types. In this paper, we consider generic discrete alphabets, region-based free energies (inclusive of the Bethe approximation) and both single-variable and pairwise variable consistency constraints. Building on a belief propagation approach we derive tools for minimizing constrained variational free energies.

1.2 Outline

In Section 2, we define a set of variational approximations and motivate the inclusion of additional constraints. In Section 3, we describe methods to minimize the free energy subject to these constraints. In Section 4, we compare the performance of constrained approximations against exact results on some standard models, demonstrating a significant advantage in many cases. In Section 5, we discuss our findings in the context of all experimental results

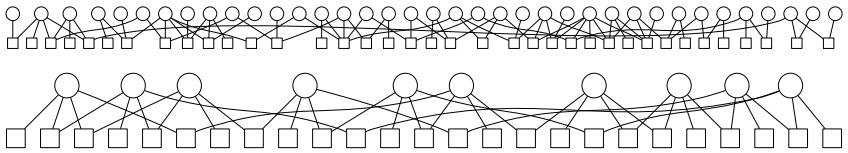

Figure 1: The constrained variational approximations we present can be applied to models with multi-variable interactions, as represented by factor graphs. Two examples are shown. Top: the alarm network is a well-known toy example of a Bayesian net, here represented as a factor graph. Squares denote factors $\psi_a(x_a)$, which act over subsets of variables x_a, each variable represented by a circle. Bottom: $N = 10$ variables interacting according to a random cubic graph is represented, each coupling (J) is represented by a factor with two connections, each field (h) by a singly connected factor.

and other insights gained, before concluding in Section 6. Appendices include exact expressions for the fully connected ferromagnet example, pseudocode and algorithmic details, proofs of convergence for some methods, discussion of solution existence and convergence, and how to select constraints for inclusion.

2. Constrained Variational Approximations

Variational free energy approximations are powerful tools for approximate inference (see Yedidia et al., 2005; Opper and Winther, 2005; Wainwright and Jordan, 2008; Mezard and Montanari, 2009). We introduce in this section the mean-field, Bethe, and region-based (also called Kikuchi) approximations. A set of simplified expressions appropriate to the Bethe approximation for an Ising model is given alongside the general expressions. We first introduce a generalization of the probability over the N variables x, introducing auxiliary parameters ν,

$$p_\nu(x) = \frac{1}{Z(\nu)} \prod_{a=1}^{M} \psi_a(x_a) \prod_{i=1}^{N} \left[\prod_{y} \exp\left(\nu_{i,y} \delta_{x_i,y}\right) \right] . \tag{2}$$

This coincides with (1) in the limit $\nu \to 0$. The product on y is over all possible states of x_i. For our method to apply the probability needs to be differentiable with respect to the parameters ν, though modifications allow for the more general case[2]. The choice of statistics $\{\delta_{x_i,y}\}$ simplifies our presentation, but more generally we might consider a set of single variable functions $\{\phi_y(x_i)\}$, this is discussed in Appendix B.2.

A Boltzmann machine will be presented as a running example. The model[3] has Ising spin variables $x \in \{-1, 1\}^N$, fields h and pairwise couplings J. A connected graphical model will be assumed for notational simplicity, so each variable has connectivity $k_i \geq 1$, and a unique connected component exists. If an edge set $E = \{(i, j)\}$ specifies the interacting

2. Special care should be taken in cases where $\psi_a(x_a) = 0$ for some x_a, in such cases it may not be meaningful to perturb by ν. Furthermore, we note that ν are a redundant set of parameters since variation of $\sum_y \nu_{i,y}$ leaves the probability unchanged.
3. For binary variables, we will use Ising spins $s = \pm 1$ in place of binary states $b \in \{0, 1\}$. The transformation $s = 1 - 2b$ allows conversion between these two conventions.

variables, then

$$p_\nu(x) = \frac{1}{Z(\nu)} \prod_{(i,j)\in E} \exp(J_{ij} x_i x_j) \prod_i \exp[(h_i + \nu_i) x_i] , \tag{3}$$

where we use a non-redundant set of auxiliary parameters $\nu_i = \nu_{i,1} - \nu_{i,-1}$.

In a variational approximation a trial probability distribution $q(x)$ is related to the log-partition function of the full model, derived from the Kullback-Leibler divergence

$$D_{KL}[q||p_\nu] = \sum_x q(x) \left[\log q(x) - \sum_{i,y} \nu_{i,y} \delta_{x_i,y} - \sum_a \log \psi_a(x_a) \right] + \log Z(\nu) . \tag{4}$$

The variational free energy (VFE) is defined

$$F_\nu(q) = D_{KL}[q||p_\nu] - \log Z(\nu) , \tag{5}$$

which is the tractable part of (4). The optimal variational parameters q^* are those minimizing (5).

In the simplest mean-field approximation a factorized variational form is considered $q(x) = \prod_{i=1}^N q_i(x_i)$. The parameters $\{q_i\}$ are precisely marginal distributions on single variables. Iterative methods are often successful in minimizing the VFE.

In another class of approximations the entropy term in the VFE, $-\sum_x q(x) \log q(x)$, is decomposed as a truncated sum of marginal entropies. In the Bethe approximation a redundant set of marginal probability distributions $\{q_a(x_a); q_i(x_i)\}$[4] are introduced in one-to-one correspondence with the model factors and variables, and the entropy is approximated as

$$-\sum_x q(x) \log q(x) \approx -\sum_a \sum_{x_a} q_a(x_a) \log q_a(x_a) - \sum_i (1 - k_i) \sum_{x_i} q_i(x_i) \log q_i(x_i) , \tag{6}$$

with k_i equal to the variable connectivity (the number of factors in which variable i participates). The reason this approximation may improve upon mean-field is that through $q_a(x_a)$ some correlations amongst variables may be explicitely represented, which are absent in the factorial form of mean-field. The variational parameters, q_a and q_i, are referred to as beliefs.

The Bethe approximation is a special case of the more general region-based approximation (see Yedidia et al., 2005), where the entropy approximation is implied by a choice of outer regions. Each outer region is defined by a set of variables x_α, and a generalized factor $\psi_\alpha(x_\alpha)$ that describes the interactions between those variables. The outer regions must be chosen to span all variables, and the factors (as well as auxiliary parameters ν) can be distributed amongst the generalized factors such that $\prod_\alpha \psi_\alpha(x) \propto p_\nu(x)$. Some examples of region selections discussed in this paper are shown in Figure 2.

The entropy approximation is implied by the choice of outer regions: it is the sum of the entropy on the outer regions α corrected by a weighted sum of entropies on region

4. $q_A(x_A)$ denotes a variational parameter, that can be interpreted as an approximation to the marginal probability $p(x_A)$.

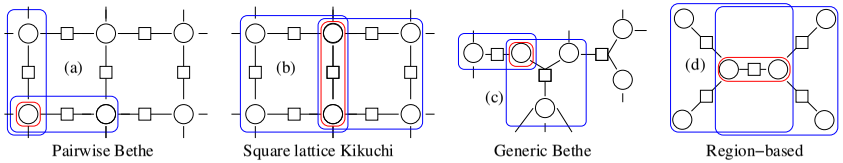

Figure 2: In a region-based approximation (Bethe is a special case), the assignment of outer regions determines the entropy approximation. Sensible choices collect nearby sets of strongly dependent variables. A region graph has outer regions (blue) and intersection regions (red), such that every factor is associated to exactly one outer region; the set of factors in a region α define an auxiliary interaction (8). Selection (a) is a Bethe approximation, the outer regions are pairs of variables, that intersect on single variables. (b) Alternatively, for a square lattice, we might consider outer regions of 4 variables (the central interaction could be assigned to either the right or left region), that intersect on pairs of variables, which in turn intersect on single variables. This approximation is powerful for square lattice models (see Raymond and Ricci-Tersenghi, 2013b; Domínguez et al., 2011; Lage-Castellanos et al., 2013). (c) The Bethe approximation on a factor graph with mixed (multi-variable) interaction types has outer regions containing exactly one factor and its variables, the intersections are single variables. (d) On a locally tree-like graph, we can also make an interesting approximation: outer regions are stars that intersect on edge regions. This approximation relates to the loop-correction algorithm of Montanari and Rizzo (2005).

intersections (β). The region based free energy is defined

$$F_\nu(q) = \sum_\alpha \sum_{x_\alpha} q_\alpha(x_\alpha) \log\left(\frac{q_\alpha(x_\alpha)}{\psi_\alpha(x_\alpha)}\right) + \sum_\beta c_\beta \sum_{x_\beta} q_\beta(x_\beta) \log q_\beta(x_\beta) \,, \tag{7}$$

where c_β take integer values according to a simple rule (see Yedidia et al., 2005; Heskes et al., 2003). Larger regions are capable of capturing more correlations between variables explicitely, but at a computational cost that scales (in the absence of further approximations) exponentially with region size. This trade-off determines the choice of regions.

In the Bethe approximation, the outer regions (α) are in one-to-one correspondence with the factors (a) of the model, and intersection regions are single variables. In our running example of the Boltzmann machine (3), a Bethe approximation has edges as regions. Generalized factors can be chosen as

$$\psi_{(i,j)}(x_i, x_j) = \exp\left(J_{ij} x_i x_j + \frac{h_i + \nu_i}{k_i} + \frac{h_j + \nu_j}{k_j}\right) \,. \tag{8}$$

We can define marginal variational parameters for each marginal probability in the free energy and then minimize (7) subject to local consistency constraints

$$\sum_{x_\alpha} q_\alpha(x_\alpha) = 1 \,; \qquad \forall \alpha \,, \tag{9}$$

$$\sum_{x_\alpha \setminus x_\beta} q_\alpha(x_\alpha) = q_\beta(x_\beta) \,; \qquad \forall \alpha, \forall \beta \subset \alpha \,. \tag{10}$$

Minimization of this free energy is a well-studied problem. Heuristic approaches normally lead to message passing algorithms, which are often convergent to good solutions even where guarantees of convergence are lacking. It is always possible to find minima of the region based free energy using a convex-concave procedure, which is guaranteed to converge to a local minima (see Yuille, 2002; Heskes et al., 2003).

Having found a minimum of the free energy at $q = q^*$, we can define the linear response in the beliefs to a perturbation in $\nu_{i,y}$, as

$$q^*_{\alpha,(i,y)}(x_\alpha) = \left.\frac{\partial q_\alpha(x_\alpha)}{\partial \nu_{i,y}}\right|_{q=q^*} \,.$$

Whereas the variational parameters q have an interpretation away from the fixed point, the linear response is only defined about a global (or heuristically, local) minima. Notation * will be used to denote an evaluation at such a fixed point.

The entropy approximations (6-7) can be interpreted as truncated series (see Pelizzola, 2005; Wainwright and Jordan, 2008), that can be made good either by considering sufficiently large regions (those defining a junction tree, see Wainwright and Jordan, 2008), or including loop corrections (see Chertkov and Chernyak, 2006). The made-good approaches are not tractable in many interesting models of modest scale. The region based methods most often lead to improvements over mean-field, but entropy expansion can also lead to counterintuitive features. For example, the entropy estimate can be negative under such an approximation.

2.1 Inconsistency of Covariance Approximations

The covariance of a pair of statistics ϕ_1 and ϕ_2, under probability distribution p is defined as

$$\begin{aligned} \mathbb{V}_p(\phi_1, \phi_2) &= \mathbb{E}_p(\phi_1\phi_2) - \mathbb{E}_p(\phi_1)\mathbb{E}_p(\phi_2) \,, \\ \text{with} \quad \mathbb{E}_p(\phi) &= \sum_x p(x)\phi(x) \,. \end{aligned}$$

For the case $\phi_1(x_\alpha) = \delta_{x_{i_1},y_1}$ and $\phi_2(x_\alpha) = \delta_{x_{i_2},y_2}$, we can replace the probability of interest p by q_α to obtain

$$\mathbb{V}_p(\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}) \approx C_{(i_1,y_1),(i_2,y_2)} \coloneqq \mathbb{V}_{q_\alpha}[\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}] \,.$$

C will be called the marginal approximation to the covariance, and is a function of the variational parameter q_α. The optimal value $C^* = C(q^*)$ is independent of the region α, owing to the consistency constraints (9)-(10).

Alternatively, we can begin with a second derivative identity. By introducing parameters ν conjugate to each statistics (2), we have

$$\mathbb{V}_p(\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}) = \frac{\partial^2 \log Z(\nu)}{\partial \nu_{i_1,y_1} \partial \nu_{i_2,y_2}} \,.$$

We obtain a tractable approximation replacing $\log Z(\nu)$ by $-F_\nu(q^*)$

$$\mathbb{V}_p(\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}) \approx \chi_{(i_1,y_1),(i_2,y_2)} \coloneqq \sum_{x_\alpha} q^*_{\alpha,(i_1,y_1)}(x_\alpha) \delta_{x_{i_2},y_2} \,, \tag{11}$$

for any α containing i_2, which is called the linear response estimate. χ will be called the linear response approximation to the covariance, it is defined only at the minima q^*, and is a symmetric matrix. We do not need to make explicit reference to the region α used in Eq. (11) since the linear response χ does not depend on that choice.

The name 'linear response' for the quantity χ comes from the fact it can be interpreted as

$$\chi_{(i_1,y_1),(i_2,y_2)} \approx \left.\frac{\partial \mathbb{E}_p[\delta_{x_{i_1},y_1}]}{\partial \nu_{i_2,y_2}}\right|_{\nu=0} = \left.\frac{\partial \mathbb{E}_p[\delta_{x_{i_2},y_2}]}{\partial \nu_{i_1,y_1}}\right|_{\nu=0} , \tag{12}$$

that is the linear variation of the mean value of a single variable statistic to a small perturbation in the the parameter ν conjugated to another single variable statistic.

We denote the difference of these estimates for two statistics on variables (i_1, i_2) contained in region α as

$$\Delta_{(i_1,y_1),(i_2,y_2),\alpha}(q_\alpha, q^*_{\alpha,(i_1,y_1)}) = C_{(i_1,y_1),(i_2,y_2)} - \chi_{(i_1,y_1),(i_2,y_2)} \, . \tag{13}$$

Except for some simple models $C^* - \chi$ is non-zero, exposing an inconsistency in the variational method. The best marginal approximation does not match the best linear response estimate. To decide which estimate to use, either connected correlations or linear responses, we might consider the distance of these two different estimates from the correct value:

$$\Delta^{(1)}_{(i_1,y_1),(i_2,y_2)} = C^*_{(i_1,y_1),(i_2,y_2)} - \mathbb{V}_p\left(\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}\right) , \tag{14}$$

$$\Delta^{(2)}_{(i_1,y_1),(i_2,y_2)} = \chi_{(i_1,y_1),(i_2,y_2)} - \mathbb{V}_p\left(\delta_{x_{i_1},y_1}, \delta_{x_{i_2},y_2}\right) . \tag{15}$$

Graphical models in which the Bethe approximation is most successful have relatively weak correlations and/or few short loops. In these cases it is known that the linear response estimate (15) improves significantly upon (14) for $i_1 \neq i_2$ (see Welling and Teh, 2004; Raymond and Ricci-Tersenghi, 2013a). However, as the approximation breaks down (due to poor approximations of loops in the graphical model), the response estimate can be much worse, even giving infinite values for bounded statistics. For pairs with $i_1 = i_2$ (called diagonal), bounds can be violated even in regimes where the approximation is good. A simple example is the model of Section 4.1 with zero field ($h = 0$): whilst it is true that $\mathbb{V}_p(x_i, x_i) \leq 1$ for any model, $\chi_{i,i} > 1$ for in the weakly coupled (high temperature) regime.

2.2 Covariance Constraints

We would like to use the linear response information, in a safe manner to select the best covariance estimate, but also to make the approximation self-consistent. Rather than simply minimizing the free energy to determine q^*, we do this in the subspace where $\{\Delta_{(i_1,y_1),(i_2,y_2),\alpha} = 0\}$ for a subset of the covariances.

An important question will be which covariances to constrain. Expansion methods indicate that adding all constraints is best when the approximation is very good (see Raymond and Ricci-Tersenghi, 2013a). More generally we wish to add important constraints in so far as it does not prevent solution existence and allows algorithmic stability as discussed in Appendices B.1-B.3.

Although general expressions are derived, experimental sections in this paper are restricted principally to the Bethe approximation, and with simple patterns of constraints

discussed in Appendix B.2. The Bethe approximation with the addition of all possible constraints (called *on and off diagonal*[5]) is considered, as well as the Bethe approximation with addition of only constraints for which $i_1 = i_2$ (*diagonal*). In Section 4.1 we also present results for the mean-field approximation with all possible constraints (since $i_1 = i_2$ in all cases, this is also called diagonal), as well as the Bethe approximation including only constraints for which $i_1 \neq i_2$ (*off-diagonal*). In other experiments, we do not present these latter two regimes since they performed consistently worse except in some narrow parameter ranges where all regimes were performing poorly.

2.3 Bethe Approximation to the Boltzmann Machine

In the case of our running example of the Boltzmann machine (3) we are considering a variation of $\nu_i = \nu_{i,1} - \nu_{i,-1}$, accordingly we can abbreviate notation everywhere (i, y) to i. In the diagonal constraint approximations, we will require consistency of $\mathbb{V}(x_i, x_i) \; \forall \; i$. In the on and off diagonal constrained approximations, we require in addition consistency of $\mathbb{V}(x_i, x_j)$ for all coupled pairs of variables.

The quantities made consistent are written more concisely as

$$\begin{aligned} \mathbb{V}_p(x_i, x_j) &\approx C_{i,j} \coloneqq \mathbb{V}_{q_{(ij)}}(x_i, x_j) \, , \\ \mathbb{V}_p(x_i, x_j) &\approx \chi_{i,j} \coloneqq \sum_{x_i x_j} q^*_{(ij),i}(x_i, x_j) x_j \, . \end{aligned}$$

When evaluated at minima of the free energy, both the approximation by marginalization C^*, and approximation by linear response χ, are symmetric.

3. Minimizing with Respect to the Constraints

We choose a Lagrangian formulation for minimizing the constrained free energy, introducing a Lagrange multiplier for each constraint connecting a linear response approximation to a marginalization approximation. Each statistic pair constraint will be associated with some unique outer region α, as this allows for a cavity heuristic that we later introduce. This association is not unique and may affect (to a limited extent) the convergence of the algorithms we will develop, but not the fixed points that might be achieved. This is discussed further in Appendix B.3. The set of constraints associated to region α are denoted $\boldsymbol{\omega}_\alpha = \{[(i_1, y_1), (i_2, y_2)]\}$ with an associated set of Lagrange multipliers $\boldsymbol{\lambda}_\alpha = \{\lambda_{(i_1,y_1),(i_2,y_2)}\}$. The constrained minimization is then achieved by minimizing the Lagrangian

$$F_\nu(q, \lambda, \chi) = F_\nu(q) + \sum_\alpha \left[\sum_{[(i_1,y_1),(i_2,y_2)] \in \boldsymbol{\omega}_\alpha} \lambda_{(i_1,y_1),(i_2,y_2)} \Delta_{\alpha,(i_1,y_1),(i_2,y_2)}(q_\alpha, q^*_{\alpha,(i_1,y_1)}) \right] , \tag{16}$$

with Lagrange multipliers set to meet the constraints. The global minima q^* for fixed λ can often be found. In cases where local minima can be avoided this is done either heuristically following a constrained loopy belief propagation (CLBP) approach, or in a more robust manner using a provably convergent method, as discussed in Appendix B. CLBP has the same (asymptotic) computational complexity as belief propagation, and is procedurally similar.

5. This terminology arises by considering which elements of the covariance matrix are constrained.

Figure 3: The basic scheme for minimizing our constrained variational free energy. The first stage is solved by a procedure closely related to belief propagation (that minimizes a convex-concave function), the second by a procedure related to susceptibility propagation (that solves a system of linear equations), and the final stage by a cavity approximation. In our experiments, we take $\lambda = 0$ as the initial condition. In the experiments presented we gradually increase or decrease T using the solution at $T \pm \delta T$ as an initial condition for the next experiment, this enables a solution to evolve continuously from a well-understood limit, but is not necessary for convergence in general.

It is shown in Appendix B.6 that given such a fixed point, whether a local or global minimum, it is subsequently relatively easy to calculate the linear response. The method we propose is procedurally similar to susceptibility propagation, originally introduced in Mezard and Mora (2008), which is a computational procedure that minimizes the variational parameters. If the number of constraints is linear in the size of the system the computational complexity is quadratic in system size. We call the linear response scheme constrained loopy susceptibility propagation (CLSP). Yasuda and Tanaka (2013) proposed a closely related approach, specific to the case of diagonal constraints in the Bethe approximation.

Suppose we also have a method for iteratively determining λ, then we can approach the problem of finding a constrained local minima by a 3-stage iterative procedure (the same as proposed in Yasuda and Tanaka (2013)), and shown schematically in Figure 3. We also experimented with other minimization schemes, but found this to be algorithmically the most stable, and also pleasing in that we move all uncertainty in convergence of the method onto the two questions: (1) does there exist a fixed point at all and (2) does the iterative scheme for λ converge. These two questions are unfortunately very difficult to answer in general. To determine λ a heuristic *cavity* method is proposed in Section 3.1.

We found that in weakly correlated regimes the CLBP and CLSP, and iterative updating of λ quickly converges. However, in some other regimes where the variational approximation is less accurate, we found that the effect of non-zero λ could be either a help or a hindrance to the convergence of the CLBP. We also found that λ would sometimes not converge, even with strong damping (implementation of damping is discussed in Appendix C). Associated with regimes of non-convergence, we normally find a divergence of some λ values as discussed in the experimental section. This indicates that failure of the method is most likely related to non-existence (or criticality) of constrained solutions, the issue of solution existence is discussed in Appendix B.1.

3.0.1 Bethe Approximation to the Boltzmann Machine

For the on-and-off diagonal constrained case, the Lagrangian for the Boltzmann machine can be written in the form[6].

$$F_\nu(\boldsymbol{q}, \boldsymbol{\lambda}, \chi) = \sum_{(i,j)\in E} \sum_{x_i,x_j} q_{ij}(x_i, x_j) \log q_{ij}(x_i, x_j) + \sum_i (1 - k_i) \sum_{x_i} q_i(x_i) \log q_i(x_i)$$
$$+ \frac{1}{2} \sum_i \lambda_{i,i} \left[(1 - M_i^2) - \chi_{i,i} \right] + \sum_{(i,j)\in E} \lambda_{(i,j)} \left[\sum_{x_i,x_j} q_{ij}(x_i, x_j) x_i x_j - M_i M_j - \chi_{i,j} \right] , \quad (17)$$

introducing abbreviations for single variable magnetization $M_i := \sum_{x_i} q_i(x_i) x_i$. We recover the diagonal constraint regime when $\lambda_{i,j} = 0 \quad \forall i, j$, and the unconstrained regime when all multipliers are zero. Constraints introduce quadratic functions of q, but terms are neither convex nor concave.

For given λ, a set of message passing equations can be written as a generalization of loopy belief propagation, a simplification of the general case in Appendix B.5 is presented here. At time t the edge-belief is approximated as the solution to the equation

$$q_{ij}^t(x_i, x_j) \propto \mu_{i\to(i,j)}^t(x_i) \mu_{j\to(i,j)}^t(x_j)$$
$$\exp\left[(J_{ij} - \lambda_{ij}) x_i x_j + (h_i + \lambda_{ij} M_{ij,j}^t + \lambda_i M_{ij,i}^t) x_i + (h_j + \lambda_{ij} M_{ij,i}^t + \lambda_j M_{ij,j}^t) x_j \right] ,$$

where we introduce two auxiliary magnetization parameters per edge[7]

$$M_{ij,i}^t = \sum_{x_i x_j} x_i q_{ij}^t(x_i, x_j) . \quad (18)$$

Then we can define messages[8] μ which are determined iteratively as

$$\mu_{(i,j)\to i}^t(x_i) \propto \sum_{x_j} \mu_{j\to(i,j)}^t(x_j)$$
$$\exp\left[(J_{ij} - \lambda_{ij}) x_i x_j + (h_j + \lambda_j M_{ij,j}^t + \lambda_{ij} M_{ij,i}^t) x_j + \lambda_{ij} M_{ij,j}^t x_i \right] ,$$
$$\mu_{i\to(i,j)}^{t+1}(x_i) = \prod_{k\in\partial_i\setminus j} \mu_{(i,k)\to i}^t(x_i) , \quad (19)$$

where ∂_i are the variables interacting with i. Following message updates q^t and M^t must be made consistent, in the examples of this paper (and in general for small λ) this can be achieved simply by iterating Equations (18) and (19). For the experiments messages and beliefs are initialized as constants.

There are several methods by which linear response can be established. One standard approach is susceptibility propagation, which simply involves linearizing the above equations accounting for a small perturbation in some component of ν, this is the approach taken for the examples of this paper; for the general case, expressions are provided in Appendix B.6.

6. To maintain consistency with published research on Ising spin models a factor $1/2$ precedes the diagonal constraint term.
7. Note that at intermediate stages of the message passing, magnetizations for variable i on different beliefs (say $M_{ij,i}$, $M_{ik,i}$) may not agree, but will agree after convergence.
8. These differ by a simple transformation from the messages of the Appendix B.5, so that the limiting case ($\lambda = 0$) agrees with standard presentations for Ising models in the literature.

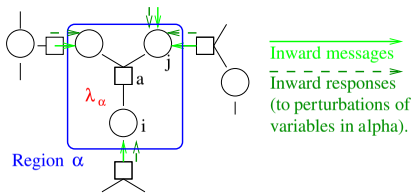

Figure 4: Given C^* and χ, determination of λ breaks into a set of independent problems on outer regions α. This can be understood as a cavity approximation. Assuming the incoming messages, and responses, to be fixed and approximately independent of the Lagrange multipliers to be set ($\boldsymbol{\lambda}_\alpha$), we can independently, on each region, solve the system of equations $\boldsymbol{\Delta}_\alpha = 0$ for $\boldsymbol{\lambda}_\alpha$. A similar assumption often justifies message passing and mean-field iterative heuristics.

3.1 Determination of λ

To determine λ we propose the following scheme. We wish to solve at each α a set of non-linear equations $\{\boldsymbol{\Delta}_\alpha(q_\alpha, q^*_{\alpha,(\cdot)}) = 0\}$, where q_α and $q^*_{\alpha,(\cdot)}$ are functions of all $\boldsymbol{\lambda}$ (through the system of message passing equations). One possibility is to linearize these equations about the current estimate (that is apply Newton's method), but this leads to an impractical $O(N^3)$ procedure, dominating other algorithmic time-scales for moderately sized systems.

Instead, we resort to a locally consistent and parallelizable approximation: For some $\boldsymbol{\lambda}$ we find a minimum defined by messages $\boldsymbol{\mu}$ (Appendix B.5), and the linear response for these messages (Appendix B.6). If $\boldsymbol{\lambda}$ is approximately correct then the messages passing into the region α should be weakly dependent on any changes to $\boldsymbol{\lambda}_\alpha$ in that region. Since we can define $\boldsymbol{\Delta}_\alpha$ in terms of the local parameters $\boldsymbol{\lambda}_\alpha$, and the incoming messages (which we argue are unchanged by an update of $\boldsymbol{\lambda}_\alpha$) the problem for determining $\boldsymbol{\lambda}$ is reduced to solving for $\boldsymbol{\lambda}_\alpha$ independently on every region.

In this way, we arrive at a cavity-approximation style argument common in the motivation of message passing algorithms, see Figure 4. However, it is noteworthy that unlike LBP, incoming messages and responses depend on $\boldsymbol{\lambda}_\alpha$ locally. There is a direct feedback that exists even in the absence of loops.

Unfortunately, $\boldsymbol{\Delta}_\alpha = \mathbf{0}$ remains a (small) system of non-linear equations in $\boldsymbol{\lambda}_\alpha$, that does not allow a closed form solution in general. One exception is when only diagonal constraints are applied (see Yasuda, 2013; Yasuda and Tanaka, 2013), and the cavity argument is applied to single-variable regions. More generally we use Newton's method to solve these equations

$$\left[\frac{\partial \boldsymbol{\Delta}_\alpha(q^*, q^*_{(\cdot)})}{\partial \boldsymbol{\lambda}_\alpha}\right]^{-1} \boldsymbol{\Delta}_\alpha\Big|_{\lambda=\lambda^t} \quad \delta\boldsymbol{\lambda}_\alpha^{t+1} = -\,\boldsymbol{\Delta}_\alpha(q^*, q^*_{(\cdot)})\Big|_{\lambda=\lambda^t} \;, \tag{20}$$

where the dependence of q^* and $q^*_{(\cdot)}$ on λ follows from (??) and (28) with messages fixed.

An alternative expression based on a closed form for the covariance matrix approximation χ is discussed in Appendix C, alongside some other technical details on the determination of λ.

4. Results

In this section, we study the performance of our method on well-understood toy model frameworks. The scale and/or symmetries of these models mean they are exactly solvable, allowing precise statistical estimates to evaluate the method quality.

In Section 4.1 we study a fully connected ferromagnetic model (that is a model with a positive coupling between any pair of variables) with symmetry broken (that is with a non-zero mean value for each variable). This is a simple model for which we can present analytic results and understanding. There is either no mode (for weak coupling), or one dominating mode (for strong couplings). We expect the method to be weakest for intermediate coupling strength since the Bethe approximation becomes exact (with corrections $O(1/N)$) in the limit of strong (a single mode) or weak (no modes) coupling. In Section 4.2 we study a model with frustration (that is couplings have different signs and it is not possible to find a configuration satisfying them all at the same time) and a random distribution of optima and sub-optima. The problem is multi-modal in the limit of strong couplings and the Bethe approximation breaks down. In Section 4.3 we consider a simple model with an expanded discrete alphabet, where randomness is introduced through a random graphical structure. Like the ferromagnetic example, a single mode dominates for strong couplings. We anticipate the Bethe approximation to become exact in the limit of large problems, but for smaller problems the presence of short loops leads to inaccuracy. In the final example of Section 4.4 we consider a well-studied toy model involving both multi-variable interactions and multi-states, both the Bethe approximation and linear response perform poorly on this model. These examples cover a range of scenarios in which our method might be applied. Special cases of the variational approximation we present have previously been applied to lattice models commonly studied in statistical physics, and sparse prior models in Bayesian image modeling (see Raymond and Ricci-Tersenghi, 2013b,a; Yasuda and Tanaka, 2013; Yasuda, 2013).

We present behaviour of the Lagrange multipliers λ, the self-consistency error (13), errors on the pair statistics when using either marginals (14) or linear responses (15), and errors on the marginal estimates

$$\Delta^{(0)}_{(i,y)}(q^*) = q^*(x_i = y) - p(x_i = y) \;.$$

The maximum absolute deviation (MAD) on the marginals is defined as the largest error over all variables, or pairs of variables, depending on error type.

It is interesting to understand how the quality of approximation changes as a function of the goodness of the approximation, to do this we introduce a temperature parameter T in each model, that can sharpen or flatten the distribution.

$$p_T(x) \propto p(x)^{1/T} \;.$$

We can minimize with relative ease both the constrained and unconstrained free energies in the large T regime, and expect approximations to be correct at leading order in $1/T$ (see Raymond and Ricci-Tersenghi, 2013a). In some cases of small T, in which the probability is well described by a single mode, concentrated about some unique value $x_{GS} = \operatorname{argmax} p_T(x)$, the approximations we present are also exact up to $O(T)$ corrections.

We find that in many of the models, minimization of the constrained free energy is slow or impossible for T over some intermediate range, or below some threshold. To extend the range of T for which solutions could be found, an annealing procedure is employed: beginning at large (or small) T and proceeding through a sequence of models slowly changing T, and using the solution to the previous model as the initial condition for the subsequent minimization. Under this procedure, we find that $\lambda(T)$ and the variational parameters q evolve smoothly, but that there appears still to be a limit in the accessible temperature range. In the applications presented we did not find fixed points that appeared discontinuously. Solutions are reached by annealing from low temperature, from high temperature, or are absent.

Our motivation for introducing T is threefold: to study the breakdown of the approximation (absence of solutions), to mitigate for non-convergence, and to increase the speed of convergence. The annealing procedure introduces additional computational costs. We have not made timing comparisons against loopy belief propagation or other competitors, for either the simple or annealed procedure. Instead, we have prioritized an exploration of the nature of solutions that can be discovered, and we have sought very accurate estimates to the parameters describing those solutions. Compromises in the accuracy of constraint satisfaction, annealing rate (or absence of annealing), and damping can all have a significant impact on the speed of the method.

4.1 The Fully Connected Ferromagnet

We begin with a simple but informative case, that of a fully connected ferromagnetic Ising model in an external field.

$$p_T(x) = \frac{1}{Z} \exp\left[\frac{1}{2T}\left(h + \sum_{i=1}^{N} x_i\right)^2\right] . \tag{21}$$

Variables are Ising spins $x_i = \pm 1$. The marginals for this model can be solved up to $O(1/N)$ by the mean-field approximation, and up to $O(1/N^2)$ by the Bethe approximation. Accuracy is a function of temperature; when this is large or small compared to $1/N$, the accuracy is correspondingly high. Under our method the equations to be solved and associated errors can be expressed concisely; this is done in Appendix A.

Three kinds of constraint are considered: diagonal $\{\Delta_{ii} = 0,\ \forall\, i\}$; off-diagonal $\{\Delta_{ij} = 0,\ \forall i \neq j\}$; and on-and-off diagonal applying both sets. Results for both the mean-field and Bethe approximations are presented. Only diagonal constraints can be applied in the mean-field case since the variational parameters are consistent only with zero off-diagonal covariances.

The left panel in Figure 5 shows the behavior of the magnetizations, $\mathbb{E}(x_i)$ for the case $N = 10$ and $h = 1$. The most accurate estimates are obtained with on and off-diagonal constraints applied at the Bethe approximation at high and low temperature. The unconstrained approximations overestimate the magnetization (bias in variables). The addition of constraints corrects this bias: in one constrained regime (off-diagonal constraints only) the suppression is clearly too strong at intermediate T, while in all other cases effective.

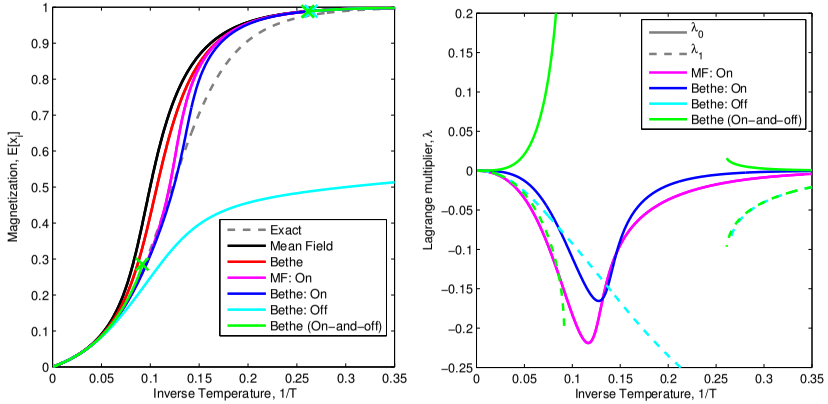

Figure 5: Results for the fully connected model (21) with $N = 10$ and $h = 1$. Results are presented for the mean-field and Bethe approximation schemes, with and without constraints. (left) The magnetization is overestimated in the Bethe and Mean-field approximations, the effect of the constraints is to suppress the magnetization. Certain solutions exist only in the high-temperature or low-temperature regimes, those solutions are demarcated by 'x'. One solution to the Bethe approximation with off-diagonal constraints only suppresses the magnetization too strongly, there is another solution that is present only at low temperature, where the estimate is more reasonable. Where it exists, the Bethe approximation with on and off-diagonal constraints is the most accurate. (right) There are at most two independent values for λ in this model: diagonal λ_0 and off-diagonal λ_1. The Lagrange multipliers deviate most from zero at $T \sim 1/N$ (this is related to a ferromagnetic phase transition). λ diverge rapidly in some solutions demarcating regions where no solutions can be found.

In some constrained approximations there is a smooth evolution of the optimal beliefs with T, which reflects the behavior of the exact marginals. In others, the optimal beliefs for different T are not continuously related.

When off-diagonal constraints are applied in the Bethe approximation, either alongside or without diagonal constraints, we see a discontinuous emergence of the strongly magnetized solution. In the case of only off-diagonal constraints, there is a coexistence of two fixed points for small T. This means that as we vary the parameter T the q^* moves discontinuously from a relatively smooth approximation to one characterized by a single mode. As N increases the domain with coexistence shrinks, and all approximation approach the correct result for large N.

With on and off-diagonal constraints we find a range of T for which no solutions can be found by a continuous evolution of the low or high-temperature solutions. It seems highly likely that no solution exists, and empirically we were not able to find fixed points (for any model) that were not continuously related to either a high or low-temperature solution.

The behaviour of λ (see right panel in Figure 5) and indeed a careful examination of the fixed points indicate why solutions disappear in this simple case. The values of the Lagrange multipliers diverge, and this is related to marginals approaching their boundary values where variational inference breaks down due to the inflexibility of the parameters. By decreasing h or N we decrease the accuracy of the Bethe approximation at intermediate T, this can lead to discontinuity also for the diagonal constrained solution, and reduces the range of temperatures over which the low-temperature solution (the one with a large magnetization) can be found for constrained problems.

4.2 The Wainwright-Jordan Set-up

A common toy model on spin variables $x_i = \pm 1$ is the Wainwright-Jordan set-up where $N = L \times L$ Ising spins are arranged on a square grid (see Opper et al., 2009).

$$p_T(x) = \prod_{(i,j)\in E} \exp(J_{ij} x_i x_j / T) \prod_i \exp(h_i x_i / T) \; .$$

Fields h_i are independent and identically distributed (iid) samples from $[-0.25, 0.25]$ and couplings J_{ij} are sampled i.i.d on $[-1, 1]$. The Bethe approximation fails on these models for smaller T owing to multi-modality of the distribution, but for larger T (where correlations are weaker) the approximation is a significant improvement upon the mean-field approximation.

Diagonal $\{\Delta_{i,i} = 0, \; \forall \; i\}$, or diagonal and off-diagonal $\{\Delta_{i,j} = 0, \forall (i,j) \in E\}$ constraint regimes are studied for the Bethe approximation.

We considered 20 instances for $L = 4$ and $L = 7$, and plot the MAD results in Figures 6 and 7. Shown are the quartiles, for cases where methods did not converge we assigned value +Inf to the MAD so that the quartile values are truncated in cases where the fraction of non-convergent cases exceeded the quartile. For the smaller ($L = 4$) system, the Bethe approximation succeeds for typical cases to full scale ($T = 1$) either without constraints or with only diagonal constraints; the on-and-off diagonal scheme fails in a larger fraction of cases. For the larger ($L = 7$) system, LBP and CLBP fail at full scale: the model which prevails to lowest temperature is CLBP with diagonal constraints; the model failing soonest

is CLBP with on and off-diagonal constraints. The exact range of T for which methods were convergent was sensitive to the annealing procedure, the amount of damping used, and the convergence criteria; strong damping and slow annealing broaden the range for all methods.

Where the algorithm is convergent, there is significant improvement adding diagonal constraints, and more so with on and off-diagonal constraints.We find the improvement in the maximum deviation represents well the changes seen across the entire distribution of marginals in most models, almost all marginals are improved. The quartiles in figures 6 and 7 reflect model to model variations, and demonstrate that the MAD advantage is robust. For $N = 16$, we can compare the median behavior against that reported in Opper, Paquet, and Winther (2009); where the strongest method (tree-EP) also improves the MAD result for marginals by approximately one order of magnitude. Expansion methods offer some further, but modest gains (see Paquet et al., 2009; Opper et al., 2013).

On-diagonal constraints allow an increased range (in T) for convergence. Qualitatively, we offer the following explanation. In the constrained regimes (in the high-temperature regime, the only one for which we demonstrate solutions) the majority of Lagrange multipliers are negative. The effect is to suppress biases and decrease susceptibility (the sensitivity of biases to small changes in the parameters). We assume that reduced susceptibility also correlates with reduced sensitivity to small fluctuations in the messages, which should aid algorithmic stability. With on-and-off diagonal constraints the diagonal and off-diagonal Lagrange multipliers are strongly dependent where they constrain the same variable. The off-diagonal multipliers are typically negative, and suppressing biases; by contrast, the diagonal multipliers are positive and reinforce biases. The typical net effect is to reduce biases and susceptibility, as with the on-diagonal case. However, the strongly correlated nature of the parameters may be the source of convergence problems.

The failure of CLBP is most often due to non-convergence of λ, rather than a failure in the CLBP or CLSP iterative algorithms (at fixed λ). Figure 8 indicates why the iterative update is failing: some Lagrange multipliers are diverging in a strongly correlated manner and it seems likely there is a critical value of T close to the failure point beyond which no solutions exist, as found in Section 4.1.

The LBP implementation follows the same procedure as the constrained cases of Appendix B, with the difference that the innermost do-while loop is always convergent in one iteration, and $\boldsymbol{\lambda} = 0$. Using a double loop procedure we might force convergence to a minimum of the Bethe approximation, but the convergence properties of LBP are still an interesting point of comparison.

We might seek to extend the range of convergence for CLBP by clever modifications. However, it seems that breakdown of convergence is closely related to breakdown of the underlying (Bethe) approximation. Algorithmic innovations would not extend significantly the range of problems for which the constrained approximation is useful in practice; just as the availability of double loop methods has not revolutionized the use of the Bethe approximation: where LBP fails the Bethe approximation is almost always a poor approximation.

For this type of problem a significant improvement to the Bethe approximation is made in moving to a plaquette-based Kikuchi approximations for the case of regular lattices (see Domínguez et al., 2011; Lage-Castellanos et al., 2013). Limited experiments on constrained

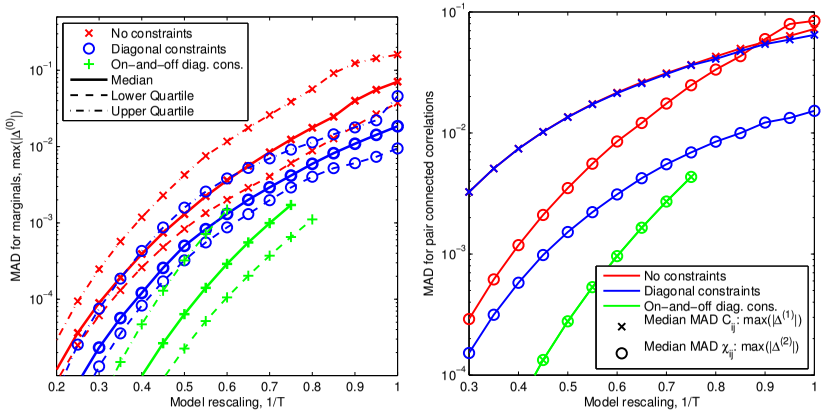

Figure 6: $L = 4$ Wainwright-Jordan set-up: The error on the marginals, and connected correlations (which together provide a sufficient description of pair probabilities) are improved everywhere by adding constraints, as long as the method converges. As discussed, the MAD for C_{ij} is worse than for χ_{ij}, although they are becoming comparable approaching $T = 1$. On the right the median over 20 models is shown, on the left the median and quartiles. The advantage is consistent across all models.

Kikuchi approximations also indicate a modest decrease in error on marginals with the application of constraints.

4.3 Potts Model in an External Field

Next we consider random 3-regular graphs $G = \{V, E\}$ of $N = |V|$ variables, where each variable is allowed 3 states: $x_i \in \{0, 1, 2\}$. The problems are defined by the probability

$$p(x) \propto \prod_{(ij)\in E} \exp\left(J_{ij}\delta_{x_i,x_j}/T\right) \prod_{i\in V} \exp\left(4\delta_{x_i,0}/T\right) \ ,$$

where couplings are i.i.d. random variables $J_{ij} \in \{-1, 1\}$. An example of a corresponding factor graph is shown in Figure 1 (lower panel). Like the fully connected Ising model, typical instances of this model are solved at leading in order in N by the Bethe approximation, with finite size effects strongest at intermediate temperatures. At high temperature, the probability is relatively flat and disperse, whereas at low temperatures there is a single dominating mode concentrated about the value $\mathbf{0} = \text{argmax}_x\, p(x)$.

We consider a diagonal constrained Bethe approximation: a set of 4 non-redundant statistic pairs are constrained per variable.

Figure 9 demonstrates that in graphs of size $N = 40$, the MAD on $p(x_i)$ is significantly improved with the addition of diagonal constraints. Furthermore, we see that as the Bethe approximation becomes accurate (high and low temperature, or large N) it becomes easier to enforce the constraints, as indicated by smaller values for the Lagrange multipliers.

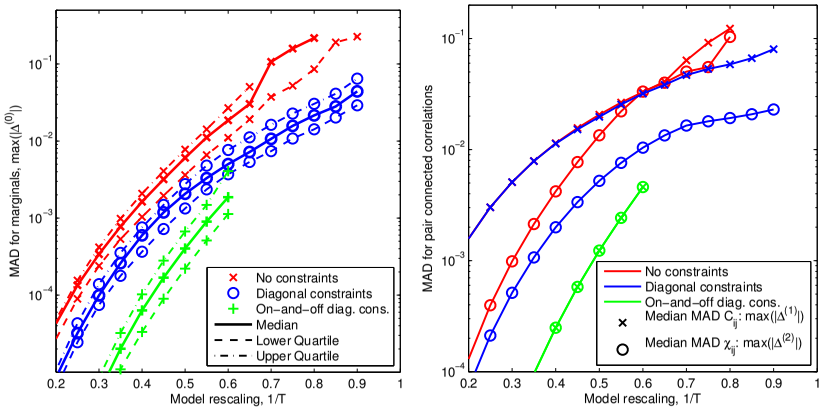

Figure 7: $L = 7$ Wainwright-Jordan set up: Trends are comparable to the smaller system in Figure 6. Where solutions exist, significant gains are made in all models with the addition of constraints. However, all approximations are now failing to reach full scale ($T = 1$). The method which is stable to lowest temperature is the model with diagonal constraints only, while the one with on-and-off constraints is the most accurate.

4.4 The Alarm Network

The alarm net is a pedagogical example of a graphical model that has been studied in the context of loop correction algorithms and is available in libDAI repository (see Mooij et al., 2007; Mooij, 2010). It has 37 variables, each variable takes either 2, 3 or 4 states (a mixture of Ising and Potts spins). Variables have biases, and participate in 2, 3 and 4 point interactions as shown in Figure 1 (upper graph). The model involves a mixture of factor types and variables. The Bethe approximation performs relatively poorly, due to short loops. We can again add a temperature and consider solutions up to the full scale $T = 1$ that defines the model.

Two constraint regimes were applied: in the first pure-diagonal constraints were applied: $\{(i, y), (i, y) : \forall i, y\}$, and in the second all block-diagonal constraints were applied $\{(i, y_1), (i, y_2) : \forall i, y_1, y_2\}$. The ability of both methods to improve local statistics were comparable and modest; for both the local diagonal and off-diagonal statistics as shown in Figure 10. Other schemes such as tree-EP and LCBP show improvements of one or two orders of magnitude on this problem (see Mooij et al., 2007; Opper et al., 2009). However, the Bethe approximation and linear response estimates are known to be poor on this model, so it is not a surprise to see modest gains for our scheme.

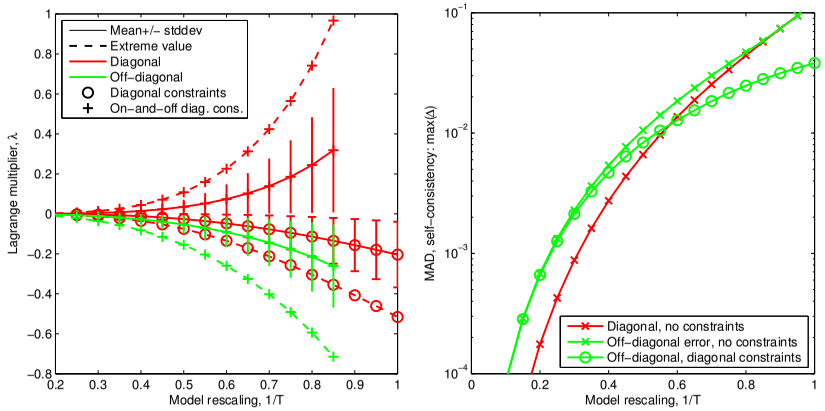

Figure 8: A typical problem in the Wainwright Jordan set up for $N = 16$. (left) Negative λ has the effect of effectively reducing the coupling strength; as with the fully connected ferromagnetic model, a mode of failure for the approximation is to over-estimate the bias in variables, and constraints appear to work by mitigating this effect. Bars indicate the 3 quartiles of the distribution, and the extremal values are also plotted. In the Bethe approximation with only diagonal constraints, most λ including the extremal value are negative. With on and off-diagonal constraints λ with a net effect of reducing interaction strength, values diverge approaching the point of algorithmic failure. (right) Adding diagonal constraints not only removes the diagonal self-consistency error, but also reduces the error in the unconstrained (off-diagonal) statistic. Adding both on and off diagonal constraints removes inconsistency for both types. The self consistency errors (13) grow with decreasing temperature.

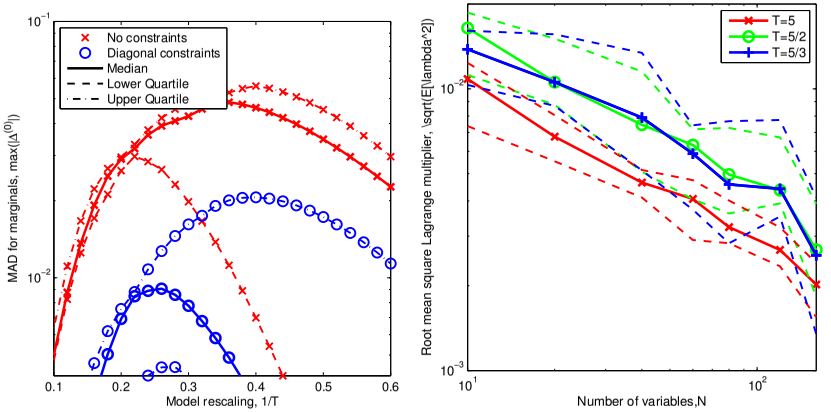

Figure 9: Errors and Lagrange multipliers are shown for the 3-states Potts model on 3-regular random graphs. (left) The diagonal constraint regime yields a significant improvement in maximum absolute deviation of $p(x_i)$ over the raw approximation on graphs with $N = 40$. (right) The Bethe approximation improves as $N \to \infty$ at all temperatures (due to the disappearance of many short loops). The Lagrange multipliers enforcing diagonal consistency typically decrease (in mean squared value) as system size increase. Quartiles are based on at least 20 samples per system size.

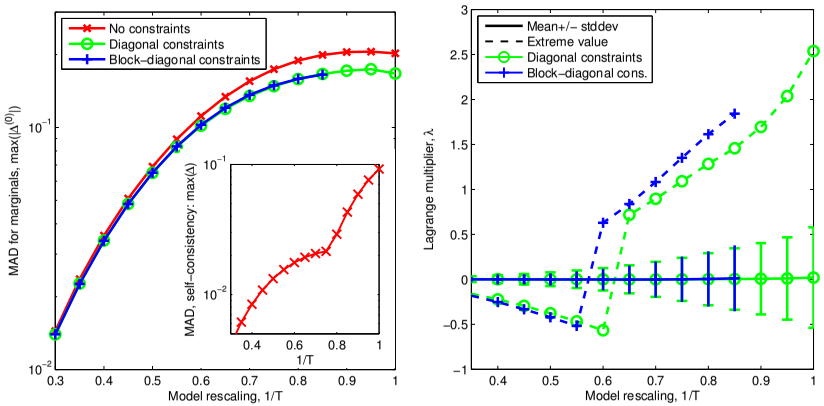

Figure 10: Results for the alarm network. (left) The diagonal and block-diagonal constraint regimes have indistinguishable performance in the MAD for $p(x_i)$, and improve modestly on the unconstrained problem. (inset) At intermediate T there is a qualitative change in the self-consistency error, as some variable subsets become strongly polarized. (right) The values for λ are for the most part small, with extreme values diverging as T approaches 1; a mixture of positive and negative Lagrange multipliers are required to enforce constraints.

5. Discussion

The aim of this paper is to show that for a range of models and variational methods we can have improved accuracy in marginal estimates by inclusion of a set of self-consistent constraints, and to propose this as a general mechanism by which to improve approximations with inconsistency between marginalization (first derivative) and linear response (second derivative) approximations.

We have expanded upon results for rather simple approximations, in easy to understand model frameworks: the marginals are improved in all cases, and in many scenarios by amounts measurable in orders of magnitude. The combination of a weak approximation method with constraints may result in there being no solutions and in marginal cases in a slow convergence of our proposed algorithm. On the other hand, if we are looking for a mechanism by which to leverage a good approximation this approach seems appropriate.

An interesting direction for investigation would be understanding whether partially reducing the violation, rather than eliminating it, might yield comparable results within a more robust algorithmic framework. There are two possibilities: (1) softening the constraint, introducing a penalty term that increases with $|\Delta|$ rather than requiring strict compliance; (2) expanding the range of solution existence by bounding λ. This would presumably maintain a large part of the method advantage by removing some pathologies. Further work could also relate to the choice of constraints, especially for non-Ising models

where the number of statistics available to constrain is large. Two directions are proposed in Appendix B.2.

Some powerful approximation methods are not variational and so the insight we provide cannot be leveraged. In other cases there is no inconsistency to exploit, this is true of adaptive-TAP and some moment matching methods. These have variational free energy frameworks, but by the Gaussian approximations therein used, there is a consistency of pairwise approximations, making redundant the constraints we suggest. This is in line with our thinking that good approximations should not violate these constraints.

We believe our method also sheds light on, or is inclusive of, previous attempts to leverage linear response. Consider the region-based free energy built on the set of regions indicated by Figure 2(d). Every outer region is a hub surrounded by leaves, and if we add constraints over the leaves within each region, a linear expansion in the Lagrange multipliers agrees with the linear expansion obtained in the scheme of Montanari and Rizzo (2005); however, outside of the linearized regime there are important differences.

There are three reasons one might not want to improve a variational approximation by adding self-consistency constraints: 1) The cost of the method which is dominated by a linear response evaluation (a cost that can be as large as $O(N^2)$ using susceptibility propagation), might be prohibitive in some applications. 2) Introducing such constraints may prevent the existence of any solutions (the method may reveal the uncomfortable truth that the approximation used is quite bad). 3) Even where a fixed point exists, it may be slow to reach it using a local iterative scheme for λ such as (20).

6. Conclusion

We have demonstrated that adding covariance constraints, which make the linear response and marginalization estimates consistent, improves the performance of the Bethe approximation for a variety of simple model types. We have argued this is true more generally of variational frameworks, and have provided an algorithmic framework for mean-field and region-based frameworks, generalizing previous results. The regimes of adding all possible constraints (on-and-off diagonal) and adding constraints only over single variable covariances (diagonal) were examined. The former tends to lead to better results, whilst the latter is simpler to implement and can yield solutions across a broader range of models.

The usefulness of this paper is not in the specific algorithm developed, but in the principle of statistical consistency. We hope it might be extended to other variational frameworks in which inconsistencies exist between first and second derivative estimates. We have presented and tested an algorithmic framework; the framework can solve the constrained free energy where solutions exist, but a rather expensive (annealed in T) procedure was exploited to obtain our results. Further work is required to make this reliable and competitive with state of the art marginal estimation.

Appendix A. Exact Expressions for the Fully Connected Ising model

It is straightforward to calculate the exact marginal distributions for (21), for any pair of variables

$$p_T(x_i,x_j) \propto \sum_{n=0}^{N-2} \binom{N-2}{n} \exp\left[\frac{(h+[N-2-2n])^2}{2T} + \frac{1}{T}x_i x_j + \frac{h+[N-2-2n]}{T}(x_i+x_j)\right] .$$

By contrast in the Bethe approximation

$$q_{ij}(x_i,x_j) \propto \exp\left[\frac{1}{T}x_i x_j + \frac{h_{\rightarrow}}{T}(x_i+x_j)\right] , \tag{22}$$

where the log-ratio messages $h_{\rightarrow}$ are defined as the solution to

$$h_{\rightarrow} = h + (N-1)T\text{atanh}\left[\tanh(1/T)\tanh(h_{\rightarrow}/T)\right] ; \qquad h_{\rightarrow} = \frac{1}{2}\log\left(\frac{\mu_{i\rightarrow(ij)}(1)}{\mu_{i\rightarrow(ij)}(-1)}\right) .$$

Since we will place constraints on $\mathbb{V}_q(x_i,x_j)$ a convenient parameterization for the pair probability in our approximation will be

$$q_{ij}(x_i,x_j) = \frac{(1+M_i x_i)(1+M_j x_j) + C_{ij}x_i x_j}{4} . \tag{23}$$

We can restrict attention to symmetric solutions $M_i = M$ and $C_{ij} = C$, similarly at most two distinct Lagrange multiplier values need be considered: $\lambda_{i,i} = \lambda_0$, when diagonal constraints are applied, and $\lambda_{i,j} = \lambda_1$ when off-diagonal constraints are applied. Minimizing the variational free energy (17) with respect to M and C leads to the following pair of equations

$$0 = -[(n-1)M/T + \lambda_0 M] + \text{atanh}(M) + (N-1)\sum_{x_1,x_2}\frac{x_1}{2}q_j(x_2)\log\left(\frac{q_{ij}(x_1,x_2)}{q_i(x_1)}\right) , \tag{24}$$

$$0 = -[1/T - \lambda_1] + \sum_{x_1,x_2}\frac{x_1 x_2}{4}\log q_{ij}(x_1,x_2) . \tag{25}$$

If we solve this pair of equations for $\lambda = 0$, we find an alternative representation of (22). Explicit expressions for the covariance matrix approximation χ are derived in Raymond and Ricci-Tersenghi (2013b) and Raymond and Ricci-Tersenghi (2013a), these can be concisely expressed in the inverse as

$$[\chi^{-1}]_{i,j} = \begin{cases} \frac{1}{1-M^2}\left[1+(n-1)\frac{C^2}{(1-M^2)^2-C^2}\right] - \lambda_0 & \text{if } i=j . \\ -1/T + \sum_{x_1,x_2}\left[\frac{x_1 x_2}{4}\log q_{ij}(x_1,x_2)\right] - \frac{C}{(1-M^2)^2-C^2} & \text{otherwise.} \end{cases}$$

Abbreviating $\chi^{-1}_{i,i} = a$ and $\chi^{-1}_{i,j(j\neq i)} = b$ we can write the components of the covariance matrix approximation

$$\chi_{i,j} = \frac{1}{(a-b)(a+(N-1)b)} \begin{cases} a+(N-2)b & \text{if } i=j . \\ -b & \text{otherwise.} \end{cases}$$

Thus we have up to four parameters $\{M, C, \lambda_0, \lambda_1\}$, depending which constraints are applied. We solve (24) and (25) in combination with either, or both, $(1-M^2 = \chi_{i,i})$ and $(C_{ij} = \chi_{i,j})$. These are non-linear equations in M, C and λ_0; we resort to local search to find solutions; solutions are possible by expansions at small or large T, or for large N. For the solution to be valid, we also check that the Hessian is positive definite, and that $p(x_i,x_j) \geq 0$.

Solutions for the equations are trivial for large or small T, and approach the solutions of the unconstrained approximation. By slowly varying T we can discover the solutions that evolve continuously from these two fixed points. We did not find any solutions appearing discontinuously, nor did we find any evidence for symmetry breaking (that is solutions in which the magnetizations, or correlations, differed by label index).

It is also straightforward to apply the same methodology for the mean-field approximation: there is one saddle-point equation, (24) with $C = 0$; and up to one type of covariance constraint ($\chi_{i,i} = 1-M^2$), where the inverse covariance matrix elements become $[\chi^{-1}]_{i,j} = -1/T$, and $[\chi^{-1}]_{i,i} = 1/(1-M^2) - \lambda_0$.

Appendix B. Algorithm for Finding Optimized Lagrangian Parameters, and the Linear Responses

Our approach to find solutions depends on their existence, this is discussed generically before we consider the impact of constraint selection strategies (and constraint representation) on solution existence and algorithmic stablity. We then show that an exact method for minimizing the Lagrangian exists for some fixed values of the Lagrange parameters λ. The CLBP and CLSP algorithms are then presented in pseudocode. Finally, we discuss heuristics for the calculation of λ.

B.1 Existence

Certain models are known to be solved at leading order in some control parameter by region-based, Bethe or mean-field approximation. Examples are ferromagnetic random graphs or fully connected models in the limit of large number of variables (N), arbitrary models in the weakly interacting limit (also called high temperature T), finite models in the limit of strong biases on the variables (h). In these models, we find, of course, that the deviation between the linear response and marginal estimates are small in the corresponding control parameter. Expanding in this parameter (for example $1/T$, $1/N$) it is straightforward to show the existence of solutions, and quantify the effectiveness of the constraints (see Raymond and Ricci-Tersenghi, 2013a). However, even outside the regime where expansions about the Bethe approximation are appropriate, we find solutions: this includes models where the covariance matrix has divergent terms, due to a mean-field phase transition as described in Raymond and Ricci-Tersenghi (2013b).

However, in experiments, we present it is shown that variation of the temperature (which controls the smoothness of the probability) can lead to models with no solutions, for some constraint sets. In the case of both on and off-diagonal constraints in Ising models defined on some graph $G = \{V, E\}$, with $|V|$ variables and $|E|$ edges, we have $|E|+|V|$ variational parameters but also $|E|+|V|$ constraints—solving a system of non-linear equations where the number of parameters matches the number of constraints seems optimistic; and perhaps it should not be surprising that as the Bethe approximation breaks down solutions fail to

exist; applying all constraints is certainly a marginal case unless some are redundant. If we move to alphabets with more than 2 states per variable the number of pair-statistics for on-and-off diagonal constraints exceeds the number of variables (with no obvious redundancy); certainly such a system can have no solutions. We must think carefully on which constraints to implement, and this is discussed in Appendix B.2.

In the experiments of this paper we have introduced for all models the control parameter T, with all models being well approximated by Bethe (and Mean-field) approximations in the weak coupling limit ($T \to \infty$), and some models also being well approximated in the strong coupling limit ($T \to 0$). To extend the regime in which our algorithms are convergent, an annealing approach was taken—slowly increasing $1/T$ (or T) and following a solution which evolved continuously in the marginals and Lagrange multipliers from the exactly solved regime. In many cases, solutions were found to reach a critical point T^* beyond which they could not be continuously evolved to new solutions. At these points we invariably found no new solutions emerging discontinuously by simply iterating our procedures. By undertaking annealing, it would in principle be possible to miss some solution that emerges discontinuously; the example of Section 4.1 shows this is possible (there is coexistence of two solutions at low temperature for the case of off-diagonal constraints only), but in the other examples of this paper we found no evidence for this. We expect in most practical applications, and for good choices of the constraints, coexistence will be absent.

A common feature in solution discontinuity during annealing is the divergence of some Lagrange multiplier(s); this indicates that the failure was due to inviability of solutions rather than a breakdown of algorithmic dynamics. Unlike the Bethe approximation, which can be forced to converge to a local minimum at any T, replacing LBP by a convex-concave procedure. We speculate that the constrained free energy has no solutions in strongly coupled regimes and that where practical solutions do exist the cavity based algorithms will be sufficient if combined with appropriate damping and/or annealing.

B.2 Selection of Constraints for Best Solutions

In this section we consider reasonable choices for the constraints, assuming a solution existents, and algorithmic convergence is possible.

Since we are applying constraints to discrete models it is clear that the apriori constraints selection should be independent of the labeling convention. Furthermore, we note that we made the rather arbitrary choice in (2) of perturbations in the set of statistics $\{\delta_{x_i,y} : y = 1 \dots Y\}$, Y being the number of states. Whilst this is invariant under relabeling, and spans all possible perturbation directions (and one redundant direction $\sum_y \delta_{x_i,y}$), we might get different covariances according to our choice. It would seem sensible to choose our constraint regime so that any set of statistics that spans the set of perturbations yields the same result. To achieve this we must pick a complete basis $\{\phi\}$, and apply constraints on all-covariance pairs.

The consideration of bases motivates the regimes we have explored: diagonal, off-diagonal, on-and-off diagonal. These schemes are basis-independent. If the condition $C_{(i,\cdot),(j,\cdot)} = \chi_{(i,\cdot),(j,\cdot)}$ is met in one basis for all elements, then a change between two (orthonormal) basis is a rotation, and the identities remain intact.

We found that off-diagonal typically performed worse than on-diagonal, as well as being computationally more challenging. In the final experiment of Section 4.4 we also tried one basis dependent set of constraints, the so-called *pure-diagonal* regime. Despite breaking the paradigm of basis independence, it performed just as well as the *block-diagonal* regime that is basis independent, so this indicates that basis independence is not an essential feature in constraint selection.

Topological distinctions amongst constraints can also be made. In a region-based approximation, we can distinguish the "2-core" from the rest of the graph. The 2-core is the set of variables that are found by recursively removing variables that are involved in at most one "outer region" (generalized interaction). We advise constraining variables on the 2-core only. The reason for this is that the set of variables that are not in the 2-core form a forest—a set of disconnected trees for which the approximation is conditionally exact even without constraints. If we have the core correct, then other constraints will be redundant. It is only in the case of the alarm net (Figure 1, Section 4.4) that the 2-core is distinguished from the full graph and we make this approximation. Other topological distinctions could be applied, distinguishing constraints by the distance between variables might be one possibility (in Figure 2(b) for example there are nearest, and next nearest neighbors within the regions); however, in the Bethe approximation (all experiments we present) only nearest neighbors might be constrained so the example is mute.

Beyond these considerations, we did not attempt to further restrict the set of constraints in a model specific manner, but several options might be worth exploring, in particular: (1) Consider the covariance matrix restricted to a single variable "block", $\chi_{(i,\cdot),(i,\cdot)}$. For a given approximation (for example Bethe) there is a unique orthonormal basis $\{\phi_i\}$ that diagonalizes the covariance matrix. This would provide a natural choice for the statistic basis. The eigenvalue-vector pairs determine which direction is most susceptible to a change in parameters, and so (loosely speaking) most sensitive to approximation errors. We might, therefore, rank constraints by this eigenvalues for inclusion. (2) If we can solve the problem to obtain q_i^*, then we can consider defining only one perturbation statistic per variable as $\phi(x_i) \propto \log(Yq^*(x_i))$. Since we know approximations tend to be overconfident, it would seem a natural choice to constrain in line with the belief, rather than wasting resources on unimportant directions in parameter space.

B.3 Assignment of Constraints to Regions, and Basis selection, for Best Convergence

For our constraint regimes (diagonal, on-diagonal and on-and-off diagonal), the allocation of constraints to specific regions, the choice of statistical basis, the initial condition of the algorithm and the damping, leave the algorithmic fixed points unchanged. Owing to our slow annealing approach (increasing or decreasing T) our results were not very sensitive to the other implementation details. However, these choices do impact convergence significantly.

We find that a non-redundant orthonormal set of statistics leads to faster convergence. Orthonormality ensures that, at leading order, the Lagrange multipliers are independent of one another, which is the criterium that guarantees the success of our method. A redundant statistic is $\phi(x_i) = \sum_{y=0}^{Y-1} \delta_{x_i,y}$, where x_i has Y states, and so only $Y-1$ orthonormal

statistics need be implemented. A nice approach to the selection of an orthonormal basis is discussed in Yasuda (2013), for Ising spins, a unique choice per variable is x_i.

We allocated constraints in a naive manner, assigning each constraint to the first available "outer region". For diagonal constraints an approach where constraints are allocated to single-variable regions was proposed by Yasuda et al., and this allows some simplifications as well as implying a unique allocation (see Yasuda, 2013). Approaches that do not allocate constraints to regions, such as iteration by linear expansion of the covariance matrix have been attempted (29), but those were slower to converge.

As a general rule, we wish to group Lagrange multipliers together as much as possible. In this way, correlations amongst the Lagrange multipliers are accounted for locally. A potentially better approach than our fixed assignment suggestion might be to update all Lagrange within some outer region. Where a constraint could be allocated to more than one region, the results could be averaged, or regions could be selected differently on each cycle to avoid conflicting assignments.

A damping factor that begins as 1 and decreases during the annealing procedure (as required to enable convergence) is applied in the experiments. In simulations without an annealing scheme, a rate $\lesssim 0.5$ could be essential to prevent oscillations that arise from correlated updating of Lagrange multipliers. In particular, off-diagonal values λ_{ij} and diagonal values λ_{ii} can be anti-correlated. If they are not updated on the same region undamped iteration can lead to slow convergence or oscillations.

Initial conditions are chosen as $\lambda = 0$; so that the first iteration is equivalent to an unconstrained approximation. One advantage of the annealing approach (where we first solve the trivial model $T = 0$ or $+\infty$, and then increase or decrease T, initializing by the current solution), is that we do not require the convergence of the unconstrained approximation to find a solution in the constrained regime.

B.4 Convex Concave Procedure

We prove that it is possible to minimize (16) in q by a convex-concave decomposition. In Heskes, Albers, and Kappen (2003) by introducing auxiliary parameters q' over the inner regions, a pair of convex optimization procedures were developed that led to minima of the region based free energy. With the addition of our constraints, we only need to make a minor modification to their argument. Consider an auxiliary free energy $F(q, q')$, where q' are additional parameters in one to one correspondence with the original variational parameters. Heskes et al. outline three requirements of this free energy

1 Convexity of $F(q, q')$ with respect to q.

2 $F(q, q' = q) = F(q)$

3 $F(q, q') \geq F(q)$

that guarantee that the iterative procedure

$$q'_{t+1} = \text{argmin}_q F(q, q'_t) \; , \tag{26}$$

converges to values that are minimizing arguments of $F(q)$.

Since the violation term (13) is a quadratic function of the variational parameters $q(x_\alpha)$, it can be expressed by a constant A_0, a vector of linear coefficients A_1 and quadratic coefficients A_2 that define a symmetric matrix. A_2 can be decomposed as a positive definite and negative semi-definite part (A_2^+ and A_2^-). It is then easy to define a function in vector notation

$$\Delta^+(q, q', q^*_{(\cdot)}) = A_0(q^*_{(\cdot)}) + q^T A_1 + (q')^T A_2 q' + (q - q')^T A_2^+ (q - q') \; . \tag{27}$$

To minimize our region-based free energy with constraints (16) we substitute (27) for (13) and follow the procedure in Heskes, Albers, and Kappen (2003) for the remaining terms. The free energy meets the criteria for convergence under the iterative scheme (26).

The double loop procedure, despite not changing the asymptotic complexity of message passing $O(N)$ is often considered impractical, but, in the framework we are proposing, the largest cost is the evaluation of the linear response, implementing a double loop procedure may be sensible. In practice we have used the variation on loopy belief propagation, rather than the double-loop procedure, to extremize the Lagrangian. Despite the absence of theoretical guarantees, the 3-fold scheme proves to be reliable: solving for variational parameters (by CLBP); solving for the linear response (by CLSP); and update of the Lagrange multipliers.

B.5 Pseudocode for Determining the Fixed Point of q Given λ

We determine q by the constrained loopy belief propagation (CLBP) algorithm, described in Algorithm 1, which is a modified form of the Heskes, Albers, and Kappen (2003) loopy belief propagation algorithm, that uses the convex-concave procedure with guaranteed convergence.

In Algorithm 1 we consider an auxiliary region interaction including both interactions and the Lagrange multiplier terms

$$\psi_\alpha(x_\alpha; \boldsymbol{\lambda}_\alpha, q_\alpha) = \psi_\alpha(x_\alpha) \prod_{[(i,s_1),(j,s_2)] \in \omega_\alpha} \exp\left\{ -\lambda_{(i_1,y_1),(i_2,y_2)} \hat{\phi}_{(i_1,y_1),(i_2,y_2)}(x_\alpha; q_\alpha) \right\} \; ,$$

and

$$\hat{\phi}_{(i_1,y_1),(i_2,y_2)}(x_\alpha; q_\alpha) = \left(\delta_{x_{i_1},y_1} - \mathbb{E}_{q_\alpha}(\delta_{x_{i_1},y_1}) \right) \left(\delta_{x_{i_2},y_2} - \mathbb{E}_{q_\alpha}(\delta_{x_{i_2},y_2}) \right) + \mathbb{E}_{q_\alpha}(\delta_{x_{i_2},y_2}) \mathbb{E}_{q_\alpha}(\delta_{x_{i_1},y_1}) \; .$$

Simplified expressions for the Ising model are presented in the main text. Terms here have an interpretation compatible with Heskes, Albers, and Kappen (2003), with U are the set of *outer regions*, and V are the set of intersection regions (see Figure 2). In the case of a Bethe approximation U are the set of edges, and V are the set of variables.

B.6 Linear Response about the Fixed Point

By linearizing the CLBP method, we obtain a constrained loopy susceptibility propagation (CLSP) method. Qualitatively similar is the I-SUSP algorithm of Yasuda and Tanaka (2013), which applies only to the case of diagonal constraints and the Bethe approximation.

The implementation we use follows Algorithm 1, but with the following replacements for each equation (in order):

$$\begin{aligned}
\delta\hat{q}_\alpha(x_\beta) &= \sum_{x_{\alpha \setminus \beta}} \frac{q_\alpha(x_\alpha)}{q_\beta(x_\beta)} \delta\hat{q}_\alpha(x_\alpha) \; ; \\
\delta\hat{\mu}_{\alpha \to \beta}(x_\beta) &= \delta\hat{q}_\alpha(x_\beta) - \delta\hat{\mu}_{\beta \to \alpha}(x_\beta) \; ; \\
\delta\hat{q}_\beta^{(num)}(x_\beta) &= \sum_{\alpha \supset \beta} \delta\hat{\mu}_{\alpha \to \beta}(x_\beta) \; ; \\
\delta\hat{q}_\beta(x_\beta) &= \delta\hat{q}_\beta^{(num)}(x_\beta) - \sum_{x_\beta} q_\beta(x_\beta) \delta\hat{q}_\beta^{(num)}(x_\beta) \; ; \\
\delta\hat{\mu}_{\beta \to \alpha}(x_\beta) &= \delta\hat{q}_\beta(x_\beta) - \delta\hat{\mu}_{\alpha \to \beta}(x_\beta) \; ; \\
\delta\hat{q}_\alpha^{(num)}(x_\alpha) &= \frac{\delta_{x_i, y} \mathbb{I}(i \in \alpha)}{k_i} + \sum_{\beta \subset \alpha} \delta\hat{\mu}_{\beta \to \alpha}(x_\beta) \\
&+ \sum_{x'_\alpha} q_\alpha(x'_\alpha) \delta\hat{q}_\alpha(x'_\alpha) \frac{\partial \log \psi(x_\alpha; \boldsymbol{\lambda}_\alpha, q_\alpha)}{\partial q_\alpha(x'_\alpha)} \; ; \\
\delta\hat{q}_\alpha(x_\alpha) &= \delta\hat{q}_\alpha^{(num)}(x_\alpha) - \sum_{x'_\alpha} q_\alpha(x'_\alpha) \delta\hat{q}_\alpha^{(num)}(x'_\alpha) \; ;
\end{aligned}$$

where $\mathbb{I}(i \in \alpha)$ is an indicator function evaluating to one if i is contained in α, and k_i is the number of outer regions containing i. From the converged quantities we can identify

$$q^*_{\alpha,(i,y)}(x_\alpha) = q_\alpha(x_\alpha) \delta\hat{q}_\alpha(x_\alpha) \; . \tag{28}$$

Since the linear response is a linearized method, the innermost do-while loop of Algorithm 1 could be replaced by a method for solving linear equations. Both have been tried with similar outcomes.

Appendix C. Solving for λ, Explicit Expressions and Simplification

The diagonal update scheme of I-SUSP relies on a similar reasoning as that undertaken in Yasuda and Tanaka (2013) and Yasuda (2013). The difference between the two approaches is that in the works by Yasuda et al. only diagonal constraints (restricted to single variable consistency relations) are considered. As such it is possible to choose in general a single variable cavity i, rather than a region cavity α (see Figure 4). To consider statistics not restricted to single variables our scheme is required. The I-SUSP method has an advantage over our method in that there is a simplification of the expressions on a single variable region that allows a closed form for updating the Lagrange multipliers. One advantage of our scheme is that we may fix several Lagrange multipliers on a region simultaneously, thus accounting for correlations in their values, and perhaps reducing the number of updates to convergence.

In practice, damping within the 3-cycle of Figure 3 can be necessary for convergence. In practice, we replace $\lambda^{t+1} = d\lambda^t + (1-d)\lambda^*$, where λ^* is the cavity approximation. As $1/T$ was increased (or decreased) at a constant rate we increased d whenever the solution failed to converge, and this modification extended the region of convergence.

An exact expression for the correlation matrix χ as a function of the variational parameters was derived in Raymond and Ricci-Tersenghi (2013b) and Raymond and Ricci-Tersenghi (2013a), the special case for homogeneous graphs is made explicit (Appendix A). The inverse covariance matrix χ^{-1} is, in the basis where variational parameters are beliefs q, a linear function of λ. Updating a single λ can be achieved by the Shermann-Morrison formula, which in its linearized form becomes

$$\chi_{i,i}\,\delta\lambda_{i,j}\,\chi_{j,j} = (C^*_{i,j} - \chi_{i,j})\ . \tag{29}$$

It is also possible to write a similar expression blockwise (over $\boldsymbol{\lambda_\alpha}$). This scheme and variations were considered, but were found to require more iterations or stronger damping (for convergence) than the linearized cavity formula (20).

In our approach we associate each constraint to a unique region, but some statistics such as $\mathbb{V}_p(x_i, x_i)$ may be approximated by different α for the same variational approach (for example by q_{ij} or q_{ik} if i participates in two interactions). Though these estimates agree finally at the solution point, they disagree at intermediate stages of CLBP. Since updates for λ may be correlated (consider Figure 8 where diagonal and off-diagonal are strongly anti-correlated), the grouping of λ may be very important. Updating non-disjoint sets and averaging over results may be more stable than our scheme where closely correlated λ (for example $\lambda_{i,i}$ and $\lambda_{i,j}$) may be updated on different regions.

Abstract

Recurrent neural networks (RNNs) have drawn interest from machine learning researchers because of their effectiveness at preserving past inputs for time-varying data processing tasks. To understand the success and limitations of RNNs, it is critical that we advance our analysis of their fundamental memory properties. We focus on echo state networks (ESNs), which are RNNs with simple memoryless nodes and random connectivity. In most existing analyses, the short-term memory (STM) capacity results conclude that the ESN network size must scale linearly with the input size for unstructured inputs. The main contribution of this paper is to provide general results characterizing the STM capacity for linear ESNs with multidimensional input streams when the inputs have common low-dimensional structure: sparsity in a basis or significant statistical dependence between inputs. In both cases, we show that the number of nodes in the network must scale linearly with the information rate and poly-logarithmically with the input dimension. The analysis relies on advanced applications of random matrix theory and results in explicit non-asymptotic bounds on the recovery error. Taken together, this analysis provides a significant step forward in our understanding of the STM properties in RNNs.

Keywords: short-term memory, recurrent neural networks, sparse signal recovery, low-rank recovery, restricted isometry property

1. Introduction

Recurrent neural networks (RNNs) have drawn interest from researchers because of their effectiveness at processing sequences of data (Jaeger, 2001; Lukoševičius, 2012; Hinaut et al., 2014). While deep networks have shown remarkable performance improvements at task such as image classification, RNNs have recently been successfully employed as layers in conventional deep neural networks to expand these tools into tasks with time-varying data (Sukhbaatar et al.; Gregor et al., 2015; Graves et al., 2013; Bashivan et al., 2016). This inclusion is becoming increasingly important as neural networks are being applied to a growing variety of inherently temporal high-dimensional data, such as video (Donahue et al., 2015), audio (Graves et al., 2013), EEG data (Bashivan et al., 2016), two-photon calcium imaging (Apthorpe et al., 2016). Despite the growing use of both deep and recurrent networks, theory characterizing the properties of such networks remain relatively unexplored. For deep neural networks, much of the computational power is often attributed to flexibility in learned representations (Mallat, 2016; Vardan et al., 2016; Patel et al., 2015). The power of RNNs, however, is tied to the ability of the recurrent network dynamics to act as a distributed memory substrate, preserving information about past inputs to leverage temporal dependencies for data processing tasks such as classification and prediction. To understand the success and limitations of RNNs, it is critical that we advance our analysis of the fundamental memory properties of these network structures.

There are many types of recurrent network structures that have been employed in machine learning applications, each with varying complexity in the network elements and the training procedures. In this paper we will focus on RNN structures known as echo state networks (ESNs). These networks have discrete time continuous-valued nodes $\boldsymbol{x}[n] \in \mathbb{R}^M$ that evolve at time n in response to the inputs $\boldsymbol{s}[n] \in \mathbb{R}^L$ according to the dynamics:

$$\boldsymbol{x}[n+1] = f(\boldsymbol{W}\boldsymbol{x}[n] + \boldsymbol{Z}\boldsymbol{s}[n] + \boldsymbol{\epsilon}[n]), \tag{1}$$

where $\boldsymbol{W} \in \mathbb{R}^{M\times M}$ is the connectivity matrix defining the recurrent dynamics, $\boldsymbol{Z} \in \mathbb{R}^{M\times L}$ is the weight vector describing how the input drives the network, $f(\cdot) : \mathbb{R}^M \to \mathbb{R}^M$ is an element-wise nonlinearity evaluated at each node and $\boldsymbol{\epsilon}[n] \in \mathbb{R}^M$ represents the error due to potential system imperfections (Jaeger, 2001; Wilson and Cowan, 1972; Amari, 1972; Sompolinsky et al., 1988; Maass et al., 2002). In an ESN, the connectivity matrix $\boldsymbol{W}$ is random and untrained, while the simple individual nodes have a single state variable with no memory. This is in contrast to approaches such as long short-term memory units (Sak et al., 2014; Lipton et al., 2016; Kalchbrenner et al., 2016) which have individual nodes with complex memory properties. As with many other recent papers, we will also focus on linear networks where $f(\cdot)$ is the identity function (Jaeger, 2001; Jaeger and Haas, 2004; White et al., 2004; Ganguli et al., 2008; Ganguli and Sompolinsky, 2010; Charles et al., 2014; Wallace et al., 2013).

The memory capacity of these networks has been studied in both the machine learning and computational neuroscience literature. In the approach of interest, the short-term memory (STM) of a network is characterized by quantifying the relationship between the transient network activity and the recent history of the exogenous input stream driving the network (Jaeger and Haas, 2004; Maass et al., 2002; Ganguli and Sompolinsky, 2010; Wallace et al., 2013; Verstraeten et al., 2007; White et al., 2004; Lukoševičius and Jaeger, 2009; Buonomano and Maass, 2009; Charles et al., 2014). Note that this is in contrast to alternative approaches that characterize long-term memory in RNNs through quantifying the number of distinct network attractors that can be used to stably remember

input patterns with the asymptotic network state. In the vast majority of the existing theoretical analysis of STM, the results conclude that networks with M nodes can only recover inputs of length $N \leq M$ (White et al., 2004; Wallace et al., 2013) when the inputs are unstructured.

However, in any machine-learning problem of interest, the input statistical structure is precisely what we intend to exploit to accomplish meaningful tasks. For one example, many signals are well-known to admit a sparse representation in a transform dictionary (Elad et al., 2010; Davies and Daudet, 2006). In fact, some classes of deep neural networks have been designed to induce sparsity at higher layers that may serve as inputs into the recurrent layers (LeCun et al., 2010; Kavukcuoglu et al., 2010). For another example, a collection of time-varying input streams (e.g., pixels or image features in a video stream) are often heavily correlated. In the specific case of single input streams ($L = 1$) with inputs that are K-sparse in a basis, recent work (Charles et al., 2014) has shown that the STM capacity can scale as favorably as $M = \mathcal{O}(K \log^{\gamma}(N)) \leq N$, where $\gamma \geq 1$ is a constant. In other words, the memory capacity can scale linearly with the information rate in the signal and only logarithmically with the signal dimension, resulting in the potential for recovery of inputs of length $N \gg M$. Unfortunately, existing analyses (Jaeger, 2001; White et al., 2004; Ganguli and Sompolinsky, 2010; Charles et al., 2014) are generally specific to the restricted case of single time-series inputs ($L = 1$) or unstructured inputs (Verstraeten et al., 2010).

Conventional wisdom is that structured inputs should lead to much higher STM capacity, though this has never been addressed with strong analysis in the general case of ESNs with multidimensional input streams. The main contribution of this paper is to provide general results characterizing the STM capacity for linear randomly connected ESNs with multidimensional input streams when the inputs are either sparse in a basis or have significant statistical dependence (with no sparsity assumption). In both cases, we show that the number of nodes in the network must scale linearly with the information rate and poly-logarithmically with the total input dimension. The analysis relies on advanced applications of random matrix theory, and results in non-asymptotic analysis of explicit bounds on the recovery error. Taken together, this analysis provides a significant step forward in our understanding of the STM properties in RNNs. While this paper is primarily focused on network structures in the context of RNNs in machine learning, these results also provide foundation for the theoretical understanding of recurrent network structures in biological neural networks, as well as the memory properties in other network structures with similar dynamics (e.g., opinion dynamics in social networks).

2. Background and Related Work

2.1 Short Term Memory in Recurrent Networks

Many approaches have been used to analyze the STM of randomly connected networks, including nonlinear networks (Sompolinsky et al., 1988; Massar and Massar, 2013; Faugeras et al., 2009; Rajan et al., 2010; Galtier and Wainrib, 2016; Wainrib, 2015) and linear networks (Jaeger, 2001; Jaeger and Haas, 2004; White et al., 2004; Ganguli et al., 2008; Ganguli and Sompolinsky, 2010; Charles et al., 2014; Wallace et al., 2013) with both discrete-time and continuous-time dynamics. These methods can be broadly be classified as either correlation-based methods (White et al., 2004; Ganguli et al., 2008) or uniqueness methods (Jaeger, 2001; Maass et al., 2002; Jaeger and Haas, 2004; Charles et al., 2014; Legenstein and Maass, 2007; Büsing et al., 2010). Correlation methods focus on quantifying the correlation between the network state and recent network inputs. In these studies, the STM is defined as the time of the oldest input where the correlation between the network

state and that input remains above a given threshold (White et al., 2004; Ganguli et al., 2008). These methods have mostly been applied to discrete-time systems, and have resulted in bounds on the STM that scale linearly with the number of nodes (i.e. $M > N$).

In contrast, uniqueness methods instead aim to show that different network states correspond to unique input sequences (i.e. the network dynamics are bijective).[1] For uniqueness methods, the STM is defined as the longest input length where this input-network state bijection still holds. These methods have been used under the term *separability property* for continuous-time liquid state machines (Maass et al., 2002; Vapnik and Chervonenkis, 1971; Legenstein and Maass, 2007; Wallace et al., 2013; Büsing et al., 2010) and under the term *echo-state property* for discrete-time ESNs (Jaeger, 2001; Yildiz et al., 2012; Buehner and Young, 2006; Manjunath and Jaeger, 2013). The echo-state property is the method most related to the approach we take here, and essentially derives the maximum length of the input signal such that the resulting network states remain unique. While this property guarantees a bijection between inputs and network states, it does not take into account input signal structure, does not capture the robustness of the mapping, and does not provide guarantees for stably recovering the input from the network activity.

2.2 Compressed Sensing

The compressed sensing literature and its recent extensions include many tools for studying the effects of random matrices applied to low-dimensional signals. Specifically, in the basic compressed sensing problem we desire to recover the signal $\boldsymbol{s} \in \mathbb{R}^N$ from M measurements[2] generated from a random linear measurement operator,

$$\boldsymbol{x} = \mathcal{A}(\boldsymbol{s}) + \boldsymbol{\epsilon}, \tag{2}$$

where $\boldsymbol{\epsilon} \in \mathbb{R}^M$ represents the potential measurement errors. Typically, $\boldsymbol{s}$ is assumed to have low-dimensional structure and recovery is performed via a convex optimization program. The most common example is a sparsity model where $\boldsymbol{s}$ can be represented as

$$\boldsymbol{s} = \boldsymbol{\Psi}\boldsymbol{a},$$

where $\boldsymbol{\Psi} \in \mathbb{R}^{N \times N}$ is a transform matrix and $\boldsymbol{a} \in \mathbb{R}^N$ is the sparse coefficient representation of $\boldsymbol{s}$ with $K \ll N$ of its entries non-zero. Under this sparsity assumption, the coefficient representation is recoverable if the linear operator $\mathcal{A}$ satisfies the restricted isometry property (RIP) that guarantees uniqueness of the compressed measurements. Specifically, we say that $\mathcal{A}$ satisfies the RIP($2K$,δ) if for every $2K$-sparse signal $\boldsymbol{s}$, the following condition is satisfied:

$$C(1-\delta) \leq ||\mathcal{A}\boldsymbol{s}||_2^2 / \, ||\boldsymbol{s}||_2^2 \leq C(1+\delta),$$

where $0 < \delta < 1$ and $C > 0$ is a positive constant. When $\mathcal{A}$ satisfies the RIP($2K$,δ) the sparse coefficients $\boldsymbol{a}$ can be recovered by solving an ℓ_1-norm based optimization function

$$\boldsymbol{a} = \arg\min_{\boldsymbol{a}} ||\boldsymbol{a}||_1 \quad \text{such that} \quad ||\boldsymbol{x} - \mathcal{A}(\boldsymbol{\Psi}\boldsymbol{a})||_2 \leq ||\boldsymbol{\epsilon}||_2, \tag{3}$$

1. We note that uniqueness-based methods imply recovery-based methods, modulo a recovery algorithm, as often recovery guarantees are based on some semblance of a bijection.
2. In the case of RNNs, the network node values act as the measurements of our system, prompting the use of M as the number of measurements in this section

up to a reconstruction error given by

$$||\boldsymbol{s}-\widehat{\boldsymbol{s}}||_2 \leq \alpha\,||\boldsymbol{\epsilon}||_2 + \beta\frac{\left|\left|\boldsymbol{\Psi}^T\left(\boldsymbol{s}-\boldsymbol{s}_K\right)\right|\right|_1}{\sqrt{K}}, \tag{4}$$

where α and β are constants (Candès et al., 2006). The first term of this recovery error bound depends on the norm of the measurement error $\boldsymbol{\epsilon}$, while the second term depends on the ℓ_1 difference between the true signal and the best K-sparse approximation of the true vector ($\boldsymbol{s}_K$). This term essentially measures how closely the signal matches the sparsity model. The ℓ_1 optimization program in (3) required for recovery can be solved by many efficient algorithms, including neurally plausible architectures (Rozell et al., 2010; Balavoine et al., 2012; Shapero et al., 2014; Charles et al., 2012).

When the data of interest is a matrix $\boldsymbol{S} \in \mathbb{R}^{L\times N}$, other low-dimensional models have also been explored. For example, as an alternative to a sparsity assumption, the successful low-rank model assumes that there are correlations between rows and columns such that $\boldsymbol{S}$ has rank $R < \min\{L,N\}$. We can then write the decomposition of the matrix as

$$\boldsymbol{S} = \boldsymbol{Q}\boldsymbol{V}^*,$$

where $\boldsymbol{Q} \in \mathbb{R}^{L\times R}$ and $\boldsymbol{V}^* \in \mathbb{R}^{R\times N}$. There is a rich and growing literature dedicated to establishing guarantees for recovering low-rank matrices from incomplete measurements. Due to the difficulty of establishing a general matrix-RIP property for observations of a matrix (Recht et al., 2010), the guarantees in this literature more commonly use the optimality conditions for specific optimization procedures to show that the resulting solution has bounded error with high probability. The most common optimization program used for low-rank matrix recovery is the nuclear norm minimization,

$$\boldsymbol{S} = \arg\min_{\boldsymbol{S}} ||\boldsymbol{S}||_* \quad \text{such that} \quad ||\boldsymbol{x}-\mathcal{A}\left(\boldsymbol{S}\right)||_2 \leq ||\boldsymbol{\epsilon}||_2\,, \tag{5}$$

where the nuclear norm $||\boldsymbol{S}||_*$ is defined as the sum of the singular values of $\boldsymbol{S}$ (Candès and Tao, 2010; Candès and Plan, 2010; Recht et al., 2010; Chen and Suter, 2004; Fazel, 2002; Singer and Cucuringu, 2010; Toh and Yun, 2010; Liu and Vandenberghe, 2009; Jaggi et al., 2010). This optimization procedure is similar to the ℓ_1-regularized optimization of Equation (3), however the nuclear-norm induces sparsity in the singular values rather than the matrix entries directly.

The solution to Equation (5) can be shown to satisfy performance guarantees via the dual-certificate approach (Candès and Plan, 2010; Ahmed and Romberg, 2015). This technique is a proof by construction and shows that a dual certificate (i.e., a vector whose projections into and out of the space spanned by the singular vectors of $\boldsymbol{S}$ are bounded) exists. Showing that such a certificate exists demonstrates that Equation (5) converges to a valid solution and is key to deriving accuracy bounds (Candès and Plan, 2010; Ahmed and Romberg, 2015). Specifically, if the dual certificate exists, then the solution to Equation (5) satisfies the recovery bound

$$\left|\left|\widehat{\boldsymbol{S}}-\boldsymbol{S}\right|\right|_F \leq \left(4\sqrt{\min(N,L)\frac{2NL+M}{M}}+2\right)\epsilon, \tag{6}$$

where the Forbenius norm $\|\cdot\|_F^2$ is defined as the sum of the squares of all the matrix entries. This bound demonstrates that perfect recovery is achievable in the case where there is no error ($\epsilon = 0$). We note that alternate optimization programs with similar guarantees have been proposed in the literature for inferring low-rank matrices (i.e. Ahmed and Romberg, 2015), but we will focus on nuclear norm optimization approaches due to the extensive literature on nuclear-norm solvers and the connections to sparse vector inference.

2.3 STM Capacity via the RIP

The ideas and tools from the compressed sensing literature have recently been used to show that *a-priori* knowledge of the input sparsity can lead to improvements recovery-based STM capacity results for ESNs. For a single input stream under a sparsity assumption, Ganguli and Sompolinsky (2010) analyzed an annealed version of the network dynamics to show that the network memory capacity can be larger than the network size. Building on this observation, Charles et al. (2014) provided an analysis of the exact network dynamics in an ESN (for the single input case of $L = 1$), yielding precise bounds on a network's STM capacity captured in the following theorem:

Theorem 1 (Theorem 4.1.1, Charles et al., 2014) *Suppose $N \geq M$, $N \geq K$, $N \geq O(1)$,*[3] *and $L = 1$. Let $\boldsymbol{U}$ be any unitary matrix of eigenvectors (containing complex conjugate pairs) of the connectivity matrix $\boldsymbol{W}$ and for M an even integer, denote the eigenvalues of $\boldsymbol{W}$ by $\{e^{jw_m}\}_{m=1}^{M}$. Let the first $M/2$ eigenvalues ($\{e^{jw_m}\}_{m=1}^{M/2}$) be chosen uniformly at random on the complex unit circle (i.e., $\{w_m\}_{m=1}^{M/2}$ is uniformly distributed over $[0,2\pi)$) and the other $M/2$ eigenvalues as the complex conjugates of these values. Furthermore, let the entries of the input weights $\boldsymbol{z}$ be i.i.d. zero-mean Gaussian random variables with variance $\frac{1}{M}$. Given RIP conditioning δ and failure probability $N^{-\log^4 N} \leq \eta \leq \frac{1}{e}$, if*

$$M \geq C\frac{K}{\delta^2}\mu^2\left(\boldsymbol{\Psi}\right)\log^5\left(N\right)\log(\eta^{-1}),$$

then for a universal constant C, with probability $1-\eta$ the mapping of length-N input sequences into M network state variables satisfies the RIP($2K$, δ).

This theorem proves a rigorous and non-asymptotic bound on the length of the input that can be robustly extracted from the network nodes. By showing the RIP property on the network dynamics, the recovery bound given in Equation (4) establishes the recovery performance for any N-length, K-sparse signal from the resulting network state at time N. In short, the number of required nodes scales linearly with the information rate of the signal (i.e., the sparsity level) and poly-logarithmically with the length of the input. The coherence factor $\mu^2(\boldsymbol{\Psi})$, defined as

$$\mu\left(\boldsymbol{\Psi}\right) = \max_{n=1,\ldots,N}\sup_{t\in[0,2\pi]}\left|\sum_{m=0}^{N-1}\boldsymbol{\Psi}_{m,n}e^{-jtm}\right|,$$

expresses the *types* of sparsity that are efficiently stored in the network. Essentially this coherence factor is large (on the order of $\sqrt{N}$) for inputs sparse in the Fourier basis, and is very low (essentially a small constant) for inputs that are sparse in bases different from the Fourier bases (e.g. wavelet transforms). For the extreme case of Fourier-sparse inputs, the number of nodes must again exceed the number of inputs. When this coherence is low and $K \ll M$, this bound is a clear improvement over existing results as it allows for $N > M$. However, this result is restricted to single input streams with one type of low-dimensional structure. The current paper addresses the much more general problem of multidimensional inputs and other types of low-dimensional structure.

3. We use $O(1)$ notation to indicate that a variable is a finite constant.

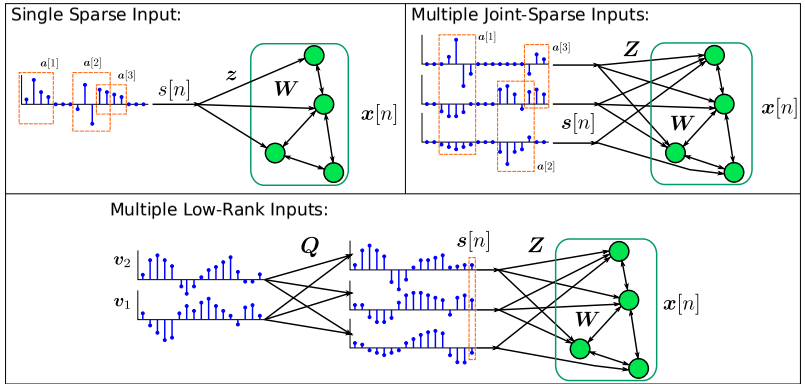

Figure 1: Echo-state networks can efficiently store inputs with a variety of low-dimensional structures. Top-Left: With a single input stream, the coefficients $\boldsymbol{a}$ represent chunks of activity in the input stream $s[n]$ (shown in red boxes). The raw input stream values then drive the network via Equation (1), resulting in a transient network state $\boldsymbol{x}[N]$ that encodes the input stream. Top-Right: In the case of multiple inputs that are jointly sparse, each coefficient can now represent a chunk of activity both across time and across input streams (as depicted by the red boxes). Bottom: When the multiple input streams are instead low-rank, each input stream is instead described by a linear combination of prototypical vectors $\boldsymbol{v}_k$. The matrix $\boldsymbol{Q}$ represents how the prototypical vectors are combined in order to obtain the input sequences fed into the network.

3. STM for Multi-Input Networks

In this work we will use the tools of random matrix theory to establish STM capacity results for recurrent networks under the general conditions of multiple simultaneous input streams and a variety of low-dimensional models. The temporal evolution of the linear network with multiple inputs is similar to the previous ESN definition, with the main difference being that the input at each time-step $\boldsymbol{s}[n] \in \mathbb{R}^L$ is a length L vector that drives the network through a feed-forward matrix $\boldsymbol{Z} \in \mathbb{R}^{M \times L}$ rather than a feed-forward vector,

$$\begin{aligned} \boldsymbol{x}[n] &= \boldsymbol{W}\boldsymbol{x}[n-1] + \sum_{l=1}^{L} \boldsymbol{z}_l s_l[n] + \widetilde{\boldsymbol{\epsilon}}[n] \\ &= \boldsymbol{W}\boldsymbol{x}[n-1] + \boldsymbol{Z}\boldsymbol{s}[n] + \widetilde{\boldsymbol{\epsilon}}[n]. \end{aligned} \tag{7}$$

We denote the columns of $\boldsymbol{Z}$ as $\boldsymbol{z}_l$ to separately notate the vectors mapping each input stream.

We can write the current network state as a linear function of the inputs by iterating Equation (7),

$$\boldsymbol{x}[N] = \sum_{k=1}^{N} \boldsymbol{W}^{N-k}\boldsymbol{Z}\boldsymbol{s}[k] + \boldsymbol{\epsilon},$$

where the error term $\boldsymbol{\epsilon} = \sum_{k=1}^{N} \boldsymbol{W}^{N-k}\widetilde{\boldsymbol{\epsilon}}[k]$ is the accumulated error, and then rewriting sum as a matrix-vector multiply,

$$\boldsymbol{x}[N] = \left[\boldsymbol{Z}, \boldsymbol{W}\boldsymbol{Z}, \cdots, \boldsymbol{W}^{N-1}\boldsymbol{Z}\right] \left[\boldsymbol{s}^T[N], \boldsymbol{s}^T[N-1], \cdots, \boldsymbol{s}^T[1]\right]^T + \boldsymbol{\epsilon}.$$

Depending on the signal statistics in question, we will find it convenient in some cases to express the network dynamics in terms of a linear operator applied to an input matrix, i.e.

$$\boldsymbol{x}[N] = \mathcal{A}(\boldsymbol{S}) + \boldsymbol{\epsilon},$$

where $\boldsymbol{S} = \left[\boldsymbol{s}^T[N], \boldsymbol{s}^T[N-1], \cdots, \boldsymbol{s}^T[1]\right]^T$. In other cases, we find it more convenient to reorganize the columns into an effective measurement matrix applied to a vector of inputs. By defining the eigen-decomposition of $\boldsymbol{W} = \boldsymbol{U}\boldsymbol{D}\boldsymbol{U}^{-1}$, we can re-write the dynamics process as

$$\boldsymbol{x}[N] = \boldsymbol{U}\left[\boldsymbol{D}^0\boldsymbol{U}^{-1}\boldsymbol{Z}, \boldsymbol{D}\boldsymbol{U}^{-1}\boldsymbol{Z}, \cdots, \boldsymbol{D}^{N-1}\boldsymbol{U}^{-1}\boldsymbol{Z}\right] \left[\boldsymbol{s}^T[N], \boldsymbol{s}^T[N-1], \cdots, \boldsymbol{s}^T[1]\right]^T + \boldsymbol{\epsilon}.$$

To simplify this expression, we can reorganize the columns of the linear operator (and the rows of the vector of inputs) such that all the inputs corresponding to the l^{th} input vector $\boldsymbol{z}_l$ create a single block. The k^{th} row of the l^{th} block of out matrix is now represented by $\boldsymbol{D}^{k-1}\boldsymbol{U}^{-1}\boldsymbol{z}_l$, which can be written as $\widetilde{\boldsymbol{Z}}_l\boldsymbol{d}_{k-1}$, where $\widetilde{\boldsymbol{Z}}_l = \boldsymbol{U}^{-1}\boldsymbol{z}_l$ and $\boldsymbol{d}_{k-1}$ is the vector of the diagonal elements of $\boldsymbol{D}$ raised to the $(k-1)$ power. We can more concisely by defining the matrix $\boldsymbol{F}$ consisting of the eigenvalues of $\boldsymbol{W}$ raised to different powers (i.e. $\boldsymbol{F}_{i,j} = d_i^{j-1}$), resulting in the expression

$$\boldsymbol{x}[N] = \boldsymbol{U}\left[\widetilde{\boldsymbol{Z}}_1\boldsymbol{F}, \widetilde{\boldsymbol{Z}}_2\boldsymbol{F}, \cdots, \widetilde{\boldsymbol{Z}}_L\boldsymbol{F}\right] \left[\boldsymbol{s}_1^T, \boldsymbol{s}_2^T, \cdots, \boldsymbol{s}_L^T\right]^T + \boldsymbol{\epsilon} = \boldsymbol{A}\widetilde{\boldsymbol{s}} + \boldsymbol{\epsilon}. \tag{8}$$

Since the eigenvalues of $\boldsymbol{W}$ here are restricted to reside on the unit circle, we note that $\boldsymbol{F}$ is a Vandermonde matrix whose rows are Fourier basis vectors. From Equation (8) we see that the current state is simply the sum of L compressed input streams, where the compression for each block essentially performs the same compression as for a single stream, but modulated by the different feed-forward vectors $\boldsymbol{z}_l$.

3.1 Sparse Multiple Inputs

To begin, we consider the direct extension of previous results based on sparsity models to the multi-input setting. In this setting we consider the model where the composite of all input signals is sparse in a basis $\boldsymbol{\Psi} \in \mathbb{R}^{NL \times NL}$ so that $\widetilde{\boldsymbol{s}} = \boldsymbol{\Psi}\widetilde{\boldsymbol{a}}$. This means that each signal stream can be written as $\boldsymbol{s}_l = \sum_{k=1}^{L} \boldsymbol{\Psi}^{l,k}\boldsymbol{a}_k$ where $\boldsymbol{\Psi}^{l,k}$ is the $\{l,k\}^{th}$ $N \times N$ block of $\widetilde{\boldsymbol{\Psi}}$. This signal model captures dependencies between input streams because a given coefficient can influence multiple channels. While in many application the basis $\boldsymbol{\Psi}$ is pre-specified (i.e. wavelet decomposition in image processing; Christopoulos et al., 2000), these bases can also be learned from exemplar data via dictionary learning algorithms (Olshausen and Field, 1996; Aharon et al.). This sparsity model can be a useful model for signals of interest, such as video signals, where similar sparse decompositions have been used for action recognition (Guha and Ward, 2012) and video categorization (Chiang et al., 2013). With this model, we will use a generalized notion of the coherence parameter used in (Charles et al., 2014):

$$\mu_S(\boldsymbol{\Psi}) = \max_{l,k=1,\ldots,L} \max_{n=1,\ldots,N} \sup_{t \in [0,2\pi]} \frac{\left|\sum_{m=0}^{N-1} \boldsymbol{\Psi}_{m,n}^{l,k} e^{-jtm}\right|}{\|\boldsymbol{\Psi}_m^{l,k}\|_2}. \tag{9}$$

In this case, each $N \times N$ block must be different from the Fourier basis to achieve high STM capacity. This restriction is reasonable, since if a single sub-block of $\boldsymbol{\Psi}$ was coherent with the Fourier basis, then at least one input stream could be sparse in a Fourier-like basis and hence would be unrecoverable. Using this network and signal model, we obtain the following theorem on the stability of the network representation:

Theorem 2 *Suppose $NL \geq M$, $N \geq K$ and $N \geq O(1)$. Let $\boldsymbol{U}$ be any unitary matrix of eigenvectors (containing complex conjugate pairs) and the entries of $\boldsymbol{Z}$ be i.i.d. zero-mean Gaussian random variables with variance $\frac{1}{M}$. For M an even integer, denote the eigenvalues of $\boldsymbol{W}$ by $\{e^{jw_m}\}_{m=1}^{M}$. Let the first $M/2$ eigenvalues ($\{e^{jw_m}\}_{m=1}^{M/2}$) be chosen uniformly at random on the complex unit circle (i.e., we chose $\{w_m\}_{m=1}^{M/2}$ uniformly at random from $[0, 2\pi)$) and the other $M/2$ eigenvalues as the complex conjugates of these values. For a given RIP conditioning δ, failure probability $N^{-\log^4 N} \leq \eta \leq \frac{1}{e}$, and coherence $\mu_S(\boldsymbol{\Psi})$ as defined as in Equation* (9)*, if*

$$M \geq C \frac{K}{\delta^2} \mu_S^2(\boldsymbol{\Psi}) \log^5(NL) \log(\eta^{-1}),$$

then $\boldsymbol{A}$ satisfies RIP-$(2K, \delta)$ with probability exceeding $1 - \eta$ for a universal constant C.

The proof of Theorem 2 is provided in Appendix A.1. Note that when $L = 1$, Theorem 2 reduces to Theorem 1. In this result we see that that the number of nodes relies only linearly on the underlying dimensionality (K) and poly-logarithmically on the total size of the input (NL). This means that under favorable coherence and sparsity conditions on the input, the network can again have STM capacities that are higher than the number of nodes in the network. Specifically, showing that $\boldsymbol{A}$ satisfies the RIP property, Theorem 2 ensures that standard recovery guarantees from the sparse inference literature hold. In particular, any K-sparse input is recoverable from the network state at time N up to the error bound of Equation (4) by solving the ℓ_1-regularized least-squares optimization of Equation (3).

3.2 Low Rank Multiple Inputs

Next we consider the case of a very different type of low-dimensional structure where the input signals are correlated but not necessarily sparse. Specifically, in this setting we assume that the inputs arise from a process where R prototypical signals combine linearly to form the various input streams. Such a signal structure could arise, for instance, due to correlations between input streams at spatially neighboring locations. A number of interesting applications display such correlations, including important measurement modalities in neuroscience (e.g. two-photon calcium imaging; Denk et al., 1990; Maruyama et al., 2014 and neural electrophysiological recordings; Berényi et al., 2014; Ahmed and Romberg, 2015), and remote sensing applications (e.g. hyperspectral imagery; Zhang et al., 2014; Veganzones et al., 2016). The applicability of RNNs and machine learning methods to data well described by this low-rank model is also increasingly relevant as there is increasing interest in applying neural network techniques to such data, either for detection (Apthorpe et al., 2016), classification (Chen et al., 2016, 2014), or as samplers via variational auto-encoders (Gao et al., 2016). In this case, we can write out the input matrix in the reduced form $\boldsymbol{S} = \boldsymbol{Q}\boldsymbol{V}^*$, where $\boldsymbol{V}^* \in \mathbb{R}^{R \times N}$ is the matrix whose rows may represent environmental causes generating the data and $\boldsymbol{Q} \in \mathbb{R}^{L \times R}$ represents the mixing matrix that defines the input stream. We

will assume both $L \geq R$ and $N \geq R$, meaning that $\boldsymbol{S}$ is low-rank. With this model we use a definition of coherence given by:

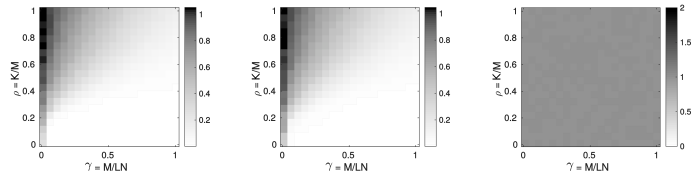
$$\mu_L^2 = R^{-1} \sup_{\omega \in [0, 2\pi]} ||\boldsymbol{V}^* \boldsymbol{f}_\omega||_2^2 . \tag{10}$$

where $\boldsymbol{f}_\omega = [1, e^{-j\omega}, \cdots e^{-j(N-1)\omega}]^T$ is the Fourier vector with frequency ω. This coherence parameter mirrors the coherence used for the sparse-input case. As μ_S measured the similarity between the measurement vectors and the sparsity basis $\boldsymbol{\Psi}$, μ_L measures the similarity between the measurements and the left singular vectors of the measured matrix. The intuition here is that measurements that align with the left singular vectors are unlikely to measure significant information about the $\boldsymbol{S}$.

To analyze the STM of the network dynamics with respect to low-rank signal statistics, we leverage the dual certificate approach (Candès and Plan, 2010, 2011a; Ahmed and Romberg, 2015) to derive the following theorem,

Theorem 3 *Suppose $NL \geq M$, $N \geq R$, $N \geq O(1)$ and $L \geq O(1)$. Let $\boldsymbol{z}$ be i.i.d. zero-mean Gaussian random variables with variance $\frac{1}{M}$. For M an even integer, denote the eigenvalues of $\boldsymbol{W}$ by $\{e^{jw_m}\}_{m=1}^{M}$. Let the first $M/2$ eigenvalues ($\{e^{jw_m}\}_{m=1}^{M/2}$) be chosen uniformly at random on the complex unit circle (i.e., we chose $\{w_m\}_{m=1}^{M/2}$ uniformly at random from $[0, 2\pi)$) and the other $M/2$ eigenvalues as the complex conjugates of these values. For a given coherence μ_L as defined as in Equation* (10)*, if*

$$M \geq cR\left(N + \mu_L^2 L\right) \log^3(LN),$$



then, with probability at least $1 - O((LN)^{1-\beta}$, the minimization in Equation (5) *recovers the rank-R input matrix $\boldsymbol{S}$ up to the error bound in Equation* (6)*.*

The proof of Theorem 3 is in Appendix A.2 and follows a golfing scheme to find an inexact dual certificate. In fact, we note that since our architecture is extremely similar mathematically to the architecture in (Ahmed and Romberg, 2015), our proof is also very similar. The main difference is that due to the unbounded nature of our distributions (i.e. the feed-forward vectors $\boldsymbol{Z}$ are Gaussian random variables) and the fact that our Fourier vectors are on the unit circle (rather than gridded), we can consider our proof as a generalization of the proof in (Ahmed and Romberg, 2015).

Theorem 3 is qualitatively similar to Theorem 2 in the way the STM capacity scales. In this case, the bound still scales linearly with the information rate as captured by the number of elements in the left and right matrices that compose $\boldsymbol{S}$: $RN + RL$. Interestingly, due to the left singular vectors interacting with the measurement operator first, the coherence term only affects the portion of the bound related to the number of elements in $\boldsymbol{Q}$. Additionally, as before, the number of total inputs LN only impacts the bound poly-logarithmically.

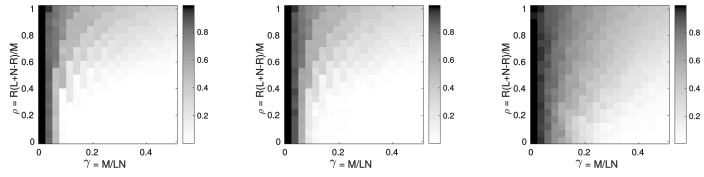
4. Simulation

To empirically verify that these theoretical STM scaling laws are representative of the empirical behavior, we generated a number of random networks and evaluated the recovery of (sparse or low-rank) input sequences in the presence of noise. For each simulation we generate a $M \times M$ random

(a) RMSE: No basis (b) RMSE: Haar wavelet basis (c) RMSE: DCT basis

Figure 2: ESNs can have high STM capacity for multidimensional sparse inputs. Relative mean-squared error (rMSE) of the recovery for canonical sparse inputs (a) and Haar wavelet-sparse inputs (b) is very low for a range of sparsity and network sizes satisfying $M < LN$. The rMSE for DCT-sparse inputs (c), as predicted by our theoretical results, remains high (approximately 100% error).

orthogonal connectivity matrix $\boldsymbol{W}$[4] and a $M \times L$ random Gaussian feed-forward matrix $\boldsymbol{Z}$. In both cases we fixed the number of inputs to $L = 40$ and the number of time-steps to $N = 100$ while varying the network size M and underlying dimensionality of the input (i.e., the sparsity level or the input matrix rank). For the sparse input simulations, inputs were chosen with a uniformly random support pattern with random Gaussian values on the support. For low-rank simulations, the right singular vectors were chosen to be Gaussian random vectors, and the left singular values were chosen at random from a number of different basis sets.



In Figure 2 we show the relative mean-squared error of the input recovery as a function of the sparsity-to-network size ratio $\rho = K/M$ and the network size-to-input ratio $\gamma = M/NL$. Each pixel value represents the average recovery relative mean-squared error (rMSE), as calculated by

$$\text{RMSE} = \frac{\|\widehat{\boldsymbol{s}} - \boldsymbol{s}\|_2^2}{\|\boldsymbol{s}\|_2^2},$$

over 20 randomly generated trials with a noise level of $\|\boldsymbol{\epsilon}\|_2 \approx 0.01$. We show results for recovery of three different types of sparse signals: signals sparse in the canonical basis, signals sparse in a Haar wavelet basis, and signals sparse in a discrete cosine transform (DCT) basis. As our theory predicts, for canonical- and Haar wavelet-sparse signals the network has very favorable STM capacity results. The fact that the capacity achieves $M < NL$ is demonstrated by the area left of the $M = NL$ point ($\gamma = 1$) where the signal is recovered with high accuracy. Likewise, for the DCT-sparse signals we find that the inputs are never recovered well for any $M < NL$. This behavior is also predicted by our theory because of the unfavorable coherence properties of the DCT basis.

For the low-rank trials we see that recovery of low-rank inputs for a range of $M < LN$ is possible as predicted by the theoretical results. As with the sparse input case we consider three types of low-rank inputs. Instead of changing the sparsity basis, however, we change the right singular vectors $\boldsymbol{V}$ of the low-rank input matrix $\boldsymbol{S}$. We explore the cases where the elements of $\boldsymbol{V}$

4. Orthogonal connectivity matrices were obtained by running an orthogonalization procedure on a random Gaussian matrix.

(a) RMSE: No basis (b) RMSE: Haar wavelet basis (c) RMSE: DCT basis

Figure 3: ESNs can have high STM capacity for multidimensional inputs with low-rank structure. The rMSE of the input recovery for inputs with canonical right singular vectors (a) and Haar wavelets for right singular vectors (b) is very low for a range of input rank and network sizes satisfying $M < LN$. The rMSE for inputs with DCT right singular vectors (c) remains high, a behavior predicted by our theoretical results.

are chosen from the canonical basis, the haar basis and the DCT basis. These results are shown in Figure 3 with plots similar to those in Figure 2, but with only showing the range $\gamma < 0.5$ to reduce computational time. As our theory predicts, the recovery of inputs with canonical- and Haar right singular vectors is more accurate for a larger range of ρ, γ pairs than the inputs with DCT right singular vectors.

5. Conclusions

Determining the fundamental limits of memory in recurrent networks is critical to understanding their behavior in machine learning tasks. In this work we show that randomly connected echo-state networks can exploit the low-dimensional structure in multidimensional input streams to achieve very high short-term memory capacity. Specifically, we show non-asymptotic bounds on recovery error for input sequences that have underlying low-dimensional statistics described by either joint sparsity or low-rank properties (with no sparsity). For multiple sparse inputs, we find that the network size must be linearly proportional to the input sparsity and only logarithmically dependent on the total input size (a combination of the input length and number of inputs). For inputs with low-rank structure, we find a similar dependency where the network size depends linearly on the underlying dimension of the inputs (the product of the input rank with the input length and the number of inputs) and logarithmically on the total input size. Both results continue to demonstrate that ESNs can have STM capacities much larger than the network size.

These results are a significant (conceptual and technical) generalization over previous work that provided theoretical guarantees in the case of a single sparse input (Charles et al., 2014). While the linear ESN structure is a simplified model, rigorous analysis of these networks has remained elusive due to the recurrence itself. These results isolate the properties of the transient dynamics due to the recurrent connections, and may provide one foundation for which to explore the analysis of other complex network attributes such as nonlinearities and spiking properties. We also note that knowledge of how well neural networks compresses structured signals could indicate methods to pick the size of recurrent network layers. Specifically, if a task is thought to require a certain time-

frame of an input signal, the overall sparsity (or rank) of the signal in that time-frame can be used in conjunction with the length of that time-frame to give a lower bound for the required number of nodes in the recurrent layer of the network.

While the current paper is restricted to orthogonal connectivity matrices, previous work (Charles et al., 2014) has shown that a number of network structures can satisfy these criteria, including some types of small-world network topologies. Additionally, we explored here low-rank and sparse inputs separately. The methods we have used to prove Theorem 3, however, have also been used to analyze recovery signals with other related structures (e.g. matrices that can be decomposed into the sum of a sparse and low-rank matrix) from compressive measurements (Candès and Plan, 2011b). Our bounds presented here therefore could open up avenues for similar analysis of other low-dimensional signal classes.

While the context of this paper is focused on the role of recurrent networks as a tool in machine learning tasks, these results may also lead to a better understanding of the STM properties in other networked systems (e.g., social networks, biological networks, distributed computing, etc.). With respect to the literature relating recurrent ESN and liquid-state machines to working memory in biological systems, the notion of sparsity has much of the same flavor as the concept of *chunking* (Gobet et al., 2001). Chunking is the concept of humans learning to remember items in highly correlated groups rather than remembering items individually as a way of artificially increasing their working memory. Similarly, the use of sparsity bases allow RNNs to 'chunk' items according to the basis elements. Thus, each basis counts only as one item (the true underlying sparsity) and the network needs only store these elements rather than storing every input separately.

A. Appendix

A.1 RIP for Multiple Gaussian Feed-forward Vectors

In this appendix we prove Theorem 2, showing that the matrix representing the network evolution with L inputs and *i.i.d.* Gaussian feed-forward vectors satisfies the RIP. Recall that we have $\boldsymbol{x}[N] = \boldsymbol{A}\widetilde{\boldsymbol{s}}$, where $\boldsymbol{A} \in \mathbb{R}^{M\times NL}$ is derived in Section 3 and that $\widetilde{\boldsymbol{s}}$ (the vectorization of $\boldsymbol{S}$) is sparse with respect to the basis Ψ, meaning that there is a K-sparse signal $\boldsymbol{a}$ such that $\widetilde{\boldsymbol{s}} = \Psi\boldsymbol{a}$. Similar to (Charles et al., 2014), this proof is based on showing conditions on M such that $\boldsymbol{A}$ satisfies the RIP with respect to $\boldsymbol{\Psi}$, i.e.

$$(1-\delta)\left|\left|\boldsymbol{a}\right|\right|_2^2 \leq \left|\left|\boldsymbol{A}\boldsymbol{\Psi}\boldsymbol{a}\right|\right|_2^2 \leq (1+\delta)\left|\left|\boldsymbol{a}\right|\right|_2^2,$$

holds with high probability for all K-sparse $\boldsymbol{a}$. This is equivalent to bounding the following probability of the event

$$\left|\left|(\boldsymbol{A}\boldsymbol{\Psi})^H\boldsymbol{A}\boldsymbol{\Psi} - I\right|\right|_K \leq \delta. \tag{11}$$

where the norm $\left|\left|\boldsymbol{A}\right|\right|_K$ is defined as

$$\left|\left|\boldsymbol{A}\right|\right|_K := \sup_{\boldsymbol{y}\ is\ K-sparse} \frac{\boldsymbol{y}^H\boldsymbol{A}\boldsymbol{y}}{\left|\left|\boldsymbol{y}\right|\right|_2^2}.$$

First we bound the expectation of $\left|\left|(\boldsymbol{A}\boldsymbol{\Psi})^H\boldsymbol{A}\boldsymbol{\Psi} - I\right|\right|_K$, and use the result to bound the tail probability of the event (11).

Proof

A.1.1 EXPECTATION

First we let

$$\widehat{\boldsymbol{A}} = \begin{bmatrix}\widetilde{\boldsymbol{Z}}_1\boldsymbol{F} & \widetilde{\boldsymbol{Z}}_2F & \cdots & \widetilde{\boldsymbol{Z}}_L\boldsymbol{F}\end{bmatrix}\boldsymbol{\Psi},$$

Since $(\boldsymbol{A}\boldsymbol{\Psi})^H\boldsymbol{A}\boldsymbol{\Psi} = \widehat{\boldsymbol{A}}^H\widehat{\boldsymbol{A}}$, then for any $\boldsymbol{a} \in \mathbb{R}^{NL}$, $\left|\left|\boldsymbol{A}\boldsymbol{\Psi}\boldsymbol{a}\right|\right|_2 = \left|\left|\widehat{\boldsymbol{A}}\boldsymbol{a}\right|\right|_2$. Therefore we only need to prove that

$$\left|\left|\widehat{\boldsymbol{A}}^H\widehat{\boldsymbol{A}} - \boldsymbol{I}\right|\right|_K \leq \delta,$$

holds with high probability when M is large enough. Let V_i^{H} denote the ith row of $\widehat{\boldsymbol{A}}$, i.e.,

$$V_i^{\mathrm{H}} = \sum_{l=1}^{L}\tilde{\boldsymbol{z}}_{i,l}\boldsymbol{F}_i^H\boldsymbol{\Psi}_i.$$

Let $\boldsymbol{B}_1 = \sum_{i=1}^{M/2}V_iV_i^H - \boldsymbol{I}/2$ and $\boldsymbol{B}_2 = \sum_{i=M/2+1}^{M}V_iV_i^H - \boldsymbol{I}/2$; it is easy to check that $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ are complex conjugates, and that $\widehat{\boldsymbol{A}}^H\widehat{\boldsymbol{A}} - \boldsymbol{I} = \boldsymbol{B}_1 + \boldsymbol{B}_2$. Therefore $\left|\left|\widehat{\boldsymbol{A}}^H\widehat{\boldsymbol{A}} - \boldsymbol{I}\right|\right|_K \leq 2\left|\left|\boldsymbol{B}_1\right|\right|_K$, and we only need to show that $\left|\left|\boldsymbol{B}_1\right|\right|_K \leq \delta$ with high probability when M is large enough. We can easily see that when $i \neq j$, $1 \leq i, j \leq M/2$, V_i^H and V_j^H are independent.

First we show that $\mathbb{E}\left[\left|\left|\boldsymbol{B}_1\right|\right|_K\right]$ is small with high probability when M is large enough. We then show that $\left|\left|\boldsymbol{B}_1\right|\right|_K$ is concentrated around its mean with high probability when M is large enough. By Lemma 6.7 in Rauhut (2010), for a Rademacher sequence ϵ_i, $i = 1, ..., M/2$, we have

$$\mathbb{E}\left[\left|\left|\boldsymbol{B}_1\right|\right|_K\right] = \mathbb{E}\left[\left|\left|\sum_{i=1}^{M/2}(V_iV_i^H - \frac{1}{M}\boldsymbol{I})\right|\right|_K\right] \leq 2\mathbb{E}\left[\left|\left|\sum_{i=1}^{M/2}\epsilon_iV_iV_i^H\right|\right|_K\right].$$

We can now apply Lemma 8.2 from Rauhut (2010), giving us

$$\begin{aligned}
\mathbb{E}\left[\left|\left|\boldsymbol{B}_1\right|\right|_K\right] &\leq 2\mathbb{E}\left[\left|\left|\sum_{i=1}^{M/2}\epsilon_iV_iV_i^H\right|\right|_K\right] \\
&\leq 2\mathbb{E}\left[\mathbb{E}\left[C_0V_{\max}\sqrt{K}\log\left(100K\right)\sqrt{\log\left(4NL\right)\ln\left(5M\right)}\right.\right. \\
&\qquad \left.\left.\cdot\sqrt{\left|\left|\sum_{i=1}^{M/2}V_iV_i^H\right|\right|_K}\ \middle|V_i, i = 1, ..., M/2\right]\right] \\
&\leq \sqrt{C_1K\log^4(NL)}\sqrt{\mathbb{E}\left[V_{\max}^2\right]\mathbb{E}\left[\left|\left|\boldsymbol{B}_1\right|\right|_K + \frac{1}{2}\right]},
\end{aligned} \tag{12}$$

where the last inequality results due to $25K \leq NL$, $5M \leq 4NL$, the Cauthy-Schwarz inequality and the triangle inequality, and $V_{\max} = \max_{1\leq l\leq M/2} ||V_l||_\infty$. Note that the pth element of V_l^H can be written

$$V_l^H(p) = \sum_{i=1}^{L} \tilde{\boldsymbol{z}}_{l,i} \boldsymbol{F}_l^H \boldsymbol{\Psi}_i(p).$$

and since we know that

$$\sum_{i=1}^{L} |\boldsymbol{F}_l^H \boldsymbol{\Psi}_i(p)|^2 \leq \sum_{i=1}^{L} ||\boldsymbol{\Psi}_i(p)||_2^2 \, \mu^2(\boldsymbol{\Psi}) = \mu^2(\boldsymbol{\Psi}),$$

and

$$V_{\max} = \max_{\substack{1\leq l\leq M/2 \\ 1\leq p\leq NL}} |V_l(p)|$$

we can now use Corollary 5. Setting $Q = MNL/2$, $\mu_0 = \mu(\boldsymbol{\Psi})$ in Corollary 5 yields

$$\mathcal{P}\left[V_{\max}^2 > \frac{\mu^2(\boldsymbol{\Psi})}{M} \log \frac{MNL}{2\eta}\right] \leq \eta, \tag{13}$$

and

$$\mathbb{E}\left[V_{\max}^2\right] \leq \frac{\mu^2(\boldsymbol{\Psi})}{M}(\log \frac{MNL}{2} + 1) \leq C_2 \frac{\mu^2(\boldsymbol{\Psi})}{M} \log(NL). \tag{14}$$

Returning to the inequality in Equation (12), considering (14), we have

$$\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] \leq a\sqrt{\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] + 1},$$

where $a = \sqrt{C_1 C_2 K \log^5(NL)\mu^2(\boldsymbol{\Psi})/M}$. Then $\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] \leq \frac{a^2}{2} + a\sqrt{\frac{1}{2} + \frac{a^2}{4}}$. When $a \leq 1/2$, we get $\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] \leq a$. Let $0 < \boldsymbol{A}' \leq a \leq 1/2$, and we can conclude that when

$$M \geq \frac{C_3 K \mu^2(\boldsymbol{\Psi}) \log^5(NL)}{\delta'},$$

then

$$\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] \leq \delta'.$$

A.1.2 TAIL BOUND

Now we study the tail bound of $||\boldsymbol{B}_1||_K$. First we construct a second set of random variables V_l', which are independent of V_l and are identically distributed as V_l. Additionally, we let

$$\widetilde{\boldsymbol{B}}_1 = \sum_{i=1}^{M/2} \left(V_i V_i^H - V_i' V_i'^H\right),$$

and then according to Charles et al. (2014), there is

$$\mathbb{E}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K\right] \leq 2\mathbb{E}\left[||\boldsymbol{B}_1||_K\right], \tag{15}$$

$$\mathcal{P}\left[||\boldsymbol{B}_1||_K > 2\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] + u\right] \leq 2\mathcal{P}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K > u\right]. \tag{16}$$

Now since we have

$$\left|\left|V_i V_i^H - V_i' V_i'^H\right|\right|_K \leq 2\max\{\left|\left|V_i V_i^H\right|\right|_K, \left|\left|V_i' V_i'^H\right|\right|_K\},$$

and

$$\left|\left|V_i V_i^H\right|\right|_K \leq \sup_{y \text{ is } K-sparse} ||V_i||_\infty^2 \frac{||y||_1^2}{||y||_2^2} \leq K V_{\max}^2,$$

then we know that $\max_{1\leq i\leq M/2} \left|\left|V_i V_i^H\right|\right|_K \leq K V_{\max}^2$ and $\max_{1\leq i\leq M/2} \left|\left|V_i' V_i'^H\right|\right|_K \leq K V_{\max}'^2$, where $V_{\max}' = \max_{1\leq l\leq M/2} ||V_l'||_\infty$ then by Equation (13), we obtain

$$\mathcal{P}\left[\max_{1\leq i\leq M/2} \left|\left|V_i V_i^H\right|\right|_K > \frac{K\mu^2(\boldsymbol{\Psi})}{M} \log \frac{MNL}{2\eta}\right] \leq \mathcal{P}\left[V_{\max}^2 > \frac{\mu^2(\boldsymbol{\Psi})}{M} \log \frac{MNL}{2\eta}\right] \leq \eta.$$

Since the probability theorems depend on bounded random variables, we define $\mathbf{F}$ to denote the following event

$$\mathbf{F} = \left\{\max\left\{\max_{1\leq i\leq M/2} \left|\left|V_i V_i^H\right|\right|_K, \max_{1\leq i\leq M/2} \left|\left|V_i' V_i'^H\right|\right|_K\right\} \leq \frac{K\mu^2(\boldsymbol{\Psi})}{M} \log \frac{MNL}{2\eta}\right\},$$

such that $\mathcal{P}\left[\mathbf{F}^C\right] \leq 2\eta$. Furthermore, we define $\mathbf{I}_F$ as the indicator function of $\mathbf{F}$, and let $\widehat{\boldsymbol{B}}_1 = \sum_{i=1}^{M/2} \xi_i \left(V_i V_i^H - V_i' V_i'^H\right) \mathbf{I}_F$, where $\xi = \{\xi_i\}$, $i = 1, 2, ..., M/2$ is a Rademacher sequence and independent of V_i. The truncated variable $Y_i = \xi_i \left(V_i V_i^H - V_i' V_i'^H\right) \mathbf{I}_F$ has a symmetric distribution and $||Y_i||_K$ is bounded by $B_{\max} := \frac{2K\mu^2(\boldsymbol{\Psi})}{M} \ln \frac{MNL}{2\eta}$. By Proposition 19 in Tropp et al. (2009), we have

$$\mathcal{P}\left[\left|\left|\widehat{\boldsymbol{B}}_1\right|\right|_K > C_4(u\mathbb{E}\left[\left|\left|\widehat{\boldsymbol{B}}_1\right|\right|_K\right] + tB_{\max})\right] \leq e^{-u^2} + e^{-t}, \tag{17}$$

for all $u,\ t \geq 1$. Following Tropp et al. (2009), we find that

$$\mathcal{P}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K > v\right] \leq \mathcal{P}\left[\left|\left|\widehat{\boldsymbol{B}}_1\right|\right|_K > v\right] + \mathcal{P}\left[\mathbf{F}^C\right], \tag{18}$$

and

$$\mathbb{E}\left[\left|\left|\widehat{\boldsymbol{B}}_1\right|\right|_K\right] \leq \mathbb{E}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K\right]. \tag{19}$$

By combining Equations (17), (18), and (19), we get

$$\mathcal{P}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K > C_4(u\mathbb{E}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K\right] + tB_{\max})\right] \leq e^{-u^2} + e^{-t} + 2\eta.$$

In Equation (20), let $\eta < 1/e$, $u = \sqrt{\log \eta^{-1}}$ and $t = \log \eta^{-1}$. These values yield

$$\mathcal{P}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K > C_4(\sqrt{\log \eta^{-1}}\mathbb{E}\left[\left|\left|\widetilde{\boldsymbol{B}}_1\right|\right|_K\right] + (\log \eta^{-1})B_{\max})\right] \leq 4\eta. \tag{20}$$

Now we can combine Equations (15), (16), and (20) to get

$$\mathcal{P}\left[||\boldsymbol{B}_1||_K > 2\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] + 2C_4\sqrt{\log\eta^{-1}}\mathbb{E}\left[||\boldsymbol{B}_1||_K\right] + C_4(\log\eta^{-1})B_{\max}\right] \leq 8\eta.$$

By choosing

$$M \geq \frac{C_3 K\mu^2(\boldsymbol{\Psi})\log^5(NL)}{\delta'^2}, \tag{21}$$

where $\delta' < 1/2$, we obtain

$$\mathcal{P}\left[||\boldsymbol{B}_1||_K > 2\delta' + 2C_4\delta'\sqrt{\log\eta^{-1}} + C_5\log\eta^{-1}\frac{\delta'^2\log\left(\frac{1}{2}MNL\eta^{-1}\right)}{\log^5(NL)}\right] \leq 8\eta.$$

We observe now that

$$\frac{\log(\frac{1}{2}MNL\eta^{-1})}{\log^5(NL)} \leq \frac{2\log(NL) + \log\eta^{-1}}{\log^5(NL)},$$

indicating that when $\eta \geq (NL)^{-\log^4(NL)}$, i.e., $\log\eta^{-1} \leq \log^5(NL)$, then

$$\frac{\log(\frac{1}{2}MNL\eta^{-1})}{\log^5(NL)} \leq C_6,$$

, for a constant C_6. This inequality reduces our probability statement to

$$\mathcal{P}\left[||\boldsymbol{B}_1||_K > 2\delta' + 2C_4\delta'\sqrt{\log\eta^{-1}} + C_5C_6\log\eta^{-1}\delta'^2\right] \leq 8\eta.$$

For an arbitrary δ with $0 < \delta < 1/2$, we let

$$\delta' = \frac{\delta}{2C_4C_7\sqrt{\log\eta^{-1}}}, \tag{22}$$

resulting in

$$2C_4\delta'\sqrt{\log\eta^{-1}} = \frac{\delta}{C_7},$$

$$2\delta' = \frac{\delta}{C_4C_7\sqrt{\log\eta^{-1}}} \leq \frac{\delta}{C_4C_7},$$

$$C_5C_6\log\eta^{-1}\delta'^2 = C_5C_6\frac{\delta^2}{4C_4^2C_7^2} \leq \frac{C_5C_6}{8C_4^2C_7^2}\delta.$$

Then we can see that if

$$C_7 \geq \max\left\{3, \frac{3}{C_4}, \sqrt{\frac{3C_5C_6}{8C_4^2}}\right\},$$

then

$$\mathcal{P}\left[||\boldsymbol{B}_1||_K > \frac{\delta}{3} + \frac{\delta}{3} + \frac{\delta}{3}\right] < 8\eta.$$

Now by plugging (22) into (21), we know that when $(NL)^{-\ln^4(NL)} \leq \eta < 1/e$, there exists a constant C such that when

$$M \geq \frac{CK\mu^2(\boldsymbol{\Psi})\log^5(NL)\log(\eta^{-1})}{\delta^2},$$

there is

$$\mathrm{P}(||\boldsymbol{B}_1||_K > \delta) \leq 8\eta,$$

which completes the proof. ■

A.1.3 LEMMAS FOR THEOREM 2

Lemma 4 *Suppose we have n complex Gaussian random variables, $z_1,\ z_2, \cdots\ z_n$, $z_i = x_i + \mathrm{j}y_i$, where x_i and y_i denote the real and imaginary parts of z_i. Let x_i and y_i i.i.d Gaussian r.v.'s with mean 0 and variance $1/2M$. $\phi_1,\ \phi_2,\ \cdots\ \phi_n$ r.v.'s which are independent of z_i for all i and satisfy*

$$\sum_{i=1}^{n}|\phi_i|^2 \leq \mu_0^2,$$

then for $w = \sum_{i=1}^{n} z_i\phi_i$,

$$\mathcal{P}\left[|w|^2 > u\right] \leq e^{-\frac{Mu}{\mu_0^2}}.$$

Proof We use x and y to denote the real and imaginary parts of w, and a_i and b_i to denote the real and imaginary parts of ϕ_i. We have

$$w = \sum_{i=1}^{n}(a_ix_i - b_iy_i) + \mathrm{j}\sum_{i=1}^{n}(a_iy_i + b_ix_i)x + \mathrm{j}y.$$

Then conditioned on a_i and b_i, x and y have distribution $\mathcal{N}(0, \frac{1}{2M}\sum_{i=1}^{n}(a_i^2 + b_i^2))$.

The next step is to prove the conditional independence of x and y. Since

$$\mathrm{Cov}(a_ix_i - b_iy_i, a_iy_i + b_ix_i|a_i, b_i) = \frac{a_ib_i}{2M} - \frac{a_ib_i}{2M} = 0,$$

when $i \neq j$, x_i, y_i are independent of x_j, y_j, and x and y are conditionally independent. Thus, conditioned on a_i and b_i,

$$\frac{2M}{\sum_{i=1}^{n}(a_i^2 + b_i^2)}|w|^2,$$

is χ^2 distributed. We use χ_2 to denote a two-degree χ^2 distributed random variable. According to the results on χ^2 distributions, we have

$$\mathcal{P}\left[|w|^2 > u|a_i, b_i\right] = \mathcal{P}\left[\chi_2 > \frac{2Mu}{\sum_{i=1}^{n}(a_i^2 + b_i^2)}|a_i, b_i\right] = e^{-\frac{Mu}{\sum_{i=1}^{n}(a_i^2+b_i^2)}} \leq e^{-\frac{Mu}{\mu_0^2}}. \tag{23}$$

Noticing that Equation (23) holds for all possible values of a_i and b_i completes the proof. ■

Corollary 5 *For Q r.v.'s, $w_1,\ w_2,\ \cdots,\ w_Q$, let $w_i = \sum_{l=1}^{n} z_{il}\phi_{il}$ and $z_{il} = x_{il} + \mathrm{j}y_{il}$, where x_{il}, y_{il}, $1 \leq i \leq Q$, $1 \leq l \leq n$ are i.i.d. Gaussian distributed with mean 0 and variance $1/2M$. Suppose for any i, there is*

$$\sum_{l=1}^{n} |\phi_{il}|^2 \leq \mu_0^2.$$

And let $w_{\max} = \max_{1\leq i\leq Q} |w_i|$, then for $\eta > 0$, we have

$$\mathcal{P}\left[w_{\max}^2 > \frac{\mu_0^2}{M}\log\frac{Q}{\eta}\right] \leq \eta,$$

and

$$\mathbb{E}\left[w_{\max}^2\right] \leq \frac{\mu_0^2}{M}(\ln Q + 1).$$

Proof According to Lemma 4 and by using union bound, we have

$$\mathcal{P}\left[w_{\max}^2 > u\right] \leq Qe^{-\frac{Mu}{\mu_0^2}}.$$

Let $\eta = Qe^{-\frac{Mu}{\mu_0^2}}$ and there is

$$\mathcal{P}\left[w_{\max}^2 > \frac{\mu_0^2}{M}\log\frac{Q}{\eta}\right] \leq \eta.$$

Then we have

$$\begin{aligned}\mathbb{E}\left[w_{\max}^2\right] &= \int_0^\infty \mathcal{P}\left[w_{\max}^2 > u\right] du \\ &\leq \int_0^{\frac{\mu_0^2}{M}\ln Q} 1du + \int_{\frac{\mu_0^2}{M}\log Q}^{\infty} Qe^{-\frac{Mu}{\mu_0^2}} du \\ &= \frac{\mu_0^2}{M}(\log Q + 1).\end{aligned}$$

■

A.2 Proof of Low-rank Recovery

In this appendix we prove Theorem 3 where a low-rank input matrix $\boldsymbol{S}$ can be recovered from the network state $\boldsymbol{x}[N]$ via nuclear norm optimization (Candès and Tao, 2010; Candès and Plan, 2010; Recht et al., 2010). To prove this theorem we use the dual certificate approach used to prove similar results in (Ahmed and Romberg, 2015; Candès and Plan, 2011a). In this methodology we seek a certificate $\boldsymbol{Y}$ whose projections into and out of the space spanned by the singular vectors of $\boldsymbol{S}$ are bounded appropriately. Specifically if we consider the singular value decomposition of $\boldsymbol{S}$ as

$$\boldsymbol{S} = \boldsymbol{Q}\boldsymbol{\Sigma}\boldsymbol{V}^*$$

and we consider the projection $\mathcal{P}_T$ which projects a matrix into the space T spanned by the left and right singular vectors,

$$\mathcal{P}_T(\boldsymbol{W}) = \boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{W} + \boldsymbol{W}\boldsymbol{V}\boldsymbol{V}^* - \boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{W}\boldsymbol{V}\boldsymbol{V}^* \tag{24}$$

the conditions for the dual certificate are that $\mathcal{A}$ is injective on T and there exists a matrix $\boldsymbol{Y}$ which satisfies

$$\left|\left|\mathcal{P}_T(\boldsymbol{Y}) - \boldsymbol{Q}\boldsymbol{V}^H\right|\right|_F \leq \frac{1}{2\sqrt{2}\gamma} \tag{25}$$

$$||\mathcal{P}_{T^\perp}(\boldsymbol{Y})|| \leq \frac{1}{2} \tag{26}$$

where the projection $\mathcal{P}_{T^\perp}$ is the projection onto the perpendicular space to T,

$$\mathcal{P}_{T^\perp}(\boldsymbol{W}) = (\boldsymbol{I} - \boldsymbol{Q}\boldsymbol{Q}^*)\boldsymbol{W}(\boldsymbol{I} - \boldsymbol{V}\boldsymbol{V}^*)$$

The remainder of this proof will be devoted to demonstrating that there does exist a certificate $\boldsymbol{Y}$ by iteratively devising $\boldsymbol{Y}$ via a golfing scheme (Gross, 2011; Candès and Plan, 2011a; Ahmed et al., 2014). The golfing scheme essentially generates an iterative method which defined a series of certificate vectors $\boldsymbol{Y}_k$ for $k \in [1, \cdots, \kappa]$ which converge to a certificate $\boldsymbol{Y}_\kappa$ which satisfies the necessary conditions. As in (Ahmed and Romberg, 2015), we can initialize the 0^{th} iterate to zero, and define the k^{th} iterate in terms of the $\boldsymbol{Y}_{k-1}$ as

$$\boldsymbol{Y}_k = \boldsymbol{Y}_{k-1} + \kappa\mathcal{A}_k^*\mathcal{A}_k(\boldsymbol{Q}\boldsymbol{V}^* - \mathcal{P}_T(\boldsymbol{Y}_{k-1})),$$

where

$$\mathcal{A}(\boldsymbol{W}) = \mathrm{vec}\left(\langle \boldsymbol{A}_n, \boldsymbol{W}\rangle\right). \tag{27}$$

We can see that since every iterate has $\mathcal{A}_k^*$ applied to it, every iteration is projected in to the range of $\mathcal{A}^*$, indicating that the final iteration $\boldsymbol{Y}$ will also be in the range of $\mathcal{A}^*$. In (Ahmed and Romberg, 2015), Asif and Romberg define a simpler iteration

$$\widetilde{\boldsymbol{Y}}_k = (\mathcal{P}_T - \kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T)\widetilde{\boldsymbol{Y}}_{k-1},$$

which is expressed in terms of the modified certificate

$$\widetilde{\boldsymbol{Y}}_k = \mathcal{P}_T(\boldsymbol{Y}_k) - \boldsymbol{Q}\boldsymbol{V}^*.$$

What remains now is to demonstrate that this iterative procedure converges, with high probability, to a certificate which satisfies the desired dual certificate conditions. We start by using Lemma 9 and observing that the Forbenious norm of the k^{th} iterate is well bounded with probability $1 - O((LN)^{-\beta})$ by

$$\begin{aligned}\left|\left|\widetilde{\boldsymbol{Y}}_k\right|\right|_F &\leq \max_k ||\mathcal{P}_T - \kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T|| \left|\left|\widetilde{\boldsymbol{Y}}_{k-1}\right|\right|_F \\ &\leq 2^{-k}\left|\left|\widetilde{\boldsymbol{Y}}_0\right|\right|_F \\ &\leq 2^{-k}||\boldsymbol{Q}\boldsymbol{V}^*||_F \\ &\leq 2^{-k}\sqrt{R},\end{aligned}$$

so long that $M \leq c\beta\kappa R(N+\mu_0^2 L)\log^2(LN)$. As in (Ahmed and Romberg, 2015) we observe that when we choose $\kappa \geq 0.5\log_2(8\gamma^2 R)$, the bound for the Frobenious norm of $\widetilde{\boldsymbol{Y}}_\kappa$ is bounded by $\left|\left|\widetilde{\boldsymbol{Y}}_\kappa\right|\right|_F \leq (2\sqrt{2}\gamma)^{-1}$.

To show that the second condition on the certificate is also satisfies, we apply Lemma 10. We begin with writing the quantity we wish to bound in terms of the past golfing scheme iterate

$$\begin{aligned}
||\mathcal{P}_{T^\perp}(\boldsymbol{Y}_\kappa)|| &\leq \sum_{k=1}^{\kappa}\left|\left|\mathcal{P}_{T^\perp}\left(\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}\right)\right|\right| \\
&= \sum_{k=1}^{\kappa}\left|\left|\mathcal{P}_{T^\perp}\left(\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}-\widetilde{\boldsymbol{Y}}_{k-1}\right)\right|\right| \\
&\leq \sum_{k=1}^{\kappa}\left|\left|\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}-\widetilde{\boldsymbol{Y}}_{k-1}\right|\right| \\
&\leq \sum_{k=1}^{\kappa}\left|\left|\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}-\widetilde{\boldsymbol{Y}}_{k-1}\right|\right|_F \\
&\leq \sum_{k=1}^{\kappa}\max_{k\in[1,\dots\kappa]}\left|\left|\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}-\widetilde{\boldsymbol{Y}}_{k-1}\right|\right|_F \\
&\leq \sum_{k=1}^{\kappa}\frac{1}{2}2^{-k} \\
&\leq \frac{1}{2}
\end{aligned}$$

We use Lemma 10 to bound the maximum spectral norm of $\kappa\mathcal{A}_k^*\mathcal{A}_k\widetilde{\boldsymbol{Y}}_{k-1}-\widetilde{\boldsymbol{Y}}_{k-1}$ with probability $1-O((LN)^{1-\beta}$. Taking $\kappa \geq \log(LN)$ shows that the final certificate $\boldsymbol{Y}_\kappa$ satisfies all the desired properties, completing the proof.

A.2.1 MATRIX BERNSTEIN INEQUALITY AND OLICZ NORM

The lemmas required in our main result depend heavily on the matrix Bernstein inequality (Tropp, 2012). This inequality uses the variance measure and Oricz norm of a matrix to bound the largest singular value of the matrix. The matrix Bernstein inequality is summarized as

Theorem 6 (Matrix Bernstein's Inequality) *Let $\boldsymbol{X}_i \in \mathbb{R}^{L,N}$, $i \in [1,\dots,M]$ be M random matrices such that $\mathbb{E}[\boldsymbol{X}_i]=0$ and $||\boldsymbol{X}_i||_{\psi_\alpha} < U_\alpha < \infty$ for some $\alpha \geq 1$. Then with probability $1-e^{-t}$, the spectral norm of the sum is bounded by*

$$\left|\left|\sum_{i=1}^{M}\boldsymbol{X}_i\right|\right| \leq C\max\left\{\sigma_X\sqrt{t+\log(L+N)}, U_\alpha\log^{1/\alpha}\left(\frac{MU_\alpha^2}{\sigma_X^2}\right)(t+\log(L+N))\right\},$$

for some constant C and the variance parameter defined by

$$\sigma_X = \max\left\{\left|\left|\sum_{i=1}^{M}\mathbb{E}[\boldsymbol{X}_i\boldsymbol{X}_i^*]\right|\right|^{1/2}, \left|\left|\sum_{i=1}^{M}\mathbb{E}[\boldsymbol{X}_i^*\boldsymbol{X}_i]\right|\right|^{1/2}\right\}.$$

where Orlicz-α norm $||X||_{\psi_\alpha}$ is defined as

$$||X||_{\psi_\alpha} = \inf\left\{y>0|\mathbb{E}\left[e^{||X||^\alpha/y^\alpha}\right]\leq 2\right\}. \tag{28}$$

In particular we will use the matrix Bernstein inequality with the Orlicz-1 and Orlicz-2 norms, since subgaussian and subexponential random variables have bounded Orlicz-2 and -1 norms, respectively. To calculate these norms, we find the following lemmas from (Tropp, 2012; Ahmed and Romberg, 2015) useful:

Lemma 7 (Lemma 5.14, Tropp, 2012) *A random variable X is subgaussian iff X^2 is subexponential. Furthermore,*

$$||X||_{\psi_2}^2 \leq \left|\left|X^2\right|\right|_{\psi_1} \leq 2||X||_{\psi_2}^2.$$

Lemma 8 (Lemma 7, Ahmed and Romberg, 2015) *Let X_1 and X_2 be two subgaussian ranfom variables. Then the product X_1X_2 is a subexponential random variable with*

$$||X_1X_2||_{\psi_1} \leq c||X_1||_{\psi_2}||X_2||_{\psi_2}.$$

Lemma 7 relates the Orlicz-1 and -2 norms for a random variable and it's square. Lemma 8 allows us to factor an Orlicz-1 norm of a sub-exponential random variable as the product of two subgaussian random variables. Finally we find useful the following calculation for the Orlicz-1 norm of the norm of a random Gaussian vector $\boldsymbol{z}_n$ with *i.i.d.* zero-mean and variance σ^2 entries:

$$\begin{aligned}
\left|\left|||\boldsymbol{z}_n||_2^2\right|\right|_{\psi_1} &= \inf\left\{y:\mathbb{E}\left[e^{||\boldsymbol{z}_n||_2^2/y}\right]\leq 2\right\} \\
&= \inf\left\{y:\frac{1}{\sqrt{2\pi\sigma}}\int_{\mathbb{R}}e^{-z_n^2(1/2\sigma^2-1/y)}dz_n \leq 2^{\frac{1}{M}}\right\} \\
&= \frac{2\sigma^2}{1-4^{-\frac{1}{M}}}.
\end{aligned} \tag{29}$$

A.2.2 BOUND ON $||\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T-\mathcal{P}_T||$

Lemma 9 *Let $\mathcal{P}_T$ be defined as in Equation (24) and $\mathcal{A}_k$ be the restricted measurement operator as defined in Equation (27). Then if the number of nodes scale as*

$$M \geq c\beta\kappa R\left(N+\mu_0^2L\right)\log^2(LN),$$

for a constant $\beta>1$, then with probability greater then $1-O(\kappa(LN)^{-\beta}$, we have

$$\max_{k\in[1,\dots,\kappa]}||\kappa\mathcal{P}_T\mathcal{A}^*\mathcal{A}\mathcal{P}_T-\mathcal{P}_T|| \leq \frac{1}{2}.$$

Proof

Lemma 9 bounds the operator norm

$$||\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T-\mathcal{P}_T||.$$

Since $\mathbb{E}\left[\mathcal{A}_k^*\mathcal{A}_k\right] = \frac{1}{\kappa}\mathcal{I}$, this norm is equivalent to

$$\begin{aligned}\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T - \mathcal{P}_T &= \kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T - \mathbb{E}\left[\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T\right] \\ &= \kappa\sum_{n\in\Gamma_k}\left(\mathcal{P}_T(\boldsymbol{A}_n)\otimes\mathcal{P}_T(\boldsymbol{A}_n) - \mathbb{E}\left[\mathcal{P}_T(\boldsymbol{A}_n)\otimes\mathcal{P}_T(\boldsymbol{A}_n)\right]\right).\end{aligned}$$

We can also define here $\mathcal{L}_n(\boldsymbol{C}) = \langle\mathcal{P}_T(\boldsymbol{A}_n), \boldsymbol{C}\rangle\mathcal{P}_T(\boldsymbol{A}_n)$ which has $||\mathcal{L}_n|| = ||\mathcal{P}_T(\boldsymbol{A}_n)||_F^2$ which gives us

$$\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T - \mathbb{E}\left[\kappa\mathcal{P}_T\mathcal{A}_k^*\mathcal{A}_k\mathcal{P}_T\right] = \kappa\sum_{n\in\Gamma_k}\left(\mathcal{L}_n - \mathbb{E}\left[\mathcal{L}_n\right]\right).$$

To calculate the variance, we can use the symmetry of $\mathcal{L}_n$ to only calculate

$$\kappa^2\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\mathcal{L}_n^2\right] - \mathbb{E}\left[\mathcal{L}_n\right]^2\right|\right| \leq \kappa^2\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\mathcal{L}_n^2\right]\right|\right| = \kappa^2\left|\left|\mathbb{E}\left[\sum_{n\in\Gamma_k}\|\mathcal{P}_T(\boldsymbol{A}_n)\|_F^2\mathcal{L}_n\right]\right|\right|.$$

We now need to bound $\|\mathcal{P}_T(\boldsymbol{A}_n)\|_F^2$, which can be done by the following:

$$\begin{aligned}||\mathcal{P}_T(\boldsymbol{A}_n)||_F^2 &= \langle\mathcal{P}_T(\boldsymbol{A}_n), \boldsymbol{A}_n\rangle \\ &= \langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*, \boldsymbol{z}_n\boldsymbol{f}_n^*\rangle + \langle\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{z}_n\boldsymbol{f}_n^*\rangle - \langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{z}_n\boldsymbol{f}_n^*\rangle \\ &= \|\boldsymbol{f}_n\|_2^2\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2 + \|\boldsymbol{z}_n\|_2^2\|\boldsymbol{V}^*\boldsymbol{f}_n\|_2^2 - \|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\|\boldsymbol{V}^*\boldsymbol{f}_n\|_2^2 \\ &\leq N\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2 + \|\boldsymbol{z}_n\|_2^2\|\boldsymbol{V}^*\boldsymbol{f}_n\|_2^2.\end{aligned}$$

Using this calculation we can write

$$\begin{aligned}\left|\left|\mathbb{E}\left[\sum_{n\in\Gamma_k}||\mathcal{P}_T\left(\boldsymbol{A}_n\right)||_F^2\mathcal{L}_n\right]\right|\right| &\leq \left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\left(N\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2 + \|\boldsymbol{z}_n\|_2^2\|\boldsymbol{V}^*\boldsymbol{f}_n\|_2^2\right)\mathcal{L}_n\right]\right|\right| \\ &\leq N\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\mathcal{L}_n\right]\right|\right| \\ &\quad + \sup\|\boldsymbol{V}^*\boldsymbol{f}_n\|_\infty\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{z}_n\|_2^2\mathcal{L}_n\right]\right|\right| \\ &\leq N\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\mathcal{L}_n\right]\right|\right| + R\mu_0^2\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{z}_n\|_2^2\mathcal{L}_n\right]\right|\right|\end{aligned}$$

We now need to bound these two quantities. First we look to bound the first quantity

$$\begin{aligned}\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2(\mathcal{P}_T(\boldsymbol{A}_n)\otimes\mathcal{P}_T(\boldsymbol{A}_n))\right]\right|\right| &\leq \|\mathcal{P}_T\|\left|\left|\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2(\boldsymbol{A}_n\otimes\boldsymbol{A}_n)\right]\right|\right|\|\mathcal{P}_T\| \\ &\leq \left|\left|\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\{z_n[\alpha]z_n^*[\beta]\boldsymbol{f}_n\boldsymbol{f}_n^*\}_{\alpha,\beta}\right]\right|\right|.\end{aligned}$$

Expanding, we have:

$$\begin{aligned}* &= \left|\left|\mathbb{E}\left[\left(\sum_{l=1}^{L}\|\boldsymbol{q}_l\|_2^2|z_n[l]|^2 + 2\sum_{l\neq m}\mathrm{Re}(\langle\boldsymbol{q}_l, \boldsymbol{q}_m\rangle z_n[l]z_n^*[m])\right)z_n[\alpha]z_n^*[\beta]\boldsymbol{I}_N\right]_{\alpha,\beta}\right|\right| \\ &= \left|\left|\left\{\frac{1}{M^2}\sum_{l=1}^{L}\|\boldsymbol{q}_l\|_2^2\boldsymbol{I}_N\delta_{\alpha=\beta} + \frac{2}{M^2}\langle\boldsymbol{q}_\alpha, \boldsymbol{q}_\beta\rangle\boldsymbol{I}_N\delta_{\alpha\neq\beta}\right\}_{\alpha,\beta}\right|\right| \\ &= \frac{1}{M^2}\left|\left|\left\{\|\boldsymbol{Q}\|_F^2\boldsymbol{I}_N\delta_{\alpha=\beta} + 2\langle\boldsymbol{q}_\alpha, \boldsymbol{q}_\beta\rangle\boldsymbol{I}_N\delta_{\alpha\neq\beta}\right\}_{\alpha,\beta}\right|\right|,\end{aligned}$$

giving us

$$\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2(\mathcal{P}_T(\boldsymbol{A}_n)\otimes\mathcal{P}_T(\boldsymbol{A}_n))\right]\right|\right| \leq \frac{1}{M\kappa}\|\boldsymbol{Q}\|_F^2 + \|\boldsymbol{Q}\boldsymbol{Q}^*\| \leq \frac{R+1}{M\kappa}.$$

Similarly, for the second term we can take $\boldsymbol{Q} = \boldsymbol{I}_L$ to get

$$\left|\left|\sum_{n\in\Gamma_k}\mathbb{E}\left[\|\boldsymbol{z}_n\|_2^2(\mathcal{P}_T(\boldsymbol{A}_n)\otimes\mathcal{P}_T(\boldsymbol{A}_n))\right]\right|\right| \leq \frac{1}{M\kappa}\|\boldsymbol{I}\|_F^2 = \frac{L}{M\kappa}.$$

Putting the pieces together, we get

$$\sigma_X^2 = \kappa R\frac{N + \mu_0^2 L}{M}.$$

To use the matrix Bernstein inequality, it now remains to bound the following Orlicz-1 norm: $\kappa\,||\mathcal{L}_n - \mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1}$. By the PSD quality of $\mathcal{L}_n$ and its expectation,

$$||\mathcal{L}_n - \mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1} \leq \max\left\{||\mathcal{L}_n||_{\psi_1} - ||\mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1}\right\}.$$

The norm of $||\mathbb{E}\left[\mathcal{L}_n\right]||$ can be calculated via

$$||\mathbb{E}\left[\mathcal{L}_n\right]|| = ||\mathbb{E}\left[\mathcal{P}_T\left(\boldsymbol{A}_n\right)\right]||_F^2 = \mathbb{E}\left[\sum_m|z_n[m]|^2|f_n[m]|^2\right] = \frac{1}{M}\|\boldsymbol{f}_n\|_2^2 = \frac{N}{M},$$

indicating that the second term is simply $||\mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1} = N/(M\log(2))$. To calculate $||\mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1}$, we use the definition of the Orlitcz-1 norm in Equation (28) to see that

$$||\mathcal{L}_n||_{\psi_1} = \left|\left|||\mathcal{P}_T\left(\boldsymbol{A}_n\right)||_2^2\right|\right|_{\psi_1} \leq N\left|\left|\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\right|\right|_{\psi_1} + RN\mu_0^2\left|\left|\|\boldsymbol{z}_n\|_2^2\right|\right|_{\psi_1},$$

where the inequality stems form the fact that $\|\boldsymbol{V}^*\boldsymbol{f}_n\|_2^2 \leq RN\mu_0^2$ and $\|\boldsymbol{f}_n\|_2^2 \leq N$. Using the result in Equation (29) with $\sigma^2 = 1/M$ in the first term and in $\sigma^2 = R/M$ in the second term yields

$$\begin{aligned}||\mathbb{E}\left[\mathcal{L}_n\right]||_{\psi_1} &\leq N\left|\left|\|\boldsymbol{Q}^*\boldsymbol{z}_n\|_2^2\right|\right|_{\psi_1} + RN\mu_0^2\left|\left|\|\boldsymbol{z}_n\|_2^2\right|\right|_{\psi_1} \\ &\leq \frac{1}{M}\left(\frac{N}{M(1-4^{-\frac{1}{R}})} + \frac{R\mu_0^2}{1-4^{-\frac{1}{L}}}\right) \\ &\leq \frac{2R\left(N + L\mu_0^2\right)}{\log(2)M}.\end{aligned}$$

We now have appropriate bounds on both the variance and Orliscz norm, permitting a bound on the largest singular value via the Matrix Bernstein inequality. Specifically, we can see that the first term in Theorem 6 with $t = \beta \log(LN) > \log(N+L)$ is bounded as

$$\sigma_X \sqrt{t + \log(L+N)} \leq \sqrt{2\kappa R\beta \frac{N+\mu_0^2 L}{M} \log(LN)}.$$

Likewise we can bound the second term:

$$\begin{aligned} U_1 \log\left(\frac{MU_1^2}{\sigma_X^2}\right)(t + \log(L+N)) &\leq 2\beta U_1 \log\left(\frac{4\Delta\kappa R(N+\mu_0^2 L)}{\log^2(2)M}\right)\log(LN) \\ &\leq c\frac{\beta\kappa R(N+\mu_0^2 L)}{M}\log^2(LN). \end{aligned}$$

Thus to appropriately bound

$$||\kappa \mathcal{P}_T \mathcal{A}_k^* \mathcal{A}_k \mathcal{P}_T - \mathcal{P}_T|| \leq c\max\left\{\sqrt{\frac{\kappa R\beta(N+\mu_0^2 L)}{M}\log(LN)}, \frac{\beta\kappa R(N+\mu_0^2 L)}{M}\log^2(LN)\right\},$$

we can see that we would need

$$M \geq C\beta\kappa R(N+\mu_0^2 L)\log^2(LN).$$

Taking the union bound over the κ partitions completes the proof of the lemma. ■

A.2.3 BOUND ON $\|(\mathcal{A}^*\mathcal{A} - \mathcal{I})(\boldsymbol{G})\|$

Lemma 10 *Let $\mathcal{A}_k$ be defined as in Equation (27), $\kappa < M$ be the number of steps in the golfing scheme and assume that $M \leq LN$. Then as long as*

$$M \geq c\beta\kappa \max\left(N + \mu_0^2 L\right)\log^2(NL),$$

where μ_k^2 is the coherence term defined by

$$\mu_k^2 = R^{-1} \sup_{\omega\in[0,2\pi]} \left|\left|\widetilde{\boldsymbol{Y}}_k^* \boldsymbol{f}_\omega\right|\right|_2^2, \tag{30}$$

then with probability at least $1 - O(M(LN)^{-\beta})$, we have

$$\max_k \left|\left|\kappa \mathcal{A}_k^* \mathcal{A}_k(\widetilde{\boldsymbol{Y}}_{k-1}) - \widetilde{\boldsymbol{Y}}_{k-1}\right|\right| \leq 2^{-(k+1)}.$$

Proof

Lemma 10 essentially bounds the operator norm of $\kappa\mathcal{A}^*\mathcal{A} - \mathcal{I}$. In particular, to prove Theorem 2, the reduced version with $\kappa = 1$ is needed. Lemma 2 essentially uses the matrix Bernstein inequality to accomplish this task, taking

$$X_n = \kappa(\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle \boldsymbol{A}_n - \mathbb{E}\left[\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle \boldsymbol{A}_n\right]),$$

and we just need to control $||\sum \mathbb{E}\left[X_n X_n^*\right]||$ and $||\sum \mathbb{E}\left[X_n^* X_n\right]||$. To bound the second of these, we can calculate

$$\begin{aligned} \left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[X_n^* X_n\right]\right|\right| &\leq \kappa^2 \left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[|\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{A}_n \boldsymbol{A}_n^*\right]\right|\right| \\ &= \kappa^2 \left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[||\boldsymbol{f}_n||_2^2 |\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right]\right|\right| \\ &\leq \frac{3N\kappa}{M}||\boldsymbol{G}||_F^2, \end{aligned}$$

where the second inequality is due to Lemma 11 and $||\boldsymbol{f}_n||_2^2 \leq N$. For the other expectation

$$\begin{aligned} \left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[X_n X_n^*\right]\right|\right| &\leq \kappa^2 \left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[|\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{A}_n^* \boldsymbol{A}_n\right]\right|\right| \\ &= \frac{L\kappa^2}{M^2}\left|\left|\sum_{n\in\Gamma_k} \mathbb{E}\left[\|\boldsymbol{G}\boldsymbol{f}_n\|_2^2 \boldsymbol{f}_n \boldsymbol{f}_n^*\right]\right|\right| \\ &\leq \frac{L\kappa^2}{M^2}\sup_\omega(\|\boldsymbol{G}\boldsymbol{f}_\omega\|_2^2)\left|\left|\sum_{n\in\Gamma_k} \mathbf{1}_N\right|\right| \\ &\leq \frac{L\kappa}{M}\sup_\omega(\|\boldsymbol{G}\boldsymbol{f}_\omega\|_2^2) \\ &= \frac{L\kappa}{M}\mu^2\|\boldsymbol{G}\|_F^2. \end{aligned}$$

Using these bounds, we can write

$$\sigma_X^2 \leq \frac{\kappa}{M}\|\boldsymbol{G}\|_F^2 \max\left\{\mu_0 L, 3N\right\},$$

and to use Proposition 1 we just need to bound $\|X\|_{\psi_2}$. To start, we can see that

$$\begin{aligned} U_1 &= ||X||_{\psi_1} \leq 2\kappa\,||\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle \boldsymbol{A}_n||_{\psi_1} \\ &\leq c\kappa\,||\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle||_{\psi_2}\,||||\boldsymbol{A}_n||_F||_{\psi_2} \\ &\leq c\kappa\,||\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle||_{\psi_2}\sqrt{\left|\left|||\boldsymbol{f}_n||_2^2 ||\boldsymbol{z}_n||_2^2\right|\right|_{\psi_2}} \\ &= c\kappa\sqrt{\frac{N}{M\left(1-4^{-1/L}\right)}}\,|||\text{trace}(\boldsymbol{f}_n \boldsymbol{z}_n^* \boldsymbol{G})||_{\psi_2} \\ &\leq c\kappa\sqrt{\frac{N}{M^2\left(1-4^{-1/L}\right)}}\sum_{l=1}^L ||\langle \boldsymbol{g}_l, \boldsymbol{f}_n\rangle||_{\psi_2} \\ &\leq c\kappa\sqrt{\frac{N^2 L\mu_0^2\|\boldsymbol{G}\|_F^2}{M^2}}. \end{aligned}$$

We can now apply the matrix Bernstein theorem with the calculated values of U_1 and σ_X. Again using $t = \beta \log(LN)$, the first portion of the bound is

$$\sigma_X \sqrt{t + \log(L+N)} \leq c \left|\left|\boldsymbol{G}\right|\right|_F \sqrt{\frac{\kappa\beta}{M} \max\{\mu_k^2 L, N\} \log(LN)},$$

and the second portion of the bound is

$$\begin{aligned} U_1 \log\left(\frac{\Delta U_1^2}{\sigma_X}\right)&(t + \log(L+N)) \\ &\leq c \left|\left|\boldsymbol{G}\right|\right|_F \kappa \sqrt{\frac{LN\mu_k^2}{M}} \log\left(\frac{LN\mu_k^2}{M^2} \frac{Mc \left|\left|\boldsymbol{G}\right|\right|_F^2 \kappa^2}{\kappa \left|\left|\boldsymbol{G}\right|\right|_F^2 \max\{\mu_k^2 L, N\}}\right) \beta \log(LN) \\ &\leq c \left|\left|\boldsymbol{G}\right|\right|_F \kappa \sqrt{\frac{LN\mu_k^2}{M}} \log\left(\frac{c\Delta\kappa LN\mu_k^2}{M \max\{\mu_k^2 L, N\}}\right) \beta \log(LN) \\ &\leq c\beta \left|\left|\boldsymbol{G}\right|\right|_F \kappa \sqrt{\frac{LN\mu_k^2}{M}} \log\left(\min\{\mu_k^2 L, N\}\right) \log(LN). \end{aligned}$$

We can now use Lemma 12 to bound $\mu_k^2 \leq \mu_0^2$ with probability $1 - O(M(LN)^{-\beta})$ and Lemma 9 to bound $\left|\left|\boldsymbol{G}_k\right|\right|_F \leq 2^{-k}\sqrt{R}$, which gives us a bound of

$$\begin{aligned} \left|\left|(\mathcal{A}^*\mathcal{A} - \mathcal{I})\boldsymbol{G}\right|\right| \leq c 2^{-k/2} \max\Bigg\{ &\sqrt{\frac{\kappa\beta R \log(LN)}{M} \log(\max\{\mu_0^2 L, N\})}, \\ &\sqrt{\mu_0^2 LN} \frac{\beta\kappa}{M} \log(LN) \log(\min\{\mu_0^2 L, N\}) \Bigg\}. \end{aligned}$$

Simplifying the bound using $R \leq \min\{L, N\}$,

$$\left|\left|(\mathcal{A}^*\mathcal{A} - \mathcal{I})\boldsymbol{G}\right|\right| \leq c 2^{-k/2} \max\left\{ \sqrt{\frac{\kappa\beta R \log(LN)}{M} \log(LN)}, \sqrt{\mu_0^2 LN} \frac{\beta\kappa}{M} \log^2(LN)) \right\}$$

Taking

$$M \geq c\beta\kappa R \max\{N, L\mu_0^2\} \log^2(LN),$$

proves the lemma. To simplify the bound on the probability, we note that Lemma 12 holds with probability $1 - O(M(LN)^{-\beta})$ and this lemma holds with probability $1 - O(\kappa(LN)^{-\beta})$. Since $\kappa < M$ and assuming that $M \leq LN$, we can write that the result holds with probability $1 - O((LN)^{1-\beta})$. Additionally, since Lemma 12 holds when

$$M \geq c\beta\kappa R \left(N + L\mu_0^2\right) \log^2(LN) \geq c\beta\kappa R \max\{N, L\mu_0^2\} \log^2(LN),$$

Then both lemmas hold under the same condition. ■

A.2.4 BOUND ON $\mathbb{E}\left[|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right]$

Lemma 11 bounds the spectrum of the expected matrix

$$\mathbb{E}\left[|\langle \boldsymbol{G}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right]:$$

Lemma 11 *Suppose $\boldsymbol{A}_n = \boldsymbol{z}_n \boldsymbol{f}_n^*$ be defined as the outer product of an* i.i.d. *random Gaussian vector $\boldsymbol{z}_n$ with zero mean and variance $1/M$ and a random Fourier vector $\boldsymbol{f}_n$. Then the operator $|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*$ satisfies*

$$\mathbb{E}_z\left[|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right] \preceq \frac{3}{M^2} \|\boldsymbol{C}^* \boldsymbol{f}_n\|_2^2 \boldsymbol{I}_M,$$

and

$$\mathbb{E}_{z,f}\left[|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right] \preceq \frac{3}{M^2} \|\boldsymbol{C}\|_F^2 \boldsymbol{I}_M.$$

Proof

To begin the proof, we look at the expectation of each element of the matrix. We first calculate the expectation with respect to $\boldsymbol{z}_n$,

$$\begin{aligned} * &= \mathbb{E}_z\left[\left|\sum_{l=1}^L z_n[l] \boldsymbol{c}_l^* \boldsymbol{f}_n\right|^2 z_n[\alpha] z_n^*[\beta]\right] \\ &= \mathbb{E}_z\left[\left(\sum_{l=1}^L z_n[l] \boldsymbol{c}_l^* \boldsymbol{f}_n\right)^* \left(\sum_{l=1}^L z_n[l] \boldsymbol{c}_l^* \boldsymbol{f}_n\right) z_n[\alpha] z_n^*[\beta]\right] \\ &= \mathbb{E}_z\left[\sum_{l=1}^L |z_n[l]|^2 |\boldsymbol{c}_l^* \boldsymbol{f}_n|^2 z_n[\alpha] z_n^*[\beta] + 2\sum_{k \neq l} \mathrm{Re}\left(z_n^*[l] z_n[k] \langle \boldsymbol{c}_l^* \boldsymbol{f}_n, \boldsymbol{c}_k^* \boldsymbol{f}_n\rangle\right) z_n[\alpha] z_n^*[\beta]\right] \\ &= \left(\frac{3}{2M^2} |\boldsymbol{c}_\alpha^* \boldsymbol{f}_n|^2 + \frac{1}{M^2} \|\boldsymbol{C}\boldsymbol{f}_n\|_2^2\right) \delta_{\alpha=\beta} + \frac{2}{M^2} \langle \boldsymbol{c}_\alpha^* \boldsymbol{f}_n, \boldsymbol{c}_\beta^* \boldsymbol{f}_n\rangle \delta_{\alpha\neq\beta}. \end{aligned}$$

We can then use the matrix formulation

$$\begin{aligned} \mathbb{E}_z\left[|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right] &= \frac{3}{2M^2} \mathrm{diag}(\boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^*) + \frac{1}{M^2} \|\boldsymbol{C}\boldsymbol{f}_n\|_2^2 \boldsymbol{I}_M \\ &\quad + \frac{2}{M^2} \boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^* + \frac{2}{M^2} \mathrm{diag}(\boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^*) \\ &= \frac{1}{M^2} \|\boldsymbol{C}\boldsymbol{f}_n\|_2^2 \boldsymbol{I}_M + 2\boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^* - \frac{1}{2} \mathrm{diag}(\boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^*) \\ &\preceq \frac{3}{M^2} \|\boldsymbol{C}\boldsymbol{f}_n\|_2^2 \boldsymbol{I}_M, \end{aligned}$$

where to obtain the result we first use the linearity of the expectation along with the with the positive-semidefinite property of $\mathrm{diag}(\boldsymbol{C}\boldsymbol{f}_n \boldsymbol{f}_n^* \boldsymbol{C}^*)$, proving the fist portion of the Lemma. To prove the second portion we simply take an expectation with respect to $\boldsymbol{f}_n$:

$$\mathbb{E}_{z,f}\left[|\langle \boldsymbol{C}, \boldsymbol{A}_n\rangle|^2 \boldsymbol{z}_n \boldsymbol{z}_n^*\right] \preceq \mathbb{E}_f\left[\frac{3}{M^2} \|\boldsymbol{C}\boldsymbol{f}_n\|_2^2 \boldsymbol{I}_M\right] \preceq \frac{3}{M^2} \|\boldsymbol{C}\|_F^2 \boldsymbol{I}_{,M},$$

completing the proof. ■

A.2.5 CONTRACTIVE PROPERTY OF μ_k^2

Lemma 12 *Let μ_k^2 be the coherence factor as defined in Equation* (30)*, and additionally assume that $L > 1$ and that $LN > R\mu_0^4$. If*

$$M \geq c\beta\kappa R\left(N + L\mu_0^2\right)\log^2(LN),$$

then with probability at least $1 - O(\kappa(LN)^{-\beta})$,

$$\mu_k^2 \leq 2^{-1}\mu_{k-1}^2,$$

for all $k \in [1, \cdots, \kappa]$.

Proof

In Lemma 12 we show that the coherence term reduces at each golfing iteration. Observe that

$$\mu_k^2 = \frac{1}{R}\sup_{\omega}\sum_{l=1}^{L}\langle\widetilde{\boldsymbol{Y}}_k, \boldsymbol{e}_l\boldsymbol{f}^*\rangle^2$$

$$\begin{aligned}
&= \frac{1}{R}\sup_{\omega}\sum_{l=1}^{L}\left(\sum_{n\in\Gamma_k}\kappa\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle - \langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{e}_l\boldsymbol{f}^*\rangle\right)^2 \\
&= \frac{1}{R}\sup_{\omega}\sum_{l=1}^{L}\left(\sum_{n\in\Gamma_k}\kappa\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle - \mathbb{E}\left[\kappa\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle\right]\right)^2.
\end{aligned}$$

To bound this quantity we use the scalar Bernstein inequality on each of the inner quantities

$$\sum_{n\in\Gamma_k}X_n = \sum_{n\in\Gamma_k}\kappa\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle - \mathbb{E}\left[\kappa\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle\right].$$

As in the matrix Bernstein formulation, we require both the variance and Orlicz norm. First we find the variance,

$$\begin{aligned}
\sum_{n\in\Gamma_k}\mathbb{E}\left[X_nX_n^*\right] &= \kappa^2\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad -|\mathbb{E}\left[\langle\mathcal{P}_T\left(\boldsymbol{A}_n\right), \boldsymbol{e}_l\boldsymbol{f}^*\rangle\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle\right]|^2 \\
&\leq \kappa^2\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle + \langle\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}, \boldsymbol{e}_l\boldsymbol{f}^*\rangle\right. \\
&\qquad \left.+\langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\leq \kappa^2\sum_{n\in\Gamma_k}\mathbb{E}\left[\left(|\langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2 + |\langle\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{f}^*\rangle z_n[l]|^2\right.\right. \\
&\qquad \left.\left.+|\langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2\right)|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right].
\end{aligned}$$

This sum consists of three terms. The first of which can be bounded using Lemma 11,

$$\begin{aligned}
&\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad = \sum_{n\in\Gamma_k}\mathbb{E}\left[|\boldsymbol{f}_n^*\boldsymbol{f}\langle\boldsymbol{q}_l, \boldsymbol{Q}^*\boldsymbol{z}_n\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad \leq 3\sum_{n\in\Gamma_k}\mathbb{E}\left[\boldsymbol{f}^*\boldsymbol{f}_n\boldsymbol{f}_n^*\boldsymbol{f}\boldsymbol{q}_l^*\boldsymbol{Q}^*\left|\left|\widetilde{\boldsymbol{Y}}_{k-1}\boldsymbol{f}_n\right|\right|_2^2\boldsymbol{I}_L\boldsymbol{Q}\boldsymbol{q}_l\right] \\
&\qquad \leq \frac{3R\mu_{k-1}^2}{M^3}\left|\left|\boldsymbol{q}_l\right|\right|_2^2\sum_{n\in\Gamma_k}\boldsymbol{f}^*\mathbb{E}\left[\boldsymbol{f}_n\boldsymbol{f}_n^*\right]\boldsymbol{f} \\
&\qquad = \frac{3NR\mu_{k-1}^2}{\kappa M^2}\left|\left|\boldsymbol{q}_l\right|\right|_2^2.
\end{aligned}$$

For the second term we have

$$\begin{aligned}
&\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{f}^*\rangle|^2|z_n[l]|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad = \sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\boldsymbol{V}^*\boldsymbol{f}_n, \boldsymbol{V}^*\boldsymbol{f}\rangle|^2|z_n[l]|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad = \sum_{n\in\Gamma_k}\mathbb{E}\left[\boldsymbol{f}^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}|\langle\widetilde{\boldsymbol{Y}}_{k-1}, z_n[l]\boldsymbol{z}_n\boldsymbol{f}_n^*\rangle|^2\right].
\end{aligned}$$

Using the fact that $|z_n[l]|^2 = \boldsymbol{e}_l^*\boldsymbol{z}_n\boldsymbol{z}_n^*\boldsymbol{e}_l$ and Lemma 11, we obtain

$$\begin{aligned}
&\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{f}^*\rangle|^2|z_n[l]|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1}, \boldsymbol{A}_n\rangle|^2\right] \\
&\qquad \leq \frac{3}{M^2}\sum_{n\in\Gamma_k}\mathbb{E}\left[\boldsymbol{f}^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}\boldsymbol{e}_l^*\left|\left|\widetilde{\boldsymbol{Y}}_{k-1}\boldsymbol{f}_n\right|\right|_2^2\boldsymbol{I}_L\boldsymbol{e}_l\right] \\
&\qquad \leq \frac{3R\mu_{k-1}^2}{M^2}\sum_{n\in\Gamma_k}\mathbb{E}\left[\boldsymbol{f}^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}\right] \\
&\qquad \leq \frac{3R\mu_{k-1}^2}{M^2}|\Gamma_k|\left|\left|\boldsymbol{V}^*\boldsymbol{f}\right|\right|_2^2 \\
&\qquad \leq \frac{3R^2\mu_{k-1}^2\mu_0^2}{\kappa M^1}.
\end{aligned}$$

Finally, for the third term, we have

$$\begin{aligned}
&\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle \boldsymbol{Q}\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*, \boldsymbol{e}_l\boldsymbol{f}^*\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1},\boldsymbol{A}_n\rangle|^2\right]\\
&\quad=\sum_{n\in\Gamma_k}\mathbb{E}\left[|\langle \boldsymbol{V}^*\boldsymbol{f}_n,\boldsymbol{V}^*\boldsymbol{f}\rangle|^2|\langle \boldsymbol{q}_l,\boldsymbol{Q}^*\boldsymbol{z}_n\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1},\boldsymbol{A}_n\rangle|^2\right]\\
&\quad=\sum_{n\in\Gamma_k}\mathbb{E}\left[\boldsymbol{f}^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}_n\boldsymbol{f}_n^*\boldsymbol{V}\boldsymbol{V}^*\boldsymbol{f}|\langle \boldsymbol{q}_l,\boldsymbol{Q}^*\boldsymbol{z}_n\rangle|^2|\langle\widetilde{\boldsymbol{Y}}_{k-1},\boldsymbol{A}_n\rangle|^2\right]\\
&\quad\le\sum_{n\in\Gamma_k}\mathbb{E}\left[||\boldsymbol{V}^*\boldsymbol{f}||_2^2\,\boldsymbol{q}_l^*\boldsymbol{Q}^*\boldsymbol{z}_n\boldsymbol{z}_n^*|\langle\widetilde{\boldsymbol{Y}}_{k-1},\boldsymbol{A}_n\rangle|^2\boldsymbol{Q}\boldsymbol{q}_l\right]\\
&\quad\le\frac{3}{M^2}\,||\boldsymbol{q}_l||_2^2\,||\boldsymbol{V}^*\boldsymbol{f}||_2^2\sum_{n\in\Gamma_k}\mathbb{E}\left[\left|\left|\widetilde{\boldsymbol{Y}}_{k-1}\boldsymbol{f}_n\right|\right|_2^2\right]\\
&\quad\le\frac{3R^2\mu_0^2\mu_{k-1}^2}{\kappa M}\,||\boldsymbol{q}_l||_2^2\,.
\end{aligned}$$

Summing the three bounds and using $||\boldsymbol{q}_l||\le 1$ yields

$$\sigma_X^2\le 9\kappa\left(\frac{NR\mu_{k-1}^2}{M^2}\,||\boldsymbol{q}_l||_2^2+2\frac{R^2\mu_0^2\mu_{k-1}^2}{M}\right).$$

To use the Bernstein inequality it remains to find the Orlicz-1 norm of X_n. From Lemma 10 we have

$$\left|\left|\langle\widetilde{\boldsymbol{Y}}_{k-1},\boldsymbol{A}_n\rangle\right|\right|_{\psi_2}^2=\left|\left|\boldsymbol{z}_n^*\widetilde{\boldsymbol{Y}}_{k-1}\boldsymbol{f}_n\right|\right|_{\psi_2}^2\le\left|\left|\,||\boldsymbol{Q}^*\boldsymbol{z}_n||_2\,||\boldsymbol{\Lambda_{k-1}}\boldsymbol{V}^*\boldsymbol{f}_n||_2\right|\right|_{\psi_2}^2\le c\frac{R\mu_{k-1}^2}{M}.$$

For the first term we have

$$\begin{aligned}
||\boldsymbol{f}_n^*\boldsymbol{f}\langle \boldsymbol{q}_l,\boldsymbol{Q}^*\boldsymbol{z}_n\rangle||_{\psi_2}^2 &\le ||||\boldsymbol{f}_n^*||_2\,||\boldsymbol{f}||_2\,|\langle \boldsymbol{q}_l,\boldsymbol{Q}^*\boldsymbol{z}_n\rangle||_{\psi_2}^2\\
&\le N^2\,||\boldsymbol{q}_l^*\boldsymbol{Q}^*\boldsymbol{z}_n||_{\psi_2}^2\\
&\le c\frac{N^2\,||\boldsymbol{q}_l||_2^2}{M^2}.
\end{aligned}$$

For the second term we have

$$||\langle \boldsymbol{V}^*\boldsymbol{f}_n,\boldsymbol{V}^*\boldsymbol{f}\rangle z_n[l]||_{\psi_2}^2\le||||\boldsymbol{V}^*\boldsymbol{f}_n||_2\,||\boldsymbol{V}^*\boldsymbol{f}||_2\,z_n[l]||_{\psi_2}^2\le c\frac{R^2}{M}\mu_0^4.$$

Similarly, for the final term we have

$$||\langle \boldsymbol{V}^*\boldsymbol{f}_n,\boldsymbol{V}^*\boldsymbol{f}\rangle\langle \boldsymbol{q}_l,\boldsymbol{Q}^*\boldsymbol{z}_n\rangle||_{\psi_2}^2\le||||\boldsymbol{V}^*\boldsymbol{f}_n||_2\,||\boldsymbol{V}^*\boldsymbol{f}||_2\,\boldsymbol{q}_l^*\boldsymbol{Q}^*\boldsymbol{z}_n||_{\psi_2}^2\le c\frac{R^2}{M}\mu_0^4\,||\boldsymbol{q}_l||_2^2\,.$$

Now we can calculate the total Orlicz norm as

$$\begin{aligned}
||X_n||_{\psi_1}^2 &\le c\kappa^2\frac{R\mu_{k-1}^2}{M}\left(\frac{N^2\,||\boldsymbol{q}_l||_2^2}{M^2}+\frac{R^2}{M}\mu_0^4+\frac{R^2}{M}\mu_0^4\,||\boldsymbol{q}_l||_2^2\right)\\
&\le c\frac{\kappa^2RN^2}{M^3}\,||\boldsymbol{q}_l||_2^2\,\mu_{k-1}^2+c\frac{2\kappa^2R^3}{M^2}\mu_0^4\mu_{k-1}^2.
\end{aligned}$$

Since we wish to bound the square of the sum of terms, we calculate the square values of the two terms in the Bernstein inequality. The first term is bounded by

$$t\sigma_X^2\le c\beta\kappa\frac{R}{M}\mu_{k-1}^2\left(\frac{N}{M}\,||\boldsymbol{q}_l||_2^2+2R\mu_0^2\right)\log(LN),$$

and the second term is bounded by

$$t^2U_\alpha^2\log^2\left(\frac{|\Gamma_k|U_\alpha^2}{\sigma_X^2}\right)\le t^2U_\alpha^2\log^2\left(c\frac{|\Gamma_k|M\kappa^2R\mu_{k-1}^2\left(\frac{N^2}{M}\,||\boldsymbol{q}_l||_2^2+2R^2\mu_0^4\right)}{M^2\kappa R\mu_{k-1}^2\left(\frac{N}{M}\,||\boldsymbol{q}_l||_2^2+2R\mu_0^2\right)}\right)$$

$$\begin{aligned}
&\le t^2c\kappa^2\frac{R}{M^2}\mu_{k-1}^2\left(\frac{N^2}{M}\,||\boldsymbol{q}_l||_2^2+2R^2\mu_0^4\right)\log^2\left(c\frac{N^2\,||\boldsymbol{q}_l||_2^2+2MR^2\mu_0^4}{N\,||\boldsymbol{q}_l||_2^2+2RM\mu_0^2}\right)\\
&\le c\beta^2\kappa^2\frac{R}{M^2}\mu_{k-1}^2\left(\frac{N^2}{M}\,||\boldsymbol{q}_l||_2^2+2R^2\mu_0^4\right)\log^4(LN)\,,
\end{aligned}$$

where the last step assumes $L>1$ and $LN>R\mu_0^4$. Each summand is then bounded by the maximum of these two quantities with probability $1-O(|\Gamma_k|(LN)^{-\beta})$, the $|\Gamma_k|$ term coming from the union bound over all terms in each inner sum.

Using this bound on each summand, we obtain the total bound by taking a union bound, summing over $l\in[1,\cdots,L]$, and dividing by R, yielding a bound of the maximum of

$$t\sigma_X^2\le c\beta\kappa\frac{R}{M}\mu_{k-1}^2\left(\frac{N}{M}+2L\mu_0^4\right)\log(LN),$$

and

$$t^2U_\alpha^2\log^2\left(\frac{|\Gamma_k|U_\alpha^2}{\sigma_X^2}\right)\le\beta^2c\kappa^2\frac{R}{M^2}\mu_{k-1}^2\left(\frac{N}{M}+2RL\mu_0^2\right)\log^4(LN)\,,$$

with probability $1-O(M(NL)^{-\beta})$. To complete the proof, we note that if we have

$$M\ge c\beta\kappa R\left(N+L\mu_0^2\right)\log^2(LN),$$

then both terms in this bound are less than μ_{k-1}^2. ■

Abstract

Many data sets can be viewed as a noisy sampling of an underlying space, and tools from topological data analysis can characterize this structure for the purpose of knowledge discovery. One such tool is persistent homology, which provides a multiscale description of the homological features within a data set. A useful representation of this homological information is a *persistence diagram* (PD). Efforts have been made to map PDs into spaces with additional structure valuable to machine learning tasks. We convert a PD to a finite-dimensional vector representation which we call a *persistence image* (PI), and prove the stability of this transformation with respect to small perturbations in the inputs. The discriminatory power of PIs is compared against existing methods, showing significant performance gains. We explore the use of PIs with vector-based machine learning tools, such as linear sparse support vector machines, which identify features containing discriminating topological information. Finally, high accuracy inference of parameter values from the dynamic output of a discrete dynamical system (the *linked twist map*) and a partial differential equation (the *anisotropic Kuramoto-Sivashinsky equation*) provide a novel application of the discriminatory power of PIs.

Keywords: topological data analysis, persistent homology, persistence images, machine learning, dynamical systems

1. Introduction

In recent years, the field of topology has grown to include a large set of computational tools (Edelsbrunner and Harer, 2010). One of the fundamental tools is persistent homology, which tracks how topological features appear and disappear in a nested sequence of topological spaces (Edelsbrunner and Harer, 2008; Zomorodian and Carlsson, 2005). This multiscale information can be represented as a *persistence diagram* (PD), a collection of points in the plane where each point (x, y) corresponds to a topological feature that appears at scale x and disappears at scale y. We say the feature has a persistence value of $y - x$. This compact summary of topological characteristics by finite multi-sets of points in the plane is responsible, in part, for the surge of interest in applying persistent homology to the analysis of complex, often high-dimensional data. Computational topology has been successfully applied to a broad range of data-driven disciplines (Perea and Harer, 2013; Dabaghian et al., 2012; Chung et al., 2009; Heath et al.; Singh et al., 2008; Topaz et al., 2015; Pearson et al., 2015).

Concurrent with this revolution in computational topology, a growing general interest in data analysis has driven advances in data mining, pattern recognition, and machine learning (ML). Since the space of PDs can be equipped with a metric structure (*bottleneck* or *Wasserstein* (Mileyko et al., 2011; Turner et al., 2014)), and since these metrics reveal the stability of PDs under small perturbations of the data they summarize (Cohen-Steiner et al., 2007, 2010; Chazal et al., 2014), it is possible to perform a variety of ML techniques using PDs as a statistic for clustering data sets. However, many other useful ML tools and techniques (e.g., support vector machines (SVM), decision tree classification, neural networks, feature selection, and dimension reduction methods) require more than a metric structure. In addition, the cost of computing the bottleneck or Wasserstein distance grows quickly as the number of off-diagonal points in the diagrams increases (Di Fabio and Ferri, 2015). To resolve these issues, considerable effort (which we review in §2) has been made to map PDs into spaces which are suitable for other ML tools (Bubenik, 2015; Reininghaus et al., 2015; Rouse et al., 2015; Adcock et al., 2016; Donatini et al., 1998; Ferri et al., 1997; Chung et al., 2009; Pachauri et al., 2011; Bendich et al., 2016; Chen et al., 2015; Carrière et al., 2015; Di Fabio and Ferri, 2015). With the benefits and drawbacks of these approaches in mind, we pose the following question:

Problem Statement: How can we represent a persistence diagram so that

(i) the output of the representation is a vector in $\mathbb{R}^n$,

(ii) the representation is stable with respect to input noise,

©2017 Adams, et al.

License: CC-BY 4.0, see https://creativecommons.org/licenses/by/4.0/. Attribution requirements are provided at http://jmlr.org/papers/v18/16-337.html.

(iii) the representation is efficient to compute,

(iv) the representation maintains an interpretable connection to the original PD, and

(v) the representation allows one to adjust the relative importance of points in different regions of the PD?

The main contribution of this paper is to study a finite-dimensional-vector representation of a PD called a *persistence image* (PI). We first map a persistence diagram B to an integrable function $\rho_B \colon \mathbb{R}^2 \to \mathbb{R}$ called a *persistence surface*. The surface ρ_B is defined as a weighted sum of Gaussian functions,[1] one centered at each point in the PD. The idea of persistence surfaces has appeared even prior to the development of persistent homology, in Donatini et al. (1998) and Ferri et al. (1997). Taking a discretization of a subdomain of ρ_B defines a grid. A persistence image, i.e., a matrix of pixel values, can be created by computing the integral of ρ_B on each grid box. This PI is a "vectorization" of the PD, and provides a solution to the problem statement above.

Criterion (i) is the primary motivation for developing PIs. A large suite of ML techniques and statistical tools (means and variances) already exist to work with data in $\mathbb{R}^n$. Additionally, such a representation allows for the use of various distance metrics (p-norms and angle based metrics) and other measures of (dis)similarity. The remaining criteria of the problem statement (ii-v) further ensure the usefulness of this representation.

The desired flexibility of (v) is accomplished by allowing one to build a PI as a weighted sum of Gaussians, where the weightings may be chosen from a broad class of weighting functions.[2] For example, a typical interpretation is that points in a PD of high persistence are more important than points of low persistence (which may correspond to noise). One may therefore build a PI as a weighted sum of Gaussians where the weighting function is non-decreasing with respect to the persistence value of each PD point. However, there are situations in which one may prefer different measures of importance. Indeed, Bendich et al. (2016) find that, in their regression task of identifying a human brain's age from its arterial geometry, the points of medium persistence (not high persistence) best distinguish the data. In such a setting, one may choose a weighting function with largest values for the points of medium persistence. In addition, the Homology Inference Theorem (Cohen-Steiner et al., 2007) states that when given a sufficiently dense finite sample from a space X, the points in the PD with sufficiently small birth times (and sufficiently high persistence) recover the homology groups of the space; hence one may choose a weighting function that emphasizes points near the death-axis and away from the diagonal, as indicated in the leftmost yellow rectangle of Figure 2.4 in Bendich (2009). A potential disadvantage of the flexibility in (v) is that it requires a choice; however, prior knowledge of one's particular problem may inform that choice. Moreoever, our examples illustrate the effectiveness of a standard choice of weighting function that is non-decreasing with the persistence value.

The remainder of this article is organized as follows. Related work connecting topological data analysis and ML is reviewed in §2, and §3 gives a brief introduction to persistent homology, PDs from point cloud data, PDs from functions, and the bottleneck and Wasserstein metrics. PIs are defined in §4 and their stability with respect to the 1-Wasserstein distance

1. In general, ρ_B can be a weighted sum of probability density functions
2. Weighting functions are restricted only to the extent necessary for our stability results in §5.

between PDs is proved in §5. Lastly, §6 contains examples of ML techniques applied to PIs generated from samples of common topological spaces, an applied dynamical system modeling turbulent mixing, and a partial differential equation describing pattern formation in extended systems driven far from equilibrium. Our code for producing PIs is publicly available at `https://github.com/CSU-TDA/PersistenceImages`.

2. Related Work

The space of PDs can be equipped with the bottleneck or Wasserstein metric (defined in §3), and one reason for the popularity of PDs is that these metrics are stable with respect to small deviations in the inputs (Cohen-Steiner et al., 2007, 2010; Chazal et al., 2014). Furthermore, the bottleneck metric allows one to define Fréchet means and variances for a collection of PDs (Mileyko et al., 2011; Turner et al., 2014). However, the structure of a metric space alone is insufficient for many ML techniques, and a recent area of interest in the topological data analysis community has been encoding PDs in ways that broaden the applicability of persistence. For example, Adcock et al. (2016) study a ring of algebraic functions on the space of persistence diagrams, and Verovšek (2016) identifies tropical coordinates on the space of diagrams. Ferri and Landi (1999) and Di Fabio and Ferri (2015) encode a PD using the coefficients of a complex polynomial that has the points of the PD as its roots.

Bubenik (2015) develops the notion of a persistence landscape, a stable functional representation of a PD that lies in a Banach space. A persistence landscape (PL) is a function $\lambda \colon \mathbb{N} \times \mathbb{R} \to [-\infty, \infty]$, which can equivalently be thought of as a sequence of functions $\lambda_k \colon \mathbb{R} \to [-\infty, \infty]$. For $1 \leq p \leq \infty$ the p-landscape distance between two landscapes λ and λ' is defined as $\|\lambda - \lambda'\|_p$; the ∞-landscape distance is stable with respect to the bottleneck distance on PDs, and the p-landscape distance is continuous with respect to the p-Wasserstein distance on PDs. One of the motivations for defining persistence landscapes is that even though Fréchet means of PDs are not necessarily unique (Mileyko et al., 2011), a set of persistence landscapes does have a unique mean. Unique means are also a feature of PIs as they are vector representations. An advantage of PLs over PIs is that the map from a PD to a PL is easily invertible; an advantage of PIs over PLs is that PIs live in Euclidean space and hence are amenable to a broader range of ML techniques. In §6, we compare PDs, PLs, and PIs in a classification task on synthetic data sampled from common topological spaces. We find that PIs behave comparably or better than PDs when using ML techniques available to both representations, but PIs are significantly more efficient to compute. Also, PIs outperform PLs in the majority of the classification tasks and are of comparable computational efficiency.

A vector representation of a PD, due to Carrière et al. (2015), can be obtained by rearranging the entries of the distance matrix between points in a PD. In their Theorem 3.2, they prove that both the L^∞ and L^2 norms between their resulting vectors are stable with respect to the bottleneck distance on PDs. They remark that while the L^∞ norm is useful for nearest-neighbor classifiers, the L^2 norm allows for more elaborate algorithms such as SVM. However, though their stability result for the L^∞ norm is well-behaved, their constant for the L^2 norm scales undesirably with the number of points in the PD. We provide this as motivation for our Theorem 10, in which we prove the L^∞, L^1, and L^2 norms for PI vectors

are stable with respect to the 1-Wasserstein distance between PDs, and in which none of the constants depend on the number of points in the PD.

By superimposing a grid over a PD and counting the number of topological features in each bin, Rouse et al. (2015) create a feature vector representation. An advantage of this approach is that the output is easier to interpret than other more complicated representations, but a disadvantage is that the vectors are not stable for two reasons:

(i) an arbitrarily small movement of a point in a PD may move it to another bin, and

(ii) a PD point emerging from the diagonal creates a discontinuous change.

Source (i) of instability can be improved by first smoothing a PD into a surface. This idea has appeared multiple times in various forms—even prior to the development of persistent homology, Donatini et al. (1998) and Ferri et al. (1997) convert size functions (closely related to 0-dimensional PDs) into surfaces by taking a sum of Gaussians centered on each point in the diagram. This conversion is not stable due to (ii), and we view our work as a continued study of these surfaces, now also in higher homological dimensions, in which we introduce a weighting function[3] to address (ii) and obtain stability. Chung et al. (2009) produce a surface by convolving a PD with the characteristic function of a disk, and Pachauri et al. (2011) produce a surface by centering a Gaussian on each point, but both of these methods lack stability again due to (ii). Surfaces produced from random PDs are related to the empirical intensity plots of Edelsbrunner et al. (2012).

Reininghaus et al. (2015) produce a stable surface from a PD by taking the sum of a positive Gaussian centered on each PD point together with a negative Gaussian centered on its reflection below the diagonal; the resulting surface is zero along the diagonal. This approach is similar to PIs, and indeed we use a result of Reininghaus et al. (2015, Theorem 3) to show that persistence surfaces are stable only with respect to the 1-Wasserstein distance (Remark 6). Nevertheless, we propose our independently-developed surfaces as an alternative stable representation of PDs with the following potential advantages. First, the sum of non-negatively weighted Gaussians in PIs may be easier to interpret than a sum including negative Gaussians. Second, we produce vectors from persistence surfaces with well-behaved stability bounds, allowing one to use vector-based learning methods such as linear SVM. Indeed, Zeppelzauer et al. (2016) report that while the kernel of Reininghaus et al. (2015) can be used with nonlinear SVMs, in practice, this becomes inefficient for a large number of training vectors because the entire kernel matrix must be computed. Third, while the surface of Reininghaus et al. (2015) weights persistence points further from the diagonal more heavily, there are situations in which one may prefer different weightings, as discussed in §1 and item (v) of our Problem Statement. Hence, one may want weightings on PD points that are non-increasing or even decreasing when moving away from the diagonal, an option available in the PI approach.

We produce a persistence surface from a PD by taking a weighted sum of Gaussians centered at each point. We create vectors, or PIs, by integrating our surfaces over a grid, allowing ML techniques for finite-dimensional vector spaces to be applied to PDs. Persistence images are stable, and distinct homology dimensions may be concatenated together into a single vector to be analyzed simultaneously. Persistence surfaces are studied from the

3. Our weighting function is continuous and zero for points of zero persistence, i.e., points along the diagonal.

statistical point of view by Chen et al. (2015); their applications in Section 4 use the L^1 norm between these surfaces, which can be justified as a reasonable notion of distance due to Theorem 9 that proves the L^1 distance between such surfaces is stable.

Zeppelzauer et al. (2016) apply PIs to 3D surface analysis for archeological data, in which the machine learning task is to distinguish scans of natural rock surfaces from those containing ancient human-made engravings. The authors state they select PIs over other topological methods because PIs are computationally efficient and can be used with a broader set of ML techniques. PIs are compared to an aggregate topological descriptor for a PD: the first entry of this vector is the number of points in the diagram, and the remaining entries are the minimum, maximum, mean, standard deviation, variance, 1st-quartile, median, 3rd-quartile, sum of square roots, sum, and sum of squares of all the persistence values. In their three experiments, the authors find the following.

- When classifying natural rock surfaces from engravings using PDs produced from the sublevel set filtration, PIs outperform the aggregate descriptor.
- When the natural rock and engraved surfaces are first preprocessed using the completed local binary pattern (CLBP) operator for texture classificiation (Guo et al., 2010), PIs outperform the aggregate descriptor.
- The authors added PIs and the aggregate descriptor to eleven different non-topological baseline descriptors, and found that the classification accuracy of the baseline descriptor was improved more by the addition of PIs than by the addition of the aggregate descriptor.

Furthermore, Zeppelzauer et al. (2016, Table 1) demonstrate that for their machine learning task, PIs have low sensitivity to the parameter choices of resolution and variance (§4).

3. Background on Persistent Homology

Homology is an algebraic topological invariant that, roughly speaking, describes the holes in a space. The k-dimensional holes (connected components, loops, trapped volumes, etc.) of a topological space X are encoded in an algebraic structure called the k-th homology group of X, denoted $H_k(X)$. The rank of this group is referred to as the *k-th Betti number*, β_k, and counts the number of independent k-dimensional holes. For a comprehensive study of homology, see the textbook by Hatcher (2002).

Given a nested sequence of topological spaces $X_1 \subseteq X_2 \subseteq \ldots \subseteq X_n$, the inclusion $X_i \subseteq X_{i'}$ for $i \leq i'$ induces a linear map $H_k(X_i) \to H_k(X_{i'})$ on the corresponding k-th homology for all $k \geq 0$. The idea of *persistent homology* is to track elements of $H_k(X_i)$ as the scale (or "time") parameter i increases (Edelsbrunner and Harer, 2008; Zomorodian and Carlsson, 2005; Edelsbrunner and Harer, 2010). A standard way to represent persistent homology information is a *persistence diagram* (PD),[4] which is a multiset of points in the Cartesian plane $\mathbb{R}^2$. For a fixed choice of homological dimension k, each homological feature is represented by a point (x, y), whose *birth* and *death* indices x and y are the scale parameters at which that feature first appears and disappears, respectively. Since all topological

4. Another standard representation is the barcode (Ghrist, 2008).

features die after they are born, necessarily each point appears on or above the diagonal line $y = x$. A PD is a multiset of such points, as distinct topological features may have the same birth and death coordinates.[5] Points near the diagonal are often considered to be noise while those further from the diagonal represent more robust topological features.

In this paper, we produce PDs from two different types of input data:

(i) When the data is a point cloud, i.e., a finite set of points in some space, then we produce PDs using the Vietoris–Rips filtration.

(ii) When the data is a real-valued function, we produce PDs using the sublevel set filtration.[6]

For setting (i), point cloud data often comes equipped with a metric or a measure of internal (dis)similarity and is rich with latent geometric content. One approach to identifying geometric shapes in data is to consider the data set as the vertices of a simplicial complex and to add edges, triangles, tetrahedra, and higher-dimensional simplices whenever their diameter is less than a fixed choice of scale. This topological space is called the Vietoris–Rips simplicial complex, which we introduce in more detail in §A.2. The homology of the Vietoris–Rips complex depends crucially on the choice of scale, but persistent homology eliminates the need for this choice by computing homology over a range of scales (Carlsson, 2009; Ghrist, 2008). In §6.1–6.4.1, we obtain PDs from point cloud data using the Vietoris–Rips filtered simplicial complex, and we use ML techniques to classify the point clouds by their topological features.

In setting (ii), our input is a real valued function $f\colon X \to \mathbb{R}$ defined on some domain X. One way to understand the behavior of map f is to understand the topology of its sublevel sets $f^{-1}((-\infty, \epsilon])$. By letting ϵ increase, we obtain an increasing sequence of topological spaces, called the sublevel set filtration, which we introduce in more detail in §A.3. In §6.4.2, we obtain PDs from surfaces $u\colon [0,1]^2 \to \mathbb{R}$ produced from the Kuramoto-Sivashinsky equation, and we use ML techniques to perform parameter classification.

In both settings, the output of the persistent homology computation is a collection of PDs encoding homological features of the data across a range of scales. Let $\mathcal{D}$ denote the set of all PDs. The space $\mathcal{D}$ can be endowed with metrics as studied by Cohen-Steiner et al. (2007) and Mileyko et al. (2011). The *p-Wasserstein distance* defined between two PDs B and B' is given by

$$W_p(B, B') = \inf_{\gamma: B \to B'} \Big(\sum_{u \in B} ||u - \gamma(u)||_\infty^p \Big)^{1/p},$$

where $1 \leq p < \infty$ and γ ranges over bijections between B and B'. Another standard choice of distance between diagrams is $W_\infty(B, B') = \inf_{\gamma: B \to B'} \sup_{u \in B} ||u - \gamma(u)||_\infty$, referred to as the *bottleneck distance*. These metrics allow us to measure the (dis)similarity between the homological characteristics of two data sets.

5. By convention, all points on the diagonal are taken with infinite multiplicity. This facilitates the definitions of the p-Wasserstein and bottleneck distances below.
6. As explained in §A.3, (i) can be viewed as a special case of (ii).

4. Persistence Images

We propose a method for converting a PD into a vector while maintaining an interpretable connection to the original PD. Figure 1 illustrates the pipeline from data to PI starting with spectral and spatial information in $\mathbb{R}^5$ from an immunofluorescent image of a circulating tumor cell (Emerson et al., 2015).

Precisely, let B be a PD in birth-death coordinates.[7] Let $T\colon \mathbb{R}^2 \to \mathbb{R}^2$ be the linear transformation $T(x, y) = (x, y - x)$, and let $T(B)$ be the transformed multiset in birth-persistence coordinates,[8] where each point $(x, y) \in B$ corresponds to a point $(x, y - x) \in T(B)$. Let $\phi_u\colon \mathbb{R}^2 \to \mathbb{R}$ be a differentiable probability distribution with mean $u = (u_x, u_y) \in \mathbb{R}^2$. In all of our applications, we choose this distribution to be the normalized symmetric Gaussian $\phi_u = g_u$ with mean u and variance σ^2 defined as

$$g_u(x, y) = \frac{1}{2\pi\sigma^2} e^{-[(x-u_x)^2 + (y-u_y)^2]/2\sigma^2}.$$

We fix a nonnegative weighting function $f\colon \mathbb{R}^2 \to \mathbb{R}$ that is zero along the horizontal axis, continuous, and piecewise differentiable. With these ingredients, we transform the PD into a scalar function over the plane.

Definition 1 *For B a PD, the corresponding* persistence surface $\rho_B\colon \mathbb{R}^2 \to \mathbb{R}$ *is the function*

$$\rho_B(z) = \sum_{u \in T(B)} f(u)\phi_u(z).$$

The weighting function f is critical to ensure the transformation from a PD to a persistence surface is stable, which we prove in §5.

Finally, the surface $\rho_B(z)$ is reduced to a finite-dimensional vector by discretizing a relevant subdomain and integrating $\rho_B(z)$ over each region in the discretization. In particular, we fix a grid in the plane with n boxes (pixels) and assign to each the integral of ρ_B over that region.

Definition 2 *For B a PD, its* persistence image *is the collection of pixels $I(\rho_B)_p = \iint_p \rho_B \, dydx$.*

PIs provide a convenient way to combine PDs of different homological dimensions into a single object. Indeed, suppose in an experiment the PDs for H_0, H_1, …, H_k are computed. One can concatenate the PI vectors for H_0, H_1, …, H_k into a single vector representing all homological dimensions simultaneously, and then use this concatenated vector as input into ML algorithms.

When generating a PI, the user makes three choices: the resolution, the distribution (and its associated parameters), and the weighting function. A strength of PIs is that they are flexible; a weakness is that these choices are noncanonical.

7. We omit points that correspond to features with infinite persistence, e.g., the H_0 feature corresponding to the connectedness of the complete simplicial complex.
8. Instead of birth-persistence coordinates, one could also use other choices such as birth-death or (average size)-persistence coordinates. Our stability results (§5) still hold with only a slight modification to the constants.

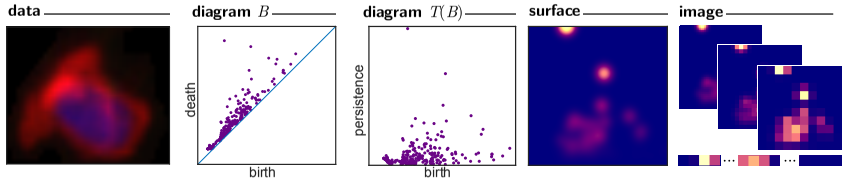

Figure 1: Algorithm pipeline to transform data into a persistence image.

Resolution of the image: The resolution of the PI corresponds to the grid being overlaid on the PD. The classification accuracy in the PI framework appears to be fairly robust to choice of resolution, as discussed in §6.2 and by Zeppelzauer et al. (2016).

The Distribution: Our method requires the choice of a probability distribution associated to each point in the PD. The examples in this paper use a Gaussian centered at each point, but other distributions may be used. The Gaussian distribution depends on a choice of variance: we leave this choice as an open problem, though the experiments in §6.2 and those of Zeppelzauer et al. (2016) show a low sensitivity to the choice of variance.

The Weighting Function: In order for our stability results in §5 to hold, our weighting function $f\colon \mathbb{R}^2 \to \mathbb{R}$ must be zero along the horizontal axis (the analogue of the diagonal in birth-persistence coordinates), continuous, and piecewise differentiable. A simple choice is a weighting function that depends only on the vertical persistence coordinate y. In order to weight points of higher persistence more heavily, functions which are nondecreasing in y, such as sigmoidal functions, are a natural choice. However, in certain ML tasks such as the work of Bendich et al. (2016) the points of small or medium persistence may perform best, and hence one may choose to use more general weighting functions. In our experiments in §6, we use a piecewise linear weighting function $f\colon \mathbb{R}^2 \to \mathbb{R}$ which only depends on the persistence coordinate y. Given $b > 0$, define $w_b\colon \mathbb{R} \to \mathbb{R}$ via

$$w_b(t) = \begin{cases} 0 & \text{if } t \le 0, \\ \frac{t}{b} & \text{if } 0 < t < b, \text{ and} \\ 1 & \text{if } t \ge b. \end{cases}$$

We use $f(x, y) = w_b(y)$, where b is the persistence value of the most persistent feature in all trials of the experiment.

In the event that the birth coordinate is zero for all points in the PD, as is often the case for H_0, it is possible to generate a 1-dimensional (instead of 2-dimensional) PI using 1-dimensional distributions. This is the approach we adopt. Appendix B displays examples of PIs for the common topological spaces of a circle and a torus with various parameter choices.

5. Stability of Persistence Surfaces and Images

Due to the unavoidable presence of noise or measurement error, tools for data analysis ought to be stable with respect to small perturbations of the inputs. Indeed, one reason for the popularity of PDs in topological data analysis is that the transformation of a data

set to a PD is stable (Lipschitz) with respect to the bottleneck metric and—given some mild assumptions about the underlying data—is also stable with respect to the Wasserstein metrics (Edelsbrunner and Harer (2010)). In §5.1, we show that persistence surfaces and images are stable with respect to the 1-Wasserstein distance between PDs. In §5.2, we prove stability with improved constants when the PI is constructed using the Gaussian distribution.

5.1 Stability for general distributions

For $h\colon \mathbb{R}^2 \to \mathbb{R}$ differentiable, define $|\nabla h| = \sup_{z \in \mathbb{R}^2} \|\nabla h(z)\|_2$ to be the maximal norm of the gradient vector of h, i.e., the largest directional derivative of h. It follows by the fundamental theorem of calculus for line integrals that for all $u, v \in \mathbb{R}^2$, we have

$$|h(u) - h(v)| \le |\nabla h| \, \|u - v\|_2. \tag{1}$$

Recall $\phi_u\colon \mathbb{R}^2 \to \mathbb{R}$ is a differentiable probability distribution with mean $u = (u_x, u_y) \in \mathbb{R}^2$. We may safely denote $|\nabla \phi_u|$ by $|\nabla \phi|$ and $\|\phi_u\|_\infty$ by $\|\phi\|_\infty$ since the maximal directional derivative and supremum of a fixed differentiable probability distribution are invariant under translation. Note that

$$\|\phi_u - \phi_v\|_\infty \le |\nabla \phi| \, \|u - v\|_2 \tag{2}$$

since for any $z \in \mathbb{R}^2$ we have $|\phi_u(z) - \phi_v(z)| = |\phi_u(z) - \phi_u(z + u - v)| \le |\nabla \phi| \, \|u - v\|_2$.

Recall that our nonnegative weighting function $f\colon \mathbb{R}^2 \to \mathbb{R}$ is defined to be zero along the horizontal axis, continuous, and piecewise differentiable.

Lemma 3 *For $u, v \in \mathbb{R}^2$, we have $\|f(u)\phi_u - f(v)\phi_v\|_\infty \le \big(\|f\|_\infty |\nabla \phi| + \|\phi\|_\infty |\nabla f|\big)\|u - v\|_2$.*

Proof For any $z \in \mathbb{R}^2$, we have

$$\begin{aligned} |f(u)\phi_u(z) - f(v)\phi_v(z)| &= \big|f(u)\big(\phi_u(z) - \phi_v(z)\big) + \big(f(u) - f(v)\big)\phi_v(z)\big| \\ &\le \|f\|_\infty \, |\phi_u(z) - \phi_v(z)| + \|\phi\|_\infty |f(u) - f(v)| \\ &\le \|f\|_\infty |\nabla \phi| \, \|u - v\|_2 + \|\phi\|_\infty |\nabla f| \, \|u - v\|_2 \qquad \text{by (2) and (1)} \\ &= \big(\|f\|_\infty |\nabla \phi| + \|\phi\|_\infty |\nabla f|\big)\|u - v\|_2. \end{aligned}$$

■

Theorem 4 *The persistence surface ρ is stable with respect to the 1-Wasserstein distance between diagrams: for $B, B' \in \mathcal{D}$ we have*

$$\|\rho_B - \rho_{B'}\|_\infty \le \sqrt{10}\big(\|f\|_\infty |\nabla \phi| + \|\phi\|_\infty |\nabla f|\big) W_1(B, B').$$

Proof Since we assume B and B' consist of finitely many points, there exists a matching γ that achieves the infimum in the Wasserstein distance. Then

$$\begin{aligned}
\|\rho_B - \rho_{B'}\|_\infty &= \| \sum_{u\in T(B)} f(u)\phi_u - \sum_{u\in T(B)} f(\gamma(u))\phi_{\gamma(u)}\|_\infty \\
&\le \sum_{u\in T(B)} \|f(u)\phi_u - f(\gamma(u))\phi_{\gamma(u)}\|_\infty \\
&\le \big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big) \sum_{u\in T(B)} \|u-\gamma(u)\|_2 \qquad \text{by Lemma 3.} \\
&\le \sqrt{2}\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big) \sum_{u\in T(B)} \|u-\gamma(u)\|_\infty \quad \text{since } \|\cdot\|_2 \le \sqrt{2}\|\cdot\|_\infty \text{ in } \mathbb{R}^2 \\
&\le \sqrt{10}\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big) \sum_{u\in B} \|u-\gamma(u)\|_\infty \quad \text{since } \|T(\cdot)\|_2 \le \sqrt{5}\|\cdot\|_\infty \\
&= \sqrt{10}\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big) W_1(B,B').
\end{aligned}$$

The step transforming from a sum over all $u \in T(B)$ to one over all $u \in B$ is necessary because the Wasserstein distance is defined using birth-death coordinates, not birth-persistence coordinates. The bound $\|T(\cdot)\|_2 \le \sqrt{5}\|\cdot\|_\infty$ follows from the fact the unit ball with respect to the L^∞ norm in $\mathbb{R}^2$ (i.e., a square) gets mapped under T to a parallelogram contained inside a ball with respect to the L^2 norm of radius $\sqrt{5}$. ■

It follows that persistence images are also stable.

Theorem 5 *The persistence image $I(\rho_B)$ is stable with respect to the 1-Wasserstein distance between diagrams. More precisely, if A is the maximum area of any pixel in the image, A' is the total area of the image, and n is the number of pixels in the image, then*

$$\begin{aligned}
\|I(\rho_B) - I(\rho_{B'})\|_\infty &\le \sqrt{10}A\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B') \\
\|I(\rho_B) - I(\rho_{B'})\|_1 &\le \sqrt{10}A'\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B') \\
\|I(\rho_B) - I(\rho_{B'})\|_2 &\le \sqrt{10n}A\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B').
\end{aligned}$$

The constant for the L^2 norm bound containing $\sqrt{n}$ goes to infinity as the resolution of the image increases. For this reason, in Theorem 10 we provide bounds with better constants in the specific case of Gaussian distributions.

Proof Note for any pixel p with area $A(p)$ we have

$$\begin{aligned}
|I(\rho_B)_p - I(\rho_{B'})_p| &= \Big|\iint_p \rho_B\, dydz - \iint_p \rho_{B'}\, dydx\Big| \\
&= \Big|\iint_p \rho_B - \rho_{B'}\, dydx\Big| \\
&\le A(p)\|\rho_B - \rho_{B'}\|_\infty \\
&\le \sqrt{10}A(p)\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B') \qquad \text{by Theorem 4.}
\end{aligned}$$

Hence we have

$$\begin{aligned}
\|I(\rho_B) - I(\rho_{B'})\|_\infty &\le \sqrt{10}A\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B') \\
\|I(\rho_B) - I(\rho_{B'})\|_1 &\le \sqrt{10}A'\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B') \\
\|I(\rho_B) - I(\rho_{B'})\|_2 &\le \sqrt{n}\|I(\rho_B) - I(\rho_{B'})\|_\infty \\
&\le \sqrt{10n}A\big(\|f\|_\infty|\nabla\phi| + \|\phi\|_\infty|\nabla f|\big)W_1(B,B').
\end{aligned}$$

■

Remark 6 *Recall $\mathcal{D}$ is the set of all PDs. The kernel $k\colon \mathcal{D}\times\mathcal{D}\to\mathbb{R}$ defined by $k(B,B') = \langle I(\rho_B), I(\rho_{B'})\rangle_{\mathbb{R}^n}$ is non-trivial and additive, and hence Theorem 3 of Reininghaus et al. (2015) implies that k is not stable with respect to W_p for any $1 < p \le \infty$. That is, when $1 < p \le \infty$ there is no constant c such that for all $B, B' \in \mathcal{D}$ we have $\|I(\rho_B) - I(\rho_{B'})\|_2 \le cW_p(B,B')$.*

5.2 Stability for Gaussian distributions

In this section, we provide stability results with better constants in the case of Gaussian distributions. With Gaussian distributions, we can control not only the L^∞ distance but also the L^1 distance between two persistence surfaces.

Our results for 2-dimensional Gaussians will rely on the following lemma for 1-dimensional Gaussians.

Lemma 7 *For $u, v \in \mathbb{R}$, let $g_u, g_v\colon \mathbb{R}\to\mathbb{R}$ be the normalized 1-dimensional Gaussians, defined via $g_u(z) = \dfrac{1}{\sigma\sqrt{2\pi}}e^{-(z-u)^2/2\sigma^2}$. If $a, b > 0$, then*

$$\|ag_u - bg_v\|_1 \le |a-b| + \sqrt{\frac{2}{\pi}}\frac{\min\{a,b\}}{\sigma}|u-v|.$$

Proof Let $\mathrm{Erf}(t) = \frac{2}{\sqrt{\pi}}\int_0^t e^{-u^2}du$. We show in Appendix C that

$$\|ag_u - bg_v\|_1 = F(v-u), \tag{3}$$

where $F\colon \mathbb{R}\to\mathbb{R}$ is defined by

$$F(z) = \begin{cases} |a-b| & \text{if } z = 0 \\ \left|a\mathrm{Erf}\left(\frac{z^2+2\sigma^2\ln(a/b)}{z\sigma 2\sqrt{2}}\right) - b\mathrm{Erf}\left(\frac{-z^2+2\sigma^2\ln(a/b)}{z\sigma 2\sqrt{2}}\right)\right| & \text{otherwise.}\end{cases}$$

The roots of F'' are $z = \pm\sigma\sqrt{2\ln(a/b)}$ and $z = \pm i\sigma\sqrt{2\ln(a/b)}$. If $a > b$, the unique positive real root is $z_a \equiv \sigma\sqrt{2\ln(a/b)}$ while if $b > a$, the unique positive real root is $z_b \equiv -i\sigma\sqrt{2\ln(a/b)}$. Since $F'(z_a) = b\sqrt{2/\pi}/\sigma$ and $F'(z_b) = a\sqrt{2/\pi}/\sigma$, we conclude that

$$\|F'\|_\infty = \sqrt{\frac{2}{\pi}}\frac{\min\{a,b\}}{\sigma}, \quad \text{and hence} \quad F(z) \le |a-b| + \sqrt{\frac{2}{\pi}}\frac{\min\{a,b\}}{\sigma}|z|.$$

The result follows by letting $z = v - u$. ■

Lemma 8 *For $u, v \in \mathbb{R}^2$, let $g_u, g_v \colon \mathbb{R}^2 \to \mathbb{R}$ be normalized 2-dimensional Gaussians. Then*

$$\|f(u)g_u - f(v)g_v\|_1 \leq \left(|\nabla f| + \sqrt{\frac{2}{\pi}} \frac{\min\{f(u), f(v)\}}{\sigma} \right) \|u - v\|_2.$$

The proof of Lemma 8 is shown in Appendix C and uses a similar construction to that of Lemma 7. We are prepared to prove the stability of persistence surfaces with Gaussian distributions.

Theorem 9 *The persistence surface ρ with Gaussian distributions is stable with respect to the 1-Wasserstein distance between diagrams: for $B, B' \in \mathcal{D}$ we have*

$$\|\rho_B - \rho_{B'}\|_1 \leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B').$$

Proof Since we assume B and B' consist of finitely many off-diagonal points, there exists a matching γ that achieves the infimum in the Wasserstein distance. Then

$$\begin{aligned}
&\|\rho_B - \rho_{B'}\|_1 = \left\| \sum_{u \in T(B)} f(u) g_u - \sum_{u \in T(B)} f(\gamma(u)) g_{\gamma(u)} \right\|_1 \\
&\leq \sum_{u \in T(B)} \|f(u)g_u - f(\gamma(u))g_{\gamma(u)}\|_1 \\
&\leq \left(|\nabla f| + \sqrt{\frac{2}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) \sum_{u \in T(B)} \|u - \gamma(u)\|_2 \quad \text{by Lemma 8, where } \min\{f(u), f(v)\} \leq \|f\|_\infty \\
&\leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) \sum_{u \in B} \|u - \gamma(u)\|_\infty \quad \text{since } \|T(\cdot)\|_2 \leq \sqrt{5}\|\cdot\|_\infty \\
&= \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B').
\end{aligned}$$

■

It follows that persistence images are also stable.

Theorem 10 *The persistence image $I(\rho_B)$ with Gaussian distributions is stable with respect to the 1-Wasserstein distance between diagrams. More precisely,*

$$\|I(\rho_B) - I(\rho_{B'})\|_1 \leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B')$$

$$\|I(\rho_B) - I(\rho_{B'})\|_2 \leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B')$$

$$\|I(\rho_B) - I(\rho_{B'})\|_\infty \leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B').$$

Proof We have

$$\begin{aligned}
\|I(\rho_B) - I(\rho_{B'})\|_1 &= \sum_p \left| \iint_p \rho_B \, dydz - \iint_p \rho_{B'} \, dydx \right| \leq \iint_{\mathbb{R}^2} |\rho_B - \rho_{B'}| \, dydz \\
&= \|\rho_B - \rho_{B'}\|_1 \leq \left(\sqrt{5}|\nabla f| + \sqrt{\frac{10}{\pi}} \frac{\|f\|_\infty}{\sigma} \right) W_1(B, B')
\end{aligned}$$

by Theorem 9. The claim follows since $\|\cdot\|_2 \leq \|\cdot\|_1$ and $\|\cdot\|_\infty \leq \|\cdot\|_1$ for vectors in $\mathbb{R}^n$. ■

6. Experiments

We perform several experiments in order to assess the added value of our vector representation of PDs. First, in §6.1, we compare the performance of PDs, PLs, and PIs in a classification task for a synthetic data set consisting of point clouds sampled from six different topological spaces using K-medoids, which requires only a metric space (instead of a vector space) structure. We find that PIs produce consistently high classification accuracy, and furthermore, the computation time for PIs is significantly faster than computing bottleneck or Wasserstein distances between PDs. In §6.2, we explore the impact that the choices of parameters determining our PIs have on classification accuracy. We find that the accuracy is insensitive to the particular choices of PI resolution and distribution variance. In §6.3, we combine PIs with a sparse support vector machine classifier to identify the most strongly differentiating pixels for classification; this is an example of a ML task which is facilitated by the fact that PIs are finite vectors. Finally, as a novel machine learning application, we illustrate the utility of PIs to infer dynamical parameter values in both continuous and discrete dynamical systems: a discrete time system called the linked twist map in §6.4.1, and a partial differential equation called the anisotropic Kuramoto-Sivashinsky equation in §6.4.2.

6.1 Comparison of PDs, PLs, and PIs using K-medoids Classification

Our synthetic data set consists of six shape classes: a unit cube, a circle of diameter one, a sphere of diameter one, three clusters with centers randomly chosen in the unit cube, three clusters within three clusters (where the centers of the minor clusters are chosen as small—i.e., $<$0.1—random perturbations from the major cluster centers), and a torus with a major diameter of one and a minor diameter of one half. We produce 25 point clouds of 500 points sampled uniformly at random from each of the six shapes, and then add a level of Gaussian noise. This gives 150 point clouds in total.

We then compute the H_0 and H_1 PDs for the Vietoris–Rips filtration (§A.2) built from each point cloud which have been endowed with the ambient Euclidean metric on $\mathbb{R}^3$.

Our goal is to compare various methods for transforming PDs into distance matrices to be used to establish proximity of topological features extracted from data. We create $3^2 \cdot 2^2 = 36$ distance matrices of size 150×150, using three choices of representation (PDs,

PLs, PIs), three choices of metric (L^1, L^2, L^∞),[9] two choices of Gaussian noise ($\eta = 0.05$, 0.1), and two homological dimensions (H_0, H_1). For example, the PD, H_1, L^2, $\eta = 0.1$, distance matrix contains the 2-Wasserstein distances between the H_1 PDs for the random point clouds with noise level 0.1. By contrast, the PI, H_1, L^2, $\eta = 0.1$ distance matrix contains all pairwise L^2 distances between the PIs[10] produced from the H_1 PDs with noise level 0.1.

We first compare these distance matrices based on how well they classify the random point clouds into shape classes via K-medoids clustering (Kaufman and Rousseeuw, 1987; Park and Jun, 2009). K-medoids produces a partition of a metric space into K clusters by choosing K points from the data set called *medoids* and assigning each metric space point to its closest medoid. The *score* of such a clustering is the sum of the distances from each point to its closest medoid. The desired output of K-medoids is the clustering with the minimal clustering score. Unfortunately, an exhaustive search for the global minimum is often prohibitively expensive. A typical approach to search for this global minimum is to choose a large selection of K random initial medoids, improve each selection of medoids iteratively in rounds until the clustering score stabilizes and then return the identified final clustering with the lowest score for each initialization. In our experiments, we choose 1,000 random initial selections of $K = 6$ medoids (as there are six shape classes) for each distance matrix, improve each selection of medoids using the Voronoi iteration method (Park and Jun, 2009), and return the clustering with the lowest classification score. To each K-medoids clustering we assign an accuracy which is equal to the percentage of random point clouds identifed with a medoid of the same shape class. In Table 1, we report the classification accuracy of the K-medoids clustering with the lowest clustering score, for each distance matrix.

Our second criterion for comparing methods to produce distance matrices is computational efficiency. In Table 1, we report the time required to produce each distance matrix, starting with 150 precomputed PDs as input. In the case of PLs and PIs, this time includes the intermediate step of transforming each PD into the alternate representation, as well as computing the pairwise distance matrix. All timings are computed on a laptop with a 1.3 GHz Intel Core i5 processor and 4 GB of memory. We compute bottleneck, 1-Wasserstein, and 2-Wasserstein distance matrices using the software of Kerber et al. (2016). For PL computations, we use the Persistence Landscapes Toolbox by Bubenik and Dlotko (2016). Our MATLAB code for producing PIs is publically available at `https://github.com/CSU-TDA/PersistenceImages`.

We see in Table 1 that PI distance matrices have higher classification accuracy than nearly every PL distance matrix, and higher classification accuracy than PDs in half of the trials.

Furthermore, the computation times for PI distance matrices are significantly lower than the time required to produce distance matrices from PDs using the bottleneck or p-Wasserstein metrics. There is certainly no guarantee that PIs will outperform PDs or PLs in any given machine learning task. However, in this experiment, persistent images provide

9. The L^1, L^2, L^∞ distances on PDs are more commonly known as the 1-Wasserstein, 2-Wasserstein, and bottleneck distances.

10. For PIs in this experiment, we use variance $\sigma = 0.1$, resolution 20×20, and the weighting function defined in §4.

Table 1: Comparing classification accuracy and times of PDs, PLs, and PIs. The timings contain the computation time in seconds for producing a 150×150 distance matrix from 150 precomputed PDs. In the case of PLs and PIs, this requires first transforming each PD into its alternate representation and then computing a distance matrix. We consider 36 distinct distance matrices: three representations (PDs, PLs, PIs), two homological dimensions (H_0, H_1), three choices of metric (L^1, L^2, L^∞), and two levels of Gaussian noise ($\eta = 0.05$, 0.1).

Distance Matrix	Accuracy (Noise 0.05)	Time (Noise 0.05)	Accuracy (Noise 0.1)	Time (Noise 0.1)
PD, H_0, L^1	96.0%	37346s	96.0%	42613s
PD, H_0, L^2	91.3%	24656s	91.3%	25138s
PD, H_0, L^∞	60.7%	1133s	63.3%	1149s
PD, H_1, L^1	100%	657s	96.0%	703s
PD, H_1, L^2	100%	984s	97.3%	1042s
PD, H_1, L^∞	81.3%	527s	66.7%	564s
PL, H_0, L^1	92.7%	29s	96.7%	33s
PL, H_0, L^2	77.3%	29s	82.0%	34s
PL, H_0, L^∞	60.7%	2s	63.3%	2s
PL, H_1, L^1	83.3%	36s	80.7%	48s
PL, H_1, L^2	83.3%	50s	66.7%	69s
PL, H_1, L^∞	74.7%	8s	66.7%	9s
PI, H_0, L^1	93.3%	9s	95.3%	9s
PI, H_0, L^2	92.7%	9s	95.3%	9s
PI, H_0, L^∞	94.0%	9s	96.0%	9s
PI, H_1, L^1	100%	17s	95.3%	18s
PI, H_1, L^2	100%	17s	96.0%	18s
PI, H_1, L^∞	100%	17s	96.0%	18s

a representation of persistent diagrams which is both useful for the classification task and also computationally efficient.

6.2 Effect of PI Parameter Choice

In any system that relies on multiple parameters, it is important to understand the effect of parameter values on the system. As such, we complete a search of the parameter space used to generate PIs on the shape data set described in §6.1 and measure K-medoids classification accuracy as a function of the parameters. We use 20 different resolutions (ranging from 5×5 to 100×100 in increments of 5), a Gaussian function with 20 different choices of variance (ranging from 0.01 to 0.2 in increments of 0.01), and the weighting function described in §4. For each set of parameters, we compute the classification accuracy of the K-medoids

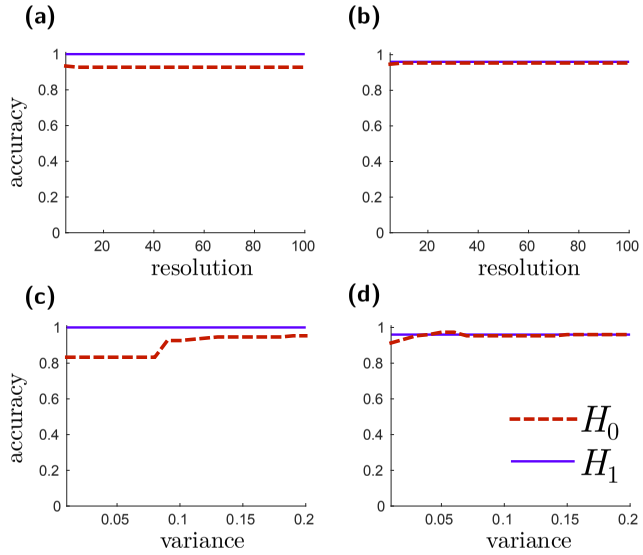

Figure 2: K-medoids classification accuracy as a function of resolution and variance for the data set of six shape classes. First column: noise level $\eta = 0.05$. Second column: noise level $\eta = 0.1$. First row: fixed variance 0.1 with resolutions ranging from 5×5 to 100×100 in increments of 5. Second row: fixed resolution 20×20 with variances ranging from 0.01 to 0.2 in increments of 0.01.

clustering with the minimum clustering score on the two sets of noise levels for the homology dimensions H_0 and H_1. We observe that the classification accuracy is insensitive to the choice of resolution and variance.

The plots in Figure 2 are characteristic of the 2-dimensional accuracy surface over all combinations of parameters in the ranges of variances and resolutions we tested. In an application to archeology, Zeppelzauer et al. (2016) find a similar robustness of PIs to the choices of resolution and variance.

6.3 Differentiating Homological Features by Sparse Support Vector Machine

The 1-norm regularized *linear* support vector machine (SVM), a.k.a. sparse SVM (SSVM) classifies data by generating a separating hyperplane that depends on very few input space features (Bradley and Mangasarian, 1998; Zhu et al., 2004; Zhang and Zhou, 2010). Such a model can be used for reducing data dimension or selecting discriminatory features. Note that linear SSVM feature selection is implemented on vectors and therefore, can be used on our PIs to select discriminatory pixels during classification. Other PD representations in the literature (Reininghaus et al., 2015; Pachauri et al., 2011) are designed to use kernel ML methods, such as *kernel* (nonlinear) SVMs. However, constructing kernel SVM classifiers

using the 1-norm results in minimizing the number of kernel functions, not the number of features in the input space (i.e., pixels in our application) (Fung and Mangasarian, 2004). Hence, for the purpose of feature selection or more precisely, PI pixel selection, we employ the linear SSVM.

We adopt the one-against-all (OAA) SSVM on the sets of H_0 and H_1 PIs from the six class shape data. In a one-against-all SSVM, there is one binary SSVM for each class to separate members of that class from members of all other classes. The PIs were generated using resolution 20×20, variance 0.0001, and noise level 0.05. Note that because of the resolution parameter choice of 20×20, each PI is a 400-dimensional vector, and the selected features will be a subset of indices corresponding to pixels within the PI. Using 5-fold cross-validated SSVM resulted in 100% accuracy comparing six sparse models with indications of the discriminatory features. Feature selection is performed by retaining the features (again, in this application, pixels) with non-zero SSVM weights, determined by magnitude comparison using weight ratios; for details see Chepushtanova et al. (2014). Figure 3 provides two examples, indicating the pixels of H_1 PIs that discriminate circles and tori from the other classes in the synthetic data set.

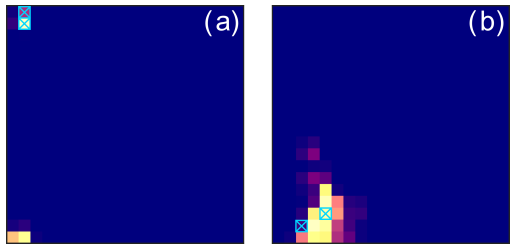

Figure 3: SSVM-based feature (pixel) selection for H_1 PIs from two classes of the synthetic data. Selected pixels are marked by blue crosses. (a) A noisy circle with the two selected pixels (indices 21 and 22 out of 400). (b) A noisy torus with the two selected pixels (indices 59 and 98 out of 400). The PI parameters used are resolution 20×20 and variance 10^{-4}, for noise level 0.05.

Feature selection produces highly interpretable results. The discriminatory pixels in the H_1 PIs that separate circles from the other classes correspond to the region where highly persistent H_1 topological features exist across all samples of a noisy circle (highlighted in Figure 3a). Alternatively, the discriminatory pixels in H_1 PIs that separate tori from the other classes correspond to points of short to moderate persistence (see Figure 3b). In this way, Figure 3b reiterates an observation of Bendich et al. (2016) that points of short to moderate persistence can contain important discriminatory information. Similar conclusions can be drawn from the discriminatory pixels of others classes (Appendix D). Our classification accuracy of 100% is obtained using only those pixels selected by SSVM (a cumulative set of only 10 distinct pixels).

6.4 Application: Determination of Dynamical System Parameters

Models of dynamic physical phenomenon rarely agree perfectly with the reality they represent. This is often due to the presence of poorly-resolved (or poorly-understood) processes which are parameterized rather than treated explicitly. As such, determination of the influence of a model parameter—which may itself be an incompletely-described conglomeration of several physical parameters—on model dynamics is a mainstay of dynamical system analysis. In the case of fitting a dynamic model to data, i.e., explicit determination of optimal model parameters, a variety of techniques exist for searching through parameter space, which often necessitate costly simulations. Furthermore, such approaches struggle when applied to models exhibiting sensitivity to initial conditions. We recast this problem as a machine-learning exercise based on the hypotheses that model parameters will be reflected directly in dynamic data in a way made accessible by persistent homology.

6.4.1 A discrete dynamical model

We approach a classification problem with data arising from the linked twist map, a discrete dynamical system modeling fluid flow. Hertzsch et al. (2007) use the linked twist map to model flows in DNA microarrays with a particular interest in understanding turbulent mixing. This demonstrates a primary mechanism giving rise to chaotic advection. The linked twist map is a Poincaré section of *eggbeater-type flow* (Hertzsch et al., 2007) in continuous dynamical systems. The Poincaré section captures the behavior of the flow by viewing a particle's location at discrete time intervals. The linked twist map is given by the discrete dynamical system

$$\begin{aligned} x_{n+1} &= x_n + r y_n(1-y_n) \mod 1 \\ y_{n+1} &= y_n + r x_n(1-x_n) \mod 1, \end{aligned}$$

where r is a positive parameter. For some values of r, the orbits $\{(x_n, y_n) : n = 0, \ldots, \infty\}$ are dense in the domain. However, for other parameter values, voids form. In either case, the truncated orbits $\{(x_n, y_n) : n = 0, \ldots, N \in \mathbb{N}\}$ exhibit complex structure.

For this experiment, we choose a set of parameter values, $r = 2.5$, 3.5, 4.0, 4.1 and 4.3, which produce a variety of orbit patterns. For each parameter value, 50 randomly-chosen initial conditions are selected, and 1000 iterations of the linked twist map are used to generate point clouds in $\mathbb{R}^2$. Figure 4 shows examples of typical orbits generated for each parameter value. The goal is to classify the trials by parameter value using PIs to capitalize on distinguishing topological features of the data. We use resolution 20×20 and a Gaussian with variance $\sigma = 0.005$ to generate the PIs. These parameters were chosen after a preliminary parameter search and classification effort. Similar results hold for a range of PI parameter values.

For a fixed r parameter value and a large number of points (many thousands), the patterns in the distributions of iterates show only small visible variations for different choices of the initial condition (x_0, y_0). However, with few points, such as in Figure 5, there are more significant variations in the patterns for different choices of initial conditions, making classification more difficult.

We perform classification and cross-validation with a discriminant subspace ensemble. This ML algorithm trains many "weak" learners on randomly chosen subspaces of the data

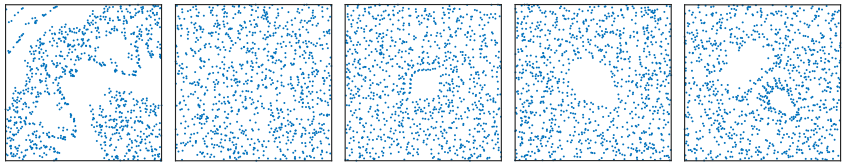

Figure 4: Examples of the first 1000 iterations, $\{(x_n, y_n) : n = 0, \ldots, 1000\}$, of the linked twist map with parameter values $r = 2$, 3.5, 4.0, 4.1 and 4.3, respectively.

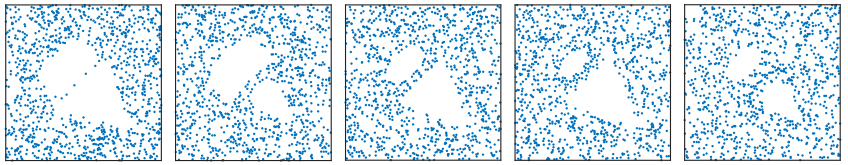

Figure 5: Truncated orbits, $\{(x_n, y_n) : n = 0, \ldots, 1000\}$, of the linked twist map with fixed $r = 4.3$ for different initial conditions (x_0, y_0).

(of a fixed dimension), and classifies and assigns a score to each point based on the current subspace. The final classification arises from an average of the scores of each data point over all learners (Ho, 1998). We perform 10 trials and average the classification accuracies. For the concatenated H_0 and H_1 PIs, this method achieves a classification accuracy of 82.5%; compared to 49.8% when using only H_0 PIs and 65.7% when using H_1 PIs. This experiment highlights two strengths of PIs: they offer flexibility in choosing a ML algorithm that is well suited to the data under consideration, and homological information from multiple dimensions may be leveraged simultaneously for greater discriminatory power.

This application is a brief example of the utility of PIs in classification of data from dynamical systems and modeling real-world phenomena, which provides a promising direction for further applications of PIs.

6.4.2 A partial differential equation

The Kuramoto-Sivashinsky (KS) equation is a partial differential equation for a function $u(x, y, t)$ of spatial variables x, y and time t that has been independently derived in a variety of problems involving pattern formation in extended systems driven far from equilibrium. Applications involving surface dynamics include surface nanopatterning by ion-beam erosion (Cuerno and Barabási, 1995; Motta et al., 2012), epitaxial growth (Villain, 1991; Wolf, 1991; Rost and Krug, 1995), and solidification from a melt (Golovin and Davis, 1998). In these applications, the nonlinear term in the KS equation may be anisotropic, resulting in the anisotropic Kuramoto-Sivashinsky (aKS) equation

$$\frac{\partial}{\partial t} u = -\nabla^2 u - \nabla^2 \nabla^2 u + r \left(\frac{\partial}{\partial x} u \right)^2 + \left(\frac{\partial}{\partial y} u \right)^2, \tag{4}$$

where $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$, and the real parameter r controls the degree of anisotropy. At a fixed time t^*, $u(x, y, t^*)$ is a patterned surface (periodic in both x and y) defined over the (x, y)-plane. Visibly, the anisotropy appears as a slight tendency for the pattern to be elongated in the vertical or horizontal direction.

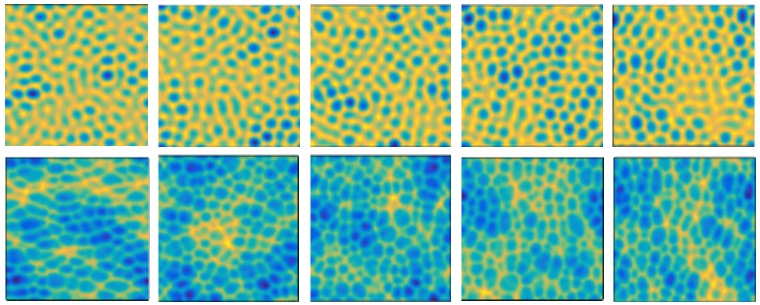

Figure 6: Plots of height-variance-normalized surfaces $u(x, y, \cdot)$ resulting from numerical simulations of the aKS equation (4). Each column represents a different parameter value: (from left) $r = 1$, 1.25, 1.5, 1.75 and 2. Each row represents a different time: $t = 3$ (top) and $t = 5$ (bottom). By $t = 5$ any anisotropic elongation of the surface pattern has visibly stabilized.

Numerical simulations of the aKS equation for a range of parameter values (columns) and simulation times (rows) are shown in Figure 6. For all simulations, the initial conditions were low-amplitude white noise. We employed a Fourier spectral method with periodic boundary conditions on a 512×512 spatial grid, with a fourth-order exponential time differencing Runge-Kutta method for the time stepping. Five values for the parameter r were chosen, namely $r = 1$, 1.25, 1.5, 1.75 and 2, and thirty trials were performed for each parameter value. Figure 7 shows the similarity between surfaces associated to two parameter values $r = 1.75$ and $r = 2$ at an early time.

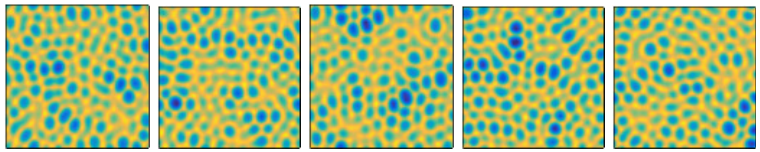

Figure 7: To illustrate the difficulty of our classification task, consider five instances of surfaces $u(x, y, 3)$ for $r = 1.75$ or $r = 2$, plotted on the same color axis. These surfaces are found by numerical integration of Equation (4), starting from random initial conditions. Can you group the images by eye?

Answer: (from left) $r = 1.75, 2, 1.75, 2, 2$.

We aim to identify the anisotropy parameter for each simulation using snapshots of surfaces $u(x, y, \cdot)$ as they evolve in time. Inference of the parameter using the surface alone proves difficult for several reasons. First, Equation (4) exhibits sensitivity to initial conditions: initially nearby solutions diverge quickly. Second, although the surface $u(x, y, t^*)$ at a fixed time is an approximation due to the finite discretization of its domain, the spatial resolution is still very large: in fact, these surfaces may be thought of as points in $\mathbb{R}^{266144}$. We were unable to perform standard classification techniques in this space. It was therefore necessary to perform some sort of dimension reduction. One such method is to simply 'resize' the surface by coarsening the discretization of the spatial domain after computing the simulation at a high resolution by replacing a block of grid elements with their average surface height. The surfaces were resized in this way to a resolution of 10×10 and a subspace discriminant ensemble was used to perform classification. Unsurprisingly, this method performs very poorly at all times (first row of Table 2).

The anisotropy parameter also influences the mean and amplitude of the surface pattern. We eliminate differences in the mean by mean-centering each surface after the simulation. To assess the impact of the variance of surface height on our task, classification was performed using a normal distribution-based classifier built on the variances of the surface heights. In this classifier, a normal distribution was fit to a training set of 2/3 of the variances for each parameter value, and the testing data was classified based on a z-test for each of the different models. That is, a p-value for each new variance was computed for membership to the five normal distributions (corresponding to the five parameter choices of r), and the surface was classified based on the model yielding the highest p-value. After the pattern has more fully emerged (by, say, time $t = 5$) this method of classification yields 75% accuracy,[11] as shown in Table 2. However, early on in the formation of the pattern, this classifier performs very poorly because height variance is not yet a discriminating feature. Figure 8 shows the normal distribution fit to the variance of the surfaces for each parameter value at times $t = 3$ and 5, and illustrates why the variance of surface height is informative only after a surface is allowed to evolve for a sufficiently long time.

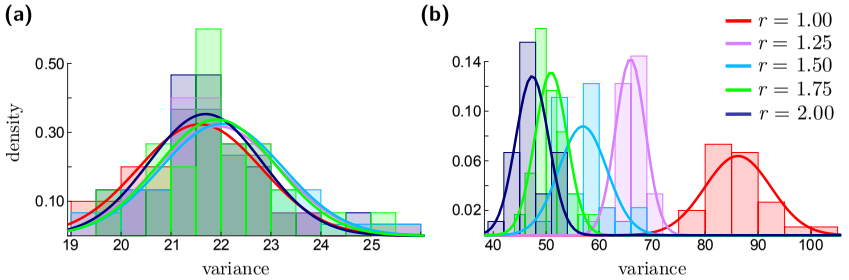

Figure 8: Histograms of the variances of surface heights for each parameter value, and the normal distribution fit to each histogram, for times (a) $t = 3$ and (b) $t = 5$.

11. Accuracy reported is averaged over 100 different training and testing partitions.

Table 2: Classification accuracies at different times of the aKS solution, using different classification approaches. Classification of times $t = 15$ and 20 result in accuracies similar to t =10.

Classification Approach	Time t=3	Time t=5	Time t=10
Subspace Discriminant Ensemble, Resized Surfaces	26.0 %	19.3%	19.3 %
Variance Normal Distribution Classifier	20.74%	75.2%	77.62 %
Subspace Discriminant Ensemble, H_0 PIs	58.3 %	96.0 %	94.7 %
Subspace Discriminant Ensemble, H_1 PIs	67.7 %	87.3 %	93.3%
Subspace Discriminant Ensemble, H_0 and H_1 PIs	72.7 %	95.3 %	97.3 %

Variance of a surface is reflected in its sublevel set filtration (see §A.3 for more details) PD. Yet, the PD and the subsequent PI contain additional topological structure, which may reveal other influences of the anisotropy parameter on the evolution of the surface. Persistence diagrams were computed using the sublevel set filtration, and PIs were generated with resolution 10×10 and a Gaussian with variance $\sigma = 0.01$. We think of our pipeline to a PI as a dimensionality reduction in this case, taking a surface which in actuality is a very high-dimensional point and producing a much lower dimensional one that retains meaningful characteristics of the original surface.

We again use a subspace discriminant ensemble to classify PIs by parameter. Table 2 compares these results to the same technique applied to low dimensional approximations of the raw surfaces and the normal distribution-based classifier built from surface variance alone. At each time in the system evolution, the best classification accuracy results from using PIs, improving accuracies over using either low resolution approximations of the surfaces or variance of surface height alone by at least 20%, including at early times in the evolution of the surface when pattern amplitudes are not visibly differentiated (see Figure 7). We postulate that PIs capture more subtle topological information that is useful for identifying the parameter used to generate each surface.

As we observed in §6.4.1, concatenating H_0 and H_1 PIs can notably improve the classification accuracy over either feature vector individually. We again note that classification accuracy appears insensitive to the PI parameters. For example, when the variance of the Guassians used to generate the PIs was varied from 0.0001 to 0.1, the classification accuracy of the H_0 PIs, changed by less than one percentage point. The classification accuracy for H_1 fluctuated in a range of approximately five points. For a fixed variance, when the resolution of the image was varied from 5 to 20, the H_0 accuracy varied by little more than three points until the accuracy dropped by six points for a resolution of 25.

PIs performed remarkably well in this classification task, allowing one to capitalize on subtle structural differences in the patterns and significantly reduce the dimension of the data for classification. There is more to be explored in the realm of pattern formation and persistence that is outside the scope of this paper.

7. Conclusion

PIs offer a stable representation of the topological characteristics captured by a PD. Through this vectorization, we open the door to a myriad of ML tools. This serves as a vital bridge between the fields of ML and topological data analysis and enables one to capitalize on topological structure (even in multiple homological dimensions) in the classification of data.

We have shown PIs yield improved classification accuracy over PLs and PDs on sampled data of common topological spaces at multiple noise levels using K-medoids. Additionally, computing distances between PIs requires significantly less computation time compared to computing distances between PDs, and comparable computation times with PLs. Through PIs, we have gained access to a wide variety of ML tools, such as SSVM which can be used for feature selection. Features (pixels) selected as discriminatory in a PI are interpretable because they correspond to regions of a PD. We have explored data sets derived from dynamical systems and illustrated that topological information of solutions can be used for inference of parameters since PIs encapsulate this information in a form amenable to ML tools, resulting in high accuracy rates for data that is difficult to classify.

The classification accuracy is robust to the choice of parameters for building PIs, providing evidence that it is not necessary to perform large-scale parameter searches to achieve reasonable classification accuracy. This indicates the utility of PIs even when there is not prior knowledge of the underlying data (i.e., high noise level, expected holes, etc.). The flexibility of PIs allows for customization tailored to a wide variety of real-world data sets.

Acknowledgments

We would like to acknowledge the research group of Paul Bendich at Duke University for allowing us access to a persistent homology package, which greatly reduced computational time and made analysis of large point clouds feasible. This code can be accessed via GitLab after submitting a request to Paul Bendich. Appendix A. Homology and Data

Homology is an invariant that characterizes the topological properties of a topological space X. In particular, homology measures the number of connected components, loops, trapped volumes, and so on of a topological space, and can be used to distinguish distinct spaces from one another. More explicitly, the k-dimensional holes of a space generate a homology group, $H_k(X)$. The rank of this group is referred to as the *k-th Betti number*, β_k, and counts the number of k-dimensional holes of X. For a comprehensive study of homology, see the textbook of Hatcher (2002).

A.1 Simplicial Complexes and Homology

Simplicial complexes are one way to define topological spaces combinatorially. More precisely, a *simplicial complex* S consists of vertices (0-simplices), edges (1-simplices), triangles (2-simplices), tetrahedra (3-simplices), and higher-dimensional k-simplices (containing $k+1$ vertices), such that

- if σ is a simplex in S then S contains all lower-dimensional simplices of σ, and
- the non-empty intersection of any two simplices in S is a simplex in S.

The following setup is necessary for a rigorous definition of (simplicial) homology. To a simplicial complex, one can associate a chain complex of vector spaces over a field $\mathbb{F}$ (often a finite field $\mathbb{Z}/p\mathbb{Z}$ for p a small prime),

$$\cdots \to C_{k+1} \xrightarrow{\partial_{k+1}} C_k \xrightarrow{\partial_k} C_{k-1} \to \cdots .$$

Here, vector space C_k consists of all $\mathbb{F}$-linear combinations of the k simplices of S, and has as a basis the set of all k-simplices. The linear map $\partial_k : C_k \to C_{k-1}$, known as the *boundary operator*, maps a k-simplex to its boundary, a sum of its $(k-1)$-faces. More formally, the boundary map acts on a k-simplex $[v_0, v_1, \ldots, v_k]$ by

$$\partial_k([v_0, v_1, \ldots, v_k]) = \sum_{i=0}^{k} (-1)^i [v_0, \ldots, \hat{v_i}, \ldots, v_k],$$

where $[v_0, \ldots, \hat{v_i}, \ldots, v_k]$ is the $(k-1)$-simplex obtained from $[v_0, \ldots, v_k]$ by removing vertex v_i. We define two subspaces of C_k: subspace $Z_k = \mathsf{ker}(\partial_k)$ is known as the *k-cycles*, and subspace $B_k = \mathsf{im}(\partial_{k+1}) = \partial_{k+1}(C_{k+1})$ is known as the *k-boundaries*. The boundary operator satisfies the property $\partial_k \circ \partial_{k+1} = 0$, which implies the inclusion $B_k \subseteq Z_k$.

Homology seeks to uncover an equivalence class of cycles that enclose a k-dimensional hole—that is, cycles which are not also boundaries of k-simplices. To this end, the k-th order homology is defined as $H_k(S) = Z_k/B_k$, a quotient of vector spaces. The k-th Betti number $\beta_k = \dim(H_k(S))$ is the dimension of this vector space, and counts the number of independent holes of dimension k. More explicitly, β_0 counts the number of connected components, β_1 the number of loops, β_2 the number of trapped volumes, and so on. Betti numbers are a topological invariant, meaning that topologically equivalent spaces have the same Betti numbers.

A.2 Persistence Diagrams from Point Cloud Data

One way to approximate the topological characteristics of a point cloud data set is to build a simplicial complex on top of it. Though there are a variety of methods to do so, we restrict attention to the *Vietoris–Rips simplicial complex* due to its computational tractability (Ghrist, 2008). Given a data set Y (equipped with a metric) and a scale parameter $\epsilon \geq 0$, the Vietoris–Rips complex S_ϵ has Y as its set of vertices and has a k-simplex for every collection of $k+1$ vertices whose pairwise distance is at most ϵ. However, it is often not apparent how to choose scale ϵ. Selecting ϵ too small results in a topological space with

a large number of connected components, and selecting ϵ too large results in a topological space that is contractible (equivalent to a single point).

The idea of persistent homology is to compute homology at many scales and observe which topological features persist across those scales (Ghrist, 2008; Carlsson, 2009; Edelsbrunner and Harer, 2008). Indeed, if $\epsilon_1 \leq \epsilon_2 \leq \ldots \leq \epsilon_m$ is an increasing sequence of scales, then the corresponding Vietoris–Rips simplicial complexes form a filtered sequence $S_{\epsilon_1} \subseteq S_{\epsilon_2} \subseteq \ldots \subseteq S_{\epsilon_m}$. As ϵ varies, so does the homology of S_ϵ, and for any homological dimension k we get a sequence of linear maps $H_k(S_{\epsilon_1}) \to H_k(S_{\epsilon_2}) \to \ldots \to H_k(S_{\epsilon_m})$. Persistent homology tracks the homological features over a range of values of ϵ. Those features which persist over a larger range are considered to be true topological characteristics, while short-lived features are often considered as noise.

For each choice of homological dimension k, the information measured by persistent homology can be presented as a *persistence diagram* (PD), a multiset of points in the plane. Each point $(x, y) = (\epsilon, \epsilon')$ corresponds to a topological feature that appears (is 'born') at scale parameter ϵ and which no longer remains ('dies') at scale ϵ'. Since all topological features die after they are born, this is an embedding into the upper half plane, above the diagonal line $y = x$. Points near the diagonal are considered to be noise while those further from the diagonal represent more robust topological features.

A.3 Persistence Diagrams from Functions

Let X be a topological space and let $f\colon X \to \mathbb{R}$ be a real-valued function. One way to understand the behavior of map f is to understand the topology of its sublevel sets $f^{-1}((-\infty, \epsilon])$, where $\epsilon \in \mathbb{R}$. Indeed, given $\epsilon_1 \leq \epsilon_2 \leq \ldots \leq \epsilon_m$, one can study map f using the persistent homology of the resulting filtration of topological spaces, known as the sublevel set filtration:

$$f^{-1}((-\infty, \epsilon_1]) \subseteq f^{-1}((-\infty, \epsilon_2]) \subseteq \ldots \subseteq f^{-1}((-\infty, \epsilon_m]).$$

If X is a simplicial complex, then one can produce an increasing sequence of simplicial complexes using a modification of this procedure called the lower star filtration (Edelsbrunner and Harer, 2010). Similarly, if X is a cubical complex (an analogue of a simplicial complex that is instead a union of vertices, edges, squares, cubes, and higher-dimensional cubes), then one can produce an increasing sequence of cubical complexes.

In §6.4.2, we study surfaces $u\colon [0,1]^2 \to \mathbb{R}$ produced from the Kuramoto-Sivashinsky equation. The domain $[0,1]^2$ is discretized into a grid of 512×512 vertices, i.e., a 2-dimensional cubical complex with 512^2 vertices, $511 \cdot 512$ horizontal edges, $511 \cdot 512$ vertical edges, and 511^2 squares. We produce an increasing sequence of cubical complexes as follows:

- A vertex v is included at scale ϵ if $u(v) \leq \epsilon$.
- An edge is included at scale ϵ if both of its vertices are present.
- A square is included at scale ϵ if all four of its vertices are present.

Our PDs are obtained by taking the persistent homology of the sublevel set filtration of this cubical complex.

We remark that PDs from point cloud data in §A.2 can be viewed as a specific case of PDs from functions. Indeed, given a data set X in some metric space (M, d), let $d_X : M \to \mathbb{R}$ be the distance function to set X, defined by $d_X(m) = \inf_{x \in X} d(x, m)$ for all $m \in M$. Note that $d_X^{-1}((-\infty, \epsilon])$ is the union of the metric balls of radius ϵ centered at each point in X. For $\epsilon_1 \leq \epsilon_2 \leq \ldots \leq \epsilon_m$, the persistent homology of

$$d_X^{-1}((-\infty, \epsilon_1]) \subseteq d_X^{-1}((-\infty, \epsilon_2]) \subseteq \ldots \subseteq d_X^{-1}((-\infty, \epsilon_m])$$

is identical to the persistent homology of a simplicial complex filtration called the *Čech complex*. Furthermore, the persistent homology of the Vietoris–Rips complex is an approximation of the persistent homology of the Čech complex (Edelsbrunner and Harer, 2010, Section III.2).

Appendix B. Examples of Persistence Images

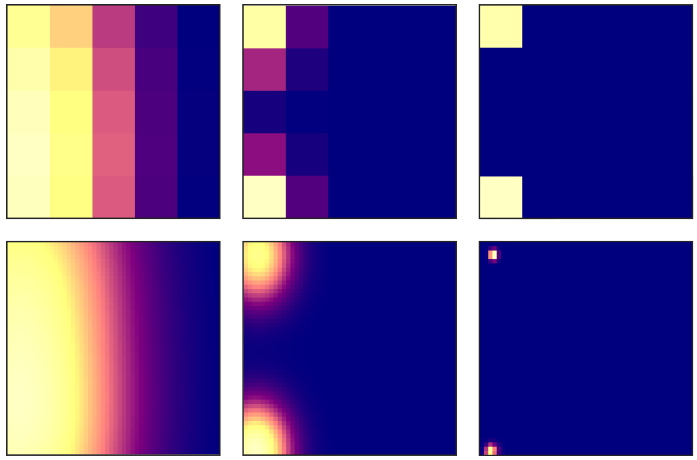

Figure 9: Examples of PIs for homology dimension H_1 arising from a noisy circle with a variety of resolutions and variances. The first row has resolution 5×5 while the second has 50×50. The columns have variance $\sigma = 0.2$, $\sigma = 0.01$, and $\sigma = 0.0001$, respectively.

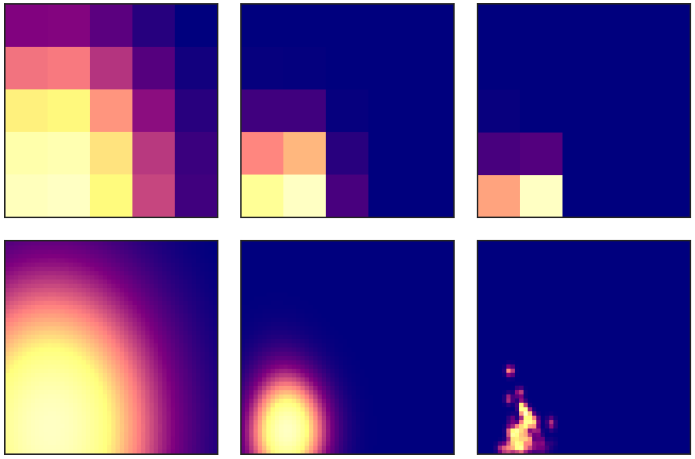

Figure 10: Examples of PIs for homology dimension H_1 arising from a noisy torus with a variety of resolutions and variances. The first row has resolution 5×5 while the second has 50×50. The columns have variance $\sigma = 0.2$, $\sigma = 0.01$, and $\sigma = 0.0001$, respectively.

Appendix C. Proofs of Equation (3) and Lemma 8

Let $u, v \in \mathbb{R}$ and $a, b > 0$. Equation (3) states that $\|ag_u - bg_v\|_1 = F(v-u)$, where $F : \mathbb{R} \to \mathbb{R}$ is defined by

$$F(z) = \begin{cases} |a-b| & \text{if } z = 0 \\ \left| a\text{Erf}\left(\frac{z^2+2\sigma^2\ln(a/b)}{z\sigma 2\sqrt{2}}\right) - b\text{Erf}\left(\frac{-z^2+2\sigma^2\ln(a/b)}{z\sigma 2\sqrt{2}}\right)\right| & \text{otherwise.} \end{cases}$$

Proof If $v = u$ then the statement follows from the fact that g_u and g_v are normalized to have unit area under the curve. Hence we may assume $u \neq v$.

For $u \neq v$ a straightforward calculation shows there is a unique real solution z^* to $ag_u(z) = bg_v(z)$, namely

$$z^* = \frac{v^2 - u^2 + 2\sigma^2 \ln(a/b)}{2(v-u)}.$$

Note

$$\|ag_u - bg_v\|_1 = \int_{-\infty}^{\infty} |ag_u(z) - bg_v(z)|dz = \left| \int_{-\infty}^{z^*} ag_u(z) - bg_v(z)dz + \int_{z^*}^{\infty} bg_v(z) - ag_u(z)dz \right|. \quad (5)$$

There are four integrals to compute, and we do each one in turn. We have

$$\begin{aligned}
\int_{-\infty}^{z^*} a g_u(z)\, dz &= \frac{a}{\sigma\sqrt{2\pi}} \int_{-\infty}^{z^*} e^{-(z-u)^2/2\sigma^2}\, dz \\
&= \frac{a}{\sqrt{\pi}} \int_{-\infty}^{P(v-u)} e^{-t^2}\, dt \qquad \text{by substitution } t = \tfrac{z-u}{\sigma\sqrt{2}} \\
&= \frac{a}{\sqrt{\pi}} \left(\int_{-\infty}^{0} e^{-t^2}\, dt + \int_{0}^{P(v-u)} e^{-t^2}\, dt \right) \\
&= \frac{a}{\sqrt{\pi}} \left(\frac{\sqrt{\pi}}{2} + \frac{\sqrt{\pi}}{2} \mathrm{Erf}(P(v-u)) \right) \\
&= \frac{a}{2} \left(1 + \mathrm{Erf}(P(v-u)) \right),
\end{aligned}$$

where $P(z) = \frac{z^2 + 2\sigma^2 \ln(a/b)}{z\sigma 2\sqrt{2}}$. Nearly identical calculations show

$$\begin{aligned}
\int_{z^*}^{\infty} a g_u(z)\, dz &= \frac{a}{2} \left(1 - \mathrm{Erf}(P(v-u)) \right) \\
\int_{-\infty}^{z^*} b g_v(z)\, dz &= \frac{b}{2} \left(1 + \mathrm{Erf}(Q(v-u)) \right) \\
\int_{z^*}^{\infty} b g_v(z)\, dz &= \frac{b}{2} \left(1 - \mathrm{Erf}(Q(v-u)) \right),
\end{aligned}$$

where $Q(z) = \frac{-z^2 + 2\sigma^2 \ln(a/b)}{z\sigma 2\sqrt{2}}$. Plugging back into (5) gives $\|a g_u - b g_v\|_1 = F(v-u)$. ■

We now give the proof of Lemma 8.

Lemma 8. For $u, v \in \mathbb{R}^2$, let $g_u, g_v \colon \mathbb{R}^2 \to \mathbb{R}$ be normalized 2-dimensional Gaussians. Then

$$\|f(u) g_u - f(v) g_v\|_1 \leq \left(|\nabla f| + \sqrt{\frac{2}{\pi}} \frac{\min\{f(u), f(v)\}}{\sigma} \right) \|u - v\|_2.$$

Proof The result will follow from the observation that we can reduce the two-dimensional case involving Gaussians centered at $u, v \in \mathbb{R}^2$ to one-dimensional Gaussians centered at 0 and $r = \|u - v\|_2$. Let $u = (u_x, u_y)$ and $v = (v_x, v_y)$; we may assume $u_x > v_x$ w.l.o.g. Let (r, θ) be the magnitude and angle of vector $u - v$ when expressed in polar coordinates. The change of variables $(z, w) = R_\theta(x - v_x, y - v_y)$, where R_θ is the clockwise rotation of the

plane by θ, gives

$$\begin{aligned}
&\|f(u) g_u - f(v) g_v\|_1 \\
&= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left| \frac{f(u)}{2\pi\sigma^2} e^{-[(x-u_x)^2 + (y-u_y)^2]/2\sigma^2} - \frac{f(v)}{2\pi\sigma^2} e^{-[(x-v_x)^2 + (y-v_y)^2]/2\sigma^2} \right| dy\, dx \\
&= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left| \frac{f(u)}{2\pi\sigma^2} e^{-[w^2 + (z-r)^2]/2\sigma^2} - \frac{f(v)}{2\pi\sigma^2} e^{-[w^2 + z^2]/2\sigma^2} \right| dz\, dw \\
&= \int_{-\infty}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-w^2/2\sigma^2} \left[\int_{-\infty}^{\infty} \left| \frac{f(u)}{\sigma\sqrt{2\pi}} e^{-(z-r)^2/2\sigma^2} - \frac{f(v)}{\sigma\sqrt{2\pi}} e^{-z^2/2\sigma^2} \right| dz \right] dw \\
&= \|f(u) g_r - f(v) g_0\|_1 \int_{-\infty}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-w^2/2\sigma^2} dw \quad \text{with } g_0, g_r \text{ 1-dimensional Gaussians} \\
&= \|f(u) g_r - f(v) g_0\|_1 \\
&\leq |f(u) - f(v)| + \sqrt{\frac{2}{\pi}} \frac{\min\{f(u), f(v)\}}{\sigma} \|u - v\|_2 \quad \text{by Lemma 7} \\
&\leq \left(|\nabla f| + \sqrt{\frac{2}{\pi}} \frac{\min\{f(u), f(v)\}}{\sigma} \right) \|u - v\|_2.
\end{aligned}$$

■

Appendix D. SSVM-based Feature Selection

We performed feature selection using one-against-all (OAA) SSVM on the six classes of synthetic data with noise level $\eta = 0.05$. The PIs used in the experiments were generated from the H_1 PDs, with the parameter choices of resolution 20×20 and variance $\sigma = 0.0001$. Note that because of the resolution parameter choice of 20×20, each PI is a vector in $\mathbb{R}^{400}$, and the selected features will be a subset of indices corresponding to pixels within the PI. We trained an OAA SSVM model for PIs of dimension H_1. In the experiment, we used 5-fold cross-validation and obtained 100% overall accuracy. Feature selection was performed by retaining the features with non-zero SSVM weights, determined by magnitude comparison using weight ratios (Chepushtanova et al., 2014). The resulting six sparse models contain subsets of discriminatory features for each class. Note that one can use only these selected features for classification without loss in accuracy. These features correspond to discriminatory pixels in the persistence images.

Figure 11 shows locations of pixels in the vectorized PIs selected by OAA SSVM that discriminate each class from all the others.

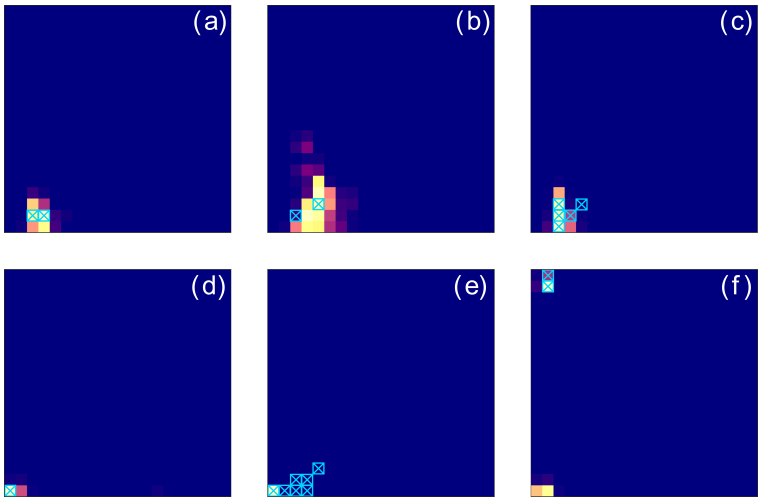

Figure 11: SSVM-based feature (pixel) selection for H_1 PIs from the six classes of the synthetic data. The parameters used are resolution 20×20 and variance 0.0001, for noise level 0.05. Selected pixels are marked by blue crosses. (a) A noisy solid cube with the two selected pixels (indices 59 and 79 out of 400). (b) A noisy torus with the two selected pixels (indices 59 and 98 out of 400). (c) A noisy sphere with the five selected pixels (indices 58, 59, 60, 79, and 98 out of 400). (d) Noisy three clusters with the one selected pixel (index 20 out of 400). (e) Noisy three clusters within three clusters with the seven selected pixels (indices 20, 40, 59, 60, 79, 80, and 98 out of 400). (f) A noisy circle with the two selected pixels (indices 21 and 22 out of 400).

Abstract

We propose a spectral clustering method based on local principal components analysis (PCA). After performing local PCA in selected neighborhoods, the algorithm builds a nearest neighbor graph weighted according to a discrepancy between the principal subspaces in the neighborhoods, and then applies spectral clustering. As opposed to standard spectral methods based solely on pairwise distances between points, our algorithm is able to resolve intersections. We establish theoretical guarantees for simpler variants within a prototypical mathematical framework for multi-manifold clustering, and evaluate our algorithm on various simulated data sets.

Keywords: multi-manifold clustering, spectral clustering, local principal component analysis, intersecting clusters

1. Introduction

The task of multi-manifold clustering, where the data are assumed to be located near surfaces embedded in Euclidean space, is relevant in a variety of applications. In cosmology, it arises as the extraction of galaxy clusters in the form of filaments (curves) and walls (surfaces) (Valdarnini, 2001; Martínez and Saar, 2002); in motion segmentation, moving objects tracked along different views form affine or algebraic surfaces (Ma et al., 2008; Fu et al., 2005; Vidal and Ma, 2006; Chen et al., 2009); this is also true in face recognition, in the context of images of faces in fixed pose under varying illumination conditions (Ho et al., 2003; Basri and Jacobs, 2003; Epstein et al., 1995).

We consider a stylized setting where the underlying surfaces are nonparametric in nature, with a particular emphasis on situations where the surfaces intersect. Specifically, we assume the surfaces are smooth, for otherwise the notion of continuation is potentially ill-posed. For example, without smoothness assumptions, an L-shaped cluster is indistinguishable from the union of two line-segments meeting at right angle.

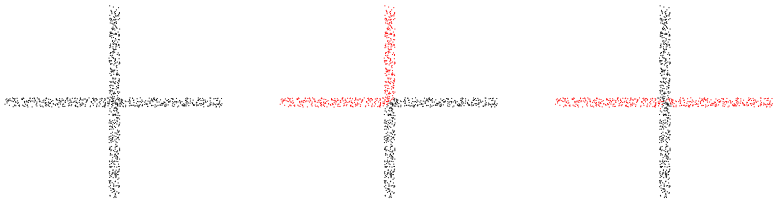

Figure 1: Two rectangular clusters intersecting at right angle. Left: the original data. Center: a typical output of the standard spectral clustering method of Ng et al. (2002), which is generally unable to resolve intersections. Right: a typical output of our method.

Spectral methods (Luxburg, 2007) are particularly suited for nonparametric settings, where the underlying clusters are usually far from convex, making standard methods like K-means irrelevant. However, a drawback of standard spectral approaches such as the well-known variant of Ng, Jordan, and Weiss (2002) is their inability to separate intersecting clusters. Indeed, consider the simplest situation where two straight clusters intersect at right angle, pictured in Figure 1 below. The algorithm of Ng et al. (2002) is based on pairwise affinities that are decreasing in the distances between data points, making it insensitive to smoothness and, therefore, intersections. And indeed, this algorithm typically fails to separate intersecting clusters, even in the easiest setting of Figure 1.

As argued in (Agarwal et al., 2005, 2006; Shashua et al., 2006), a multiway affinity is needed to capture complex structure in data (here, smoothness) beyond proximity attributes. For example, Chen and Lerman (2009a) use a flatness affinity in the context of *hybrid linear modeling*, where the surfaces are assumed to be affine subspaces, and subsequently extended to algebraic surfaces via the 'kernel trick' (Chen, Atev, and Lerman, 2009). Moving beyond parametric models, Arias-Castro, Chen, and Lerman (2011) introduce a localized measure of flatness.

Continuing this line of work, we suggest a spectral clustering method based on the estimation of the local linear structure (tangent bundle) via local principal component analysis (PCA). The idea of using local PCA combined with spectral clustering has precedents in the literature. In particular, our method is inspired by the work of Goldberg, Zhu, Singh, Xu, and Nowak (2009), where the authors develop a spectral clustering method within a semi-supervised learning framework. This approach is in the zeitgeist. While writing this paper, we became aware of two concurrent publications, by Wang, Jiang, Wu, and Zhou (2011) and by Gong, Zhao, and Medioni (2012), both proposing approaches very similar to ours.[1] We also mention the multiscale, spectral-flavored algorithm of Kushnir, Galun, and Brandt (2006), which is also based on local PCA. We comment on these spectral methods

1. The present paper was indeed developed in parallel with these two, first as a short version submitted to ICML in 2011.

in more detail later on. In fact, an early proposal also based on local PCA appears in the literature on subspace clustering (Fan et al., 2006)—although the need for localization is perhaps less intuitive in this setting.

The basic proposition of local PCA combined with spectral clustering has two main stages. The first one forms an affinity between a pair of data points that takes into account both their Euclidean distance and a measure of discrepancy between their tangent spaces. Each tangent space is estimated by PCA in a local neighborhood around each point. The second stage applies standard spectral clustering with this affinity. As a reality check, this relatively simple algorithm succeeds at separating the straight clusters in Figure 1. We tested our algorithm in more elaborate settings, some of them described in Section 4.

Other methods with a spectral component include those of Polito and Perona (2001) and Goh and Vidal (2007), which (roughly speaking) embed the points by a variant of LLE (Saul and Roweis, 2003) and then group the points by K-means clustering. There is also the method of Elhamifar and Vidal (2011), which chooses the neighborhood of each point by computing a sparse linear combination of the remaining points followed by an application of the spectral graph partitioning algorithm of Ng et al. (2002). Note that these methods work under the assumption that the surfaces do not intersect.

Besides spectral-type approaches to multi-manifold clustering, other methods appear in the literature. Among these, Gionis et al. (2005) and Haro et al. (2007) allow for intersecting surfaces but assume that they have different intrinsic dimension or density—and the proposed methodology is entirely based on such assumptions. We also mention the K-manifold method of Souvenir and Pless (2005), which propose an EM-type algorithm; and that of Guo et al. (2007), which propose to minimize an energy functional based on pairwise distances and local curvatures, leading to a combinatorial optimization.

Our contribution is the design and detailed study of a prototypical spectral clustering algorithm based on local PCA, tailored to settings where the underlying clusters come from sampling in the vicinity of smooth surfaces that may intersect. We endeavored to simplify the algorithm as much as possible without sacrificing performance. We provide theoretical results for simpler variants within a standard mathematical framework for multi-manifold clustering. To our knowledge, these are the first mathematically backed successes at the task of resolving intersections in the context of multi-manifold clustering, with the exception of (Arias-Castro et al., 2011), where the corresponding algorithm is shown to succeed at separating intersecting curves. The salient features of our algorithm are illustrated via numerical experiments.

The rest of the paper is organized as follows. In Section 2, we introduce our method in various variants. In Section 3, we analyze the simpler variants in a standard mathematical framework for multi-manifold learning. In Section 4, we perform some numerical experiments illustrating several features of our approach. In Section 5, we discuss possible extensions.

2. The Methodology

We introduce our algorithm and simpler variants that are later analyzed in a mathematical framework. We start with some review of the literature, zooming in on the most closely related publications.

2.1 Some Precedents

Using local PCA within a spectral clustering algorithm was implemented in four other publications we know of (Goldberg et al., 2009; Kushnir et al., 2006; Gong et al., 2012; Wang et al., 2011). As a first stage in their semi-supervised learning method, Goldberg, Zhu, Singh, Xu, and Nowak (2009) design a spectral clustering algorithm. The method starts by subsampling the data points, obtaining 'centers' in the following way. Draw $\boldsymbol{y}_1$ at random from the data and remove its ℓ-nearest neighbors from the data. Then repeat with the remaining data, obtaining centers $\boldsymbol{y}_1, \boldsymbol{y}_2, \dots$. Let $\boldsymbol{C}_i$ denote the sample covariance in the neighborhood of $\boldsymbol{y}_i$ made of its ℓ-nearest neighbors. An m-nearest-neighbor graph is then defined on the centers in terms of the Mahalanobis distances. Explicitly, the centers $\boldsymbol{y}_i$ and $\boldsymbol{y}_j$ are connected in the graph if $\boldsymbol{y}_j$ is among the m nearest neighbors of $\boldsymbol{y}_i$ in Mahalanobis distance

$$\|\boldsymbol{C}_i^{-1/2}(\boldsymbol{y}_i - \boldsymbol{y}_j)\|, \tag{1}$$

or vice-versa. The parameters ℓ and m are both chosen of order $\log n$. An existing edge between $\boldsymbol{y}_i$ and $\boldsymbol{y}_j$ is then weighted by $\exp(-H_{ij}^2/\eta^2)$, where H_{ij} denotes the Hellinger distance between the probability distributions $\mathcal{N}(\boldsymbol{0}, \boldsymbol{C}_i)$ and $\mathcal{N}(\boldsymbol{0}, \boldsymbol{C}_j)$. The spectral graph partitioning algorithm of Ng, Jordan, and Weiss (2002)—detailed in Algorithm 1—is then applied to the resulting affinity matrix, with some form of constrained K-means. We note that Goldberg et al. (2009) evaluate their method in the context of semi-supervised learning where the clustering routine is only required to return subclusters of actual clusters. In particular, the data points other than the centers are discarded. Note also that their evaluation is empirical.

Algorithm 1 Spectral Graph Partitioning (Ng, Jordan, and Weiss, 2002)

Input:
Affinity matrix $\boldsymbol{W} = (W_{ij})$, size of the partition K

Steps:
1: Compute $\boldsymbol{Z} = (Z_{ij})$ according to $Z_{ij} = W_{ij}/\sqrt{\Delta_i \Delta_j}$, with $\Delta_i := \sum_{j=1}^n W_{ij}$.
2: Extract the top K eigenvectors of $\boldsymbol{Z}$.
3: Renormalize each row of the resulting $n \times K$ matrix.
4: Apply K-means to the row vectors.

The algorithm proposed by Kushnir, Galun, and Brandt (2006) is multiscale and works by coarsening the neighborhood graph and computing sampling density and geometric information inferred along the way such as obtained via PCA in local neighborhoods. This bottom-up flow is then followed by a top-down pass, and the two are iterated a few times. The algorithm is too complex to be described in detail here, and probably too complex to be analyzed mathematically. The clustering methods of Goldberg et al. (2009) and ours can be seen as simpler variants that only go bottom up and coarsen the graph only once.

In the last stages of writing this paper, we learned of the works of Wang, Jiang, Wu, and Zhou (2011) and Gong, Zhao, and Medioni (2012), who propose algorithms very similar to our Algorithm 3 detailed below. Note that these publications do not provide any theoretical guarantees for their methods, which is one of our main contributions here.

2.2 Our Algorithms

We now describe our method and propose several variants. Our setting is standard: we observe data points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n \in \mathbb{R}^D$ that we assume were sampled in the vicinity of K smooth surfaces embedded in $\mathbb{R}^D$. The setting is formalized later in Section 3.1.

2.2.1 Connected Component Extraction: Comparing Local Covariances

We start with our simplest variant, which is also the most natural. The method depends on a neighborhood radius $r > 0$, a spatial scale parameter $\varepsilon > 0$ and a covariance (relative) scale $\eta > 0$. For a vector $\boldsymbol{x}$, $\|\boldsymbol{x}\|$ denotes its Euclidean norm, and for a (square) matrix $\boldsymbol{A}$, $\|\boldsymbol{A}\|$ denotes its spectral norm. For $n \in \mathbb{N}$, we denote by $[n]$ the set $\{1, \ldots, n\}$. Given a data set $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$, for any point $\boldsymbol{x} \in \mathbb{R}^D$ and $r > 0$, define the neighborhood

$$N_r(\boldsymbol{x}) = \{\boldsymbol{x}_j : \|\boldsymbol{x} - \boldsymbol{x}_j\| \leq r\}.$$

Algorithm 2 Connected Component Extraction: Comparing Covariances

Input:

Data points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$; neighborhood radius $r > 0$; spatial scale $\varepsilon > 0$, covariance scale $\eta > 0$.

Steps:

1: For each $i \in [n]$, compute the sample covariance matrix $\boldsymbol{C}_i$ of $N_r(\boldsymbol{x}_i)$.
2: Remove $\boldsymbol{x}_i$ when there is $\boldsymbol{x}_j$ such that $\|\boldsymbol{x}_j - \boldsymbol{x}_i\| \leq r$ and $\|\boldsymbol{C}_j - \boldsymbol{C}_i\| > \eta r^2$.
3: Compute the following affinities between data points:

$$W_{ij} = \mathbb{1}_{\{\|\boldsymbol{x}_i - \boldsymbol{x}_j\| \leq \varepsilon\}} \cdot \mathbb{1}_{\{\|\boldsymbol{C}_i - \boldsymbol{C}_j\| \leq \eta r^2\}}. \tag{2}$$

4: Extract the connected components of the resulting graph.
5: Each point removed in Step 2 is grouped with the closest point that survived Step 2.

In words, the algorithm first computes local covariances (Step 1). It removes points that are believed to be very near an intersection (Step 2)—we elaborate on this below. With the remaining points, it creates an unweighted graph: the nodes of this graph are the data points and edges are formed between two nodes if both the distance between these nodes and the distance between the local covariance structures at these nodes are sufficiently small (Step 3). The connected components of the resulting graph are extracted (Step 4) and the points that survived Step 2 are labeled accordingly. Each point removed in Step 2 receives the label of its closest labeled point (Step 5).

In principle, the neighborhood size r is chosen just large enough that performing PCA in each neighborhood yields a reliable estimate of the local covariance structure. For this, the number of points inside the neighborhood needs to be large enough, which depends on the sample size n, the sampling density, intrinsic dimension of the surfaces and their surface area (Hausdorff measure), how far the points are from the surfaces (i.e., noise level), and the regularity of the surfaces. The spatial scale parameter ε depends on the sampling density and r. It is meant to be larger than r and needs to be large enough that a point has plenty

of points within distance ε, including some across an intersection, so each cluster is strongly connected. At the same time, ε needs to be small enough that a local linear approximation to the surfaces is a relevant feature of proximity. Its choice is rather similar to the choice of the scale parameter in standard spectral clustering (Ng et al., 2002; Zelnik-Manor and Perona, 2005). The covariance scale η needs to be large enough that centers from the same cluster and within distance ε of each other have local covariance matrices within distance ηr^2, but small enough that points from different clusters near their intersection have local covariance matrices separated by a distance substantially larger than ηr^2. This depends on the curvature of the surfaces and the incidence angle at the intersection of two (or more) surfaces. Note that a typical covariance matrix over a ball of radius r has norm of order r^2, which justifies using our choice of parametrization. In the mathematical framework we introduce later on, these parameters can be chosen automatically as done in (Arias-Castro et al., 2011), at least when the points are sampled exactly on the surfaces. We will not elaborate on that since in practice this does not inform our choice of parameters.

The rationale behind Step 2 is as follows. As we just discussed, the parameters need to be tuned so that points from the same cluster and within distance ε have local covariance matrices within distance ηr^2. Strictly speaking, this is true of points away from the boundary of the underlying surface. Hence, although $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ in Step 2 are meant to be from different clusters, they could be from the same surface near its boundary. In the former situation, since they are near each other, in our model this will imply that they are close to an intersection. Therefore, roughly speaking, Step 2 removes points near an intersection, but also points near the boundaries of the underlying surfaces. The reason that we require $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$ to be within distance r, as opposed to ε, is because otherwise removing the points in Step 2 would create a "gap" of ε near an intersection which then cannot be bridged in Steps 3-4. (Alternatively, one could replace r with $\xi \in (r, \varepsilon)$ in Step 2, but this would add this additional parameter ξ to the algorithm.) This step is in fact crucial as the local covariance varies smoothly along the intersection of two smooth surfaces.

Although this method works in simple situations like that of two intersecting segments (Figure 1), it is not meant to be practical. Indeed, extracting connected components is known to be sensitive to spurious points and therefore unstable. Furthermore, we found that comparing local covariance matrices as in affinity (2) tends to be less stable than comparing local projections as in affinity (3), which brings us to our next variant.

2.2.2 Connected Component Extraction: Comparing Local Projections

We present another variant also based on extracting the connected components of a neighborhood graph that compares orthogonal projections onto the largest principal directions. See Algorithm 3.

We note that the local intrinsic dimension is determined by thresholding the eigenvalues of the local covariance matrix, keeping the directions with eigenvalues within some range of the largest eigenvalue. The same strategy is used by Kushnir et al. (2006), but with a different threshold. The method is a hard version of what we implemented, which we describe in Algorithm 4.

We note that neither algorithm includes an intersection-removal step as Step 2 in Algorithm 2. The reason is that the algorithms work without such a step. Indeed, we show in

Algorithm 3 Connected Component Extraction: Comparing Projections

Input:

Data points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$; neighborhood radius $r > 0$, spatial scale $\varepsilon > 0$, projection scale $\eta > 0$.

Steps:

1: For each $i \in [n]$, compute the sample covariance matrix $\boldsymbol{C}_i$ of $N_r(\boldsymbol{x}_i)$.

2: Compute the projection $\boldsymbol{Q}_i$ onto the eigenvectors of $\boldsymbol{C}_i$ with corresponding eigenvalue exceeding $\sqrt{\eta}\,\|\boldsymbol{C}_i\|$.

3: Compute the following affinities between data points:

$$W_{ij} = \mathbb{1}_{\{\|\boldsymbol{x}_i - \boldsymbol{x}_j\| \le \varepsilon\}} \cdot \mathbb{1}_{\{\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| \le \eta\}}. \tag{3}$$

4: Extract the connected components of the resulting graph.

Theorem 1 that Algorithm 3 is able to separate the clusters—the only drawback is that it may possibly treat the intersection of two surfaces as a cluster. And we show via numerical experiments in Section 4 that Algorithm 4 performs well in a number of situations.

2.2.3 Covariances or Projections?

In our numerical experiments, we tried working both directly with covariance matrices as in (2) and with projections as in (3). Note that in our experiments we used spectral graph partitioning with soft versions of these affinities, as described in Section 2.2.4. We found working with projections to be more reliable. The problem comes, in part, from boundaries. When a surface has a boundary, local covariances over neighborhoods that overlap with the boundary are quite different from local covariances over nearby neighborhoods that do not touch the boundary. Consider the example of two segments, S_1 and S_2, intersecting at an angle of $\theta \in (0, \pi/2)$ at their middle point, specifically

$$S_1 = [-1, 1] \times \{0\}, \qquad S_2 = \{(x, x\tan\theta) : x \in [-\cos\theta, \cos\theta]\}.$$

Assume there is no noise and that the sampling is uniform. Assume $r \in (0, \frac{1}{2}\sin\theta)$ so that the disc centered at $\boldsymbol{x}_1 := (1/2, 0)$ does not intersect S_2, and the disc centered at $\boldsymbol{x}_2 := (\frac{1}{2}\cos\theta, \frac{1}{2}\sin\theta)$ does not intersect S_1. Let $\boldsymbol{x}_0 = (1, 0)$. For $\boldsymbol{x} \in S_1 \cup S_2$, let $\boldsymbol{C}_{\boldsymbol{x}}$ denote the local covariance at $\boldsymbol{x}$ over a ball of radius $r < \frac{1}{2}\sin\theta$, so that the neighborhoods of $\boldsymbol{x}_0, \boldsymbol{x}_1, \boldsymbol{x}_2$ are "pure". The situation is described in Figure 2.

Simple calculations yield

$$\boldsymbol{C}_{\boldsymbol{x}_0} = \frac{r^2}{12}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \boldsymbol{C}_{\boldsymbol{x}_1} = \frac{r^2}{3}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \boldsymbol{C}_{\boldsymbol{x}_2} = \frac{r^2}{3}\begin{pmatrix} \cos^2\theta & \sin(\theta)\cos(\theta) \\ \sin(\theta)\cos(\theta) & \sin^2\theta \end{pmatrix},$$

so that

$$\|\boldsymbol{C}_{\boldsymbol{x}_0} - \boldsymbol{C}_{\boldsymbol{x}_1}\| = \frac{r^2}{4}, \quad \|\boldsymbol{C}_{\boldsymbol{x}_1} - \boldsymbol{C}_{\boldsymbol{x}_2}\| = \frac{r^2}{3}\sin\theta.$$

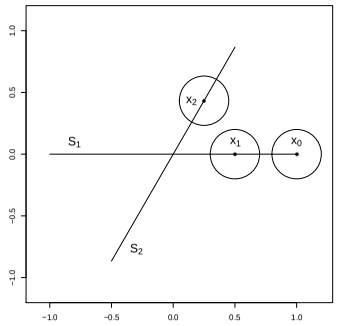

Figure 2: Two segments intersecting. The local covariances (within the disc neighborhoods drawn) at $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ are closer than the local covariances at $\boldsymbol{x}_1$ and $\boldsymbol{x}_0$, even though $\boldsymbol{x}_0$ and $\boldsymbol{x}_1$ are on the same segment.

Therefore, when $\sin\theta \le \frac{3}{4}$ (roughly, $\theta \le 48^o$), the local covariances at $\boldsymbol{x}_0, \boldsymbol{x}_1 \in S_1$ are farther (in operator norm) than those at $\boldsymbol{x}_1 \in S_1$ and $\boldsymbol{x}_2 \in S_2$. As for projections, however,

$$\boldsymbol{Q}_{\boldsymbol{x}_0} = \boldsymbol{Q}_{\boldsymbol{x}_1} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \boldsymbol{Q}_{\boldsymbol{x}_2} = \begin{pmatrix} \cos^2\theta & \sin(\theta)\cos(\theta) \\ \sin(\theta)\cos(\theta) & \sin^2\theta \end{pmatrix},$$

so that

$$\|\boldsymbol{Q}_{\boldsymbol{x}_0} - \boldsymbol{Q}_{\boldsymbol{x}_1}\| = 0, \quad \|\boldsymbol{Q}_{\boldsymbol{x}_1} - \boldsymbol{Q}_{\boldsymbol{x}_2}\| = \sqrt{2}\sin\theta.$$

While in theory points within distance r from the boundary account for a small portion of the sample, in practice this is not the case, at least not with the sample sizes that we are able to rapidly process. In fact, we find that spectral graph partitioning is challenged by having points near the boundary that are far (in affinity) from nearby points from the same cluster. This may explain why the (soft version of) affinity (3) yields better results than the (soft version of) affinity (2) in our experiments.

2.2.4 Spectral Clustering Based on Local PCA

The following variant is more robust in practice and is the algorithm we actually implemented. The method assumes that the surfaces are of same dimension d and that there are K of them, with both parameters K and d known.

We note that $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{n_0}$ forms an r-packing of the data. The underlying rationale for this coarsening is justified in (Goldberg et al., 2009) by the fact that the covariance matrices, and also the top principal directions, change smoothly with the location of the neighborhood, so that without subsampling these characteristics would not help detect the abrupt event of an intersection. The affinity (4) is of course a soft version of (3).

Algorithm 4 Spectral Clustering Based on Local PCA

Input:

Data points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$; neighborhood radius $r > 0$; spatial scale $\varepsilon > 0$, projection scale $\eta > 0$; intrinsic dimension d; number of clusters K.

Steps:

0: Pick one point $\boldsymbol{y}_1$ at random from the data. Pick another point $\boldsymbol{y}_2$ among the data points not included in $N_r(\boldsymbol{y}_1)$, and repeat the process, selecting centers $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{n_0}$.

1: For each $i = 1, \ldots, n_0$, compute the sample covariance matrix $\boldsymbol{C}_i$ of $N_r(\boldsymbol{y}_i)$. Let $\boldsymbol{Q}_i$ denote the orthogonal projection onto the space spanned by the top d eigenvectors of $\boldsymbol{C}_i$.

2: Compute the following affinities between center pairs:

$$W_{ij} = \exp\left(-\frac{\|\boldsymbol{y}_i - \boldsymbol{y}_j\|^2}{\varepsilon^2}\right) \cdot \exp\left(-\frac{\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\|^2}{\eta^2}\right). \tag{4}$$

3: Apply spectral graph partitioning (Algorithm 1) to $\boldsymbol{W}$.

4: The data points are clustered according to the closest center in Euclidean distance.

2.2.5 Comparison with Closely Related Methods

We highlight some differences with the other proposals in the literature. We first compare our approach to that of Goldberg et al. (2009), which was our main inspiration.

- *Neighborhoods.* Comparing with Goldberg et al. (2009), we define neighborhoods over r-balls instead of ℓ-nearest neighbors, and connect points over ε-balls instead of m-nearest neighbors. This choice is for convenience, as these ways are in fact essentially equivalent when the sampling density is fairly uniform. This is elaborated at length in (Maier et al., 2009; Brito et al., 1997; Arias-Castro, 2011).

- *Mahalanobis distances.* Goldberg et al. (2009) use Mahalanobis distances (1) between centers. In our version, we could for example replace the Euclidean distance $\|\boldsymbol{x}_i - \boldsymbol{x}_j\|$ in the affinity (2) with the average Mahalanobis distance

$$\|\boldsymbol{C}_i^{-1/2}(\boldsymbol{x}_i - \boldsymbol{x}_j)\| + \|\boldsymbol{C}_j^{-1/2}(\boldsymbol{x}_j - \boldsymbol{x}_i)\|.$$

  We actually tried this and found that the algorithm was less stable, particularly under low noise. Introducing a regularization in this distance—which requires the introduction of another parameter—solves this problem, at least partially.

  That said, using Mahalanobis distances makes the procedure less sensitive to the choice of ε, in that neighborhoods may include points from different clusters. Think of two parallel line segments separated by a distance of δ, and assume there is no noise, so the points are sampled exactly from these segments. Assuming an infinite sample size, the local covariance is the same everywhere so that points within distance ε are connected by the affinity (2). Hence, Algorithm 2 requires that $\varepsilon < \delta$. In terms of Mahalanobis distances, points on different segments are infinitely separated, so a version based on these distances would work with any $\varepsilon > 0$. In the case of curved surfaces and/or noise, the situation is similar, though not as evident. Even then, the gain in performance is not obvious since we only require that ε be slightly larger in order of magnitude than r.

- *Hellinger distances.* As we mentioned earlier, Goldberg et al. (2009) use Hellinger distances of the probability distributions $\mathcal{N}(\boldsymbol{0}, \boldsymbol{C}_i)$ and $\mathcal{N}(\boldsymbol{0}, \boldsymbol{C}_j)$ to compare covariance matrices, specifically

$$\left(1 - 2^{D/2}\frac{\det(\boldsymbol{C}_i\boldsymbol{C}_j)^{1/4}}{\det(\boldsymbol{C}_i + \boldsymbol{C}_j)^{1/2}}\right)^{1/2}, \tag{5}$$

  if $\boldsymbol{C}_i$ and $\boldsymbol{C}_j$ are full-rank. While using these distances or the Frobenius distances makes little difference in practice, we find it easier to work with the latter when it comes to proving theoretical guarantees. Moreover, it seems more natural to assume a uniform sampling distribution in each neighborhood rather than a normal distribution, so that using the more sophisticated similarity (5) does not seem justified.

- *K-means.* We use K-means++ for a good initialization. We found that the more sophisticated size-constrained K-means (Bradley et al., 2000) used in (Goldberg et al., 2009) did not improve the clustering results.

As we mentioned above, our work was developed in parallel to that of Wang et al. (2011) and Gong et al. (2012). We highlight some differences. First, there is no subsampling, but rather, the local tangent space is estimated at each data point $\boldsymbol{x}_i$. Wang et al. (2011) fit a mixture of d-dimensional affine subspaces to the data using MPPCA (Tipping and Bishop, 1999), which is then used to estimate the tangent subspaces at each data point. Gong et al. (2012) develop some sort of robust local PCA. While Wang et al. (2011) assume all surfaces are of same dimension known to the user, Gong et al. (2012) estimate that locally by looking at the largest gap in the spectrum of estimated local covariance matrix. This is similar in spirit to what is done in Step 2 of Algorithm 3, but we did not include this step in Algorithm 4 because we did not find it reliable in practice. We also tried estimating the local dimensionality using the method of Little et al. (2009), but this failed in the most complex cases.

Wang et al. (2011) use a nearest-neighbor graph and their affinity is defined as

$$W_{ij} = \Delta_{ij} \cdot \left(\prod_{s=1}^{d} \cos\theta_s(i,j)\right)^{\alpha},$$

where $\Delta_{ij} = 1$ if $\boldsymbol{x}_i$ is among the ℓ-nearest neighbors of $\boldsymbol{x}_j$, or vice versa, while $\Delta_{ij} = 0$ otherwise; $\theta_1(i,j) \geq \cdots \geq \theta_d(i,j)$ are the principal (a.k.a., canonical) angles (Stewart and Sun, 1990) between the estimated tangent subspaces at $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$. ℓ and α are parameters of the method. Gong et al. (2012) define an affinity that incorporates the self-tuning method of Zelnik-Manor and Perona (2005); in our notation, their affinity is

$$\exp\left(-\frac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|^2}{\varepsilon_i\varepsilon_j}\right) \cdot \exp\left(-\frac{(\sin^{-1}(\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\|))^2}{\eta^2\|\boldsymbol{x}_i - \boldsymbol{x}_j\|^2/(\varepsilon_i\varepsilon_j)}\right).$$

where ε_i is the distance from $\boldsymbol{x}_i$ to its ℓ-nearest neighbor. ℓ is a parameter.

Although we do not analyze their respective ways of estimating the tangent subspaces, our analysis provides essential insights into their methods, and for that matter, any other method built on spectral clustering based on tangent subspace comparisons.

3. Mathematical Analysis

While the analysis of Algorithm 4 seems within reach, there are some complications due to the fact that points near the intersection may form a cluster of their own—we were not able to discard this possibility. Instead, we study the simpler variants described in Algorithm 2 and Algorithm 3. Even then, the arguments are rather complex and interestingly involved. The theoretical guarantees that we obtain for these variants are stated in Theorem 1 and proved in Section 6. We comment on the analysis of Algorithm 4 right after that. We note that there are very few theoretical results on resolving intersecting manifolds—in fact, we are only aware of (Arias-Castro et al., 2011) (under severe restrictions on the dimension of the intersection). Some such results have been established for a number of methods for subspace clustering (affine surfaces), for example, in (Chen and Lerman, 2009b; Soltanolkotabi and Candès, 2012; Soltanolkotabi et al., 2014; Wang and Xu, 2013; Heckel and Bölcskei, 2013; Tsakiris and Vidal, 2015; Ma et al., 2008).

The generative model we assume is a natural mathematical framework for multi-manifold learning where points are sampled in the vicinity of smooth surfaces embedded in Euclidean space. For concreteness and ease of exposition, we focus on the situation where two surfaces (i.e., $K = 2$) of same dimension $1 \leq d \leq D$ intersect. This special situation already contains all the geometric intricacies of separating intersecting clusters. On the one hand, clusters of different intrinsic dimension may be separated with an accurate estimation of the local intrinsic dimension without further geometry involved (Haro et al., 2007). On the other hand, more complex intersections (3-way and higher) complicate the situation without offering truly new challenges. For simplicity of exposition, we assume that the surfaces are submanifolds without boundary, though it will be clear from the analysis (and the experiments) that the method can handle surfaces with (smooth) boundaries that may self-intersect. We discuss other possible extensions in Section 5.

Within that framework, we show that Algorithm 2 and Algorithm 3 are able to identify the clusters accurately except for points near the intersection. Specifically, with high probability with respect to the sampling distribution, Algorithm 2 divides the data points into two groups such that, except for points within distance $C\varepsilon$ of the intersection, all points from the first cluster are in one group and all points from the second cluster are in the other group. The constant C depends on the surfaces, including their curvatures, separation between them and intersection angle. The situation for Algorithm 3 is more complex, as it may return more than two clusters, but most of the two clusters (again, away from the intersection) are in separate connected components.

3.1 Generative Model

Each surface we consider is a connected, C^2 and compact submanifold without boundary and of dimension d embedded in $\mathbb{R}^D$. Any such surface has a positive reach, which is what we use to quantify smoothness. The notion of reach was introduced by Federer (1959).

Intuitively, a surface has reach exceeding r if and only if one can roll a ball of radius r on the surface without obstruction (Walther, 1997; Cuevas et al., 2012). Formally, for $\boldsymbol{x} \in \mathbb{R}^D$ and $S \subset \mathbb{R}^D$, let

$$\operatorname{dist}(\boldsymbol{x}, S) = \inf_{\boldsymbol{s} \in S} \|\boldsymbol{x} - \boldsymbol{s}\|,$$

and

$$B(S, r) = \{\boldsymbol{x} : \operatorname{dist}(\boldsymbol{x}, S) < r\},$$

which is often called the r-tubular neighborhood (or r-neighborhood) of S. The reach of S is the supremum over $r > 0$ such that, for each $\boldsymbol{x} \in B(S, r)$, there is a unique point in S nearest $\boldsymbol{x}$. It is well-known that, for C^2 submanifolds, the reach bounds the radius of curvature from below (Federer, 1959, Lem. 4.17). For submanifolds without boundaries, the reach coincides with the condition number introduced in (Niyogi et al., 2008).

When two surfaces S_1 and S_2 intersect, meaning $S_1 \cap S_2 \neq \emptyset$, we define their incidence angle as

$$\theta(S_1, S_2) := \inf \left\{ \theta_{\min}(T_{S_1}(\boldsymbol{s}), T_{S_2}(\boldsymbol{s})) : \boldsymbol{s} \in S_1 \cap S_2 \right\}, \tag{6}$$

where $T_S(\boldsymbol{s})$ denote the tangent subspace of submanifold S at point $\boldsymbol{s} \in S$, and $\theta_{\min}(T_1, T_2)$ is the smallest *nonzero* principal (a.k.a., canonical) angle between subspaces T_1 and T_2 (Stewart and Sun, 1990).

The clusters are generated as follows. Each data point $\boldsymbol{x}_i$ is drawn according to

$$\boldsymbol{x}_i = \boldsymbol{s}_i + \boldsymbol{z}_i, \tag{7}$$

where $\boldsymbol{s}_i$ is drawn from the uniform distribution over $S_1 \cup S_2$ and $\boldsymbol{z}_i$ is an additive noise term satisfying $\|\boldsymbol{z}_i\| \leq \tau$—thus τ represents the noise or jitter level. When $\tau = 0$ the points are sampled exactly on the surfaces. We assume the points are sampled independently of each other. We let

$$I_k = \{i : \boldsymbol{s}_i \in S_k\},$$

and the goal is to recover the groups I_1 and I_2, up to some errors.

3.2 Performance Guarantees

We state some performance guarantees for Algorithm 2 and Algorithm 3.

Theorem 1. *Consider two connected, compact, twice continuously differentiable submanifolds without boundary, of same dimension d, intersecting at a strictly positive angle, with the intersection set having strictly positive reach. Assume the parameters are set so that*

$$\tau \leq r\eta/C, \quad r \leq \varepsilon/C, \quad \varepsilon \leq \eta/C, \quad \eta \leq 1/C, \tag{8}$$

for a large-enough constant $C \geq 1$ that depends on the configuration. Then with probability at least $1 - Cn \exp\left[-nr^d\eta^2/C\right]$:

- *Algorithm 2 returns exactly two groups such that two points from different clusters are not grouped together unless one of them is within distance Cr from the intersection.*
- *Algorithm 3 returns at least two groups, and such that two points from different clusters are not grouped together unless one of them is within distance Cr from the intersection.*

Thus, as long as, (8) is satisfied, the algorithms have the above properties with high probability when $r^d\eta^2 \geq C' \log n/n$, where $C' > C$ is fixed. In particular, we may choose $\eta \asymp 1$ and $\varepsilon \asymp r \asymp \tau \vee (\log(n)/n)^{1/d}$, which lightens the computational burden.

We note that, while the constant $C > 0$ does not depend on the sample size n, it depends in somewhat complicated ways on characteristics of the surfaces and their position relative to each other, such as their reach and intersection angle, but also aspects that are harder to quantify, like their separation away from their intersection. We note, however, that it behaves as expected: C is indeed decreasing in the reach and the intersection angle, and increasing in the intrinsic dimensions of the surfaces, for example.

The algorithms may make clustering mistakes within distance Cr of the intersection, where $Cr \asymp \tau \vee (\log(n)/n)^{1/d}$ with the choice of parameters just described. Whether this is optimal in the nonparametric setting that we consider—for example, in a minimax sense—we do not know.

We now comment on the challenge of proving a similar result for Algorithm 4. This algorithm relies on knowledge of the intrinsic dimension of the surfaces d and the number of clusters (here $K = 2$), but these may be estimated as in (Arias-Castro et al., 2011), at least in theory, so we assume these parameters are known. The subsampling done in Step 0 does not pose any problem whatsoever, since the centers are well-spread when the points themselves are. The difficulty resides in the application of the spectral graph partitioning, Algorithm 1. If we were to include the intersection-removal step (Step 2 of Algorithm 2) before applying spectral graph partitioning, then a simple adaptation of arguments in (Arias-Castro, 2011) would suffice. The real difficulty, and potential pitfall of the method in this framework (without the intersection-removal step), is that the points near the intersection may form their own cluster. For example, in the simplest case of two affine surfaces intersecting at a positive angle and no sampling noise, the projection matrix at a point near the intersection—meaning a point whose r-ball contains a substantial piece of both surfaces—would be the projection matrix onto $S_1 + S_2$ seen as a linear subspace. We were not able to discard this possibility, although we do not observe this happening in practice. A possible remedy is to constrain the K-means part to only return large-enough clusters. However, a proper analysis of this would require a substantial amount of additional work and we did not engage seriously in this pursuit.

4. Numerical Experiments

4.1 Some Illustrative Examples

We started by applying our method[2] on a few artificial examples to illustrate the theory. As we argued earlier, the methods of Wang et al. (2011) and Gong et al. (2012) are quite similar to ours, and we encourage the reader to also look at the numerical experiments they performed. Our numerical experiments should be regarded as a proof of concept, only here to show that our method can be implemented and works on some stylized examples.

In all experiments, the number of clusters K and the dimension of the manifolds d are assumed known. We choose the spatial scale ε and the projection scale η automatically as

2. The code is available online at `https://math.cos.ucf.edu/tengz`.

follows: we let

$$\varepsilon = \max_{1 \leq i \leq n_0} \min_{j \neq i} \|\boldsymbol{y}_i - \boldsymbol{y}_j\|, \tag{9}$$

and

$$\eta = \operatorname*{median}_{(i,j):\|\boldsymbol{y}_i - \boldsymbol{y}_j\| < \varepsilon} \|\boldsymbol{Q}_i - \boldsymbol{Q}_j\|.$$

Here, we implicitly assume that the union of all the underlying surfaces forms a connected set. In that case, the idea behind choosing ε as in (9) is that we want the ε-graph on the centers $\boldsymbol{y}_1, \dots, \boldsymbol{y}_n$ to be connected. Then η is chosen so that a center $\boldsymbol{y}_i$ remains connected in the (ε, η)-graph to most of its neighbors in the ε-graph.

The neighborhood radius r is chosen by hand for each situation. Although we do not know how to choose r automatically, there are some general ad hoc guidelines. When r is too large, the local linear approximation to the underlying surfaces may not hold in neighborhoods of radius r, resulting in local PCA becoming inappropriate. When r is too small, there might not be enough points in a neighborhood of radius r to accurately estimate the local tangent subspace to a given surface at that location, resulting in local PCA becoming inaccurate. From a computational point of view, the smaller r, the larger the number of neighborhoods and the heavier the computations, particularly at the level of spectral graph partitioning. In our numerical experiments, we find that our algorithm is more sensitive to the choice of r when the clustering problem is more difficult. We note that automatic choice of tuning parameters remains a challenge in clustering, and machine learning at large, especially when no labels are available whatsoever. See (Zelnik-Manor and Perona, 2005; Zhang et al., 2012; Little et al., 2009; Kaslovsky and Meyer, 2011).

Since the algorithm is randomized (see Step 0 in Algorithm 4) we repeat each simulation 100 times and report the median misclustering rate and number of times where the misclustering rate is smaller than 5%, 10%, and 15%.

We first run Algorithm 4 on several artificial data sets, which are demonstrated in the LHS of Figures 3 and 4. Table 1 reports the local radius r used for each data set (R is the global radius of each data set), and the statistics for misclustering rates. Typical clustering results are demonstrated in the RHS of Figures 3 and 4. It is evident that Algorithm 4 performs well in these simulations.

data set	r	median misclustering rate	5%	10%	15%
Three curves	0.02 ($0.034R$)	4.16%	76	89	89
Self-intersecting curves	0.1 ($0.017R$)	1.16%	85	85	86
Two spheres	0.2 ($0.059R$)	3.98%	100	100	100
Möbius strips	0.1 ($0.028R$)	2.22%	85	86	88
Monkey saddle	0.1 ($0.069R$)	9.73%	0	67	97
Paraboloids	0.07 ($0.048R$)	10.42%	0	12	91

Table 1: Choices for r and misclustering statistics for the artificial data sets demonstrated in Figures 3 and 4. The statistics are based on 100 repeats and include the median misclustering rate and number of repeats where the misclustering rate is smaller than 5%, 10% and 15%.

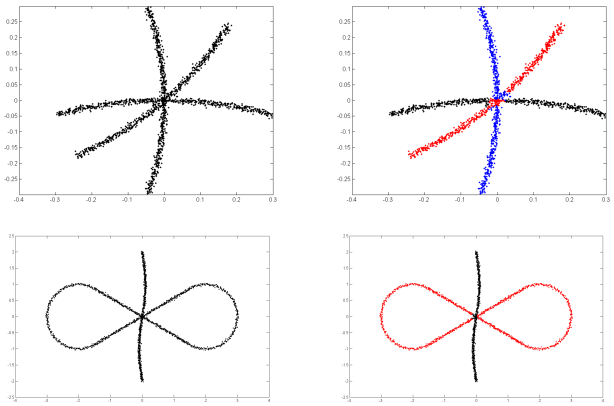

Figure 3: Performance of Algorithm 4 on data sets "Three curves" and "Self-intersecting curves". Left column is the input data sets, and right column demonstrates the typical clustering.

In another simulation, we show the dependence of the success of our algorithm on the intersecting angle between curves in Table 2 and Figure 5. Here, we fix two curves intersecting at a point, and gradually decrease the intersection angle by rotating one of them while holding the other one fixed. The angles are $\pi/2$, $\pi/4$, $\pi/6$ and $\pi/8$. From the table we can see that our algorithm performs well when the angle is $\pi/4$, but the performance deteriorates as the angle becomes smaller, and the algorithm almost always fails when the angle is $\pi/8$.

Intersecting angle	r	median misclustering rate	5%	10%	15%
$\pi/2$	0.02 (0.034R)	2.08%	98	98	98
$\pi/4$	0.02 (0.034R)	3.33%	92	94	94
$\pi/6$	0.02 (0.034R)	5.53%	32	59	59
$\pi/8$	0.02 (0.033R)	27.87%	0	2	2

Table 2: Choices for r and misclustering statistics for the instances of two intersecting curves demonstrated in Figure 5. The statistics are based on 100 repeats and include the median misclustering rate and number of repeats where the misclustering rate is smaller than 5%, 10% and 15%.

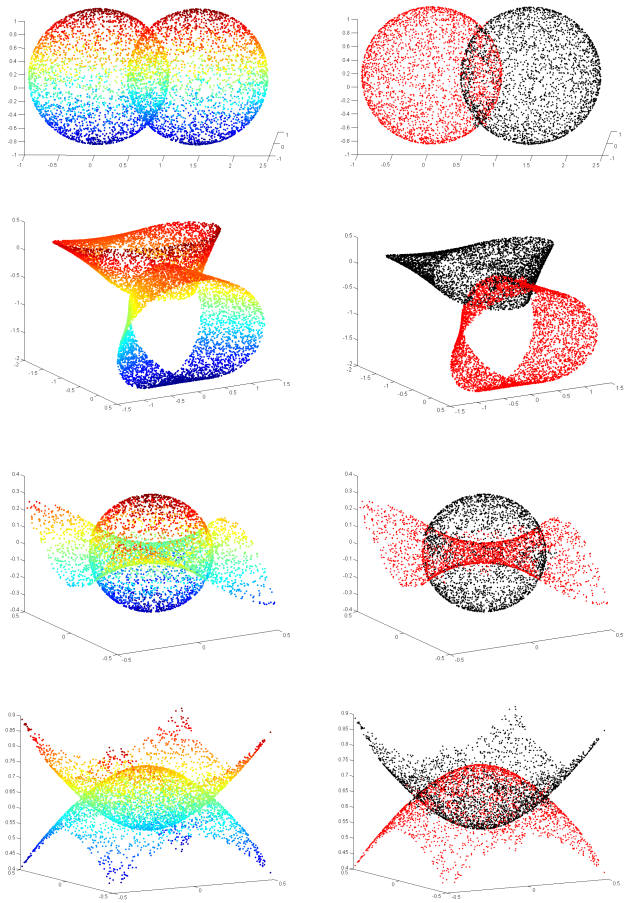

Figure 4: Performance of Algorithm 4 on data sets "Two spheres", "Möbius strips", "Monkey saddle" and "Paraboloids". Left column is the input data sets, and right column demonstrates the typical clustering.

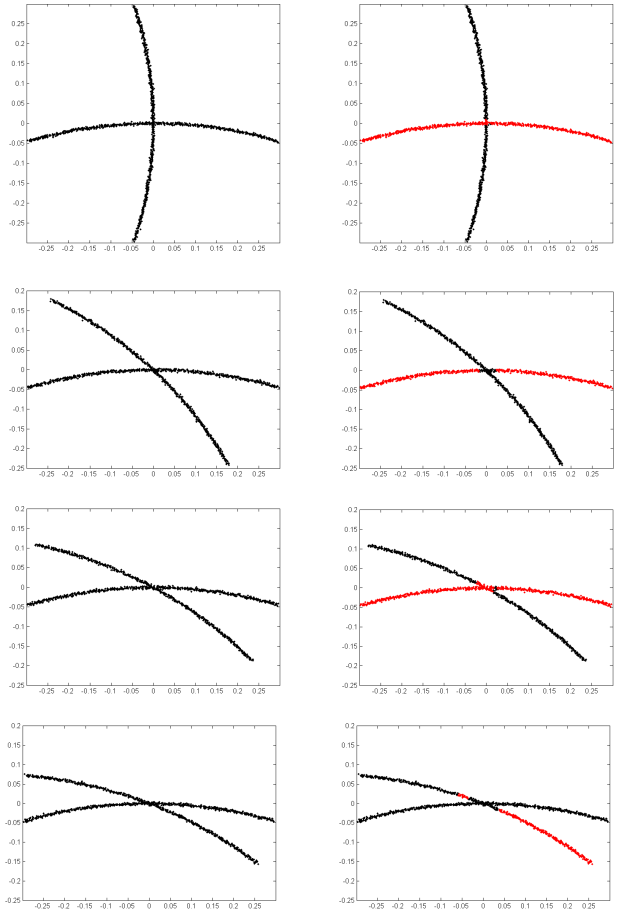

Figure 5: Performance of Algorithm 4 on two curves intersecting at angles $\frac{\pi}{2}$, $\frac{\pi}{4}$, $\frac{\pi}{6}$, $\frac{\pi}{8}$.

4.2 Comparison with Other Multi-manifold Clustering Algorithms

In this section, we compare our algorithm with several existing algorithms on multi-manifold clustering. While many algorithms have been proposed, we focus on the methods based on spectral clustering, including Sparse Manifold Clustering and Embedding (SMCE) (Elhamifar and Vidal, 2011) and Local Linear Embedding of (Polito and Perona, 2001; Goh and Vidal, 2007). Compared to these methods, a major difference of Algorithm 4 is the size of the affinity matrix $\boldsymbol{W}$: SMCE and LLE each creates an $n \times n$ affinity matrix while our method creates a smaller affinity matrix of size $n_0 \times n_0$, based on the centers chosen in step 0 of Algorithm 4. This difference enables our algorithm to handle large data sets such as $n > 10^4$, while these other two methods are computationally expensive due to eigenvalue decomposition of the $n \times n$ affinity matrix. In order to make a fair comparison, we will run simulations and experiments on small data sets. We modified our algorithm to make it more competitive in such a setting: we modify Steps 0 and 1 in Algorithm 4 slightly and use all data points $\{\boldsymbol{x}_i\}_{i=1}^n$ as centers, that is, $\boldsymbol{y}_i = \boldsymbol{x}_i$ for all $1 \le i \le n$. The motivation is that, when there is no computational constraint on the eigenvalue decomposition (due to small n), we may improve Algorithm 4 by constructing a larger affinity matrix by including all points as centers. The resulting algorithm is summarized in Algorithm 5.

Algorithm 5 Spectral Clustering Based on Local PCA (for small data sets)

Input:

Data points $\boldsymbol{x}_1, \dots, \boldsymbol{x}_n$; neighborhood size $N > 0$; spatial scale $\varepsilon > 0$, projection scale $\eta > 0$; intrinsic dimension d; number of clusters K.

Steps:

1: For each $i = 1, \dots, n$, compute the sample covariance matrix $\boldsymbol{C}_i$ of from the N nearest neighbors of $\boldsymbol{x}_i$. Let $\boldsymbol{Q}_i$ denote the orthogonal projection onto the space spanned by the top d eigenvectors of $\boldsymbol{C}_i$.

2: Compute the following affinities between n data points:

$$W_{ij} = \exp\left(-\frac{\|\boldsymbol{x}_i - \boldsymbol{x}_j\|^2}{\varepsilon^2}\right) \cdot \exp\left(-\frac{\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\|^2}{\eta^2}\right).$$

3: Apply spectral graph partitioning (Algorithm 1) to $\boldsymbol{W}$.

First we test the algorithms on a simulated data set of two curves, which is subsampled from the first data set in Figure 5 with 300 data points. We plot the clustering result from Algorithm 5, SMCE, LLE in Figure 6. For Algorithm 5, K is set to be 10. For SMCE[3], $\lambda = 10$ and $L = 60$, and we remark that similar results are obtained for a wide range of parameters. For LLE, we follow the implementation in (Polito and Perona, 2001), use 10-nearest neighbors to embed the data set into $\mathbb{R}^2$ and run K-means on the embedded data set. It is clear from the figure that Algorithm 5 resolves the problem of intersection well

3. In (Elhamifar and Vidal, 2011), λ is the ℓ_1-penalty parameter and at each point the optimization is restricted to the L nearest neighbors.

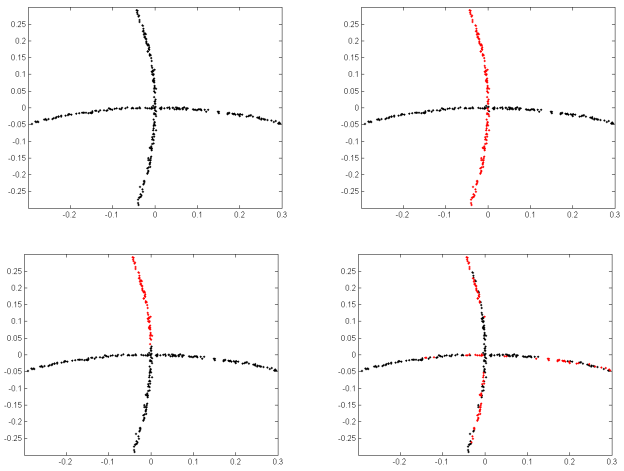

Figure 6: Performance of Algorithm 5 on two intersecting curves. Left top: the input data set. Right top: the clustering result by Algorithm 5. Left bottom: the clustering result by SMCE. Right bottom: the clustering result by LLE.

by using the affinity from estimated local subspaces, while SMCE and LLE tend to give a larger affinity between nearby data points and have difficulties in handling intersection.

Next, we run experiments on the Extended Yale Face Database B (Lee et al., 2005), with the goal of clustering face images of two different subjects. This data set contains face images from 39 subjects, and each subject has 64 images of 192 pixels under varying lightening conditions. In our experiments, we found that the images of a person in this database lie roughly in a 4-dimensional subspace. We preprocess the data set by applying PCA and reducing the dimension to 8. We also "normalize" the covariance of the data set when performing dimension reduction, such that the projected data set has a unit covariance. We record the misclustering rates of Algorithm 5, SMCE and LLE in Table 3. For SMCE, we follow (Elhamifar and Vidal, 2011) by setting $\lambda = 10$ and we let $L = 30$. For Algorithm 5, we let the neighborhood size be 40. From the table, we can see that the two methods perform similarly.

subjects	[1,2]	[1,3]	[1,4]	[1,5]	[1,6]	[1,7]	[1,8]	[1,9]
Local PCA	8.59%	11.72%	10.94%	4.69%	8.59%	7.81%	5.47%	7.03%
SMCE	8.59%	11.72%	8.59%	0.00%	4.69%	8.59%	9.38%	4.69%

Table 3: Some misclustering rates for the Extended Yale Face Database B.

5. Discussion

We distilled the ideas of Goldberg et al. (2009) and of Kushnir et al. (2006) to cluster points sampled near smooth surfaces. The key ingredient is the use of local PCA to learn about the local spread and orientation of the data, so as to use that information in an affinity when building a neighborhood graph.

In a typical stylized setting for multi-manifold clustering, we established performance bounds for the simple variants described in Algorithm 2 and Algorithm 3, which essentially consist of connecting points that are close in space and orientation, and then extracting the connected components of the resulting graph. Both are shown to resolve general intersections as long as the incidence angle is strictly positive and the parameters are carefully chosen. As is commonly the case in such analyses, our setting can be generalized to other sampling schemes, to multiple intersections, to some features of the surfaces changing with the sample size, and so on, in the spirit of (Arias-Castro et al., 2011; Arias-Castro, 2011; Chen and Lerman, 2009b). We chose to simplify the setup as much as possible while retaining the essential features that make resolving intersecting clusters challenging. The resulting arguments are nevertheless rich enough to satisfy the mathematically thirsty reader. Whether the conditions required in Theorem 1 are optimal in some sense is an interesting and challenging open question for future research. Note that very few optimality results exist for manifold clustering; see (Arias-Castro, 2011) for an example.

We implemented a spectral version of Algorithm 3, described in Algorithm 4, that assumes the intrinsic dimensionality and the number of clusters are known. The resulting approach is very similar to what is offered by Wang et al. (2011) and Gong et al. (2012), although it was developed independently of these works. Algorithm 4 is shown to perform well in some simulated experiments, although it is somewhat sensitive to the choice of parameters. This is the case of all other methods for multi-manifold clustering we know of and choosing the parameters automatically remains an open challenge in the field.

6. Proofs

We start with some additional notation. The ambient space is $\mathbb{R}^D$ unless noted otherwise. For a vector $\boldsymbol{v} \in \mathbb{R}^D$, $\|\boldsymbol{v}\|$ denotes its Euclidean norm and for a real matrix $\boldsymbol{M} \in \mathbb{R}^{D\times D}$, $\|\boldsymbol{M}\|$ denotes the corresponding operator norm. For a point $\boldsymbol{x} \in \mathbb{R}^D$ and $r > 0$, $B(\boldsymbol{x}, r)$ denotes the open ball of center $\boldsymbol{x}$ and radius r, i.e., $B(\boldsymbol{x}, r) = \{\boldsymbol{y} \in \mathbb{R}^D : \|\boldsymbol{y} - \boldsymbol{x}\| < r\}$. For a set S and a point $\boldsymbol{x}$, define $\operatorname{dist}(\boldsymbol{x}, S) = \inf\{\|\boldsymbol{x} - \boldsymbol{y}\| : \boldsymbol{y} \in S\}$. For two points $\boldsymbol{a}, \boldsymbol{b}$ in the same Euclidean space, $\boldsymbol{b} - \boldsymbol{a}$ denotes the vector moving $\boldsymbol{a}$ to $\boldsymbol{b}$. For a point $\boldsymbol{a}$ and a vector $\boldsymbol{v}$ in the same Euclidean space, $\boldsymbol{a} + \boldsymbol{v}$ denotes the translate of $\boldsymbol{a}$ by $\boldsymbol{v}$. We identify an affine subspace T with its corresponding linear subspace, for example, when saying that a vector belongs to T.

For two subspaces T and T', of possibly different dimensions, let $0 \le \theta_{\max}(T, T') \le \pi/2$ denote the largest and by $\theta_{\min}(T, T')$ the smallest nonzero principal angle between T and T' (Stewart and Sun, 1990). When $\boldsymbol{v}$ is a vector and T is a subspace, $\angle(\boldsymbol{v}, T) := \theta_{\max}(\mathbb{R}\boldsymbol{v}, T)$ this is the usual definition of the angle between $\boldsymbol{v}$ and T.

For a subset $A \subset \mathbb{R}^D$ and positive integer d, $\mathrm{vol}_d(A)$ denotes the d-dimensional Hausdorff measure of A, and $\mathrm{vol}(A)$ is defined as $\mathrm{vol}_{\dim(A)}(A)$, where $\dim(A)$ is the Hausdorff dimension of A. For a Borel set A, let λ_A denote the uniform distribution on A.

For a set $S \subset \mathbb{R}^D$ with reach at least $1/\kappa$, and $\boldsymbol{x}$ with $\mathrm{dist}(\boldsymbol{x}, S) < 1/\kappa$, let $P_S(\boldsymbol{x})$ denote the metric projection of $\boldsymbol{x}$ onto S, that is, the point on S closest to $\boldsymbol{x}$. Note that, if T is an affine subspace, then P_T is the usual orthogonal projection onto T, and we let $\boldsymbol{P}_T$ denote the orthogonal projection onto the linear subspace of same dimension and parallel to T. Let $\mathcal{S}_d(\kappa)$ denote the class of connected, C^2 and compact d-dimensional submanifolds without boundary embedded in $\mathbb{R}^D$, with reach at least $1/\kappa$. For a submanifold $S \in \mathbb{R}^D$, let $T_S(\boldsymbol{x})$ denote the tangent space of S at $\boldsymbol{x} \in S$.

We will often identify a linear map with its matrix in the canonical basis. For a symmetric (real) matrix $\boldsymbol{M}$, let $\beta_1(\boldsymbol{M}) \geq \beta_2(\boldsymbol{M}) \geq \cdots$ denote its eigenvalues in decreasing order.

We say that $f : \Omega \subset \mathbb{R}^D \to \mathbb{R}^D$ is C-Lipschitz if $\|f(\boldsymbol{x}) - f(\boldsymbol{y})\| \leq C\|\boldsymbol{x} - \boldsymbol{y}\|, \forall \boldsymbol{x}, \boldsymbol{y} \in \Omega$.

For two reals a and b, $a \vee b = \max(a, b)$ and $a \wedge b = \min(a, b)$. Additional notation will be introduced as needed.

6.1 Preliminaries

This section gathers a number of general results from geometry and probability. We took time to package them into standalone lemmas that could be of potential independent interest, particularly to researchers working in machine learning and computational geometry. When needed, we use C to denote a constant that may change with each appearance.

6.1.1 Smooth Surfaces and Their Tangent Subspaces

The following comes directly from (Federer, 1959, Th. 4.18(12)). It gives us a simple criterion for identifying the metric projection of a point on a surface with given reach.

Lemma 1. *Consider $S \in \mathcal{S}_d(\kappa)$ and $\boldsymbol{x} \in \mathbb{R}^D$ such that $\mathrm{dist}(\boldsymbol{x}, S) < 1/\kappa$. Then $\boldsymbol{s} = P_S(\boldsymbol{x})$ if and only if $\|\boldsymbol{x} - \boldsymbol{s}\| < 1/\kappa$ and $\boldsymbol{x} - \boldsymbol{s} \perp T_S(\boldsymbol{s})$.*

The following result is on approximating a smooth surface near a point by the tangent subspace at that point. It is based on (Federer, 1959, Th. 4.18(2)).

Lemma 2. *For $S \in \mathcal{S}_d(\kappa)$, and any two points $\boldsymbol{s}, \boldsymbol{s}' \in S$,*

$$\mathrm{dist}(\boldsymbol{s}', T_S(\boldsymbol{s})) \leq \frac{\kappa}{2}\|\boldsymbol{s}' - \boldsymbol{s}\|^2, \tag{10}$$

and when $\mathrm{dist}(\boldsymbol{s}', T_S(\boldsymbol{s})) \leq 1/\kappa$,

$$\mathrm{dist}(\boldsymbol{s}', T_S(\boldsymbol{s})) \leq \kappa\|P_{T_S(\boldsymbol{s})}(\boldsymbol{s}') - \boldsymbol{s}\|^2. \tag{11}$$

Moreover, for $\boldsymbol{t} \in T_S(\boldsymbol{s})$ such that $\|\boldsymbol{s} - \boldsymbol{t}\| \leq \frac{1}{3\kappa}$,

$$\mathrm{dist}(\boldsymbol{t}, S) \leq \kappa\|\boldsymbol{t} - \boldsymbol{s}\|^2. \tag{12}$$

Proof. Let T be short for $T_S(\boldsymbol{s})$. (Federer, 1959, Th. 4.18(2)) says that

$$\mathrm{dist}(\boldsymbol{s}' - \boldsymbol{s}, T) \leq \frac{\kappa}{2}\|\boldsymbol{s}' - \boldsymbol{s}\|^2. \tag{13}$$

Immediately, we have

$$\mathrm{dist}(\boldsymbol{s}' - \boldsymbol{s}, T) = \|\boldsymbol{s}' - P_T(\boldsymbol{s}')\| = \mathrm{dist}(\boldsymbol{s}', T),$$

and (10) comes from that. Based on that and Pythagoras theorem, we have

$$\mathrm{dist}(\boldsymbol{s}', T) = \|P_T(\boldsymbol{s}') - \boldsymbol{s}'\| \leq \frac{\kappa}{2}\|\boldsymbol{s}' - \boldsymbol{s}\|^2 = \frac{\kappa}{2}\big(\|P_T(\boldsymbol{s}') - \boldsymbol{s}'\|^2 + \|P_T(\boldsymbol{s}') - \boldsymbol{s}\|^2\big),$$

so that

$$\mathrm{dist}(\boldsymbol{s}', T)\big(1 - \frac{\kappa}{2}\,\mathrm{dist}(\boldsymbol{s}', T)\big) \leq \frac{\kappa}{2}\|P_T(\boldsymbol{s}') - \boldsymbol{s}\|^2,$$

and (11) follows easily from that. For (12), let $r = 1/(3\kappa)$ and $\boldsymbol{s}' = P_T^{-1}(\boldsymbol{t})$, the latter being well-defined by Lemma 5 below and belongs to $B(\boldsymbol{s}, r(1 + \kappa r)) \subset B(\boldsymbol{s}, 4/(9\kappa))$. By (10), $\|\boldsymbol{s}' - \boldsymbol{s}\| \leq 8/(81\kappa) < 1/\kappa$, and by (11),

$$\mathrm{dist}(\boldsymbol{t}, S) \leq \|\boldsymbol{t} - \boldsymbol{s}'\| = \mathrm{dist}(\boldsymbol{s}', T) \leq \kappa\|\boldsymbol{t} - \boldsymbol{s}\|^2.$$

This concludes the proof of (12). □

We will need a bound on the angle between tangent subspaces on a smooth surface as a function of the distance between the corresponding points of contact.

Lemma 3 (Boissonnat et al. (2013))**.** *For $S \in \mathcal{S}_d(\kappa)$, and any $\boldsymbol{s}, \boldsymbol{s}' \in S$,*

$$\sin\theta_{\max}(T_S(\boldsymbol{s}), T_S(\boldsymbol{s}')) \leq 6\kappa\|\boldsymbol{s}' - \boldsymbol{s}\|. \tag{14}$$

The following bounds the difference between the metric projection onto a surface and the orthogonal projection onto one of its tangents.

Lemma 4. *Consider $S \in \mathcal{S}_d(\kappa)$ and $\boldsymbol{s} \in S$. Then for any $\boldsymbol{x} \in B(S, r)$, we have*

$$\|P_S(\boldsymbol{x}) - P_{T_S(\boldsymbol{s})}(\boldsymbol{x})\| \leq C_4\kappa\|\boldsymbol{x} - \boldsymbol{s}\|^2,$$

for a numeric constant $C_4 > 0$.

Proof. Let $T = T_S(\boldsymbol{s})$ and define $\boldsymbol{t} = P_T(\boldsymbol{x})$, $\boldsymbol{s}' = P_S(\boldsymbol{x})$ and $\tilde{\boldsymbol{t}} = P_T(\boldsymbol{s}')$, and also $T' = T_S(\boldsymbol{s}')$ and $\theta = \theta_{\max}(T, T')$. We have

$$\begin{aligned} P_S(\boldsymbol{x}) &= P_{T'}(\boldsymbol{x}) = \boldsymbol{P}_{T'}(\boldsymbol{x} - \boldsymbol{s}') + \boldsymbol{s}' \\ P_T(\boldsymbol{x}) &= \boldsymbol{P}_T(\boldsymbol{x} - \tilde{\boldsymbol{t}}) + \tilde{\boldsymbol{t}} = \boldsymbol{P}_T(\boldsymbol{x} - \boldsymbol{s}') + \boldsymbol{P}_T(\boldsymbol{s}' - \tilde{\boldsymbol{t}}) + \tilde{\boldsymbol{t}}. \end{aligned}$$

Hence,

$$\|P_S(\boldsymbol{x}) - P_T(\boldsymbol{x})\| \leq \|\boldsymbol{P}_{T'}(\boldsymbol{x} - \boldsymbol{s}') - \boldsymbol{P}_T(\boldsymbol{x} - \boldsymbol{s}')\| + \|\boldsymbol{P}_T(\boldsymbol{s}' - \tilde{\boldsymbol{t}})\| + \|\boldsymbol{s}' - \tilde{\boldsymbol{t}}\|.$$

On the one hand,

$$\|\boldsymbol{P}_T(\boldsymbol{s}'-\tilde{\boldsymbol{t}})\| \le \|\boldsymbol{s}'-\tilde{\boldsymbol{t}}\| = \mathrm{dist}(\boldsymbol{s}',T) \le \frac{\kappa}{2}\|\boldsymbol{s}'-\boldsymbol{s}\|^2 \le 2\kappa\|\boldsymbol{x}-\boldsymbol{s}\|^2,$$

by (10) and the fact that

$$\|\boldsymbol{s}'-\boldsymbol{s}\| \le \|\boldsymbol{s}'-\boldsymbol{x}\| + \|\boldsymbol{x}-\boldsymbol{s}\| = \mathrm{dist}(\boldsymbol{x},S) + \|\boldsymbol{x}-\boldsymbol{s}\| \le 2\|\boldsymbol{x}-\boldsymbol{s}\|.$$

On the other hand, applying Lemma 18 (see further down)

$$\|\boldsymbol{P}_{T'}(\boldsymbol{x}-\boldsymbol{s}') - \boldsymbol{P}_T(\boldsymbol{x}-\boldsymbol{s}')\| \le \|\boldsymbol{P}_{T'}-\boldsymbol{P}_T\|\|\boldsymbol{x}-\boldsymbol{s}'\| = (\sin\theta)\|\boldsymbol{x}-\boldsymbol{s}'\|,$$

with $\|\boldsymbol{x}-\boldsymbol{s}'\| \le \|\boldsymbol{x}-\boldsymbol{s}\|$ and, applying Lemma 3,

$$\sin\theta \le 6\kappa\|\boldsymbol{s}'-\boldsymbol{s}\| \le 12\kappa\|\boldsymbol{x}-\boldsymbol{s}\|.$$

All together, we conclude. □

Below we state some properties of a projection onto a tangent subspace. A result similar to the first part was proved in (Arias-Castro et al., 2011, Lem. 2) based on results in (Niyogi et al., 2008), but the arguments are simpler here and the constants are sharper.

Lemma 5. *There is a numeric constant $C_5 \ge 1$ such that the following holds. Take $S \in \mathcal{S}_d(\kappa)$, $\boldsymbol{s} \in S$ and $r \le 1/C_5\kappa$, and let T be short for $T_S(\boldsymbol{s})$. P_T is injective on $B(\boldsymbol{s},r)\cap S$ and its image contains $B(\boldsymbol{s},r')\cap T$, where $r' := (1-C_5(\kappa r)^2)r$. Moreover, P_T^{-1} has Lipschitz constant bounded by $1+C_5(\kappa r)^2 \le 1+\kappa r$ over $B(\boldsymbol{s},r)\cap T$.*

Proof. Take $\boldsymbol{s}', \boldsymbol{s}'' \in S$ distinct such that $P_T(\boldsymbol{s}') = P_T(\boldsymbol{s}'')$. Equivalently, $\boldsymbol{s}''-\boldsymbol{s}'$ is perpendicular to T. Let T' be short for $T_S(\boldsymbol{s}')$. By (13) and the fact that $\mathrm{dist}(\boldsymbol{v},T) = \|\boldsymbol{v}\|\sin\angle(\boldsymbol{v},T)$ for any vector $\boldsymbol{v}$ and any linear subspace T, we have

$$\sin\angle(\boldsymbol{s}''-\boldsymbol{s}',T') \le \frac{\kappa}{2}\|\boldsymbol{s}''-\boldsymbol{s}'\|,$$

and by (14),

$$\sin\theta_{\max}(T,T') \le 6\kappa\|\boldsymbol{s}-\boldsymbol{s}'\|.$$

Now, by the triangle inequality,

$$\frac{\pi}{2} = \angle(\boldsymbol{s}''-\boldsymbol{s}',T) \le \angle(\boldsymbol{s}''-\boldsymbol{s}',T') + \theta_{\max}(T,T'),$$

so that

$$\frac{\kappa}{2}\|\boldsymbol{s}''-\boldsymbol{s}'\| \wedge 1 \ge \frac{\pi}{2} - \sin^{-1}\left(6\kappa\|\boldsymbol{s}'-\boldsymbol{s}\| \wedge 1\right).$$

When $\|\boldsymbol{s}'-\boldsymbol{s}\| \le 1/12\kappa$, the RHS is bounded from below by $\pi/2 - \sin^{-1}(1/2)$, which then implies that $\frac{\kappa}{2}\|\boldsymbol{s}''-\boldsymbol{s}'\| \ge \sin(\pi/2-\sin^{-1}(1/2)) = \sqrt{3}/2$, that is, $\|\boldsymbol{s}''-\boldsymbol{s}'\| \ge \sqrt{3}/\kappa$. This precludes the situation where $\boldsymbol{s}', \boldsymbol{s}'' \in B(\boldsymbol{s}, 1/12\kappa)$, so that P_T is injective on $B(\boldsymbol{s},r)$ when $r \le 1/12\kappa$.

The same arguments imply that P_T is an open map on $R := B(\boldsymbol{s},r)\cap S$. In particular, $P_T(R)$ contains an open ball in T centered at $\boldsymbol{s}$ and $P_T(\partial R) = \partial P_T(R)$, with $\partial R = S \cap \partial B(\boldsymbol{s},r)$ since $\partial S = \emptyset$. Now take any ray out of $\boldsymbol{s}$ within T, which is necessarily of the form $\boldsymbol{s}+\mathbb{R}_+\boldsymbol{v}$, where $\boldsymbol{v}$ is a unit vector in T. Let $\boldsymbol{t}_a = \boldsymbol{s}+a\boldsymbol{v} \in T$ for $a \in [0,\infty)$. Let a_* be the infimum over all $a > 0$ such that $\boldsymbol{t}_a \in P_T(R)$. Note that $a_* > 0$ and $\boldsymbol{t}_{a_*} \in P_T(\partial R)$, so that there is $\boldsymbol{s}_* \in \partial R$ such that $P_T(\boldsymbol{s}_*) = \boldsymbol{t}_{a_*}$. Let $\boldsymbol{s}_a = P_T^{-1}(\boldsymbol{t}_a)$, which is well-defined on $[0,a_*]$ by definition of a_* and the fact that P_T is injective on R. Let $J_{\boldsymbol{t}}$ denote the differential of P_T^{-1} at $\boldsymbol{t}$. We have that $\dot{\boldsymbol{s}}_a = J_{\boldsymbol{t}_a}\boldsymbol{v}$ is the unique vector in $T_a := T_S(\boldsymbol{s}_a)$ such that $P_T(\dot{\boldsymbol{s}}_a) = \boldsymbol{v}$. Elementary geometry shows that

$$\|P_T(\dot{\boldsymbol{s}}_a)\| = \|\dot{\boldsymbol{s}}_a\|\cos\angle(\dot{\boldsymbol{s}}_a,T) \ge \|\dot{\boldsymbol{s}}_a\|\cos\theta_{\max}(T_a,T),$$

with

$$\cos\theta_{\max}(T_a,T) \ge \cos\left[\sin^{-1}\left(6\kappa\|\boldsymbol{s}_a-\boldsymbol{s}\| \wedge 1\right)\right] \ge \zeta := 1-(6\kappa r)^2,$$

by (14) and fact that $\|\boldsymbol{s}_a-\boldsymbol{s}\| \le r$ (and assuming $6\kappa r \le 1$). Since $\|P_T(\dot{\boldsymbol{s}}_a)\| = \|\boldsymbol{v}\| = 1$, we have $\|\dot{\boldsymbol{s}}_a\| \le 1/\zeta$, and this holds for all $a < a_*$. So we can extend $\boldsymbol{s}_a$ to $[0,a_*]$ into a Lipschitz function with constant $1/\zeta$. Together with the fact that $\boldsymbol{s}_* \in \partial B(\boldsymbol{s},r)$, this implies that

$$r = \|\boldsymbol{s}_*-\boldsymbol{s}\| = \|\boldsymbol{s}_{a_*}-\boldsymbol{s}_0\| \le a_*/\zeta.$$

Hence, $a_* \ge \zeta r$ and therefore $P_T(R)$ contains $B(\boldsymbol{s},\zeta r)\cap T$ as stated.

For the last part, assume $r \le 1/C\kappa$, with C large enough that there is a unique $h \le 1/12\kappa$ such that $\zeta h = r$, where ζ is redefined as $\zeta := 1-(6\kappa h)^2$. Take $\boldsymbol{t}' \in B(\boldsymbol{s},r)\cap T$ and let $\boldsymbol{s}' = P_T^{-1}(\boldsymbol{t}')$ and $T' = T_S(\boldsymbol{s}')$. We saw that P_T^{-1} is Lipschitz with constant $1/\zeta$ on any ray emanating from $\boldsymbol{s}$ of length $\zeta h = r$, so that $\|\boldsymbol{s}'-\boldsymbol{s}\| \le (1/\zeta)\|\boldsymbol{t}'-\boldsymbol{s}\| \le r/\zeta = h$. The differential of P_T at $\boldsymbol{s}'$ is P_T itself, seen as a linear map between T' and T. Then for any vector $\boldsymbol{u} \in T'$, we have

$$\|P_T(\boldsymbol{u})\| = \|\boldsymbol{u}\|\cos\angle(\boldsymbol{u},T) \ge \|\boldsymbol{u}\|\cos\theta_{\max}(T',T),$$

with

$$\cos\theta_{\max}(T',T) \ge \cos\left[\sin^{-1}\left(6\kappa\|\boldsymbol{s}'-\boldsymbol{s}\|\right)\right] \ge 1-(6\kappa h)^2 = \zeta,$$

as before. Hence, $\|J_{\boldsymbol{t}'}\| \le 1/\zeta$, and we proved this for all $\boldsymbol{t}' \in B(\boldsymbol{s},r)\cap T$. This last set being convex, we can apply Taylor's theorem and get that P_T^{-1} is Lipschitz on that set with constant $1/\zeta$. We then note that $\zeta = 1+O(\kappa r)^2$. □

6.1.2 Volumes and Uniform Distributions

Below is a result that quantifies how much the volume of a set changes when applying a Lipschitz map. This is well-known in measure theory and we only provide a proof for completeness.

Lemma 6. *Suppose Ω is a measurable subset of $\mathbb{R}^D$ and $f : \Omega \subset \mathbb{R}^D \to \mathbb{R}^D$ is C-Lipschitz. Then for any measurable set $A \subset \Omega$ and real $d > 0$, $\mathrm{vol}_d(f(A)) \le C^d\,\mathrm{vol}_d(A)$.*

Proof. By definition,

$$\mathrm{vol}_d(A) = \lim_{t\to 0} V_d^t(A), \qquad V_d^t(A) := \inf_{(R_i)\in\mathcal{R}^t(A)} \sum_{i\in\mathbb{N}} \mathrm{diam}(R_i)^d,$$

where $\mathcal{R}^t(A)$ is the class of countable sequences $(R_i : i \in \mathbb{N})$ of subsets of $\mathbb{R}^D$ such that $A \subset \bigcup_i R_i$ and $\operatorname{diam}(R_i) < t$ for all i. Since f is C-Lipschitz, $\operatorname{diam}(f(R)) \leq C \operatorname{diam}(R)$ for any $R \subset \Omega$. Hence, for any $(R_i) \in \mathcal{R}^t(A)$, $(f(R_i)) \in \mathcal{R}^{Ct}(f(A))$. This implies that

$$V_d^{Ct}(f(A)) \leq \sum_{i\in\mathbb{N}} \operatorname{diam}(f(R_i))^d \leq C^d \sum_{i\in\mathbb{N}} \operatorname{diam}(R_i)^d.$$

Taking the infimum over $(R_i) \in \mathcal{R}^t(A)$, we get $V_d^{Ct}(f(A)) \leq C^d V_d^t(A)$, and we conclude by taking the limit as $t \to 0$, noticing that $V_d^{Ct}(f(A)) \to \operatorname{vol}_d(f(A))$ while $V_d^t(A) \to \operatorname{vol}_d(A)$. □

We compare below two uniform distributions. For two Borel probability measures P and Q on $\mathbb{R}^D$, $\operatorname{TV}(P, Q)$ denotes their total variation distance, meaning,

$$\operatorname{TV}(P, Q) = \sup\{|P(A) - Q(A)| : A \text{ Borel}\}.$$

Remember that for a Borel set A, λ_A denotes the uniform distribution on A.

Lemma 7. *Suppose A and B are two Borel subsets of $\mathbb{R}^D$. Then*

$$\operatorname{TV}(\lambda_A, \lambda_B) \leq 4\, \frac{\operatorname{vol}(A \triangle B)}{\operatorname{vol}(A \cup B)}.$$

Proof. If A and B are not of same dimension, say $\dim(A) > \dim(B)$, then $\operatorname{TV}(\lambda_A, \lambda_B) = 1$ since $\lambda_A(B) = 0$ while $\lambda_B(B) = 1$. And we also have

$$\operatorname{vol}(A \triangle B) = \operatorname{vol}_{\dim(A)}(A \triangle B) = \operatorname{vol}_{\dim(A)}(A) = \operatorname{vol}(A),$$

and

$$\operatorname{vol}(A \cup B) = \operatorname{vol}_{\dim(A)}(A \cup B) = \operatorname{vol}_{\dim(A)}(A) = \operatorname{vol}(A),$$

in both cases because $\operatorname{vol}_{\dim(A)}(B) = 0$. So the result works in that case.

Therefore assume that A and B are of same dimension. Assume WLOG that $\operatorname{vol}(A) \geq \operatorname{vol}(B)$. For any Borel set U,

$$\lambda_A(U) - \lambda_B(U) = \frac{\operatorname{vol}(A \cap U)}{\operatorname{vol}(A)} - \frac{\operatorname{vol}(B \cap U)}{\operatorname{vol}(B)},$$

so that

$$\begin{aligned} |\lambda_A(U) - \lambda_B(U)| &= \left| \frac{\operatorname{vol}(A \cap U)}{\operatorname{vol}(A)} - \frac{\operatorname{vol}(B \cap U)}{\operatorname{vol}(A)} + \frac{\operatorname{vol}(B \cap U)}{\operatorname{vol}(A)} - \frac{\operatorname{vol}(B \cap U)}{\operatorname{vol}(B)} \right| \\ &\leq \frac{|\operatorname{vol}(A \cap U) - \operatorname{vol}(B \cap U)|}{\operatorname{vol}(A)} + \frac{\operatorname{vol}(B \cap U)}{\operatorname{vol}(B)} \frac{|\operatorname{vol}(A) - \operatorname{vol}(B)|}{\operatorname{vol}(A)} \\ &\leq \frac{2 \operatorname{vol}(A \triangle B)}{\operatorname{vol}(A)}, \end{aligned}$$

and we conclude with the fact that $\operatorname{vol}(A \cup B) \leq \operatorname{vol}(A) + \operatorname{vol}(B) \leq 2 \operatorname{vol}(A)$. □

We now look at the projection of the uniform distribution on a neighborhood of a surface onto a tangent subspace. For a Borel probability measure P and measurable function $f : \mathbb{R}^D \to \mathbb{R}^D$, P^f denotes the push-forward (Borel) measure defined by $P^f(A) = P(f^{-1}(A))$.

Lemma 8. *Suppose $A \subset \mathbb{R}^D$ is Borel and $f : A \to \mathbb{R}^D$ is invertible on $f(A)$, and that both f and f^{-1} are C-Lipschitz. Then*

$$\operatorname{TV}(\lambda_A^f, \lambda_{f(A)}) \leq 2(C^{\dim(A)} - 1).$$

Proof. First, note that A and $f(A)$ are both of same dimension, and that $C \geq 1$ necessarily. Let d be short for $\dim(A)$. Take $U \subset f(A)$ Borel and let $V = f^{-1}(U)$. Then

$$\lambda_A^f(U) = \frac{\operatorname{vol}(A \cap V)}{\operatorname{vol}(A)}, \qquad \lambda_{f(A)}(U) = \frac{\operatorname{vol}(f(A) \cap U)}{\operatorname{vol}(f(A))},$$

and as in (16),

$$|\lambda_A^f(U) - \lambda_{f(A)}(U)| \leq \frac{|\operatorname{vol}(A \cap V) - \operatorname{vol}(f(A) \cap U)|}{\operatorname{vol}(A)} + \frac{|\operatorname{vol}(A) - \operatorname{vol}(f(A))|}{\operatorname{vol}(A)}.$$

f being invertible, we have $f(A \cap V) = f(A) \cap U$ and $f^{-1}(f(A) \cap U) = A \cap V$. Therefore, applying Lemma 6, we get

$$C^{-d} \leq \frac{\operatorname{vol}(f(A) \cap U)}{\operatorname{vol}(A \cap V)} \leq C^d,$$

so that

$$|\operatorname{vol}(A \cap V) - \operatorname{vol}(f(A) \cap U)| \leq (C^d - 1) \operatorname{vol}(A \cap V) \leq (C^d - 1) \operatorname{vol}(A).$$

And taking $V = A$, we also get

$$|\operatorname{vol}(A) - \operatorname{vol}(f(A))| \leq (C^d - 1) \operatorname{vol}(A).$$

From this we conclude. □

Now comes a technical result on the intersection of a smooth surface and a ball.

Lemma 9. *There is a constant $C_9 \geq 3$ depending only on d such that the following is true. Take $S \in \mathcal{S}_d(\kappa)$, $r < \frac{1}{C_9 \kappa}$ and $\boldsymbol{x} \in \mathbb{R}^D$ such that $\operatorname{dist}(\boldsymbol{x}, S) < \kappa$. Let $\boldsymbol{s} = P_S(\boldsymbol{x})$ and $T = T_S(\boldsymbol{s})$. Then*

$$\operatorname{vol}\left(P_T(S \cap B(\boldsymbol{x}, r)) \triangle (T \cap B(\boldsymbol{x}, r))\right) \leq C_9 \kappa (\|\boldsymbol{x} - \boldsymbol{s}\| + \kappa r^2) \operatorname{vol}(T \cap B(\boldsymbol{x}, r)).$$

Proof. If $\operatorname{dist}(\boldsymbol{x}, S) > r$, then $S \cap B(\boldsymbol{x}, r) = T \cap B(\boldsymbol{x}, r) = \emptyset$, and if $\operatorname{dist}(\boldsymbol{x}, S) = r$, then $S \cap B(\boldsymbol{x}, r) = T \cap B(\boldsymbol{x}, r) = \{\boldsymbol{s}\}$, and in both cases the inequality holds trivially. So it suffices to consider the case where $\operatorname{dist}(\boldsymbol{x}, S) < r$.

Let $A_r = B(\boldsymbol{s}, r)$, $B_r = B(\boldsymbol{x}, r)$ and $g = P_T$ for short. Note that $T \cap B_r = T \cap A_{r_0}$ where $r_0 := (r^2 - \delta^2)^{1/2}$ and $\delta := \|\boldsymbol{x} - \boldsymbol{s}\|$. Take $\boldsymbol{s}_1 \in S \cap B_r$ such that $g(\boldsymbol{s}_1)$ is farthest from $\boldsymbol{s}$, so that $g(S \cap B_r) \subset A_{r_1}$ where $r_1 := \|\boldsymbol{s} - g(\boldsymbol{s}_1)\|$—note that $r_1 \leq r$. Let $\ell_1 = \|\boldsymbol{s}_1 - g(\boldsymbol{s}_1)\|$ and $\boldsymbol{y}_1$ be the orthogonal projection of $\boldsymbol{s}_1$ onto the line $(\boldsymbol{x}, \boldsymbol{s})$. By Pythagoras theorem,

we have $\|\boldsymbol{x}-\boldsymbol{s}_1\|^2 = \|\boldsymbol{x}-\boldsymbol{y}_1\|^2 + \|\boldsymbol{y}_1-\boldsymbol{s}_1\|^2$. We have $\|\boldsymbol{x}-\boldsymbol{s}_1\| \le r$ and $\|\boldsymbol{y}_1-\boldsymbol{s}_1\| = \|\boldsymbol{s}-g(\boldsymbol{s}_1)\| = r_1$. And because $\ell_1 \le \kappa r_1^2 < r$ by (11), either $\boldsymbol{y}_1$ is between $\boldsymbol{x}$ and $\boldsymbol{s}$, in which case $\|\boldsymbol{x}-\boldsymbol{y}_1\| = \delta - \ell_1$, or $\boldsymbol{s}$ is between $\boldsymbol{x}$ and $\boldsymbol{y}_1$, in which case $\|\boldsymbol{x}-\boldsymbol{y}_1\| = \delta + \ell_1$. In any case, $r^2 \ge r_1^2 + (\delta-\ell_1)^2$, which together with $\ell_1 \le \kappa r_1^2$ implies $r_1^2 \le r^2 - \delta^2 + 2\delta\ell_1 \le r_0^2 + 2\kappa r_1^2\delta$, leading to $r_1 \le (1-2\kappa\delta)^{-1/2} r_0 \le (1+4\kappa\delta) r_0$ after noticing that $\delta \le r < 1/(3\kappa)$. From $g(S\cap B_r) \subset T \cap A_{r_1}$, we get

$$\begin{aligned}\mathrm{vol}\left(g(S\cap B_r)\setminus(T\cap B_r)\right) &\le \mathrm{vol}(T\cap A_{r_1}) - \mathrm{vol}(T\cap A_{r_0}) \\ &= ((r_1/r_0)^d - 1)\,\mathrm{vol}(T\cap A_{r_0}).\end{aligned}$$

We follow similar arguments to get a sort of reverse relationship. Take $\boldsymbol{s}_2 \in S\cap B_r$ such that $g(S\cap B_r) \supset T\cap A_{r_2}$, where $r_2 := \|\boldsymbol{s}-g(\boldsymbol{s}_2)\|$ is largest. Assuming r is small enough, by Lemma 5, g^{-1} is well-defined on $T\cap A_r$, so that necessarily $\boldsymbol{s}_2 \in \partial B_r$. Let $\ell_2 = \|\boldsymbol{s}_2 - g(\boldsymbol{s}_2)\|$ and $\boldsymbol{y}_2$ be the orthogonal projection of $\boldsymbol{s}_2$ onto the line $(\boldsymbol{x},\boldsymbol{s})$. By Pythagoras theorem, we have $\|\boldsymbol{x}-\boldsymbol{s}_2\|^2 = \|\boldsymbol{x}-\boldsymbol{y}_2\|^2 + \|\boldsymbol{y}_2-\boldsymbol{s}_2\|^2$. We have $\|\boldsymbol{x}-\boldsymbol{s}_2\| = r$ and $\|\boldsymbol{y}_2-\boldsymbol{s}_2\| = \|\boldsymbol{s}-g(\boldsymbol{s}_2)\| = r_2$. And by the triangle inequality, $\|\boldsymbol{x}-\boldsymbol{y}_2\| \le \|\boldsymbol{x}-\boldsymbol{s}\| + \|\boldsymbol{y}_2-\boldsymbol{s}\| = \delta + \ell_2$. Hence, $r^2 \le r_2^2 + (\delta+\ell_2)^2$, which together with $\ell_2 \le \kappa r_2^2$ by (11), implies $r_2^2 \ge r^2 - \delta^2 - 2\delta\ell_2 - \ell_2^2 \ge r_0^2 - (2\delta + \kappa r^2)\kappa r_2^2$, leading to $r_2 \ge (1 + 2\kappa\delta + \kappa^2 r^2)^{-1/2} r_0 \ge (1 - 2\kappa\delta - \kappa^2 r^2) r_0$. From $g(S\cap B_r) \supset T\cap A_{r_2}$, we get

$$\begin{aligned}\mathrm{vol}\left((T\cap B_r)\setminus g(S\cap B_r)\right) &\le \mathrm{vol}(T\cap A_{r_0}) - \mathrm{vol}(T\cap A_{r_2}) \\ &= (1-(r_2/r_0)^d)\,\mathrm{vol}(T\cap A_{r_0}).\end{aligned}$$

All together, we have

$$\begin{aligned}\mathrm{vol}\left(g(S\cap B_r)\,\triangle\,(T\cap B_r)\right) &\le \left((r_1/r_0)^d - (r_2/r_0)^d\right)\ \mathrm{vol}(T\cap A_{r_0}) \\ &\le \left((1+4\kappa\delta)^d - (1-2\kappa\delta-\kappa^2r^2)^d\right)\mathrm{vol}((T\cap B_r)) \\ &\le Cd\kappa(\delta+\kappa r^2)\,\mathrm{vol}((T\cap B_r)),\end{aligned}$$

when $\delta \le r \le 1/(C\kappa)$ and C is a large-enough numerical constant. □

We bound below the d-volume of a the intersection of a ball with a smooth surface. Although it could be obtained as a special case of Lemma 9, we provide a direct proof because this result is at the cornerstone of many results in the literature on sampling points uniformly on a smooth surface.

Lemma 10. *Suppose $S \in \mathcal{S}_d(\kappa)$. Then for any $\boldsymbol{s} \in S$ and $r < \frac{1}{(d\vee C_5)\kappa}$, we have*

$$1 - 2d\kappa r \le \frac{\mathrm{vol}(S\cap B(\boldsymbol{s},r))}{\mathrm{vol}(T\cap B(\boldsymbol{s},r))} \le 1 + 2d\kappa r,$$

where $T := T_S(\boldsymbol{s})$ is the tangent subspace of S at $\boldsymbol{s}$.

Proof. Let $T = T_S(\boldsymbol{s})$, $B_r = B(\boldsymbol{s},r)$ and $g = P_T$ for short. By Lemma 5, g is 1-Lipschitz and g^{-1} is $(1+\kappa r)$-Lipschitz on $T\cap B_r$, so by Lemma 6 we have

$$(1+\kappa r)^{-d} \le \frac{\mathrm{vol}(g(S\cap B_r))}{\mathrm{vol}(S\cap B_r)} \le 1.$$

That g^{-1} is Lipschitz with constant $1+\kappa r$ on $g(S\cap B_r)$ also implies that $g(S\cap B_r)$ contains $T\cap B_{r'}$ where $r' := r/(1+\kappa r)$. From this, and the fact that $g(S\cap B_r) \subset T\cap B_r$, we get

$$1 \le \frac{\mathrm{vol}(T\cap B_r)}{\mathrm{vol}(g(S\cap B_r))} \le \frac{\mathrm{vol}(T\cap B_r)}{\mathrm{vol}(T\cap B_{r'})} = \frac{r^d}{r'^d} = (1+\kappa r)^d.$$

We therefore have

$$\mathrm{vol}(S\cap B_r) \ge \mathrm{vol}(g(S\cap B_r)) \ge (1+\kappa r)^{-d}\,\mathrm{vol}(T\cap B_r),$$

and

$$\mathrm{vol}(S\cap B_r) \le (1+\kappa r)^d\,\mathrm{vol}(g(S\cap B_r)) \le (1+\kappa r)^d\,\mathrm{vol}(T\cap B_r).$$

And we conclude with the inequality $(1+x)^d \le 1 + 2dx$ valid for any $x \in [0, 1/d]$ and any $d \ge 1$. □

We now look at the density of a sample from the uniform on a smooth, compact surface.

Lemma 11. *Consider $S \in \mathcal{S}_d(\kappa)$. There is a constant $C_{11} > 0$ depending on S such that the following is true. Sample n points $\boldsymbol{s}_1, \dots, \boldsymbol{s}_n$ independently and uniformly at random from S. Take $0 < r < 1/(C_{11}\kappa)$. Then with probability at least $1 - C_{11} r^{-d} \exp(-nr^d/C_{11})$, any ball of radius r with center on S has between nr^d/C_{11} and $C_{11} nr^d$ sample points.*

Proof. For a set R, let $N(R)$ denote the number of sample points in R. For any R measurable, $N(R) \sim \mathrm{Bin}(n, p_R)$, where $p_R := \mathrm{vol}(R\cap S)/\mathrm{vol}(S)$. Let $\boldsymbol{x}_1, \dots, \boldsymbol{x}_m$ be a maximal $(r/2)$-packing of S, and let $B_i = B(\boldsymbol{x}_i, r/4) \cap S$. For any $\boldsymbol{s} \in S$, there is i such that $\|\boldsymbol{s} - \boldsymbol{x}_i\| \le r/2$, which implies $B_i \subset B(\boldsymbol{s}, r)$ by the triangle inequality. Hence, $\min_{\boldsymbol{s}\in S} N(B(\boldsymbol{s},r)) \ge \min_i N(B_i)$.

By the fact that $B_i \cap B_j = \emptyset$ for $i \ne j$,

$$\mathrm{vol}(S) \ge \sum_{i=1}^m \mathrm{vol}(B_i) \ge m \min_i \mathrm{vol}(B_i),$$

and assuming that κr is small enough, we have

$$\min_i \mathrm{vol}(B_i) \ge \frac{\omega_d}{2}(r/4)^d,$$

by Lemma 10, where ω_d is the volume of the d-dimensional unit ball. This leads to $m \le Cr^{-d}$ and $p := \min_i p_{B_i} \ge r^d/C$, when $\kappa r \le 1/C$, where $C > 0$ depends only on S.

Now, applying Bernstein's inequality to the binomial distribution, we get

$$\mathbb{P}\left(N(B_i) \le np/2\right) \le \mathbb{P}\left(N(B_i) \le np_{B_i}/2\right) \le e^{-(3/32)np_{B_i}} \le e^{-(3/32)np}.$$

We follow this with the union bound, to get

$$\mathbb{P}\left(\min_{\boldsymbol{s}\in S} N(B(\boldsymbol{s},r)) \le nr^d/(2C)\right) \le me^{-(3/32)np} \le\ Cr^{-d} e^{-\frac{3}{32C}nr^d}.$$

From this the lower bound follows. The proof of the upper bound is similar. □

Next, we bound the volume of the symmetric difference between two balls.

Lemma 12. *Take $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^d$ and $0 < \delta \leq 1$. Then*

$$\frac{\mathrm{vol}(B(\boldsymbol{x}, \delta) \triangle B(\boldsymbol{y}, 1))}{2\,\mathrm{vol}(B(0,1))} \leq 1 - (1 - \|\boldsymbol{x} - \boldsymbol{y}\|)_+^d \wedge \delta^d.$$

Proof. It suffices to prove the result when $\|\boldsymbol{x} - \boldsymbol{y}\| < 1$. In that case, with $\gamma := (1 - \|\boldsymbol{x} - \boldsymbol{y}\|) \wedge \delta$, we have $B(\boldsymbol{x}, \gamma) \subset B(\boldsymbol{x}, \delta) \cap B(\boldsymbol{y}, 1)$, so that

$$\begin{aligned} \mathrm{vol}(B(\boldsymbol{x}, \delta) \triangle B(\boldsymbol{y}, 1)) &= \mathrm{vol}(B(\boldsymbol{x}, \delta)) + \mathrm{vol}(B(\boldsymbol{y}, 1)) - 2\,\mathrm{vol}(B(\boldsymbol{x}, \delta) \cap B(\boldsymbol{y}, 1)) \\ &\leq 2\,\mathrm{vol}(B(\boldsymbol{y}, 1)) - 2\,\mathrm{vol}(B(\boldsymbol{x}, \gamma)) \\ &= 2\,\mathrm{vol}(B(0,1))(1 - \gamma^d). \end{aligned}$$

This concludes the proof. □

6.1.3 Covariances

The result below describes explicitly the covariance matrix of the uniform distribution over the unit ball of a subspace.

Lemma 13. *Let T be a subspace of dimension d. Then the covariance matrix of the uniform distribution on $T \cap B(0, a)$ (seen as a linear map) is equal to $a^2 c \boldsymbol{P}_T$, where $c := \frac{1}{d+2}$.*

Proof. Assume WLOG that $T = \mathbb{R}^d \times \{0\}$. Let X be distributed according to the uniform distribution on $T \cap B(0,1)$ and let $R = \|X\|$. Note that

$$\mathbb{P}(R \leq r) = \frac{\mathrm{vol}(T \cap B(0,r))}{\mathrm{vol}(T \cap B(0,1))} = r^d, \quad \forall r \in [0,1].$$

By symmetry, $\mathbb{E}(X_i X_j) = 0$ if $i \neq j$, while

$$\mathbb{E}(X_1^2) = \frac{1}{d}\,\mathbb{E}(X_1^2 + \cdots + X_d^2) = \frac{1}{d}\,\mathbb{E}(R^2) = \frac{1}{d}\int_0^t r^2 (d r^{d-1}) \mathrm{d}r = \frac{1}{d+2}.$$

Now the covariance matrix of the uniform distribution on $T \cap B(0,a)$ equals $\mathbb{E}[(aX)(aX)^\top] = a^2\,\mathbb{E}[X X^\top]$, which is exactly the representation of $a^2 c \boldsymbol{P}_T$ in the canonical basis of $\mathbb{R}^D$. □

We now show that a bound on the total variation distance between two compactly supported distributions implies a bound on the difference between their covariance matrices. For a measure P on $\mathbb{R}^D$ and an integrable function f, let $P(f)$ denote the integral of f with respect to P, that is,

$$P(f) = \int f(x) P(dx),$$

and let $\mathbb{E}(P) = P(\boldsymbol{x})$ and $\mathrm{Cov}(P) = P(\boldsymbol{x}\boldsymbol{x}^\top) - P(\boldsymbol{x})P(\boldsymbol{x})^\top$ denote the mean and covariance matrix of P, respectively.

Lemma 14. *Suppose λ and ν are two Borel probability measures on $\mathbb{R}^d$ supported on $B(0,1)$. Then*

$$\|\,\mathbb{E}(\lambda) - \mathbb{E}(\nu)\| \leq \sqrt{d}\,\mathrm{TV}(\lambda, \nu), \qquad \|\,\mathrm{Cov}(\lambda) - \mathrm{Cov}(\nu)\| \leq 3d\,\mathrm{TV}(\lambda, \nu).$$

Proof. Let $f_k(\boldsymbol{t}) = t_k$ when $\boldsymbol{t} = (t_1, \ldots, t_d)$, and note that $|f_k(\boldsymbol{t})| \leq 1$ for all k and all $\boldsymbol{t} \in B(0,1)$. By the fact that

$$\mathrm{TV}(\lambda, \nu) = \sup\{\lambda(f) - \nu(f) : f : \mathbb{R}^d \to \mathbb{R} \text{ measurable with } |f| \leq 1\},$$

we have

$$|\lambda(f_k) - \nu(f_k)| \leq \mathrm{TV}(\lambda, \nu), \quad \forall k = 1, \ldots, d.$$

Therefore,

$$\|\,\mathbb{E}(\lambda) - \mathbb{E}(\nu)\|^2 = \sum_{k=1}^d (\lambda(f_k) - \nu(f_k))^2 \leq d\,\mathrm{TV}(\lambda, \nu)^2,$$

which proves the first part.

Similarly, let $f_{k\ell}(\boldsymbol{t}) = t_k t_\ell$. Since $|f_{k\ell}(\boldsymbol{t})| \leq 1$ for all k, ℓ and all $\boldsymbol{t} \in B(0,1)$, we have

$$|\lambda(f_{k\ell}) - \nu(f_{k\ell})| \leq \mathrm{TV}(\lambda, \nu), \quad \forall k, \ell = 1, \ldots, d.$$

Since for any probability measure μ on $\mathbb{R}^d$,

$$\mathrm{Cov}(\mu) = \big(\mu(f_{k\ell}) - \mu(f_k)\mu(f_\ell) : k, \ell = 1, \ldots, d\big),$$

we have

$$\begin{aligned} \|\,\mathrm{Cov}(\lambda) - \mathrm{Cov}(\nu)\| &\leq d \max_{k,\ell} \big(|\lambda(f_{k\ell}) - \nu(f_{k\ell})| + |\lambda(f_k)\lambda(f_\ell) - \nu(f_k)\nu(f_\ell)|\big) \\ &\leq d \max_{k,\ell} \big(|\lambda(f_{k\ell}) - \nu(f_{k\ell})| + |\lambda(f_k)||\lambda(f_\ell) - \nu(f_\ell)| \\ &\qquad + |\nu(f_\ell)||\lambda(f_k) - \nu(f_k)|\big) \\ &\leq 3d\,\mathrm{TV}(\lambda, \nu), \end{aligned}$$

using the fact that $|\lambda(f_k)| \leq 1$ and $|\nu(f_k)| \leq 1$ for all k. □

The following compares the mean and covariance matrix of a distribution before and after transformation by a function.

Lemma 15. *Let λ be a Borel distribution with compact support $A \subset \mathbb{R}^D$ and consider a measurable function $g : A \mapsto \mathbb{R}^D$ such that $\|g(x) - x\| \leq \eta$. Then*

$$\|\,\mathbb{E}(\lambda^g) - \mathbb{E}(\lambda)\| \leq \eta, \quad \|\,\mathrm{Cov}(\lambda^g) - \mathrm{Cov}(\lambda)\| \leq \eta(\mathrm{diam}(A) + \eta).$$

Proof. Take $X \sim \lambda$ and let $Y = g(X) \sim \lambda^g$. For the means, by Jensen's inequality,

$$\|\,\mathbb{E}\,X - \mathbb{E}\,Y\| \leq \mathbb{E}\,\|X - Y\| = \mathbb{E}\,\|X - g(X)\| \leq \eta.$$

For the covariances, we first note that

$$\mathrm{Cov}(X) - \mathrm{Cov}(Y) = \frac{1}{2}\big(\mathrm{Cov}(X - Y, X + Y) + \mathrm{Cov}(X + Y, X - Y)\big),$$

where $\mathrm{Cov}(U,V) := \mathbb{E}((U-\mathbb{E}\,U)(V-\mathbb{E}\,V)^T)$ is the cross-covariance of random vectors U and V. By Jensen's inequality, the fact $\|\boldsymbol{u}\boldsymbol{v}^T\| = \|\boldsymbol{u}\|\|\boldsymbol{v}\|$ for any pair of vectors $\boldsymbol{u},\boldsymbol{v}$, and then the Cauchy-Schwarz inequality,

$$\|\mathrm{Cov}(U,V)\| \le \mathbb{E}(\|U-\mathbb{E}\,U\|\cdot\|V-\mathbb{E}\,V\|) \le \mathbb{E}(\|U-\mathbb{E}\,U\|^2)^{1/2}\cdot\mathbb{E}(\|V-\mathbb{E}\,V\|^2)^{1/2}.$$

Hence,

$$\begin{aligned}\|\mathrm{Cov}(X)-\mathrm{Cov}(Y)\| &\le \|\mathrm{Cov}(X-Y,X+Y)\| \\ &\le \mathbb{E}\left[\|X-Y-\mathbb{E}\,X+\mathbb{E}\,Y\|^2\right]^{1/2}\mathbb{E}\left[\|X+Y-\mathbb{E}\,X-\mathbb{E}\,Y\|^2\right]^{1/2}.\end{aligned}$$

By the fact that the mean minimizes the mean-squared error,

$$\mathbb{E}\left[\|X-Y-\mathbb{E}\,X+\mathbb{E}\,Y\|^2\right]^{1/2} \le \mathbb{E}\left[\|X-Y\|^2\right]^{1/2} = \mathbb{E}\left[\|X-g(X)\|^2\right]^{1/2} \le \eta.$$

In the same vein, letting $\boldsymbol{z}\in\mathbb{R}^D$ be such that $\|\boldsymbol{x}-\boldsymbol{z}\| \le \frac{1}{2}\,\mathrm{diam}(A)$ for all $\boldsymbol{x}\in A$, we get

$$\begin{aligned}\mathbb{E}\left[\|X+Y-\mathbb{E}\,X-\mathbb{E}\,Y\|^2\right]^{1/2} &\le \mathbb{E}\left[\|X-\boldsymbol{z}+Y-\boldsymbol{z}\|^2\right]^{1/2} \\ &\le \mathbb{E}\left[\|X-\boldsymbol{z}\|^2\right]^{1/2} + \mathbb{E}\left[\|Y-\boldsymbol{z}\|^2\right]^{1/2} \\ &\le 2\,\mathbb{E}\left[\|X-\boldsymbol{z}\|^2\right]^{1/2} + \mathbb{E}\left[\|X-g(X)\|^2\right]^{1/2} \\ &\le \mathrm{diam}(A)+\eta.\end{aligned}$$

Using the triangle inequality twice. From this, we conclude. □

Next we compare the covariance matrix of the uniform distribution on a small piece of smooth surface with that of the uniform distribution on the projection of that piece onto a nearby tangent subspace.

Lemma 16. *There is a constant $C_{16}>0$ depending only on d such that the following is true. Take $S\in\mathcal{S}_d(\kappa)$, $r<\frac{1}{C_{16}\kappa}$ and $\boldsymbol{x}\in\mathbb{R}^D$ such that $\mathrm{dist}(\boldsymbol{x},S)\le r$. Let $\boldsymbol{s}=P_S(\boldsymbol{x})$ and $T=T_S(\boldsymbol{s})$. If $\boldsymbol{\zeta}$ and $\boldsymbol{\xi}$ are the means, and $\boldsymbol{M}$ and $\boldsymbol{N}$ are the covariance matrices, of the uniform distributions on $S\cap B(\boldsymbol{x},r)$ and $T\cap B(\boldsymbol{x},r)$, respectively, then*

$$\|\boldsymbol{\zeta}-\boldsymbol{\xi}\| \le C_{16}\kappa r^2, \qquad \|\boldsymbol{M}-\boldsymbol{N}\| \le C_{16}\kappa r^3.$$

Proof. We focus on proving the bound on the covariances, and leave the bound on the means—whose proof is both similar and simpler—as an exercise to the reader. Let $T=T_S(\boldsymbol{s})$, $B_r=B(\boldsymbol{x},r)$ and $g=P_T$ for short. Let $A=S\cap B_r$ and $A'=T\cap B_r$.

First, applying Lemma 15, assuming κr is sufficiently small, we get that

$$\|\mathrm{Cov}(\lambda_A)-\mathrm{Cov}(\lambda_A^g)\| \le \frac{\kappa}{2}r^2\Big(2r+\frac{\kappa}{2}r^2\Big) \le 2\kappa r^3, \tag{38}$$

because $\mathrm{diam}(A)\le 2r$ and $\|g(\boldsymbol{x})-\boldsymbol{x}\| \le \frac{\kappa}{2}\|\boldsymbol{x}-\boldsymbol{s}\|^2 \le \frac{\kappa}{2}r^2$ for all $\boldsymbol{x}\in A$ by (10).

Let $\lambda_{g(A)}$ denote the uniform distribution on $g(A)$. λ_A^g and $\lambda_{g(A)}$ are both supported on B_r, so that applying Lemma 14 with proper scaling, we get

$$\|\mathrm{Cov}(\lambda_A^g)-\mathrm{Cov}(\lambda_{g(A)})\| \le 3dr^2\,\mathrm{TV}(\lambda_A^g,\lambda_{g(A)}).$$

When κr is small enough, we know that g is 1-Lipschitz, and by Lemma 5, g^{-1} is well-defined and is $(1+\kappa r)$-Lipschitz on A'. Hence, by Lemma 8 and the fact that $\dim(A)=d$, we have

$$\mathrm{TV}(\lambda_A^g,\lambda_{g(A)}) \le 2((1+\kappa r)^d-1) \le 4d\kappa r,$$

using the inequality $(1+x)^d\le 1+2dx$, valid for any $x\in[0,1/d]$ and any $d\ge 1$.

Noting that $\lambda_{A'}$ is also supported on B_r, applying Lemma 14 with proper scaling, we get

$$\|\mathrm{Cov}(\lambda_{g(A)})-\mathrm{Cov}(\lambda_{A'})\| \le 3dr^2\,\mathrm{TV}(\lambda_{g(A)},\lambda_{A'}),$$

with

$$\mathrm{TV}(\lambda_{g(A)},\lambda_{A'}) \le 4\frac{\mathrm{vol}(g(A)\triangle A')}{\mathrm{vol}(A')} \le 4C_9\kappa(r+\kappa r^2) \le 8C_9\kappa r,$$

by Lemma 7 and Lemma 9, and assuming that κr is small enough.

By the triangle inequality,

$$\begin{aligned}\|\boldsymbol{M}-\boldsymbol{N}\| &= \|\mathrm{Cov}(\lambda_A)-\mathrm{Cov}(\lambda_{A'})\| \\ &\le \|\mathrm{Cov}(\lambda_A)-\mathrm{Cov}(\lambda_A^g)\| + \|\mathrm{Cov}(\lambda_A^g)-\mathrm{Cov}(\lambda_{g(A)})\| \\ &\qquad + \|\mathrm{Cov}(\lambda_{g(A)})-\mathrm{Cov}(\lambda_{A'})\| \\ &\le 2\kappa r^3 + 12d^2\kappa r^3 + 24dC_9\kappa r^3.\end{aligned}$$

From this, we conclude. □

Next is a lemma on the estimation of a covariance matrix. The result is a simple consequence of the matrix Hoeffding inequality of Tropp (2012). Note that simply bounding the operator norm by the Frobenius norm, and then applying the classical Hoeffding inequality (Hoeffding, 1963) would yield a bound sufficient for our purposes, but this is a good opportunity to use a more recent and sophisticated result.

Lemma 17. *Let $\boldsymbol{C}_m$ denote the empirical covariance matrix based on an i.i.d. sample of size m from a distribution with support in $B(0,r)\subset\mathbb{R}^d$ with covariance $\boldsymbol{\Sigma}$. Then*

$$\mathbb{P}\left(\|\boldsymbol{C}_m-\boldsymbol{\Sigma}\| > r^2t\right) \le 4d\exp\left(-\frac{mt}{16}\min\left(\frac{t}{32},\frac{m}{d}\right)\right), \quad \forall t\ge 0. \tag{43}$$

Proof. Without loss of generality, we assume that the distribution has zero mean and is now supported on $B(0,2r)$. In fact, by a simple rescaling, we may also assume that $r=1$. Let $\boldsymbol{x}_1,\dots,\boldsymbol{x}_m$ denote the sample, with $\boldsymbol{x}_i=(x_{i,1},\dots,x_{i,d})$. We have

$$\boldsymbol{C}_m = \boldsymbol{C}_m^\star - \frac{1}{m}\bar{\boldsymbol{x}}\bar{\boldsymbol{x}}^T,$$

where

$$\boldsymbol{C}_m^\star := \frac{1}{m}\sum_{i=1}^m \boldsymbol{x}_i\boldsymbol{x}_i^T, \quad \bar{\boldsymbol{x}} := \frac{1}{m}\sum_{i=1}^m \boldsymbol{x}_i.$$

Note that

$$\|\boldsymbol{C}_m-\boldsymbol{\Sigma}\| \le \|\boldsymbol{C}_m^\star-\boldsymbol{\Sigma}\| + \frac{1}{m}\|\bar{\boldsymbol{x}}\|^2.$$

Applying the union bound and then Hoeffding's inequality to each coordinate—which is in $[-2,2]$—we get

$$\mathbb{P}(\|\bar{\boldsymbol{x}}\| > t) \leq \sum_{j=1}^{d} \mathbb{P}(|\bar{x}_j| > t/\sqrt{d}) \leq 2d \exp\left(-\frac{mt^2}{8d}\right).$$

Noting that $\frac{1}{m}(\boldsymbol{x}_i\boldsymbol{x}_i^T - \boldsymbol{\Sigma}), i = 1,\dots,m$, are independent, zero-mean, self-adjoint matrices with spectral norm bounded by $4/m$, we may apply the matrix Hoeffding inequality (Tropp, 2012, Th. 1.3), to get

$$\mathbb{P}\left(\|\boldsymbol{C}_m^\star - \boldsymbol{\Sigma}\| > t\right) \leq 2d \exp\left(-\frac{t^2}{8\sigma^2}\right), \quad \sigma^2 := m(4/m)^2 = 16/m.$$

Applying the union bound and using the previous inequalities, we arrive at

$$\begin{aligned}
\mathbb{P}\left(\|\boldsymbol{C}_m - \boldsymbol{\Sigma}\| > t\right) &\leq \mathbb{P}\left(\|\boldsymbol{C}_m^\star - \boldsymbol{\Sigma}\| > t/2\right) + \mathbb{P}\left(\|\bar{\boldsymbol{x}}\| > \sqrt{mt/2}\right) \\
&\leq 2d \exp\left(-\frac{mt^2}{512}\right) + 2d \exp\left(-\frac{m^2 t}{16d}\right) \\
&\leq 4d \exp\left(-\frac{mt}{16} \min\left(\frac{t}{32}, \frac{m}{d}\right)\right),
\end{aligned}$$

which concludes the proof. □

6.1.4 Projections

We relate below the difference of two orthogonal projections with the largest principal angle between the corresponding subspaces.

Lemma 18. *For two affine non-null subspaces T, T',*

$$\|\boldsymbol{P}_T - \boldsymbol{P}_{T'}\| = \begin{cases} \sin\theta_{\max}(T,T'), & \text{if } \dim(T) = \dim(T'), \\ 1, & \text{otherwise.} \end{cases}$$

Proof. For two affine subspaces $T, T' \subset \mathbb{R}^D$ of same dimension, let $\frac{\pi}{2} \geq \theta_1 \geq \cdots \geq \theta_D \geq 0$, denote the principal angles between them. By (Stewart and Sun, 1990, Th. I.5.5), the singular values of $\boldsymbol{P}_T - \boldsymbol{P}_{T'}$ are $\{\sin\theta_j : j = 1,\dots,q\}$, so that $\|\boldsymbol{P}_T - \boldsymbol{P}_{T'}\| = \max_j \sin\theta_j = \sin\theta_1 = \sin\theta_{\max}(T,T')$. Suppose now that T and T' are of different dimension, say $\dim(T) > \dim(T')$. We have $\|\boldsymbol{P}_T - \boldsymbol{P}_{T'}\| \leq \|\boldsymbol{P}_T\| \vee \|\boldsymbol{P}_{T'}\| = 1$, since $\boldsymbol{P}_T$ and $\boldsymbol{P}_{T'}$ are orthogonal projections and therefore positive semidefinite with operator norm equal to 1. Let $L = \boldsymbol{P}_T(T')$. Since $\dim(L) \leq \dim(T') < \dim(T)$, there is $\boldsymbol{u} \in T \cap L^\perp$ with $\boldsymbol{u} \neq 0$. Then $\boldsymbol{v}^\top \boldsymbol{u} = \boldsymbol{P}_T(\boldsymbol{v})^\top \boldsymbol{u} = 0$ for all $\boldsymbol{v} \in T'$, implying that $\boldsymbol{P}_{T'}(\boldsymbol{u}) = 0$ and consequently $(\boldsymbol{P}_T - \boldsymbol{P}_{T'})\boldsymbol{u} = \boldsymbol{u}$, so that $\|\boldsymbol{P}_T - \boldsymbol{P}_{T'}\| \geq 1$. □

The lemma below is a perturbation result for eigenspaces and widely known as the $\sin\Theta$ Theorem of Davis and Kahan (1970). See also (Luxburg, 2007, Th. 7) or (Stewart and Sun, 1990, Th. V.3.6).

Lemma 19. *Let $\boldsymbol{M}$ be positive semi-definite with eigenvalues $\beta_1 \geq \beta_2 \geq \cdots$. Suppose that $\beta_d - \beta_{d+1} > 0$. Then for any other positive semi-definite matrix $\boldsymbol{N}$,*

$$\|\boldsymbol{P}_{\boldsymbol{N}}^{(d)} - \boldsymbol{P}_{\boldsymbol{M}}^{(d)}\| \leq \frac{\sqrt{2}\|\boldsymbol{N} - \boldsymbol{M}\|}{\beta_d - \beta_{d+1}},$$

where $\boldsymbol{P}_{\boldsymbol{M}}^{(d)}$ and $\boldsymbol{P}_{\boldsymbol{M}}^{(d)}$ denote the orthogonal projections onto the top d eigenvectors of $\boldsymbol{M}$ and $\boldsymbol{N}$, respectively.

6.1.5 Intersections

We start with an elementary result on points near the intersection of two affine subspaces.

Lemma 20. *Take any two linear subspaces $T_1, T_2 \subset \mathbb{R}^D$. For any point $\boldsymbol{t}_1 \in T_1 \setminus T_2$, we have*

$$\operatorname{dist}(\boldsymbol{t}_1, T_2) \geq \operatorname{dist}(\boldsymbol{t}_1, T_1 \cap T_2) \sin\theta_{\min}(T_1, T_2).$$

Proof. We may reduce the problem to the case where $T_1 \cap T_2 = \{0\}$. Indeed, let $\tilde{T}_1 = T_1 \cap T_2^\perp$, $\tilde{T}_2 = T_1^\perp \cap T_2$ and $\tilde{\boldsymbol{t}}_1 = \boldsymbol{t}_1 - P_{T_1 \cap T_2}(\boldsymbol{t}_1)$. Then

$$\|\boldsymbol{t}_1 - P_{T_2}(\boldsymbol{t}_1)\| = \|\tilde{\boldsymbol{t}}_1 - P_{\tilde{T}_2}(\tilde{\boldsymbol{t}}_1)\|, \quad \|\boldsymbol{t}_1 - P_{T_1 \cap T_2}(\boldsymbol{t}_1)\| = \|\tilde{\boldsymbol{t}}_1\|,$$

and

$$\sin\theta_{\min}(T_1, T_2) = \sin\theta_{\min}(\tilde{T}_1, \tilde{T}_2).$$

So assume that $T_1 \cap T_2 = \{0\}$. By (Afriat, 1957, Th. 10.1), the angle formed by $\boldsymbol{t}_1$ and $P_{T_2}(\boldsymbol{t}_1)$ is at least as large as the smallest principal angle between T_1 and T_2, which is $\theta_{\min}(T_1, T_2)$ since $T_1 \cap T_2 = \{0\}$. From this the result follows immediately. □

The following result says that a point cannot be close to two compact and smooth surfaces intersecting at a positive angle without being close to their intersection. Note that the constant there cannot be solely characterized by κ, as it also depends on the separation between the surfaces away from their intersection.

Lemma 21. *Suppose $S_1, S_2 \in \mathcal{S}_d(\kappa)$ intersect at a strictly positive angle and that $\operatorname{reach}(S_1 \cap S_2) \geq 1/\kappa$. Then there is a constant C_{21} such that*

$$\operatorname{dist}(\boldsymbol{x}, S_1 \cap S_2) \leq C_{21} \max\left\{\operatorname{dist}(\boldsymbol{x}, S_1), \operatorname{dist}(\boldsymbol{x}, S_2)\right\}, \quad \forall \boldsymbol{x} \in \mathbb{R}^D.$$

Proof. Assume the result is not true, so there is a sequence $(\boldsymbol{x}_n) \subset \mathbb{R}^D$ such that $\operatorname{dist}(\boldsymbol{x}_n, S_1 \cap S_2) > n \max_k \operatorname{dist}(\boldsymbol{x}_n, S_k)$. Because the surfaces are bounded, we may assume WLOG that the sequence is bounded. Then $\operatorname{dist}(\boldsymbol{x}_n, S_1 \cap S_2)$ is bounded, which implies that $\max_k \operatorname{dist}(\boldsymbol{x}_n, S_k) = O(1/n)$. This also forces $\operatorname{dist}(\boldsymbol{x}_n, S_1 \cap S_2) \to 0$. Indeed, otherwise there is a constant $C > 0$ and a subsequence $(\boldsymbol{x}_{n'}) \subset (\boldsymbol{x}_n)$ such that $\operatorname{dist}(\boldsymbol{x}_{n'}, S_1 \cap S_2) \geq C$. Since $(\boldsymbol{x}_{n'})$ is bounded, there is a subsequence $(\boldsymbol{x}_{n''}) \subset (\boldsymbol{x}_{n'})$ that converges, and by the fact that $\max_k \operatorname{dist}(\boldsymbol{x}_{n''}, S_k) = o(1)$, and by compactness of S_k, the limit is necessarily in $S_1 \cap S_2$, which is incompatible with the fact that $\operatorname{dist}(\boldsymbol{x}_{n''}, S_1 \cap S_2) \geq C$. Since $\operatorname{dist}(\boldsymbol{x}_n, S_1 \cap S_2) \to 1$, we have

$$n \max_k \operatorname{dist}(\boldsymbol{x}_n, S_k) < \operatorname{dist}(\boldsymbol{x}_n, S_1 \cap S_2) = o(1). \tag{47}$$

Assume n is large enough that $\text{dist}(\boldsymbol{x}_n, S_1 \cap S_2) < 1/\kappa$ and let $\boldsymbol{s}_n^k$ be the projection of $\boldsymbol{x}_n$ onto S_k, and $\boldsymbol{s}_n^\ddagger$ the projection of $\boldsymbol{x}_n$ onto $S_1 \cap S_2$. Let $T_k = T_{S_k}(\boldsymbol{s}_n^\ddagger)$ and note that $\theta_{\min}(T_1, T_2) \geq \theta := \theta(S_1, S_2)$—see definition (6). Let $\boldsymbol{t}_n^k$ be the projection of $\boldsymbol{s}_n^k$ onto T_k. Assume WLOG that $\|\boldsymbol{t}_n^1 - \boldsymbol{s}_n^1\| \geq \|\boldsymbol{t}_n^2 - \boldsymbol{s}_n^2\|$. Let $\boldsymbol{t}_n$ denote the projection of $\boldsymbol{t}_n^1$ onto $T_1 \cap T_2$, and then let $\boldsymbol{s}_n = P_{S_1 \cap S_2}(\boldsymbol{t}_n)$.

By (47), we have

$$n \max_k \|\boldsymbol{x}_n - \boldsymbol{s}_n^k\| \leq \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\| = o(1). \tag{48}$$

We start with the RHS:

$$\|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\| = \min_{\boldsymbol{s} \in S_1 \cap S_2} \|\boldsymbol{x}_n - \boldsymbol{s}\| \leq \|\boldsymbol{x}_n - \boldsymbol{s}_n\|, \tag{49}$$

and first show that $\|\boldsymbol{x}_n - \boldsymbol{s}_n\| = o(1)$ too. We use the triangle inequality multiple times in what follows. We have

$$\|\boldsymbol{x}_n - \boldsymbol{s}_n\| \leq \|\boldsymbol{x}_n - \boldsymbol{s}_n^1\| + \|\boldsymbol{s}_n^1 - \boldsymbol{t}_n^1\| + \|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| + \|\boldsymbol{t}_n - \boldsymbol{s}_n\|. \tag{50}$$

From (48), $\|\boldsymbol{x}_n - \boldsymbol{s}_n^1\| \leq \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\| = o(1)$, so that $\|\boldsymbol{s}_n^1 - \boldsymbol{s}_n^\ddagger\| = o(1)$, and by (10),

$$\|\boldsymbol{s}_n^1 - \boldsymbol{t}_n^1\| \leq \frac{\kappa}{2}\|\boldsymbol{s}_n^1 - \boldsymbol{s}_n^\ddagger\|^2 \leq \kappa(\|\boldsymbol{s}_n^1 - \boldsymbol{x}_n\|^2 + \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\|^2) = o(1). \tag{51}$$

We also have

$$\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| = \min_{\boldsymbol{t} \in T_1 \cap T_2} \|\boldsymbol{t}_n^1 - \boldsymbol{t}\| \leq \|\boldsymbol{t}_n^1 - \boldsymbol{s}_n^\ddagger\| \leq \|\boldsymbol{t}_n^1 - \boldsymbol{s}_n^1\| + \|\boldsymbol{s}_n^1 - \boldsymbol{x}_n\| + \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\| = o(1). \tag{52}$$

Finally,

$$\|\boldsymbol{t}_n - \boldsymbol{s}_n\| = \min_{\boldsymbol{s} \in S_1 \cap S_2} \|\boldsymbol{t}_n - \boldsymbol{s}\| \leq \|\boldsymbol{t}_n - \boldsymbol{s}_n^\ddagger\| \leq \|\boldsymbol{t}_n - \boldsymbol{t}_n^1\| + \|\boldsymbol{t}_n^1 - \boldsymbol{s}_n^\ddagger\| = o(1).$$

We now proceed. The last upper bound is rather crude. Indeed, using (12) for $S = S_1 \cap S_2$ and $\boldsymbol{s} = \boldsymbol{s}_n^\ddagger$, and noting that $T_{S_1 \cap S_2}(\boldsymbol{s}_n^\ddagger) = T_1 \cap T_2$, and using the fact that $\|\boldsymbol{t}_n - \boldsymbol{s}_n^\ddagger\| = o(1)$, we get

$$\|\boldsymbol{t}_n - \boldsymbol{s}_n\| \leq \kappa\|\boldsymbol{t}_n - \boldsymbol{s}_n^\ddagger\|^2 \leq \kappa(\|\boldsymbol{t}_n - \boldsymbol{s}_n\| + \|\boldsymbol{s}_n - \boldsymbol{x}_n\| + \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\|)^2.$$

Using (49),

$$\|\boldsymbol{t}_n - \boldsymbol{s}_n\| \leq \kappa(\|\boldsymbol{t}_n - \boldsymbol{s}_n\| + 2\|\boldsymbol{s}_n - \boldsymbol{x}_n\|)^2 \leq 5\kappa\|\boldsymbol{x}_n - \boldsymbol{s}_n\|^2, \tag{53}$$

eventually, since $\|\boldsymbol{t}_n - \boldsymbol{s}_n\| = o(1)$.

Combining (49), (50), (51) and (53), we get

$$\|\boldsymbol{x}_n - \boldsymbol{s}_n\| \leq \|\boldsymbol{x}_n - \boldsymbol{s}_n^1\| + O(\|\boldsymbol{x}_n - \boldsymbol{s}_n^1\|^2 + \|\boldsymbol{x}_n - \boldsymbol{s}_n\|^2) + \|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| + O(\|\boldsymbol{x}_n - \boldsymbol{s}_n\|^2),$$

which leads to

$$\|\boldsymbol{x}_n - \boldsymbol{s}_n\| \leq 2\|\boldsymbol{x}_n - \boldsymbol{s}_n^1\| + 2\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\|, \tag{54}$$

when n is large enough. Using this bound in (48) combined with (49), we get

$$\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| \geq \frac{n-2}{2} \max_k \|\boldsymbol{x}_n - \boldsymbol{s}_n^k\|.$$

We then have

$$\begin{aligned}
\max_k \|\boldsymbol{x}_n - \boldsymbol{s}_n^k\| &\geq \frac{1}{2}\|\boldsymbol{s}_n^1 - \boldsymbol{s}_n^2\| \\
&\geq \frac{1}{2}(\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n^2\| - \|\boldsymbol{s}_n^1 - \boldsymbol{t}_n^1\| - \|\boldsymbol{s}_n^2 - \boldsymbol{t}_n^2\|) \\
&\geq \frac{1}{2}\,\text{dist}(\boldsymbol{t}_n^1, T_2) - \|\boldsymbol{s}_n^1 - \boldsymbol{t}_n^1\|,
\end{aligned}$$

with

$$\|\boldsymbol{s}_n^1 - \boldsymbol{t}_n^1\| = O(\|\boldsymbol{x}_n - \boldsymbol{s}_n^1\|^2 + \|\boldsymbol{x}_n - \boldsymbol{s}_n^\ddagger\|^2) = O(\|\boldsymbol{x}_n - \boldsymbol{s}_n\|^2) = O(\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\|^2),$$

due (in the same order) to (51), (48)-(49), and (54). Recalling that $\|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| = \text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2)$, we conclude that

$$\text{dist}(\boldsymbol{t}_n^1, T_2) = O(1/n)\,\text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2) + O(1)\,\text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2)^2.$$

However, by Lemma 20, we have $\text{dist}(\boldsymbol{t}_n^1, T_2) \geq (\sin\theta)\,\text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2)$, so that dividing by $\text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2)$ above leads to

$$1 = O(1/n) + O(1)\,\text{dist}(\boldsymbol{t}_n^1, T_1 \cap T_2),$$

which is in contradiction with the fact that $\text{dist}(\boldsymbol{t}_n^1, T_2) \leq \|\boldsymbol{t}_n^1 - \boldsymbol{t}_n\| = o(1)$, established in (52). □

6.1.6 Covariances near an Intersection

The following compares a covariance matrix of a distribution supported on the union of two smooth surfaces with that of the projection of that distribution on tangent subspaces.

Lemma 22. *Consider $S_1, S_2 \in \mathcal{S}_d(\kappa)$ intersecting at a positive angle, with $\text{reach}(S_1 \cap S_2) \geq 1/\kappa$. Fix $\boldsymbol{s} \in S_1$ and let $A = B(\boldsymbol{s}, r) \cap (S_1 \cup S_2)$, where $r < 1/\kappa$. Let $\boldsymbol{C}$ denote the empirical covariance of an i.i.d. sample from a distribution ν supported on A of size m and define $\boldsymbol{\Sigma} = \text{Cov}(\nu)$. Then*

$$\mathbb{P}\left(\|\boldsymbol{C}_m - \boldsymbol{\Sigma}\| > r^2 t + 3\kappa r^3\right) \leq C_{22} \exp\left(-\frac{mt}{C_{22}} \min(t, m)\right), \quad \forall t \geq 0,$$

where C_{22} depends only on d.

Proof. Let $T_1 = T_{S_1}(\boldsymbol{s})$, and if $\text{dist}(\boldsymbol{s}, S_2) \leq r$, let $\boldsymbol{s}_2 = P_{S_2}(\boldsymbol{s})$ and $T_2 = T_{S_2}(\boldsymbol{s}_2)$. Define $g : A \mapsto T_1 \cup T_2$ where $g(\boldsymbol{x}) = P_{T_1}(\boldsymbol{x})$ if $\boldsymbol{x} \in S_1$, and $g(\boldsymbol{x}) = P_{T_2}(\boldsymbol{x})$ otherwise. By (10), $\|g(\boldsymbol{x}) - \boldsymbol{x}\| \leq \frac{\kappa}{2} r^2$ for all $\boldsymbol{x} \in A$. Let $\boldsymbol{\Sigma}^g = \text{Cov}(\nu^g)$. Also, let ν_m denote the sample distribution and note that $\boldsymbol{C}_m = \text{Cov}(\nu_m)$. Let $\boldsymbol{C}_m^g = \text{Cov}(\nu_m^g)$. Note that ν_m^g is the empirical distribution of an i.i.d. sample of size m from ν^g, so the notation is congruent. If $\text{dist}(\boldsymbol{s}, S_2) > r$, ν^g is supported on $B(\boldsymbol{s}, r) \cap T_1$, which is a d-dimensional ball of radius r, so that (43) applies to $\boldsymbol{C}_m^g$ and $\boldsymbol{\Sigma}^g$. If $\text{dist}(\boldsymbol{s}, S_2) \leq r$, ν^g is supported on

$$(B(\boldsymbol{s}, r) \cap T_1) \cup (B(\boldsymbol{s}_2, r) \cap T_2) \subset B(\boldsymbol{s}, 2r) \cap (T_1 \cup T_2) \subset B(\boldsymbol{s}, 2r) \cap (T_1 + T_2),$$

where the latter is a ball in dimension $d' := \dim(T_1 + T_2) \le 2d$ of radius $2r$, so that (43)—with $2r$ in place of r and $2d$ in place of d—applies to $\boldsymbol{C}_m^g$ and $\boldsymbol{\Sigma}^g$. Then, by the triangle inequality and Lemma 15,

$$\begin{aligned}\|\boldsymbol{C}_m - \boldsymbol{\Sigma}\| &\le \|\boldsymbol{C}_m - \boldsymbol{C}_m^g\| + \|\boldsymbol{C}_m^g - \boldsymbol{\Sigma}^g\| + \|\boldsymbol{\Sigma}^g - \boldsymbol{\Sigma}\| \\ &\le 2\kappa r^3 + \kappa^2 r^4/2 + \|\boldsymbol{C}_m^g - \boldsymbol{\Sigma}^g\|,\end{aligned}$$

as in (38). □

Here is a continuity result.

Lemma 23. *Let T_1 and T_2 be two linear subspaces of same dimension d. For $\boldsymbol{x} \in T_1$, denote by $\boldsymbol{\Sigma}_T(\boldsymbol{x})$ the covariance matrix of the uniform distribution over $B(\boldsymbol{x}, r) \cap (T_1 \cup T_2)$. Then, for all $\boldsymbol{x}, \boldsymbol{y} \in T_1$,*

$$\|\boldsymbol{\Sigma}_T(\boldsymbol{x}) - \boldsymbol{\Sigma}_T(\boldsymbol{y})\| \le \begin{cases} 5dr\,\|\boldsymbol{x} - \boldsymbol{y}\|, & \text{if } d \ge 2, \\ r\,\|\boldsymbol{x} - \boldsymbol{y}\| + 2\sqrt{r^3\,\|\boldsymbol{x} - \boldsymbol{y}\|}, & \text{if } d = 1. \end{cases}$$

We note that, when $d = 1$, we also have the bound

$$\|\boldsymbol{\Sigma}_T(\boldsymbol{x}) - \boldsymbol{\Sigma}_T(\boldsymbol{y})\| \le 4\gamma r\,\|\boldsymbol{x} - \boldsymbol{y}\|, \quad \text{if } \min(\operatorname{dist}(\boldsymbol{x}, T_2), \operatorname{dist}(\boldsymbol{y}, T_2)) \le r\sqrt{1 - 1/\gamma^2}.$$

Proof. Assume without loss of generality that $r = 1$. Let $A_{\boldsymbol{x}}^j = B(\boldsymbol{x}, 1) \cap T_j$ for any $\boldsymbol{x}$ and $j = 1, 2$. By Lemma 14 and then Lemma 7, we have

$$\begin{aligned}\|\boldsymbol{\Sigma}_T(\boldsymbol{x}) - \boldsymbol{\Sigma}_T(\boldsymbol{y})\| &= \|\operatorname{Cov}(\lambda_{A_{\boldsymbol{x}}^1 \cup A_{\boldsymbol{x}}^2}) - \operatorname{Cov}(\lambda_{A_{\boldsymbol{y}}^1 \cup A_{\boldsymbol{y}}^2})\| \\ &\le 3d\,\mathrm{TV}(\lambda_{A_{\boldsymbol{x}}^1 \cup A_{\boldsymbol{x}}^2}, \lambda_{A_{\boldsymbol{y}}^1 \cup A_{\boldsymbol{y}}^2}) \\ &\le 12d\,\frac{\operatorname{vol}\left((A_{\boldsymbol{x}}^1 \cup A_{\boldsymbol{x}}^2) \triangle (A_{\boldsymbol{y}}^1 \cup A_{\boldsymbol{y}}^2)\right)}{\operatorname{vol}\left((A_{\boldsymbol{x}}^1 \cup A_{\boldsymbol{x}}^2) \cup (A_{\boldsymbol{y}}^1 \cup A_{\boldsymbol{y}}^2)\right)} \\ &\le 12d\,\frac{\operatorname{vol}(A_{\boldsymbol{x}}^1 \triangle A_{\boldsymbol{y}}^1) + \operatorname{vol}(A_{\boldsymbol{x}}^2 \triangle A_{\boldsymbol{y}}^2)}{\operatorname{vol}(A_{\boldsymbol{x}}^1)}.\end{aligned}$$

Note that $A_{\boldsymbol{x}}^2 = B(\boldsymbol{x}_2, \eta) \cap T_2$ where $\boldsymbol{x}_2 := P_{T_2}(\boldsymbol{x})$ and $\eta := \sqrt{1 - \|\boldsymbol{x} - \boldsymbol{x}_2\|^2 \wedge 1}$. Similarly, $A_{\boldsymbol{y}}^2 = B(\boldsymbol{y}_2, \delta) \cap T_2$ where $\boldsymbol{y}_2 := P_{T_2}(\boldsymbol{y})$ and $\delta := \sqrt{1 - \|\boldsymbol{y} - \boldsymbol{y}_2\|^2 \wedge 1}$. Therefore, applying Lemma 12, we get

$$\frac{\operatorname{vol}(A_{\boldsymbol{x}}^1 \triangle A_{\boldsymbol{y}}^1)}{2\operatorname{vol}(A_{\boldsymbol{x}}^1)} \le 1 - (1 - t)_+^d, \tag{64}$$

and assuming WLOG that $\delta \le \eta$ (i.e., $\|\boldsymbol{y} - \boldsymbol{y}_2\| \ge \|\boldsymbol{x} - \boldsymbol{x}_2\|$) and after proper scaling, we get

$$\frac{\operatorname{vol}(A_{\boldsymbol{x}}^2 \triangle A_{\boldsymbol{y}}^2)}{2\operatorname{vol}(A_{\boldsymbol{x}}^1)} \le \zeta := \eta^d - (\eta - t_2)_+^d \wedge \delta^d, \tag{65}$$

where $t := \|\boldsymbol{x} - \boldsymbol{y}\|$ and $t_2 := \|\boldsymbol{x}_2 - \boldsymbol{y}_2\|$. Note that $t_2 \le t$ by the fact that P_{T_2} is 1-Lipschitz.

For (64), we have $1 - (1 - t)_+^d \le dt$. This is obvious when $t \ge 1$, while when $t \le 1$ it is obtained using the fact that, for any $0 \le a < b \le 1$,

$$b^d - a^d = (b - a)(b^{d-1} + ab^{d-2} + \cdots + a^{d-2}b + a^{d-1}) \le db^{d-1}(b - a) \le d(b - a). \tag{66}$$

For (65), we consider several cases.

- When $\eta \le t_2$, then $\zeta = \eta^d \le \eta \le t_2 \le t$.
- When $t_2 < \eta \le t_2 + \delta$, then $\zeta = \eta^d - (\eta - t_2)^d \le dt_2 \le dt$, by (66).
- When $\eta \ge t_2 + \delta$ and $d \ge 2$, we have

$$\begin{aligned}\zeta &= \eta^d - \delta^d \le d\eta^{d-1}(\eta - \delta) \le d\eta(\eta - \delta) \le d(\eta^2 - \delta^2) \\ &= d(\|\boldsymbol{y} - \boldsymbol{y}_2\|^2 \wedge 1 - \|\boldsymbol{x} - \boldsymbol{x}_2\|^2 \wedge 1) \\ &= d(\|\boldsymbol{y} - \boldsymbol{y}_2\| \wedge 1 + \|\boldsymbol{x} - \boldsymbol{x}_2\| \wedge 1)(\|\boldsymbol{y} - \boldsymbol{y}_2\| \wedge 1 - \|\boldsymbol{x} - \boldsymbol{x}_2\| \wedge 1) \\ &\le 2d(t + t_2) \le 4dt,\end{aligned}$$

  where (66) was applied in the first line and the triangle inequality was applied in the last line, in the form of

$$\|\boldsymbol{y} - \boldsymbol{y}_2\| \le \|\boldsymbol{y} - \boldsymbol{x}\| + \|\boldsymbol{x} - \boldsymbol{x}_2\| + \|\boldsymbol{x}_2 - \boldsymbol{y}_2\| = \|\boldsymbol{x} - \boldsymbol{x}_2\| + t + t_2.$$

- When $\eta \ge t_2 + \delta$ and $d = 1$, we have

$$\zeta = \eta - \delta \le \sqrt{\|\boldsymbol{y} - \boldsymbol{y}_2\|^2 \wedge 1 - \|\boldsymbol{x} - \boldsymbol{x}_2\|^2 \wedge 1} \le 2\sqrt{t},$$

  using (70), preceded by the fact that, for any $0 \le a < b \le 1$,

$$0 \le \sqrt{1 - a} - \sqrt{1 - b} = \frac{b - a}{\sqrt{1 - a} + \sqrt{1 - b}} \le \frac{b - a}{\sqrt{1 - b + b - a}} \le \frac{b - a}{\sqrt{b - a}} = \sqrt{b - a}.$$

In summary, when $d \ge 2$, we can therefore bound $\|\boldsymbol{\Sigma}_T(\boldsymbol{x}) - \boldsymbol{\Sigma}_T(\boldsymbol{y})\|$ by $dt + 4dt = 5dt$; and when $d = 1$, we bound that by $t + 2\sqrt{t}$. □

The following is in some sense a converse to Lemma 23, in that we lower-bound the distance between covariance matrices near an intersection of linear subspaces. Note that the covariance matrix does not change when moving parallel to the intersection; however, it does when moving perpendicular to the intersection.

Lemma 24. *Let T_1 and T_2 be two linear subspaces of same dimension d with $\theta_{\min}(T_1, T_2) \ge \theta_0 > 0$. Fix a unit norm vector $\boldsymbol{v} \in T_1 \cap (T_1 \cap T_2)^\perp$. With $\boldsymbol{\Sigma}_T(h\boldsymbol{v})$ denoting the covariance of the uniform distribution over $B(h\boldsymbol{v}, r) \cap (T_1 \cup T_2)$, we have*

$$\inf_h \sup_\ell \|\boldsymbol{\Sigma}_T(h\boldsymbol{v}) - \boldsymbol{\Sigma}_T(\ell\boldsymbol{v})\| \ge r^2/C_{24},$$

where the infimum is over $0 \le h \le 1/\sin\theta_0$ and the supremum over $\max(0, h - 1/2) \le \ell \le \min(1/\sin\theta_0, h + 1/2)$, and $C_{24} \ge 1$ depends only on d and θ_0.

Proof. Assume without loss of generality that $r = 1$. If the statement of the lemma is not true, there are subspaces T_1 and T_2 of same dimension d, a unit length vector $\boldsymbol{v} \in T_1 \cap (T_1 \cap T_2)^\perp$ and $0 \le h \le 1/\sin\theta_0$, such that

$$\boldsymbol{\Sigma}_T(\ell\boldsymbol{v}) = \boldsymbol{\Sigma}_T(h\boldsymbol{v}) \text{ for all } \max(0, h - 1/2) \le \ell \le \min(1/\sin\theta_0, h + 1/2). \tag{71}$$

This is because $\ell \mapsto \mathbf{\Sigma}_T(\ell \boldsymbol{v})$ is continuous once T_1, T_2 and $\boldsymbol{v}$ are chosen. By projecting onto $(T_1 \cap T_2)^\perp$, we may assume that $T_1 \cap T_2 = \{0\}$ without loss of generality. Let $\theta = \angle(\boldsymbol{v}, T_2)$ and note that $\theta \geq \theta_0$ since $T_1 \cap T_2 = \{0\}$. Define $\boldsymbol{u} = (\boldsymbol{v} - P_{T_2}\boldsymbol{v})/\sin\theta$ and also $\boldsymbol{w} = P_{T_2}\boldsymbol{v}/\cos\theta$ when $\theta < \pi/2$, and $\boldsymbol{w} \in T_2$ is any vector perpendicular to $\boldsymbol{v}$ when $\theta = \pi/2$. $B(h\boldsymbol{v}, 1) \cap T_1$ is the d-dimensional ball of T_1 of radius 1 and center $h\boldsymbol{v}$, while—using Pythagoras theorem—$B(h\boldsymbol{v}, 1) \cap T_2$ is the d-dimensional ball of T_2 of radius $t := (1 - (h\sin\theta)^2)^{1/2}$ and center $(h\cos\theta)\boldsymbol{w}$. Let λ denote the uniform distribution over $B(h\boldsymbol{v}, 1) \cap (T_1 \cup T_2)$ and λ_k the uniform distribution over $B(h\boldsymbol{v}, 1) \cap T_k$. Note that $\lambda = \alpha\lambda_1 + (1-\alpha)\lambda_2$, where

$$\alpha := \frac{\mathrm{vol}(B(h\boldsymbol{v}, 1) \cap T_1)}{\mathrm{vol}(B(h\boldsymbol{v}, 1) \cap (T_1 \cup T_2))} = \frac{\mathrm{vol}(B(h\boldsymbol{v}, 1) \cap T_1)}{\mathrm{vol}(B(h\boldsymbol{v}, 1) \cap T_1) + \mathrm{vol}(B((h\cos\theta)\boldsymbol{w}, t) \cap T_2)} = \frac{1}{1+t^d}.$$

By the law of total covariance,

$$\mathrm{Cov}(\lambda) = \alpha\,\mathrm{Cov}(\lambda_1) + (1-\alpha)\,\mathrm{Cov}(\lambda_2) + \alpha(1-\alpha)(\mathbb{E}(\lambda_1) - \mathbb{E}(\lambda_2))(\mathbb{E}(\lambda_1) - \mathbb{E}(\lambda_2))^\top. \quad (72)$$

with $\mathbb{E}(\lambda_1) = h\boldsymbol{v}$ and $\mathbb{E}(\lambda_2) = h\cos(\theta)\boldsymbol{w}$, and $\mathrm{Cov}(\lambda_1) = c\boldsymbol{P}_{T_1}$ and $\mathrm{Cov}(\lambda_2) = t^2 c\boldsymbol{P}_{T_2}$, by Lemma 13. Hence,

$$\mathbf{\Sigma}_T(h\boldsymbol{v}) = \alpha c\boldsymbol{P}_{T_1} + (1-\alpha)t^2 c\boldsymbol{P}_{T_2} + \alpha(1-\alpha)(1-t^2)\boldsymbol{u}\boldsymbol{u}^\top,$$

using the fact that $\boldsymbol{v} - (\cos\theta)\boldsymbol{w} = (\sin\theta)\boldsymbol{u}$ and the definition of t. Let $\theta_1 = \theta_{\max}(T_1, T_2)$ and let $\boldsymbol{v}_1 \in T_1$ be of unit length and such that $\angle(\boldsymbol{v}_1, T_2) = \theta_1$. Then for any $0 \leq h, \ell \leq 1/\sin\theta_0$, we have

$$\|\mathbf{\Sigma}_T(h\boldsymbol{v}) - \mathbf{\Sigma}_T(\ell\boldsymbol{v})\| \geq |\boldsymbol{v}_1^\top \mathbf{\Sigma}_T(h\boldsymbol{v})\boldsymbol{v}_1 - \boldsymbol{v}_1^\top \mathbf{\Sigma}_T(\ell\boldsymbol{v})\boldsymbol{v}_1| = |f(t_h) - f(t_\ell)|, \quad (73)$$

where $t_h := (1 - (h\sin\theta)^2)^{1/2}$ and

$$f(t) \;=\; \frac{c}{1+t^d} + \frac{ct^{d+2}(\cos\theta_1)^2}{1+t^d} + \frac{t^d(1-t^2)(\boldsymbol{u}^\top\boldsymbol{v}_1)^2}{(1+t^d)^2}.$$

It is easy to see that the interval

$$I_h = \{t_\ell : (h - 1/2)_+ \leq \ell \leq (1/\sin\theta_0) \wedge (h + 1/2)\}$$

is non empty. Because of (71) and (73), $f(t)$ is constant over $t \in I_h$, but this is not possible since f is a rational function not equal to a constant and therefore cannot be constant over an interval of positive length. □

We now look at the eigenvalues of the covariance matrix.

Lemma 25. *Let T_1 and T_2 be two linear subspaces of same dimension d. For $\boldsymbol{x} \in T_1$, denote by $\mathbf{\Sigma}_T(\boldsymbol{x})$ the covariance matrix of the uniform distribution over $B(\boldsymbol{x}, 1) \cap (T_1 \cup T_2)$. Then, for all $\boldsymbol{x} \in T_1$,*

$$c\big(1 - (1-\delta^2(\boldsymbol{x}))_+^{d/2}\big) \leq \beta_d(\mathbf{\Sigma}_T(\boldsymbol{x})), \qquad \beta_1(\mathbf{\Sigma}_T(\boldsymbol{x})) \leq c + \delta^2(\boldsymbol{x})(1-\delta^2(\boldsymbol{x}))_+^{d/2}, \quad (75)$$

$$\frac{c}{8}(1 - \cos\theta_{\max}(T_1, T_2))^2(1-\delta^2(\boldsymbol{x}))_+^{d/2+1} \leq \beta_{d+1}(\mathbf{\Sigma}_T(\boldsymbol{x})) \leq (c + \delta^2(\boldsymbol{x}))(1-\delta^2(\boldsymbol{x}))_+^{d/2}, \quad (76)$$

where $c := 1/(d+2)$ and $\delta(\boldsymbol{x}) := \mathrm{dist}(\boldsymbol{x}, T_2)$.

Proof. Applying (72), we have

$$\mathbf{\Sigma}_T(x) = \alpha c\boldsymbol{P}_{T_1} + (1-\alpha)ct^2\boldsymbol{P}_{T_2} + \alpha(1-\alpha)(\boldsymbol{x} - \boldsymbol{x}_2)(\boldsymbol{x} - \boldsymbol{x}_2)^\top, \quad (77)$$

where $\boldsymbol{x}_2 := P_{T_2}(\boldsymbol{x})$ and $\alpha := (1+t^d)^{-1}$ with $t := (1 - \delta^2(\boldsymbol{x}))_+^{1/2}$. Because all the matrices in this display are positive semidefinite, we have

$$\beta_d(\mathbf{\Sigma}_T(\boldsymbol{x})) \geq \alpha c\|\boldsymbol{P}_{T_1}\| = \alpha c,$$

with $\alpha \geq 1 - t^d$. And because of the triangle inequality, we have

$$\beta_1(\mathbf{\Sigma}_T(\boldsymbol{x})) \leq \alpha c\|\boldsymbol{P}_{T_1}\| + (1-\alpha)ct^2\|\boldsymbol{P}_{T_2}\| + \alpha(1-\alpha)\|\boldsymbol{x} - \boldsymbol{x}_2\|^2 \leq c + \alpha(1-\alpha)\delta^2(\boldsymbol{x}),$$

with $\alpha(1-\alpha) \leq t^d$. Hence, (75) is proved.

For the upper bound in (76), by Weyl's inequality (Stewart and Sun, 1990, Cor. IV.4.9) and the fact that $\beta_{d+1}(\boldsymbol{P}_{T_1}) = 0$, and then the triangle inequality, we get

$$\begin{aligned}\beta_{d+1}(\mathbf{\Sigma}_T(\boldsymbol{x})) &\leq \|\mathbf{\Sigma}_T(\boldsymbol{x}) - \alpha c\boldsymbol{P}_{T_1}\| \\ &\leq c(1-\alpha)t^2\|\boldsymbol{P}_{T_2}\| + \alpha(1-\alpha)\delta^2(\boldsymbol{x}) \\ &\leq (1-\alpha)(c + \delta^2(\boldsymbol{x})),\end{aligned}$$

and we then use the fact that $1 - \alpha \leq t^d$.

For the lower bound in (76), let $\theta_1 \geq \theta_2 \geq \cdots \geq \theta_d$ denote the principal angles between T_1 and T_2. By the definition of principal angles, there are orthonormal bases for T_1 and T_2, denoted $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d$ and $\boldsymbol{w}_1, \ldots, \boldsymbol{w}_d$, such that $\boldsymbol{v}_j^\top \boldsymbol{w}_k = \mathbb{1}_{j=k} \cdot \cos\theta_j$. Take $\boldsymbol{u} \in \mathrm{span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_d, \boldsymbol{w}_1)$, that is, of the form $\boldsymbol{u} = a\boldsymbol{v}_1 + \boldsymbol{v} + b\boldsymbol{w}_1$, with $\boldsymbol{v} \in \mathrm{span}(\boldsymbol{v}_2, \ldots, \boldsymbol{v}_d)$. Since $\boldsymbol{P}_{T_1} = \boldsymbol{v}_1\boldsymbol{v}_1^\top + \cdots + \boldsymbol{v}_d\boldsymbol{v}_d^\top$ and $\boldsymbol{P}_{T_2} = \boldsymbol{w}_1\boldsymbol{w}_1^\top + \cdots + \boldsymbol{w}_d\boldsymbol{w}_d^\top$, when $\|\boldsymbol{u}\| = 1$, we have

$$\frac{1}{c}\boldsymbol{u}^\top \mathbf{\Sigma}_T(\boldsymbol{x})\boldsymbol{u} \geq \alpha\boldsymbol{u}^\top \boldsymbol{P}_{T_1}\boldsymbol{u} + (1-\alpha)t^2\boldsymbol{u}^\top \boldsymbol{P}_{T_2}\boldsymbol{u}$$

with

$$\boldsymbol{u}^\top \boldsymbol{P}_{T_1}\boldsymbol{u} = a^2 + \|\boldsymbol{v}\|^2 + 2ab\cos\theta_1 + b^2\cos^2\theta_1 = 1 - b^2\sin^2\theta_1 \geq 0,$$

and

$$\boldsymbol{u}^\top \boldsymbol{P}_{T_2}\boldsymbol{u} = b^2 + 2ab\cos\theta_1 + a^2\cos^2\theta_1 = (a\cos\theta_1 + b)^2.$$

If $|b| \leq 1/2$, then $\boldsymbol{u}^\top \boldsymbol{P}_{T_1}\boldsymbol{u} \geq 3/4$, implying that $\frac{1}{c}\boldsymbol{u}^\top \mathbf{\Sigma}_T(\boldsymbol{x})\boldsymbol{u} \geq 3\alpha/4 \geq 3/8$. Otherwise,

$$\begin{aligned}\boldsymbol{u}^\top \boldsymbol{P}_{T_1}\boldsymbol{u} + \boldsymbol{u}^\top \boldsymbol{P}_{T_2}\boldsymbol{u} &\geq (a + b\cos\theta_1)^2 + (a\cos\theta_1 + b)^2 \\ &\geq (1 - \cos\theta_1)^2(a^2 + b^2) \geq (1 - \cos\theta_1)^2/4,\end{aligned}$$

and using the fact that $\alpha \geq 1 - \alpha \geq (1-\alpha)t^2$, we get

$$\frac{1}{c}\boldsymbol{u}^\top \mathbf{\Sigma}_T(\boldsymbol{x})\boldsymbol{u} \geq (1-\alpha)t^2(1 - \cos\theta_1)^2/4.$$

This last bound is always worst. Hence, by the Courant-Fischer theorem (Stewart and Sun, 1990, Cor. IV.4.7), we have

$$\beta_{d+1}(\mathbf{\Sigma}_T(\boldsymbol{x})) \geq \frac{c}{4}(1-\alpha)t^2(1 - \cos\theta_1)^2,$$

and we conclude with $1 - \alpha \geq t^d/2$. □

Below are two technical results on the covariance matrix of the uniform distribution on the intersection of a ball and the union of two smooth surfaces, near where the surfaces intersect. The first one is in fact a stepping stone to the second. The latter will enable us to apply Lemma 23.

Lemma 26. *There is a constant $C_{26} \geq 3$ such that the following holds. Consider $S_1, S_2 \in \mathcal{S}_d(\kappa)$. Fix $r \leq \frac{1}{C_{26}\kappa}$, and for $\boldsymbol{s} \in S_1$ with $\mathrm{dist}(\boldsymbol{s}, S_2) < 1/\kappa$, let $\boldsymbol{\Sigma}(\boldsymbol{s})$ and $\boldsymbol{\Sigma}_T(\boldsymbol{s})$ denote the covariance matrices of the uniform distributions over $B(\boldsymbol{s}, r) \cap (S_1 \cup S_2)$ and $B(\boldsymbol{s}, r) \cap (T_1 \cup T_2)$, respectively, where $T_1 := T_{S_1}(\boldsymbol{s})$ and $T_2 := T_{S_2}(P_{S_2}(\boldsymbol{s}))$. Then*

$$\|\boldsymbol{\Sigma}(\boldsymbol{s}) - \boldsymbol{\Sigma}_T(\boldsymbol{s})\| \leq C_{26}\kappa r^3. \tag{83}$$

Proof. We note that it is enough to prove the result when r is small enough. Let $\delta = \mathrm{dist}(\boldsymbol{s}, S_2)$ and let $\boldsymbol{s}_2 = P_{S_2}(\boldsymbol{s})$, so that $\|\boldsymbol{s} - \boldsymbol{s}_2\| = \delta$. We first treat the case where $\delta \leq r$. Let B_r be short for $B(\boldsymbol{s}, r)$ and define $A_k = B_r \cap S_k$, $\boldsymbol{\mu}_k = \mathbb{E}(\lambda_{A_k})$ and $\boldsymbol{D}_k = \mathrm{Cov}(\lambda_{A_k})$, for $k = 1, 2$. Applying (72), we have

$$\boldsymbol{\Sigma}(\boldsymbol{s}) = \alpha \boldsymbol{D}_1 + (1-\alpha)\boldsymbol{D}_2 + \alpha(1-\alpha)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)^\top,$$

where

$$\alpha := \frac{\mathrm{vol}(A_1)}{\mathrm{vol}(A_1) + \mathrm{vol}(A_2)}.$$

Recall that $T_1 = T_{S_1}(\boldsymbol{s})$ and $T_2 = T_{S_2}(\boldsymbol{s}_2)$, and define $A'_k = B_r \cap T_k$, so that $B_r \cap (T_1 \cup T_2) = A'_1 \cup A'_2$. Note that $\mathbb{E}(\lambda_{A'_1}) = \boldsymbol{s}$ and $\mathbb{E}(\lambda_{A'_2}) = \boldsymbol{s}_2$, and by Lemma 13, $\boldsymbol{D}'_1 := \mathrm{Cov}(\lambda_{A'_1}) = cr^2 \boldsymbol{P}_{T_1}$ and $\boldsymbol{D}'_2 := \mathrm{Cov}(\lambda_{A'_2}) = c(r^2 - \delta^2)\boldsymbol{P}_{T_2}$, where $c := 1/(d+2)$. Applying (72), we have

$$\boldsymbol{\Sigma}_T(\boldsymbol{s}) = \alpha' \boldsymbol{D}'_1 + (1-\alpha')\boldsymbol{D}'_2 + \alpha'(1-\alpha')(\boldsymbol{s} - \boldsymbol{s}_2)(\boldsymbol{s} - \boldsymbol{s}_2)^\top,$$

where

$$\alpha' := \frac{\mathrm{vol}(A'_1)}{\mathrm{vol}(A'_1) + \mathrm{vol}(A'_2)}.$$

By the triangle inequality, we have

$$\|\alpha \boldsymbol{D}_1 - \alpha' \boldsymbol{D}'_1\| \leq |\alpha' - \alpha| \|\boldsymbol{D}'_1\| + \alpha \|\boldsymbol{D}_1 - \boldsymbol{D}'_1\| \leq cr^2 |\alpha' - \alpha| + \|\boldsymbol{D}_1 - \boldsymbol{D}'_1\|,$$

and similarly,

$$\|(1-\alpha)\boldsymbol{D}_2 - (1-\alpha')\boldsymbol{D}'_2\| \leq cr^2 |\alpha' - \alpha| + (1-\alpha)\|\boldsymbol{D}_2 - \boldsymbol{D}'_2\|.$$

Assuming that $\kappa r \leq 1/C_{16}$, by Lemma 16, we have $\|\boldsymbol{D}_1 - \boldsymbol{D}'_1\| \vee \|\boldsymbol{D}_2 - \boldsymbol{D}'_2\| \leq C_{16}\kappa r^3$. Because $|\alpha'(1-\alpha') - \alpha(1-\alpha)| \leq |\alpha' - \alpha|$ and the identity $\|\boldsymbol{a}\boldsymbol{a}^\top - \boldsymbol{b}\boldsymbol{b}^\top\| \leq (\|\boldsymbol{a}\| + \|\boldsymbol{b}\|)\|\boldsymbol{a} - \boldsymbol{b}\|$, we also have

$$\begin{aligned}
&\|\alpha(1-\alpha)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_2)^\top - \alpha'(1-\alpha')(\boldsymbol{s} - \boldsymbol{s}_2)(\boldsymbol{s} - \boldsymbol{s}_2)^\top\| \\
&\leq |\alpha' - \alpha| \|\boldsymbol{s} - \boldsymbol{s}_2\|^2 + \alpha(1-\alpha) 3r\big(\|\boldsymbol{\mu}_1 - \boldsymbol{s}\| + \|\boldsymbol{\mu}_2 - \boldsymbol{s}_2\|\big).
\end{aligned}$$

By Lemma 16, we have $\|\boldsymbol{\mu}_1 - \boldsymbol{s}\| \vee \|\boldsymbol{\mu}_2 - \boldsymbol{s}_2\| \leq C_{16}\kappa r^2$. Assuming that $\kappa r \leq 1/3$, $P_{T_k}^{-1}$ is well-defined and $(1+\kappa r)$-Lipschitz on $S_k \cap B_r$. And being an orthogonal projection, P_{T_k} is 1-Lipschitz . Hence, applying Lemma 6, we have

$$1 \leq \frac{\mathrm{vol}(A_k)}{\mathrm{vol}(P_{T_k}(A_k))} \leq 1 + \kappa r, \quad k = 1, 2.$$

Then by Lemma 9,

$$\frac{\mathrm{vol}(P_{T_k}(A_k) \triangle A'_k)}{\mathrm{vol}(A'_k)} \leq C_9\kappa(r + \kappa r^2) \leq 2C_9\kappa r, \quad k = 1, 2,$$

when κr is small enough, implying

$$1 - 2C_9\kappa r \leq \frac{\mathrm{vol}(P_{T_k}(A_k))}{\mathrm{vol}(A'_k)} \leq 1 + 2C_9\kappa r, \quad k = 1, 2.$$

Hence,

$$1 - C\kappa r \leq 1 - 2C_9\kappa r \leq \frac{\mathrm{vol}(A_k)}{\mathrm{vol}(A'_k)} \leq (1+\kappa r)(1 + 2C_9\kappa r) \leq 1 + C\kappa r, \quad k = 1, 2,$$

for some constant $C > 0$. Since for all $a, b, a', b' > 0$ we have

$$\left|\frac{a}{a+b} - \frac{a'}{a'+b'}\right| \leq \frac{|a - a'| \vee |b - b'|}{(a+b) \vee (a'+b')} \leq \big|1 - a/a'\big| \vee \big|1 - b/b'\big|,$$

we then get

$$|\alpha - \alpha'| \leq C\kappa r.$$

Applying the triangle inequality to $\|\boldsymbol{\Sigma}(\boldsymbol{s}) - \boldsymbol{\Sigma}_T(\boldsymbol{s})\|$ and using the bounds above, we conclude.

We assumed above that $\delta \leq r$. When $\delta > r$, $A_2 = A'_2 = \emptyset$ and $\alpha = \alpha' = 1$. In this case, $\boldsymbol{\mu}_2, \boldsymbol{D}_2, \mathrm{D}'_2$ are not well-defined, but one can easily check that the above calculations, and the resulting bound, remain valid. In fact, in this case $\boldsymbol{\Sigma}(\boldsymbol{s}) = \boldsymbol{D}_1$ and $\boldsymbol{\Sigma}_T(\boldsymbol{s}) = \boldsymbol{D}'_1$. □

Lemma 27. *Consider $S_1, S_2 \in \mathcal{S}_d(\kappa)$ intersecting at a positive angle, with $\mathrm{reach}(S_1 \cap S_2) \geq 1/\kappa$. There is a constant $C_{27} \geq 1$, depending on S_1 and S_2, such that the following holds. For $\boldsymbol{s} \in S_1$ with $\mathrm{dist}(\boldsymbol{s}, S_2) \leq 2r$, assuming $r \leq \frac{1}{C_{27}}$, let $\boldsymbol{\Sigma}(\boldsymbol{s})$ and $\boldsymbol{\Sigma}^0_T(\boldsymbol{s})$ denote the covariance matrices of the uniform distributions over $B(\boldsymbol{s}, r) \cap (S_1 \cup S_2)$ and $B(P_{T^0_1}(\boldsymbol{s}), r) \cap (T^0_1 \cup T^0_2)$, where $T^0_k := T_{S_k}(\boldsymbol{s}^0)$ and $\boldsymbol{s}^0 := P_{S_1 \cap S_2}(\boldsymbol{s})$. Then*

$$\|\boldsymbol{\Sigma}(\boldsymbol{s}) - \boldsymbol{\Sigma}^0_T(\boldsymbol{s})\| \leq C_{27}\, r^{5/2}.$$

Proof. We use the notation of Lemma 26 and its proof. In addition, we let $C > 0$ denote a constant that depends only on S_1 and S_2 whose value increases with each appearance.

Define $\boldsymbol{t}_1 = P_{T^0_1}(\boldsymbol{s})$ and $\boldsymbol{t}_2 = P_{T^0_2}(\boldsymbol{t}_1)$. Let $\delta_0 = \|\boldsymbol{t}_1 - \boldsymbol{t}_2\|$, $\delta_1 = \|\boldsymbol{s} - \boldsymbol{t}_1\|$, $\delta_2 = \|\boldsymbol{s}_2 - \boldsymbol{t}_2\|$. Define $A^0_1 = T^0_1 \cap B(\boldsymbol{t}_1, r)$ and $A^0_2 = T^0_2 \cap B(\boldsymbol{t}_1, r)$. Note that $A^0_2 = T^0_2 \cap B(\boldsymbol{t}_2, \sqrt{r^2 - \delta_0^2})$

when $\delta_0 \le r$, and $A_2^0 = \emptyset$ when $\delta_0 > r$. We have $\|\boldsymbol{s} - \boldsymbol{s}^0\| \le Cr$ by Lemma 21, which then implies $\delta_1 \le Cr^2$ by Lemma 2. Assuming that κr is small enough,

$$\begin{aligned}\delta_2 = \|\boldsymbol{s}_2 - \boldsymbol{t}_2\| &\le \|P_{S_2}(\boldsymbol{s}) - P_{T_2^0}(\boldsymbol{s})\| + \|P_{T_2^0}(\boldsymbol{s}) - P_{T_2^0}(\boldsymbol{t}_1)\| \\ &\le C_4\kappa\|\boldsymbol{s} - \boldsymbol{s}^0\|^2 + \|\boldsymbol{s} - \boldsymbol{t}_1\| \le Cr^2,\end{aligned}$$

where in the second line we used Lemma 4 and the fact that any metric projection is 1-Lipschitz. Hence,

$$|\delta_0 - \delta| \le \big|\|\boldsymbol{t}_1 - \boldsymbol{t}_2\| - \|\boldsymbol{s} - \boldsymbol{s}_2\|\big| \le \|\boldsymbol{t}_1 - \boldsymbol{s}\| + \|\boldsymbol{t}_2 - \boldsymbol{s}_2\| = \delta_1 + \delta_2 \le Cr^2.$$

Note that $\mathbb{E}(\lambda_{A_1^0}) = \boldsymbol{t}_1$ and, by Lemma 13 (with c denoting the constant defined there), $\boldsymbol{D}_1^0 := \mathrm{Cov}(\lambda_{A_1^0}) = cr^2\boldsymbol{P}_{T_1^0}$. If $\delta_0 \le r$, $\mathbb{E}(\lambda_{A_2^0}) = \boldsymbol{t}_2$ and $\boldsymbol{D}_2^0 := \mathrm{Cov}(\lambda_{A_2^0}) = c(r^2 - \delta_0^2)\boldsymbol{P}_{T_2^0}$; if $\delta_0 > r$, then $A_2^0 = \emptyset$, and we define $\boldsymbol{D}_2^0 = 0$ in that case. Applying (72), we have

$$\boldsymbol{\Sigma}_T^0(\boldsymbol{s}) = \alpha^0\boldsymbol{D}_1^0 + (1-\alpha^0)\boldsymbol{D}_2^0 + \alpha^0(1-\alpha^0)(\boldsymbol{t}_1 - \boldsymbol{t}_2)(\boldsymbol{t}_1 - \boldsymbol{t}_2)^\top,$$

where

$$\alpha^0 := \frac{\mathrm{vol}(A_1^0)}{\mathrm{vol}(A_1^0) + \mathrm{vol}(A_2^0)}.$$

Note that $\alpha^0 = 1$ when $\delta_0 > r$ (i.e., when $A_2^0 = \emptyset$). We focus on the case where $\max(\delta, \delta_0) \le r$, which is the most complex one. We have

$$\|\boldsymbol{D}_1' - \boldsymbol{D}_1^0\| = \|cr^2\boldsymbol{P}_{T_1} - cr^2\boldsymbol{P}_{T_1^0}\| = cr^2\|\boldsymbol{P}_{T_1} - \boldsymbol{P}_{T_1^0}\|,$$

and

$$\|\boldsymbol{D}_2' - \boldsymbol{D}_2^0\| = \|c(r^2 - \delta^2)\boldsymbol{P}_{T_2} - c(r^2 - \delta_0^2)_+\boldsymbol{P}_{T_2^0}\| \le cr^2\|\boldsymbol{P}_{T_2} - \boldsymbol{P}_{T_2^0}\| + c|\delta^2 - \delta_0^2|,$$

by the triangle inequality and the fact that $\|\boldsymbol{P}_T\| \le 1$ for any affine subspace T. By Lemma 3 and Lemma 18, we have

$$\|\boldsymbol{P}_{T_1} - \boldsymbol{P}_{T_1^0}\| \le 6\kappa\|\boldsymbol{s} - \boldsymbol{s}^0\| \le Cr, \qquad \|\boldsymbol{P}_{T_2} - \boldsymbol{P}_{T_2^0}\| \le 6\kappa\|\boldsymbol{s}_2 - \boldsymbol{s}^0\| \le Cr,$$

since

$$\|\boldsymbol{s}_2 - \boldsymbol{s}^0\| \le \|\boldsymbol{s}_2 - \boldsymbol{s}\| + \|\boldsymbol{s} - \boldsymbol{s}^0\| \le 2r + Cr.$$

And since $|\delta^2 - \delta_0^2| \le 2r|\delta - \delta_0| \le Cr^3$, we have $\|\boldsymbol{D}_k' - \boldsymbol{D}_k^0\| \le Cr^3$ for $k = 1, 2$. Let ω_d denote the volume of the d-dimensional unit ball. Then

$$\mathrm{vol}(A_1') = \omega_d r^d, \quad \mathrm{vol}(A_2') = \omega_d(r^2 - \delta^2)^{d/2}, \quad \mathrm{vol}(A_1^0) = \omega_d r^2, \quad \mathrm{vol}(A_2^0) = \omega_d(r^2 - {\delta_0}^2)^{d/2},$$

so that

$$\begin{aligned}|\alpha' - \alpha^0| &= \left|\frac{1}{1 + (1-\delta/r)^{d/2}} - \frac{1}{1 + (1-\delta_0/r)^{d/2}}\right| \\ &\le \big|(1-\delta/r)^{d/2} - (1-\delta_0/r)^{d/2}\big|.\end{aligned}$$

Proceeding as when we bounded ζ in the proof of Lemma 23, we get

$$|\alpha' - \alpha^0| \le d\sqrt{|\delta - \delta_0|/r} \le C\sqrt{r}.$$

Hence, we proved that

$$\|\boldsymbol{\Sigma}_T(\boldsymbol{s}) - \boldsymbol{\Sigma}_T^0(\boldsymbol{s})\| \le Cr^{5/2}.$$

We use this inequality, (83), and the triangle inequality, to get

$$\|\boldsymbol{\Sigma}(\boldsymbol{s}) - \boldsymbol{\Sigma}_T^0(\boldsymbol{s})\| \le \|\boldsymbol{\Sigma}(\boldsymbol{s}) - \boldsymbol{\Sigma}_T(\boldsymbol{s})\| + \|\boldsymbol{\Sigma}_T(\boldsymbol{s}) - \boldsymbol{\Sigma}_T^0(\boldsymbol{s})\| \le Cr^{5/2},$$

which is what we needed to prove. □

6.2 Performance Guarantees for Algorithm 2

We deal with the case where there is no noise, that is, $\tau = 0$ in (7), so that the data points are $\boldsymbol{s}_1, \dots, \boldsymbol{s}_N$ and sampled exactly on $S_1 \cup S_2$ according to the uniform distribution. We explain how things change when there is noise, meaning $\tau > 0$, in Section 6.4.

We start with some notation. Let $\Xi_i = \{j \ne i : \boldsymbol{s}_j \in N_r(\boldsymbol{s}_i)\}$, with (random) cardinality $N_i = |\Xi_i|$. For $i \in [n]$, let $K_i = 1$ if $\boldsymbol{s}_i \in S_1$ and $= 2$ otherwise, and let $T_i = T_{S_{K_i}}(\boldsymbol{s}_i)$, which is the tangent subspace associated with data point $\boldsymbol{s}_i$. Let $\boldsymbol{P}_i$ be short for $\boldsymbol{P}_{T_i}$. Let

$$I_\star = \{i : K_j = K_i,\ \forall j \in \Xi_i\},$$

or equivalently,

$$I_\star^c = \{i : \exists j \text{ s.t. } K_j \ne K_i \text{ and } \|\boldsymbol{s}_j - \boldsymbol{s}_i\| \le r\}.$$

Thus $I_\star$ indexes the points whose neighborhoods do not contain points from the other cluster.

We will soon define a constant $C_\bullet$ and will require the following

$$C_\bullet \ge C, \quad r \le \varepsilon/C, \quad \varepsilon \le \eta/C, \quad \eta \le 1/C, \tag{90}$$

for a large enough constant $C \ge 1$ that depends only on S_1 and S_2.

6.2.1 A Concentration Bound for Local Covariances

Objective. *We derive a concentration bound for the local covariances.*

Let $\Xi_i = \{j \ne i : \boldsymbol{s}_j \in N_r(\boldsymbol{s}_i)\}$, with (random) cardinality $N_i = |\Xi_i|$. When there is no noise, $\boldsymbol{C}_i$ is the sample covariance of $\{\boldsymbol{s}_j : j \in \Xi_i\}$. Also, let $\boldsymbol{\Sigma}(\boldsymbol{s})$ denote the covariance matrix of the uniform distribution over $B(\boldsymbol{s}, r) \cap (S_1 \cup S_2)$, and note that $\boldsymbol{\Sigma}_i := \boldsymbol{\Sigma}(\boldsymbol{s}_i) = \mathbb{E}(\boldsymbol{C}_i|\boldsymbol{s}_i)$. Given N_i, $\{\boldsymbol{s}_j : j \in \Xi_i\}$ are uniformly distributed on $B(\boldsymbol{s}_i, r) \cap (S_1 \cup S_2)$, and applying Lemma 22, we get that for any $t > 0$

$$\mathbb{P}\left(\|\boldsymbol{C}_i - \boldsymbol{\Sigma}_i\| > r^2t + 3\kappa r^3 \,\middle|\, \boldsymbol{s}_i, N_i\right) \le C_{22}\exp\left(-\frac{N_i t}{C_{22}}\min\left(t, N_i\right)\right). \tag{91}$$

Assume that $r < 1/(C_{11}\kappa)$ and let $n_\ddagger := nr^d/(2C_{11}/\chi)$ where $\chi := \frac{\mathrm{vol}_d(S_1) \wedge \mathrm{vol}_d(S_2)}{\mathrm{vol}_d(S_1) + \mathrm{vol}_d(S_2)}$. Define

$$\Omega_1 = \{\forall i : N_i > n_\ddagger\}.$$

Note that, for any i,

$$N_i \geq N_i' := \#\{j \neq i : K_i = K_j \text{ and } \boldsymbol{s}_j \in B(\boldsymbol{s}_i, r)\},$$

meaning that N_i' counts the number of neighboring points from the same surface. We have that $\#\{i : K_i = k\} \sim \mathrm{Bin}(n, \chi_k)$ where $\chi_k := \frac{\mathrm{vol}_d(S_k)}{\mathrm{vol}_d(S_1)+\mathrm{vol}_d(S_2)}$, and using a standard concentration inequality for the binomial distribution, there is a numeric constant $C > 0$ such that

$$\mathbb{P}(\#\{i : K_i = k\} \geq \chi n/2) \geq 1 - \exp(-\chi n/C).$$

(We also used the fact that $\chi = \chi_1 \wedge \chi_2$.) With this, we may apply Lemma 11, to get

$$\begin{aligned}\mathbb{P}(\Omega_1^c) &\leq 2\exp(-\chi n/C) + C_{11} r^{-d} \exp(-(\chi n/2) r^d / C_{11}) \\ &\leq Cn \exp(-nr^d/C),\end{aligned}$$

for some other constant $C > 0$. (We used the fact that the left-hand side can be made greater than 1 when $nr^d \leq 1$ by choosing C large enough, so that we may focus on the case where $nr^d \geq 1$.) Define the event

$$\Omega_2 = \Big\{\forall i : \|\boldsymbol{C}_i - \boldsymbol{\Sigma}_i\| \leq r^2\eta/C_\bullet + 3\kappa r^3\Big\},$$

where $C_\bullet$ will be chosen large enough, but fixed, later on. Assume that $n_\ddagger \geq \eta/C_\bullet$. Note that $\eta \leq 1$ by assumption, and we may assume $n_\ddagger$ to be larger than any given constant, for if not, the statement in Theorem 1 is void. Based on the union bound and (91), we have

$$\begin{aligned}\mathbb{P}(\Omega_2^c) &\leq \mathbb{P}(\Omega_2^c|\Omega_1) + \mathbb{P}(\Omega_1^c) \\ &\leq nC_{22}\exp(-n_\ddagger(\eta/C_\bullet)^2/C_{22}) + Cn\exp(-nr^d/C) \\ &\leq Cn\exp(-nr^d\eta^2/C),\end{aligned}$$

for another constant C that depends on $C_\bullet$ and d.

6.2.2 Away from the Intersection

Objective. *We show that there is an appropriate choice of parameters as in Theorem 1 such that, away from the intersection—when confined to $I_\star$—two points belonging to the same surface and within distance ε are neighbors, while two points belonging to different surfaces are not neighbors.*

For $i \in [n]$, let $K_i = 1$ if $\boldsymbol{s}_i \in S_1$ and $= 2$ otherwise. Let $T_i = T_{S_{K_i}}(\boldsymbol{s}_i)$, which is the tangent subspace associated with data point $\boldsymbol{s}_i$. Let

$$I_\star = \{i : K_j = K_i,\ \forall j \in \Xi_i\},$$

or equivalently,

$$I_\star^c = \{i : \exists j \text{ s.t. } K_j \neq K_i \text{ and } \|\boldsymbol{s}_j - \boldsymbol{s}_i\| \leq r\}.$$

By definition, $I_\star$ indexes the points whose neighborhoods do not contain points from the other cluster.

For $i \in I_\star$, let $\boldsymbol{\Sigma}_{T,i}$ denote the covariance of the uniform distribution on $T_i \cap B(\boldsymbol{s}_i, r)$. Applying Lemma 16, this leads to

$$\|\boldsymbol{\Sigma}_i - \boldsymbol{\Sigma}_{T,i}\| \leq C_{16}\kappa r^3, \quad \forall i \in I_\star. \tag{95}$$

Under Ω_2, by the triangle inequality and (95), we have

$$\|\boldsymbol{C}_i - \boldsymbol{\Sigma}_{T,i}\| \leq \|\boldsymbol{C}_i - \boldsymbol{\Sigma}_i\| + \|\boldsymbol{\Sigma}_i - \boldsymbol{\Sigma}_{T,i}\| \leq \zeta r^2, \quad \forall i \in I_\star, \tag{96}$$

where

$$\zeta := \eta/C_\bullet + (3 + C_{16})\kappa r. \tag{97}$$

The inequality (96) leads, via the triangle inequality, to the decisive bound

$$\|\boldsymbol{C}_i - \boldsymbol{C}_j\| \leq \|\boldsymbol{\Sigma}_{T,i} - \boldsymbol{\Sigma}_{T,j}\| + 2\zeta r^2, \qquad \forall i, j \in I_\star. \tag{98}$$

Take $i, j \in I_\star$ such that $K_i = K_j$ and $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq \varepsilon$. Then by Lemma 13, Lemma 18 and Lemma 3, and the triangle inequality, we have

$$\frac{1}{cr^2}\|\boldsymbol{\Sigma}_{T,i} - \boldsymbol{\Sigma}_{T,j}\| = \sin\theta_{\max}(T_i, T_j) \leq 6\kappa\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq 6\kappa\varepsilon, \tag{99}$$

where $c := 1/(d+2)$. This implies that

$$\frac{1}{r^2}\|\boldsymbol{C}_i - \boldsymbol{C}_j\| \leq 6c\kappa\varepsilon + 2\zeta,$$

by the triangle inequality and (98). Therefore, if $\eta > 6c\kappa\varepsilon + 2\zeta$, then any pair of points indexed by $i, j \in I_\star$ from the same cluster and within distance ε are direct neighbors in the graph built by Algorithm 2.

Take $i, j \in I_\star$ such that $K_i \neq K_j$ and $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq \varepsilon$. By Lemma 21,

$$\max\big[\operatorname{dist}(\boldsymbol{s}_i, S_1 \cap S_2), \operatorname{dist}(\boldsymbol{s}_j, S_1 \cap S_2)\big] \leq C_{21}\|\boldsymbol{s}_i - \boldsymbol{s}_j\|.$$

Let $\boldsymbol{z}$ be the mid-point of $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$. By convexity and the display above,

$$\operatorname{dist}(\boldsymbol{z}, S_1 \cap S_2) \leq \frac{1}{2}\operatorname{dist}(\boldsymbol{s}_i, S_1 \cap S_2) + \frac{1}{2}\operatorname{dist}(\boldsymbol{s}_j, S_1 \cap S_2) \leq C_{21}\varepsilon.$$

Assuming $C_{21}\varepsilon < 1/\kappa$, let $\boldsymbol{s} = P_{S_1 \cap S_2}(\boldsymbol{z})$. Then, by the triangle inequality again,

$$\max\big[\|\boldsymbol{s} - \boldsymbol{s}_i\|, \|\boldsymbol{s} - \boldsymbol{s}_j\|\big] \leq \operatorname{dist}(\boldsymbol{z}, S_1 \cap S_2) + \frac{1}{2}\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq C_{21}\varepsilon + \frac{1}{2}\varepsilon.$$

Let T_i' denote the tangent subspace of S_{K_i} at $\boldsymbol{s}$ and let $\boldsymbol{\Sigma}_i'$ be the covariance of the uniform distribution over $T_i' \cap B(\boldsymbol{s}, r)$. Define T_j' and $\boldsymbol{\Sigma}_j'$ similarly. Then, as in (99) we have

$$\frac{1}{cr^2}\|\boldsymbol{\Sigma}_{T,i} - \boldsymbol{\Sigma}_i'\| \leq 6\kappa\|\boldsymbol{s}_i - \boldsymbol{s}\| \leq 6\kappa(C_{21} + 1/2)\varepsilon,$$

and similarly,

$$\frac{1}{cr^2}\|\boldsymbol{\Sigma}_{T,j} - \boldsymbol{\Sigma}_j'\| \leq 6\kappa(C_{21} + 1/2)\varepsilon.$$

Moreover, by Lemma 13 and Lemma 18,

$$\frac{1}{cr^2}\|\mathbf{\Sigma}'_i - \mathbf{\Sigma}'_j\| = \sin\theta_{\max}(T'_i, T'_j) \geq \sin\theta_S,$$

where θ_S is short for $\theta(S_1, S_2)$, defined in (6). Hence, by the triangle inequality,

$$\frac{1}{cr^2}\|\mathbf{\Sigma}_{T,i} - \mathbf{\Sigma}_{T,j}\| \geq \sin\theta_S - 12\kappa(C_{21} + 1/2)\varepsilon,$$

and then

$$\frac{1}{r^2}\|\boldsymbol{C}_i - \boldsymbol{C}_j\| \geq c\sin\theta_S - 12c\kappa(C_{21} + 1/2)\varepsilon - 2\zeta, \tag{100}$$

by the triangle inequality and (98). Therefore, if $\eta < c\sin\theta_S - 12c\kappa(C_{21} + 1/2)\varepsilon - 2\zeta$, then any pair of points indexed by $i, j \in I_\star$ from different clusters are *not* direct neighbors in the graph built by Algorithm 2.

In summary, we would like to choose η such that

$$c\kappa\varepsilon + 2\zeta < \eta < c\sin\theta_S - 12c\kappa(C_{21} + 1/2)\varepsilon - 2\zeta.$$

Recalling the definition of ζ in (97), this holds under (90).

6.2.3 The Different Clusters are Disconnected in the Graph

Objective. *We show that Step 2 in Algorithm 2 eliminates all points $i \notin I_\star$, implying by our conclusion in Section 6.2.2 that the two clusters are not connected in the graph.*

Hence, take $i \notin I_\star$ with $K_i = 1$ (say), so that $\mathrm{dist}(\boldsymbol{s}_i, S_2) \leq r$. By Lemma 21, we have $\mathrm{dist}(\boldsymbol{s}_i, S_1 \cap S_2) \leq C_{21}r$. Assume r is small enough that $C_{21}\kappa r < 1/2$. Let $\boldsymbol{s}^0 = P_{S_1\cap S_2}(\boldsymbol{s}_i)$ and define $T_k^0 = T_{S_k}(\boldsymbol{s}^0)$ for $k \in \{1, 2\}$. For $\boldsymbol{s} \in S_1$ such that $\mathrm{dist}(\boldsymbol{s}, S_2) \leq 2r$, define $\mathbf{\Sigma}_T^0(\boldsymbol{s})$ as in Lemma 27.

Assuming that $\boldsymbol{s}_i \neq \boldsymbol{s}^0$ (which is true with probability one) and $\boldsymbol{s}^0 = 0$ (by translation invariance), let $h = \|\boldsymbol{s}_i - \boldsymbol{s}^0\|$ and $\boldsymbol{v} = (\boldsymbol{s}_i - \boldsymbol{s}^0)/h$. Note that $\boldsymbol{s}_i = h\boldsymbol{v}$. Because $\boldsymbol{v} \perp T_1^0 \cap T_2^0$ by Lemma 1, and that $\theta_{\min}(T_1^0, T_2^0) \geq \theta_S$, we apply Lemma 24 to find $\ell \in h \pm r/2$ such that $\|\mathbf{\Sigma}_T^0(\ell\boldsymbol{v}) - \mathbf{\Sigma}_T^0(h\boldsymbol{v})\| \geq r^2/C_{24}$, where $C_{24} \geq 1$ depends only on θ_S and d. Letting $\tilde{\boldsymbol{s}} = \ell\boldsymbol{v}$, we have $\|\tilde{\boldsymbol{s}} - \boldsymbol{s}_i\| = |h - \ell| \leq r/2$, so that

$$\mathrm{dist}(\tilde{\boldsymbol{s}}, S_2) \leq \|\tilde{\boldsymbol{s}} - \boldsymbol{s}_i\| + \mathrm{dist}(\boldsymbol{s}_i, S_2) \leq r/2 + r \leq 3r/2.$$

By Lemma 21, we have $\mathrm{dist}(\tilde{\boldsymbol{s}}, S_1 \cap S_2) \leq C_{21}2r < 1/\kappa$, and consequently, $P_{S_1\cap S_2}(\tilde{\boldsymbol{s}}) = \boldsymbol{s}^0$, by Lemma 1. Hence, by the triangle inequality and Lemma 27,

$$\begin{aligned}\|\mathbf{\Sigma}(\boldsymbol{s}_i) - \mathbf{\Sigma}(\tilde{\boldsymbol{s}})\| &\geq \|\mathbf{\Sigma}_T^0(\boldsymbol{s}) - \mathbf{\Sigma}_T^0(\tilde{\boldsymbol{s}})\| - \|\mathbf{\Sigma}(\boldsymbol{s}_i) - \mathbf{\Sigma}_T^0(\boldsymbol{s}_i)\| - \|\mathbf{\Sigma}(\tilde{\boldsymbol{s}}) - \mathbf{\Sigma}_T^0(\tilde{\boldsymbol{s}})\| \\ &\geq r^2/C_{24} - 2C_{27}r^{5/2}.\end{aligned}$$

Take any $\bar{\boldsymbol{s}} \in S_1$ such that $\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\| \leq r/2$. By Lemma 23,

$$\|\mathbf{\Sigma}_T^0(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}_T^0(\tilde{\boldsymbol{s}})\| \leq 5dr\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\| + 2\sqrt{r^3\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\|} \leq (5d + 2)r^{3/2}\sqrt{\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\|}.$$

Noting that

$$\mathrm{dist}(\bar{\boldsymbol{s}}, S_2) \leq \|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\| + \mathrm{dist}(\tilde{\boldsymbol{s}}, S_2) \leq r/2 + 3r/2 \leq 2r,$$

we apply the triangle inequality and Lemma 27, and we get

$$\begin{aligned}\|\mathbf{\Sigma}(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}(\tilde{\boldsymbol{s}})\| &\leq \|\mathbf{\Sigma}_T^0(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}_T^0(\tilde{\boldsymbol{s}})\| + \|\mathbf{\Sigma}(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}_T^0(\bar{\boldsymbol{s}})\| + \|\mathbf{\Sigma}(\tilde{\boldsymbol{s}}) - \mathbf{\Sigma}_T^0(\tilde{\boldsymbol{s}})\| \\ &\leq (5d + 2)r^{3/2}\sqrt{\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\|} + 2C_{27}r^{5/2}.\end{aligned}$$

When $\|\bar{\boldsymbol{s}} - \tilde{\boldsymbol{s}}\| \leq r/C_\ddagger$, we have

$$\begin{aligned}\|\mathbf{\Sigma}(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}(\boldsymbol{s}_i)\| &\geq \|\mathbf{\Sigma}(\boldsymbol{s}_i) - \mathbf{\Sigma}(\tilde{\boldsymbol{s}})\| - \|\mathbf{\Sigma}(\bar{\boldsymbol{s}}) - \mathbf{\Sigma}(\tilde{\boldsymbol{s}})\| \\ &\geq r^2\big(1/C_{24} - (5d + 2)/\sqrt{C_\ddagger} - 4C_{27}r^{1/2}\big) \geq r^2/(2C_{24}),\end{aligned}$$

assuming $C_\ddagger$ is large enough and r is small enough. Fixing such a constant $C_\ddagger \geq 2$, define the event

$$\Omega_3 = \bigcap_{k=1}^{2}\Big\{\forall \boldsymbol{s} \in S_k : \#\{i : K_i = k \text{ and } \boldsymbol{s}_i \in B(\boldsymbol{s}, r/C_\ddagger)\} \geq 2\Big\}.$$

By the same arguments bounding $\mathbb{P}(\Omega_1^c)$ in Section 6.2.1, we have that there is a constant C such that, when $r \leq 1/(C\kappa)$,

$$\mathbb{P}(\Omega_3^c) \leq Cn\exp(-nr^d/C).$$

Under Ω_3, there is $\boldsymbol{s}_j \in S_1 \cap B(\tilde{\boldsymbol{s}}, r/C_\ddagger)$. Taking $\bar{\boldsymbol{s}} = \boldsymbol{s}_j$ above, we have that $\|\mathbf{\Sigma}_j - \mathbf{\Sigma}_i\| \geq r^2/(2C_{24})$. Under Ω_2, by the triangle inequality,

$$\begin{aligned}\|\boldsymbol{C}_j - \boldsymbol{C}_i\| &\geq \|\mathbf{\Sigma}_j - \mathbf{\Sigma}_i\| - \|\boldsymbol{C}_i - \mathbf{\Sigma}_i\| - \|\boldsymbol{C}_j - \mathbf{\Sigma}_j\| \\ &\geq r^2/(2C_{24}) - 2r^2\eta/C_\bullet \geq r^2/(3C_{24}),\end{aligned}$$

choosing $C_\bullet$ sufficiently large. (Recall that $\eta \leq 1$ by assumption.) Therefore, choosing η such that $\eta < 1/(3C_{24})$, we see that $\|\boldsymbol{C}_j - \boldsymbol{C}_i\| > \eta r^2$, even though

$$\|\boldsymbol{s}_j - \boldsymbol{s}_i\| \leq \|\boldsymbol{s}_j - \tilde{\boldsymbol{s}}\| + \|\tilde{\boldsymbol{s}} - \boldsymbol{s}_i\| \leq r/C_\ddagger + r/2 \leq r.$$

6.2.4 The Points that are Removed are close to the Intersection

Objective. *We show that the points removed by Step 2 are within distance Cr of the intersection.*

Let $I_\circ = \{i \in I_\star : \Xi_i \cap I_\star\}$. By our choice of parameters in (90), we see that $i \in I_\circ$ is neighbor with any $j \in \Xi_i$, so that i survives Step 2. Hence, the nodes removed at Step 2 are in $I_\circ^c = \{i \in I_\star : \Xi_i \cap I_\star^c \neq \emptyset\} \cup I_\star^c$, with the possibility that some nodes in $I_\circ^c$ survive. Now, for any $i \in I_\star^c$, there is j with $K_j \neq K_i$ such that $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq r$, so by Lemma 21,

$$\mathrm{dist}(\boldsymbol{s}_i, S_1 \cap S_2) \leq C_{21}\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq C_{21}r.$$

And for any $i \in I_\circ \setminus I_\star^c$, there is $j \in I_\star^c$ such that $\|\boldsymbol{s}_j - \boldsymbol{s}_i\| \leq r$, by definition of Ξ_i, so that $\mathrm{dist}(\boldsymbol{s}_i, S_1 \cap S_2) \leq C_{21}r + r$, by the triangle inequality. In fact, we just proved that the last inequality holds for all $i \in I_\circ^c$. Hence, the points removed in Step 2 are within distance $(C_{21} + 1)r$ of $S_1 \cap S_2$.

6.2.5 Each Cluster is (essentially) Connected in the Graph

Objective. *We show that the points that survive Step 2 and belong to the same cluster are connected in the graph, except for possible spurious points within distance Cr of the intersection.*

Take, for example, the cluster generated from sampling S_1. Before we start, we recall that $I_\star^c$ was eliminated in Step 2, so that by our choice of η in (90), to show that two points $\boldsymbol{s}_i, \boldsymbol{s}_j$ sampled from S_1 are neighbors it suffices to show that $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \le \varepsilon$.

Define $R = S_1 \setminus B(S_1 \cap S_2, r')$, where $r' := (C_{21}+2)r$. By our conclusion in Section 6.2.4, we have that

$$\text{any } \boldsymbol{s}_i \in S_1 \text{ such that } \operatorname{dist}(\boldsymbol{s}_i, R) < r \text{ survives Step 2,} \tag{109}$$

so that it suffices to show that the subset of nodes $\{i : \boldsymbol{s}_i \in R\}$ is connected.

Define $W = S_1 \setminus S_2$ and let $\{W_m\}$ denote the connected components of W. (Note that there might only be one, for example, when S_1 and S_2 are circles in dimension $D = 3$, not in the same plane, that intersect at a single point.) Define $R_m = W_m \setminus B(S_1 \cap S_2, r')$. Since $W = \sqcup_m W_m = S_1 \setminus (S_1 \cap S_2)$, we have $R = \sqcup_m R_m$. In fact, when r (and therefore r') is small enough, R_m is connected, and assuming this is the case, $\{R_m\}$ are the connected components of R.

Suppose R_1 and R_2 are two adjacent connected components of R, meaning that $R_1 \cup R_2 \cup S_2$ is connected. We show that there is at least one pair j_1, j_2 of direct neighbors in the graph such that $\boldsymbol{s}_{j_m} \in R_m$. Take $\boldsymbol{s}$ on the connected component of $S_1 \cap S_2$ separating R_1 and R_2. We construct two points, $\boldsymbol{s}^1 \in R_1$ and $\boldsymbol{s}^2 \in R_2$, that are within distance of order ε from $\boldsymbol{s}$, and then select $\boldsymbol{s}_{j_m}$ as the closest data point to $\boldsymbol{s}^m$. Let $T^k = T_{S_k}(\boldsymbol{s})$ and let H be the affine subspace parallel to $(T^1 \cap T^2)^\perp$ passing through $\boldsymbol{s}$. Take $\boldsymbol{t}^m \in P_{T^1}(R_m) \cap H \cap \partial B(\boldsymbol{s}, \varepsilon_1)$, where $\varepsilon_1 := \varepsilon/4$, which exists when ε is sufficiently small. Note that $\boldsymbol{t}^1, \boldsymbol{t}^2 \in T^1$ and assuming that ε is sufficiently small that $\varepsilon_1 < 1/\kappa$, we have $P_{S_1 \cap S_2}(\boldsymbol{t}^m) = \boldsymbol{s}$ by Lemma 1. Define $\boldsymbol{s}^m = P_{T^1}^{-1}(\boldsymbol{t}^m)$ and note that $\boldsymbol{s}^1, \boldsymbol{s}^2 \in S_1$. Lemma 5 not only justifies this construction when $\kappa\varepsilon_1 < 1/C_5$, it also says that $P_{T^1}^{-1}$ has Lipschitz constant bounded by $1 + \kappa\varepsilon_1$, which implies that

$$\|\boldsymbol{s}^m - \boldsymbol{s}\| \le (1 + \kappa\varepsilon_1)\|\boldsymbol{t}^m - \boldsymbol{s}\| = (1 + \kappa\varepsilon_1)\varepsilon_1 \le \varepsilon/3.$$

We also have

$$\begin{aligned}
\operatorname{dist}(\boldsymbol{s}^m, S_1 \cap S_2) &\ge \operatorname{dist}(\boldsymbol{t}^m, S_1 \cap S_2) - \|\boldsymbol{s}^m - \boldsymbol{t}^m\| \\
&= \|\boldsymbol{t}^m - \boldsymbol{s}\| - \|\boldsymbol{s}^m - \boldsymbol{t}^m\| \\
&\ge \varepsilon_1 - \frac{\kappa}{2}\|\boldsymbol{s}^m - \boldsymbol{s}\|^2 \\
&\ge \big(1 - \frac{\kappa}{2}(1 + \kappa\varepsilon_1)^2\varepsilon_1\big)\varepsilon_1 \\
&\ge \varepsilon/5,
\end{aligned}$$

when ε is sufficiently small. We used (10) in the second inequality. We assume r/ε is sufficiently small that $\varepsilon/5 \ge r' + r$. Then under Ω_3, there are j_1, j_2 such that $\boldsymbol{s}_{j_m} \in B(\boldsymbol{s}^m, r) \cap S_1$, and by the triangle inequality, we then have that $\operatorname{dist}(\boldsymbol{s}_{j_m}, S_1 \cap S_2) \ge \varepsilon/5 - r \ge r'$, so

that $\boldsymbol{s}_{j_m} \in R_m$. Moreover,

$$\begin{aligned}
\|\boldsymbol{s}_{j_1} - \boldsymbol{s}_{j_2}\| &\le \|\boldsymbol{s}_{j_1} - \boldsymbol{s}^1\| + \|\boldsymbol{s}^1 - \boldsymbol{s}\| + \|\boldsymbol{s} - \boldsymbol{s}^2\| + \|\boldsymbol{s}^2 - \boldsymbol{s}_{j_2}\| \\
&\le r + \varepsilon/3 + \varepsilon/3 + r \\
&= \frac{2}{3}\varepsilon + 2r \le \varepsilon,
\end{aligned}$$

assuming r/ε is sufficiently small.

Now, we show that the points sampled from any connected component, say R_1, form a connected subgraph. Take $\boldsymbol{s}^1, \dots, \boldsymbol{s}^M$ an r-packing of R_1, so that

$$\bigsqcup_m (R_1 \cap B(\boldsymbol{s}^m, r/2)) \subset R_1 \subset \bigcup_m (R_1 \cap B(\boldsymbol{s}^m, r)).$$

Because R_1 is connected, $\cup_m B(\boldsymbol{s}^m, r)$ is necessarily connected. Under Ω_1, and $C_{26} \ge 2$, all the balls $B(\boldsymbol{s}^m, r), m = 1, \dots, M$, contain at least one $\boldsymbol{s}_i \in S_1$, and any such point survives Step 2, because of $\operatorname{dist}(\boldsymbol{s}_i, R_1) < r$ and (109). Assume $r/\varepsilon \le 1/4$. Then two points $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$ such that $\boldsymbol{s}_i, \boldsymbol{s}_j \in B(\boldsymbol{s}^m, r)$ are connected, since $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \le 2r \le \varepsilon$. And when $B(\boldsymbol{s}^{m_1}, r) \cap B(\boldsymbol{s}^{m_2}, r) \ne \emptyset$, $\boldsymbol{s}_i \in B(\boldsymbol{s}^{m_1}, r)$ and $\boldsymbol{s}_j \in B(\boldsymbol{s}^{m_2}, r)$ are such that $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \le 4r \le \varepsilon$. Hence, the points sampled from R_1 are connected in the graph under Ω_1.

6.2.6 Summary and Conclusion

We worked under the assumption that (90), with a constant C large enough and depending only on S_1 and S_2. This is compatible with the statement of Theorem 1. In Section 6.2.1, we derived a concentration inequality for local covariances. This lead to a uniform bound (defining the event Ω_2) which holds with probability at least $1 - Cn\exp(-nr^d\eta^2/C)$ for some constant $C > 0$. In Section 6.2.2, we showed that among points away from the intersection (indexed by $I_\star$), those that are in the same cluster are neighbors in the graph if they are within distance ε, while those in different clusters cannot be neighbors in the graph. In Section 6.2.3, we showed that Step 2 removes points not indexed by $I_\star$, thus implying that the two clusters are not connected in the graph. In the process, we assumed that an event (denoted Ω_3) held, which happens with probability at least $1 - Cn\exp(-nr^d/C)$ for some constant $C > 0$. In Section 6.2.4, we showed that the points removed in Step 2 are within distance $O(r)$ from the intersection of the surfaces. In Section 6.2.5, we showed that, except for points within distance $O(r)$ of the intersection, two points in the same cluster are connected in the graph.

We conclude that, after Step 4, Algorithm 2 returns two groups, and each group covers an entire cluster except for points within distance $O(r)$ of the intersection. In Step 5, each point removed in Step 2 is included in the group which contains its closest point (in Euclidean distance). Theorem 1 is silent on the accuracy of doing this step. So the proof of Theorem 1, as it relates to Algorithm 2, is complete.

6.3 Performance Guarantees for Algorithm 3

We keep the same notation as in Section 6.2 and go a little faster here as the arguments are parallel. Let d_i denote the estimated dimensionality at point $\boldsymbol{s}_i$, meaning the number

of eigenvalues of $\boldsymbol{C}_i$ exceeding $\sqrt{\eta}\,\|\boldsymbol{C}_i\|$. Recall that $\boldsymbol{Q}_i$ denotes the orthogonal projection onto the top d_i eigenvectors of $\boldsymbol{C}_i$.

6.3.1 Estimation of the Intrinsic Dimension

Objective. *We show that, for $i \in I_\star$, $d_i = d$ (the correct intrinsic dimension) with high probability.*

Take $i \in I_\star$. Under Ω_2, (96) holds, and applying Weyl's inequality (Stewart and Sun, 1990, Cor. IV.4.9), we have

$$|\beta_m(\boldsymbol{C}_i) - \beta_m(\boldsymbol{\Sigma}_{T,i})| \le \zeta r^2, \quad \forall m = 1, \dots, D.$$

By Lemma 13, $\boldsymbol{\Sigma}_{T,i} = cr^2\boldsymbol{P}_i$, so that $\beta_m(\boldsymbol{\Sigma}_{T,i}) = cr^2$ when $m \le d$ and $\beta_m(\boldsymbol{\Sigma}_{T,i}) = 0$ when $m > d$. Hence,

$$\beta_1(\boldsymbol{C}_i) \le (c+\zeta)r^2, \qquad \beta_d(\boldsymbol{C}_i) \ge (c-\zeta)r^2, \qquad \beta_{d+1}(\boldsymbol{C}_i) \le \zeta r^2.$$

This implies that

$$\frac{\beta_d(\boldsymbol{C}_i)}{\beta_1(\boldsymbol{C}_i)} \ge \frac{c-\zeta}{c+\zeta} > \sqrt{\eta}, \qquad \frac{\beta_{d+1}(\boldsymbol{C}_i)}{\beta_1(\boldsymbol{C}_i)} \le \frac{\zeta}{c+\zeta} < \sqrt{\eta},$$

when $\zeta \le \eta/2$ and η is sufficiently small, which is the case under (90). When this is so, $d_i = d$ by definition of d_i. (Note that $\|\boldsymbol{C}_i\| = \beta_1(\boldsymbol{C}_i)$.)

6.3.2 Each Cluster is (essentially) Connected in the Graph

Objective. *We show that each cluster is connected in the graph, except possibly for some points near the intersection.*

Note that the top d eigenvectors of $\boldsymbol{\Sigma}_{T,i}$ generate T_i. Hence, applying Lemma 19, and (96) again, we get that (recall that $c = 1/(d+1)$)

$$\|\boldsymbol{Q}_i - \boldsymbol{P}_i\| \le \frac{\sqrt{2}\,\zeta r^2}{cr^2} = \zeta' := \sqrt{2}(d+2)\zeta, \quad \forall i \in I_\star.$$

This is the equivalent of (96), which leads to the equivalent of (98):

$$\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| \le \frac{1}{cr^2}\|\boldsymbol{\Sigma}_{T,i} - \boldsymbol{\Sigma}_{T,j}\| + 2\zeta', \qquad \forall i, j \in I_\star,$$

using the fact that $\boldsymbol{\Sigma}_{T,i} = cr^2\boldsymbol{P}_i$. When $i, j \in I_\star$ are such that $K_i = K_j$, based on (99), we have

$$\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| \le 6\kappa\varepsilon + 2\zeta'.$$

Hence, when $\eta > 6\kappa\varepsilon + 2\zeta'$ (which is the case under (90)), two nodes $i, j \in I_\star$ such that $K_i = K_j$ and $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \le \varepsilon$ are neighbors in the graph. The arguments provided in Section 6.2.5 now apply in exactly the same way to show that nodes $i \in I_\circ$ such that $K_i = 1$ are connected in the graph. The same is true of nodes $i \in I_\circ$ such that $K_i = 2$.

6.3.3 The Clusters are (essentially) Disconnected in the Graph

Objective. *We show that the two sets of nodes $\{i \in I_\circ : K_i = 1\}$ and $\{i \in I_\circ : K_i = 2\}$—shown to be connected above—are disconnected in the graph.*

When we take $i, j \in I_\star$ such that $K_i \ne K_j$, we have the equivalent of (100), meaning,

$$\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| \ge \sin\theta_S - 12\kappa(C_{21} + 1/2)\varepsilon - 2\zeta'.$$

We choose η smaller than the RHS, so that these nodes are not neighbors in the graph.

We next prove that a point indexed by $I_\star$ is not neighbor to a point near the intersection because of different estimates for the local dimension. Let C denote a positive constant which increases with each appearance. Take $\boldsymbol{s} \in S_1$ such that $\delta(\boldsymbol{s}) := \mathrm{dist}(\boldsymbol{s}, S_2) \le r$. Reinstate the notation used in Section 6.2.3, in particular $\boldsymbol{s}^0$, T_1^0 and T_2^0, as well as $\boldsymbol{\Sigma}_T^0(\boldsymbol{s})$. Define $\boldsymbol{\Sigma}_T(\boldsymbol{s})$ as in Lemma 26. Also, let $T_1' = T_{S_1}(\boldsymbol{s})$ and $T_2' = T_{S_2}(\boldsymbol{s}^2)$ where $\boldsymbol{s}^2 := P_{S_2}(\boldsymbol{s})$. By Lemma 26 and Weyl's inequality, we have

$$\beta_{d+1}(\boldsymbol{\Sigma}(\boldsymbol{s})) \ge \beta_{d+1}(\boldsymbol{\Sigma}_T(\boldsymbol{s})) - C_{26}r^3, \qquad \beta_1(\boldsymbol{\Sigma}(\boldsymbol{s})) \le \beta_1(\boldsymbol{\Sigma}_T(\boldsymbol{s})) + C_{26}r^3,$$

which together with Lemma 25 (and proper scaling), implies that

$$\frac{\beta_{d+1}(\boldsymbol{\Sigma}(\boldsymbol{s}))}{\beta_1(\boldsymbol{\Sigma}(\boldsymbol{s}))} \ge \frac{\frac{c}{8}(1-\cos\theta_{\max}(T_1', T_2'))^2(1-\delta(\boldsymbol{s})^2/r^2)^{d/2+1} - C_{26}r^3}{c + (\delta(\boldsymbol{s})/r)^2(1-\delta(\boldsymbol{s})^2/r^2)^{d/2} + C_{26}r^3}.$$

Then, by the triangle inequality,

$$\theta_{\max}(T_1', T_2') \ge \theta_{\max}(T_1^0, T_2^0) - \theta_{\max}(T_1', T_1^0) - \theta_{\max}(T_2', T_2^0).$$

By definition, $\theta_{\max}(T_1^0, T_2^0) \ge \theta_S$, and by Lemma 3,

$$\theta_{\max}(T_1', T_1^0) \le \sin^{-1}\left(6\kappa\|\boldsymbol{s} - \boldsymbol{s}^0\| \wedge 1\right) \le Cr,$$

and similarly,

$$\theta_{\max}(T_2', T_2^0) \le \sin^{-1}\left(6\kappa\|\boldsymbol{s}^2 - \boldsymbol{s}^0\| \wedge 1\right) \le Cr,$$

because $\|\boldsymbol{s} - \boldsymbol{s}^0\| \le Cr$ by Lemma 21 and then $\|\boldsymbol{s}^2 - \boldsymbol{s}^0\| \le r + \|\boldsymbol{s} - \boldsymbol{s}^0\| \le Cr$. Hence, for r small enough, $\theta_{\max}(T_1', T_2') \ge \theta_S/2$, and furthermore,

$$\frac{\beta_{d+1}(\boldsymbol{\Sigma}(\boldsymbol{s}))}{\beta_1(\boldsymbol{\Sigma}(\boldsymbol{s}))} \ge \sqrt{\eta} \quad \text{when} \quad 1 - \delta(\boldsymbol{s})^2/r^2 \ge \xi := C_*\eta^{1/(d+2)}, \tag{118}$$

where C_* is a large enough constant, assuming r/η and η are small enough. The same is true for points on $\boldsymbol{s} \in S_2$ if we redefine $\delta(\boldsymbol{s}) = \mathrm{dist}(\boldsymbol{s}, S_1)$. Hence, for $\boldsymbol{s}_i$ close enough to the intersection that $\delta(\boldsymbol{s}_i)$ satisfies (118), $d_i > d$. Then, by Lemma 18, $\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| = 1$ for any $j \in I_\star$. By our choice of $\eta < 1$, this means that i and j are not neighbors.

So the only way $\{i \in I_\star : K_i = 1\}$ and $\{i \in I_\star : K_i = 2\}$ are connected in the graph is if there are $\boldsymbol{s}_i \in S_1$ and $\boldsymbol{s}_j \in S_2$ such that $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| \le \varepsilon$ and both $\delta(\boldsymbol{s}_i)$ and $\delta(\boldsymbol{s}_j)$ fail to satisfy (118). We now show this is not possible. Let $\boldsymbol{\Sigma}_{T,i} = \boldsymbol{\Sigma}_T(\boldsymbol{s}_i)$ and define $\boldsymbol{\Sigma}_{T,j}$ similarly. (These are well-defined when $\varepsilon < 1/\kappa$, which we assume.) By Lemma 26, we have

$$\|\boldsymbol{\Sigma}_i - \boldsymbol{\Sigma}_{T,i}\| \le C_{26}\, r^3. \tag{119}$$

Define $\alpha_i = (1+t_i^d)^{-1}$ with $t_i := (1-\delta^2(\boldsymbol{s}_i))_+^{1/2}$. As in (77), with the triangle inequality, we get

$$\begin{aligned}\|\boldsymbol{\Sigma}_{T,i} - \alpha_i c r^2 \boldsymbol{P}_i\| &\leq c(1-\alpha_i)t_i^2 r^2 + \alpha_i(1-\alpha_i)\delta^2(\boldsymbol{s}_i) \\ &\leq 2(1-\alpha_i)r^2 \leq 2(1-\delta(\boldsymbol{s}_i)^2/r^2)_+^{d/2} r^2 \leq 2\xi^{d/2} r^2,\end{aligned}$$

where the second inequality we used the fact that $\alpha_i = 1$ if $\delta(\boldsymbol{s}_i) > r$, and in very last inequality comes from $\delta(\boldsymbol{s}_i)$ not satisfying (118). Hence, under Ω_2, with (119) and the triangle inequality, we get

$$\|\boldsymbol{C}_i - \alpha_i c r^2 \boldsymbol{P}_i\| \leq r^2\eta/C_\bullet + 3\kappa r^3 + 2\xi^{d/2} r^2 + C_{26}\, r^3.$$

Since $\beta_d(\boldsymbol{P}_i) = 1$ and $\beta_{d+1}(\boldsymbol{P}_i) = 0$, by Lemma 19, we have

$$\|\boldsymbol{Q}_i - \boldsymbol{P}_i\| \leq \frac{1}{\alpha_i c r^2}\left[r^2\eta/C_\bullet + 2\xi^{d/2} r^2 + (3\kappa + C_{26})r^3\right] \leq C(\eta/C_\bullet + \xi^{d/2} + r).$$

Similarly,

$$\|\boldsymbol{Q}_j - \boldsymbol{P}_j\| \leq C(\eta/C_\bullet + \xi^{d/2} + r).$$

By Lemma 18, $\|\boldsymbol{P}_i - \boldsymbol{P}_j\| = \sin\theta_{\max}(T_i, T_j)$. Let $\boldsymbol{s}^0 = P_{S_1\cap S_2}(\boldsymbol{s}_i)$, and define T_1^0 and T_2^0 as before. Not that $\|\boldsymbol{s}_i - \boldsymbol{s}^0\| \leq C\varepsilon$ by Lemma 21 and the fact that $\mathrm{dist}(\boldsymbol{s}_i, S_2) \leq \|\boldsymbol{s}_i - \boldsymbol{s}_j\| \leq \varepsilon$. Also, $\|\boldsymbol{s}_j - \boldsymbol{s}^0\| \leq \|\boldsymbol{s}_i - \boldsymbol{s}^0\| + \|\boldsymbol{s}_j - \boldsymbol{s}_i\| \leq C\varepsilon$. We then have

$$\theta_{\max}(T_i, T_j) \geq \theta_{\max}(T_1^0, T_2^0) - \theta_{\max}(T_i, T_1^0) - \theta_{\max}(T_j, T_2^0) \geq \theta_S - C\varepsilon,$$

by Lemma 3. Hence, by the triangle inequality,

$$\begin{aligned}\|\boldsymbol{Q}_i - \boldsymbol{Q}_j\| &\geq \|\boldsymbol{P}_i - \boldsymbol{P}_j\| - \|\boldsymbol{Q}_i - \boldsymbol{P}_i\| - \|\boldsymbol{Q}_j - \boldsymbol{P}_j\| \\ &\geq \sin(\theta_S - C\varepsilon) - C(\eta/C_\bullet + \xi^{d/2} + r) \geq \frac{1}{2}\sin\theta_S > \eta,\end{aligned}$$

when the constant in (90) is large enough. (Recall the definition of ξ above.) Therefore i and j are not neighbors, as we needed to show.

6.4 Noisy Case

So far we only dealt with the case where $\tau = 0$ in (7). When $\tau > 0$, a sample point $\boldsymbol{x}_i$ is in general different than its corresponding point $\boldsymbol{s}_i$ sampled from one of the surfaces. However, when τ/r is small, this does not change things much. For one thing, the points are close to each other, since we have $\|\boldsymbol{x}_i - \boldsymbol{s}_i\| \leq \tau$ by assumption, and τ is small compared to r. And the corresponding covariance matrices are also close to each other. To see this, redefine $\Xi_i = \{j \neq i : \boldsymbol{x}_j \in N_r(\boldsymbol{x}_i)\}$ and $\boldsymbol{C}_i$ as the sample covariance of $\{\boldsymbol{x}_j : j \in \Xi_i\}$. Let $\boldsymbol{D}_i$ denote the sample covariance of $\{\boldsymbol{s}_j : j \in \Xi_i\}$. Let X be uniform over $\{\boldsymbol{x}_j : j \in \Xi_i\}$ and define $Y = \sum_j \boldsymbol{s}_j \mathbb{1}_{\{X=\boldsymbol{x}_j\}}$. Starting from (33), we have

$$\begin{aligned}\|\boldsymbol{D}_i - \boldsymbol{C}_i\| &= \|\operatorname{Cov}(X) - \operatorname{Cov}(Y)\| \\ &\leq \mathbb{E}\left[\|X-Y\|^2\right]^{1/2} \cdot \left(\mathbb{E}\left[\|X-\boldsymbol{x}_i\|^2\right]^{1/2} + \mathbb{E}\left[\|Y-\boldsymbol{x}_i\|^2\right]^{1/2}\right) \\ &\leq \tau\cdot(r+(r+\tau)) = r^2\big(2\tau/r + (\tau/r)^2\big),\end{aligned}$$

which is small compared to r^2, and r^2 is the operating scale for covariance matrices in our setting.

Using these facts, the arguments are virtually the same, except for some additional terms due to triangle inequalities, for example, $\|\boldsymbol{s}_i - \boldsymbol{s}_j\| - 2\tau \leq \|\boldsymbol{x}_i - \boldsymbol{x}_j\| \leq \|\boldsymbol{s}_i - \boldsymbol{s}_j\| + 2\tau$. In particular, this results in ζ in (97) being now redefined as $\zeta = \frac{3\tau}{r} + \eta/C_\bullet + (3 + C_{16})\kappa r$. We omit further technical details.

Acknowledgments

This work was partially supported by grants from the National Science Foundation (DMS 0915160, 0915064, 0956072, 1418386, 1513465). We would like to thank Jan Rataj for helpful discussion around Lemma 3 and Xu Wang for his sharp proofreading. We also gratefully acknowledge the comments, suggestions, and scrutiny of an anonymous referee. We would also like to acknowledge support from the Institute for Mathematics and its Applications (IMA). For one thing, the authors first learned about the research of Goldberg et al. (2009) there, at the *Multi-Manifold Data Modeling and Applications* workshop in the Fall of 2008, and this was the main inspiration for our paper. Also, part of our work was performed while TZ was a postdoctoral fellow at the IMA, and also while EAC and GL were visiting the IMA.

Abstract

We study a version of the proximal gradient algorithm for which the gradient is intractable and is approximated by Monte Carlo methods (and in particular Markov Chain Monte Carlo). We derive conditions on the step size and the Monte Carlo batch size under which convergence is guaranteed: both increasing batch size and constant batch size are considered. We also derive non-asymptotic bounds for an averaged version. Our results cover both the cases of biased and unbiased Monte Carlo approximation. To support our findings, we discuss the inference of a sparse generalized linear model with random effect and the problem of learning the edge structure and parameters of sparse undirected graphical models.

Keywords: Proximal Gradient Methods; Stochastic Optimization; Monte Carlo approximations; Perturbed Majorization-Minimization algorithms.

1. Introduction

This paper deals with statistical optimization problems of the form:

$$\textbf{(P)} \quad \min_{\theta\in\mathbb{R}^d} F(\theta) \qquad \text{with } F = f + g \; .$$

This problem occurs in a variety of statistical and machine learning problems, where f is a measure of fit depending implicitly on some observed data and g is a regularization term that imposes structure to the solution. Typically, f is a differentiable function with a Lipschitz gradient, whereas g might be non-smooth (typical examples include sparsity inducing penalty).

H1 *The function $g:\ \mathbb{R}^d \to [0,+\infty]$ is convex, not identically $+\infty$, and lower semi-continuous. The function $f:\mathbb{R}^d\to\mathbb{R}$ is convex, continuously differentiable on $\mathbb{R}^d$ and there exists a finite non-negative constant L such that, for all $\theta,\theta'\in\mathbb{R}^d$,*

$$\|\nabla f(\theta) - \nabla f(\theta')\| \le L\|\theta-\theta'\| \; ,$$

where ∇f denotes the gradient of f.

We denote by Θ the domain of g: $\Theta \stackrel{\text{def}}{=} \{\theta\in\mathbb{R}^d : g(\theta) < \infty\}$.

H2 *The set $\operatorname{argmin}_{\theta\in\Theta} F(\theta)$ is a non empty subset of Θ.*

In this paper, we focus on the case where $f+g$ and ∇f are both intractable. This setting has not been widely considered despite the considerable importance of such models in statistics and machine learning. Intractable likelihood problems naturally occur for example in inference for bayesian networks (e.g. learning the edge structure and the parameters in an undirected graphical models), regression with latent variables or random effets, missing data, etc... In such applications, f is the negated log-likelihood of a conditional Gibbs measure π_θ known only up to a normalization constant and the gradient of $\nabla f(\theta)$ is typically expressed as a very high-dimensional integral w.r.t. the associated Gibbs measure $\nabla f(\theta) = \int H_\theta(x)\pi_\theta(\mathrm{d}x)$. Of course, this integral cannot be computed in closed form and should be approximated. Most often, some forms of Monte Carlo integration (such as Markov Chain Monte Carlo, or MCMC) is the only option.

To cope with problems where $f+g$ is intractable and possibly non-smooth, various methods have been proposed. Some of these works focused on stochastic sub-gradient and mirror descent algorithms; see Nemirovski et al. (2008); Duchi et al. (2011); Cotter et al. (2011); Lan (2012); Juditsky and Nemirovski (2012a,b). Other authors have proposed algorithms based on proximal operators to better exploit the smoothness of f and the properties of g (see e.g. Combettes and Wajs (2005); Hu et al. (2009); Xiao (2010); Juditsky and Nemirovski (2012a,b)).

The current paper focuses on the proximal gradient algorithm (see e.g. Beck and Teboulle (2010); Combettes and Pesquet (2011); Parikh and Boyd (2013) for literature review and further references). The proximal map (Moreau (1962)) associated to g is defined for $\gamma>0$ and $\theta\in\mathbb{R}^d$ by:

$$\operatorname{Prox}_{\gamma,g}(\theta) \stackrel{\text{def}}{=} \operatorname{argmin}_{\vartheta\in\Theta}\left\{ g(\vartheta) + \frac{1}{2\gamma}\|\vartheta-\theta\|^2 \right\}. \tag{1}$$

Note that under H1, there exists an unique point ϑ minimizing the RHS of (1) for any $\theta\in\mathbb{R}^d$ and $\gamma>0$. The proximal gradient algorithm is an iterative algorithm which, given an initial value $\theta_0\in\Theta$ and a sequence of positive step sizes $\{\gamma_n, n\in\mathbb{N}\}$, produces a sequence of parameters $\{\theta_n, n\in\mathbb{N}\}$ as follows:

Algorithm 1 (Proximal gradient algorithm) *Given θ_n, compute*

$$\theta_{n+1} = \operatorname{Prox}_{\gamma_{n+1},g}\left(\theta_n - \gamma_{n+1}\nabla f(\theta_n)\right) \; . \tag{2}$$

When $\gamma_n=\gamma$ for any n, it is known that the iterates of the proximal gradient algorithm $\{\theta_n, n\in\mathbb{N}\}$ (Algorithm 1) converges to θ_∞, this point is a fixed point of the proximal-gradient map

$$T_\gamma(\theta) \stackrel{\text{def}}{=} \operatorname{Prox}_{\gamma,g}\left(\theta - \gamma\nabla f(\theta)\right) \; . \tag{3}$$

Under H1 and H2, when $\gamma_n \, (0, 2/L]$ and $\inf_n \gamma_n > 0$, it is indeed known that the iterates of the proximal gradient algorithm $\{\theta_n,\, n \in \mathbb{N}\}$ defined in (2) converges to a point in the set $\mathcal{L}$ of the solutions of (P) which coincides with the fixed points of the mapping T_γ for any $\gamma \in (0, 2/L)$

$$\mathcal{L} \stackrel{\text{def}}{=} \operatorname{argmin}_{\theta\in\Theta} F(\theta) = \{\theta \in \Theta : \theta = T_\gamma(\theta)\} \; . \tag{4}$$

(see e.g. (Combettes and Wajs, 2005, Theorem 3.4. and Proposition 3.1.(iii))).

Since $\nabla f(\theta)$ is intractable, the gradient $\nabla f(\theta_n)$ at n-th iteration is replaced by an approximation H_{n+1}:

Algorithm 2 (Perturbed Proximal Gradient algorithm) *Let $\theta_0 \in \Theta$ be the initial solution and $\{\gamma_n,\, n \in \mathbb{N}\}$ be a sequence of posi–tive step–sizes. For $n \geq 1$, given $(\theta_0, \ldots, \theta_n)$ construct an approximation H_{n+1} of $\nabla f(\theta_n)$ and compute*

$$\theta_{n+1} = \operatorname{Prox}_{\gamma_{n+1},g} \left(\theta_n - \gamma_{n+1} H_{n+1}\right) \; . \tag{5}$$

We provide in Theorem 2 sufficient conditions on the perturbation $\eta_{n+1} = H_{n+1} - \nabla f(\theta_n)$ to obtain the convergence of the perturbed proximal gradient sequence given by (5). We then consider an averaging scheme of the perturbed proximal gradient algorithm: given non-negative weights $\{a_n,\, n \in \mathbb{N}\}$, Theorem 3 provides non-asymptotic bound of the deviation between $\sum_{k=1}^n a_k F(\theta_k) / \sum_{k=1}^n a_k$ and the minimum of F. Our results complement and extend Rosasco et al. (2014); Nitanda (2014); Xiao and Zhang (2014).

We then consider the case where the gradient $\nabla f(\theta) = \int_{\mathsf{X}} H_\theta(x) \pi_\theta(\mathrm{d}x)$ is defined as an expectation (see H3 in section 3). In this case, at each iteration $\nabla f(\theta_n)$ is approximated by a Monte Carlo average $H_{n+1} = m_{n+1}^{-1} \sum_{j=1}^{m_{n+1}} H_{\theta_n}(X_{n+1}^{(j)})$ where m_{n+1} is the size of the Monte Carlo batch and $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ is the Monte Carlo batch. Two different settings are covered. In the first setting, the samples $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ are conditionally independent and identically distributed (i.i.d.) with distribution π_{θ_n}. In such case, the conditional expectation of H_{n+1} given all the past iterations, denoted by $\mathbb{E}\left[H_{n+1} \,|\, \mathcal{F}_n\right]$ (see section 3), is equal to $\nabla f(\theta_n)$. In the second setting, the Monte Carlo batch $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ is produced by running a MCMC algorithm. In such case, the conditional distribution of $X_{n+1}^{(j)}$ given the past is no longer exactly equal to π_{θ_n} which implies that $\mathbb{E}\left[H_{n+1} \,|\, \mathcal{F}_n\right] \neq \nabla f(\theta_n)$.

Theorem 4 (resp. Theorem 6) establish the convergence of the sequence $\{\theta_n, n \in \mathbb{N}\}$ when the batch size m_n is either fixed or increases with the number of iterations n. When the Monte Carlo batch $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ is i.i.d. conditionally to the past the two theorems essentially say that with probability one, $\{\theta_n, n \in \mathbb{N}\}$ converges to an element of the set of minimizer $\mathcal{L}$ as soon as $\sum_n \gamma_n = +\infty$ and $\sum_n \gamma_{n+1}^2 / m_{n+1} < \infty$. Hence, one can choose either a fixed step size $\gamma_n = \gamma$ and a batch size $\{m_n, n \in \mathbb{N}\}$ increasing at least linearly (up to a logarithmic factor); or a decreasing step size and a fixed batch size $m_n = m$. When $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ is produced by a MCMC algorithm (under appropriate assumptions) our theorems essentially say that the same convergence result holds if $\sum_n \gamma_n = \infty$ and $\sum_n \gamma_{n+1}^2 < \infty$ when $m_n = m$ is constant across iterations or $\sum_n \gamma_{n+1} / m_{n+1} < \infty$ if the batch size is increased.

Theorem 4 and Theorem 6 also provide non asymptotic bounds for the difference $\Delta_n = \sum_{k=1}^n a_k F(\theta_k) / \sum_{k=1}^n a_k - \min F$ in L^q-norm for $q \geq 1$. When the batch size sequence m_{n+1} increases linearly at each iteration while the step size γ_{n+1} is held constant, $\Delta_n = O(\ln n / n)$. We recover (up to a logarithmic factor) the rate of the proximal gradient algorithm. If we now compare the complexity of the algorithms in terms of the number of simulations N needed (and not the number of iterations), the error bound decreases like $O(N^{-1/2})$. The same error bound can be achieved by choosing a fixed batch size and a decreasing step size $\gamma_n = O(1/\sqrt{n})$.

In section 4, these results are illustrated with the problem of estimating a high-dimensional discrete graphical models. In section 5, we consider high-dimensional random effect logistic regression model. All the proofs are postponed to section 6.

2. Perturbed proximal gradient algorithms

The key property to study the behavior of the sequence the perturbed proximal gradient algorithm is the following elementary lemma which might be seen as a deterministic version of the Robbins-Siegmund lemma (see e.g. (Polyak, 1987, Lemma 11, Chapter 2)). It replaces in our analysis (Combettes, 2001, Lemma 3.1) for quasi-Fejer sequences and modified Fejer monotone sequences (see Lin et al. (2015)). Compared to the Robbins-Siegmund Lemma, the sequence $(\xi_n)_n$ is not assumed to be nonnegative. When applied in the stochastic context as in Section 3, the fact that the result is purely deterministic and deals with signed perturbations ξ_n allows more flexibility in the study of the dynamics.

Lemma 1 *Let $\{v_n,\, n \in \mathbb{N}\}$ and $\{\chi_n,\, n \in \mathbb{N}\}$ be non-negative sequences and $\{\xi_n,\, n \in \mathbb{N}\}$ be such that $\sum_n \xi_n$ exists. If for any $n \geq 0$,*

$$v_{n+1} \leq v_n - \chi_{n+1} + \xi_{n+1}$$

then $\sum_n \chi_n < \infty$ and $\lim_n v_n$ exists.

Proof See Section 6.2.1 ∎

Applied with $v_n = \|\theta_n - \theta_\star\|$ for some $\theta_\star \in \mathcal{L}$, this lemma is the key result for the proof of the following theorem, which provides sufficient conditions on the stepsize sequence $\{\gamma_n,\, n \in \mathbb{N}\}$ and on the *approximation error*:

$$\eta_{n+1} \stackrel{\text{def}}{=} H_{n+1} - \nabla f(\theta_n) \; , \tag{6}$$

for the sequence $\{\theta_n,\, n \in \mathbb{N}\}$ to converge to a point θ_∞ in the set $\mathcal{L}$ of the minimizers of F. Denote by $\langle \cdot, \cdot \rangle$ the usual inner product on $\mathbb{R}^d$ associated to the norm $\|\cdot\|$.

Theorem 2 *Assume H1 and H2. Let $\{\theta_n,\, n \in \mathbb{N}\}$ be given by Algorithm 2 with step sizes satisfying $\gamma_n \in (0, 1/L]$ for any $n \geq 1$ and $\sum_n \gamma_n = +\infty$. If the following series converge*

$$\sum_{n\geq 0} \gamma_{n+1} \left\langle T_{\gamma_{n+1}}(\theta_n), \eta_{n+1} \right\rangle \; , \quad \sum_{n\geq 0} \gamma_{n+1} \eta_{n+1} \; , \quad \sum_{n\geq 0} \gamma_{n+1}^2 \|\eta_{n+1}\|^2 \; , \tag{7}$$

then there exists $\theta_\infty \in \mathcal{L}$ such that $\lim_n \theta_n = \theta_\infty$.

Proof See Section 6.2.2. ■

Theorem 2 applied with $\eta_{n+1} = 0$ provides sufficient conditions for the convergence of Algorithm 1 to $\mathcal{L}$: the algorithm converges as soon as $\gamma_n \in (0, 1/L]$ and $\sum_n \gamma_n = +\infty$.

Sufficient conditions for the convergence of $\{\theta_n,\ n \in \mathbb{N}\}$ are also provided in Combettes and Wajs (2005). When applied to our settings (Combettes and Wajs, 2005, Theorem 3.4.) requires $\sum_n \|\eta_{n+1}\| < \infty$ and $\inf_n \gamma_n > 0$, which for instance cannot accommodate the fixed Monte Carlo batch size stochastic algorithms considered in this paper. The same limitation applies to the analysis of the stochastic quasi-Fejer iterations (see Combettes and Pesquet (2015a)) which in our particular case requires $\sum_n \gamma_{n+1}\|\eta_{n+1}\| < \infty$. These conditions are weakened in Theorem 2. However in all fairness we should mention that unlike the present work, Combettes and Wajs (2005) and Combettes and Pesquet (2015a) deal with infinite-dimensional problems which raises additional technical difficulties, and study algorithms that include a relaxation parameter. Furthermore, in the case where $\eta_n \equiv 0$, larger values of the stepsize γ_n are allowed ($\gamma_n \in (0, 2/L]$).

Let $\{a_0, \cdots, a_n\}$ be non-negative real numbers. Theorem 3 provides a control of the weighted sum $\sum_{k=1}^n a_k(F(\theta_k) - \min F)$.

Theorem 3 *Assume H1 and H2. Let $\{\theta_n,\ n \in \mathbb{N}\}$ be given by Algorithm 2 with $\gamma_n \in (0, 1/L]$ for any $n \geq 1$. For any non-negative weights $\{a_0, \cdots, a_n\}$, any $\theta_\star \in \mathcal{L}$ and any $n \geq 1$,*

$$\sum_{k=1}^n a_k \left\{F(\theta_k) - \min F\right\} \leq U_n(\theta_\star)$$

where T_γ and η_n are given by (3) and (6) respectively and

$$U_n(\theta_\star) \stackrel{\text{def}}{=} \frac{1}{2}\sum_{k=1}^n \left(\frac{a_k}{\gamma_k} - \frac{a_{k-1}}{\gamma_{k-1}}\right)\|\theta_{k-1} - \theta_\star\|^2 + \frac{a_0}{2\gamma_0}\|\theta_0 - \theta_\star\|^2 - \sum_{k=1}^n a_k \left\langle T_{\gamma_k}(\theta_{k-1}) - \theta_\star, \eta_k\right\rangle + \sum_{k=1}^n a_k\gamma_k\|\eta_k\|^2 \,. \quad (8)$$

Proof See Section 6.2.3. ■

When applied with $\eta_n = 0$, Theorem 3 gives an explicit bound of the difference $\Delta_n = A_n^{-1}\sum_{j=1}^n a_j F(\theta_j) - \min F$ where $A_n = \sum_{k=1}^n a_k$ for the (exact) proximal gradient sequence $\{\theta_n,\ n \in \mathbb{N}\}$ given by Algorithm 1. When the sequence $\{a_n/\gamma_n, n \geq 1\}$ is non decreasing, (8) shows that $\Delta_n = O(a_n A_n^{-1}\gamma_n^{-1})$.

Taking $a_k = 1$ for any $k \geq 0$ provides a bound for the cumulative regret. When $a_k = 1$, $\gamma_k = 1/L$ for any $k \geq 0$, (Schmidt et al., 2011, Proposition 1) provides a bound of order $O(1)$ under the assumption that $\sum_n \|\eta_{n+1}\| < \infty$. Using the inequality $|\left\langle T_{1/L}(\theta_k) - \theta_\star, \eta_{k+1}\right\rangle| \leq \|\theta_k - \theta_\star\|\|\eta_{k+1}\|$ (see Lemma 9), the upper bound $U_n(\theta_\star)$ in (8) is also $O(1)$.

When $a_n = \gamma_n$ for any $n \geq 0$, then $\sup_n U_n(\theta_\star) < \infty$ under the assumptions that the series

$$\sum_n \gamma_n \left\langle T_{\gamma_n}(\theta_{n-1}) - \theta_\star, \eta_n\right\rangle \,, \qquad \sum_n \gamma_n^2\|\eta_n\|^2 \,,$$

converge. In this case, we have

$$\left(\frac{\sum_{k=1}^n \gamma_k F(\theta_k)}{\sum_{k=1}^n \gamma_k} - \min F\right) = O\left(\left(\sum_{k=1}^n \gamma_k\right)^{-1}\right).$$

Consider the weighted averaged sequence $\{\bar{\theta}_n,\ n \in \mathbb{N}\}$ defined by

$$\bar{\theta}_n \stackrel{\text{def}}{=} \frac{1}{A_n}\sum_{k=1}^n a_k\theta_k \,. \quad (9)$$

Under H1 and H2, F is convex so that $F\left(\bar{\theta}_n\right) \leq A_n^{-1}\sum_{k=1}^n a_k F(\theta_k)$. Therefore, Theorem 3 also provides convergence rates for $F(\bar{\theta}_n) - \min F$.

3. Stochastic Proximal Gradient algorithm

In this section, it is assumed that H_{n+1} is a Monte Carlo approximation of $\nabla f(\theta_n)$, where $\nabla f(\theta)$ satisfies the following assumption:

H3 *for all $\theta \in \Theta$,*

$$\nabla f(\theta) = \int_{\mathsf{X}} H_\theta(x)\pi_\theta(\mathrm{d}x) \,, \quad (10)$$

for some probability measure π_θ on a measurable space $(\mathsf{X}, \mathcal{X})$ and an integrable function $(\theta, x) \mapsto H_\theta(x)$ from $\Theta \times \mathsf{X}$ to Θ.

Note that X is not necessarily a topological space, even if, in many applications, $\mathsf{X} \subseteq \mathbb{R}^d$.

Assumption H3 holds in many problems (see section 4 and section 5). To approximate $\nabla f(\theta)$, several options are available. Of course, when the dimension of the state space X is small to moderate, it is always possible to perform a numerical integration using either Gaussian quadratures or low-discrepancy sequences. Another possibility is to approximate these integrals: nested Laplace approximations have been considered recently for example in Schelldorfer et al. (2014) and further developed in Ogden (2015). Such approximations necessarily introduce some bias, which might be difficult to control. In addition, these techniques are not applicable when the dimension of the state space X becomes large. In this paper, we rather consider some form of Monte Carlo approximation.

When sampling π_θ is doable, then an obvious choice is to use a naive Monte Carlo estimator which amounts to sample a batch $\{X_{n+1}^{(j)}, 1 \leq j \leq m_{n+1}\}$ independently of the past values of the parameters $\{\theta_j, j \leq n\}$ and of the past draws i.e. independently of the σ-algebra

$$\mathcal{F}_n \stackrel{\text{def}}{=} \sigma(\theta_0, X_k^{(j)}, 0 \leq k \leq n, 0 \leq j \leq m_k) \,. \quad (11)$$

We then form

$$H_{n+1} = m_{n+1}^{-1}\sum_{j=1}^{m_{n+1}} H_{\theta_n}(X_{n+1}^{(j)}) \,.$$

Conditionally to $\mathcal{F}_n$, H_{n+1} is an unbiased estimator of $\nabla f(\theta_n)$. The batch size m_{n+1} can either be chosen to be fixed across iterations or to increase with n at a certain rate. In the first case, H_{n+1} is not converging. In the second case, the approximation error is vanishing. The fixed batch-size case is closely related to Robbins-Monro stochastic approximation (the mitigation of the error is performed by letting the stepsize $\gamma_n \to 0$); the increasing batch-size case is related to Monte Carlo assisted optimization; see for example Geyer (1994).

The situation that we are facing in section 4 and section 5 is more complicated because direct sampling from π_θ is not an option. Nevertheless, it is fairly easy to construct a Markov kernel P_θ with invariant distribution π_θ. Monte Carlo Markov Chains (MCMC) provide a set of principled tools to sample from complex distributions over large dimensional spaces. In such case, conditional to the past, $\{X_{n+1}^{(j)}, 1 \le j \le m_{n+1}\}$ is a realization of a Markov chain with transition kernel P_{θ_n} and started from $X_n^{(m_n)}$ (the last sample draws in the previous minibatch).

Recall that a Markov kernel P is an application on $\mathsf{X} \times \mathcal{X}$, taking values in $[0,1]$ such that for any $x \in \mathsf{X}$, $P(x,\cdot)$ is a probability measure on $\mathcal{X}$; and for any $A \in \mathcal{X}$, $x \mapsto P(x,A)$ is measurable. Furthermore, if P is a Markov kernel on X, we denote by P^k the k-th iterate of P defined recursively as $P^0(x,A) \stackrel{\text{def}}{=} \mathbb{1}_A(x)$, and $P^k(x,A) \stackrel{\text{def}}{=} \int P^{k-1}(x,\mathrm{d}z)P(z,A)$, $k \ge 1$. Finally, the kernel P acts on probability measure: for any probability measure μ on $\mathcal{X}$, μP is a probability measure defined by

$$\mu P(A) \stackrel{\text{def}}{=} \int \mu(\mathrm{d}x)P(x,A), \qquad A \in \mathcal{X};$$

and P acts on positive measurable functions: for a measurable function $f : \mathsf{X} \to \mathbb{R}_+$, Pf is a function defined by

$$Pf(x) \stackrel{\text{def}}{=} \int f(y)\, P(x,\mathrm{d}y).$$

We refer the reader to Meyn and Tweedie (2009) for the definitions and basic properties of Markov chains.

In this Markovian setting, it is possible to consider the fixed batch case and the increasing batch case. From a mathematical standpoint, the fixed batch case is trickier, because H_{n+1} is no longer an unbiased estimator of $\nabla f(\theta_n)$, i.e. the bias B_n defined by

$$\begin{aligned} B_n \stackrel{\text{def}}{=} \mathbb{E}\left[H_{n+1} \,|\, \mathcal{F}_n\right] - \nabla f(\theta_n) &= m_{n+1}^{-1} \textstyle\sum_{j=1}^{m_{n+1}} \mathbb{E}\left[H_{\theta_n}(X_{n+1}^{(j)}) \,\middle|\, \mathcal{F}_n \right] - \nabla f(\theta_n) \\ &= m_{n+1}^{-1} \textstyle\sum_{j=1}^{m_{n+1}} P_{\theta_n}^j H_{\theta_n}(X_{n+1}^{(0)}) - \nabla f(\theta_n)\,, \end{aligned} \quad (12)$$

does not vanish. When $m_n = m$ is small, the bias can even be pretty large, and the way the bias is mitigated in the algorithm requires substantial mathematical developments, which are not covered by the results currently available in the literature (see e.g. Combettes and Pesquet (2015a); Rosasco et al. (2014); Combettes and Pesquet (2015b); Rosasco et al. (2015); Lin et al. (2015)).

To capture in a common unifying framework these two different situations we assume that

H4 *H_{n+1} is a Monte Carlo approximation of the expectation $\nabla f(\theta_n)$:*

$$H_{n+1} = m_{n+1}^{-1} \sum_{j=1}^{m_{n+1}} H_{\theta_n}(X_{n+1}^{(j)})\,;$$

for all $n \ge 0$, conditionally to the past, $\{X_{n+1}^{(j)}, 1 \le j \le m_{n+1}\}$ is a Markov chain started from $X_n^{(m_n)}$ and with transition kernel P_{θ_n} (we set $X_0^{(m_0)} = x_\star \in \mathsf{X}$). For all $\theta \in \Theta$, P_θ is a Markov kernel with invariant distribution π_θ.

For a measurable function $V : \mathsf{X} \to [1,\infty)$, a signed measure μ on the σ-field of X, and a function $f : \mathsf{X} \to \mathbb{R}$, define

$$|f|_V \stackrel{\text{def}}{=} \sup_{x \in \mathsf{X}} \frac{|f(x)|}{V(x)}\,, \qquad \|\mu\|_V \stackrel{\text{def}}{=} \sup_{f,|f|_V \le 1} \left| \int f \,\mathrm{d}\mu \right|\,.$$

H5 *There exist $\lambda \in (0,1)$, $b < \infty$, $p \ge 2$ and a measurable function $W : \mathsf{X} \to [1,+\infty)$ such that*

$$\sup_{\theta \in \Theta} |H_\theta|_W < \infty\,, \qquad \sup_{\theta \in \Theta} P_\theta W^p \le \lambda W^p + b\,.$$

In addition, for any $\ell \in (0,p]$, there exist $C < \infty$ and $\rho \in (0,1)$ such that for any $x \in \mathsf{X}$,

$$\sup_{\theta \in \Theta} \|P_\theta^n(x,\cdot) - \pi_\theta\|_{W^\ell} \le C\rho^n W^\ell(x)\,. \quad (13)$$

Sufficient conditions for the uniform-in-θ ergodic behavior (13) are given e.g. in (Fort et al., 2011, Lemma 2.3), in terms of aperiodicity, irreducibility and minorization conditions on the kernels $\{P_\theta, \theta \in \Theta\}$. Examples of MCMC kernels P_θ satisfying this assumption can be found in (Andrieu and Moulines, 2006, Proposition 12), (Saksman and Vihola, 2010, Proposition 15), (Fort et al., 2011, Proposition 3.1.), (Schreck et al., 2013, Proposition 3.2.), (Allassonnière and Kuhn, 2015, Proposition 1), and (Fort et al., 2015, Proposition 3.1.).

The proof of the results below consists in verifying the conditions of Theorem 2 with the error term defined by $\eta_{n+1} = m_{n+1}^{-1} \sum_{j=1}^{m_{n+1}} H_{\theta_n}(X_{n+1}^{(j)}) - \nabla f(\theta_n)$. If the approximation is unbiased in the sense that $\mathbb{E}\left[\eta_{n+1} \,|\, \mathcal{F}_n\right] = 0$, then $\{\eta_n,\, n \in \mathbb{N}\}$ is a martingale increment sequence. In all the other cases, we decompose η_{n+1} as the sum of a martingale increment term and a remainder term. When the batch size $\{m_n,\, n \in \mathbb{N}\}$ is increasing, the martingale increment sequence can be set to $\eta_{n+1} - \mathbb{E}\left[\eta_{n+1} \,|\, \mathcal{F}_n\right]$ and the remainder term $\mathbb{E}\left[\eta_{n+1} \,|\, \mathcal{F}_n\right]$ will be shown to be vanishingly small. When the batch size $\{m_n,\, n \in \mathbb{N}\}$ is constant, then $\mathbb{E}\left[\eta_{n+1} \,|\, \mathcal{F}_n\right]$ does not vanish. A more subtle definition of the martingale increment has to be done, introducing the Poisson equation for Markov chain (see Proposition 19 in section 6).

3.1 Monte Carlo approximation with fixed batch-size

We first study the case when $m_n = m$ for any $n \in \mathbb{N}$. Theorem 4 provides sufficient conditions for the convergence towards the limiting set $\mathcal{L}$ and for a bound for $\sum_{k=1}^n a_k F(\theta_k) - \min F$. Consider the following assumption

H6 *(i) there exists a constant C such that for any $\theta, \theta' \in \Theta$*

$$|H_\theta - H_{\theta'}|_W + \sup_x \frac{\|P_\theta(x,\cdot) - P_{\theta'}(x,\cdot)\|_W}{W(x)} + \|\pi_\theta - \pi_{\theta'}\|_W \le C\,\|\theta - \theta'\| .$$

(ii) $\sup_{\gamma\in(0,1/L]} \sup_{\theta\in\Theta} \gamma^{-1}\ \|\mathrm{Prox}_{\gamma,g}(\theta) - \theta\| < \infty$.

(iii) $\sum_n |\gamma_{n+1} - \gamma_n| < \infty$.

Assumption H6-(i) requires a Lipschitz-regularity in the parameter θ of the Markov kernel P_θ which, for MCMC algorithms, is inherited under mild additional conditions from the Lipschitz regularity in W-norm of the target distribution. Such conditions have been worked out for general families of MCMC kernels including Hastings-Metropolis dynamics, Gibbs samplers, and hybrid MCMC algorithm; see for example Proposition 12 in Andrieu and Moulines (2006), the proof of Theorem 3.4. in Fort et al. (2011), Lemmas 4.6. and 4.7. in Fort et al. (2015) and the references therein. It is a classical assumption when studying Stochastic Approximation with conditionally Markovian dynamic (see e.g. Benveniste et al. (1990), Andrieu et al. (2005), Fort et al. (2014)).

We prove in Proposition 11 that when g is proper, convex, Lipschitz on Θ, then H6-(ii) is satisfied. In particular, if Θ is a closed convex set, H6-(ii) is satisfied with the Lasso or fused Lasso penalty. If Θ is a compact convex set, then H6-(ii) is satisfied by the elastic-net penalty.

For a random variable Y, denote by $\|Y\|_{L^q} = (\mathbb{E}[|Y|^q])^{1/q}$.

Theorem 4 *Assume Θ is bounded. Let $\{\theta_n, n \ge 0\}$ be given by Algorithm 2 with $\gamma_n \in (0, 1/L]$ for any $n \ge 0$. Assume H1–H5, $m_n = m \ge 1$ and, if the Monte Carlo approximation is biased, assume also H6.*

(i) Assume that $\sum_n \gamma_n = \infty$ and $\sum_n \gamma_n^2 < \infty$. With probability one, there exists $\theta_\infty \in \mathcal{L}$ such that $\lim_{n\to\infty} \theta_n = \theta_\infty$.

(ii) For any $q \in (1, p/2]$ there exists a constant C such that for any non-negative numbers $\{a_0, \cdots, a_n\}$

$$\left\| \sum_{k=1}^n a_k \{F(\theta_k) - \min F\} \right\|_{L^q} \le C \left(\frac{a_0}{\gamma_0} + \sum_{k=1}^n \left| \frac{a_k}{\gamma_k} - \frac{a_{k-1}}{\gamma_{k-1}} \right| + \left(\sum_{k=1}^n a_k^2 \right)^{1/2} + \sum_{k=1}^n a_k\gamma_k + \upsilon \sum_{k=1}^n |a_k - a_{k-1}| \right)$$

and

$$\sum_{k=1}^n a_k \{\mathbb{E}[F(\theta_k)] - \min F\} \le C \left(\frac{a_0}{\gamma_0} + \sum_{k=1}^n \left| \frac{a_k}{\gamma_k} - \frac{a_{k-1}}{\gamma_{k-1}} \right| + \sum_{k=1}^n a_k\gamma_k + \upsilon \sum_{k=1}^n |a_k - a_{k-1}| \right)$$

where $\upsilon = 0$ if the Monte Carlo approximation is unbiased and $\upsilon = 1$ otherwise.

Proof The proof is postponed to Section 6.3. ■

When $a_n = 1$ and $\gamma_n = (n+1)^{-1/2}$, Theorem 4 shows that when $n \to \infty$,

$$\left\| n^{-1} \sum_{k=1}^n F(\theta_k) - \min F \right\|_{L^q} = O\left(\frac{1}{\sqrt{n}} \right) .$$

An upper bound $O(\ln n/\sqrt{n})$ can be obtained from Theorem 4 by choosing $a_n = \gamma_n = (n+1)^{-1/2}$.

3.2 Monte Carlo approximation with increasing batch size

The key property to discuss the asymptotic behavior of the algorithm is the following result

Proposition 5 *Assume H3, H4 and H5. There exists a constant C such that w.p. 1 for any $n \ge 0$,*

$$\|\mathbb{E}[\,\eta_{n+1} \,|\, \mathcal{F}_n]\,\| \le C\, m_{n+1}^{-1} W(X_n^{(m_n)}) , \qquad \mathbb{E}[\|\eta_{n+1}\|^p | \mathcal{F}_n] \le C\ m_{n+1}^{-p/2} W^p(X_n^{(m_n)}) .$$

Proof The first inequality follows from (12) and (13). The second one is established in (Fort and Moulines, 2003, Proposition 12). ■

Theorem 6 *Assume Θ is bounded. Let $\{\theta_n, n \ge 0\}$ be given by Algorithm 2 with $\gamma_n \in (0, 1/L]$ for any $n \ge 0$. Assume H1–H5.*

(i) Assume $\sum_n \gamma_n = +\infty$, $\sum_n \gamma_{n+1}^2 m_{n+1}^{-1} < \infty$ and, if the approximation is biased, $\sum_n \gamma_{n+1} m_{n+1}^{-1} < \infty$. With probability one, there exists $\theta_\infty \in \mathcal{L}$ such that $\lim_{n\to\infty} \theta_n = \theta_\infty$.

(ii) For any $q \in (1, p/2]$, there exists a constant C such that for any non-negative numbers $\{a_0, \cdots, a_n\}$

$$\left\| \sum_{k=1}^n a_k \{F(\theta_k) - \min F\} \right\|_{L^q} \le C \left(\frac{a_0}{\gamma_0} + \sum_{k=1}^n \left| \frac{a_k}{\gamma_k} - \frac{a_{k-1}}{\gamma_{k-1}} \right| + \left(\sum_{k=1}^n a_k^2 m_k^{-1} \right)^{1/2} + \sum_{k=1}^n a_k\gamma_k m_k^{-1} + \upsilon \sum_{k=1}^n a_k m_k^{-1} \right)$$

and

$$\sum_{k=1}^n a_k \{\mathbb{E}[F(\theta_k)] - \min F\} \le C \left(\frac{a_0}{\gamma_0} + \sum_{k=1}^n \left| \frac{a_k}{\gamma_k} - \frac{a_{k-1}}{\gamma_{k-1}} \right| + \sum_{k=1}^n a_k\gamma_k m_k^{-1} + \upsilon \sum_{k=1}^n a_k m_k^{-1} \right) ,$$

where $\upsilon = 0$ if the Monte-Carlo approximation is unbiased and $\upsilon = 1$ otherwise.

Proof See Section 6.4. ■

Theorem 6 shows that when $n \to \infty$,

$$\left\| \left(\sum_{k=1}^{n} a_k \right)^{-1} \sum_{k=1}^{n} a_k F(\theta_k) - \min F \right\|_{L^q} = O\left(\frac{\ln n}{n} \right)$$

by choosing a fixed stepsize $\gamma_n = \gamma$, a linearly increasing batch-size $m_n \sim n$ and a uniform weight $a_n = 1$. Note that this is the rate after n iterations of the Stochastic Proximal Gradient algorithm but $\sum_{k=1}^{n} m_k = O(n^2)$ Monte Carlo samples. Therefore, the rate of convergence expressed in terms of complexity is $O(\ln n/\sqrt{n})$.

4. Application to network structure estimation

To illustrate the algorithm we consider the problem of fitting discrete graphical models in a setting where the number of nodes in the graph is large compared to the sample size. Let X be a nonempty finite set, and $p \geq 1$ an integer. We consider a graphical model on X^p with joint probability mass function

$$f_\theta(x_1, \ldots, x_p) = \frac{1}{Z_\theta} \exp\left\{ \sum_{k=1}^{p} \theta_{kk} B_0(x_k) + \sum_{1 \leq j < k \leq p} \theta_{kj} B(x_k, x_j) \right\}, \qquad (14)$$

for a non-zero function $B_0 : \mathsf{X} \to \mathbb{R}$ and a symmetric non-zero function $B : \mathsf{X} \times \mathsf{X} \to \mathbb{R}$. The term Z_θ is the normalizing constant of the distribution (the partition function), which cannot (in general) be computed explicitly. The real-valued symmetric matrix θ defines the graph structure and is the parameter of interest. It has the same interpretation as the precision matrix in a multivariate Gaussian distribution.

We consider the problem of estimating θ from N realizations $\{x^{(i)}, 1 \leq i \leq N\}$ from (14) where $x^{(i)} = (x_1^{(i)}, \ldots, x_p^{(i)}) \in \mathsf{X}^p$, and where the true value of θ is assumed sparse. This problem is relevant for instance in biology (Ekeberg et al. (2013); Kamisetty et al. (2013)), and has been considered by many authors in statistics and machine learning (Banerjee et al. (2008); Höfling and Tibshirani (2009); Ravikumar et al. (2010); Guo et al. (2010); Xue et al. (2012)).

The main difficulty in dealing with this model is the fact that the log-partition function $\log Z_\theta$ is intractable in general. As a result, most of the existing works estimate θ by using the sub-optimal approach of replacing the likelihood function by a pseudo-likelihood function. One notable exception that tackles the log-likelihood function is Höfling and Tibshirani (2009), using an active set strategy (to preserve sparsity), and the junction tree algorithm for computing the partial derivatives of the log-partition function. However, the success of this strategy depends crucially on the sparsity of the solution[1]. We will see that Algorithm 2 implemented with a MCMC

1. Indeed the implementation of their algorithm in the BMN package is very sensitive to the sparsity of the solution, and their solver typically fails to converge if the regularization parameter is not large enough to produce a sufficiently sparse solution. In our numerical experiments, we were not able to obtain a successful run from their package for $p = 100$.

approximation of the gradient gives a simple and effective approach for computing the penalized maximum likelihood estimate of θ.

Let $\mathcal{M}_p$ denote the space of $p \times p$ symmetric matrices equipped with the (modified) Frobenius inner product

$$\langle \theta, \vartheta \rangle \stackrel{\text{def}}{=} \sum_{1 \leq k \leq j \leq p} \theta_{jk} \vartheta_{jk}, \text{ with norm } \|\theta\| \stackrel{\text{def}}{=} \sqrt{\langle \theta, \theta \rangle}.$$

Equipped with this norm, $\mathcal{M}_p$ is the same space as the Euclidean space $\mathbb{R}^d$ where $d = p(p+1)/2$. Using a ℓ^1-penalty on θ, we see that the computation of the penalized maximum likelihood estimate of θ is a problem of the form (P) with $F = -\ell + g$ where

$$\ell(\theta) = \frac{1}{N} \sum_{i=1}^{N} \left\langle \theta, \bar{B}(x^{(i)}) \right\rangle - \log Z_\theta \text{ and } \quad g(\theta) = \lambda \sum_{1 \leq k \leq j \leq p} |\theta_{jk}| \, ;$$

the matrix-valued function $\bar{B} : \mathsf{X}^p \to \mathbb{R}^{p \times p}$ is defined by

$$\bar{B}_{kk}(x) = B_0(x_k) \qquad \bar{B}_{kj}(x) = B(x_k, x_j) \, , k \neq j \, .$$

It is easy to see that in this example, Problem (P) admits at least one solution $\theta_\star$ that satisfies $\lambda \sum_{1 \leq k \leq j \leq p} |\theta_{jk}| \leq p \log |\mathsf{X}|$, where $|\mathsf{X}|$ denotes the size of X. To see this, note that since $f_\theta(x)$ is a probability, $-\ell(\theta) = -N^{-1} \sum_{i=1}^{N} \log f_\theta(x^{(i)}) \geq 0$. Hence $F(\theta) \geq g(\theta) \to \infty$, as $\sum_{1 \leq k \leq j \leq p} |\theta_{jk}| \to \infty$ and since F is continuous, we conclude that it admits at least one minimizer $\theta_\star$ that satisfies $F(\theta_\star) \leq F(\mathbf{0}) = \log Z_{\mathbf{0}} = p \log |\mathsf{X}|$. As a result, and without any loss of generality, we consider Problem (P) with the penalty g replaced by $g(\theta) = \lambda \sum_{1 \leq k \leq j \leq p} |\theta_{jk}| + \mathbb{1}(\theta)$, where $\mathbb{1}(\theta) = 0$ if $\max_{ij} |\theta_{ij}| \leq (p/\lambda) \log |\mathsf{X}|$, and $\mathbb{1}(\theta) = +\infty$ otherwise. Hence in this problem, the domain of g is $\Theta = \{\theta \in \mathcal{M}_p : \max_{ij} |\theta_{ij}| \leq (p/\lambda) \log |\mathsf{X}|\}$.

Upon noting that (14) is a canonical exponential model, (Shao, 2003, Section 4.4.2) shows that $\theta \mapsto -\ell(\theta)$ is convex and

$$\nabla \ell(\theta) = \frac{1}{N} \sum_{i=1}^{N} \bar{B}(x^{(i)}) - \int_{\mathsf{X}^p} \bar{B}(z) f_\theta(z) \mu(\mathrm{d}z) \, , \qquad (15)$$

where μ is the counting measure on X^p. In addition, (see section B)

$$\|\nabla \ell(\theta) - \nabla \ell(\vartheta)\| \leq p \left((p-1) \mathsf{osc}^2(B) + \mathsf{osc}^2(B_0) \right) \|\theta - \vartheta\|, \qquad (16)$$

where for a function $\tilde{B} : \mathsf{X} \times \mathsf{X} \to \mathbb{R}$, $\mathsf{osc}(\tilde{B}) = \sup_{x,y,u,v \in \mathsf{X}} |\tilde{B}(x,y) - \tilde{B}(u,v)|$.

Therefore, in this example, the assumption H1 and H2 are satisfied.

The representation of the gradient in (15) shows that H3 holds, with $\pi_\theta(\mathrm{d}z) = f_\theta(z)\mu(\mathrm{d}z)$, and $H_\theta(z) = N^{-1} \sum_{i=1}^{N} \bar{B}(x^{(i)}) - \bar{B}(z)$. Direct simulation from the distribution f_θ is rarely feasible, so we turn to MCMC. These Markov kernels are easy to construct, and can be constructed in many ways. For instance if the set X is not too large, then a Gibbs sampler (see e.g. Robert and Casella (2005)) that samples from the full conditional distributions of f_θ can be easily implemented. In the case of the

Gibbs sampler, since X^p is a finite set, Θ is compact, $f_\theta(x) > 0$ for all $(x, \theta) \in \mathsf{X}^p \times \Theta$, and, $\theta \mapsto f_\theta(x)$ is continuously differentiable, the assumptions H4, H5 and H6(i)-(ii) automatically hold with $W \equiv 1$. We should point out that the Gibbs sampler is a generic algorithm that in some cases is known to mix poorly. Whenever possible we recommend the use of specialized problem-specific MCMC algorithms with better mixing properties.

Illustrative example We consider the particular case where $\mathsf{X} = \{1, \dots, M\}$, $B_0(x) = 0$, and $B(x, y) = \mathbb{1}_{\{x=y\}}$, which corresponds to the well known Potts model. We report in this section some simulation results showing the performances of the stochastic proximal gradient algorithm. We use $M = 20$, $B_0(x) = x$, $N = 250$ and for $p \in \{50, 100, 200\}$. We generate the 'true' matrix θ_{true} such that it has on average p non-zero elements below the diagonal which are simulated from a uniform distribution on $(-4, -1) \cup (1, 4)$. All the diagonal elements are set to 0.

By trial-and-error we set the regularization parameter to $\lambda = 2.5\sqrt{\log(p)/n}$ for all the simulations. We implement Algorithm 2, drawing samples from a Gibbs sampler to approximate the gradient. We compare the following two versions of Algorithm 2:

1. Solver 1: A version with a fixed Monte Carlo batch size $m_n = 500$, and decreasing step size $\gamma_n = \frac{25}{p}\frac{1}{n^{0.7}}$.

2. Solver 2: A version with increasing Monte Carlo batch size $m_n = 500 + n^{1.2}$, and fixed step size $\gamma_n = \frac{25}{p}\frac{1}{\sqrt{50}}$.

We run Solver 2 for $\mathsf{Niter} = 5p$ iterations, where $p \in \{50, 100, 200\}$ is as above. And we set the number of iterations of Solver 1 so that both solvers draw approximately the same number of Monte Carlo samples. For stability in the results, we repeat the solvers 30 times and average the sample paths. We evaluate the convergence of each solver by computing the relative error $\|\theta_n - \theta_\infty\|/\|\theta_\infty\|$, along the iterations, where θ_∞ denotes the value returned by the solver on its last iteration. Note that we compare the optimizer output to θ_∞, not θ_{true}. Ideally, we would like to compare the iterates to the solution of the optimization problem. However in the present setting a solution is not available in closed form (and there could be more than one solution). Furthermore, whether the solution of the optimization problem approaches $\theta_\star$ is a complicated statistical problem[2] that is beyond the scope of this work. The relative errors are presented on Figure 1 and suggest that, when measured as function of resource used, Solver 1 and Solver 2 have roughly the same convergence rate.

We also compute the statistic $\mathsf{F}_n \stackrel{\text{def}}{=} \frac{2\mathsf{Sen}_n \mathsf{Prec}_n}{\mathsf{Sen}_n + \mathsf{Prec}_n}$ which measures the recovery of the sparsity structure of θ_∞ along the iteration. In this definition Sen_n is the sensitivity, and Prec_n is the precision defined as

$$\mathsf{Sen}_n = \frac{\sum_{j<i} \mathbb{1}_{\{|\theta_{n,ij}|>0\}} \mathbb{1}_{\{|\theta_{\infty,ij}|>0\}}}{\sum_{j<i} \mathbb{1}_{\{|\theta_{\infty,ij}|>0\}}}, \quad \text{and} \quad \mathsf{Prec}_n = \frac{\sum_{j<i} \mathbb{1}_{\{|\theta_{n,ij}|>0\}} \mathbb{1}_{\{|\theta_{\infty,ij}|>0\}}}{\sum_{j<i} \mathbb{1}_{\{|\theta_{n,ij}|>0\}}}.$$

2. this depends heavily on n, p, the actual true matrix θ_{true}, and depends also heavily the choice of the regularization parameter λ

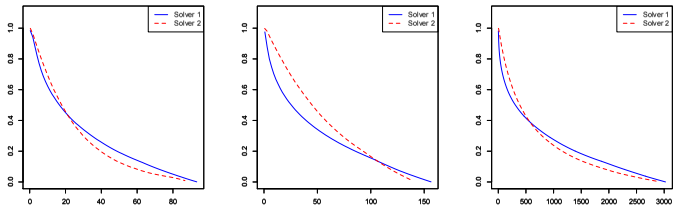

Figure 1: Relative errors plotted as function of computing time for Solver 1 and Solver 2.

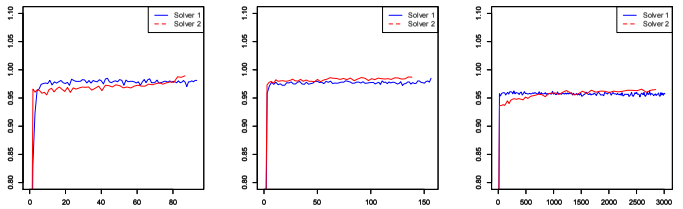

Figure 2: Statistic F_n plotted as function of computing time for Solver 1 and Solver 2.

The values of F_n are presented on Figure 2 as function of computing time. It shows that for both solvers, the sparsity structure of θ_n converges very quickly towards that of θ_∞. We note also that Figure 2 seems to suggest that Solver 2 tends to produce solutions with slightly more stable sparsity structure than Solver 1 (less variance on the red curves). Whether such subtle differences exist between the two algorithms (a diminishing step-size and fixed Monte Carlo size versus a fixed step-size and increasing Monte Carlo size) is an interest question. Our analysis does not deal with the sparsity structure of the solutions, hence cannot offer any explanation.

5. A non convex example: High-dimensional logistic regression with random effects

We numerically investigate the extension of our results to a situation where the assumptions H2 and H3 hold but H1 is not in general satisfied and the domain Θ is not bounded. The numerical study below shows that the conclusions reached in sec-

tion 2 and section 3 provide useful information to tune the design parameters of the algorithms.

5.1 The model

We model binary responses $\{Y_i\}_{i=1}^N \in \{0,1\}$ as N conditionally independent realizations of a random effect logistic regression model,

$$Y_i|\mathbf{U} \overset{ind.}{\sim} \mathsf{Ber}\left(s(x_i'\beta + \sigma z_i'\mathbf{U})\right), \quad 1 \leq i \leq N\,, \tag{17}$$

where $x_i \in \mathbb{R}^p$ is the vector of covariates, $z_i \in \mathbb{R}^q$ are (known) loading vector, $\mathsf{Ber}(\alpha)$ denotes the Bernoulli distribution with parameter $\alpha \in [0,1]$, $s(x) = \mathrm{e}^x/(1+\mathrm{e}^x)$ is the cumulative distribution function of the standard logistic distribution. The random effect $\mathbf{U}$ is assumed to be standard Gaussian $\mathbf{U} \sim \mathrm{N}_q(0, I)$.

The log-likelihood of the observations at $\theta = (\beta, \sigma) \in \mathbb{R}^p \times (0,\infty)$ is given by

$$\ell(\theta) = \log \int \prod_{i=1}^N s(x_i'\beta + \sigma z_i'\mathbf{u})^{Y_i} \left(1 - s(x_i'\beta + \sigma z_i'\mathbf{u})\right)^{1-Y_i} \phi(\mathbf{u})\mathrm{d}\mathbf{u}\,, \tag{18}$$

where ϕ is the density of a $\mathbb{R}^q$-valued standard Gaussian random vector. The number of covariates p is possibly larger than N, but only a very small number of these covariates are relevant which suggests to use the elastic-net penalty

$$\lambda\left(\frac{1-\alpha}{2}\|\beta\|_2^2 + \alpha\|\beta\|_1\right)\,, \tag{19}$$

where $\lambda > 0$ is the regularization parameter, $\|\beta\|_r = (\sum_{i=1}^p |\beta_i|^r)^{1/r}$ and $\alpha \in [0,1]$ controls the trade-off between the ℓ^1 and the ℓ^2 penalties. In this example,

$$g(\theta) = \lambda\left(\frac{1-\alpha}{2}\|\beta\|_2^2 + \alpha\|\beta\|_1\right) + \mathbb{1}_{(0,+\infty)}(\sigma)\,, \tag{20}$$

where $\mathbb{1}_A(x) = +\infty$ is $x \notin A$ and 0 otherwise. Define the conditional log-likelihood of $\mathbf{Y} = (Y_1, \ldots, Y_N)$ given $\mathbf{U}$ (the dependence upon $\mathbf{Y}$ is omitted) by

$$\ell_c(\theta|\mathbf{u}) = \sum_{i=1}^N \left\{Y_i\left(x_i'\beta + \sigma z_i'\mathbf{u}\right) - \ln\left(1 + \exp\left(x_i'\beta + \sigma z_i'\mathbf{u}\right)\right)\right\}\quad,$$

and the conditional distribution of the random effect $\mathbf{U}$ given the observations $\mathbf{Y}$ and the parameter θ

$$\pi_\theta(\mathbf{u}) = \exp\left(\ell_c(\theta|\mathbf{u}) - \ell(\theta)\right)\phi(\mathbf{u})\,. \tag{21}$$

The Fisher identity implies that the gradient of the log-likelihood (18) is given by

$$\nabla\ell(\theta) = \int \nabla_\theta \ell_c(\theta|\mathbf{u})\ \pi_\theta(\mathbf{u})\ \mathrm{d}\mathbf{u} = \int \left\{\sum_{i=1}^N (Y_i - s(x_i'\beta + \sigma z_i'\mathbf{u}))\begin{bmatrix} x_i \\ z_i'\mathbf{u}\end{bmatrix}\right\}\pi_\theta(\mathbf{u})\ \mathrm{d}\mathbf{u}\,.$$

The Hessian of the log-likelihood ℓ is given by (see e.g.(McLachlan and Krishnan, 2008, Chapter 3))

$$\nabla^2\ell(\theta) = \mathbb{E}_{\pi_\theta}\left[\nabla_\theta^2\ell_c(\theta|\mathbf{U})\right] + \mathrm{Cov}_{\pi_\theta}\left(\nabla_\theta\ell_c(\theta|\mathbf{U})\right)$$

where $\mathbb{E}_{\pi_\theta}$ and $\mathrm{Cov}_{\pi_\theta}$ denotes the expectation and the covariance with respect to the distribution π_θ, respectively. Since

$$\nabla_\theta^2\ell_c(\theta|\mathbf{u}) = -\sum_{i=1}^N s(x_i'\beta + \sigma z_i'\mathbf{u})\ \left(1 - s(x_i'\beta + \sigma z_i'\mathbf{u})\right)\begin{bmatrix} x_i \\ z_i'\mathbf{u}\end{bmatrix}\begin{bmatrix} x_i \\ z_i'\mathbf{u}\end{bmatrix}'\,,$$

and $\sup_{\theta\in\Theta}\int \|\mathbf{u}\|^2\pi_\theta(\mathbf{u})\,\mathrm{d}\mathbf{u} < \infty$ (see section A), $\nabla^2\ell(\theta)$ is bounded on Θ. Hence, $\nabla\ell(\theta)$ satisfies the Lipschitz condition showing that H1 is satisfied.

5.2 Numerical application

The assumption H3 is satisfied with π_θ given by (21) and

$$H_\theta(\mathbf{u}) = -\sum_{i=1}^N (Y_i - F(x_i'\beta + \sigma z_i'\mathbf{u}))\begin{bmatrix} x_i \\ z_i'\mathbf{u}\end{bmatrix}\,. \tag{22}$$

The distribution π_θ is sampled using the MCMC sampler proposed in Polson et al. (2013) based on data-augmentation. We write $-\nabla\ell(\theta) = \int_{\mathbb{R}^q\times\mathbb{R}^N} H_\theta(\mathbf{u})\tilde{\pi}_\theta(\mathbf{u},\mathbf{w})\,\mathrm{d}\mathbf{u}\mathrm{d}\mathbf{w}$ where $\tilde{\pi}_\theta(\mathbf{u},\mathbf{w})$ is defined for $\mathbf{u} \in \mathbb{R}^q$ and $\mathbf{w} = (w_1, \cdots, w_N) \in \mathbb{R}^N$ by

$$\tilde{\pi}_\theta(\mathbf{u},\mathbf{w}) = \left(\prod_{i=1}^N \bar{\pi}_{\mathsf{PG}}\left(w_i; x_i'\beta + \sigma z_i'\mathbf{u}\right)\right)\pi_\theta(\mathbf{u})\,;$$

in this expression, $\bar{\pi}_{\mathsf{PG}}(\cdot; c)$ is the density of the Polya-Gamma distribution on the positive real line with parameter c given by

$$\bar{\pi}_{\mathsf{PG}}(w; c) = \cosh(c/2)\ \exp\left(-wc^2/2\right)\ \rho(w)\mathbb{1}_{\mathbb{R}^+}(w)\,,$$

where $\rho(w) \propto \sum_{k\geq 0}(-1)^k(2k+1)\exp(-(2k+1)^2/(8w))w^{-3/2}$ (see (Biane et al., 2001, Section 3.1)). Thus, we have

$$\tilde{\pi}_\theta(\mathbf{u},\mathbf{w}) = C_\theta\phi(\mathbf{u})\prod_{i=1}^N \exp\left(\sigma(Y_i - 1/2)z_i'\mathbf{u} - w_i(x_i'\beta + \sigma z_i'\mathbf{u})^2/2\right)\ \rho(w_i)\mathbb{1}_{\mathbb{R}^+}(w_i)\,,$$

where $\ln C_\theta = -N\ln 2 - \ell(\theta) + \sum_{i=1}^N (Y_i - 1/2)x_i'\beta$. This target distribution can be sampled using a Gibbs algorithm: given the current value $(\mathbf{u}^t, \mathbf{w}^t)$ of the chain, the next point is obtained by sampling $\mathbf{u}^{t+1}$ under the conditional distribution of $\mathbf{u}$ given $\mathbf{w}^t$, and $\mathbf{w}^{t+1}$ under the conditional distribution of $\mathbf{w}$ given $\mathbf{u}^{t+1}$. In the present case, these conditional distributions are given respectively by

$$\tilde{\pi}_\theta(\mathbf{u}|\mathbf{w}) \equiv \mathrm{N}_q\left(\mu_\theta(\mathbf{w}); \Gamma_\theta(\mathbf{w})\right) \qquad \tilde{\pi}_\theta(\mathbf{w}|\mathbf{u}) = \prod_{i=1}^N \bar{\pi}_{\mathsf{PG}}(w_i; |x_i'\beta + \sigma z_i'\mathbf{u}|)$$

with

$$\Gamma_\theta(\mathbf{w}) = \left(I + \sigma^2 \sum_{i=1}^N w_i z_i z_i' \right)^{-1}, \qquad \mu_\theta(\mathbf{w}) = \sigma \Gamma_\theta(\mathbf{w}) \sum_{i=1}^N \left((Y_i - 1/2) - w_i x_i' \beta \right) z_i \,. \tag{23}$$

Exact samples of these conditional distributions can be obtained (see (Polson et al., 2013, Algorithm 1) for sampling under a Polya-Gamma distribution). It has been shown by Choi and Hobert (2013) that the Polya-Gamma Gibbs sampler is uniformly ergodic. Hence H5 is satisfied with $W \equiv 1$. Checking H6 is also straightforward.

We test the algorithms with $N = 500$, $p = 1,000$ and $q = 5$. We generate the $N \times p$ covariates matrix X columnwise, by sampling a stationary $\mathbb{R}^N$-valued autoregressive model with parameter $\rho = 0.8$ and Gaussian noise $\sqrt{1-\rho^2}\mathcal{N}_N(0, I)$. We generate the vector of regressors β_{true} from the uniform distribution on $[1, 5]$ and randomly set 98% of the coefficients to zero. The variance of the random effect is set to $\sigma^2 = 0.1$. We consider a repeated measurement setting so that $z_i = e_{\lceil iq/N \rceil}$ where $\{e_j, j \leq q\}$ is the canonical basis of $\mathbb{R}^q$ and $\lceil \cdot \rceil$ denotes the upper integer part. With such a simple expression for the random effect, we will be able to approximate the value $F(\theta)$ in order to illustrate the theoretical results obtained in this paper. We use the Lasso penalty ($\alpha = 1$ in (19)) with $\lambda = 30$.

We first illustrate the ability of Monte Carlo Proximal Gradient algorithms to find a minimizer of F. We compare the Monte Carlo proximal gradient algorithm

(i) with fixed batch size: $\gamma_n = 0.01/\sqrt{n}$ and $m_n = 275$ (Algo 1); $\gamma_n = 0.5/n$ and $m_n = 275$ (Algo 2).

(ii) with increasing batch size: $\gamma_n = \gamma = 0.005$, $m_n = 200 + n$ (Algo 3); $\gamma_n = \gamma = 0.001$, $m_n = 200 + n$ (Algo 4); and $\gamma_n = 0.05/\sqrt{n}$ and $m_n = 270 + \lceil \sqrt{n} \rceil$ (Algo 5).

Each algorithm is run for 150 iterations. The batch sizes $\{m_n, n \geq 0\}$ are chosen so that after 150 iterations, each algorithm used approximately the same number of Monte Carlo samples. We denote by β_∞ the value obtained at iteration 150. A path of the relative error $\|\beta_n - \beta_\infty\|/\|\beta_\infty\|$ is displayed on Figure 3[right] for each algorithm; a path of the sensitivity Sen_n and of the precision Prec_n (see section 4 for the definition) are displayed on Figure 4. All these sequences are plotted versus the total number of Monte Carlo samples up to iteration n. These plots show that with a fixed batch-size (Algo 1 or Algo 2), the best convergence is obtained with a step size decreasing as $O(1/\sqrt{n})$; and for an increasing batch size (Algo 3 to Algo 5), it is better to choose a fixed step size. These findings are consistent with the results in section 3. On Figure 3[left], we report on the bottom row the indices j such that $\beta_{\mathsf{true},j}$ is non null and on the rows above, the indices j such that $\beta_{\infty,j}$ given by Algo 1 to Algo 5 is non null.

We now study the convergence of $\{F(\theta_n), n \in \mathbb{N}\}$ where θ_n is obtained by one of the algorithms described above. We repeat 50 independent runs for each algorithm and estimate $\mathbb{E}[F(\theta_n)]$ by the empirical mean over these runs. On Figure 5[left], $n \mapsto F(\theta_n)$ is displayed for several runs of Algo 1 and Algo 3. The figure shows

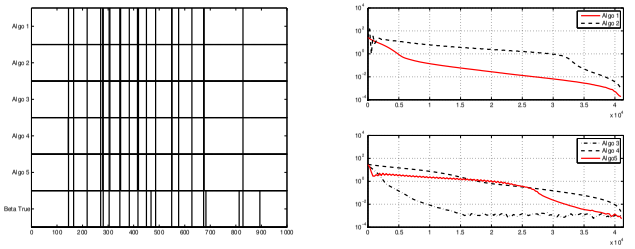

Figure 3: [left] The support of the sparse vector β_∞ obtained by Algo 1 to Algo 5; for comparison, the support of β_{true} is on the bottom row. [right] Relative error along one path of each algorithm as a function of the total number of Monte Carlo samples.

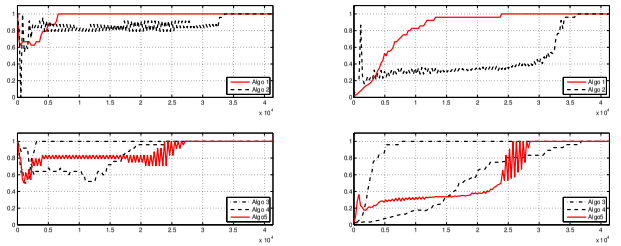

Figure 4: The sensitivity Sen_n [left] and the precision Prec_n [right] along a path, versus the total number of Monte Carlo samples up to time n

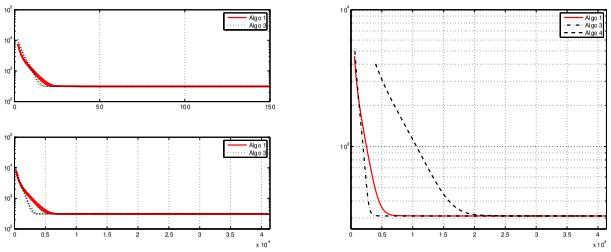

Figure 5: [left] $n \mapsto F(\theta_n)$ for several independent runs. [right] $\mathbb{E}\left[F(\theta_n)\right]$ versus the total number of Monte Carlo samples up to iteration n

that all the paths have the same limiting value, which is approximately $F_\star = 311$; we observed the same behavior on the 50 runs of each algorithm. On Figure 5[right], we report the Monte Carlo estimation of $\mathbb{E}[F(\theta_n)]$ versus the total number of Monte Carlo samples used up to iteration n for the best strategies in the fixed batch size case (Algo 1) and in the increasing batch size case (Algo 3 and Algo 4).

6. Proofs

6.1 Preliminary lemmas

Lemma 7 *Assume that g is lower semi-continuous and convex. For $\theta, \theta' \in \Theta$ and $\gamma > 0$*

$$g\Big(\operatorname{Prox}_{\gamma,g}(\theta)\Big) - g(\theta') \leq -\frac{1}{\gamma}\left\langle \operatorname{Prox}_{\gamma,g}(\theta) - \theta', \operatorname{Prox}_{\gamma,g}(\theta) - \theta \right\rangle . \tag{24}$$

For any $\gamma > 0$ and for any $\theta, \theta' \in \Theta$,

$$\|\operatorname{Prox}_{\gamma,g}(\theta) - \operatorname{Prox}_{\gamma,g}(\theta')\|^2 + \|\big(\operatorname{Prox}_{\gamma,g}(\theta) - \theta\big) - \big(\operatorname{Prox}_{\gamma,g}(\theta') - \theta'\big)\|^2 \leq \|\theta - \theta'\|^2 . \tag{25}$$

Proof See (Bauschke and Combettes, 2011, Propositions 4.2., 12.26 and 12.27). ■

Lemma 8 *Assume H1 and let $\gamma \in (0, 1/L]$. Then for all $\theta, \theta' \in \Theta$,*

$$-2\gamma\Big(F(\operatorname{Prox}_{\gamma,g}(\theta)) - F(\theta')\Big) \geq \|\operatorname{Prox}_{\gamma,g}(\theta) - \theta'\|^2 + 2\left\langle \operatorname{Prox}_{\gamma,g}(\theta) - \theta', \theta' - \gamma\nabla f(\theta') - \theta \right\rangle . \tag{26}$$

If in addition f is convex, then for all $\theta, \theta', \xi \in \Theta$,

$$-2\gamma\Big(F\big(\operatorname{Prox}_{\gamma,g}(\theta)\big) - F(\theta')\Big) \geq \|\operatorname{Prox}_{\gamma,g}(\theta) - \theta'\|^2 + 2\left\langle \operatorname{Prox}_{\gamma,g}(\theta) - \theta', \xi - \gamma\nabla f(\xi) - \theta \right\rangle - \|\theta' - \xi\|^2 . \tag{27}$$

Proof Since ∇f is Lipschitz, the descent lemma implies that for any $\gamma^{-1} \geq L$

$$f(p) - f(\theta') \leq \left\langle \nabla f(\theta'), p - \theta' \right\rangle + \frac{1}{2\gamma}\|p - \theta'\|^2 . \tag{28}$$

This inequality applied with $p = \operatorname{Prox}_{\gamma,g}(\theta)$ combined with (24) yields (26). When f is convex, $f(\xi) + \langle \nabla f(\xi), \theta' - \xi \rangle - f(\theta') \leq 0$ which, combined again with (24) and (28) applied with $(p, \theta') \leftarrow (\operatorname{Prox}_{\gamma,g}(\theta), \xi)$ yields the result. ■

Lemma 9 *Assume H1. Then for any $\gamma > 0$, $\theta, \theta' \in \Theta$,*

$$\|\theta - \gamma\nabla f(\theta) - \theta' + \gamma\nabla f(\theta')\| \leq (1 + \gamma L)\|\theta - \theta'\| , \tag{29}$$

$$\|T_\gamma(\theta) - T_\gamma(\theta')\| \leq (1 + \gamma L)\|\theta - \theta'\| . \tag{30}$$

If in addition f is convex then for any $\gamma \in (0, 2/L]$,

$$\|\theta - \gamma\nabla f(\theta) - \theta' + \gamma\nabla f(\theta')\| \leq \|\theta - \theta'\| , \tag{31}$$

$$\|T_\gamma(\theta) - T_\gamma(\theta')\| \leq \|\theta - \theta'\| . \tag{32}$$

Proof (30) and (32) follows from (29) and (31) respectively by the Lipschitz property of the proximal map $\operatorname{Prox}_{\gamma,g}$ (see Lemma 7). (29) follows directly from the Lipschitz property of f. It remains to prove (31). Since f is a convex function with Lipschitz-continuous gradients, (Nesterov, 2004, Theorem 2.1.5) shows that, for all $\theta, \theta' \in \Theta$, $L\left\langle \nabla f(\theta) - \nabla f(\theta'), \theta - \theta' \right\rangle \geq \|\nabla f(\theta) - \nabla f(\theta')\|^2$. The result follows. ■

Lemma 10 *Assume H1. Set $S_\gamma(\theta) \stackrel{\text{def}}{=} \operatorname{Prox}_{\gamma,g}(\theta - \gamma H)$ and $\eta \stackrel{\text{def}}{=} H - \nabla f(\theta)$. For any $\theta \in \Theta$ and $\gamma > 0$,*

$$\|T_\gamma(\theta) - S_\gamma(\theta)\| \leq \gamma\|\eta\| . \tag{33}$$

Proof We have $\|T_\gamma(\theta) - S_\gamma(\theta)\| = \|\operatorname{Prox}_{\gamma,g}(\theta - \gamma\nabla f(\theta)) - \operatorname{Prox}_{\gamma,g}(\theta - \gamma H)\|$ and (33) follows from Lemma 7. ■

6.2 Proof of section 2

6.2.1 Proof of Lemma 1

Set $w_n = v_n + \sum_{k \geq n+1} \xi_k + M$ with $M \stackrel{\text{def}}{=} -\inf_n \sum_{k \geq n} \xi_k$ so that $\inf_n w_n \geq 0$. Then

$$0 \leq w_{n+1} \leq v_n - \chi_{n+1} + \xi_{n+1} + \sum_{k \geq n+2} \xi_k + M \leq w_n - \chi_{n+1} .$$

$\{w_n,\ n \in \mathbb{N}\}$ is non-negative and non increasing; therefore it converges. Furthermore, $0 \leq \sum_{k=0}^{n} \chi_k \leq w_0$ so that $\sum_n \chi_n < \infty$. The convergence of $\{w_n,\ n \in \mathbb{N}\}$ also implies the convergence of $\{v_n,\ n \in \mathbb{N}\}$. This concludes the proof.

6.2.2 Proof of Theorem 2

Let $\theta_\star \in \mathcal{L}$, which is not empty by H2; note that $F(\theta_\star) = \min F$. We have by (27) applied with $\theta \leftarrow \theta_n - \gamma_{n+1} H_{n+1}$, $\xi \leftarrow \theta_n$, $\theta' \leftarrow \theta_\star$, $\gamma \leftarrow \gamma_{n+1}$

$$\|\theta_{n+1} - \theta_\star\|^2 \leq \|\theta_n - \theta_\star\|^2 - 2\gamma_{n+1}\left(F(\theta_{n+1}) - \min F\right) - 2\gamma_{n+1}\left\langle \theta_{n+1} - \theta_\star, \eta_{n+1}\right\rangle \ .$$

We write $\theta_{n+1} - \theta_\star = \theta_{n+1} - T_{\gamma_{n+1}}(\theta_n) + T_{\gamma_{n+1}}(\theta_n) - \theta_\star$. By Lemma 10, $\|\theta_{n+1} - T_{\gamma_{n+1}}(\theta_n)\| \leq \gamma_{n+1}\|\eta_{n+1}\|$ so that,

$$-\left\langle \theta_{n+1} - \theta_\star, \eta_{n+1}\right\rangle \leq \gamma_{n+1}\|\eta_{n+1}\|^2 - \left\langle T_{\gamma_{n+1}}(\theta_n) - \theta_\star, \eta_{n+1}\right\rangle \ .$$

Hence,

$$\begin{aligned}\|\theta_{n+1} - \theta_\star\|^2 \leq \|\theta_n - \theta_\star\|^2 - 2\gamma_{n+1}\left(F(\theta_{n+1}) - \min F\right) \\ + 2\gamma_{n+1}^2\|\eta_{n+1}\|^2 - 2\gamma_{n+1}\left\langle T_{\gamma_{n+1}}(\theta_n) - \theta_\star, \eta_{n+1}\right\rangle \ . \quad (34)\end{aligned}$$

Under (7) and (34), Lemma 1 shows that $\sum_n \gamma_n \left(F(\theta_n) - \min F\right) < \infty$ and $\lim_n \|\theta_n - \theta_\star\|$ exists. This implies that $\sup_n \|\theta_n\| < \infty$. Since $\sum_n \gamma_n = +\infty$, there exists a subsequence $\{\theta_{\phi_n}, n \in \mathbb{N}\}$ such that $\lim_n F(\theta_{\phi_n}) = \min F$. The sequence $\{\theta_{\phi_n}, n \geq 0\}$ being bounded, we can assume without loss of generality that there exists $\theta_\infty \in \mathbb{R}^d$ such that $\lim_n \theta_{\phi_n} = \theta_\infty$.

Let us prove that $\theta_\infty \in \mathcal{L}$. Since g is lower semi-continuous on Θ, $\liminf_n g(\theta_{\phi_n}) \geq g(\theta_\infty)$ so that $\theta_\infty \in \Theta$. Since F is lower semi-continuous on Θ, we have

$$\min F = \liminf_{n\to\infty} F(\theta_{\phi_n}) \geq F(\theta_\infty) \geq \min F \ ,$$

showing that $F(\theta_\infty) = \min F$.

By (34), for any m and $n \geq \phi_m$

$$\|\theta_{n+1} - \theta_\infty\|^2 \leq \|\theta_{\phi_m} - \theta_\infty\|^2 - 2\sum_{k=\phi_m}^{n} \gamma_{k+1}\{\left\langle T_{\gamma_{k+1}}(\theta_k) - \theta_\infty, \eta_{k+1}\right\rangle + \gamma_{k+1}\|\eta_{k+1}\|^2\} \ .$$

For any $\epsilon > 0$, there exists m such that the RHS is upper bounded by ϵ. Hence, for any $n \geq \phi_m$, $\|\theta_{n+1} - \theta_\infty\|^2 \leq \epsilon$, which proves the convergence of $\{\theta_n,\ n \in \mathbb{N}\}$ to θ_∞.

6.2.3 Proof of Theorem 3

Let $\theta_\star \in \mathcal{L}$; note that $F(\theta_\star) = \min F$. We first apply (27) with $\theta \leftarrow \theta_j - \gamma_{j+1} H_{j+1}$, $\xi \leftarrow \theta_j$, $\theta' \leftarrow \theta_\star$, $\gamma \leftarrow \gamma_{j+1}$:

$$F(\theta_{j+1}) - \min F \leq (2\gamma_{j+1})^{-1}\left(\|\theta_j - \theta_\star\|^2 - \|\theta_{j+1} - \theta_\star\|^2\right) - \left\langle \theta_{j+1} - \theta_\star, \eta_{j+1}\right\rangle \ .$$

Multiplying both sides by a_{j+1} gives:

$$\begin{aligned}a_{j+1}\Big(F(\theta_{j+1}) - \min F\Big) \leq \frac{1}{2}\left(\frac{a_{j+1}}{\gamma_{j+1}} - \frac{a_j}{\gamma_j}\right)\|\theta_j - \theta_\star\|^2 + \frac{a_j}{2\gamma_j}\|\theta_j - \theta_\star\|^2 \\ - \frac{a_{j+1}}{2\gamma_{j+1}}\|\theta_{j+1} - \theta_\star\|^2 - a_{j+1}\left\langle \theta_{j+1} - \theta_\star, \eta_{j+1}\right\rangle .\end{aligned}$$

Summing from $j = 0$ to $n-1$ gives

$$\begin{aligned}\frac{a_n}{2\gamma_n}\|\theta_n - \theta_\star\|^2 + \sum_{j=1}^{n} a_j\{F(\theta_j) - \min F\} \leq \frac{1}{2}\sum_{j=1}^{n}\left(\frac{a_j}{\gamma_j} - \frac{a_{j-1}}{\gamma_{j-1}}\right)\|\theta_{j-1} - \theta_\star\|^2 \\ - \sum_{j=1}^{n} a_j\left\langle \theta_j - \theta_\star, \eta_j\right\rangle + \frac{a_0}{2\gamma_0}\|\theta_0 - \theta_\star\|^2 \ . \quad (35)\end{aligned}$$

We decompose $\left\langle \theta_j - \theta_\star, \eta_j\right\rangle$ as follows:

$$\left\langle \theta_j - \theta_\star, \eta_j\right\rangle = \left\langle \theta_j - T_{\gamma_j}(\theta_{j-1}), \eta_j\right\rangle + \left\langle T_{\gamma_j}(\theta_{j-1}) - \theta_\star, \eta_j\right\rangle \ .$$

By Lemma 10, we get $\left|\left\langle \theta_j - T_{\gamma_j}(\theta_{j-1}), \eta_j\right\rangle\right| \leq \gamma_j\|\eta_j\|^2$ which concludes the proof.

6.3 Proof of Section 3.1

The proof of Theorem 4 is given in the case $m = 1$; we simply denote by X_n the sample $X_n^{(1)}$. The proof for the case $m > 1$ can be adapted from the proof below, by substituting the functions $H_\theta(x)$ and $W(x)$ by

$$\overline{H}_\theta(x_1, \cdots, x_m) = \frac{1}{m}\sum_{k=1}^{m} H_\theta(x_k) \qquad \overline{W}(x_1, \cdots, x_m) = \frac{1}{m}\sum_{k=1}^{m} W(x_k) \ ;$$

the kernel P_θ and its invariant measure π_θ by

$$\begin{aligned}\overline{P}_\theta(x_1, \cdots, x_m; B) &= \int \cdots \int P_\theta(x_m, \mathrm{d}y_1)\prod_{k=2}^{m} P_\theta(y_{k-1}, \mathrm{d}y_k)\mathbb{1}_B(y_1, \ldots, y_m) \ , \\ \overline{\pi}_\theta(B) &= \int \cdots \int \pi_\theta(\mathrm{d}y_1)\prod_{k=2}^{m} P_\theta(y_{k-1}, \mathrm{d}y_k)\mathbb{1}_B(y_1, \ldots, y_m) \ ,\end{aligned}$$

for any $(x_1, \ldots, x_m) \in \mathsf{X}^n$ and $B \in \mathcal{X}^{\times n}$.

6.3.1 Preliminary results

Proposition 11 *Assume that g is proper convex and Lipschitz on Θ with Lipschitz constant K. Then, for all $\theta \in \Theta$,*

$$\|\mathrm{Prox}_{\gamma,g}(\theta) - \theta\| \leq K\gamma \ . \quad (36)$$

Proof For all $\theta \in \Theta$, we get by Lemma 7

$$0 \leq \gamma^{-1}\left\|\theta - \mathrm{Prox}_{\gamma,g}(\theta)\right\|^2 \leq g(\theta) - g(\mathrm{Prox}_{\gamma,g}(\theta)) \leq K\left\|\theta - \mathrm{Prox}_{\gamma,g}(\theta)\right\| \ .$$

■

Proposition 12 *Assume H1, H2 and Θ is bounded. Then*

$$\sup_{\gamma\in(0,1/L]}\sup_{\theta\in\Theta}\|T_\gamma(\theta)\|<\infty\ .$$

If in addition H6-(ii) holds, then there exists a constant C such that for any $\theta,\bar\theta\in\Theta$, $\gamma,\bar\gamma\in(0,1/L]$

$$\left\|T_\gamma(\theta)-T_{\bar\gamma}(\bar\theta)\right\|\le C\left(\gamma+\bar\gamma+\|\theta-\bar\theta\|\right)\ .$$

Proof Let $\theta_\star$ such that for any $\gamma>0$, $\theta_\star=T_\gamma(\theta_\star)$ (such a point exists by H2 and (4)). We write $T_\gamma(\theta)=(T_\gamma(\theta)-\theta_\star)+\theta_\star$. By Lemma 9, there exists a constant C such that for any $\theta\in\Theta$ and any $\gamma\in(0,1/L]$, $\|T_\gamma(\theta)-\theta_\star\|\le 2\,\|\theta-\theta_\star\|\le 2\,\|\theta\|+2\,\|\theta_\star\|$. This concludes the proof of the first statement. We write $T_\gamma(\theta)-T_{\bar\gamma}(\bar\theta)=T_\gamma(\theta)-T_{\bar\gamma}(\theta)+T_{\bar\gamma}(\theta)-T_{\bar\gamma}(\bar\theta)$. By Lemma 7

$$\left\|T_{\bar\gamma}(\theta)-T_{\bar\gamma}(\bar\theta)\right\|\le\left\|\theta-\bar\theta-\bar\gamma\nabla f(\theta)+\bar\gamma\nabla f(\bar\theta)\right\|\le\|\theta-\bar\theta\|+\bar\gamma\sup_{\theta\in\Theta}\|\nabla f(\theta)\|\ .$$

By H1 and since Θ is bounded, $\sup_{\theta\in\Theta}\|\nabla f(\theta)\|<\infty$. In addition, using again Lemma 7,

$$\|T_\gamma(\theta)-T_{\bar\gamma}(\theta)\|\le(\gamma+\bar\gamma)\ \sup_{\theta\in\Theta}\|\nabla f(\theta)\|+\|\mathrm{Prox}_{\gamma,g}(\theta)-\mathrm{Prox}_{\bar\gamma,g}(\theta)\|\ .$$

We conclude by using

$$\begin{aligned}\|\mathrm{Prox}_{\bar\gamma,g}(\theta)-\mathrm{Prox}_{\gamma,g}(\theta)\|&\le\|\mathrm{Prox}_{\bar\gamma,g}(\theta)-\theta\|+\|\theta-\mathrm{Prox}_{\gamma,g}(\theta)\|\\&\le(\gamma+\bar\gamma)\ \sup_{\gamma\in(0,1/L]}\sup_{\theta\in\Theta}\gamma^{-1}\ \|\mathrm{Prox}_{\gamma,g}(\theta)-\theta\|\ .\end{aligned}$$

■

Lemma 13 *Assume H5 and H6-(i).*

(i) There exists a measurable function $(\theta,x)\mapsto\widehat H_\theta(x)$ such that $\sup_{\theta\in\Theta}\left|\widehat H_\theta\right|_W<\infty$ and for any $(\theta,x)\in\Theta\times\mathsf X$,

$$\widehat H_\theta(x)-P_\theta\widehat H_\theta(x)=H_\theta(x)-\int H_\theta(y)\pi_\theta(\mathrm dy)\ . \tag{37}$$

(ii) There exists a constant C such that for any $\theta,\theta'\in\Theta$,

$$\left\|P_\theta\widehat H_\theta-P_{\theta'}\widehat H_{\theta'}\right\|_W\le C\ \ \|\theta-\theta'\|\ .$$

Proof See (Fort et al., 2011, Lemma 4.2). ■

Lemma 14 *Assume H4 and H5. Then, $\sup_n\mathbb E\left[W^p(X_n)\right]<\infty$.*

Proof The conditional distribution of X_j given the past $\mathcal F_{j-1}$ is $P_{\theta_{j-1}}(X_{j-1},\cdot)$. Therefore, we write

$$\mathbb E\left[W^p(X_n)\right]=\mathbb E\left[\mathbb E\left[W^p(X_n)\,|\,\mathcal F_{n-1}\right]\right]=\mathbb E\left[P_{\theta_{n-1}}W^p(X_{n-1})\right].$$

We then use the drift inequality to obtain $\mathbb E\left[W^p(X_n)\right]\le\lambda\mathbb E\left[W^p(X_{n-1})\right]+b$. The proof then follows from a trivial induction. ■

Lemma 15 *Assume H1, H6-(ii) and Θ is bounded. There exists a constant C such that w.p.1, for all $n\ge0$,*

$$\|\theta_{n+1}-\theta_n\|\le C\gamma_{n+1}\left(1+\|\eta_{n+1}\|\right)\ .$$

Proof We write

$$\theta_{n+1}-\theta_n=\theta_{n+1}-\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n)+\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n)-\theta_n.$$

Since by Lemma 7, $\theta\mapsto\mathrm{Prox}_{\gamma,g}(\theta)$ is Lipschitz for any $\gamma>0$, we get

$$\begin{aligned}&\left\|\theta_{n+1}-\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n)\right\|\\&=\left\|\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n-\gamma_{n+1}\eta_{n+1}-\gamma_{n+1}\nabla f(\theta_n))-\mathrm{Prox}_{\gamma_{n+1},g}\left(\theta_n\right)\right\|\\&\le\gamma_{n+1}\left\|\eta_{n+1}+\nabla f(\theta_n)\right\|\le\gamma_{n+1}\left(\|\eta_{n+1}\|+\sup_{\theta\in\Theta}\|\nabla f(\theta)\|\right)\ .\end{aligned}$$

By H1, w.p.1. $\sup_{\theta\in\Theta}\|\nabla f(\theta)\|<\infty$; hence, there exists C_1 such that w.p.1. for all $n\ge0$, $\left\|\theta_{n+1}-\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n)\right\|\le C_1\gamma_{n+1}\left(1+\|\eta_{n+1}\|\right)$. Finally, under H6-(ii), there exists a constant C_2 such that, w.p.1.,

$$\sup_n\gamma_{n+1}^{-1}\left\|\mathrm{Prox}_{\gamma_{n+1},g}(\theta_n)-\theta_n\right\|\le\sup_{\gamma\in(0,1/L]}\sup_{\theta\in\Theta}\gamma^{-1}\left\|\mathrm{Prox}_{\gamma,g}(\theta)-\theta\right\|\le C_2\ .$$

This concludes the proof. ■

Lemma 16 *Assume H1, H4, H5 and Θ is bounded. There exists a constant C such that w.p.1, for all $n\ge0$, $\|\eta_{n+1}\|\le CW(X_{n+1})$.*

Proof By H4 and H5, $\|\eta_{n+1}\|\le\left(\sup_{\theta\in\Theta}|H_\theta|_W\right)W(X_{n+1})+\sup_{\theta\in\Theta}\|\nabla f(\theta)\|$. The result follows since ∇f is Lipschitz by H1, and since $W\ge1$. ■

6.3.2 Proof of Theorem 4

The proof of the almost-sure convergence consists in verifying the assumptions of Theorem 2. Let us start with the proof that almost-surely, $\sum_n \gamma_{n+1}^2 \|\eta_{n+1}\|^2 < \infty$. This property is a consequence of Lemma 17 applied with $a_n \leftarrow \gamma_n^2$. It remains to prove that almost-surely

$$\sum_n \gamma_n \eta_n < \infty, \qquad \sum_n \gamma_{n+1} \left\langle T_{\gamma_{n+1}}(\theta_n), \eta_{n+1} \right\rangle < \infty;$$

note that they are both of the form $\sum_n \gamma_{n+1} \mathsf{A}_{\gamma_{n+1}}(\theta_n)\eta_{n+1}$ with, respectively, $\mathsf{A}_\gamma(\theta)$ equal to the identity matrix, and $\mathsf{A}_\gamma(\theta) = T_\gamma(\theta)$. In the case the Monte Carlo is unbiased, we apply Proposition 18 with $a_n \leftarrow \gamma_n$ and $A_\gamma(\theta)$ equal to the identity matrix and we obtain the almost-sure convergence of $\sum_n \gamma_n \eta_n$; we then apply Proposition 18 with $a_n \leftarrow \gamma_n$ and $A_\gamma(\theta) = T_\gamma(\theta)$, and we obtain the almost-sure convergence of $\sum_n \gamma_{n+1} \left\langle T_{\gamma_{n+1}}(\theta_n), \eta_{n+1} \right\rangle$ - note that by Proposition 12, $T_\gamma(\theta)$ satisfies the assumptions on $\mathsf{A}_\gamma(\theta)$. In the case the Monte Carlo is biased, the steps are the same except we use Proposition 19 instead of Proposition 18.

For the control of the moments, we use Theorem 3 and again Lemma 17 and Proposition 18 for the unbiased case (or Proposition 19 for the biased case).

Lemma 17 *Assume H1, H4, H5 and Θ is bounded.*

(i) If $a_k \geq 0$ and $\sum_{k=1}^\infty a_k < \infty$ then with probability one, $\sum_{n\geq 1} a_n \|\eta_n\|^2 < \infty$.

(ii) for any $q \in [1, p/2]$, there exists a constant C such that for any non-negative numbers $\{a_1, \cdots, a_n\}$,

$$\left\| \sum_{k=1}^n a_k \|\eta_k\|^2 \right\|_{L^q} \leq C \sum_{k=1}^n a_k \ .$$

Proof We write

$$\mathbb{E}\left[\sum_{n\geq 0} a_{n+1} \|\eta_{n+1}\|^2 \right] \leq \sup_n \left(\mathbb{E}\left[\|\eta_{n+1}\|^2 \right] \right) \sum_{n\geq 0} a_{n+1} \ .$$

By Lemma 14 and Lemma 16, $\sup_n \|\eta_{n+1}\|_{L^2} < \infty$ so the RHS is finite. By the Minkovski inequality, we write since $a_k > 0$,

$$\left\| \sum_{k=0}^n a_{k+1} \|\eta_{k+1}\|^2 \right\|_{L^q} \leq \sup_n \|\eta_n\|_{L^{2q}}^2 \sum_{k=1}^{n+1} a_k \ .$$

The supremum is finite by Lemma 14 and Lemma 16. ∎

Proposition 18 *Assume H1, H3, H4, H5, Θ is bounded and the Monte Carlo approximation is unbiased. Let $\{a_n,\ n \in \mathbb{N}\}$ be a deterministic positive sequence and $\{\mathsf{A}_\gamma(\theta), \gamma \in (0, 1/L], \theta \in \Theta\}$ be deterministic matrices such that*

$$\sup_{\gamma \in (0,1/L]} \sup_{\theta \in \Theta} \|\mathsf{A}_\gamma(\theta)\| < \infty \ . \tag{38}$$

(i) If $\sum_{n\geq 0} a_n^2 < \infty$, then the series $\sum_{n\geq 0} a_{n+1} \mathsf{A}_{\gamma_{n+1}}(\theta_n)\eta_{n+1}$ converges $\mathbb{P}$-a.s.

(ii) For any $q \in (1, p/2]$, there exists a constant C such that

$$\left\| \sum_{k=0}^n a_{k+1} \mathsf{A}_{\gamma_{k+1}}(\theta_k)\eta_{k+1} \right\|_{L^q} \leq C \ \left(\sum_{k=0}^n a_{k+1}^2 \right)^{1/2} \ .$$

Proof Since $\theta_n \in \mathcal{F}_n$, we have $\mathbb{E}\left[a_{n+1} \mathsf{A}_{\gamma_{n+1}}(\theta_n)\ \eta_{n+1} | \mathcal{F}_n \right] = 0$, thus showing that $\{M_n = \sum_{k=0}^n a_{k+1} \mathsf{A}_{\gamma_{k+1}}(\theta_k)\eta_{k+1}, n \in \mathbb{N}\}$ is a martingale. This martingale converges almost-surely if $S = \sum_{n\geq 0} a_{n+1}^2 \|\mathsf{A}_{\gamma_{n+1}}(\theta_n)\|^2 \|\eta_{n+1}\|^2 < \infty$ $\mathbb{P}$-a.s. (see e.g. (Hall and Heyde, 1980, Theorem 2.17)). Using (38) and Lemma 17, $S < \infty$ $\mathbb{P}$-a.s.

Consider now the L^q-moment of M_n. We apply (Hall and Heyde, 1980, Theorem 2.10): for any $q \in (1, p/2]$, there exists a constant C such that for any $n \geq 0$,

$$\left\| \sum_{k=0}^n a_{k+1} \mathsf{A}_{\gamma_{k+1}}(\theta_k)\eta_{k+1} \right\|_{L^q} \leq C \left(\sum_{k=0}^n \left\| a_{k+1} \mathsf{A}_{\gamma_{k+1}}(\theta_k)\eta_{k+1} \right\|_{L^q}^2 \right)^{1/2} \ .$$

Lemma 14 and Lemma 16 imply that $\sup_n \|\eta_{n+1}\|_{L^q} < \infty$; we then conclude with (38). ∎

Proposition 19 *Assume H1, H3–H6 and Θ is bounded. Let $\{a_n, n \geq 0\}$ be a positive sequence and $\{\mathsf{A}_\gamma(\theta), \gamma \in (0, 1/L], \theta \in \Theta\}$ be (deterministic) function-valued matrices such that there exists C_A and for any $\gamma, \bar{\gamma} \in (0, 1/L]$ and $\theta, \bar{\theta} \in \Theta$*

$$\sup_{\gamma \in (0,1/L]} \sup_{\theta \in \Theta} \|\mathsf{A}_\gamma(\theta)\| < \infty \ , \qquad \left\| \mathsf{A}_\gamma(\theta) - \mathsf{A}_{\bar{\gamma}}(\bar{\theta}) \right\| \leq C_\mathsf{A} \left(\gamma + \bar{\gamma} + \left\| \theta - \bar{\theta} \right\| \right) \ . \tag{39}$$

(i) If $\sum_n a_n \gamma_n < \infty$, $\sum_n a_n^2 < \infty$ and $\sum_n |a_{n+1} - a_n| < \infty$ then the series $\sum_{n\geq 0} a_{n+1} \mathsf{A}_{\gamma_{n+1}}(\theta_n)\eta_{n+1}$ converges $\mathbb{P}$-a.s.

(ii) For any $q \in (1, p/2]$, there exists a constant C such that

$$\left\| \sum_{k=0}^n a_{k+1} \mathsf{A}_{\gamma_{k+1}}(\theta_k)\eta_{k+1} \right\|_{L^q} \leq C \ \left\{ 1 + \left(\sum_{k=0}^n a_{k+1}^2 \right)^{1/2} + \sum_{k=1}^n |a_{k+1} - a_k| + \sum_{k=1}^n a_k \gamma_k \right\} \ .$$

Proof

(i) By H4 and Lemma 13-(i), we write

$$\begin{aligned} \eta_{n+1} &= \widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n} \widehat{H}_{\theta_n}(X_{n+1}) \\ &= \left(\widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n} \widehat{H}_{\theta_n}(X_n) \right) + \left(P_{\theta_n} \widehat{H}_{\theta_n}(X_n) - P_{\theta_{n+1}} \widehat{H}_{\theta_{n+1}}(X_{n+1}) \right) \\ &+ \left(P_{\theta_{n+1}} \widehat{H}_{\theta_{n+1}}(X_{n+1}) - P_{\theta_n} \widehat{H}_{\theta_n}(X_{n+1}) \right) \ . \end{aligned}$$

We prove successively that w.p.1,

$$\sum_n a_{n+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n)\ \left(\widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_n)\right) < \infty\ , \tag{40}$$

$$\sum_{n\geq 0} a_{n+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n)\ \left(P_{\theta_n}\widehat{H}_{\theta_n}(X_n) - P_{\theta_{n+1}}\widehat{H}_{\theta_{n+1}}(X_{n+1})\right) < \infty\ , \tag{41}$$

$$\sum_{n\geq 0} a_{n+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n)\left(P_{\theta_{n+1}}\widehat{H}_{\theta_{n+1}}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_{n+1})\right) < \infty\ . \tag{42}$$

Proof [Proof of (40)] By H4, $\{\widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_n), n\in\mathbb{N}\}$ is a martingale increment w.r.t. the filtration $\{\mathcal{F}_n, n\geq 0\}$. The proof is along the same lines as the proof of Proposition 18 upon noting that by Lemma 13 and H5, there exists C such that w.p.1 for all $n\geq 0$,

$$\|\widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_n)\| \leq C\ \{W(X_{n+1}) + W(X_n)\}\ .$$

■

Proof [Proof of (41)] The sum is equal to $\sum_{n\geq 0}\Delta_{n+1}P_{\theta_n}\widehat{H}_{\theta_n}(X_n)$ with $\Delta_{n+1} = a_{n+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n) - a_n\mathsf{A}_{\gamma_n}(\theta_{n-1})$. On one hand, by Lemma 13 and H5, there exists C such that w.p.1 for all $n\geq 0$,

$$\left\|P_{\theta_n}\widehat{H}_{\theta_n}(X_n)\right\| \leq C\,W(X_n)\ .$$

On the other hand, by (39), Lemma 15 and Lemma 16, there exists C such that a.s.

$$\text{for all } n\geq 0, \qquad \|\Delta_{n+1}\| \leq C\Big(\,|a_{n+1}-a_n| + a_n\,(\gamma_n+\gamma_{n+1})\,\Big)W(X_n)\ .$$

By Lemma 14, $\sup_n \mathbb{E}\left[W^2(X_n)\right] < \infty$. Therefore, by (39) and the assumptions on $\{a_n, n\geq 0\}$, we have $\sum_n \mathbb{E}\left[\left\|\Delta_{n+1}\ P_{\theta_n}\widehat{H}_{\theta_n}(X_n)\right\|\right] < \infty$; which concludes the proof. ■

Proof [Proof of (42)] By (39) and Lemma 13, there exists a constant C such that w.p.1 for any n

$$\left\|\mathsf{A}_{\gamma_{n+1}}(\theta_n)\left(P_{\theta_{n+1}}\widehat{H}_{\theta_{n+1}}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_{n+1})\right)\right\| \leq C\ \|\theta_{n+1}-\theta_n\|\ W(X_{n+1})\ .$$

By Lemma 15 and Lemma 16, there exists a constant C such that w.p.1,

$$\text{for all } n\geq 0, \qquad \|\theta_{n+1}-\theta_n\|\,W(X_{n+1}) \leq C\gamma_{n+1}\,W^2(X_{n+1})\ .$$

From Lemma 14 and the assumptions on $\{a_n, n\geq 0\}$, $\sum_n a_{n+1}\,\gamma_{n+1}\mathbb{E}\left[W^2(X_{n+1})\right] < \infty$ from which (42) follows. ■

(ii) We start from the same decomposition of η_{n+1} in three terms. The first one is a martingale, and following the same lines as in the proof of Proposition 18, we obtain

$$\left\|\sum_{k=0}^n a_{k+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n)\ \left(\widehat{H}_{\theta_n}(X_{n+1}) - P_{\theta_n}\widehat{H}_{\theta_n}(X_n)\right)\right\|_{L^q} \leq C\left(\sum_{k=0}^n a_{k+1}^2\right)^{1/2}\ .$$

For the second term, we write

$$\begin{aligned}\sum_{k=0}^n a_{k+1}\mathsf{A}_{\gamma_{k+1}}(\theta_k)\ &\left(P_{\theta_k}\widehat{H}_{\theta_k}(X_k) - P_{\theta_{k+1}}\widehat{H}_{\theta_{k+1}}(X_{k+1})\right)\\ &\leq a_1\mathsf{A}_{\gamma_1}(\theta_0)P_{\theta_0}\widehat{H}_{\theta_0}(X_0) - a_{n+1}\mathsf{A}_{\gamma_{n+1}}(\theta_n)P_{\theta_{n+1}}\widehat{H}_{\theta_{n+1}}(X_{n+1})\\ &+\sum_{k=1}^n \Delta_{k+1}\ P_{\theta_k}\widehat{H}_{\theta_k}(X_k)\ .\end{aligned}$$

By the Minkovski inequality, it is easily seen that there exists a constant C such that

$$\begin{aligned}&\left\|\sum_{k=0}^n a_{k+1}\mathsf{A}_{\gamma_{k+1}}(\theta_k)\ \left(P_{\theta_k}\widehat{H}_{\theta_k}(X_k) - P_{\theta_{k+1}}\widehat{H}_{\theta_{k+1}}(X_{k+1})\right)\right\|_{L^q}\\ &\qquad\leq\left(1 + a_{n+1} + \sum_{k=1}^n\Big(\,|a_{k+1}-a_k| + a_k\,(\gamma_k+\gamma_{k+1})\,\Big)\right)\ .\end{aligned}$$

Finally, for the last term, following the same computations as above, we have by the Minkovski inequality

$$\left\|\sum_{k=0}^n a_{k+1}\mathsf{A}_{\gamma_{k+1}}(\theta_k)\ \left(P_{\theta_{k+1}}\widehat{H}_{\theta_{k+1}}(X_{k+1}) - P_{\theta_k}\widehat{H}_{\theta_k}(X_{k+1})\right)\right\|_{L^q} \leq C\sum_{k=0}^n a_{k+1}\gamma_{k+1}\ .$$

■

6.4 Proof of Theorem 6

We write $\eta_{n+1} = B_n + (\eta_{n+1} - B_n)$ where B_n is given by (12). Observe that $\{\eta_{n+1} - B_n, n\in\mathbb{N}\}$ is a martingale-increment sequence. Sufficient conditions for the almost-sure convergence of a martingale and the control of L^q-moments can be found in (Hall and Heyde, 1980, Theorems 2.10 and 2.17). Then the proof follows from Proposition 5 and Lemma 14.

Appendix A. Proofs of section 4

By using the Cauchy-Schwartz inequality, it holds

$$\int \exp(\ell_c(\theta|\mathbf{u}))\,\phi(\mathbf{u})\mathrm{d}\mathbf{u} \geq \left(\int \exp(0.5\ell_c(\theta|\mathbf{u}))\,\phi(\mathbf{u})\mathrm{d}\mathbf{u}\right)^{1/2}$$

$$\left(\int \exp(\ell_c(\theta|\mathbf{u}))\,\|u\|^2\,\phi(\mathbf{u})\,\mathrm{d}\mathbf{u}\right)^2 \leq \left(\int \exp(0.5\ell_c(\theta|\mathbf{u}))\phi(\mathbf{u})\,\mathrm{d}\mathbf{u}\right)\,\left(\int \exp(3\ell_c(\theta|\mathbf{u})/2)\|u\|^4\phi(\mathbf{u})\mathrm{d}\mathbf{u}\right)$$

which implies that

$$\int \|u\|^2\pi_\theta(\mathbf{u})\mathrm{d}\mathbf{u} = \frac{\int \exp(\ell_c(\theta|\mathbf{u}))\|u\|^2\phi(\mathbf{u})\mathrm{d}\mathbf{u}}{\int \exp(\ell_c(\theta|v))\phi(v)\mathrm{d}v} \leq \left(\int \exp\left(3\ell_c(\theta|\mathbf{u})/2\right)\,\|\mathbf{u}\|^4\,\phi(\mathbf{u})\,\mathrm{d}\mathbf{u}\right)^{1/2}$$

Since $\exp(\ell_c(\theta|\mathbf{u})) \leq 1$ and $\int \|\mathbf{u}\|^4\phi(\mathbf{u})\mathrm{d}\mathbf{u} = q(2+q)$, we have

$$\sup_{\theta\in\Theta}\int \|u\|^2\pi_\theta(\mathbf{u})\mathrm{d}\mathbf{u} \leq \sqrt{q(2+q)}\,.$$

Appendix B. Proof of section 5

For $\theta, \vartheta \in \Theta$, the (i,j)-th entry of the matrix $\nabla\ell(\theta) - \nabla\ell(\vartheta)$ is given by

$$\left(\nabla\ell(\theta) - \nabla\ell(\vartheta)\right)_{ij} = \int_{\mathsf{X}^p} \bar{B}_{ij}(x)\pi_\vartheta(\mathrm{d}x) - \int_{\mathsf{X}^p} \bar{B}_{ij}(x)\pi_\theta(\mathrm{d}x).$$

For $t \in [0,1]$ let

$$\pi_t(\mathrm{d}z) \stackrel{\mathrm{def}}{=} \frac{\exp\left(\left\langle \bar{B}(z), t\vartheta + (1-t)\theta\right\rangle\right)}{\int \exp\left(\left\langle \bar{B}(x), t\vartheta + (1-t)\theta\right\rangle\right)\mu(\mathrm{d}x)},$$

defines a probability measure on X^p. It is straightforward to check that

$$\left(\nabla\ell(\theta) - \nabla\ell(\vartheta)\right)_{ij} = \int \bar{B}_{ij}(x)\pi_1(\mathrm{d}x) - \int \bar{B}_{ij}(x)\pi_0(\mathrm{d}x),$$

and that $t \mapsto \int \bar{B}_{ij}(x)\pi_t(\mathrm{d}x)$ is differentiable with derivative

$$\begin{aligned}
&\frac{\mathrm{d}}{\mathrm{d}t}\int \bar{B}_{ij}(x)\pi_t(\mathrm{d}x)\\
&= \int \bar{B}_{ij}(x)\left\langle \bar{B}(x) - \int \bar{B}(z)\pi_t(\mathrm{d}z), \vartheta - \theta\right\rangle \pi_t(\mathrm{d}x),\\
&= \mathsf{Cov}_{\pi_t}\left(\bar{B}_{ij}(X), \left\langle \bar{B}(X), \vartheta - \theta\right\rangle\right),
\end{aligned}$$

where the covariance is taken assuming that $X \sim \pi_t$. Hence

$$\left|\left(\nabla\ell(\theta) - \nabla\ell(\vartheta)\right)_{ij}\right| = \left|\int_0^1 \mathrm{d}t\;\; \mathsf{Cov}_t\left(\bar{B}_{ij}(X), \left\langle \bar{B}(X), \vartheta - \theta\right\rangle\right)\right| \leq \mathsf{osc}(\bar{B}_{ij})\sqrt{\sum_{k\leq l}\mathsf{osc}^2(\bar{B}_{kl})}\|\theta - \vartheta\|_2.$$

This implies the inequality (16).

Abstract

Differential privacy formalises privacy-preserving mechanisms that provide access to a database. Can Bayesian inference be used directly to provide private access to data? The answer is yes: under certain conditions on the prior, sampling from the posterior distribution can lead to a desired level of privacy and utility. For a uniform treatment, we define differential privacy over arbitrary data set metrics, outcome spaces and distribution families. This allows us to also deal with non-i.i.d or non-tabular data sets. We then prove bounds on the sensitivity of the posterior to the data, which delivers a measure of robustness. We also show how to use posterior sampling to provide differentially private responses to queries, within a decision-theoretic framework. Finally, we provide bounds on the utility of answers to queries and on the ability of an adversary to distinguish between data sets. The latter are complemented by a novel use of Le Cam's method to obtain lower bounds on distinguishability. Our results hold for arbitrary metrics, including those for the common definition of differential privacy. For specific choices of the metric, we give a number of examples satisfying our assumptions.

∗. A preliminary version of this paper appeared in *Algorithmic Learning Theory 2014* (Dimitrakakis et al., 2014). This version corrects proofs, constant factors in the upper bounds and introduces new material on utility analysis, lower bounds and examples.

Keywords: Bayesian inference, differential privacy, robustness, adversarial Learning

1. Introduction

The Bayesian framework for statistical decision theory incorporates uncertainty into decision making in a probabilistic manner. This makes the framework attractive, as predictions and modelling can all be made with the machinery of probability. More specifically, a Bayesian statistician begins by assuming that the world is described by a probabilistic model within some family, and he assigns a prior belief to each one of the models. After observing data, this belief is adjusted through Bayes's theorem to the so called posterior belief. This expresses the statistician's conclusion given the data and the prior assumptions. The statistician can then release the posterior to the world, for others to build upon, or use for principled decision making under uncertainty.

Unfortunately, it is frequently the case that the data acquired by the statistician is sensitive. Consequently, there is a fear that any information released by the statistician that depends on the data—be that the posterior distribution itself or any decisions that follow from the calculated posterior—may reveal sensitive information in the original data. Recently, the framework of differential privacy has been proposed to codify this leakage of information. If an algorithm is differentially private, then its output can only leak a bounded amount of information about its input.

We are interested in the question of how one can build differentially-private algorithms within the Bayesian framework. More precisely, we examine when the choice of prior is sufficient to guarantee differential privacy for decisions that are derived from the posterior distribution. Our work develops a unified understanding of privacy and learning in adversarial environments, under a decision-theoretic framework. We show that under suitable assumptions, standard Bayesian inference and posterior sampling can achieve uniformly good utility with a fixed privacy budget in the differential privacy setting. We also indicate strong connections between robustness and privacy. Under the base level of data privacy provided by the posterior distribution, the statistician can safely respond to external queries using samples from the posterior. When estimating a linear model from sensitive data, for example, samples from the posterior correspond to different possible fits. The more samples used, the more privacy is leaked, while query responses may be more accurate.

Our proposed approach complements existing mechanisms rather well, and may be particularly useful in situations where Bayesian inference is already in use. For this reason, we provide illustrative examples in the exponential family. However, our setting is wholly general and not limited to specific distribution families, or i.i.d. observations. Any family could be chosen: so long as it either satisfies our assumptions directly, or can be restricted so that it does. For example, our framework applies to families of discrete Bayesian networks with directed-acyclic topologies (*e.g.*, Markov chains; see Lemma 24 on page 21) and multivariate Gaussians (see Lemma 23), where the observations may not satisfy the i.i.d. assumption.

Summary of setting. A Bayesian statistician ($\mathscr{B}$) wishes to communicate results about data x to a third party ($\mathscr{A}$), but without revealing the data x itself. We make no assumptions on the data x, which could be a single observation, an i.i.d. sample, or a sequence of observations. The protocol of interaction between $\mathscr{B}$ and $\mathscr{A}$ is summarised below.

1. $\mathscr{B}$ selects a model family ($\mathcal{F}_\Theta$) and a prior (ξ).
2. $\mathscr{A}$ is allowed to see $\mathcal{F}_\Theta$ and ξ and is computationally unbounded.
3. $\mathscr{B}$ observes data x and calculates the posterior $\xi(\theta \mid x)$ but does not reveal it. Then, for steps $t = 1, 2, \ldots$, repeat the following:
4. $\mathscr{A}$ sends his utility function u and a query q_t to $\mathscr{B}$.
5. $\mathscr{B}$ responds with the response r_t maximising u, in a manner that depends on the query and the posterior.

Let us now elaborate. In this framework, the choice of the model family $\mathcal{F}_\Theta$ is dictated by the problem. The choice of ξ is normally determined by the prior knowledge of $\mathscr{B}$, but we show that this also affects what level of privacy is achieved. Informally speaking, informative priors achieve better privacy, as the posterior has a weaker dependency on the data. It is natural to assume that the prior itself is public, as it should reflect publicly available information. The statistician's conclusion from the observed data x is then summarised in the posterior distribution $\xi(\theta \mid x)$, which remains private.

The second part of the process is the interaction with $\mathscr{A}$. We adopt a decision-theoretic viewpoint to characterise what the optimal responses to queries should be. More specifically, we assume the existence of a "true" parameter $\theta \in \Theta$, and that $\mathscr{A}$ has a utility function $u_\theta(q_t, r_t)$, which he wishes to maximise. For example, consider the case where $\theta = (\mu, \Sigma)$ are the parameters of a normal distribution. An example query q_t is *"what is the expected value* $\mathbb{E}_\theta\, x_i = \mu$ *of the distribution?"*. The optimal response r_t, would then be a real vector that depends on the utility function. A possible utility function is the negative squared L_2 distance:

$$u_\theta(q_t = \text{"what is the mean?"}, r_t) = -\| \mathbb{E}_\theta\, x_i - r_t \|_2^2.$$

While θ is unknown, $\mathscr{B}$ has information about it in the form of a posterior distribution. Using standard decision-theoretic notions, the optimal response of $\mathscr{B}$ would maximise the expected utility $\mathbb{E}_\xi(u \mid q_t, r_t, x)$, where the expectation is taken over the posterior distribution. However, this deterministic response cannot be differentially private.

In this paper, we promote the use of *posterior sampling* to respond to queries. The posterior sampling mechanism draws a set $\hat{\Theta}$ of i.i.d. samples from the posterior distribution. Then, all the responses only depend on the posterior through $\hat{\Theta}$. Since our algorithm only takes a single sample set $\hat{\Theta}$, further queries by the adversary reveal nothing more about the data than what can be inferred from $\hat{\Theta}$. The empirical distribution induced by $\hat{\Theta}$ serves as a private surrogate for the exact (non-private) posterior. Consequently, we can respond to an arbitrary number of queries with a bounded privacy budget, while guaranteeing good utility for all responses.

We show that if $\mathcal{F}_\Theta$ and ξ are chosen appropriately, this results in differentially-private responses, as well as robustness of the posterior.[1] In addition, we prove upper and lower bounds on how easy it is for an adversary to distinguish two ϵ-close data sets. Finally, we bound the loss in utility incurred due to privacy. The intuition behind our results

1. More specifically, that small changes in the data result in small changes in the posterior in terms of the KL divergence.

is that robustness and privacy are linked via smoothness. Learning algorithms that are smooth mappings—their output (*e.g.*, a spam filter) varies little with perturbations to input (*e.g.*, similar training corpora)—are robust: outliers have reduced influence, and adversaries cannot easily discover unknown information about the data. This suggests that robustness and privacy can be simultaneously achieved and are in fact deeply linked.

We provide a uniform mathematical treatment of the privacy and robustness properties of Bayesian inference based on generalised differential privacy to arbitrary data set distances, outcome spaces, and distribution families. This paper can be summarised as making the following distinct contributions:

- Under certain regularity conditions on the prior distribution ξ or likelihood family $\mathcal{F}_\Theta$, we show that the posterior distribution is *robust*: small changes in the data set result in small posterior changes.
- We introduce a novel *posterior sampling mechanism* that is private.[2] Unlike other common mechanisms in differential privacy, our approach sits squarely in the non-private (Bayesian) learning framework without modification.
- We provide necessary and sufficient conditions for differentially private Bayesian inference.
- We introduce the notion of *data set distinguishability* for which we provide finite-sample bounds for our mechanism: how large would $\hat{\Theta}$ need to be for $\mathscr{A}$ to distinguish two data sets with high probability.
- We provide examples of conjugate-pair distributions where our assumptions hold, including discrete Bayesian networks. We find that even though Bayesian posterior sampling does provide privacy guarantees directly, those appear to be very weak for standard conjugate families. However, with a small modification of the prior, it is easy to obtain good privacy guarantees.

Paper organisation. Section 2 specifies the setting and our assumptions. Section 3 proves results on robustness of Bayesian learning. Section 4 proves our main privacy results. In particular, Section 4.1 shows that the posterior distribution is differentially private, Section 4.2 describes our posterior sampling query response algorithm, Section 4.3 derives bounds on data set indistinguishability, Section 4.5 shows how to obtain matching lower bounds for distinguishability, while Section 4.4 shows how utility and privacy can be traded off within our framework. Examples where our assumptions hold are given in Section 5. We present a discussion of our results, related work and links to the exponential mechanism and robust Bayesian inference in Section 6. Appendix A contains proofs of the main theorems. Finally, Appendix B details proofs of the examples demonstrating our assumptions.

2. Problem Setting

We consider the problem of a Bayesian statistician ($\mathscr{B}$) communicating with an untrusted third party ($\mathscr{A}$). $\mathscr{B}$ wants to convey useful responses to the queries of $\mathscr{A}$ (*e.g.*, how

2. Although previously used *e.g.*, for efficient exploration in reinforcement learning (Thompson, 1933; Osband et al., 2013), posterior sampling has not previously been employed for privacy.

many people suffer from a disease or vote for a particular party) without revealing private information about the original data (*e.g.*, whether a particular person has cancer). This requires communicating information in a way that strikes a balance between utility and privacy. In this paper, we study the inherent privacy and robustness properties of Bayesian inference and explore the question of whether $\mathscr{B}$ can select a prior distribution so that a computationally unbounded $\mathscr{A}$ cannot obtain private information from queries.

2.1 Definitions and Notation

We begin with our notation. Let $\mathcal{S}$ be the set of all possible data sets. For example, if $\mathcal{X}$ is a finite alphabet, then we might have $\mathcal{S} = \bigcup_{n=0}^{\infty} \mathcal{X}^n$, *i.e.*, the set of all possible observation sequences over $\mathcal{X}$. However, $\mathcal{S}$ can have arbitrary structure and so social network or mobility trace data are also handled in this framework. Probability measures on parameters θ are usually denoted by ξ, while measures and densities on data are denoted by P_θ or p_θ respectively. Expectations are denoted by $\mathbb{E}_\xi\, g \triangleq \int_\Theta g(\theta)\,\mathrm{d}\xi(\theta)$, where the subscript denotes the underlying distribution with respect to which we are taking expectations. In case of ambiguity, we explicitly write *e.g.*, $\mathbb{E}_{x\sim P_\theta}\, f(x) = \int_{\mathcal{S}} f(x)\,\mathrm{d}P_\theta(x)$ to denote which variables are drawn from which distributions. Finally, we use $\mathbb{I}\{\pi\}$ to be the identity function, taking the value 1 when the predicate π is true, and 0 otherwise.

2.1.1 Distances Between Data Sets

Central to the notions of privacy and robustness, is the concept of distance between data sets. Firstly, the effect of data set perturbation on learning depends on the amount of noise as quantified by some distance. This is useful for characterising robustness to noise or adversarial manipulation of the data. Secondly, the amount that an attacker can learn from queries can be quantified in terms of the distance of his guesses to the true data set. Finally, it allows for a unified mathematical treatment, as it permits different types of neighbourhoods to be defined. To model these situations, we equip $\mathcal{S}$ with a pseudo-metric[3] $\rho : \mathcal{S} \times \mathcal{S} \to \mathbb{R}_+$. This generalisation has also been used by Chatzikokolakis et al. (2013), which has laid the groundwork for metric-based differential privacy. While this concept has many applications in the context of geographical information systems, we apply this generalisation of differential privacy without necessarily referring to some underlying physical distance.

2.1.2 Bayesian Inference

This paper focuses on the *Bayesian inference* setting, where the statistician $\mathscr{B}$ constructs a posterior distribution from a prior distribution ξ and a training data set x. More precisely, we assume that data $x \in \mathcal{S}$ have been drawn from some distribution $P_{\theta^\star}$ on $\mathcal{S}$, parameterised by $\theta^\star$, from a family of distributions $\mathcal{F}_\Theta$. $\mathscr{B}$ defines a parameter set Θ indexing a family of distributions $\mathcal{F}_\Theta$ on $(\mathcal{S}, \mathfrak{S}_\mathcal{S})$, where $\mathfrak{S}_\mathcal{S}$ is an appropriate σ-algebra on $\mathcal{S}$:

$$\mathcal{F}_\Theta \triangleq \{\, P_\theta : \theta \in \Theta \,\},$$

3. Meaning that $\rho(x, y) = 0$ does not necessarily imply $x = y$.

and where we use p_θ to denote the corresponding densities[4] when necessary. To perform inference in the Bayesian setting, $\mathscr{B}$ selects a prior measure ξ on $(\Theta, \mathfrak{S}_\Theta)$ reflecting $\mathscr{B}$'s subjective beliefs about which θ is more likely to be true, *a priori*; *i.e.*, for any measurable set $B \in \mathfrak{S}_\Theta$, $\xi(B)$ represents $\mathscr{B}$'s prior belief that $\theta^\star \in B$. In general, the posterior distribution after observing $x \in \mathcal{S}$ is:

$$\xi(B \mid x) = \frac{\int_B p_\theta(x)\,\mathrm{d}\xi(\theta)}{\phi(x)}\ , \tag{1}$$

where ϕ is the corresponding marginal density given by:

$$\phi(x) \triangleq \int_\Theta p_\theta(x)\,\mathrm{d}\xi(\theta)\ .$$

While the choice of the prior is generally arbitrary, this paper shows that its careful selection can yield good privacy guarantees. Throughout the paper, we shall use the following simple example to ground our observations and theory. This consists of a finite family of distributions, on a finite alphabet. Consequently, calculation of the posterior distribution is always simple. It is also easy to verify our assumptions on this model.

Example 1 (Finite Bernoulli family.) *Consider a finite family of distributions $\mathcal{F}_\Theta = \{\, P_\theta : \theta \in \Theta \,\}$ on alphabet $\mathcal{X} = \{\, 0, 1 \,\}$, with $\theta \in [0, 1]$, such that for any model in the family and any observation x*

$$P_\theta(x) = \theta\, \mathbb{I}\{x = 1\} + (1 - \theta)\, \mathbb{I}\{x = 0\}\,.$$

For any sequence of observations $x_1, \ldots, x_T$, we have, with some abuse of notation,

$$P_\theta(x_1, \ldots, x_T) = \prod_{t=1}^{T} P_\theta(x_t),$$

i.e., *P_θ defines an i.i.d. distribution on the alphabet. This family corresponds to a set of Bernoulli models. The set of parameters Θ will be chosen to discretise the parameter space of Bernoulli distributions over Δ-sized intervals. For this, the k-th model's parameter will be $\theta_k = \Delta k$, with $\Delta \in (0, 1)$ and $k \leq 1/\Delta$.*

For the above family, we can use a uniform prior distribution $\xi(\theta_k) = \Delta$. The posterior distribution is easily calculated, since we need only sum over a finite number of parameters.

2.1.3 Privacy

We now recall the concept of differential privacy (Dwork, 2006). This states that on *neighbouring* data sets, a randomised query response mechanism yields (pointwise) similar distributions. We adopt the view of mechanisms as conditional distributions under which differential privacy can be seen as a measure of smoothness. In our setting, conditional distributions conveniently correspond to posterior distributions. These can also be interpreted as the distribution of a mechanism that uses posterior sampling, to be introduced in Section 4.2. The precise definition depends on the notion of neighbourhood, with the following choice being common:

4. *I.e.*, the Radon-Nikodym derivative of P_θ relative to some dominating measure ν.

Definition 1 ((ϵ, δ)-differential privacy) *A conditional distribution $P(\cdot \mid x)$ on $(\Theta, \mathfrak{S}_\Theta)$ is* (ϵ, δ)-differentially private *if, for all $B \in \mathfrak{S}_\Theta$ and for any $x \in \mathcal{S} = \mathcal{X}^n$*

$$P(B \mid x) \leq e^\epsilon P(B \mid y) + \delta,$$

for all y in the Hamming-1 neighbourhood *of x. That is, y may differ in at most one entry from x: there is at most one $i \in \{1, \ldots, n\}$ such that $x_i \neq y_i$.*

A typical situation where this definition is employed, is when x, y are matrices and x_i is a single row in the matrix. Then, the data sets are neighbours if a matrix row is changed.[5]

In our setting, it is reasonable to generalise this to arbitrary data set spaces $\mathcal{S}$ that are not necessarily product spaces. To do so, we use the notion of differential privacy under a pseudo-metric ρ on the space of all data sets, which allows for more subtle representations of attacker knowledge and for a more general treatment:

Definition 2 ((ϵ, δ)-differential privacy under ρ.) *A conditional distribution $P(\cdot \mid x)$ on $(\Theta, \mathfrak{S}_\Theta)$ is* (ϵ, δ)-differentially private under *a pseudo-metric $\rho : \mathcal{S} \times \mathcal{S} \to \mathbb{R}_+$ if, for all $B \in \mathfrak{S}_\Theta$ and for any $x, y \in \mathcal{S}$,*

$$P(B \mid x) \leq e^{\epsilon\rho(x,y)} P(B \mid y) + \delta\rho(x, y)\ .$$

In our setting, ρ replaces the notion of neighbourhood. It is of course possible to use ρ that corresponds to the usual meaning of neighbourhood in differential privacy:

Remark 3 *If $\mathcal{S} = \mathcal{X}^n$ and $\rho(x, y) = \sum_{i=1}^n \mathbb{I}\{x_i \neq y_i\}$ is the Hamming distance, this definition is analogous to standard (ϵ, δ)-differential privacy. When considering only $(\epsilon, 0)$-differential privacy or $(0, \delta)$-privacy, it is an equivalent notion.*[6]

Proof For $(\epsilon, 0)$-DP, let $\rho(x, z) = \rho(z, y) = 1$; *i.e.*, the data differ in one element. Then, from standard DP, we have $P(B \mid x) \leq e^\epsilon P(B \mid z)$ and so obtain $P(B \mid x) \leq e^{2\epsilon} P(B \mid y) = e^{\rho(x,y)\epsilon} P(B \mid y)$. By induction, this holds for any x, y pair. Similarly, for $(0, \delta)$-DP, by induction we obtain $P(B \mid x) \leq P(B \mid y) + \delta\rho(x, y)$. ■

Definition 1 allows for privacy against a powerful attacker $\mathscr{A}$, who attempts to match the empirical distribution induced by the true data set, by querying the learned mechanism and comparing its responses to those given by distributions simulated using knowledge of the mechanism and knowledge of all but one datum—narrowing the data set down to a Hamming-1 ball. Indeed the requirement of differential privacy is sometimes *too strong* since it may come at the price of utility. Definition 2 allows for a much broader encoding of the attacker's knowledge via the selected pseudo-metric. It also allows a more fine-grained notion of privacy. This is quite useful for geographical information systems, as proposed by Chatzikokolakis et al. (2013), to which we refer the reader for a broader discussion of the use of metrics in differential privacy.

Finally, we can show that this generalisation of differential privacy satisfies the standard composition property.

5. Another common choice for neighbourhoods is to say that two data sets are neighbours if one results from the other by addition of a row.
6. Making the definition wholly equivalent is possible, but results in an unnecessarily complex definition.

Theorem 4 (Composition) *Let conditional distributions $P(\cdot \mid x)$ on $(\Theta, \mathfrak{S}_\Theta)$ be* (ϵ, δ)-differentially private under *a pseudo-metric $\rho : \mathcal{S} \times \mathcal{S} \to \mathbb{R}_+$ and $P'(\cdot \mid x)$ on $(\Theta', \mathfrak{S}'_{\Theta'})$ be* (ϵ', δ')-differentially private under *the same pseudo-metric. Then the conditional distribution on the product space $(\Theta \times \Theta', \mathfrak{S}_\Theta \otimes \mathfrak{S}'_{\Theta'})$ given by*

$$Q(B \times B' \mid x) = P(B \mid x) P'(B' \mid x), \forall B \times B' \in \mathfrak{S}_\Theta \otimes \mathfrak{S}'_{\Theta'}$$

satisfies $(\epsilon + \epsilon', \delta + \delta')$-differentially private under *the pseudo-metric ρ. Here $\mathfrak{S}_\Theta \otimes \mathfrak{S}'_{\Theta'}$ is the product σ-algebra on $\Theta \times \Theta'$.*

Proof For any $y \in \mathcal{S}$

$$\begin{aligned} Q(B \times B' \mid x) &\leq \left[e^{\epsilon\rho(x,y)} P(B \mid y) + \delta\rho(x, y)\right] P'(B' \mid x) \\ &\leq e^{\epsilon\rho(x,y)} P(B \mid y) \left[e^{\epsilon'\rho(x,y)} P'(B' \mid y) + \delta'\rho(x, y)\right] + \delta\rho(x, y) \\ &\leq e^{(\epsilon+\epsilon')\rho(x,y)} P(B \mid y) P'(B' \mid y) + (\delta + \delta')\rho(x, y) \end{aligned}$$

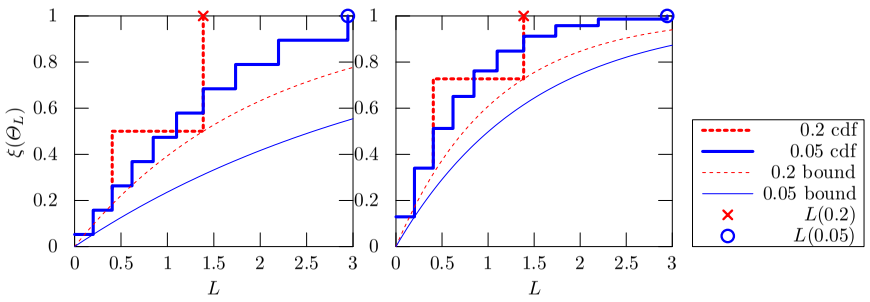
■

2.2 Our Main Assumptions

In the sequel, we show that if the distribution family $\mathcal{F}_\Theta$ or prior ξ satisfies certain assumptions, then close data sets $x, y \in \mathcal{S}$ result in posterior distributions that are close. In that case, it is difficult for a third party to use such a posterior to distinguish the true data set x from similar data sets.

To formalise these notions, we introduce two possible assumptions one could make on the smoothness of the family $\mathcal{F}_\Theta$ with respect to some metric d on $\mathbb{R}_+$. The first assumption states that the likelihood is smooth for all parameterisations of the family. First, we define our notion of smoothness. Let $f(x, \theta) \triangleq \ln p_\theta(x)$ be the log probability of x under θ. The Lipschitz constant for a parameter value θ is:

$$\ell(\theta) \triangleq \inf \{\, u : |f(x, \theta) - f(y, \theta)| \leq u\rho(x, y) \forall x, y \in \mathcal{S} \,\}. \tag{2}$$



Our first assumption is uniform smoothness for all parameters.

Assumption 1 (Lipschitz continuity) *We assume there exists some $L < \infty$ such that:*

$$\ell(\theta) \leq L, \qquad \theta \in \Theta. \tag{3}$$

In other words, this assumption says that the log probability is Lipschitz with respect to ρ for any parameter value. Consider Example 1 for the Bernoulli model. It is easy to see that a model with Δ-sized intervals satisfies the above assumption with $L = \ln 1/\Delta$.

However, it may be difficult for this assumption to hold uniformly over Θ in general. This can be seen by the following counterexample for the Bernoulli family of distributions: when the parameter is 0, then any sequence $x = 0, 0, \ldots$ has probability 1, while any

(a) Uniform prior (b) Exponential prior

Figure 1: The mass of L-Lipschitz parameters, for two finite familes of Bernoulli distributions with $\Delta \in \{0.2, 0.05\}$ (thick lines) together with their respective stochastic Lipschitz bounds (thin lines) and the corresponding uniform Lipschitz constant L.

sequence containing a 1 has probability 0. The same thing occurs when we take $\Delta \to 0$ in Example 1. To avoid such problems, we relax the assumption by only requiring that $\mathscr{B}$'s *prior* probability ξ is concentrated in the regions of the family for which the likelihood is smoothest:

Assumption 2 (Stochastic Lipschitz continuity; Norkin, 1986) *First, define the subset of parameter values*

$$\Theta_L \triangleq \{\theta \in \Theta : \ell(\theta) \leq L\} \tag{4}$$

to be those parameters for which Lipschitz continuity holds with Lipschitz constant L. Then, there are some constants $c, L_0 > 0$ such that, for all $L \geq L_0$:

$$\xi(\Theta_L) \geq 1 - \exp(-c(L - L_0)) \ . \tag{5}$$

By not requiring uniform smoothness, this weaker assumption is easier to meet but still yields useful guarantees. In fact, in Section 5, we demonstrate that this assumption is satisfied by many important example distribution families. However, it will be illustrative to consider the discrete Bernoulli family example at this point.

Example 2 (Continuation of Example 1) *These conditions can be examined in terms of the finite family of Example 1. Figure 1 demonstrates the assumptions for $\Delta = 0.2$ (red dashed lines) and $\Delta = 0.05$ (blue solid lines).*

In particular, the two thick lines Figure 1a show the probability mass of L-Lipschitz parameters for the two families. They are both step functions, as the families are discrete.[7]

7. The $\Delta = 0.2$ family only has two steps, as the Lipschitz constant is symmetric about $\theta = 0.5$.

The $\times$ and $\circ$ symbols show the corresponding Lipschitz constants for the two families respectively, and we can clearly see $\Delta = 0.2$ has about half the Lipschitz constant of $\Delta = 0.05$. The thinner curves depict the highest lower bound on the probability mass defined in Assumption 2. There we see that the higher curve is achieved by $\Delta = 0.2$.

In order to improve the lower bound, we need to modify our prior distribution on the family members so as to place less mass on the more sensitive parameters. The result of this operation is shown in Figure 1b, which uses the prior $\xi(\theta) \propto \exp(-\ell(\theta))$, i.e., it places exponentially smaller weight in more sensitive parameters. This results in both lower bounds being shifted upwards, corresponding to a higher c constant in Assumption 2. Of course, this has no effect on Assumption 1.

For completeness, we now show that verifying our assumptions for a distribution of a single random variable lifts to a corresponding property for the product distribution on i.i.d. samples.

Lemma 5 *If $\mathcal{F}_\Theta$ satisfies Assumption 1 (resp. Assumption 2) with respect to pseudo-metric ρ and constant L (or c), then, for any fixed $n \in \mathbb{N}$, the product family $\mathcal{F}_\Theta^n$ with densities (sim. measures) $p_\Theta^n(\{x_i\}) = \prod_{i=1}^n p_\Theta(x_i)$ satisfies the same assumption with respect to:*

$$\rho^n(\{x_i\}, \{y_i\}) = \sum_{i=1}^n \rho(x_i, y_i)$$

and constant L (or c).

2.2.1 Necessary Conditions

Finally, let us discuss whether the above conditions are necessary to achieve differential privacy. In fact, either the first condition must be true, or a similar condition must hold on the marginals for every possible data set pair (x, y). Our second condition can be seen as a specific case of the necessary condition for the marginals, as explained below.

Theorem 6 *For a prior ξ to be $2L$-differentially private for a family $\mathcal{F}_\Theta$, either*

$$\sup_{\theta \in \Theta} \ln \frac{P_\theta(x)}{P_\theta(y)} \leq L\rho(x, y), \qquad \text{or} \qquad \ln \frac{\phi(y)}{\phi(x)} \leq L\rho(x, y) \tag{6}$$

for all $x, y \in \mathcal{X}$.

Proof If neither condition holds for some pair (x, y) then there is θ such that $\ln \frac{P_\theta(x)}{P_\theta(y)} > L\rho(x, y)$ and $\ln \frac{\phi(y)}{\phi(x)} > L\rho(x, y)$. Simply adding the two, we obtain $\ln \frac{\xi(\theta|x)}{\xi(\theta|y)} > 2L\rho(x, y)$, and so the resulting posterior is not L-differentially private. ■

In our main results, we show that the first part of the conditions, which is equivalent to our first assumption, is also sufficient. However, the second part is too weak to imply differential privacy on its own.

2.2.2 The Choice of Metric and Sufficient Statistics

The extent to which our assumptions hold for a particular family of distributions $\mathcal{F}_\Theta$ depends mainly on ρ.[8] The choice of metric is also important for achieving differential privacy with

8. Although our results are stated in terms of metrics, it is easy to translate them to neighbourhood-based results, simply by bounding the ρ-distance of any neighbouring data sets. See also the discussion in Section 6.

respect to it. Let us specifically consider metrics defined in terms of a difference in statistics:

$$\rho(x,y) \triangleq \|\tau(x) - \tau(y)\| \ ,$$

where $\tau : \mathcal{S} \to \mathcal{V}$ is a statistic mapping from data sets to a normed vector space.

In that case, our assumptions imply that τ must be a *sufficient* statistic, since if $\tau(x) = \tau(y)$ then $\rho(x,y) = 0$ and it follows that $P_\theta(x) = P_\theta(y)$. More generally, ρ must be such that if the distance between x, y is zero, then their probabilities should be equal. We will see some examples of such statistics for conjugate distributions in the exponential family in Section 5. That means that we cannot use a metric which simply ignores part of the data, for example.

Similarly, the very definition of differential privacy (Definition 2) implies that τ must be a *Bayes-sufficient* statistic. That means that for any x, y, it holds

$$\tau(x) = \tau(y) \quad \Rightarrow \quad \xi(B \mid x) = \xi(B \mid y) \ , \quad \forall B \in \mathfrak{S}_\Theta \ .$$

Note that this is a slightly weaker condition than a sufficient statistic, which is necessary for our assumptions to hold.

2.3 Summary of Results

Given the above assumptions, we show: firstly, that if we choose an informative prior ξ, the resulting posterior is robust in terms of KL-divergence to small changes in the data. Secondly, that the posterior distribution is differentially private. Thirdly, that this implies that sampling from the posterior can be used as part of a differentially-private mechanism. We complement these with results on how easily an adversary can distinguish two similar data sets from posterior samples. Finally, we characterise the trade-off between utility and privacy, stated here informally for ease of exposition:

Claim 1 *If $\mathscr{A}$ prefers to use the prior $\xi^\star$, but $\mathscr{B}$ uses a prior ξ satisfying Assumption 1, and $\mathscr{A}$'s utility is bounded in $[0,1]$, the following is true for the posterior sampling mechanism with N samples:*

- *The mechanism is $2NL$-differentially private.*
- *$\mathscr{A}$'s utility loss is $O\left([1 - \xi^\star(\Theta_L)] + \sqrt{1/N}\right)$ w.h.p., where Θ_L is the support of ξ.*

The following sections discuss our main results in detail. We begin by proving that our assumptions result in robust posteriors, in the sense that the KL divergence between posteriors arising from similar data sets is small. Then we show that they also result in differentially private posterior distributions, and analyse the resulting posterior sampling mechanism. We conclude with some examples and a discussion of related work.

3. Robustness of the Posterior Distribution

We now show that the above assumptions provide guarantees on the robustness of the posterior. That is, if the distance between two data sets x, y is small, then so too is the distance between the two resulting posteriors, $\xi(\cdot \mid x)$ and $\xi(\cdot \mid y)$. We prove this result for

the case where we measure the distance between the posteriors in terms of the well-known KL-divergence:

$$D\left(P \parallel Q\right) = \int_S \ln \frac{\mathrm{d}P}{\mathrm{d}Q} \, \mathrm{d}P \ .$$

The following theorem shows that any distribution family $\mathcal{F}_\Theta$ and prior ξ satisfying one of our assumptions is robust, in the sense that the posterior does not change significantly with small changes to the data set. It is notable that our mechanisms are simply tuned through the choice of prior.

Theorem 7 *When ξ is a prior distribution on Θ and $\xi(\cdot \mid x)$ and $\xi(\cdot \mid y)$ are the respective posterior distributions for data sets $x, y \in \mathcal{S}$, the following results hold:*

1. *Under a pseudo-metric ρ and $L > 0$ satisfying Assumption 1,*

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \leq 2L\rho(x,y) \ . \tag{7}$$

2. *Under a pseudo-metric ρ and $c > 1$ satisfying Assumption 2,*

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \leq C_\xi^{\mathcal{F}_\Theta} \left(1 + 2L_0 + c^{-1}\right) \rho(x,y) \ , \tag{8}$$

where $C_\xi^{\mathcal{F}_\Theta}$ is the ratio between the maximum and marginal likelihoods (9), and assuming there exists $\chi \in (0,1]$ such that: $\forall x, y \in \mathcal{S}$ there is a sequence $\{z_k\} \subset \mathcal{S}$, with $z_0 = x, z_n = y$, satisfying $\chi\rho(z_k, z_{k+1}) \leq c - 1 \ \forall z_k$.

Note that the second claim bounds the KL divergence in terms of $\mathscr{B}$'s prior belief that L is small, which is expressed via the constant c. The larger c is, the less prior mass is placed in large L and so the more robust inference becomes. Of course, choosing c to be too large may decrease efficiency.

It is important to also discuss the constant $C_\xi^{\mathcal{F}_\Theta}$. To get a better intuition, consider the case where $\Theta, \mathcal{X}$ are finite. Let $\theta^\star_{\mathrm{ML}}(x)$ be the maximum-likelihood estimate for x. Then we have that:

$$C_\xi^{\mathcal{F}_\Theta} \quad = \quad \max_x \frac{P_{\theta^\star_{\mathrm{ML}}(x)}(x)}{\sum_\Theta P_\theta(x)\xi(\theta)} \quad \leq \quad \max_x \frac{1}{\xi(\theta^\star_{\mathrm{ML}}(x))} \ , \tag{9}$$

there is therefore a natural dependency on the prior mass placed on maximum-likelihood estimators.

Finally, χ is going to be 1 for most metric spaces of interest. A notable exception is when the Hamming distance is used, which requires $\chi < 1$ as an additional technical condition for $c < 2$. However, this only affects our results under the second assumption.

4. Privacy and Utility

We next examine the differential privacy of the posterior distribution. We show in Section 4.1 that this can be achieved under either of our assumptions. The result can also be

interpreted as the differential privacy of a *posterior sampling mechanism* for responding to queries (described in Section 4.2), for which we prove a bound on the utility depending on the number of samples taken. Section 4.3 examines an alternative notion of privacy, *data set distinguishability*, similar to Wasserman and Zhou (2010). For this, we prove a bound on privacy, that also depends on the number of samples taken. Together, these exhibit a trade off between utility and privacy controlled by choosing the number of samples appropriately, in a manner described in Section 4.4.

4.1 Differential Privacy of Posterior Distributions

We consider our generalised notion of differential privacy for posterior distributions (Definition 2); and show that the type of differential privacy exhibited by the posterior depends on which assumption holds.

Theorem 8 *1. Under a pseudo-metric ρ and $L > 0$ satisfying Assumption 1, for all $x, y \in \mathcal{S}$, $B \in \mathfrak{S}_\Theta$:*

$$\xi(B \mid x) \leq \exp\{2L\rho(x,y)\}\xi(B \mid y) \; .$$

i.e., *the posterior ξ is $(2L, 0)$-differentially private under pseudo-metric ρ.*

2. Under a pseudo-metric ρ and $c > 1$ satisfying Assumption 2, $C_\xi^{\mathcal{F}_\Theta}$ defined in (9), for all $x, y \in \mathcal{S}$, $B \in \mathfrak{S}_\Theta$:

$$|\xi(B \mid x) - \xi(B \mid y)| \leq \sqrt{\frac{C_\xi^{\mathcal{F}_\Theta}}{2}\left(1 + 2L_0 + c^{-1}\right)\rho(x,y)},$$

i.e., *the posterior ξ is $\left(0, O(\sqrt{C_\xi^{\mathcal{F}_\Theta}(L_0 + 1/c)})\right)$-differentially private*[9] *under pseudo-metric $\sqrt{\rho}$.*

The difference between the two bounds' form is due to the fact that while the first claim has a direct proof, the second claim arises from the KL divergence bound in Theorem 7.

Finally, we show that posterior distributions are also randomly differentially private.

Corollary 9 *Under pseudo-metric ρ, $c > 1$ and $L \geq L_0 > 0$ satisfying Assumption 2:*

$$\mathbb{P}\left[\forall B \in \mathfrak{S}_\Theta : \xi(B \mid x) \leq \exp\left\{2L\rho(x,y)\right\}\xi\left(B \mid y\right), \forall x, y \in \mathcal{S}\right] \geq 1 - \exp(-c(L - L_0)) \; .$$

i.e., *the posterior ξ is $(2L, 0, \exp(-c(L - L_0)))$-randomly differentially private (Hall et al., 2011) under pseudo-metric ρ.*

This is a conceptually different definition from the original RDP, as the measure over which the randomness is defined is not the data distribution, but the prior measure ξ.

This property of the posterior distribution directly leads to the definition of a posterior sampling mechanism which will be differentially private. This is explained in the following section.

9. This holds, for example, for hamming distance as in the Beta-Binomial example presented in Lemma 21.

4.2 Posterior Sampling Mechanism

Given that we have a full posterior distribution which is differentially private, we can use it to define a private mechanism. We may allow the adversary to submit an arbitrary set of queries $\{ q_t \}$ with each $q_t \in \mathcal{Q}$. Each query warrants a response r_t in a set of possible responses $\mathcal{R}$. The adversary is allowed to condition the queries on our previous responses.

We extend our original approach (Dimitrakakis et al., 2014) to take some utility function u into account, which scores preferences of responses given a query. The algorithm requires a prior ξ to be defined on a family $\mathcal{F}_\Theta$ of probability distributions, whose members do not necessarily generate i.i.d. observations. They could be Markov chains for example. The first step is to simply draw a number of samples from the posterior, as in the original approach (Algorithm 2). After the algorithm calculates the posterior distribution $\xi(\cdot \mid x)$, N parameter samples are drawn from it, producing a parameter set $\hat{\Theta}$. Thereafter, responses depend only on the utility function and the sample $\hat{\Theta}$, and we do not draw new samples after every query. This allows us to work with a fixed privacy budget.

Algorithm 1 BAPS: Bayesian Posterior Sampling

input prior ξ, data $x \in \mathcal{S}$
Calculate posterior $\xi(\theta \mid x)$.
for $k = 1, \ldots, N$ **do**
  Sample $\theta^{(k)} \sim \xi(\theta \mid D)$.
end for
return $\hat{\Theta} = \left\{ \theta^{(k)} : k = 1, \ldots, N \right\}$.

Corollary 10 *Algorithm 1 is differentially private under the conditions of Theorem 8, namely:*

1. Under a pseudo-metric ρ and $L > 0$ satisfying Assumption 1, the algorithm is $(2NL, 0)$-differentially private under pseudo-metric ρ; or

2. Under a pseudo-metric ρ and $c > 1$ satisfying Assumption 2, $C_\xi^{\mathcal{F}_\Theta}$ defined in (9), the algorithm is $\left(0, O(N\sqrt{C_\xi^{\mathcal{F}_\Theta}(L_0 + 1/c)})\right)$-differentially private under pseudo-metric $\sqrt{\rho}$.

Proof This follows directly from Theorems 8 and 4 (composition), as the algorithm samples from the posterior distribution, which is differentially private. ■

Utility and optimal responses. We assume the collection of a set of utility functions $\mathcal{U} = \{ u_\theta : \theta \in \Theta \}$, such that the optimal response for a given parameter θ is the one maximising a utility function $u_\theta : \mathcal{Q} \times \mathcal{R} \to [0, 1]$. If we know the true parameter θ, then we should respond to any query q with $r \in \arg\max_r u_\theta(q, r)$. However, since θ is unknown, we must select a method for conveying the required information. In a Bayesian setting, there are three main approaches we could employ. The standard methodology is to maximise

expected utility with respect to the posterior. This corresponds to marginalising out θ, and responding with:

$$r_t \quad \in \quad \arg\max_r \int_\Theta u_\theta(q_t, r) \, \mathrm{d}\xi(\theta \mid x) \ .$$

The second is to use the *maximum a posteriori* value of θ. The final, which we employ here, is to use sampling; *i.e.*, to reply to each query using parameters sampled from the posterior. This allows us to reply to arbitrary queries without compromising privacy, since the most information an adversary could obtain is the set of sampled parameters. By adjusting the number of samples used, we can easily trade off between privacy and utility.

After this we respond to a series of queries. For the t-th received query q_t, the algorithm returns the optimal response over the sampled parameter set $\hat{\Theta}$, in the manner shown in Algorithm 2. Since we allow arbitrary queries, the third party could simply ask for $\hat{\Theta}$ with a suitable choice of the utility function. Then if u is bounded, it is easy to show that the loss due to sampling is bounded.

Algorithm 2 PSAQR: Posterior Sample Query Response

1: **input** Parameter sample $\hat{\Theta}$.
2: **for** $t = 1, \ldots$ **do**
3: Observe query $q_t \in \mathcal{Q}$, perhaps depending on $r_1, \ldots, r_{t-1}$ and $q_1, \ldots, q_{t-1}$.
4: **return** $r_t \in \arg\max_r \sum_{\theta \in \hat{\Theta}} u_\theta(q_t, r)$
5: **end for**

Lemma 11 *The returned responses of the PSAQR mechanism have a utility which is within* $O\left(\sqrt{\ln(1/\delta)/N}\right)$ *of the optimal value with probability at least* $1 - \delta$ *for any* $\delta > 0$.

Now that we have demonstrated bounds on the utility for the algorithm above, we turn to the issue of how utility and privacy can be optimally tuned. First, we try and quantify the amount of samples an adversary needs to distinguish two data sets.

4.3 Distinguishability of Data Sets

In this section, we wish to relate the size of the sample $\hat{\Theta}$ to the amount of information about x that can be obtained by the adversary $\mathscr{A}$. More precisely, we need to bound how well $\mathscr{A}$ can distinguish x from all alternative data sets y. Within the posterior sampling query model, $\mathscr{A}$ has to decide whether $\mathscr{B}$'s posterior is $\xi(\cdot \mid x)$ or $\xi(\cdot \mid y)$. However, he can only do so within some neighbourhood ϵ of the original data. In this section, we bound $\mathscr{A}$'s error in determining the posterior in terms of the number of samples used. This is analogous to the data set-size bounds on queries in interactive models of differential privacy (Dwork et al., 2006), as well as the point of view of privacy as hypothesis testing (Kairouz et al., 2015; Wasserman and Zhou, 2010) where an adversary wishes to distinguish the data set from two alternatives.

For this section, we consider a utility function whose optimal response is $\hat{\Theta}$. This corresponds to the most powerful query possible under the model shown in Algorithm 2.

Then, the adversary needs only to construct the empirical distribution to approximate the posterior up to some sample error. By bounds on the KL divergence between the empirical and actual distributions we can bound his power in terms of how many samples he needs in order to distinguish between x and y.

Due to the sampling model, we first require a finite sample bound on the quality of the empirical distribution. The adversary could attempt to distinguish different posteriors by forming the empirical distribution on any sub-algebra $\mathfrak{S}$.

Lemma 12 *For any* $\delta \in (0, 1)$, *let* $\mathscr{M}$ *be a finite partition of the sample space* $\mathcal{S}$, *of size* $m \leq \log_2 \sqrt{1/\delta}$, *generating the* σ*-algebra* $\mathfrak{S} = \sigma(\mathscr{M})$. *Let* $x_1, \ldots, x_n \sim P$ *be i.i.d. samples from a probability measure* P *on* $\mathcal{S}$, *let* $P_{|\mathfrak{S}}$ *be the restriction of* P *on* $\mathfrak{S}$ *and let* $\hat{P}^n_{|\mathfrak{S}}$ *be the empirical measure on* $\mathfrak{S}$. *Then, with probability at least* $1 - \delta$*:*

$$\left\| \hat{P}^n_{|\mathfrak{S}} - P_{|\mathfrak{S}} \right\|_1 \leq \sqrt{\frac{3}{n} \ln \frac{1}{\delta}} \, . \tag{10}$$

We can combine this bound on the adversary's estimation error with Theorem 7's bound on the KL divergence between posteriors resulting from similar data to obtain a measure of how fine a distinction between data sets the adversary can make after a finite number of draws from the posterior:

Theorem 13 *Under Assumption 1, the adversary can distinguish between data* x, y *with probability* $1 - \delta$ *if:*

$$\rho(x, y) \geq \frac{3}{4Ln} \ln \frac{1}{\delta} \ .$$

Under Assumption 2, this becomes:

$$\rho(x, y) \geq \frac{3}{2n \left(C_\xi^{\mathcal{F}_\Theta} + 2L_0 c^{-1} \right)} \ln \frac{1}{\delta} \ .$$

Consequently, either smoother likelihoods (*i.e.*, decreasing L), or a larger concentration on smoother likelihoods (*i.e.*, increasing c), increases the effort required by the adversary and reduces the sensitivity of the posterior. Note that, unlike the results obtained for differential privacy of the posterior sampling mechanism, these results have the same algebraic form under both assumptions.

4.4 Trading off Utility and Privacy

By construction, in our setting there are three ways with which to tune privacy. The first is the choice of family; the second is the choice of prior; and the third is how many samples N to draw. The choice of family is usually fixed due to other considerations. However, we have the choice of either tuning the prior, so that we can satisfy our assumptions with some suitable constants L or c, or by tuning the number of samples N in the posterior sampling framework.

The following lemma bounds the regret we suffer in terms of utility when the private posterior we use is ξ, in the case where the posterior we would like to use (assuming no privacy constraints) was $\xi^\star$.

Lemma 14 *If our utility is bounded in* $[0,1]$*, the private posterior we use is* ξ*, while the ideal posterior is* $\xi^\star$*, then the regret suffered is bounded by* $2\|\xi - \xi^\star\|_1$*.*

Finally, consider the case where $\mathscr{B}$, being a true Bayesian, is convinced that $\xi^\star$ is the correct prior distribution to use, but needs to use the prior ξ in order to achieve privacy. The following theorem bounds the expected KL divergence between the two resulting posteriors.

Lemma 15 *If* $\forall \theta \in \Theta$*,* $|\ln \xi^\star(\theta)/\xi(\theta)| \leq \eta$ *then the expected KL divergence is*

$$\mathbb{E}_{x\sim\phi^\star} D(\xi^\star(\cdot \mid x) \| \xi(\cdot \mid x)) \leq 2\eta \,,$$

where $\phi^\star$ *is the* $\xi^\star$ *marginal distribution.*

We can now combine Lemmas 11 and 14 with Lemma 15, to obtain the following result:

Corollary 16 *If* $\mathscr{A}$ *has a preferred prior* $\xi^\star$*, while the private prior used by* $\mathscr{B}$ *is* ξ *and it satisfies the conditions of Lemma 15, then the loss of* $\mathscr{A}$ *in terms of the* $\xi^\star$*-expected utility is* $O\left(\eta + \sqrt{\ln(1/\delta)/N}\right)$*, with probability at least* $1-\delta$*.*

Consequently, if $\mathscr{A}$ believes the correct prior should be $\xi^\star$, he can use the private posterior sample to make decisions, incurring a small loss. Finally, we already showed that $\mathscr{A}$ cannot distinguish between data that are closer than $O(1/N)$ with high probability. Hence, in this setting we can tune N to trade off utility and privacy.

The following theorem characterises the link between the choice of prior, the number of samples, privacy and utility directly. This connects several of our results in one place.

Theorem 17 *If, instead of using a non-private prior* $\xi^\star$*, we use a prior* ξ *restricted on* Θ_L *(such that it satisfies Assumption 1 with constant* L*) and generate* N *samples from the posterior, then (a) the sample is* $2LN$*-differentially private and (b) the loss of* $\mathscr{A}$ *in terms of the* $\xi^\star$*-expected utility is* $O\left([1-\xi^\star(\Theta_L)] + \sqrt{\ln(1/\delta)/N}\right)$*, with probability at least* $1-\delta$ *for any* $\delta > 0$*.*

Proof For (a) note that due to composition, N repetitions give $2LN$-differential privacy. For (b), let Θ_L be the support of ξ. Then, because ξ is the restriction of $\xi^\star$ on Θ_L, it holds that:

$$\begin{aligned}\|\xi - \xi^\star\|_1 &= \xi(\Theta_L) - \xi^\star(\Theta_L) + \xi^\star(\Theta \setminus \Theta_L) - \xi(\Theta \setminus \Theta_L) \\ &= 2[1 - \xi^\star(\Theta_L)] \;.\end{aligned}$$

We now just need to couple this with Lemmas 14 and 11 to directly obtain the stated bound on the utility. ∎

In practice, our choice of ξ gives us a base amount of privacy that depends only on L. By keeping ξ fixed and increasing N, we can easily trade off privacy and utility.

Finally, we should note that the adversary could choose any arbitrary estimator ψ to guess x. Section 4.5 below describes how to apply Le Cam's method to obtain matching lower bounds in this case, by defining *data set estimators* as a model for the adversary.

4.5 Lower Bounds

It is possible to apply standard minimax theory to obtain lower bounds on the rate of convergence of the adversary's estimate to the true data. In order to do so, we can for example apply the method due to LeCam (1973), which places lower bounds on the expected distance between an estimator and the true parameter. In order to apply it in our case, we simply replace the parameter space with the data set space.

Le Cam's method assumes the existence of a family of probability measures indexed by some parameter, with the parameter space being equipped with a pseudo-metric. In our setting, we use Le Cam's method in a slightly unorthodox, but very natural manner. Define the family of probability measures on Θ to be:

$$\Xi \triangleq \{\, \xi(\cdot \mid x) : x \in \mathcal{S} \,\},$$

the family of posterior measures in the parameter space, for a specific prior ξ. Consequently, now $\mathcal{S}$ plays the role of the parameter space, while ρ is used as the pseudo-metric. The original family $\mathcal{F}_\Theta$ plays no further role in this construction, other than a way to specify the posterior distributions from the prior.

Now let ψ be an arbitrary estimator of the unknown data x. As in (LeCam, 1973), we extend ρ to subsets of $\mathcal{S}$ via

$$\rho(A,B) \triangleq \inf\{\, \rho(x,y) : x \in A, y \in B \,\} \;, \quad A, B \subset \mathcal{S} \;.$$

Now we can re-state the following well-known lemma for our specific setting.

Lemma 18 (Le Cam's method) *Let* ψ *be an estimator of* x *on* Ξ *taking values in the metric space* $(\mathcal{S}, \rho)$*. Suppose that there are well-separated subsets* $\mathcal{S}_1, \mathcal{S}_2$ *such that* $\rho(\mathcal{S}_1, \mathcal{S}_2) \geq 2\delta$*. Suppose also that* Ξ_1, Ξ_2 *are subsets of* Ξ *such that* $x \in \mathcal{S}_i$ *for* $\xi(\cdot \mid x) \in \Xi_i$*. Then:*

$$\sup_{x\in\mathcal{S}} \mathbb{E}_\xi(\rho(\psi, x) \mid x) \geq \delta \sup_{\xi_i \in co(\Xi_i)} \|\xi_1 \wedge \xi_2\| \;.$$

This lemma has an interesting interpretation in our case. The quantity

$$\mathbb{E}_\xi(\rho(\psi, x) \mid x) = \int_\Theta \rho(\psi(\theta), x) \,\mathrm{d}\xi(\theta \mid x) \;,$$

is the expected distance between the real data x and the guessed data $\psi(\theta)$ when θ is drawn from the posterior distribution. Consequently, it is possible to apply this method directly to obtain results for specific families of posteriors. These would of course be dependent on the family, the prior and the metric. While we shall not engage in this exercise, we point the interested reader to (Yu, 1997), which provides two simple examples with minimax rates of $O(n^{-4/9})$ and $O(n^{-4/5})$.

5. Examples Satisfying our Assumptions

In what follows we study, for different choices of likelihood and corresponding conjugate prior, what constraints can be placed on the prior's concentration to guarantee a desired level of privacy. These case studies closely follow the pattern in differential privacy research

where the main theorem for a new mechanism is a set of sufficient conditions on (*e.g.*, Laplace) noise levels to be introduced to a response in order to guarantee a level ϵ of ϵ-differential privacy.

For exponential families, we have the canonical form $p_\theta(x) = h(x)\exp\left\{\eta_\theta^\top \tau(x) - A(\eta_\theta)\right\}$, where $h(x)$ is the base measure, η_θ is the distribution's natural parameter corresponding to θ, $\tau(x)$ is the distribution's sufficient statistic, and $A(\eta_\theta)$ is its log-partition function. For distributions in this family, under the absolute log-ratio distance, the family of parameters Θ_L of Assumption 2 must satisfy, for all $x, y \in \mathcal{S}$: $\left|\ln\frac{h(x)}{h(y)} + \eta_\theta^\top(\tau(x) - \tau(y))\right| \leq L\rho(x,y)$. If the left-hand side has an amenable form, then we can quantify the set Θ_L for which this requirement holds. Particularly, for distributions where $h(x)$ is constant and $\tau(x)$ is scalar (*e.g.*, Bernoulli, exponential, and Laplace), this requirement simplifies to $\frac{|\tau(x)-\tau(y)|}{\rho(x,y)} \leq \frac{L}{\eta_\theta}$. One can then find the supremum of the left-hand side independent from θ, yielding a simple formula for the feasible L for any θ. For each example, a detailed proof can be found in Appendix B. Note that in the following examples, we are making the conventional assumption in machine learning that data are bounded ($||x|| \leq B$). Also we use $\xi(\theta)\mathbb{1}_{[c_1,c_2]}$ to denote the trimmed density function obtained by setting the density outside $[c_1, c_2]$ to zero and renormalising the density.

We begin with a few simple examples for single observations, that are nevertheless illustrative.

Lemma 19 (Exponential-Exponential conjugate prior) *The exponential distribution $\mathcal{E}xp(x;\theta)$ with a trimmed exponential conjugate prior $\theta \sim \mathcal{E}xp(\theta;\lambda)\mathbb{1}_{[c_1,c_2]}$, $\lambda > 0$, satisfies Assumption 2 with parameter $c = \lambda$, $L_0 = c_1$, $C_\xi^{\mathcal{F}_\Theta} = c_2/\min\left\{c_1 e^{-c_1 B}, c_2 e^{-c_2 B}\right\}$ and metric $\rho(x,y) = |x-y|$.*

Consequently, the trimmed-exponential prior results in a posterior sampling mechanism that is $(0,\delta)$-DP under ρ, with $\delta = \sqrt{\frac{1}{2}C_\xi^{\mathcal{F}_\Theta}(1 + 2c_1 + 1/\lambda)}$. It is also $(0,\delta)$-DP under the classical definition if $x, y \in [0,1]$.

Lemma 20 (Laplace-Exponential conjugate prior) *The distribution Laplace$(x;s,\mu)$ with a trimmed exponential conjugate prior $1/s = \theta \sim Exp(\theta;\lambda)\mathbb{1}_{[c_1,c_2]}$, $\mu \in \mathbb{R}$, $s \geq 1/L$, $\lambda > 0$ satisfies Assumption 2 with parameters $c = \lambda$, $L_0 = c_1$,*

$$C_\xi^{\mathcal{F}_\Theta} = \begin{cases} \frac{c_2}{2\min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{-B-\mu}{c_1}\right)\right\}} & , \quad x < \mu \\ \frac{c_2}{2\min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{\mu-B}{c_1}\right)\right\}} & , \quad x \geq \mu \end{cases},$$

and metric $\rho(x,y) = |x-y|$.

It should come as no surprise that the same type of $(0,\delta)$-privacy is achieved for the Laplace distribution with a trimmed exponential prior. Now we move on to an example from which we draw multiple samples.

Lemma 21 (Beta-Binomial conjugate prior) *The Binomial distribution $\mathcal{B}inom(\theta,n)$, with prior $\theta \sim \mathcal{B}eta(\alpha,\beta)$, $\alpha = \beta > 1$ satisfies Assumption 2 for $L_0 = \ln n$, $c = 2^{-2\alpha+1}/B(\alpha)$,*

where $B(\alpha)$ denotes the beta function with parameters $\alpha = \beta$,

$$C_\xi^{\mathcal{F}_\Theta} = B(\alpha)/B\left(\frac{n+2\alpha-1}{2}, \frac{n+2\alpha+1}{2}\right)$$

and metric $\rho(x,y) = \|x-y\|_1$, where $x, y \in \{0,1\}^n$.

This is an example of a conjugate prior pair that is $(0,\delta)$-DP without trimming the prior, with $\delta = \sqrt{\frac{1}{2}C_\xi^{\mathcal{F}_\Theta}(1 + 2\ln n + 2^{2\alpha-1}B(\alpha))}$. Unfortunately, δ is increasing with n, and as Zheng (2015) shows, this result is essentially unimprovable with direct posterior sampling unless the prior is trimmed.

We next present two results on normal distributions.

Lemma 22 (Normal distribution with known mean and unknown variance) *The normal distribution $N(x;\mu,\sigma^2)$ with a trimmed exponential prior $1/\sigma^2 = \theta \sim \mathcal{E}xp(\theta;\lambda)\mathbb{1}_{[c_1,c_2]}$ satisfies Assumption 2 with parameter $c = \frac{2\lambda}{\max\{|\mu|,1\}}$, $L_0 = \frac{c_1 \max\{|\mu|,1\}}{2}$,*

$$C_\xi^{\mathcal{F}_\Theta} = \min\left\{\sqrt{c_2/c_1}\exp\left(\frac{c_1 c_2^2}{2}\right), \exp\left(\frac{c_2^3}{2}\right)\right\}$$

and metric $\rho(x,y) = \left|x^2 - y^2\right| + 2\left|x-y\right|$.

This example is interesting, because privacy is achieved under a rather unusual metric. However, note that the posterior is classically $(0,3\delta)$-DP for data in $[0,1]$.

Unbounded observation spaces are generally a problem for privacy, even for finite parameter spaces, generally because likelihoods become vanishingly small, thus making log likelihood ratios arbitrarily large. However, the following two examples circumvent this problem. In the first example, we consider a general multivariate extension of Lemma 22. In the second we consider the case of discrete Bayesian networks, where privacy depends on the network connectivity and the probability of rare events—we have also considered posterior sampling of networks under complementary conditions, and output perturbation applied to posterior updates, in recent work (Zhang et al., 2016). In these examples, data is usually not i.i.d. (depending on the choice of network or covariance matrix) and the observation space is not a product space.

Lemma 23 (Multivariate normal distribution) *The multivariate normal distribution $N(x;\mu,A^{-1})$ satisfies our Assumption 1 with $L = \frac{1}{2}(\sum_{i=1}^n \lambda_i^2)^{\frac{1}{2}}\max\{1, ||\mu||_2\}$ under metric $\rho(x,y) = ||xx^\top - yy^\top||_F + 2||x-y||_2$. When $\mu = 0$, Assumption 1 is satisfied with $L = \frac{1}{2}(\sum_{i=1}^n \lambda_i^2)^{\frac{1}{2}}$ under metric $\rho(x,y) = ||(xx^\top - yy^\top)||_F$.*

Once more, we achieved $(\epsilon,0)$-DP under our metric, which implies a $(3\epsilon,0)$ classical DP for bounded data.

Lemma 24 (Discrete Bayesian networks) *Consider a family of discrete Bayesian networks on K variables, $\mathcal{F}_\Theta = \{P_\theta : \theta \in \Theta\}$. More specifically, each member P_θ, is a distribution on a finite space $\mathcal{S} = \prod_{k=1}^K \mathcal{S}_k$ and we write $P_\theta(x)$ for the probability of any outcome*

$x = (x_1, \ldots, x_K)$ in $\mathcal{S}$. Let $\varepsilon \triangleq \min_{\theta, x_k, x_{\mathcal{P}(k)}} P_\theta(x_k \mid x_{\mathcal{P}(k)})$, be the smallest conditional probability in the graph, where $\mathcal{P}(k)$ are the parents of node k.

Our observations can be independent samples $\{ x^t : t \in [T] \}$ of dependent variables $x_1^t, \ldots, x_k^t$. Define the connectivity vector $v \in \mathbb{N}^K$ such that $v_k = 1 + \deg(k)$, where $\deg(k)$ is the out-degree of node K. We now define the distance between two data sets x, y to be

$$\rho(x, y) \triangleq v^\top \delta(x, y), \qquad \delta_k(x, y) \triangleq \sum_{t=1}^{T} \mathbb{I}\left\{x_{k,t} \neq y_{k,t}\right\}.$$

Then Assumption 1 is satisfied with $L = \ln 1/\varepsilon$.

Consequently, discrete Bayesian networks, endowed with any prior on the family given in the above example, are $(2 \ln 1/\varepsilon, 0)$-DP under ρ. This also implies that they are $2\|v\|_\infty \ln 1/\varepsilon$-DP under the classical definition.

A simple application of this example is to data drawn from a Markov model on a finite state space. In particular, consider a time-homogeneous family of transition matrices $\theta_{i,j} \triangleq P_\theta(x_{t+1} = i \mid x_t = j)$. Then a prior consisting of product of truncated Dirichlet distributions that bound all multinomial probabilities above ε satisfies our assumptions and results in a $4 \ln 1/\varepsilon$-DP mechanism.

The above examples demonstrate that our assumptions are reasonable. In fact, for several of them we recover standard choices of prior distributions. However, for the privacy guarantees to be reasonable, it is best to restrict the prior to a set of parameters that is not very sensitive.

6. Discussion

We have presented a unifying framework for private and secure inference in a Bayesian setting. Under concentration conditions on the prior, we have shown that Bayesian inference is both robust and private. Firstly, we prove that similar data sets result in posterior distributions with small KL divergence. Secondly, we establish that the posterior is differentially private. This allows us to use a general posterior sampling mechanism for responding to queries, where privacy and utility are easy to trade off by adjusting the number of samples taken.

Owing to the fact that no additional machinery is required, this framework may serve as a fundamental building block for more sophisticated, private Bayesian inference. As an additional step towards this goal, we have demonstrated the application of our framework to deriving analytical expressions for well-known distribution families, and for discrete Bayesian networks. Finally, we bounded the amount of effort required of an attacker to breach privacy when observing samples from the posterior. This serves as a principled guide for how much access can be granted to querying the posterior, while still guaranteeing privacy.

Conversion of our results to the neighbourhood formulation. We state most of our results on specific models using a distance based on a sufficient statistic. Hence, to convert these to standard differential privacy, we only need to bound the ρ-distance of any neighbouring data sets. A good example are DBNs, where the case $\rho(x, y) = 1$ corresponds exactly to that of one record changing in a databse.

Practical application of our results. In general, it is hard to verify whether an existing model family will satisfy DP, because it implies checking whether the log-likelihood function is Lipschitz. Some parametric conjugate families, like the ones we examined in the examples, are amenable to analytic treatment. In practice, though, this might not be possible. It is for this reason that we propose to use rejection sampling in order to sample from the truncated posterior distribution. In particular, it is possible to resample from the posterior distribution, until a sample within the allowed interval of parameters is obtained. This is an approach we recently used in an application paper successfully (Zhang et al., 2016).

6.1 Related Work

In the past, little research in differential privacy focused on the Bayesian paradigm, with Dimitrakakis et al. (2014) being the first to establish conditions for differentially-private Bayesian inference. Nevertheless, our paper has many interesting links with both previous and follow up work, with respect to differential privacy, robustness and Bayesian inference, which we outline below. First, we discuss relations to other mechanisms achieving differential privacy and theoretical works about differential privacy; secondly, we discuss related work on the connection between robustness and privacy; and we conclude the related work section with a discussion of previous versions of this paper and follow-up work.

6.1.1 Differential Privacy

In our paper, we employ a Bayesian framework whereby optimal responses are characterised by the fact that they maximise expected utility. In Bayesian statistical decision theory (Berger, 1985; Bickel and Doksum, 2001; DeGroot, 1970), learning is cast as a statistical inference problem and decision-theoretic criteria are used as a basis for assessing, selecting and designing procedures. In particular, for a given utility function, the Bayes-optimal procedure maximises the expected utility under the posterior distribution.

In our setting, however, decisions using the data are not taken by the statistician $\mathscr{B}$. Instead, $\mathscr{A}$ provides a utility function, and trusts $\mathscr{B}$ to give him responses to queries that maximise expected utility. However $\mathscr{B}$ must also balance the need for privacy of the data provider, which results in some utility loss for $\mathscr{A}$. This is naturally captured by the difference in utility by making the decision private. This idea had already been explored in the exponential mechanism by McSherry and Talwar (2007), which connected differential privacy to mechanism design.

The exponential mechanism can be seen as a generalisation of the *Laplace mechanism*, which adds Laplace noise to released statistics (Dwork et al., 2006). The exponential mechanism releases a response with probability exponential in a utility function describing the usefulness of each response, with the best response having maximal utility. An alternate approach, employed for privatising regularised empirical-risk minimisation (Chaudhuri et al., 2011), is to alter the inferential procedure itself, in that case by adding a random term to the primal objective. We view our posterior sampling mechanism as a Bayesian counterpart. Further results on the accuracy of the exponential mechanism with respect to the Kolmogorov-Smirnov distance are given in (Wasserman and Zhou, 2010), which introduced the concept of privacy as hypothesis testing where an adversary wishes to distinguish two data sets. This is similar to our notion of data set distinguishability.

Learning from private data. In a different direction, Duchi et al. (2013) provided information-theoretic bounds for private learning. This essentially represents the protocol for interacting with an adversary as an arbitrary conditional distribution, rather than restricting it to specific mechanisms or models. In this way, they obtain fundamental bounds on rates of convergence from differentially-private views of data.

Bayesian inference and privacy. Other work at the intersection of privacy and Bayesian inference includes that of Williams and McSherry (2010) who applied Bayesian inference to improve the utility of differentially-private releases by computing posteriors in a noisy measurement model. In a similar vein, Xiao and Xiong (2012) used Bayesian credible intervals to respond to queries with as high utility as possible, subject to a privacy budget. In the PAC-Bayesian setting, Mir (2012) showed that the Gibbs estimator (McSherry and Talwar, 2007) is differentially private. While their algorithm corresponds to a posterior sampling mechanism, it is a posterior found by minimising risk bounds; by contrast, our results are purely Bayesian and come from conditions on the prior. It is also worthwhile noting that our Assumption 1 can in some cases be made equivalent to the definition of Pufferfish privacy (Kifer and Machanavajjhala, 2014), a privacy concept with Bayesian semantics. Thus, our results imply that in some cases Pufferfish privacy also results in differential privacy. Finally, independently to our preliminary work (Dimitrakakis et al., 2014), Wang et al. (2015) later proved differential privacy results for Gaussian processes under similar assumptions.

6.1.2 Robustness and Privacy

Dwork and Lei (2009) made the first connection between (frequentist) robust statistics and differential privacy, developing mechanisms for the interquartile, median and B-robust regression. While robust statistics are designed to operate near an ideal distribution, they can have prohibitively high global, worst-case sensitivity. In this case privacy was still achieved by performing a differentially-private test on local sensitivity before release (Dwork and Smith, 2009). In later work, Dwork et al. (2015) show that differentially-private views of the data result in good generalisation abilities. We discuss this more extensively in Section 6.1.3.

In a similar vein Chaudhuri and Hsu (2012) drew a quantitative connection between robust statistics and differential privacy by providing finite-sample convergence rates for differentially-private plug-in statistical estimators in terms of the *gross error sensitivity*, a common measure of robustness. These bounds can be seen as complementary to ours because our Bayesian estimators do not have private views of the data but use a suitably-defined prior instead.

Smoothness of the learning map, achieved here for Bayesian inference by appropriate concentration of the prior, is related to *algorithmic stability* which is used in statistical learning theory to establish error rates (Bousquet and Elisseeff, 2002). Rubinstein et al. (2012) used γ-uniform stability to calibrate the level of noise when using the Laplace mechanism to achieve differential privacy for the SVM. Hall et al. (2013) extended this technique to adding Gaussian process noise for differentially private release of infinite-dimensional functions lying in an RKHS.

In the Bayesian setting, robustness is typically handled through maximin policies. This is done by assuming that the prior distribution is selected arbitrarily by nature. In the field of robust statistics, the minimax asymptotic bias of a procedure incurred within an ε-contamination neighbourhood is used as a robustness criterion giving rise to the notions of a procedure's *influence function* and *breakdown point* to characterise robustness (Hampel et al., 1986; Huber, 1981). In a Bayesian context, robustness appears in several guises including minimax risk, robustness of the posterior within ε-contamination neighbourhoods, and robust priors (Berger, 1985). In this context Grünwald and Dawid (2004) demonstrated the link between robustness in terms of the minimax expected score of the likelihood function and the (generalised) maximum entropy principle, whereby nature is allowed to select a worst-case prior.

6.1.3 Previous Versions and Follow Up Work

Finally, we note that preliminary versions of this work appeared on arXiv (Dimitrakakis et al., 2013. Latest version 2015.) and ALT (Dimitrakakis et al., 2014). This version corrects technical issues with one proof, which affected the leading constants. We also replaced the original mechanism with one taking a fixed sample, which allows us to maintain a fixed privacy budget for an arbitrary number of queries. We make a novel use of Le Cam's method to prove lower bounds on indistinguishability, and we complement our original bounds with bounds for the utility of the mechanism. Finally, we discuss the relationship between posterior sampling, the exponential mechanism and the *safe Bayesian* generalisation of Bayesian inference. Follow-up work includes: Wang et al. (2015) who, under similar assumptions proved differential privacy results for Gibbs samplers; Zheng (2015) who improved some of our original bounds and also presented new results for other members of the exponential family; and Zhang et al. (2016) who recently initiated the exploration of the posterior sampler in probabilistic graphical models on multiple random variables.

Another important follow up work is that of Dwork et al. (2015). They have shown that *any* differentially private algorithm results in robustness, in the sense that the divergence between posterior distribution arising from similar data is small. This has a direct impact on the generalisation ability of statistical models and inferences drawn, and consequently allows for what they call the "re-usable hold-out". In our work, on the other hand, we have shown that with the right choice of prior, Bayesian inference is both private and robust. We have also shown that if the posterior distribution is robust, then it is also differentially private. In conclusion, robustness and privacy appear to be deeply linked, as our works have jointly shown conditions when one implies the other in three different ways: not only the same sufficient conditions can achieve both privacy and robustness, but privacy can also imply robustness, and robustness implies privacy. Further links between the two concepts are likely, as explained in the next section.

6.2 Future Directions

Although we have shown how Bayesian inference can already be differentially private by appropriately setting the prior, we have not examined how this affects learning. While larger c improves privacy, it also concentrates the prior so much that learning would be

inhibited. Thus, c could be chosen to optimise the trade-off between privacy and learning. However, we believe that the choice of the number of samples is easier to control.

From the theoretical side, we believe that the constant $C_\xi^{\mathcal{F}_\Theta}$ could be substantially improved, since right now it seems to be rather loose. It is also possible that its existence is only an artefact of the analysis, since it only appears for Assumption 2. However, we thought it crucial to include the results from this assumption in the paper, since they are connected to the second necessary condition. Hopefully, future work will uncover improved bounds for Assumption 2, or a similar condition to it.

Other future directions include investigating the links between posterior sampling and the exponential mechanism, as well as with the safe Bayesian approach (Grünwald, 2012) to inference. Consider an exponential mechanism which, given a utility function $u : \Theta \times \mathcal{Q} \to \mathbb{R}$ and a base measure μ on Θ returns $\theta \in \Theta$ sampled from the density

$$f(\theta) \propto e^{\epsilon u(\theta,q)} \frac{\mathrm{d}\mu(\theta)}{\mathrm{d}\lambda} \ .$$

As also noted by Wang et al. (2015), this has a similar form to the posterior distribution, by setting $u(\theta, q) = \ln p_\theta(x)$ and setting $\mu = \xi$ to the prior. This idea was used independently by Zhang et al. (2016) for releasing MAP point estimates. In this framework, privacy is achieved by setting ϵ to a sufficiently small value. However, it is interesting to note that this is how Grünwald (2012) obtains robustness results for modified Bayesian inference. This implies that in some cases we can gain both privacy and efficiency. We note that in our case, we have proven that privacy is attainable by altering the prior, which corresponds to the base measure in the exponential mechanism. Consequently, we believe it is worthwhile examining settings where adjusting both ϵ and the prior measure may be advantageous.

Acknowledgments

We gratefully thank Aaron Roth, Kamalika Chaudhuri, and Matthias Bussas for their discussion and insights as well as the anonymous reviewers for their comments on the paper, which helped to improve it significantly. This work was partially supported by the Marie Curie Project "Efficient Sequential Decision Making Under Uncertainty", Grant Number 237816; the People Programme (Marie Curie Actions) of the European Union's Seventh Framework Programme (FP7/2007-2013) under REA grant agreement n 608743; the SNSF Project, "SwissSenseSynergia"; and the Australian Research Council (DE160100584).

Appendix A. Proofs of Main Results

Proof of Lemma 5 For Assumption 1, the proof follows directly from the definition of the absolute log-ratio distance; namely,

$$\begin{aligned} |\ln p_\theta^n(\{x_i\}) - \ln p_\theta^n(\{y_i\})| &\leq \textstyle\sum_{i=1}^n |\ln p_\theta(x_i) - \ln p_\theta(y_i)| \\ &\leq L \textstyle\sum_{i=1}^n \rho(x_i, y_i) \ . \end{aligned}$$

For Assumption 2, consider sub-family Θ_L from Eq. (4) for marginal p_θ and pseudo-metric ρ, and define the corresponding sub-family Θ_L^n in terms of product distribution p_θ^n

and pseudo-metric ρ^n. Then the same argument as above shows that $\Theta_L \subseteq \Theta_L^n$. Hence, the same prior and parameter c yield the lower bound of Eq. (5), for Θ_L^n. ■

Proof of Theorem 7 Let us now tackle claim 1. First, we can decompose the KL-divergence into two parts.

$$\begin{aligned} D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) &= \int_\Theta \ln \frac{\mathrm{d}\xi(\theta \mid x)}{\mathrm{d}\xi(\theta \mid y)} \, \mathrm{d}\xi(\theta \mid x) \\ &= \int_\Theta \ln \frac{p_\theta(x)}{p_\theta(y)} \, \mathrm{d}\xi(\theta \mid x) + \int_\Theta \ln \frac{\phi(y)}{\phi(x)} \, \mathrm{d}\xi(\theta \mid x) \\ &\leq \int_\Theta \left| \ln \frac{p_\theta(x)}{p_\theta(y)} \right| \mathrm{d}\xi(\theta \mid x) + \int_\Theta \ln \frac{\phi(y)}{\phi(x)} \, \mathrm{d}\xi(\theta \mid x) \\ &\leq L\rho(x,y) + \left| \ln \frac{\phi(y)}{\phi(x)} \right| \ . \end{aligned} \tag{11}$$

From Assumption 1, $p_\theta(y) \leq \exp(L\rho(x,y)) p_\theta(x)$ for all θ so:

$$\begin{aligned} \phi(y) &= \int_\Theta p_\theta(y) \, \mathrm{d}\xi(\theta) \\ &\leq \exp(L\rho(x,y)) \int_\Theta p_\theta(x) \, \mathrm{d}\xi(\theta) = \exp(L\rho(x,y))\phi(x) \ . \end{aligned}$$

Combining this with (11) we obtain

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \leq 2L\rho(x,y) \ .$$

Claim 2 is dealt with similarly. Once more, we can break down the distance in parts. In more detail, we first write:

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \leq \underbrace{\int_\Theta \left| \ln \frac{p_\theta(x)}{p_\theta(y)} \right| \mathrm{d}\xi(\theta \mid x)}_{A} + \underbrace{\int_\Theta \ln \frac{\phi(y)}{\phi(x)} \, \mathrm{d}\xi(\theta \mid x)}_{B} \ ,$$

as before. Now, let us re-write the A term as

$$\int_\Theta \left| \ln \frac{p_\theta(x)}{p_\theta(y)} \right| \frac{p_\theta(x)}{\phi(x)} \, \mathrm{d}\xi(\theta) \leq \sup_{\theta'} \frac{p_{\theta'}(x)}{\phi(x)} \int_\Theta \left| \ln \frac{p_\theta(x)}{p_\theta(y)} \right| \mathrm{d}\xi(\theta) \ ,$$

so that the left-hand side term is the ratio between the maximal likelihood and marginal likelihood. Using the same steps, we can bound B in the same manner.

Now, let us define a data-dependent and a data-independent bound:

$$C_\xi^{\mathcal{F}_\Theta}(x) \triangleq \sup_\theta \frac{p_\theta(x)}{\phi(x)} \ , \qquad C_\xi^{\mathcal{F}_\Theta} \triangleq \sup_x C_\xi^{\mathcal{F}_\Theta}(x) \ .$$

Replacing, we obtain:

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \leq C_\xi^{\mathcal{F}_\Theta} \underbrace{\int_\Theta \left| \ln \frac{p_\theta(x)}{p_\theta(y)} \right| \mathrm{d}\xi(\theta)}_{A} + \underbrace{\int_\Theta \ln \frac{\phi(y)}{\phi(x)} \, \mathrm{d}\xi(\theta \mid x)}_{B} \ .$$

Now, to bound the individual terms, we start from A and note that theorem 3 of (Norkin, 1986) on the Lipschitz property of the expectation of stochastic Lipschitz functions applies.

Theorem 25 *(Norkin, 1986) If ξ is a probability measure on Θ and $f : \mathcal{S} \times \Theta \to \mathbb{R}$ is a ξ-measurable function, such that for any $\theta \in \Theta$, $f(\cdot, \theta)$ is $\ell(\theta)$-Lipschitz, then the function $f_\xi(x) \triangleq \mathbb{E}_\xi f(x, \theta)$ is L_ξ-Lipschitz, where $L_\xi = \mathbb{E}_\xi \ell(\theta)$.*

Recall that the expectation of a non-negative random variable can be written in terms of its CDF F as $\int_0^\infty [1 - F(t)]\,\mathrm{d}t$. In our case, $\ell(\theta)$ is a random variable on Θ, and we can write its cumulative distribution function as

$$F(t) \triangleq \xi\left(\{\,\theta \in \Theta : \ell(\theta) \le t\,\}\right) = \xi(\Theta_t) \ ,$$

by the definition of Θ_t. It follows that $\ln p_\theta(x)$ is L_ξ-Lipschitz, where through the formula for the expectation of positive variables:

$$L_\xi = \int_0^\infty [1 - \xi(\Theta_t)]\,\mathrm{d}t \le L_0 \xi(\Theta_{L_0}) + [1 - \xi(\Theta_{L_0})] \int_0^\infty e^{-ct}\,\mathrm{d}t \le L_0 + c^{-1} \ . \tag{12}$$

So, term A becomes $C_\xi^{\mathcal{F}_\Theta}\left(L_0 + c^{-1}\right)\rho(x, y)$.

Now let us move on to term B. For technical reasons, we start by considering a pair x, y such that $\rho(x, y) \le c - 1$. This also implies that $c > 1$, since the distance cannot be negative.

$$\frac{\phi(x)}{\phi(y)} \overset{(a)}{=} \int_\Theta \frac{p_\theta(x)}{\phi(y)}\,\mathrm{d}\xi(\theta) \overset{(b)}{\le} \int_\Theta \frac{p_\theta(y) e^{\ell(\theta)\rho(x,y)}}{\phi(y)}\,\mathrm{d}\xi(\theta) \overset{(c)}{\le} C_\xi^{\mathcal{F}_\Theta} \int_\Theta e^{\ell(\theta)\rho(x,y)}\,\mathrm{d}\xi(\theta) \ . \tag{13}$$

Note that $\left\{\,\theta \in \Theta : e^{\ell(\theta)\rho(x,y)} \le t\,\right\} = \left\{\,\theta \in \Theta : \ell(\theta) \le \rho(x, y)^{-1} \ln t\,\right\} = \Theta_{\rho(x,y)^{-1}\ln t}$. So the CDF of the random variable $e^{\ell(\theta)}$ is $F(t) = \xi(\Theta_{\rho(x,y)^{-1}\ln t})$. Then:

For positive random variables, $\mathbb{E}\, X^\rho = \rho \int_0^\infty t^{\rho-1}[1 - F(t)]dt$. Applying this to our case, we get:

$$\begin{aligned}
\mathbb{E}_\xi\, e^{\ell(\theta)\rho(x,y)} &= \mathbb{E}_\xi[e^{\ell(\theta)\rho(x,y)} \mid \ell \le L_0]\xi(\Theta_{L_0}) + \mathbb{E}_\xi[e^{\ell(\theta)\rho(x,y)} \mid \ell > L_0][1 - \xi(\Theta_{L_0})] \\
&\le e^{L_0\rho(x,y)} + \rho(x, y) \int_{t_0}^\infty t^{\rho(x,y)-1}[1 - \xi(\Theta_{\ln t})]\,\mathrm{d}t \\
&\le e^{L_0\rho(x,y)} + \rho(x, y) \int_{t_0}^\infty e^{\ln t[\rho(x,y)-1]} e^{-c(\ln t - L_0)}\,\mathrm{d}t \qquad \text{(where } t_0 = e^{L_0}\text{)} \\
&= e^{L_0\rho(x,y)} + \rho(x, y) \int_{t_0}^\infty e^{\ln t[\rho(x,y)-c-1]+cL_0}\,\mathrm{d}t \\
&= e^{L_0\rho(x,y)} + \rho(x, y) e^{cL_0} \int_{t_0}^\infty t^{\rho(x,y)-c-1}\,\mathrm{d}t \\
&= e^{L_0\rho(x,y)} + \rho(x, y) e^{cL_0} \frac{t_0^{\rho(x,y)-c}}{c - \rho(x, y)} \\
&= e^{L_0\rho(x,y)} + \rho(x, y) e^{cL_0} \frac{e^{L_0(\rho(x,y)-c)}}{c - \rho(x, y)} \\
&\le e^{L_0\rho(x,y)} + \rho(x, y) e^{cL_0} e^{L_0(\rho(x,y)-c)} \\
&= e^{L_0\rho(x,y)} + \rho(x, y) e^{L_0\rho(x,y)} = (1 + \rho(x, y)) e^{L_0\rho(x,y)} \le e^{(1+L_0)\rho(x,y)}.
\end{aligned}$$

Consequently, $\ln \phi(x)/\phi(y) \le C_\xi^{\mathcal{F}_\Theta}(1 + L_0)\rho(x, y)$.

To handle larger distances ρ, we can simply apply the above result repeatedly between k data sets $z_1, \ldots, z_k$, where $z_1 = x$, $z_k = y$ and such that $\rho(z_i, z_{i+1}) < c - 1$. By chaining logarithmic ratios, *i.e.*, using the fact that $\ln \phi(x)/\phi(y) = \ln \phi(x)/\phi(z) + \ln \phi(z)/\phi(y)$ we can now extend our result to general pairs for term B. Replacing those terms, we obtain:

$$D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right) \le C_\xi^{\mathcal{F}_\Theta}\left(1 + 2L_0 + c^{-1}\right)\rho(x, y) \ .$$

If the intermediate points do not exist under ρ, we can simply scale it by $\chi \le 1$, thus obtaining the final result. ■

Proof of Theorem 8 For part 1, we assumed that there is an $L > 0$ such that $\forall x, y \in \mathcal{S}$, $\left|\log \frac{p_\theta(x)}{p_\theta(y)}\right| \le L\rho(x, y)$, thus implying $\frac{p_\theta(x)}{p_\theta(y)} \le \exp\{L\rho(x, y)\}$. Further, in the proof of Theorem 7, we showed that $\phi(y) \le \exp\{L\rho(x, y)\}\phi(x)$ for all $x, y \in \mathcal{S}$. From Eq. (1), we can then combine these to bound the posterior of any $B \in \mathfrak{S}_\Theta$ as follows for all $x, y \in \mathcal{S}$:

$$\xi(B \mid x) = \frac{\int_B \frac{p_\theta(x)}{p_\theta(y)} p_\theta(y)\,\mathrm{d}\xi(\theta)}{\phi(y)} \cdot \frac{\phi(y)}{\phi(x)} \le \exp\{2L\rho(x, y)\}\xi(B \mid y) \ .$$

For part 2, note that from Theorem 7 part 2 that the KL divergence of the posteriors under assumption is bounded by (8). Now, recall Pinsker's inequality (cf. Fedotov et al., 2003):

$$D\left(Q \| P\right) \ge \frac{1}{2}\|Q - P\|_1^2 = 2\|Q - P\|_{\mathrm{TV}}^2 \triangleq 2 \sup_B |Q(B) - P(B)|^2 \tag{14}$$

This yields: $|\xi(B \mid x) - \xi(B \mid y)| \le \sqrt{\frac{1}{2} D\left(\xi(\cdot \mid x) \parallel \xi(\cdot \mid y)\right)} \le \sqrt{\frac{1}{2} C_\xi^{\mathcal{F}_\Theta}\left(1 + 2L_0 c^{-1}\right)\rho(x, y)}$. ■

Proof of Lemma 11 Sampling N times from the posterior, gives us the following estimate of the utility function $\hat{u_\xi}(q, r) = \frac{1}{N}\sum_{\theta \in \hat{\Theta}} u_\theta(q, r)$, which with probability at least $1 - \delta$ satisfies $|\hat{u_\xi}(q, r) - u(q, r)| < \sqrt{\frac{\ln(2/\delta)}{2N}} = \epsilon$, $\forall r, q$, via Hoeffding's inequality and the boundedness of u. Consequently, we can be at most 2ϵ-away from the optimal. ■

Proof of Lemma 12 (Note that in this proof, ε, δ do not refer to the privacy parameters.) We use the inequality due to Weissman et al. (2003) on the ℓ_1 norm, which states that for any multinomial distribution P with m outcomes, the ℓ_1 deviation of the empirical distribution $\hat{P}_n$ after n draws from the multinomial satisfies:

$$\mathbb{P}\left(\left\|\hat{P}_n - P\right\|_1 \ge \varepsilon\right) \le (2^m - 2)e^{-\frac{1}{2}n\varepsilon^2}, \qquad \forall \varepsilon > 0 \ .$$

The right hand side is bounded by $e^{m\ln 2-\frac{1}{2}n\varepsilon^2}$. Substituting $\varepsilon=\sqrt{\frac{3}{n}\ln\frac{1}{\delta}}$:

$$\begin{aligned}\mathbb{P}\left(\left\|\hat{P}_n-P\right\|_1\geq\sqrt{\frac{3}{n}\ln\frac{1}{\delta}}\right)&\leq e^{m\ln 2-\frac{3}{2}\ln\frac{1}{\delta}}\\&\leq e^{\log_2\sqrt{\frac{1}{\delta}}\ln 2-\frac{3}{2}\ln\frac{1}{\delta}}\\&=e^{\frac{1}{2}\ln\frac{1}{\delta}-\frac{3}{2}\ln\frac{1}{\delta}}\\&=\delta\ .\end{aligned}$$

where the second inequality follows from $m\leq\log_2\sqrt{1/\delta}$. ■

Proof of Theorem 13 Recall that the data processing inequality states that, for any sub-algebra $\mathfrak{S}$:

$$\left\|Q_{|\mathfrak{S}}-P_{|\mathfrak{S}}\right\|_1\leq\|Q-P\|_1\ .$$

Using this and Pinsker's inequality (14) we obtain:

$$\begin{aligned}2L\rho(x,y)&\geq D\left(\xi(\cdot\mid x)\|\xi(\cdot\mid y)\right)\\&\geq\frac{1}{2}\left\|\xi(\cdot\mid x)-\xi(\cdot\mid y)\right\|_1^2\\&\geq\frac{1}{2}\left\|\xi_{|\mathfrak{S}}(\cdot\mid x)-\xi_{|\mathfrak{S}}(\cdot\mid y)\right\|_1^2\ .\end{aligned}$$

On the other hand, due to (10) the adversary's ℓ_1 error in the posterior distribution is bounded by $\sqrt{\frac{3}{n}\ln\frac{1}{\delta}}$ with probability $1-\delta$. In order for him to be able to distinguish the two different posteriors, it must hold that

$$\left\|\xi_{|\mathfrak{S}}(\cdot\mid x)-\xi_{|\mathfrak{S}}(\cdot\mid y)\right\|_1\geq\sqrt{\frac{3}{n}\ln\frac{1}{\delta}}\ .$$

Using the above inequalities, we can bound the error in terms of the distinguishability of the real data set x from an arbitrary set y as:

$$4L\rho(x,y)\geq\frac{3}{n}\ln\frac{1}{\delta}\ .$$

Rearranging, we obtain the required result. The second case is treated similarly to obtain:

$$2C_\xi^{\mathcal{F}_\Theta}\left(1+2L_0+c^{-1}\right)\rho(x,y)\geq\frac{3}{n}\ln\frac{1}{\delta}\ .$$

■

Proof of Lemma 14 Let $r,r^\star$ be the optimal responses under $\xi,\xi^\star$ respectively. For notational convenience, let $u_\xi=\int_\Theta u_\theta\,\mathrm{d}\xi(\theta)$ denote the expected utility under a belief ξ.

Then our regret is

$$\begin{aligned}u_\xi(q,r)-u_\xi(q,r^\star)&=u_\xi(q,r)-u_{\xi^\star}(q,r)\\&\quad+u_{\xi^\star}(q,r)-u_{\xi^\star}(q,r^\star)\\&\quad+u_{\xi^\star}(q,r^\star)-u_\xi(q,r^\star)\\&\leq 2\left\|\xi-\xi^\star\right\|_1\ .\end{aligned}$$

This follows from the fact that

$$\begin{aligned}u_\xi(q,r)-u_{\xi^\star}(q,r)&=\int_\Theta u_\theta(q,r)\,\mathrm{d}[\xi-\xi^\star](\theta)\\&\leq\|u\|_\infty\|\xi-\xi^\star\|_1\end{aligned}$$

and then using the boundedness of u. The third term is dealt with identically. For the second term, note that $u_{\xi^\star}(q,r)-u_{\xi^\star}(q,r^\star)\leq 0$ since $r^\star$ maximises $u_{\xi^\star}$. ■

Proof of Lemma 15 Let $\phi^\star(x)=\int_\Theta p_\theta(x)\,\mathrm{d}\xi^\star(x)$ be the prior marginal distribution. Then the $\xi^\star$-expected KL divergence between the two posteriors is

$$\begin{aligned}&\sum_x\int_\Theta\ln\frac{\mathrm{d}\xi^\star(\theta\mid x)}{\mathrm{d}\xi(\theta\mid x)}\,\mathrm{d}\xi^\star(\theta\mid x)\phi^\star(x)\\&\leq\sum_x\int_\Theta\left(\left|\ln\frac{\mathrm{d}\xi^\star(\theta)}{\mathrm{d}\xi(\theta)}\right|+\left|\ln\frac{\phi(x)}{\phi^\star(x)}\right|\right)\mathrm{d}\xi^\star(\theta\mid x)\phi^\star(x)\\&\leq 2\eta\ .\end{aligned}$$

The first term $\left|\ln\frac{\mathrm{d}\xi^\star(\theta)}{\mathrm{d}\xi(\theta)}\right|$ is bounded by η by assumption. From the same assumption, it follows that $\phi(x)=\int_\Theta p_\theta(x)\,\mathrm{d}\xi(\theta)\leq\int_\Theta p_\theta(x)e^\eta\,\mathrm{d}\xi^\star(\theta)=e^\eta\phi^\star(x)$, and so the second term is also bounded by η. ■

Appendix B. Proofs of Examples

Proof of Lemma 19 Since $Exp(x;\theta)$ is monotonic decreasing in x and concave as a function of θ, we have $\inf_{\{||x||\leq B,\theta\in[c_1,c_2]\}}Exp(x;\theta)=\min\left\{c_1e^{-c_1B},c_2e^{-c_2B}\right\}\leq\phi(x)$. Then we have

$$C_\xi^{\mathcal{F}_\Theta}=c_2/\min\left\{c_1e^{-c_1B},c_2e^{-c_2B}\right\}\ .$$

Next we compute the absolute log-ratio distance for any x_1 and x_2 according to the exponential likelihood function:

$$|\ln p_\theta(x_1)-\ln p_\theta(x_2)|=\theta|x_1-x_2|\ .$$

Thus, for $\theta\in[c_1,c_2]$, under Assumption 2, using $\rho(x,y)=|x-y|$, the set of feasible parameters for any $L>c_1$ is $\Theta_L=(c_1,L)$. Note the density of the renormalized exponential prior on $[c_1,c_2]$ is given by $K\lambda e^{-\lambda\theta}$, where $K=(e^{-\lambda c_1}-e^{-\lambda c_2})^{-1}$. Thus the CDF at L of

this density is $K\left(e^{-\lambda c_1} - e^{-\lambda L}\right)$ for $L \in [c_1, c_2]$ and 1 for $L \geq c_2$. It is natural to choose L_0 to be c_1. Then we need to find c such that

$$\xi(\Theta_L) = \int_{c_1}^{L} K\lambda e^{-\lambda\theta} d\theta = K(e^{-\lambda c_1} - e^{-\lambda L}) \geq 1 - e^{-c(L-c_1)}$$

for $L \in (c_1, c_2)$. By plugging K into the inequality, we have

$$e^{-c(L-c_1)} \geq \frac{e^{-\lambda(L-c_2)} - 1}{e^{-\lambda(c_1-c_2)} - 1} \ .$$

Since $e^{-\lambda(L-c_2)} \leq e^{-\lambda(c_1-c_2)}$, it is sufficiency to find c such that $e^{-c(L-c_1)} \geq e^{-\lambda(L-c_1)}$. Therefore we can have $c = \lambda$. ■

Proof of Lemma 20 Note that $Laplace(x; s, \mu)$ is monotonic decreasing in x if $x < \mu$, and increasing in x if $x \geq \mu$. Since $Laplace(x; s, \mu)$ is concave as a function of s, we have $\phi(t) \geq \min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{-B-\mu}{c_1}\right)\right\}$ if $x < \mu$ and $\phi(t) \geq \min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{\mu-B}{c_1}\right)\right\}$ if $x \geq \mu$. Thus, we can take

$$C_\xi^{\mathcal{F}_\Theta} = \begin{cases} \frac{c_2}{2\min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{-B-\mu}{c_1}\right)\right\}} \ , & x < \mu \\ \frac{c_2}{2\min\left\{\frac{1}{2c_2}, \frac{1}{2c_1}\exp\left(\frac{\mu-B}{c_1}\right)\right\}} \ , & x \geq \mu \end{cases} .$$

For any x_1 and x_2, the absolute log-ratio distance for this distribution can be bounded as

$$\begin{aligned} &|\ln p_{\mu,s}(x_1) - \ln p_{\mu,s}(x_2)| \\ =&\tfrac{1}{s}\left|\|x_1 - \mu\| - \|x_2 - \mu\|\right| \leq \tfrac{1}{s}\|x_1 - x_2\| \ , \end{aligned}$$

where the inequality follows from the triangle inequality on $\|\cdot\|$. Thus, if we use $\rho(x, y) = \|x - y\|$, the set of feasible parameters for Assumption 2 is $\mu \in \mathbb{R}$ and $\frac{1}{s} = \theta \leq L$. Again we can use the trimmed exponential prior with rate parameter $\lambda > 0$ for the inverse scale, $\frac{1}{s}$, and similar to the previous example, Assumption 2 is satisfied with $c = \lambda$ and $L_0 = c_1$. ■

Proof of Lemma 21 Here, we consider data drawn from a Binomial distribution with a beta prior on its proportion parameter, θ. Thus, the likelihood and prior functions are

$$\begin{aligned} p_{\theta,n}(X = k) &= \tbinom{n}{k}\theta^k(1-\theta)^{n-k} \\ \xi_0(\theta) &= \tfrac{1}{B(a,b)}\theta^{a-1}(1-\theta)^{b-1} \ , \end{aligned}$$

where $k \in \{0, 1, 2, \ldots, n\}$, $a, b \in \mathbb{R}_+$ and $B(a, b)$ is the beta function. The resulting posterior is a Beta-Binomial distribution. Again we consider the application of Assumption 2 to this Beta-Binomial distribution. For this purpose, we must quantify the parameter sets Θ_L for a given $L > 0$ according to a distance function. The absolute log-ratio distance between the Binomial likelihood function for any pair of arguments, k_1 and k_2, is

$$|\ln p_{\theta,n}(k_1) - \ln p_{\theta,n}(k_2)| = \left|\Delta_n(k_1, k_2) + (k_1 - k_2)\ln\tfrac{\theta}{1-\theta}\right|$$

where $\Delta_n(k_1, k_2) \triangleq \ln\binom{n}{k_1} - \ln\binom{n}{k_2}$. By substituting this distance into the supremum of Eq. (4), we seek feasible values of $L > 0$ for which the supremum is non-negative; here, we explore the case where $\rho((n, k_1), (n, k_2)) \triangleq |k_1 - k_2|$. Without loss of generality, we assume $k_1 > k_2$, and thus require that

$$\sup_{k_1 > k_2} \left|\tfrac{\Delta_n(k_1,k_2)}{k_1-k_2} + \ln\tfrac{\theta}{1-\theta}\right| \leq L \ . \tag{15}$$

However, by the definition of $\Delta_n(k_1, k_2)$, the ratio $\frac{\Delta_n(k_1,k_2)}{k_1-k_2}$ is in fact the slope of the chord from k_2 to k_1 on the function $\ln\binom{n}{k}$. Since the function $\ln\binom{n}{k}$ is concave in k, this slope achieves its maximum and minimum at its boundary values; *i.e.*, it is maximised for $k_1 = 1$ and $k_2 = 0$ and minimised for $k_1 = n$ and $k_2 = n - 1$. Thus, the ratio attains a maximum value of $\ln n$ and a minimum of $-\ln n$ for which the above supremum is simply $\ln n + \left|\ln\frac{\theta}{1-\theta}\right|$. From Eq. (15), we therefore have, for all $L \geq \ln n$:

$$\Theta_L = \left[\left(1 + \tfrac{e^L}{n}\right)^{-1}, \left(1 + \tfrac{n}{e^L}\right)^{-1}\right] \ .$$

We want to bound $\xi(\Theta_L)$. We know that: $\xi(\Theta_L) = 1 - \xi\left(\Theta_L^\complement\right)$ where $\Theta_L^\complement$ is the complement of Θ_L. so $\xi(\Theta_L^\complement)$ is composed of two symmetric intervals: $\left[0, \left(1 + \frac{e^L}{n}\right)^{-1}\right)$ and $\left(\left(1 + \frac{n}{e^L}\right)^{-1}, 1\right]$. We selected $\alpha = \beta$, therefore the mass must concentrate at $\frac{1}{2}$, as we have $\alpha > 1$.

Due to symmetry, the mass outside of Θ_L is two times that is the first interval. This is:

$$\frac{2}{B(\alpha,\alpha)}\int_0^{\frac{p}{1+p}} x^{\alpha-1}(1-x)^{\alpha-1}\,\mathrm{d}x \ .$$

where p denotes $ne^{-L} \in [0, 1]$, Therefore c is upper bounded by

$$\ln\left(\frac{2A(p)}{B(\alpha,\alpha)}\right)/(L_0 - L) = \ln\left(\frac{2A(p)}{B(\alpha,\alpha)}\right)/\ln p,$$

where $A(p)$ denotes the incomplete Beta function $\int_0^{\frac{p}{1+p}} x^{\alpha-1}(1-x)^{\alpha-1}dx$. Note that we have

$$A'(p) = \frac{p^{\alpha-1}}{(1+p)^{2\alpha}} \ ,$$

$$A''(p) = \frac{p^{\alpha-2}[(\alpha-1)(1+p) - 2\alpha p]}{(1+p)^{2\alpha+1}} \ .$$

Claim 2 *$H(p) = \alpha A(p) - \frac{p^\alpha}{(1-p)(1+p)^{2\alpha-1}} \leq 0$ for all $p \in (0, 1)$.*

Proof Calculating derivatives and simplifying

$$\begin{aligned}
& H'(p) \\
= \; & \alpha A'(p) - \frac{\alpha p^{\alpha-1}(1-p)(1+p)^{2\alpha-1} - p^\alpha\left[(2\alpha-1)(1-p)(1+p)^{2\alpha-2} - (1+p)^{2\alpha-1}\right]}{[(1-p)(1+p)^{2\alpha-1}]^2} \\
= \; & \frac{\alpha p^{\alpha-1}}{(1+p)^{2\alpha}} - \frac{\alpha p^{\alpha-1}(1-p)(1+p) - p^\alpha[(2\alpha-1)(1-p) - (1+p)]}{(1-p)^2(1+p)^{2\alpha}} \\
= \; & \frac{p^{\alpha-1}}{(1+p)^{2\alpha}}\left(\alpha - \frac{\alpha(1-p^2) - 2p(\alpha-1-p\alpha)}{(1-p)^2}\right) \\
= \; & \frac{p^{\alpha-1}}{(1+p)^{2\alpha}(1-p)^2}\left(\alpha(1-2p+p^2) - \alpha(1-p^2) + 2p(\alpha-1-\alpha p)\right) \\
= \; & \frac{-2p^\alpha}{(1+p)^{2\alpha}(1-p)^2} < 0 \; .
\end{aligned}$$

Therefore $H(p)$ is strictly decreasing. Then combined with $H(0) = 0$, we claim follows. ■

Claim 3 *$G(p) = p\frac{A'(p)}{A(p)}\ln p - \ln\frac{2A(p)}{B(\alpha,\alpha)} < 0$ for all $p \in (0,1)$.*

Proof Again taking derivatives

$$\begin{aligned}
G'(p) &= \frac{A'(p)}{A(p)}(1+\ln p) + p\ln p\frac{A''(p)A(p) - A'(p)^2}{A(p)^2} - \frac{A'(p)}{A(p)} \\
&= \frac{\ln p}{A(p)^2}(A(p)A'(p) + pA''(p)A(p) - pA'(p)^2) \\
&= \frac{\ln p}{A(p)^2}\left[\frac{p^{\alpha-1}}{(1+p)^{2\alpha}}A(p)\left(1 + \frac{(\alpha-1)(1+p) - 2\alpha p}{1+p}\right) - \frac{p^{2\alpha-1}}{(1+p)^{4\alpha}}\right] \\
&= \frac{\ln p}{A(p)^2}\frac{p^{\alpha-1}}{(1+p)^{2\alpha+1}}\left[\alpha(1-p)A(p) - \frac{p^\alpha}{(1+p)^{2\alpha-1}}\right] \\
&= \frac{p^{\alpha-1}}{(p+1)^{2\alpha+1}A(p)^2}H(p)\ln p(1-p) > 0 \; .
\end{aligned}$$

So $G(p)$ is strictly increasing. Combined with $\lim_{p\to 1} G(p) = 0$, the claim follows. ■

Claim 4 *$F(p) = \ln\left(2I_{\frac{p}{1+p}}(\alpha)\right)/\ln p$ is decreasing in $p \in (0,1)$, where the incomplete Beta function $I_{\frac{p}{1+p}}(\alpha) = A(p)/B(\alpha,\alpha)$.*

Proof Taking derivatives

$$\begin{aligned}
F'(p) &= \frac{1}{\ln^2 p}\left(\frac{A'(p)}{A(p)}\ln p - \frac{1}{p}\ln\frac{2A(p)}{B(\alpha,\alpha)}\right) \\
&= \frac{1}{p\ln^2 p}\left(\frac{A'(p)}{A(p)}p\ln p - \ln\frac{2A(p)}{B(\alpha,\alpha)}\right) \\
&= \frac{1}{p\ln^2 p}G(p) < 0 \; .
\end{aligned}$$

■

Therefore $\ln\left(2I_{\frac{p}{1+p}}(\alpha)\right)/\ln p$ is monotonic decreasing in p. Thus the minimum value of $F(p)$ is $\frac{1}{B(\alpha)2^{2\alpha-1}}$ as $p \to 1$, which we can take as our c in this example.

Let us consider $C_\xi^{\mathcal{F}_\Theta}$ for this example. We have

$$\frac{p_\theta(x)}{\phi(x)} = \frac{B(\alpha,\beta)\theta^x(1-\theta)^{n-x}}{B(\alpha+x, n+\beta-x)} \; ,$$

where $\theta \in [0,1]$ and $x \in [0,1,\ldots,n]$. Note that

$$\frac{B(\alpha+x+1, n+\beta-x-1)}{B(\alpha+x, n+\beta-x)} = \frac{\Gamma(\alpha+x+1)\Gamma(n+\beta-x-1)}{\Gamma(\alpha+x)\Gamma(n+\beta+1)} = \frac{\alpha+x}{n+\beta-x-1} \; .$$

So $B(\alpha+x+1, n+\beta-x-1) \le B(\alpha+x, n+\beta-x)$ if $x \le \frac{n+\beta-\alpha-1}{2}$; $B(\alpha+x+1, n+\beta-x-1) > B(\alpha+x, n+\beta-x)$ otherwise. Thus

$$B(\alpha+x, n+\beta-x) \ge B\left(\frac{n+\alpha+\beta-1}{2}, \frac{n+\alpha+\beta+1}{2}\right) \; .$$

Hence we can take $C_\xi^{\mathcal{F}_\Theta} = B(\alpha,\beta)/B\left(\frac{n+\alpha+\beta-1}{2}, \frac{n+\alpha+\beta+1}{2}\right)$. ■

Proof of Lemma 22 Since $N(x;\mu,\theta)$ is decreasing in x^2 and concave as a function of θ. We have $\phi(t) \ge \inf_{\{x : \|x\| \le B\}, \theta \in [c_1,c_2]} N(x;\mu,\theta) = \min\left\{\sqrt{\frac{c_1}{2\pi}}e^{\frac{-c_1c_2^2}{2}}, \sqrt{\frac{c_2}{2\pi}}e^{\frac{-c_2^3}{2}}\right\}$. Then we can take

$$C_\xi^{\mathcal{F}_\Theta} = \min\left\{\sqrt{c_2/c_1}e^{\frac{c_1c_2^2}{2}}, e^{\frac{c_2^3}{2}}\right\}$$

For the normal distribution, (4) requires: $2L\rho(x,y)\sigma^2 \ge |2\mu - x - y|\,|x-y|$. Taking the absolute log ratio of the Gaussian densities we have

$$\begin{aligned}
& \frac{1}{2\sigma^2}\left|\left((x-\mu)^2 - (y-\mu)^2\right)\right| \\
\le & \frac{\max\{|\mu|, 1\}}{2\sigma^2}\left(\left|x^2 - y^2\right| + 2|x-y|\right) .
\end{aligned}$$

Consequently, we can set $\rho(x,y) = \left|x^2 - y^2\right| + 2|x-y|$ and $L(\mu,\sigma) = \frac{\max\{|\mu|,1\}}{2\sigma^2}$. Again, the trimmed exponential prior is given by $K\lambda e^{-\lambda\theta}$, where $K = (e^{-\lambda c_1} - e^{-\lambda c_2})^{-1}$. Thus the CDF at L of this density is $K\left(e^{-\lambda c_1} - e^{-\lambda L}\right)$ for $L \in [\frac{c_1\max\{|\mu|,1\}}{2}, \frac{c_2\max\{|\mu|,1\}}{2}]$ and 1 for $L \ge \frac{c_2\max\{|\mu|,1\}}{2}$. Thus the CDF at L of this density is $K\left(e^{-\lambda c_1} - e^{\frac{-2\lambda L}{\max\{|\mu|,1\}}}\right)$. We choose L_0 to be $\frac{c_1\max\{|\mu|,1\}}{2}$. Then we need to find c such that

$$\xi(\Theta_L) = \int_{c_1}^{L} K\lambda e^{-\lambda\theta}d\theta = K(e^{-\lambda c_1} - e^{-\lambda L}) \ge 1 - e^{-c\left(L - \frac{c_1\max\{|\mu|,1\}}{2}\right)}.$$

By plugging K into the inequality, we have

$$e^{-c\left(L-\frac{c_1\max\{|\mu|,1\}}{2}\right)} \geq \frac{e^{\frac{-2\lambda L}{\max\{|\mu|,1\}}+\lambda c_2}-1}{e^{-\lambda(c_1-c_2)}-1}.$$

Since $e^{-\lambda\left(\frac{2\lambda L}{\max\{|\mu|,1\}}-c_2\right)} \leq e^{-\lambda(c_1-c_2)}$, it is sufficiency to find c such that

$$e^{-c\left(L-\frac{c_1\max\{|\mu|,1\}}{2}\right)} \geq e^{-\lambda\left(\frac{2L}{\max\{|\mu|,1\}}-c_1\right)}.$$

This is equivalent to have c satisfying

$$c\left(L-\frac{c_1\max\{|\mu|,1\}}{2}\right) \leq \lambda\left(\frac{2L}{\max\{|\mu|,1\}}-c_1\right).$$

Then we can take $c=\frac{2\lambda}{\max\{|\mu|,1\}}$ to satisfy the above inequality. ■

Proof of Lemma 23 Consider the likelihood log-ratio distance of multivariate normal distributions with precision matrix A:

$$\frac{1}{2}|x^\top Ax - y^\top Ay| \ ,$$

where A is positive definite with eigenvalues $\lambda_1 \geq \ldots \geq \lambda_n > 0$). For simplicity, assume the mean to be a zero vector then

$$\begin{aligned}
|x^\top Ax - y^\top Ay| &= \left|\sum_{i,j} x_i x_j A_{i,j} - \sum_{i,j} y_i y_j A_{i,j}\right| \\
&= \left|\sum_{i,j} A_{i,j}(x_i x_j - y_i y_j)\right| \\
&= |Tr(A(xx^\top - yy^\top)')| \\
&\leq [Tr(A^2)Tr((xx^\top - yy^\top)(xx^\top - yy^\top)')]^{\frac{1}{2}} \\
&= \left(\sum_{i=1}^n \lambda_i^2\right)^{\frac{1}{2}} ||(xx^\top - yy^\top)||_F \ .
\end{aligned}$$

For mean equal to μ, we have

$$\frac{1}{2}|(x^\top-\mu)A(x-\mu) - (y^\top-\mu)A(y-\mu)| \ .$$

By the above analysis we have the difference being bounded by

$$\frac{1}{2}\left(\sum_{i=1}^n \lambda_i^2\right)^{\frac{1}{2}} ||(x-\mu)(x-\mu)' - (y-\mu)(y-\mu)')||_F \ .$$

Note that

$$\begin{aligned}
||(x-\mu)(x-\mu)' - (y-\mu)(y-\mu)')||_F =& ||xx^\top - \mu(x^\top - y^\top) - (x-y)\mu' - yy^\top||_F \\
\leq& ||xx^\top - yy^\top||_F + 2||\mu(x-y)'||_F \\
=& ||xx^\top - yy^\top||_F + 2||\mu||_2||(x-y)'||_2 \\
\leq& \max\{1, ||\mu||_2\}(||xx^\top - yy^\top||_F + 2||x-y||_2) \ .
\end{aligned}$$

■

Proof of Lemma 24 It is instructive to first examine the case where all variables are independent and we have a single draw from P_θ. Then $P_\theta(x) = \prod_{k=1}^K \theta_{k,x_k}$ and

$$\left|\ln\frac{P_\theta(x)}{P_\theta(y)}\right| = \left|\ln\prod_{k=1}^K \frac{\theta_{k,x_k}}{\theta_{k,y_k}}\right| \leq \sum_{k=1}^K \left|\ln\frac{\theta_{k,x_k}}{\theta_{k,y_k}}\right| \mathbb{I}\{x_k \neq y_k\} \leq \max_{i,j,k}\left|\ln\frac{\theta_{k,i}}{\theta_{k,j}}\right| \rho(x,y) \ . \tag{16}$$

Consequently, if $\varepsilon \triangleq \min_{k,j}\theta_{k,j}$ is the smallest probability assigned to any one sub-event, then $L > \ln 1/\varepsilon$, since $\theta_{k,j} \leq 1$.

In the general case, we have independent draws x^t, y^t, where $x^t \sim P_\theta(x)$ and the variables x_k^t have dependences defined through a graphical model, such that $P_\theta(x) = \prod_k P_\theta(x_k \mid x_{\mathcal{P}(k)})$, where $\mathcal{P}(k)$ are the parents of node k. Similarly to (16), we write

$$\begin{aligned}
\left|\ln\frac{P_\theta(x)}{P_\theta(y)}\right| &= \left|\ln\prod_t \frac{P_\theta(x^t)}{P_\theta(y^t)}\right| = \left|\ln\prod_t\prod_k \frac{P_\theta(x_k^t \mid x_{\mathcal{P}(k)}^t)}{P_\theta(y_k^t \mid y_{\mathcal{P}(k)}^t)}\right| \\
&\leq \sum_{t.k}\left|\ln\frac{P_\theta(x_k^t \mid x_{\mathcal{P}(k)}^t)}{P_\theta(y_k^t \mid y_{\mathcal{P}(k)}^t)}\right| \leq \ln\frac{1}{\epsilon}\sum_{t.k}\mathbb{I}\left\{x_k^t \neq y_k^t \vee x_{\mathcal{P}(k)}^t \neq y_{\mathcal{P}(k)}^t\right\}.
\end{aligned} \tag{17}$$

The last term is the number of times a value is different in x and y times one plus the number of variables it affects. To model this, let $v \in \mathbb{N}^K$ be such that $v_k = 1 + \deg(k)$ and define: $\rho(x,y) \triangleq v^\top \delta(x,y)$ and $\delta_k(x,y) \triangleq \sum_t \mathbb{I}\{x_{k,t} \neq y_{k,t}\}$. Rewriting (17) in terms of ρ, we obtain $\left|\ln\frac{P_\theta(x)}{P_\theta(y)}\right| \leq \ln\frac{1}{\varepsilon}\cdot\rho(x,y)$ as desired. ■

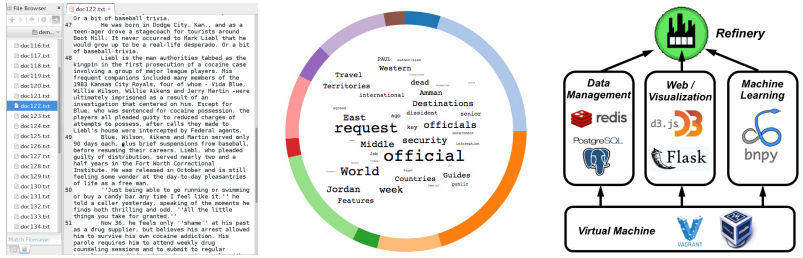
Abstract

We introduce Refinery, an open source platform for exploring large text document collections with topic models. Refinery is a standalone web application driven by a graphical interface, so it is usable by those without machine learning or programming expertise. Users can interactively organize articles by topic and also refine this organization with phrase-level analysis. Under the hood, we train Bayesian nonparametric topic models that can adapt model complexity to the provided data with scalable learning algorithms. The project website `http://daeilkim.github.io/refinery/` contains Python code and further documentation.

Keywords: topic models, visualization, software



1. Introduction

Topic models have become a ubiquitous class of tools for the analysis of large document collections (Blei, 2012). However, there is still a significant adoption barrier for individuals who have little to no background in coding or computer science. For example, librarians might be interested in understanding ways of organizing their vast archives of information while journalists could potentially use learned topics to extract insights from Freedom of Information Act (FOIA) requests. However, few have the expertise to implement necessary code nor an intuition for how to fine tune parameters associated with these models. Beyond the challenge of running statistical inference algorithms, the learned topics and word associations must be visualized in a way that is accurate but intuitive.

To make topic modeling algorithms and results more accessible, we built an open source web application called Refinery. Refinery allows users to explore a large corpus of documents and further identify a small set of relevant documents for careful study. The simple drag and drop operation of this toolbox allows researchers to focus on the process of quickly understanding their data without being encumbered by the complexities of inference.

2. Running Refinery

Refinery is an in-browser web application that builds on many existing open-source projects related to visualization, data management, and machine learning, as shown in Fig. 1. To make installation simple, it has only three dependencies: the Git version-control system,

(a) *Input:* Plain-text files, one per document (b) *Output:* Interactive visualization of learned topics (c) Technology stack

Figure 1: Refinery is a web-application that allows users to upload plain-text documents (a) and visualize the semantic themes learned by a topic-model (b). Under the hood, Refinery uses many existing technologies (c) for browser interaction, data management, machine learning, and visualization. A video demo is available online: `http://youtu.be/7yRQ1J9Z_LI`.

Virtualbox (Oracle, 2013), and Vagrant (Hashimoto, 2013). At a Unix-like command line with these dependencies installed, running Refinery requires just a few lines of code:

```
> git clone https://github.com/daeilkim/refinery.git
> vagrant up # launch machine and install required Python packages
```

After executing these lines, Refinery can be accessed from a web browser via the local address `http://11.11.11.11:8080`.

3. Topic Modeling

Uploading documents. Users submit documents for analysis in the form of a `.zip` or `.tar.gz` file, which uncompressed contains a folder of plain-text files, one for each individual document. Users do *not* need to preprocess documents or identify a vocabulary in advance. This is done automatically by Refinery, which tokenizes every unigram from the input documents. The final vocabulary excludes very rare and very common words; we discard terms appearing in more than 80% of all documents, or in less than 2 documents.

Training a topic model. The topic modeling algorithm used for Refinery comes from the BNPy toolbox (Hughes et al., 2015b). Specifically, we train a *hierarchical Dirichlet process* (HDP) topic model (Teh et al., 2006) using a memoized variational inference algorithm (Hughes et al., 2015a). While the underlying algorithm has many free parameters, we set most of these to smart defaults and only ask the user to specify an upper bound on the number of inferred topics. This bound provides a truncation for infinite-dimensional HDP model.

Browseable visualization. After training a model, users can explore the resulting topics interactively via a multi-colored ring, as shown in Fig. 2. Each segment of the ring represents one topic, with its size indicative of the topic's frequency in the overall corpus. Hovering

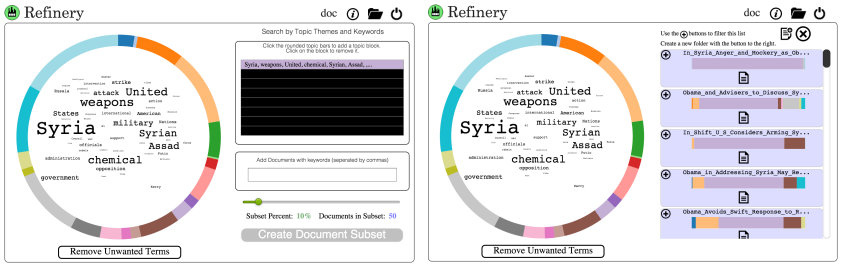

Figure 2: The results of an analysis on 500 New York Times articles that contained the keyword "obama" during the year 2013. In the figure above, the "Syria" topic has been selected along with a subset of 50 documents related to this topic.

the cursor over a topic's segment shows the top 50 words associated with that topic. In this word cloud visualization, text size is scaled according to the topic-specific word frequency.

Focused exploration of document subsets. Often, analysis of large collections requires identifying subsets of relevant documents and performing more detailed clustering of that subset. We support this by allowing the main corpus of documents to be filtered by keyword and topic presence. Refinery provides two methods for selecting relevant documents given a trained topic model with K topics. The first allows the user to directly specify a query distribution over topics which recovered documents should emulate. The second takes in a list of search terms, and averages the probability of topic given word for each term to obtain a (normalized) distribution over K topics. Given this K-dimensional query vector, documents are ranked based on the KL divergence between their MAP topic distribution and the query.

4. Phrase Extraction and Refinement

While topic modeling enables scalable first-pass analysis, often the underlying bag-of-words assumptions are too limiting. After filtering a large corpus to find only documents relevant to a small set of topics, Refinery further allows users to explore documents by phrase similarity and create a summary of the corpus composed of sentences extracted from the input documents.

We use the open-source implementation of the Splitta algorithm (Gillick, 2010), which Gillick (2009) introduced for sentence boundary detection. First, the Splitta algorithm is applied for sentence boundary detection. This algorithm processes raw text and does not make use of the topic model output. Next, to help the user efficiently select a subset of relevant sentences from their corpus, Refinery offers two exploration modes. The first, triggered by the button marked "Variety", implements the KLSum algorithm for multidocument summarization (Haghighi and Vanderwende, 2009). This algorithm ranks candidate sentences higher if their addition to the current set would bring the unigram distribution closer to that of the corpus as a whole, intuitively preferring sentences that contain globally

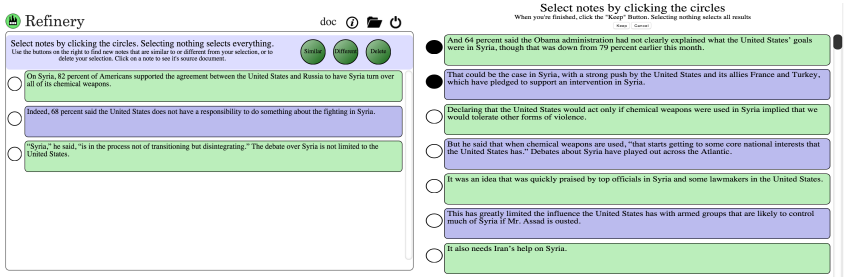

Figure 3: Refinery's phrase extraction feature. *Left:* User has selected some initial phrases related to the war in Syria from news articles. *Right:* Hitting the "similar" button brings up another set of phrases similar to the initial set.

relevant information that does not yet appear in the set of selected sentences. The second exploration method, labeled "Similar", simply ranks candidates by cosine similarity to the current summary's unigram distribution. Each sentence in the summary is linked to and highlighted in its original source document, facilitating the creation of a comprehensive set of notes with fast access to their provenance.

5. Discussion and Related Work

Refinery provides a first step towards allowing non-technical professionals to explore large document collections with modern topic models. Several others groups have strived to simplify and democratize the use of topic models. Notably, Chaney and Blei (2012) created a web-based navigator to help users understand the relationship between topics and documents, while Chuang et al. (2012) developed a visualization package for assessing the goodness of topics. Topicnets (Gretarsson et al., 2012) focuses on a graph-based exploration and visualization of topics, while other packages such as Gephi (Bastian et al., 2009) and Tethne (Peirson et al., 2015) are often used to create similar visualizations of an already-learned set of topics. Most prior work has focused on the parametric *latent Dirichlet allocation* (LDA) topic model (Blei et al., 2003).

Refinery differs from these packages in the way it simplifies the entire process of analyzing text with topic models for non-expert users. Furthermore, Refinery's use of scalable Bayesian nonparametric topic models offers the benefit of automatic model selection while parametric models like LDA require a prior knowledge of the number of topics. Refinery also supports phrase extraction, which allows for a more refined search across documents. Building on the BNPy toolbox allows potential future extensions to more advanced models that cluster documents organized as a time-series or network. Ultimately, we plan to support a larger variety of potential document file types including structured word processor files, spreadsheets, and presentations.

Acknowledgments

Refinery was a recipient of the Knight Prototype Fund in 2014.

Using Conceptors to Manage Neural Long-Term Memories for Temporal Patterns

Editor: Nando de Freitas

Abstract

Biological brains can learn, recognize, organize, and re-generate large repertoires of temporal patterns. Here I propose a mechanism of neurodynamical pattern learning and representation, called *conceptors*, which offers an integrated account of a number of such phenomena and functionalities. It becomes possible to store a large number of temporal patterns in a single recurrent neural network. In the recall process, stored patterns can be morphed and "focussed". Parametric families of patterns can be learnt from a very small number of examples. Stored temporal patterns can be content-addressed in ways that are analog to recalling static patterns in Hopfield networks.

Keywords: Recurrent neural network, temporal pattern learning, neural long-term memory, neural dynamics

1. Introduction

In the cognitive and neurosciences as well as in neural computation it is customary to distinguish between various sorts of short-term memory and long-term memory (Fusi and Wang, 2016). This article is concerned with neural long-term memory (LTM) in the sense that some information becomes permanently coded in synaptic weights at learning time, to be somehow recalled at exploitation time without changing those weights.

The paradigmatic model of a neural LTM is the *associative memory* pioneered, among others, by Willshaw et al. (1969), Cooper (1973), Kohonen (1974), Palm (1980) and Hopfield (1982). This classical family of models explains how a number of different patterns can be stored in a neural network by an explicit calculation of the network weight matrix or by iterative learning processes. A rich mathematical theory affords insights into capacity bounds and noise robustness. But, these classical associative memories are mainly devised for storing *static* patterns, for instance bit vectors or images. Biological neural systems obviously can learn and recall rich repertoires of *temporal* patterns, for instance gestures, melodies, words. It would be desirable to have a neural network model which extends the capabilities of associative networks to the domain of temporal patterns. This challenge is still largely open. I am aware of only a few proposals for neural memories of temporal patterns:

1. The classical associative memory model for static patterns has been extended on several occasions to learn sequences of patterns. The key mechanism is to replace the learning of auto-associations of stored patterns (which results in fixed-point attractors representing these) by a learning of hetero-associations of a temporal pattern frame with its successor frame. This leads to recall episodes which step through a discrete sequence of patterns (Amari, 1972). The basic discrete hetero-associative memory mechanism has been elaborated in various ways to accomodate analog values, smoother temporal development, or identical patterns at different time slices (examples: Sompolinsky and Kanter (1986); Rinkus (1996); Billard and Hayes (1999); Huang and Hagiwara (2002)). A recent extension of hetero-associative symbol sequence coding networks (Jiang et al., 2016) integrates methods from graph-based coding theory, which leads to improved memory capacities and temporal pattern completion robustness, and enables an incremental storing of patterns.

2. In the field of reservoir computing, a temporal pattern is trained into a recurrent neural network (RNN) by adapting only the weights from the ("reservoir") network to the output neuron. Thus an arbitrary number of temporal patterns can be learnt on the basis of a single reservoir network if individual patterns are represented by separate output neurons, as for example in Hinaut and Dominey (2011).

3. Since the advent of RNN models in cognitive modeling it has been recognized that RNNs can be trained to generate several temporal patterns when they are paired in training with individual pattern-addressing input signals (Kolen and Pollack, 1991; Jordan, 1997; Krause et al., 2010).

4. Another possibility to train and select several temporal patterns in a single RNN is to associate different patterns with different initial network states. An example is Paine and Tani (2005) where an RNN-based mobile robot controller was trained to steer the robot into different action sequences depending on the state initialization.

5. In machine learning, RNNs trained on sequence prediction/generation tasks are typically considered as models of a stochastic process, for instance the process whose realizations are Wikepedia texts, as in Sutskever et al. (2011), rather than as cases of neural memory. But it also makes good sense to view them as neural memories. One may say that such a network after training has memorized typical continuations of initial cue sequences. Even more generally, any neural system trained on some training data set D for whatever purpose (classification, control, ...) could be regarded as having "stored" the probabilistic structure of D. In this general sense, any network-internal, trained representation can be interpreted as a LTM.

The diversity of these examples shows that there is no unique definition of what makes a neural LTM. Here is a list of system properties that are variously attributed (or not) to a neural memory system:

Multiplicity. An neural memory system typically can store more than only one memory pattern. The number of storable pattern is a standard performance criterion for memory systems.

Addressability. When several patterns have been stored, they should be efficiently addressable at use-time, whether by content-addressing or pointer-addressing.

Generativity. Stored patterns can be re-generated at retrieval time with some degree of accuracy.

Organization and searchability. Stored items are organized in a way that brings relationships between them to the fore, for instance, abstraction or part-of relationships (as in semantic network models in AI). This organization enables a systematic navigation and search in memory space. None of the above examples of dynamical pattern memories has this characteristic, but a diversity of neural learning systems for static patterns have been proposed that have an exploitable internal organization of some sort, for instance self-organizing semantic maps (Ritter and Kohonen, 1989), connectionist-localist networks for semantic concept modeling (Shastri, 1999), or recursive auto-associative memories (Pollack, 1990).

Incremental extensibility. New memory items can be stored incrementally on top of already stored ones. Such an incremental extensibility is difficult or impossible for networks trained with backpropagation due to the "catastrophic forgetting" problem (appreciation in Douglas and Sejnowski (2008), partial solutions and further references in French (2003); Grossberg (2005); Goodrich and Arel (2014)) and for most associative memories (exception: Jiang et al. (2016)).

Differential extension. When adding a new item, store only that information about the new item that is not already present in the memory system. None of the examples has this property but arguably human LTM has it.

Forgetting. Allow the memory system to fade out memory items that are not retrieved for a long time. This characteristic is typical for biological neural networks but is absent in all examples above.

Erasibility. Selectively delete arbitrary items from the memory, freeing storage space. This is typical for digital computer memories but is not usually considered in neural network models.

In this article I describe a neuro-computational mechanism, *conceptors*, by which the dynamics of an RNN can be governed in a variety of ways. Conceptors are a general-purpose mechanism that can be used in a diversity of neural information processing tasks. In a very long techreport (Jaeger, 2014) I present elementary demonstrations of conceptors used for temporal pattern classification, one-shot learning, human motion pattern generation, de-noising and signal separation. The present article focusses on exploits of conceptors for neural LTM management. From the above list of typical LTM properties, conceptors enable or facilitate all except the last two, forgetting and erasability. To keep the length of this article within reasonable bounds, I have omitted a sizable portion of LTM-relevant material from Jaeger (2014), namely the topic of Boolean operations on conceptors and the options that such Boolean operations grant for incremental and differential memory extensibility without catastrophic forgetting.

Most of the technical content is adopted from Jaeger (2014), but assembled in a more compact and intuitive exposition, and backed up by improved simulations. For space economy I omit proofs and some mathematical detail and refer the reader to the full treatment

given in Jaeger (2014). The Matlab code for all simulations is available at the JMLR online paper repository.

The article is organized in three main sections. Section 2 introduces the basic model in a detailed step-by-step fashion. Basic pattern morphing and pattern generalization demos, a "focussing" mechanism and a real-world data demo (learn from human motion capture data to animate a body model with 61 degrees of freedom) illustrate the basic functionalities of conceptors for storing, re-generating and modulating temporal patterns in an RNN. Section 3 introduces a conceptor-based model of content-addressable RNN memories for dynamical patterns. The stored patterns can be recovered from short and possibly distorted cues by a process of conceptor auto-adaptation. In several respects this provides a temporal analog of Hopfield networks.

2. Storing a Multitude of Temporal Patterns in an RNN

This section gives a concise introduction to the basic ideas and formalism of conceptors, starting from a toy example (Subsection 2.1) and then moving on to phenomena of pattern morphing, generalization, and "focussing" in the remaining subsections.

2.1 Basic Idea and Formalism

In this subsection I explain the basic ideas of conceptors by stepping through an elementary demonstration. The task is to store two dissimilar periodic temporal patterns in a tiny RNN and subsequently retrieve them.

2.1.1 Preparations

Before patterns can be stored and recalled, an experimental set-up is installed as follows.

Procuring training patterns. In this article a "pattern" means a discrete-time signal $p(n)$, where $p(n) \in \mathbb{R}^M$ and $n \geq 0$. For this elementary demo I use two discrete-time scalar patterns $p^1(n)$ and $p^2(n)$. The first is a sinewave signal with an irrational period length sampled at integer time points. The irrational period length makes the sampled version quasi-periodic. The second is a periodic signal with integer period 2. Figure 1 (left) depicts the two patterns. I remark that later I will also be considering non-periodic and non-stationary patterns.

Network creation. An RNN with N neurons is installed by randomly creating an $N \times N$ matrix W^* of internal connection weights, an $N \times M$ input weight vector W^{in}, and a random $N \times 1$ bias vector b. Here I use an unrealistically small network with only $N = 3$ neurons, which allows me to illustrate relevant effects in 3-D graphics.

This network can be driven by a scalar pattern $p(n)$ by the following state update equation:

$$\mathbf{x}(n+1) = \tanh(W^* \mathbf{x}(n) + W^{\text{in}} p(n) + \mathbf{b}). \quad (1)$$

All parameters of W^*, W and $\mathbf{b}$ are sampled from a normal distribution and scaled such that an overall system dynamics is obtained that works well for this didactic demonstration. Details of the scaling procedure are not important here, but I remark that the internal weights W^* must be scaled small enough to ensure that the RNN has the *echo state property* with respect to the input signals that are fed to it. In intuitive terms, an RNN has the echo

state property with respect to an input signal $p(n)$ if any initial network state is "forgotten" (washed out) when the network is driven by $p(n)$ for a long enough time. The echo state property is a core concept in the field of reservoir computing (Jaeger, 2001; Lukosevicius, 2012; Manjunath and Jaeger, 2013). Because the conceptor approach borrows some ideas from reservoir computing, I refer to the RNN as the *reservoir*.

Training a readout. The conceptor-based procedures explained below lead to a memory functionality in the following sense:

- At storing time, the reservoir is driven by a to-be-stored pattern $p^j(n)$ through (1). This results in a pattern-driven network dynamics $\mathbf{x}^j(n)$ (I use upper indices to refer to patterns).
- At recall time, the reservoir is run without input (under the control of a conceptor C^j, to be explained below), resulting in a free-running network dynamics $\tilde{\mathbf{x}}^j(n)$.
- The network has successfully "memorized" $p^j(n)$ to the degree that the free-running dynamics $\tilde{\mathbf{x}}^j(n)$ is approximately the same as the original pattern-driven dynamics $\mathbf{x}^j(n)$.

Thus, the network does not in fact memorize the original pattern $p^j(n)$, but instead its own, high-dimensional dynamical response to the pattern input. I will refer to such input-driven reservoir state dynamics as *state patterns*. But for practical exploits one wishes to recall the original input pattern, not the induced neural state pattern. In order to transform state patterns $\tilde{\mathbf{x}}^j(n)$ back to the original input patterns $p^j(n)$, a network state observer $y(n)$ is trained. This is a linear output neuron which reads from the network state through output weights W^{out}. It should display the following behavior

$$\begin{aligned} \textbf{if} \quad & \mathbf{x}(n+1) \quad = \tanh(W^* \mathbf{x}(n) + W^{\text{in}} p(n) + \mathbf{b}) \\ \textbf{then} \quad & y(n) \quad := W^{\text{out}} \mathbf{x}(n) \approx p(n) \end{aligned} \tag{2}$$

for *any* driving pattern $p(n)$. That is, the output signal read through W^{out} should simply re-generate any driving input from the excited reservoir state.

The output weights W^{out} for such a generic input-redisplayer neuron can be trained by first driving the reservoir with an M-dimensional white-noise input signal $\nu(n)$ via $\mathbf{x}^\nu(n+1) = \tanh(W^* \mathbf{x}^\nu(n) + W^{\text{in}} \nu(n) + \mathbf{b})$, then compute W^{out} by linear regression to minimize the quadratic loss $\sum_n (W^{\text{out}} \mathbf{x}^\nu(n) - \nu(n))^2$, following the rationale of reservoir computing. Since this readout neuron is trained on white-noise input $\nu(n)$, it will also be able to re-generate other input signals $p(n)$ in agreement with (2).

I point out that this pattern-generic output neuron is trained prior to, and independent of, the subsequent memory learning. It is also possible to train the output weights W^{out} on network states induced by the to-be-stored input patterns, not by a generic white-noise input. That procedure gives more accurate results at recall time and therefore will usually be the preferred method. However, it obscures the essential independence of the storing procedure from the observer training. Therefore in this didactic demo I used white noise input to train W^{out}.

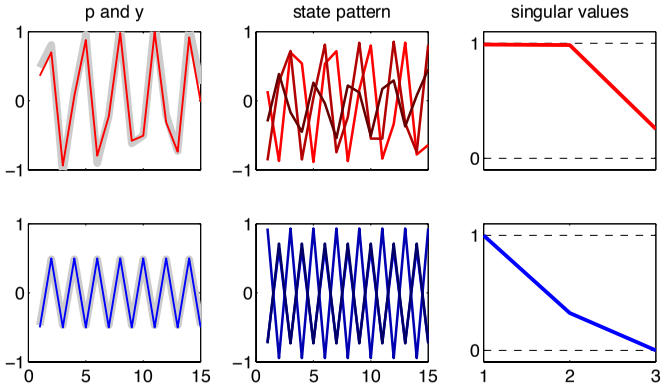

Figure 1: Left: the original patterns $p^1(n), p^2(n)$ (red/blue thin lines, 15 time steps are shown) and their recalled versions (gray thick lines; original and recalled patterns were phase-aligned for plotting). The patterns are discrete-time signals; connecting lines are drawn for better visual appearance. Center: traces of the three neurons' activations when the reservoir is driven with the respective pattern input. Right: singular value spectra of C^1 and C^2.

2.1.2 Storing Patterns

Loading the reservoir with the training patterns. I proceed to describe how the two patterns $p^1(n), p^2(n)$ of our demo are stored in the reservoir. In intuitive terms, storing patterns p^j amounts to re-compute the initial random reservoir weights W^*, giving a new set of network weights W, such that the new reservoir can mimic the impact of drivers p^j in the absence of them. I refer to the new weights W as "input internalization weights" on the grounds that they incorporate the impact of an external input into the autonomous network update dynamics.

W is computed as follows. In two separate runs, the two patterns are fed into the initial reservoir via

$$\mathbf{x}^j(n+1) = \tanh(W^* \mathbf{x}^j(n) + W^{\text{in}} p^j(n) + \mathbf{b}), \quad j = 1, 2;\ n = 0, \ldots, L. \tag{3}$$

Figure 1 (middle panels) shows the activation traces of the three neurons when the reservoir is driven with either pattern.

Then W is computed to minimize the quadratic loss

$$\sum_{j=1,2} \sum_{n=n_0+1,\ldots,L} \|W^* \mathbf{x}^j(n) + W^{\text{in}} p^j(n) - W \mathbf{x}^j(n)\|^2, \tag{4}$$

where only network states for times after n_0 are used (in order to allow for washing out the arbitrary intial state $\mathbf{x}(0)$ according to the echo state property). This again amounts

to a linear regression. If this is achieved with a small training error, one will obtain similar network updates from states $\mathbf{x}^1(n)$ or $\mathbf{x}^2(n)$ with either the original input-driven update rule, or with an input-free update rule that employs W instead of W^*:

$$\tanh(W^* \mathbf{x}^j(n) + W^{\text{in}} p^j(n) + \mathbf{b}) \approx \tanh(W \mathbf{x}^j(n) + \mathbf{b}). \quad (5)$$

I call this procedure to transform the initial random weights W^* to W *loading* the patterns into the reservoir.

Linear regressions can be computed with various algorithms. In all simulations reported below I use ridge regression. Given a collection of L argument-target vector pairs $(\mathbf{a}_i, \mathbf{t}_i) \in \mathbb{R}^\nu \times \mathbb{R}^\mu$, ridge regression computes a transformation matrix $M \in \mathbb{R}^{\mu \times \nu}$ which minimizes the regularized mean square error $1/L \sum_i \|\mathbf{t}_i - M \mathbf{a}_i\|^2 + \|\varrho M\|^2_{\text{fro}}$, where $\| \cdot \|^2_{\text{fro}}$ is the squared Frobenius matrix norm and ϱ the Tychonov regularization coefficient.

In the case of (4), $\nu = \mu = N$ and the arguments are all $\mathbf{x}^j(n)$ and the targets are the corresponding $W^* \mathbf{x}^j(n) + W^{\text{in}} p^j(n)$.

The re-computation of initial weights of a RNN to obtain what I called here input internalization weights is a procedure that has been independently proposed several times in recent years under different names and for different purposes: as *self-predicting networks* for augmenting the performance of reservoir computing techniques (Mayer and Browne, 2004), as *equilibration* for enabling external controllability of RNN dynamics (Jaeger, 2010), as *reservoir regularization* for improved stability of neural motor controllers (Reinhart and Steil, 2011), as *self-sensing networks* for making RNN training methods more flexible (Sussillo and Abbott, 2012), and as *innate training* for reliable, noise-resistant reproducible chaotic patterns in short-term memory RNNs (Laje and Buonomano, 2013).

Lower cost variants of the loading procedure. In a variant of the loading procedure, only the input term $W^{\text{in}} p^j(n)$ is replaced, leaving W^* unchanged. That is, the input-driven network state $\tanh(W^* \mathbf{x}^j(n) + W^{\text{in}} p^j(n) + \mathbf{b})$ becomes emulated by the autonomous states $\tanh(W^* \mathbf{x}^j(n) + D \mathbf{x}^j(n) + \mathbf{b})$, where D is computed by linear regression to minimize the following variant of the quadratic loss (4):

$$\sum_{j=1,\ldots,K} \sum_{n=n_0+1,\ldots,L} \|W^{\text{in}} p^j(n) - D \mathbf{x}^j(n)\|^2. \quad (6)$$

I call the $N \times N$ matrix D *input simulation weights*. Another variant of the loading procedure is even more minimalistic and aims at replacing only the very input $p^j(n)$, by finding *input replacing weights* R (size $N \times M$) that minimize

$$\sum_{j=1,\ldots,K} \sum_{n=n_0,\ldots,L} \|p^j(n) - R \mathbf{x}^j(n)\|^2,$$

leading to autonomous states $\tanh(W^* \mathbf{x}^j(n) + W^{\text{in}} R \mathbf{x}^j(n) + \mathbf{b})$.

Computing conceptors. Considering (5), the loaded reservoir should be able to generate approximate versions of the two original state patterns. However, if the network were run just by iterating $\mathbf{x}(n+1) = \tanh(W \mathbf{x}(n) + \mathbf{b})$, the resulting input-free reservoir dynamics is entirely unpredictable because the reservoir can't "decide" which of the loaded pattern dynamics it should engage in.

Here conceptors enter the stage. Each loaded pattern p^j is associated with an $N \times N$ sized *conceptor* matrix C^j which at recall time is inserted into the state update loop via

$$\mathbf{x}(n+1) = C^j \tanh(W \mathbf{x}(n) + \mathbf{b}).$$

The matrix C^j acts as a filter that leaves states $\mathbf{x}^j(n)$ from the state pattern associated with pattern p^j essentially unchanged, but suppresses state components of states $\mathbf{x}^{j'}(n)$ associated with other patterns $p^{j'}$. Stated differently, C^j should act like the identity matrix for states $\mathbf{x}^j(n)$, but like the null matrix for state components that are not typical for states $\mathbf{x}^j(n)$.

This consideration leads to a quadratic loss function

$$L(C^j) = E[\|C^j \mathbf{x}^j(n) - \mathbf{x}^j(n)\|^2] + (\alpha^j)^{-2} \|C^j\|^2_{\text{fro}}, \quad (7)$$

where the expectation E is taken over all states $\mathbf{x}^j(n)$ that arise in p^j-driven runs according to (3). Explanations:

- The first component $E[\|C^j \mathbf{x}^j(n) - \mathbf{x}^j(n)\|^2]$ of this loss function is minimal when C^j is the identity. This component reflects the objective that C^j should leave states $\mathbf{x}^j(n)$ unchanged.
- The second component $\|C^j\|^2_{\text{fro}}$ becomes minimial for $C^j = \mathbf{0}$. This takes care of the objective that C^j should suppress state components which are untypical of states $\mathbf{x}^j(n)$, i.e. such state components which do not enter the expectation of the first component.
- The machine learning view on the loss (7) is to consider it as the loss for a *regularized identity function*. It is mathematically closely related to computing a *denoising autoencoder* for state patterns corrupted by Gaussian noise with variance $(\alpha^j)^{-2}$.
- The parameter $\alpha^j \geq 0$, called *aperture* for reasons that will soon become clear, negotiates between the two objectives. When the aperture is large, C^j will be close to the identity matrix I. Conversely, for small apertures C^j will shrink toward the null matrix $\mathbf{0}$. In our example I use $\alpha^1 = 12$ and $\alpha^2 = 20$.

Minimizing the loss $L(C^j)$ leads to the solution

$$C^j = R^j (R^j + (\alpha^j)^{-2} I)^{-1}, \quad (8)$$

where $R^j = E[\mathbf{x}^j(n) \mathbf{x}^j(n)']$ is the $N \times N$ correlation matrix of states $\mathbf{x}^j(n)$ obtained in the state dynamics driven by pattern p^j. C^j has the following properties:

- C^j is positive semi-definite, with eigenvalues (= singular values) $0 \leq \sigma^j_i \leq 1$ ($i = 1, \ldots, N$).
- The N eigenvectors $\mathbf{u}^j_i$ of C^j are the same as the eigenvectors of R^j, and can be arranged column-wise in an orthonormal matrix $U^j = (\mathbf{u}^j_1 \cdots \mathbf{u}^j_N)$. These eigenvectors are the same as the principal component vectors obtained from a principal component analysis of state sets $\mathbf{x}^j(n)$.

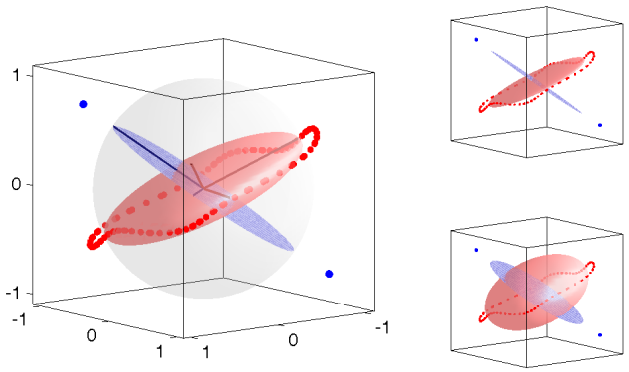

Figure 2: Conceptor geometry. Left: 3-dimensional state pattern $\mathbf{x}^1(n)$ (red dots) and $\mathbf{x}^2(n)$ (blue dots). Ellipsoids corresponding to conceptors C^1 and C^2 are rendered in red and blue respectively, with principal axes shown. They lie inside the unit sphere, shown in light gray. Right: effects of halving (top) and doubling (bottom) apertures.

I will often use the singular value decomposition (SVD) of $C^j = U^j S^j U^{j\prime}$, where S^j is the diagonal matrix containing the singular values σ_i^j on its diagonal, by convention arranged in descending order.

The derivation of (8) and the properties of C^j is elementary and can be found in Jaeger (2014). In practice, the correlation matrices R^j are estimated from states collected in training runs.

It is easily verified that $R\,(R+\alpha^{-2}I)^{-1} = \alpha^2 R\,(\alpha^2 R+I)^{-1}$. Because $\alpha^2 R = E[\alpha\mathbf{x}\,(\alpha\mathbf{x})']$, the aperture α can also be understood as a virtual scaling factor of reservoir states.

2.1.3 Geometry of Conceptors

It is instructive to contemplate the geometry of conceptors C^j and how it relates to the state dynamics $\mathbf{x}^j(n)$. The main panel in Figure 2 shows 100 instances of $\mathbf{x}^1(n)$ (red dots), which densely fill a cyclic path because of the irrational ratio between the driving sinewave period and the sampling interval. The resulting conceptor C^1 can be visualized by an ellipsoid centered at the origin. Its principal axes are the eigenvectors of C^1 scaled by their singular values (they are indicated in Figure 1, right panels). Since the singular values of conceptor matrices range in $[0, 1]$, such ellipsoids lie inside the unit sphere. The singular values of C^1 are all nonzero, hence the ellipsoid is non-degenerate and extends in three directions. The state pattern $\mathbf{x}^2(n)$ induced by the 2-periodic driver p^2 alternates between two states

(blue dots). These two states span a 2-dimensional subspace of $\mathbb{R}^3$: only two of the singular values of C^2 are nonzero, and the resulting ellipsoid is a degenerate (2-dimensional only).

The two small panels illustrate the geometrical effects of adjusting aperture. Increasing the aperture "widens" conceptors, while decreasing aperture lets conceptors contract.

2.1.4 Pattern Re-generation

The loaded reservoir will behave unpredictably when run via $\mathbf{x}(n+1) = \tanh(W\,\mathbf{x}(n) + \mathbf{b})$, but it will engage in the j-th state pattern $\mathbf{x}^j(n)$ when run with the corresponding conceptor in the loop via $\mathbf{x}(n+1) = C^j \tanh(W\,\mathbf{x}(n) + \mathbf{b})$. The conceptor C^j acts as a state filter which leaves states belonging to pattern j mostly unaffected, while other states that would belong to other patterns are projected into the ellipsoidal state volume typical for pattern j.

The original input pattern can be read from this dynamics by $W^{\text{out}}\,\mathbf{x}(n) \approx p^j(n)$. Figure 1 (left panels) shows the re-generated patterns under conceptor control overlaid with the original drivers.

2.1.5 Intuitive Summary, and Relationship to Reservoir Computing

Three kinds of matrices are trained in the conceptor-based pattern learning setup: the readout weights, the recurrent reservoir weights, and the conceptor matrices. How can the respective functional roles of these three components be intuitively understood?

In the loading process, when the random initial reservoir weights W^* are recomputed into W, information about the detailed dynamics of each training pattern is imprinted on the reservoir. A helpful metaphor is to liken the loading process to driving a vehicle over Sahara sands. Each pattern digs its individual track into the surface of the native sandscape. The original reservoir with weights W^* is like a virgin sandscape. After loading K patterns, K tracks have been engraved into the surface. These tracks are coded in the weight matrix W.

Still following that metaphor, the pattern tracks imprinted on the sand will have crossings. Sending a vehicle on a track-following mission, it wouldn't know where to turn at those crossings. If one would just run a network simulation with loaded weights W without further ado, the resulting network dynamics is unpredictable: the network doesn't know where to turn at the crossings; typically one observes a trajectory that appears like high-dimensional chaos or a trajectory that gets stuck in a point attractor.

This is where conceptors come into play. If conceptor C^j is inserted into the network update loop, it informs the network how to follow track number j. Figuratively speaking, the conceptor flattens out competing tracks but leaves track j mostly as it is. More technically speaking, this "flattening out" is effected by the large number of zero or close-to-zero singular values of C^j. In memory terminology, the conceptor acts as a *selector* for one of the loaded patterns. As we will see later on, as a side effect this "flattening out" endows the network dynamics with strong noise-suppression and dynamical stabilization characteristics.

Finally, the readout weights are not a crucial component in the conceptor approach to RNNs. This is different from the usual perspective of reservoir computing where the training of readout weights is the defining part of the entire paradigm. The focus of conceptor theory is *representation learning*, not output generation. It is all about creating representations

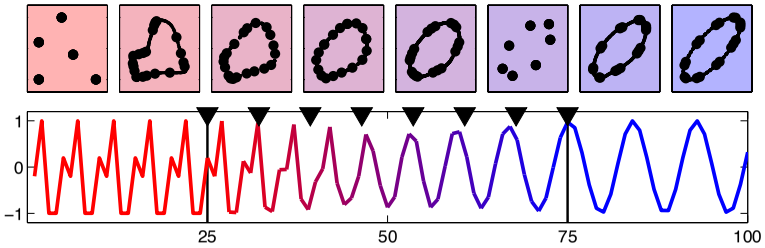

Figure 3: Morphing from an integer-5-periodic pattern p^1 to an irrational-period sine p^2 from time $n = 25$ to $n = 75$. Top: delay-embedding plots of signals $y(n)$ obtained with fixed conceptor mixes (indicated by triangle markers in center panel). Bottom: Output signal $y(n)$.

of dynamical patterns inside an RNN, where these representations (the tracks in the sand) become serviceable through conceptors. The readout weights merely provide an externally interpretable *observer* for the learnt representations, and a means to quantify the quality of the internal representations by measuring the mismatch between original patterns and re-generated output patterns.

2.2 Morphing and Generalization

When K "prototype" patterns $p^1, \ldots, p^K$ have been loaded, they can be *morphed* in recall by using linear blends of their conceptors via

$$\mathbf{x}(n+1) = (\sum_{j=1,\ldots,K} a^j\, C^j)\, \tanh(W\,\mathbf{x}(n) + \mathbf{b}), \quad y(n) = W^{\text{out}}\,\mathbf{x}(n), \tag{9}$$

where $\sum_{j=1,\ldots,K} a^j = 1$. For an elementary demonstration, an integer-5-periodic pattern p^1 and a sine pattern p^2 with an irrational period length of about 8.8 (sampled at integer time points) were loaded into a 100-neuron reservoir. Figure 3 (bottom) displays the output $y(n)$ of a recall run where for the first 25 steps, the pure conceptor C^1 was used, then for a morphing time of 50 steps C^1 was linearly blended into C^2, concluding the run with another 25 steps under the control of the pure C^2. The output signal exhibits a gradual blending from p^1 to p^2 during the morphing period from step 25 to step 75. In order to get more insight into the morphing dynamics, for eight mixing ratios (marked by triangle markers in the bottom panel), the system (9) was run separately with mixing coefficients frozen at these ratios. The panels in the top row show "fingerprints" of the resulting output signals $y_i(n)$, by plotting delay embedding state points $(y_i(n+1), y_i(n))$. Each panel shows 20 successive points as thick dots, and further 100 successive points as thin dots. The first panel, which corresponds to the pure 5-periodic pattern p^1, shows 5 cyclically repeated points, and the last panel a quasi-periodic oscillation, as expected. Intermediate dynamics are mostly quasi-periodic, but there are also mixture settings where there is a 6-, 7-, and

8-periodic behavior (of which only the 7-periodic instance happens to be captured by one of the displayed plots).

In a slightly more involved demonstration three representative patterns p^1, p^2, p^3 are loaded, which are taken from a two-parametric family of modulated sinewave patterns. One parameter changes the frequency, the other modulates the shape from "pointed upwards" to "pointed downwards" (details in the appendix). Figure 4 shows a close-up of the three loaded patterns in the separate top panels (red: slightly pointed downwards, high frequency; green: slightly pointed downwards, low frequency; blue: slightly pointed upwards, intermediate frequency). Note that three is the minimal number of patterns required to span a 2-parametric pattern space. To visualize the morphs, pattern samples generated with morphed conceptors $a^1\,C^1 + a^2\,C^2 + a^3\,C^3$ are arranged in a tesselated drawing plane. The "pure" recalled patterns (corresponding to mixtures $(a^1, a^2, a^3) = (1,0,0); (0,1,0); (0,0,1)$ respectively) are placed at the corners of an equilateral triangle (saturated red/green/blue tiles in the main figure panel). Tiles within the triangle spanned by the three loaded patterns correspond to interpolated conceptors, whereas patterns outside the triangle were obtained by *extrapolating* conceptor mixtures with coefficents outside [0 1].

By visual inspection of the signals shown in Figure 4 one finds that the system has acquired command over a sizeable portion of the parametrized pattern space by generalizing from three training instances. This generalization is effective not only in the "convex hull" of the three training examples (interpolation area within the central pattern triangle in the figure), but extends far into the extrapolation range. Going right/left from the three training patterns one sees that the mild frequency modulation indicated by the three training patterns reaches out into a wider frequency span; and going up/down one finds the "pointed up/down" characteristics, which is only feebly present in the training patterns, becomes fully expressed.

But one should not expect miracles. Upon closer inspection one will find that many re-generated patterns are not precise members of the family. Deviations grow as the mixture coefficients extend further away from the interpolation region. Also, there is no linear relationship between variations in mixing coefficients and geometric pattern characteristics. Far outside the interpolation region similiarities with correct patterns from the target family dissolve. If one wishes to obtain a wider-range faithful re-generation of patterns from the family, a larger number of reference patterns must be loaded. In Section 3.2 we will meet an altogether different way to employ conceptors to learn a pattern family from a small number of training examples.

2.3 A Real-World Data Example

In order to illustrate that the approach scales to more complex patterns, fifteen diverse human motion patterns were loaded: *slow walk*; *fast walk*; *walk with exaggerated stride*; *jog*; *sit*; *get up from stool*; *sit down on stool*; *kneel down*; *crawl*; *get up from crawl*; *waltz*; *cartwheeling*; and three *boxing punches*. These patterns are 61-dimensional signals (body pose and joint angles). Some are periodic (like *jog*), others are transient (like *get up from crawl*), yet others are irregular-stochastic (the *boxing* patterns); some patterns have multiple timescales. Training data consisted of short sequences clipped from publicly available human motion capture traces (CMU Graphics Lab)), one such clip per motion type. The length

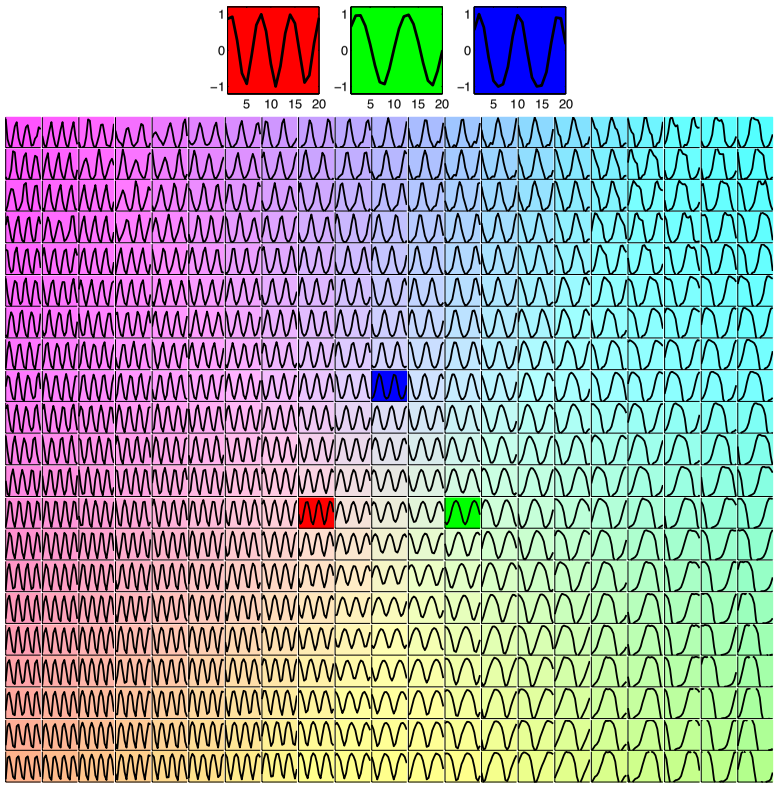

Figure 4: Morphing between and beyond three patterns from a 2-parametric family. For explanation see text.

of training patterns varied from 150 to 900 sampling points (sampling rate 120 / second). Data preprocessing and visualization was done with the help of a public Matlab motion capture toolbox (Burger and Toiviainen, 2013). Figure 5 gives an impression of the training data after preprocessing.

A 600-unit reservoir made from leaky-integrator neurons was loaded with the 15 training samples (details in the appendix). In a recall run, the 15 patterns were re-generated in a shuffled sequence according to a hand-designed choreography. In this sequence, a pattern p^j is reproduced by inserting the corresponding conceptor C^j into the reservoir update loop for some period of time. In order to achieve a smooth transition into the next motion $p^{j'}$, C^j was morphed into the following conceptor $C^{j'}$ for one simulated second before $C^{j'}$ takes over full

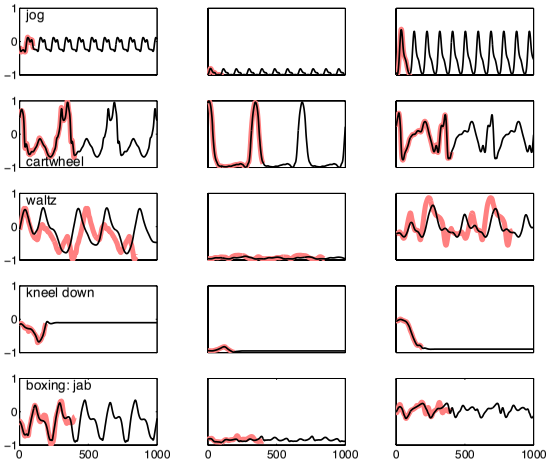

Figure 5: Exemplary human motion training data. Plots show the range-normalized versions used as input for the reservoir. The four rows show four out of the 15 loaded patterns. The three columns show three out of the 61 data dimensions. Thick red lines: training data; black lines: 1000-step free-running pattern recall under conceptor control. For explanation see text.

control. The resulting choreographed recall sequence of one minute duration was rendered into a video. The video is on YouTube (`www.youtube.com/watch?v=DkS_Yw1ldD4`). Figure 6 shows a few snapshots.

Morphing and generalizing dynamical patterns is a common but nontrivial task for training motor patterns in robots. It typically requires training demonstrations of numerous interpolating patterns (Reinhart and Steil, 2008; Coates et al., 2008; Lukic et al., 2012). Conceptor-based pattern learning and morphing appears promising for flexible robot motor pattern learning from a very small number of training patterns. I want to emphasize that this is only a method for "playback" of learnt trajectories with flexible sequence scheduling and motion blending with potential applications in computer game character animation; it is not a method for motor *control*. The procedure demonstrated here is visually superior to some existing neural-network based approaches (wyffels and Schrauwen, 2009; Sutskever et al., 2009; Boström et al., 2013; Wright and Jordanov, 2012) with respect to number of patterns, body model complexity, and smoothness of transitions. The mocap-trained human motion generation system presented by Taylor et al. (2011), which is based on restricted Boltzmann machines, comes close to the conceptor-based demo with respect to number of patterns and body model complexity, and has visually more appealing transitions between gaits.

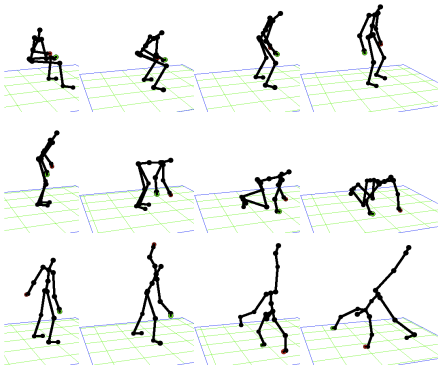

Figure 6: Snapshots from a human motion re-generation video created from a conceptor-controlled RNN. First row: standing up from a stool and starting a slow walk, second row: kneeling down and starting to crawl, third row: cartwheel.

I emphasize that this case study is solely meant as a visually appealing demo that conceptor-controlled pattern generation can scale to sizable numbers of high-dimensional, non-stationary patterns. In this it serves the same purpose as the other motion capture learning neural networks that I referenced above. It is neither a method for motor *control* in physical robots, nor does it aspire to compete with state-of-the-art game character animation engines, which each combine a diversity of sophisticated animation techniques, often including physics simulations (Gillies and Spanlang, 2010).

2.4 Aperture Adaptation

For good performance in recall, the aperture must be chosen appropriately. To illustrate this, I loaded four patterns into a $N = 500$ reservoir. The patterns were obtained from four classical chaotic attractors, p^1: Lorenz attractor; p^2: Rössler attractor; p^3: Mackey-Glass attractor; p^4: Hénon attractor (details in the appendix). Green plots in Fig. 7**A**,**B** visualize the clean training signals. In the reproduction stage, for each pattern p^j a number of different conceptors C^j with varied apertures were tried. Fig. 7**A** shows the effects for the Lorenz attractor. When α is too small, the reservoir-conceptor feedback loop becomes too constrained and the generated patterns de-differentiate. With α too large the feedback loop becomes over-excited. In this demonstration, a good aperture could be automatically found by minimizing a measurable that I call *attenuation*. This is the fraction of the reservoir signal energy which is suppressed by applying the conceptor. Formally, the attenuation $a_{C,\alpha}$ induced by a conceptor C at aperture α is

$$a_{C,\alpha} = E[\|\mathbf{r}(n) - \mathbf{z}(n)\|^2]/E[\|\mathbf{r}(n)\|^2],$$

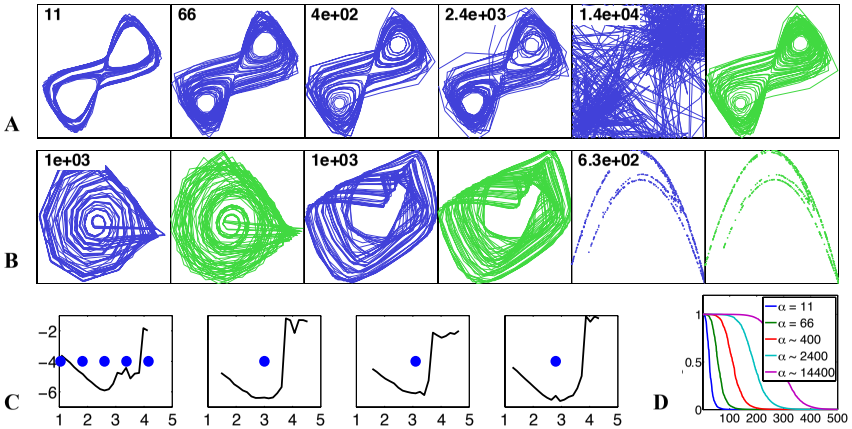

Figure 7: Reproducing four chaotic attractor patterns in a single network. Green: original training signals, blue: network-generated reproductions. The 2-dimensional plots are obtained from 1-dimensional timeseries by delay embedding, plotting $y(n)$ against $y(n-d)$ for a delay d chosen to yield instructive graphics. (**A**) The Lorenz attractor re-generated with five different aperture settings (α values inserted in panels). (**B**) From left to right: re-generations of the the Rössler, Mackey-Glass, and Hénon attractors. (**C**) Log10 of attenuation plotted against log10 of aperture. Dots mark the apertures used in the reproductions in (**A**,**B**). (**D**) Singular value spectra of conceptors used for the Lorenz attractor (compare panel **A**).

where $\mathbf{r}(n) = \tanh(W\mathbf{z}(n-1)+\mathbf{b})$, $\mathbf{z}(n) = C\,\mathbf{r}(n)$. This quantity can be cheaply estimated online and can be used to automatically adapt the aperture at recall time. Fig. 7**C** plots attenuation against aperture. The minimum of this curve marks a good aperture value, where "good" means "good visual agreement of recalled attractor with original attractor" (I did not implement an attractor comparison metric). The apertures used for the reproductions shown in Fig. 7**B** were obtained via this minimum-attenuation criterion.

While placing the aperture roughly in the right range is important, fine-tuning is unnecessary. The Lorenz attractor shown in Fig. 7**A** is quite well reproduced with apertures ranging over two orders of magnitude. This is also true for the other chaotic attractor signals, as well as for all other simulation studies that I undertook so far. While this 4-pattern demo is an academic exercise, it underlines the functionality of conceptors to stabilize neural pattern generation.

3. Autoconceptors

The definition and usage of conceptors, as described so far, invites an obvious critique: conceptor matrices have the same size as the reservoir weight matrix. Thus, for representing a pattern p^j by a conceptor matrix C^j one has to create and store an object that is as heavyweight as the hosting reservoir—one might say that each new pattern adds another brain. This is clearly inappropriate for computational neuroscience modeling, and it may become too expensive in machine learning applications. The storing cost of adding a conceptor matrix can be reduced by storing only economical SVDs of conceptor matrices, which often have low numerical rank. This however only mitigates but does not solve the principal problem.

I can offer two answers to this important critique:

Conceptor auto-adaptation and content-addressable memories. At loading time, when pattern internalization or pattern simulation weights are computed, no conceptors are created. Pattern recall functions by content-addressing: a short / incomplete cue of the target pattern is presented and an appropriate conceptor is generated on the fly by an auto-adaptation process. This leads to a memory model which is reminiscent of Hopfield networks. The present section is devoted to such auto-adapting conceptors.

Diagonal conceptors with single-neuron representations. When conceptor matrices are constrained to diagonal form, filtering a reservoir state by a conceptor reduces to unit-wise scalar multiplications, and a conceptor can be mathematically represented by a vector, which in turn could possibly be biologically implemented by a single neuron. This venue is explored in some detail in Jaeger (2014), where also proof-of-principle demos are presented of multi-reservoir hierarchical memory systems that are based on such diagonal conceptors. I am however not satisfied with the robustness properties of diagonal conceptors (they are too parameter-sensitive), and I am currently working on improved versions. Therefore I will not report on the available material from Jaeger (2014) this article.

3.1 Conceptor Auto-Adaptation

In the preceding sections I have defined conceptors as transforms $C^j = R^j\,(R^j + \alpha^{-2} I)^{-1}$ of reservoir state correlation matrices R^j (Equation 8) obtained from driving the reservoir with pattern p^j. The conceptor C^j could then be exploited for pattern re-generation via $\mathbf{x}(n+1) = C^j\,\tanh(W\mathbf{x}(n)+\mathbf{b})$ (using input internalization weights) or its variant $\mathbf{x}(n+1) = C^j\,\tanh(W^*\,\mathbf{x}(n) + D\,\mathbf{x}(n) + \mathbf{b})$ (using input simulation weights).

This way of using conceptors, however, requires that the conceptor matrices C^j are computed at loading time, and they have to be stored in some way for usage at exploitation time. Such a procedure may be useful in some practical engineering respects (for instance, for dynamical pattern morphing and pattern stabilization), but otherwise invites the critique pointed out at the beginning of this section.

This motivates to look for ways of how conceptors can be used for constraining reservoir dynamics without the necessity to create and store conceptor matrices beforehand. The network would have to create the requisite conceptors on the fly by some auto-adaptation process while it is performing some relevant task. In this section I investigate auto-adapted

conceptors for the task of realizing a content-addressable memory. They are also useful for other tasks—in Jaeger (2014) (Section 3.15) I demonstrate the use of such auto-adapted conceptors for the task of simultaneous signal denoising and classification.

For ease of discussion, I call conceptors created by auto-adaptation at use-time *autoconceptors*, as opposed to the conceptors which are created at pattern loading time and which are externally inserted into the reservoir update loop at use-time—I will refer to those as *alloconceptors*. Autoconceptors, like alloconceptors, are positive semidefinite matrices with singular values in the unit interval. Aperture operations are identical for allo- and autoconceptors. However, the way how autoconceptors are generated by auto-adaptation leads to additional constraints on their algebraic characteristics. The set of autoconceptor matrices is a proper subset of the set of alloconceptor matrices.

3.1.1 Basic Equations

The basic system equation for autoconceptor systems is

$$\mathbf{x}(n+1) = C(n)\,\tanh(W^*\,\mathbf{x}(n) + W^{\text{in}} p(n+1) + \mathbf{b}) \tag{10}$$

or variants thereof, like

$$\mathbf{x}(n+1) = C(n)\,\tanh(W\,\mathbf{x}(n) + \mathbf{b}) \tag{11}$$

or

$$\mathbf{x}(n+1) = C(n)\,\tanh(W^*\mathbf{x}(n) + D\mathbf{x}(n) + \mathbf{b}), \tag{12}$$

the latter two capturing the situation after having patterns loaded by input internalization or input simulation weights. The novel element in these equations is that $C(n)$ is time-dependent. Its evolution is governed by an adaptation rule that I will describe presently. $C(n)$ need not be positive semidefinite at all times; only after convergence the $C(n)$ matrices will have the algebraic properties of conceptors.

It is convenient to formally split the network state $\mathbf{x}$ in (10) into a "reservoir state" $\mathbf{r}$ measured directly after the neuron nonlinearity, and a "filtered" state $\mathbf{z}$ obtained after passing the reservoir state through the conceptor. This turns (10) into

$$\begin{aligned} \mathbf{r}(n+1) &= \tanh(W^*\mathbf{z}(n) + W^{\text{in}} p(n+1) + \mathbf{b}) &(13)\\ \mathbf{z}(n+1) &= C(n)\,\mathbf{r}(n+1). &(14)\end{aligned}$$

The auto-adaptation of $C(n)$ aims at minimizing a loss that at first sight looks the same as the loss (7):

$$L(C) = E[\|C\,\mathbf{z}(n) - \mathbf{z}(n)\|^2] + \alpha^{-2}\,\|C\|^2_{\text{fro}}, \tag{15}$$

which for alloconceptors was solved by $C = R\,(R + \alpha^{-2}\,I)^{-1}$ with $R = E[\mathbf{x}\,\mathbf{x}']$ being the autocorrelation matrix of reservoir states. Similarly, (15) is minimized by

$$C = R\,(R + \alpha^{-2}\,I)^{-1},\ \text{with}\ R = E[\mathbf{z}\,\mathbf{z}']. \tag{16}$$

The crucial difference is that now the state correlation matrix R depends on C:

$$R = E[\mathbf{z}\,\mathbf{z}'] = E[C\mathbf{r}\,(C\mathbf{r})'] = C\,E[\mathbf{r}\,\mathbf{r}']\,C =: CQC,$$

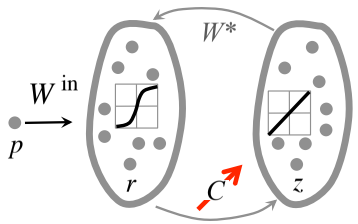

Figure 8: Network representation of a basic autoconceptor system. Bias b and readout mechanisms are omitted. The red arrow indicates that C is adapted online. For explanation see text.

where we introduce $Q = E[\mathbf{r}\,\mathbf{r}']$. This transforms the explicit solution formula (8) into a fixed-point equation:

$$C = CQC\,(CQC + \alpha^{-2}\,I)^{-1}. \tag{17}$$

Since Q depends on $\mathbf{r}$ states, which in turn depend on $\mathbf{z}$ states, which in turn depend on C again, Q depends on C and should be more appropriately be written as Q_C. A formal analysis of solutions to the fixed-point equation $C = CQ_CC\,(CQ_CC + \alpha^{-2}\,I)^{-1}$ is involved (carried out in some detail in Jaeger (2014)). Explicit solution formulas are unlikely to exist because the nonlinear reservoir is involved in Q_C. When one uses autoconceptors, however, one does not need to solve (17) explicitly. Instead, one can invoke stochastic gradient descent to minimize the loss (15). It is easily derived (Jaeger, 2014) that

$$C(n+1) = C(n) + \lambda\,\left((\mathbf{z}(n) - C(n)\,\mathbf{z}(n))\,\mathbf{z}'(n) - \alpha^{-2}\,C(n)\right) \tag{18}$$

implements stochastic gradient descent with respect to the loss (15). Here λ is an adaptation rate. Equations (13), (14) and (18) taken together—or versions where (13) is replaced by (11) or (12)—define the joint state update and conceptor adaptation working cycle.

In Jaeger (2014) I show that, if the driver $p(n)$ is a stationary process and if $C(n)$ converges under this auto-adaptation rule, the limit C is positive semidefinite with singular values in the set $(1/2, 1) \cup \{0\}$. Singular values of C asymptotically obtained under the evolution (18) are either greater than $1/2$ or they are zero. If the aperture α is fixed at increasingly smaller values, increasingly many singular values converge to zero. Furthermore, the analysis in Jaeger (2014) reveals that among the nonzero singular values, the majority will be close to 1. Both effects together endow autoconceptors with singular value spectra that are typically approximately rectangular.

3.1.2 Basic Demonstrations

In order to display how autoconcepters can be used to realize a content-addressable memory, I ran simulations according to the following scheme:

1. *Loading.* A collection of 10 scalar patterns p^j was loaded in an N-dimensional reservoir, yielding an input simulation matrix D and readout weights W^{out}. More specifically, D was computed to minimize the loss (6), using states $\mathbf{x}^j(n)$ obtained from driven runs $\mathbf{x}^j(n+1) = \tanh(W^*\,\mathbf{x}^j(n) + W^{\text{in}}\,p^j(n) + \mathbf{b})$. No conceptors were involved or computed in the loading procedure.

2. *Recall.* For each pattern p^j, a recall run was executed which consisted of three stages:

   (a) *Initial washout.* Starting from a zero network state, the reservoir was driven with p^j for n_{washout} steps, in order to obtain a task-related reservoir state.

   (b) *Cueing.* The reservoir was continued to be driven with p^j for another n_{cue} steps. During this cueing period, C^j was adapted through $\mathbf{z}(n+1) = \tanh(W^*\mathbf{z}(n) + W^{\text{in}}p(n) + \mathbf{b})$, $C^j(n+1) = C^j(n) + \lambda^{\text{cue}}\,((\mathbf{z}(n) - C^j(n)\,\mathbf{z}(n))\,\mathbf{z}'(n) - \alpha^{-2}\,C^j(n))$. At the beginning of this cueing period, $C^j(0)$ was initialized to the zero matrix. Notice that during cueing, the nascent conceptor $C^j(n)$ was not inserted in the reservoir state update loop. At the end of this period, a conceptor $C^{j\,\text{cue}}$ was obtained.

   (c) *Autonomous auto-adaptation and pattern recall.* The network run was continued with the external input switched off, using $\mathbf{z}(n+1) = C^j(n)\,\tanh(W^*\mathbf{z}(n) + D\mathbf{z}(n) + \mathbf{b})$, while continuing to auto-adapt the conceptor through $C^j(n+1) = C^j(n) + \lambda^{\text{recall}}\,((\mathbf{z}(n) - C^j(n)\,\mathbf{z}(n))\,\mathbf{z}'(n) - \alpha^{-2}\,C^j(n))$. At three test time points t_1, t_2, t_3 the conceptor $C^j(t_i)$ in its current adaptation stage was recorded for an offline quality assessment.

3. *Measuring the quality of conceptors.* The quality of the conceptors $C^{j\,\text{cue}}$ and $C^j(t_i)$ (where $i = 1, 2, 3$) was measured in separate offline runs without conceptor adaptation using $\mathbf{z}(n+1) = C\,\tanh(W^*\mathbf{z}(n) + D\mathbf{z}(n) + \mathbf{b})$, where C was one of $C^{j\,\text{cue}}, C^j(t_1), C^j(t_2), C^j(t_3)$. A reconstructed pattern $y(n) = W^{\text{out}}\,\mathbf{z}(n)$ was obtained and its similarity with the original pattern p^j was quantified in terms of a NRMSE.

I carried out two instances of this experiment, using two kinds of patterns:

5-periodic pattern. The patterns were random integer-periodic patterns of period 5. Experiment parameters: Reservoir size $N = 100$, spectral radius of W^* set to 1.5, input weight scaling 1.5, bias weight scaling 0.5, ridge regularization coefficients $\varrho^2_D, \varrho^2_{W^{\text{out}}}$ both set to 0.0001, aperture $\alpha = 1000$, $n_{\text{washout}} = 20$, $n_{\text{cue}} = 10$, $t_1, t_2, t_3 = 10, 50, 500$, auto-adaptation rates $\gamma^{\text{cue}} = 0.02$, $\gamma^{\text{recall}} = 0.01$. To make the task more challenging, during the 10-step cueing phase the cue input pattern was corrupted by additive uniform noise sampled from $[-0.05, 0.05]$, and during the autonomous recall time the reservoir states were *very strongly* perturbed by additive Gaussian noise (fed inside the tanh) whose variance equalled the average reservoir state component variance (a signal-to-noise ratio of 1).

2-parametric mix of 2 irrational-period sines. The 10 patterns were were taken from the 2-parametric family of patterns governed by

$$p(n) = a\,\sin(2\,\pi\,n/P) + (1-a)\,\sin(4\,\pi\,(b + n/P)).$$

These signals are weighted sums of two sines, the first with period length P and the second with period length $P/2$. The weights of these two components are a and $(1-a)$, and the second component is phase-shifted relative to the first by a fraction b of its period length $P/2$. The reference period length P was fixed to $P = \sqrt{30}$. The parameters a, b were freshly sampled from the uniform distribution on $[0, 1]$ for each p^j. Network parameters: $N = 100$, reservoir spectral radius 1.5, input weight scaling 1.5, bias scaling 0.5, $\varrho_D^2 = \varrho_{W^{\text{out}}}^2 = 0.0001$, $\alpha = 200, n_{\text{washout}} = 100, n_{\text{cue}} = 12$, $t_1, t_2, t_3 = 20, 1000, 10000$, $\gamma^{\text{cue}} = \gamma^{\text{recall}} = 0.01$. Cue patterns were corrupted by the same amount of additive noise as the 5-periodic patterns, and reservoir states were again perturbed with a signal-to-noise ratio of 1 during the autonomous recall.

Figure 9 illustrates the outcomes of these two experiments. For brevity I refer to the two experiments as the "IP5" and "PF" conditions. Observations and interpretations:

- The quality of the preliminary conceptor $C^{j\,\text{cue}}$ was always much improved by the subsequent auto-adaptation (panels **B**, **D**).
- The effects of autoconceptive adaptation are reflected in the singular value profiles of $C^{j\,\text{cue}}$ versus $C^j(t_3)$ (**A**, **C**). During the short cueing time, the online adaptation of the conceptor from a zero matrix to $C^{j\,\text{cue}}$ only manages to build a preliminary "nascent" profile, which then "matures" by auto-adaptation.
- The conceptors $C^j(t_3)$ have an almost rectangular singular value profile, in agreement with mathematical analyses (Jaeger, 2014).
- In PF the averge re-generation NRMSE with the final conceptor $C(t_3)$ was 0.11. For comparison I loaded and recalled the 10 patterns following the basic alloconceptor procedure with a manually optimized aperture. This gave an NRMSE of 0.087, that is, content-addressed autoconceptor recall from short and noisy cues here worked almost as well as re-generation with previously stored conceptors.
- For the 5-periodic patterns, a comparison simulation with the basic alloconceptor procedure yielded a mean NRMSE of .0033, much better than the mean NRMSE of 0.070 obtained after $t_3 = 500$ steps in the IP5 experiment. When perturbations to the cue signal and the reservoir states were switched off (not shown), the final NRMSE improved to 0.0037, almost as good as in the alloconceptor comparison. In summary, with cue and state noise the IP5 experiment worked out satisfactorily, and in a noise-free version essentially as well as with alloconceptors.
- In the FP experiment, unlike in IP5, state noise not only did not harm, but was conducive for fast adaptation. As a comparison I repeated the simulation with noiseless cues and without state noise insertion during autoconception (not shown). The outcome: in some cases the auto-adaptation failed altogether, and when it did function, it needed much longer runtimes (1,000,000 steps) to reach reconstruction qualities similar to what is reported in Figure 9 **C** **D**. State noise in auto-adaptation helps to drive the singular values of relevant state components toward 1 and considerably speeds up the adaptation.

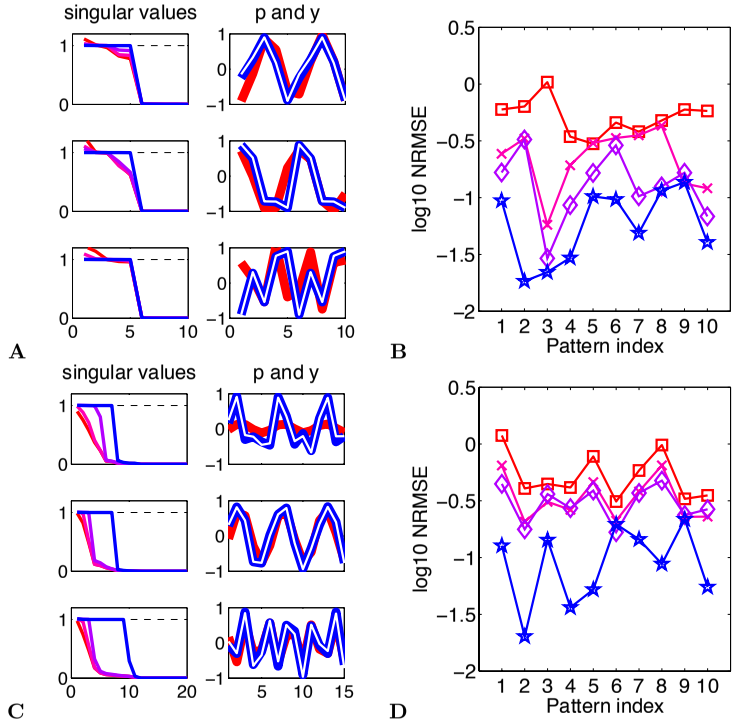

Figure 9: Basic content-addressable memory demos. **A**, **B**: 5-periodic pattern, **C**, **D**: mix of sines pattern. Panels **A**, **C** show the first three patterns, giving the first few singular values of the conceptors C^{cue}, $C(t_1)$, $C(t_2)$, $C(t_3)$. The "p and y" panels show the original patterns (white), the pattern re-generated with C^{cue} (thick red) and with the final $C(t_3)$ (thick blue) after optimal phase alignment with the original. **B**, **D**: recall log10 NRMSEs obtained from $C^{\text{cue}}, C(t_1), C(t_2), C(t_3)$.

- The robustness of auto-adaptation against very strong state noise may seem surprising at first, but is easily explained. Autoconceptor adaptation leads to singular value spectra with many zero values (Jaeger, 2014). Reservoir state noise components in directions of the nulled eigenvectors are entirely suppressed in the conceptor-reservoir loop, and state noise components within the nonzero conceptor eigenspace do not impede the development of a "clean" rectangular profile but in fact, as seen in FP, may even speed up the auto-adaptation process.

- In the simulations reported above, zero singular values were present from the start because the conceptor was initialized as the zero matrix. If it had been initialized differently (for instance, as the identity matrix), the auto-adaptation would only asymptotically pull (the majority of) singular values to zero, with noise robustness only gradually emerging to the degree that many singular values decrease toward zero. If noise robustness is desired, it can be reached by additional adaptation mechanisms for C. In particular, it is helpful to include thresholding: all singular values of $C(n)$ exceeding a suitable threshold are set to 1, all singular values dropping below a certain cutoff are zeroed (not shown).

- The simulations reported here were done with unfavorable settings on purpose, using short cueing times and strong noise. With larger reservoir networks, longer cueing times, less noise etc. much higher recall accuracies can be obtained (not shown).

An inquisitive reader may ask why I don't install auto-adaptation with respect to the reservoir output $\mathbf{r}$ instead of $\mathbf{z}$, that is, why not use the loss

$$L(C) = E[\|C\,\mathbf{r}(n) - \mathbf{r}(n)\|^2] + \alpha^{-2}\,\|C\|^2_{\mathrm{fro}}, \tag{19}$$

instead of the loss (15). This alternative loss (19) appears as natural as the loss (15) (and its solutions would be much easier to analyze mathematically). But in simulation experiments (not reported) I found that the performance of auto-adaptation based on (19) was far inferior to the version used above. Specifically, (i) all noise robustness was lost, (ii) during auto-adaptation the conceptors grew very heavy tails in their singular value spectra even for 5-periodic patterns where one would desire a spectrum with exactly 5 nonzero singular values, and (iii) singular values greater than 1 emerged under auto-adaptation, likewise undesirable within the conceptor philosophy.

The conceptor auto-adaptation dynamics in content-addressable memories is quite involved, with intriguing analogies and differences to Hopfield network adaptation dynamics. I discuss this in Section 3.3.

3.2 From Rote Learning to "Understanding"

When the cue represents a pattern that was not loaded, autoconceptors can be invoked to re-generate even such patterns. Specifically, if the reservoir was loaded with a few patterns $p^1, \ldots, p^k$ from a parametric family and then is cued with another pattern p^* from that family, an attempt can be made to re-generate this new pattern, too. This will work out provided that (i) enough patterns $p^1, \ldots, p^k$ had been loaded to instruct the reservoir about the characteristics of the pattern family, and (ii) the reservoir size is large enough to code the characteristics of the pattern family. For a demonstration I chose a 100-neuron reservoir and the mix-of-sines patterns from the 2-parametric family used before. A cue time of 12 steps and an auto-adaption time of 10,000 was used. The simulation was carried out as follows (detail in the appendix):

1. Create a random reservoir.

2. In separate trials, load this reservoir with an increasing number k of patterns (ranging from $k = 1$ to $k = 1000$), randomly taken from the parametric family.

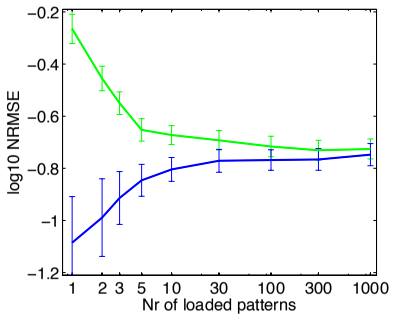

Figure 10: Class learning effect. Error bars indicate 95 % confidence intervals for mean NRMSEs. The curves are means over the 10 recall targets and the 10 experiment repetitions (blue: recall of patterns that were loaded; green: recall of patterns that were not loaded). Both axes are in logarithmic scale. For explanation see text.

3. After loading, cue (with noiseless cues) and re-generate the loaded patterns by autoconceptors. Measure the final recall accuracy for the first 10 of the loaded patterns (when fewer than 10 were loaded, do it only for these).

4. In addition, per trial, also try to cue and "recall" 10 novel patterns that were drawn randomly from the family. Monitor the "recall" accuracy of these novel patterns as well.

5. Repeat this entire scheme 10 times, with freshly sampled reservoirs and patterns. Report averaged diagnostics.

Figure 10 shows the results. Observations:

- The recall NRMSE for patterns that have been expressedly loaded is lowest when only few patterns have been loaded. As the number of loaded patterns grows, the NRMSE first rises, then levels out for very large numbers of loaded patterns.

- The recall NRMSE for non-loaded patterns is high in conditions when only few patterns have been loaded. As the number of loaded patterns grows, this NRMSE decreases and levels out at about the same goodness as the NRMSE for loaded patterns.

Similar findings were obtained in other simulations (Jaeger, 2014). Pending a formal analysis, the following interpretation suggests itself:

- For small numbers of loaded patterns the system stores and recalls individual patterns. The input simulation matrix D represents **individual** patterns.

- For large numbers of loaded patterns, the system learns a representation of the parametrized pattern family and can re-generate any pattern from that family from a cue. The input simulation matrix D represents the **class** of patterns.

In suggestive wording, as more and more patterns are loaded this memory system changes its nature from "rote learning" to "understanding" the nature of the pattern family. With the aid of autoconceptors, any member of the family can be "recognized" from a cue and become re-generated. This family learning effect becomes effective already when only a single pattern has been loaded, and when as few as about 5 patterns are loaded, the recall log10 NRMSE for novel patterns is within 20% of the accuracy for loaded patterns. This is another display of the generalization powers of conceptor-based systems, which we encountered before in connection with conceptor morphing (Section 2.2).

3.3 Analysis of Auto-Adaptation Dynamics

The dynamics of autoadaptation—that is, the evolution of $C(n)$ under the simultaneous reservoir state update (13), (14) (or variants) and conceptor matrix adaptation rule (18)—is highly nonlinear and involves at least the two timescales of reservoir updates (fast, N variables) and C adaptation (slow, N^2 variables). A full analysis is out of reach, but some core aspects are analytically accessible. In Jaeger (2014) I investigate properties of fixed points of C auto-adaptation. Here I review the most important findings and attempt an interpretation of some phenomena found in simulation studies in the light of these analytical insights. This subsection assumes some familiarity with methods from dynamical systems theory. Readers not interested in technical detail may jump to the intuitive summary at the end of this subsection.

My analysis was based on assuming an adaptation rate λ that is small enough to admit temporal averaging over the fast $\mathbf{z}(n)$ state variables. The discrete update equation (18) can then be transformed into a continuous-time ODE which is easier to analyze. This ODE is

$$\tau \dot{C} = (I - C)\, C\, Q_C\, C' - \alpha^{-2}\, C, \tag{20}$$

where $Q_C = E_{\mathbf{z}}[\tanh(W\,\mathbf{z} + \mathbf{b})\tanh(W\,\mathbf{z} + \mathbf{b})'] = E_{\mathbf{r}}[\mathbf{r}\,\mathbf{r}']$ is the autocorrelation matrix of reservoir states (here in a version with input internalization weights, versions with input simulation weights are analog) when these states evolve under the control of C. The time constant τ is of no concern for the qualitative analysis. Specifically I investigated two objects:

Fixed points F of (20). These are candidates for conceptors that are asymptotically obtained for convergent autoadaptation runs.

Jacobians J_F of fixed points F. J_F is an $N^2 \times N^2$ matrix whose (i,j)-th element is the derivative $\partial \dot{F}_i / \partial F_j$, under the dynamics (20) linearized in F, and where F_i is the i-th element of F (enumerated row-wise). The eigenvalues of J_F characterize stability properties of F.

Here is a summary of insights from this analysis:

- Fixed points F are positive-semidefinite matrices with eigenvalues (= singular values) ranging in $[0, 1]$, and thus qualify as conceptors.

- When F has singular values that are smaller than $1/2$ and greater than 0, J_F has positive eigenvalues and hence F is not a stable fixed point. Such F cannot be obtained in empirical auto-adaptation runs. Conversely, this means that if auto-adaptation converges, the resulting conceptors C have singular values that are either exactly zero or larger than $1/2$.

- The rank of F is bounded from above by the number of singular values of Q_F which are greater than $4\alpha^{-2}$. This implies that reducing the aperture α forces an increasing number of singular values of F to become zero.

- Assume F has rank k. Then J_F has $k(N-k)$ zero eigenvalues, that is, a center manifold $\mathcal{K}$ of dimension $k(N-k)$. On this center manifold the stability properties of the dynamics (20) cannot be elucidated by linearization techniques; it may be stable, instable, or neutral.

- If F is a rank-k solution of the fixed-point equation (17) which is generic in the sense that the nonzero singular values of F are pairwise different, and if Q in (17) is fixed (that is, its dependency on C is ignored), then differential changes of F along a $k(N-k)$-dimensional subspace will also lead to rank-k solutions of (17) (Jaeger (2014), Section 3.13.4). The identity of the center manifold dimension and the dimension of this local solution space implies that the center manifold coincides with the local solution space. Hence the adaptation dynamics on the center manifold $\mathcal{K}$ is neutrally stable: $\mathcal{K}$ is a plane attractor. Note however that this interpretation is based on fixing Q at Q_F in the vicinity of F. Plane attractors are non-generic in randomly parametrized ODEs, and fixed point solutions F are generically isolated (not embedded in a plane attractor). When the dependence of Q on C is included in the picture, and F is a fixed-point solution of (17), we would generically expect a separation of timescales in the autoadaptation dynamics in the vicinity of F: fast convergence toward F in directions orthogonal to $\mathcal{K}$ and (very) slow drift within $\mathcal{K}$. Below I present a numerical simulation that corroborates this intuition.

- In order to obtain a better understanding of convergence properties in directions orthogonal to $\mathcal{K}$ one needs to analyse the negative eigenvalues of the Jacobian J_F. Assume again that F has rank k, and furthermore the k nonzero singular values $s_1, \ldots, s_k$ of F are greater than $1/2$. Then the $N^2 - k(N-k)$ nonzero eigenvalues of J_F are all negative. They come in three sorts (Proposition 16 in Jaeger (2014)):

  1. $N(N-k)$ eigenvalues are equal to $-\alpha^{-2}$ ("sort 1"),
  2. k eigenvalues are associated with the k singular values s_i and have the form $-\alpha^{-2}\,(2s_i - 1)/(1 - s_i)$ ("sort 2"),
  3. the remaining $k(k-1)$ eigenvalues ("sort 3") come in pairs

$$\lambda_{1,2} = \frac{-\alpha^{-2}}{2}\left(\frac{s_l}{1-s_m} + \frac{s_m}{1-s_l} \pm \sqrt{\left(\frac{s_l}{1-s_m} - \frac{s_m}{1-s_l}\right)^2 + 4}\right),$$

  where $m < l \leq k$.

When $k \ll N$, which is often the case, the majority of all eigenvalues of F is of sort 1, revealing that in the majority of directions orthogonal to the center manifold the convergence rate toward F is inversely proportional to α^2. A relevant message here is that increasing the aperture substantially slows down convergence. An eigenvalue of sort 2 is also inversely proportional to α^2, but furthermore the term $(2s_i - 1)/(1 - s_i)$ indicates that as $s_i \downarrow 1/2$, the convergence rate in this direction slows down arbitrarily much, while conversely for $s_i \uparrow 1$, convergence becomes arbitrarily fast. Finally, eigenvalues of sort 3 are products of two factors too, the first factor being again inversely proportional to α^2. The second factor, which depends on a pair s_l, s_m, may become arbitrarily large or arbitrarily small depending on s_l, s_m and the $\pm$ choice. Specifically, this second factor approaches zero if both s_l, s_m approach $1/2$ from above and the "$-$" option is taken. In summary, outside the center manifold convergence rates are always co-determined by a factor proportional to α^2, and by factors that depend on the singular values s_i of F, where these latter factors may shrink toward zero if associated singular values s_i approach $1/2$.

- As we have just seen, singular values s_i of F which are close to $1/2$ lead to slow convergence (which implies weak stability) in some directions of C. It is therefore relevant to investigate into typical values of s_i. Unfortunately I can only provide a plausibility argument to the effect that most s_i will be close to 1 and only very few (if any at all) close to $1/2$. This argument goes as follows. Recall from (16) that F, because it is a minimizer of (15), can be written as $F = R(R + \alpha^{-2} I)^{-1}$, where $R = E[\mathbf{z}\,\mathbf{z}']$. This implies that the singular values s_i of F relate to the singular values s_i^R of R by $s_i = s_i^R / (s_i^R + \alpha^{-2})$. Furthermore, nonzero s_i must be greater than $1/2$. Assume the "worst case" that the smallest nonzero singular value of the (rank k) matrix F is $s_k = 1/2$, which translates to $s_k^R = \alpha^{-2}$. Let $s_{k-1}^R = s_k^R + \varepsilon$ be the next greater singular value of R. A simple argument based on the derivative $d\,s_i / d\,s_i^R$ evaluated at s_k^R yields that for small increments ε we get $s_{k-1} \approx 1/2 + 1/4\,\alpha^2\,\varepsilon$. In words, the singular values s_i of F grow away from $1/2$ by increments $1/4\,\alpha^2\,\varepsilon$. Since apertures are often in the order of 10 (or much larger), this means that we may expect that most if not all nonzero singular values of F will be close to 1. This is in fact what I consistently observe in simulations, like in the demos above (Figure 9). It is a desirable effect because according to the considerations made in this subsection before, singular values $s_i \approx 1$ or $s_i = 0$ foster noise robustness of auto-adaptation.

- The analyses available so far can explain the robustness of conceptor auto-adaptation to state noise. When at some stage of auto-adaptation the matrix $C(n)$ has k nonzero singular values and $N - k$ singular values equal to zero, the latter will be preserved under auto-adaptation because the states $\mathbf{z}(n) = C(n)\,\mathbf{r}(n)$ that enter the adaptation of $C(n)$ will have zero components in the $N - k$ directions associated with the zero singular values. The effect of state noise on the nonzero $s_i(n)$ is to drive them closer to 1 than they would go without state noise. Conceptors eventually converged to with state noise are not identical, but similar to variants that would be obtained without noise: the difference being that the former are (even) more rectangular than the latter. This favourable situation however hinges on the condition that the post-cue C^{cue} has (many) zero singular values. In the simulations in previous subsections

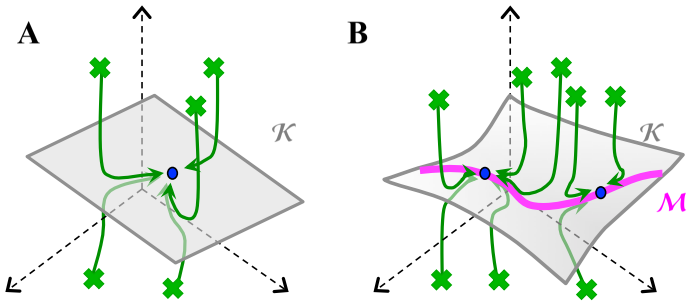

Figure 11: Hypothetical phase portraits of C autoadaptation in the parameter space of C (schematic). Blue points show stable fixed point solutions C. The gray plane in **A** represents the center manifold $\mathcal{K}$ and in **B** the merged center manifolds of neighboring fixed points C. Green arrows show sample trajectories of late stages of C adaptation. Green crosses mark the starting points of the adaptation trajectories set by the cueing procedure. **A**: When a small number of patterns has been loaded, individual stable fixed point conceptors C are created. **B**: In the case of learning a d-parametric pattern class, fixed point solutions C_i become located within a d-dimensional pattern manifold $\mathcal{M}$ (magenta line). For explanation see text.

this was achieved by (i) initializing $C(0) = \mathbf{0}$ and (ii) not inserting state noise during the cueing—state noise insertion in that sensitive period would have led to a large number of nonzero singular values in C^{cue}. If state noise or other perturbations are unavoidable during cueing, it will be a practical idea to simply zero small singular values of the developing $C(n)$ through a thresholding mechanism.

Based on these insights I tentatively offer the following qualitative account of conceptor auto-adaptation dynamics.

This dynamics evolves in the N^2-dimensional parameter space of conceptor (or conceptor candidate) matrices $C(n)$ under the assumption of a small enough adaptation rate λ, such that we may use the ODE (20). I distinguish two cases depending on whether few or many patterns have been loaded. Figure 11 gives a graphical impression.

Representing individual patterns. This corresponds to the situation called "rote learning" in Section 3.2. Here I assume that a small number of patterns p^j have been loaded, and that they become represented by corresponding isolated attracting fixed points F^j of (20). The dynamics in a neighborhood of F^j then should be characterized by a (very) slow timescale of attraction in the directions of the center manifold $\mathcal{K}$ and faster attraction in orthogonal directions (Figure 11 **A**). The attraction orthogonal to

$\mathcal{K}$ may in turn be governed by a wide range of different timescales due to what we have learnt about the dependency of eigenvalues of J_{F^j} on the singular values of F^j.

Representing a pattern family. When many patterns p^j from a family characterized by d parameters have been loaded, we have seen in Section 3.2 that any pattern from that family will be re-generated upon cue equally well. I hypothesize that during the loading procedure a d-dimensional manifold $\mathcal{M}$ is created which represents the pattern family and which superficially appears like a line/plane attractor: when by virtue of the cueing procedure the auto-adaptation is initialized into the vicinity of $\mathcal{M}$, one will observe an auto-adaptation toward $\mathcal{M}$ (Figure 11 **B**). The dimension d of $\mathcal{M}$ will typically be much smaller than the dimension $k(N-k)$ of the center manifold of conceptors in $\mathcal{M}$. I hypothesize that $\mathcal{M}$ is embedded as a submanifold in a $k(N-k)$-dimensional manifold $\mathcal{K}$ which can be understood as a merge of the (locally defined) center manifolds of conceptors sitting in $\mathcal{M}$. The convergence toward $\mathcal{M}$ leads to a good reconstruction of the cue pattern after a "reasonable" adaptation time. It is this convergence which was exploited for 10,000 step runtimes in the experiment shown in Figure 10. However, as remarked earlier, line/plane attractors are non-generic objects and unlikely to exist in empirical or randomly created systems. Therefore, for very long runtimes I would predict a very slow drift within $\mathcal{M}$ that lets auto-adaptation ultimately end up in some isolated attracting fixed point within $\mathcal{M}$. According to this view, line/plane attractors only appear phenomenally on some intermediate timescale, and hence the class learning effect described in Section 3.2 should degrade for very long adaptation times.

In order to substantiate this interpretation of an only "ephemeral" appearance of a line/plane attractor, I carried out a long-duration auto-adaptation simulation. Ten 5-periodic patterns were loaded into a small ($N = 50$) reservoir. These patterns represented ten stages of a linear morph between two similar patterns p^1 and p^{10}, resulting in a morph sequence $p^1, p^2, \ldots, p^{10}$ where $p^i = (1-(i-1)/9)\,p^1 + ((i-1)/9)\,p^{10}$, thus representing instances from a 1-parametric family. Considering what was found in Section 3.2, loading these ten patterns should enable the system to re-generate by auto-adaptation any linear morph p_{test} between p^1 and p^{10} after being cued with p_{test}.

After loading, the system was cued for 20 steps with 20 different cues. In each of these $j = 1, \ldots, 20$ conditions, the cueing pattern p^j_{test} was the j-th linear interpolation between the loaded p^1 and p^{10}. At the end of the cueing, the system will be securely driven into a state $\mathbf{z}$ that is very accurately connected to re-generating the pattern p^j_{test}, and the conceptor matrix that has developed by the end of the cueing would enable the system to re-generate a close simile of p^j_{test} (a post-cue log10 NRMSE of about -2.7 was obtained in this simulation).

After cueing, the system was left running in conceptor auto-adaptation mode for 1 Mio timesteps, with an adaptation rate of $\lambda = 0.01$. At times $n = 1, 1000, 10000, 1e^6$ the stage of convergence was assessed as follows. The pairwise distances between the twenty autoconceptors $C^j(n)$ were compared, resulting in a 20×20 distance matrix $D(n) = (\|C^k(n) - C^l(n)\|_{\text{fro}})_{k,l=1,\ldots,20}$. Figure 12 shows color plots of these distance matrices. The outcome: at the beginning of autoadaptation ($n = 1$), the 20 autoconceptors are spaced from each other by distances proportional to their morphing distances. In terms of the

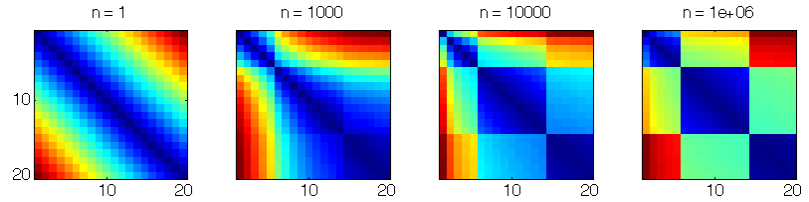

Figure 12: Numerical exploration of fixed point solutions under C auto-adaptation. Each panel shows pairwise distances of 20 conceptor matrices obtained after n auto-adaptation steps, after being cued along a 20-step morph sequence of cue signals. Color coding: blue: zero distance; red: maximum distance. For explanation see text.

schematic in Figure 11 **B**, they would all be almost equi-distantly lined up on the manifold $\mathcal{M}$, which is a line in this case of a 1-parametric pattern family. Then, as the adaptation time n grows, they contract toward three point attractors within $\mathcal{M}$ (which would correspond to a version of 11 **B** with three isolated fixed point attractors within $\mathcal{M}$). These three point attractors correspond to the three dark blue squares on the diagonal of the last distance matrix shown in Figure 12.

This singular simulation cannot, of course, provide conclusive evidence that the qualitative picture proposed in Figure 11 is correct. A rigorous mathematical characterization of the hypothetical manifold $\mathcal{M}$ and its relation to the center manifolds of fixed point solutions of the adaptation dynamics remains to be worked out.

Plane attractors have been proposed as models for a number of biological neural adaptation processes (summarized in Eliasmith (2005)). Specifically, the fact that animals can fix their gaze in arbitrary (continuously many) directions has been modelled by plane attractors in the oculomotoric neural control system. Each gaze direction corresponds to a (controlled) constant neural activation profile. It would be interesting to carry out in-vivo experiments of gaze direction fixation where the animal (or human) is cued with a direction target, which is then removed, under the instruction to preserve the gaze direction after target removal for an extended timespan. The mathematical model outlined above would predict that the gaze direction would start drifting, possibly becoming ultimately arrested in one of a number of isolated, "preferred" gaze directions.

3.4 Single-Step Content-Addressing by Thresholding

We observed above that approximately rectangular conceptors evolved in auto-adaptation and that directions in $\mathbf{z}$ states which are nulled by C^{cue} remain nulled during auto-adaptation. This suggests a drastic shortcut of the recall procedure: take the preliminary C^{cue} which is available immediately after the cue period, then transform its singular value profile to a binary 0-1-rectangular shape by thresholding to give $\overline{C^{\text{cue}}}$, and use this conceptor for pattern re-generation. Accordingly, I re-ran the 5-periodic and mix-of-sines demos from

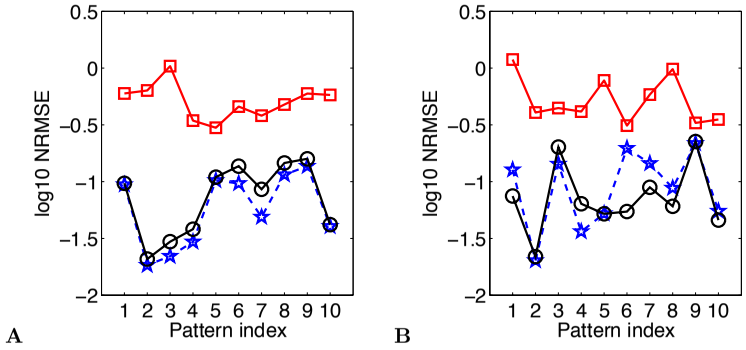

Figure 13: Using single-step adapted conceptors $\overline{C^{\text{cue}}}$ for cued pattern recall. **A**: 5-periodic patterns, **B**: mix-of-sines. Red and blue plots are identical to Figure 9 and represent post-cue NRMSE from C^{cue} and $C(t_3)$. The black plot gives the NRMSE obtained from $\overline{C^{\text{cue}}}$.

Section 3.1.2 with the same reservoirs and cueing conditions, and directly at the end of the cueing phase I computed $\overline{C^{\text{cue}}}$ from C^{cue} as follows:

1. compute the SVD $USU' = C^{\text{cue}}$,
2. recompute the entries s_i on the diagonal of S to new, binary values by thresholding, obtaining $\overline{S}$ with diagonal values

$$\overline{s_i} = \begin{cases} 1, & \text{if } s_i > \tau \\ 0, & \text{else} \end{cases}$$

   for some threshold τ,
3. recombine into $\overline{C^{\text{cue}}} = U\overline{S}U'$,
4. immediately use $\overline{C^{\text{cue}}}$ for re-generating a pattern and report the matching NRMSE with the original pattern that was used for the cue.

Figure 13 displays the outcome. I used thresholds τ of 0.5 and 0.01 respectively for the 5-periodic and mix-of-sines experiments. For both kinds of patterns the re-generation quality obtained from $\overline{C^{\text{cue}}}$ conceptors is essentially the same as the quality obtained from the auto-adapted $C(t_3)$ after 500 resp. 10,000 steps for the two kinds of patterns.

Considering that thresholded $\overline{C^{\text{cue}}}$ are much faster and cheaper to create than online-adapted conceptors, yet (in these simulations) are of the same quality, it is natural to ask why one should bother about online-adapted autoconceptors at all instead of focussing all attention on thresholded conceptors. The reasons why I spent much effort on the former (and used much of the reader's patience) are manifold:

- There are other applications of online-adapted autoconceptors besides pattern recall from a memory. In Jaeger (2014) I employ conceptor auto-adaptation in hierarchical RNN demonstrator systems for tasks of signal denoising, pattern classification, and pattern mixture recognition, and in ongoing work I am using them for single-shot training of a nonlinear channel equalizer and blind signal separation. In all of these cases, an adaptive RNN-based system has to be able to smoothly adjust its reactions to a non-stationary input stream, requiring a continuously ongoing gradual adaptation.

- A serious drawback of the above auto-adaptation mechanism is that it is based on stochastic gradient descent in a high-dimensional space, incurring the well-known stability issues which mandate small adaptation rates, hence yield slow convergence. In Jaeger (2014) I introduce a simplified version of conceptors which basically constrains conceptor matrices C to diagonal form, leading to decoupled adaptation rules for the diagonal parameters which admits individual and very large adaptation rates. While systems of this kind work well in some specific scenarios (demos in Jaeger (2014), Section 3.15), I am not satisfied with them in general, mainly because the value range for well-working apertures becomes very narrow. My current research concentrates on new types of conceptors which combine fast online adaptivity with the robustness properties found in matrix conceptors.

- In computational neuroscience, attractor-like phenomena of all sorts are widely investigated as neural mechanisms for representing and processing information in neural systems (partial overviews in Durstewitz et al. (2000); Fusi and Wang (2016); Jaeger (2012)). The multiple-timescale attractor phenomenology of conceptor auto-adaptation discussed in the previous section sheds some further light on this field, especially with respect to the role of line/plane attractors in the representation and addressing of continuous memory items.

- Biological implausibility. The fast thresholding mechanism invokes a matrix SVD computation. Much research has been devoted to determine biologically plausible neural algorithms for the closely related task of computing a PCA or of finding some cost-optimal projection subspaces (Oja, 1982; Pehlevan et al., 2015). However, these neural algorithms share with my stochastic gradient conceptor adaptation the shortcoming of slow convergence, and biological plausibility remains debatable in my view.

3.5 Comparison with Hopfield Networks

As I mentioned in the Introduction, Hopfield networks and its relatives (Willshaw et al., 1969; Cooper, 1973; Kohonen, 1974; Palm, 1980; Hopfield, 1982) are the paradigmatic model of content-addressable neural long-term memories. For brevity I will use the term *Hopfield networks* (HNs) as an umbrella term for this family of models, and refer to the networks introduced in this section as autoconceptor networks (ACNs). ACNs are analogous to HNs in some ways and different in others:

Nature of memory items. Patterns stored in (auto-associative) HNs are static (often images), though hetero-associative HN variants can be trained to re-generate sequences of static patterns—I briefly discussed this in the Introduction. ACNs intrinsically

host temporal patterns. The pattern sequences of static patterns learnt by sequence-representing HNs differ in kind from the temporal patterns in ACNs. The former are "jump" transitions between a finite number of explicitly trained "waypoint" patterns, and in principle any transition order can be learnt. Temporal patterns in ACNs have what one might call intrinsic temporality; the reservoir state sequence cannot in general be re-trained in other orders. Specifically, ACNs can host non-periodic patterns sampled from ODE evolutions which is not possible with hetero-associative HNs. One might word this as, "hetero-associative HNs can store pattern sequences, and ACNs can store sequence patterns".

States and patterns. In HNs patterns are identified with certain network states. In ACNs patterns are state evolution processes.

Symmetric vs. directed synaptic connections. Standard auto-associative HNs have symmetric connections, which admits an analysis of HN dynamics in terms of descent in an energy landscape. Reservoir networks in ACNs with their asymmetric weight matrices do not admit an energy-based interpretation.

Pattern restauration. A hallmark of HNs is their ability to restore patterns perfectly and quickly from highly corrupted cues. This striking capability results from the fact that HN training creates well-defined local minima in the HN energy landscape which correspond 1-1 to target patterns; from any arbitrary cue the HN *must* settle in one of these perfect target patterns (setting aside the issue of spurious attractors in HNs). Furthermore, perfection of restauration is aided by the circumstance that HNs often are installed with binary neurons, representing binary patterns. In contrast, the continuous-valued states in ACNs and the vastly more complex multi-timescale dynamics of auto-adaptation limit the perfection and speed of pattern re-generation.

Class learning. ACNs can learn entire continuous-parametric pattern classes (with the caveats pointed out in Section 3.3), which HNs cannot.

All in all, while both HNs and ACNs are models of content-addressable neural long-term memories, their underlying neuro-dynamical working mechanisms and their performance characteristics are fundamentally—and interestingly—different.

4. Discussion

This article is the first peer-reviewed publication about conceptors and thereby assumes the role of an "official" introduction of this concept and name. New scientific concepts and terminology should be introduced with care and circumspection. So, what is a "conceptor"?

This article dealt with conceptors that come in the specific form of positive-semidefinite matrices derived from reservoir state correlation matrices R via $C = R\,(R + \alpha^{-2} I)^{-1}$. In Jaeger (2014) I also describe conceptors that are realized by a forward- and backprojection to/from a higher-dimensional random feature space. In my initial explorations (unpublished) I also used affine maps, as well as pure linear subspace projectors. Currently I am investigating a kind of conceptors built on the basis of a variant of self-organizing maps. In

the light of this diversity I wouldn't want to make any specific mathematical or algorithmical format a defining part of "conceptors".

This article focussed on neural long-term memory for temporal patterns. In Jaeger (2014) however I use conceptors also for static patterns (where an input pattern is transformed to a single neural state, not a sequence of states), and without loading (which is not necessary when conceptors are employed for non-generative tasks like pattern classification). I am also aware of ongoing work by others in static pattern recognition where backprop-trained deep feedforward neural networks are combined with conceptors. Thus, neither temporality of patterns, nor loading them persistently, nor the use of random networks are necessary attributes of "conceptors", the way I want them to be seen.

Then what is left? Here is an outline of how I would like the concept of conceptors to be understood:

1. *Set-up: patterns encoded by states.* Given: some computational framework where a diversity of **patterns** p^j are **encoded** by probability distributions P^j over a metric state space X. *Comment: patterns can be temporal or static. The state space is typically high-dimensional, and encodings would typically be "distributed".*

2. *Filtering of encodings.* A **conceptor** C^j is a **map** associated with a pattern p^j which transforms state vectors $x \in X$ to state vectors $C^j(x) \in X$, and which is optimized in some way to preserve states x^j that are typical for pattern p^j: if $P^j(x)$ is large, then the distance $d(x, C^j(x))$ is small. Furthermore, C^j projects off-pattern states closer to pattern-typical regions of X: if $P^j(x)$ is small, then $P^j(C^j(x)) > P^j(x)$. *Comment: The map C^j can be instantiated by a mathematical formula, or by some neural circuit, or in any other way.*

3. *Conceptual operations.* Given a collection $\{p^j\}$ of patterns, on the associated collection of conceptors $\{C^j\}$ one has available an assortment of operations which can **construct** new conceptors from the conceptors contained in the original collection $\{C^j\}$. These operations should be interpretable as "cognitive-level" operations on concepts, and it is these operations that connect conceptors with concepts. *Comment: this is obviously vague. This article featured the following such operations: (i) conceptual blending by conceptor morphing, (ii) "focussing" by aperture adaptation. A large part of Jaeger (2014) is devoted to a third kind of conceptual operations on conceptors, namely, (iii) Boolean combinations of conceptors.*

My ultimate motivation to investigate conceptors is to establish an effective link between "low-level", "subsymbolic", "distributed" neural representations and processing mechanisms on the one hand, and a "high-level", "conceptual" organization and interpretability of such processing on the other hand. This intended use of conceptors, which is expressed in item 3. in the list above, is to some degree independent of the "mechanics" of conceptors, which is stated in item 2. It turns out that conceptors also can serve relevant "low-level" functionalities, especially neural noise suppression and stabilization of neural state dynamics.

Conceptors can be engineered into artificial neural architectures, and they might be instantiated in one way or the other by neural circuitry in biological systems. In such

cases they become procedurally effective in the concerned systems, implementing *conceptor mechanisms*. This was the perspective adopted in this article. But conceptors can also be used "epistemologically" by a researcher who investigates some (likely neural) information processing system which may or may not itself have have effective conceptor mechanisms inside. Then conceptors may become elements of a descriptive scientific language that talks *about* neural encodings of concepts. In Jaeger (2014) I describe in detail such scientific languages in the format of formal *conceptor logics*.

Acknowledgments

I am indebted to Emre Neftci for bringing the work of Sompolinsky and Kanter (1986) to my attention. The first ideas of conceptors were triggered by research within the European FP7 project AMARSi (contract 248311, `amarsi-project.eu`) on the modulation of neural pattern generators for humanoid robot motor control.

Appendix A. Documentation of Simulation Detail

Training and test errors are given as normalized root mean square error (NRMSE) between a signal $s(n)$ and its target $t(n)$, that is, by the square root of the mean square error divided by the variance of the target.

A.1 Detail for Section 2.1

Pattern definition: Pattern p^1 is a sinewave sampled at intervals of about 1.9944. Pattern p^2 alternates between -0.5 and 0.5.

Network set-up: Initial weights W^* were sampled from the normal distribution, then the weight matrix was rescaled to a spectral radius (largest absolute eigenvalue) of 1.3. Input and bias weights were sampled from the normal distribution, then scaled by 1.4 and 0.1 respectively.

Learning: For training W^{out} the reservoir was driven by iid input sampled from the normal distribution scaled by 1.5 for 200 steps (plus an initial washout of 100 steps). The linear regression was computed without regularization, resulting in a training NRMSE of 0.39 (training W^{out} from state patterns $\mathbf{x}^1(n), \mathbf{x}^2(n)$ would have given an NRMSE of 0.14). For the (not regularized) linear regression leading to W, again 200 states from each of the two patterns were used, leading to an NRMSE of 0.093 (average over the three neurons).

Recall: In order to numerically compare the re-generated patterns $y(n) = W^{\text{out}}\,\mathbf{x}^j(n)$ to the original patterns $p^j(n)$, sample trajectories of both were phase-aligned by (i) super-sampling with cubic spline interpolation by a factor of 20, (ii) finding the best-fitting phase shift, (iii) subsampling back to the original sampling rate, (iv) computing the NRMSE, which was 0.15 for the first and 0.13 for the second pattern.

Note: Parameters and the random seed for network set-up were hand-selected for good visual appearance of this demo example. Better recall accuracies were obtained with smaller apertures, but these would have given less instructive graphics. At any rate, a network size of $N = 3$ is far too small for high-precision results.

A.2 Detail for Section 2.2

Interpolation from 5-periodic to irrational sine (Fig. 3): A 100-unit reservoir was used, W^* scaled to a spectral radius of 1.6, input weights scaled to 1.6, bias vector to 0.3. Linear regression for W was regularized by a Tychonov regularizer of size $\varrho^2 = 0.0001$. Apertures for the two conceptors: 10 and 100.

Morphing between and beyond three patterns from a family (Fig. 4): Patterns were taken from the parametrized family with parameters A, B

$$p^{A,B}(n) = 2\left(\frac{1}{2}\sin(2\pi n/(P+A)) + \frac{1}{2}\right)^{\exp(B)} + 1, \quad A, B \in \mathbb{R}; |A| < P.$$

This family contains modulated versions of sines whose period lengths vary around a reference period P by differences A and whose shape is modulated by B. Figure 4 (top panels) shows the three stored patterns, which were defined by $P \approx 8.2$, $A = -1.1\sqrt{3}; 1.1\sqrt{3}/2; 0$, $B = -0.2, -0.2, 0.4$. Going upward by one tile changes a mixture from (a^1, a^2, a^3) to $(a^1 - 1/8, a^2 - 1/8, a^3 + 1/4)$, going right by one tile to $(a^1 - 1/4, a^2 + 1/4, a^3)$. The reservoir had 100 units, spectral radius of initial weight matrix: 2.2, input weight scaling: 2.2, bias scaling; 1.5, aperture of all conceptors 2.0. Ridge regression coefficient for loading: $\varrho = 0.001$.

A.3 Detail for Section 2.3

Preparation of training data. Fifteen human motion capture (mocap) sequences were retrieved from the public-domain mocap repository maintained by the Graphics Lab at Carnegie Mellon University (`http://mocap.cs.cmu.edu/`). Using the public mocap toolsuite provided by Burger and Toiviainen (2013), the marker trace format of the original mocap data was transformed into joint angle data in the following way. A human segment model with 17 segments was chosen. The original marker trace data was transformed into metric 3D trajectories of the segment endpoints (joints). The joint between the two hip joints was designated as "root". Let x, y denote the two ground coordinates and z the height coordinate (measured as distance from ground), and let δ (measured in rad) denote the horizontal pointing direction (in x, y) of the root.

The motion of the root joint was coded in the following four variables:

1. $h(n)$: simply the z coordinate of the Euclidean trajectory of the root,
2. $\dot{\delta}(n)$: the angular velocity (in rad/frame) of the root pointing direction,
3. $d_1(n), d_2(n)$: travel distance of root joint in the x, y plane of the current frame, relative to the horizontal pointing direction (Fig. 14), measured in mm/frame.

The locations of the other joints were coded relative to their predecessor joints in the kinematic chain tree, with the root joint as the top node, as follows:

1. The current frame n is horizontally shifted and rotated such that the root joint has (x, y)-position $(0, 0)$ and is pointing in the direction of the x-axis. For every joint j this results in three Euclidean coordinates $x_j(n), y_j(n), z_j(n)$.

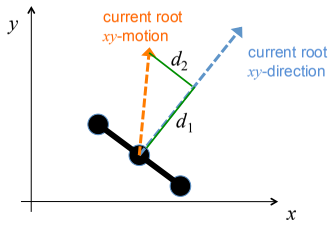

Figure 14: How the quantities d_1, d_2 geometrically relate to current root direction and root travel.

2. For each of the 19 non-root joints j, the current orientation was coded in three variables $s_j^x(n), s_j^y(n), s_j^z(n)$ as follows:

   (a) Determine the predecessor joint i of j (the adjacent joint that is closer to the root).

   (b) Compute the segment vector $s_0^j(n) = (x_j(n) - x_i(n), y_j(n) - y_i(n), z_j(n) - z_i(n))'$ and normalize it to $s^j(n) = s_0^j(n)/\|s_0^j(n)\|$. The three components of $s^j(n)$ are returned as coding the current spatial angle of the segment ending in joint j.

All in all this leads to a 61-dimensional coding of a body pose and root motion per frame. From such 61-dimensional sequences, joint trajectories in Euclidean task space can be recovered by a reversal of the coding procedure.

For each of the 15 original mocap timeseries, such a 61-dimensional encoding was produced. Each of the 61 signal components was shifted/scaled such that it ranged exactly in $[-1, 1]$, across all 15 patterns. These 15 range-normalized sequences were then loaded into the reservoir, and the readout weights were computed to recover them.

Reservoir setup. Different from all other simulations reported in the article, the motor pattern demonstration used a reservoir with leaky integration neurons:

$$\mathbf{x}(n+1) = (1-a)\,\mathbf{x}(n) + a\,\tanh(W\,\mathbf{x}(n) + W^{\text{in}}\,p(n+1) + \mathbf{b}),$$

where the leaking rate a is an additional tuning parameter. This alternative choice of network model does not affect any of the conceptor-related computations. Reservoirs based on leaky integration units effectively implement temporal smoothing which is indicated when slowly changing (relative to the network update cycle) patterns have to be processed.

Simulation parameters. Network size $N = 600$; leaking rate $a = 0.6$; spectral radius of W^* was 1; input and bias weights were sampled from the uniform distribution on $[-.8, .8]$. Loading each pattern used a washout of 50 network updates (corresponding to 5/12 seconds of simulated real time). Two of the input channels were found to act essentially only as noise sources (because they were essentially constant and after range normalization small fluctuations in the constant value were magnified); their input weights were nulled. Linear regression without regularization was used for computing W and W^{out}. The aperture was

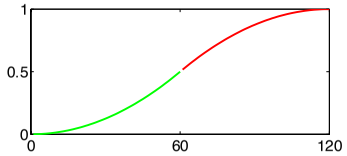

Figure 15: The morphing ramp $\varrho(n)$ used for smooth transitions between motor patterns.

set to $\alpha = 10$ for all fifteen conceptors except for the "slow walk" ($\alpha = 2$) and "boxing: jab" patterns ($\alpha = 20$; with $\alpha = 10$ the jab pattern would be reduced to a mildly active legwork without the jabs being triggered).

Training errors. The training NRMSE for W was 0.0068 and for W^{out} was 0.044.

Video creation. For creating the video, the durations of the individual patterns were set to yield an appealing overall choreography. Between every two successive pattern p^i, p^j evocations, a transition period of 120 network updates (= 1 simulated second) was inserted. In this transition period the preceding conceptor C^i was morphed into the succeeding conceptor C^j, using a morphing function $\varrho : \{1, \ldots, 120\} \to [0, 1]$ made from two suitably scaled and shifted branches of the square function (red and green lines in Fig. 15), via $C^{\text{morph}}(m) = (1 - \varrho(m))\,C^i(m) + \varrho(m)C^j(m) \quad [m = 1, \ldots, 120]$. While the reservoir was generating the behavioral sequence visualized in the video, the only external input to the system was the activation sequence of conceptors (shown in the left upper corner of the video).

The visualization of the re-generated motion sequence in the video keeps the simulated actor centered in the drawing box and illustrates its motion in the x, y plane by a moving floor tile pattern. The centering as well as the corresponding virtual floor motion is computed relative to the mean of the x, y coordinates of all 20 joints. This mean is therefore always centered on $x = y = 0$ in each displayed frame. The apparent foot slipping results from this "quick and dirty" centering method.

A.4 Detail for Section 2.4

Data generation. For the Rössler attractor, training time series were obtained from the standard Rössler ODE $\dot{x} = -(y + z),\ \ \dot{y} = x + a\,y,\ \ \dot{z} = b + x\,z - c\,z$ with $a = b = 0.2, c = 8$. The evolution of this system was Euler approximated with stepsize 1/200 and the resulting discrete time series was then subsampled by 150. The x and y coordinates were assembled in a 2-dimensional driving sequence, where each of the two channels was shifted/scaled to a range of $[0, 1]$. For the Lorenz attractor, the ODE $\dot{x} = \sigma(y - x),\ \ \dot{y} = r\,x - y - x\,z,\ \ \dot{z} = x\,y - b\,z$ with $\sigma = 10, r = 28, b = 8/3$ was Euler-approximated with stepsize 1/200 and subsequent subsampling by 15. The x and z coordinates were collected in a 2-dimensional driving sequence, again each channel normalized to a range of $[0, 1]$. The Mackey-Glass timeseries was obtained from the delay differential equation $\dot{x}(t) = \frac{\beta\,x(t-\tau)}{1+x(t-\tau)^n} - \gamma\,x(t)$ with $\beta = 0.2, n = 10, \tau = 17, \gamma = 0.1$. An Euler approximation with stepsize 1/10 was used. To obtain a 2-dim timeseries that could be fed to the reservoir through the same two input channels as the other attractor data, pairs $x(t), x(t - \tau)$ were combined into 2-dim

vectors. Again, these two signals were normalized to the $[0, 1]$ range. The Hénon attractor is governed by the iterated map $x(n+1) = y(n) + 1 - a\,x(n)$, $y(n+1) = b\,x(n)$, where I used $a = 1.4, b = 0.3$. The two components were filed into a 2-dim timeseries $(x(n), y(n))'$ with no resampling, and again normalization to a range of $[0, 1]$ in each component.

Reservoir setup. A 500-unit reservoir RNN was created with a normal distributed, 10%-sparse weight matrix W^* scaled to a spectral radius of 0.6. The bias vector b and input weights W^{in} (sized 400×2 for two input channels) were sampled from standard normal distribution and then scaled by 0.4 and 1.2, respectively. These scaling parameters were found by a coarse manual optimization of the performance of the pattern loading process. The network size was chosen large enough to warrant a robust trainability of the four chaotic patterns. Repeated executions of the experiment with different randomly initialized weights (not documented) showed no significant differences.

Pattern loading. The length of training signals used in loading was $L = 2500$ with a washout of $n_0 = 500$ for all four patterns. The ridge regression regularizer was $\varrho^2_W = 1e^{-6}$. Output weights were computed from the pattern-driven states with a regularizer $\varrho^2_{\text{out}} = 1e^{-8}$. The average (over neurons and the four patterns) NRMSEs obtained for the reservoir and readout weights were 0.0082 and 0.013, respectively.

A.5 Detail for Section 3.2

Scalings of reservoirs: spectral radius of W^*: 1.1; W^{in}: 1.1; b: 0.25. Aperture: 1000. Regularization coefficients $\varrho^2 = 0.01$ both for W^{out} and D. Data collection runlengths in loading: 500 (plus 100 washout) per pattern. Cueing: washout 100 steps, cue adaptation time 12 steps. No noise added to cue signal. State noise added during auto-adaptation with a signal-to-noise ratio of 1.

Abstract

Probabilistic modeling is iterative. A scientist posits a simple model, fits it to her data, refines it according to her analysis, and repeats. However, fitting complex models to large data is a bottleneck in this process. Deriving algorithms for new models can be both mathematically and computationally challenging, which makes it difficult to efficiently cycle through the steps. To this end, we develop automatic differentiation variational inference (ADVI). Using our method, the scientist only provides a probabilistic model and a dataset, nothing else. ADVI automatically derives an efficient variational inference algorithm, freeing the scientist to refine and explore many models. ADVI supports a broad class of models—no conjugacy assumptions are required. We study ADVI across ten modern probabilistic models and apply it to a dataset with millions of observations. We deploy ADVI as part of Stan, a probabilistic programming system.

Keywords: Bayesian inference, approximate inference, probabilistic programming

1. Introduction

We develop an automatic method that derives variational inference algorithms for complex probabilistic models. We implement our method in a probabilistic programming system that lets a user specify a model in an intuitive programming language and then compiles that model into an inference executable. Our method enables automatic inference with large datasets on a practical class of modern probabilistic models.

The context of this research is the field of probabilistic modeling, which has emerged as a powerful language for customized data analysis. Probabilistic modeling lets us express our assumptions about data in a formal mathematical way, and then derive algorithms that use those assumptions to compute about an observed dataset. It has had an impact on myriad applications in both statistics and machine learning, including natural language processing, speech recognition, computer vision, population genetics, and computational neuroscience.

Figure 14 presents an example. Say we want to analyze how people navigate a city by car. We have a dataset of all the taxi rides taken over the course of a year: 1.7 million trajectories. To explore patterns in this data, we propose a mixture model with an unknown number of components. This is a non-conjugate model that we seek to fit to a large dataset. Previously, we would have to manually derive an inference algorithm that scales to large data. With our method, we write a probabilistic program and compile it; we can then fit the model in minutes and analyze the results with ease.

Probabilistic modeling leads to a natural research cycle. First, we use our domain knowledge to posit a simple model that includes latent variables; then, we use an inference algorithm to infer those variables from our data; next, we analyze our results and identify where the model works and where it falls short; last, we refine the model and repeat the process. When we cycle through these steps, we find expressive, interpretable, and useful models (Gelman et al., 2013; Blei, 2014). One of the broad goals of machine learning is to make this process easy.

Looping around this cycle, however, is not easy. The data we study are often large and complex; accordingly, we want to propose rich probabilistic models and scale them up. But using such models requires complex algorithms that are difficult to derive, implement, and scale. The bottleneck is this computation. The efforts involved in deriving, programming, debugging, and scaling each model precludes us from taking full advantage of the probabilistic modeling cycle.

It is this problem that motivates the ideas of probabilistic programming and automated inference. Probabilistic programming allows a user to write a probability model as a computer program and then compile that program into an efficient inference executable. Automated inference is the backbone of such a system—it inputs a probability model, expressed as a program, and outputs an efficient algorithm for computing with it. Previous approaches to automatic inference have mainly relied on Markov chain Monte Carlo (MCMC) algorithms. The results have been successful, but automated MCMC can be too slow for many real-world applications.

We approach the problem through variational inference (Jordan et al., 1999; Wainwright and Jordan, 2008), a faster alternative to MCMC that has been used in many large-scale problems (Hoffman et al., 2013; Blei et al., 2016). Though it is a promising method, developing a variational inference algorithm still requires tedious model-specific derivations and implementation; it has not seen widespread use in probabilistic programming. Here we automate the process of deriving scalable variational inference algorithms. We build on recent ideas in variational inference to leverage some of the capabilities of probabilistic programming systems, namely the ability to transform the space of latent variables and to automate derivatives of the joint distribution. The result, called automatic differentiation variational inference (ADVI), provides an automated solution to variational inference: the inputs are a probabilistic model and a dataset; the outputs are posterior inferences about the model's

latent variables.[1,2] We implement and deploy ADVI as part of Stan, a probabilistic programming system (Stan Development Team, 2016).

ADVI resolves the computational bottleneck of the probabilistic modeling cycle. We can easily propose a probabilistic model, analyze a large dataset, and revise the model, without worrying about computation. ADVI enables this cycle by providing automated and scalable variational inference for an expansive class of models. Sections 3 and 4 present ten direct applications of ADVI to modern probabilistic modeling examples, including an iterative analysis of 1.7 million taxi trajectories.

Technical summary. Formally, a probabilistic model defines a joint distribution of observations $\mathbf{x}$ and latent variables $\boldsymbol{\theta}$, $p(\mathbf{x}, \boldsymbol{\theta})$. The inference problem is to compute the posterior, the conditional distribution of the latent variables given the observations $p(\boldsymbol{\theta} \mid \mathbf{x})$. The posterior reveals patterns in the data and forms predictions through the posterior predictive distribution. The problem is that, for many models, the posterior is not tractable to compute.

Variational inference turns the task of computing a posterior into an optimization problem. We posit a parameterized family of distributions $q(\boldsymbol{\theta}) \in \mathcal{Q}$ and then find the member of that family that minimizes the Kullback-Leibler (KL) divergence to the exact posterior. Traditionally, using a variational inference algorithm requires the painstaking work of developing and implementing a custom optimization routine: specifying a variational family appropriate to the model, computing the corresponding objective function, taking derivatives, and running a gradient-based or coordinate-ascent optimization.

ADVI solves this problem automatically. The user specifies the model, expressed as a program, and ADVI automatically generates a corresponding variational algorithm. The idea is to first automatically transform the inference problem into a common space and then to solve the variational optimization problem. Solving the problem in this common space solves variational inference for all models in a large class. In more detail, ADVI follows these steps.

1. ADVI transforms the model into one with unconstrained real-valued latent variables. Specifically, it transforms $p(\mathbf{x}, \boldsymbol{\theta})$ to $p(\mathbf{x}, \boldsymbol{\zeta})$, where the mapping from $\boldsymbol{\theta}$ to $\boldsymbol{\zeta}$ is built into the joint distribution. This removes all original constraints on the latent variables $\boldsymbol{\theta}$. ADVI then defines the corresponding variational problem on the transformed variables, that is, to minimize $\mathrm{KL}\left(q(\boldsymbol{\zeta}) \parallel p(\boldsymbol{\zeta} \mid \mathbf{x})\right)$. With this transformation, all latent variables are defined on the same space. ADVI can now use a single variational family for all models.

2. ADVI recasts the gradient of the variational objective function as an expectation over q. This involves the gradient of the log joint with respect to the latent variables $\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta})$. Expressing the gradient as an expectation opens the door to Monte Carlo methods for approximating it (Robert and Casella, 1999; Ranganath et al., 2014).

3. ADVI further reparameterizes the gradient in terms of a standard Gaussian. To do this, it uses another transformation, this time within the variational family. This second transformation enables ADVI to efficiently compute Monte Carlo approximations—it needs only to sample from a standard Gaussian (Kingma and Welling, 2014; Rezende et al., 2014).

4. ADVI uses noisy gradients to optimize the variational distribution (Robbins and Monro, 1951). An adaptively tuned step-size sequence provides good convergence in practice.

1. This paper extends the method presented in Kucukelbir et al. (2015).
2. Automatic differentation has enjoyed a recent resurgence in machine learning; see Section 2.7.

Each step above is carefully designed to make ADVI work "out of the box" for a practical class of modern probabilistic models. This focus on developing an automated inference algorithm differentiates ADVI from other "black box" variational methods (Ranganath et al., 2014; Ruiz et al., 2016b).

We deploy ADVI in the Stan probabilistic programming system, which gives us two important types of automatic computation around probabilistic models. First, Stan provides a library of transformations—ways to convert a variety of constrained latent variables (e.g., positive reals) to be unconstrained, without changing the underlying joint distribution. Stan's library of transformations helps us with step 1 above. Second, Stan implements automatic differentiation to calculate $\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta})$ (Carpenter et al., 2015; Baydin et al., 2015). These derivatives are crucial in step 2, when computing the gradient of the ADVI objective.

Organization of paper. Section 2 develops the recipe that makes ADVI. We expose the details of each of the steps above and present a concrete algorithm. Section 3 studies the properties of ADVI. We explore its accuracy, its stochastic nature, and its sensitivity to transformations. Section 4 applies ADVI to an array of probability models. We compare its speed to MCMC sampling techniques and present a case study using a dataset with millions of observations. Section 5 concludes the paper with a discussion.

2. Automatic Differentiation Variational Inference

ADVI offers a recipe for automating the computations involved in variational inference. The strategy is as follows: transform the latent variables of the model into a common space, choose a variational approximation in the common space, and use generic computational techniques to solve the variational problem.

2.1 Differentiable Probability Models

We begin by defining the class of probability models that ADVI supports. Consider a dataset $\mathbf{x} = x_{1:N}$ with N observations. Each x_n is a realization of a discrete or continuous (multivariate) random variable. The likelihood $p(\mathbf{x} \mid \boldsymbol{\theta})$ relates the observations to a set of latent random variables $\boldsymbol{\theta}$. A Bayesian model posits a prior density $p(\boldsymbol{\theta})$ on the latent variables. Combining the likelihood with the prior gives the joint density $p(\mathbf{x}, \boldsymbol{\theta}) = p(\mathbf{x} \mid \boldsymbol{\theta})\, p(\boldsymbol{\theta})$. The goal of inference is to compute the posterior density $p(\boldsymbol{\theta} \mid \mathbf{x})$, which describes how the latent variables vary, conditioned on data.

Many posterior densities are not tractable; their normalizing constants lack analytic (closed-form) solutions. Thus we often seek to approximate the posterior. ADVI approximates the posterior of differentiable probability models. Members of this class of models have continuous latent variables $\boldsymbol{\theta}$ and a gradient of the log-joint with respect to them $\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta})$. The gradient is valid within the support of the prior

$$\mathrm{supp}(p(\boldsymbol{\theta})) = \left\{ \boldsymbol{\theta} \mid \boldsymbol{\theta} \in \mathbb{R}^K \text{ and } p(\boldsymbol{\theta}) > 0 \right\} \subseteq \mathbb{R}^K,$$

where K is the dimension of the latent variable space. This support set is important: it will play a role later in the paper. We make no assumptions about conjugacy, either full (Diaconis and Ylvisaker, 1979) or conditional (Hoffman et al., 2013).

Consider a model that contains a Poisson likelihood with unknown rate $p(x \mid \theta)$. The observed variable x is discrete; the latent rate θ is continuous and positive. Place a Weibull prior on θ, defined over the positive real numbers. The resulting joint density describes a nonconjugate probability model:

the posterior distribution of θ is not in the same class as the prior. (The conjugate prior would be a Gamma.) However, it is in the class of differentiable models. Its partial derivative $\partial/\partial\theta \log p(x, \theta)$ is valid within the support of the Weibull distribution, $\text{supp}(p(\theta)) = \mathbb{R}_{>0} \subset \mathbb{R}$. While this model would be a challenge for classical variational inference, it is not for ADVI.

Many machine learning models are differentiable. For example: linear and logistic regression, matrix factorization with continuous or discrete observations, linear dynamical systems, and Gaussian processes. (See Table 1.) At first blush, the restriction to differentiable random variables may seem to leave out other common machine learning models, such as mixture models and topic models. However, marginalizing out the discrete variables in the likelihoods of these models renders them differentiable.

Generalized linear models	*(e.g., linear / logistic / probit)*
Mixture models	*(e.g., mixture of Gaussians)*
Deep exponential families	*(e.g., deep latent Gaussian models)*
Topic models	*(e.g., latent Dirichlet allocation)*
Linear dynamical systems	*(e.g., state space models)*
Gaussian process models	*(e.g., regression / classification)*

Table 1: Popular differentiable probability models in machine learning.

Marginalization is not tractable for all models, such as the Ising model, sigmoid belief networks, and (untruncated) Bayesian nonparametric models, such as Dirichlet process mixtures (Antoniak, 1974). These are not differentiable probability models.

2.2 Variational Inference

Variational inference (VI) turns approximate posterior inference into an optimization problem (Wainwright and Jordan, 2008; Blei et al., 2016). Consider a family of approximating densities of the latent variables $q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})$, parameterized by a vector $\boldsymbol{\phi} \in \boldsymbol{\Phi}$. VI finds the parameters that minimize the KL divergence to the posterior,

$$\boldsymbol{\phi}^* = \arg\min_{\boldsymbol{\phi}\in\boldsymbol{\Phi}} \text{KL}\left(q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi}) \parallel p(\boldsymbol{\theta} \mid \mathbf{x})\right). \tag{1}$$

The optimized $q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi}^*)$ then serves as an approximation to the posterior.

The KL divergence lacks an analytic form because it involves the posterior. Instead we maximize the evidence lower bound (ELBO)

$$\mathcal{L}(\boldsymbol{\phi}) = \mathbb{E}_{q(\boldsymbol{\theta})}\big[\log p(\mathbf{x}, \boldsymbol{\theta})\big] - \mathbb{E}_{q(\boldsymbol{\theta})}\big[\log q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})\big]. \tag{2}$$

The first term is an expectation of the joint density under the approximation, and the second is the entropy of the variational density. The ELBO is equal to the negative KL divergence up to the constant $\log p(\mathbf{x})$. Maximizing the ELBO minimizes the KL divergence (Jordan et al., 1999; Bishop, 2006).

Optimizing the KL divergence implies a constraint that the support of the approximation $q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})$ lie within the support of the posterior $p(\boldsymbol{\theta} \mid \mathbf{x})$.[3] With this constraint made explicit, the optimization

3. If $\text{supp}(q) \not\subseteq \text{supp}(p)$ then outside the support of p we have $\text{KL}\left(q \parallel p\right) = \mathbb{E}_q[\log q] - \mathbb{E}_q[\log p] = \infty$.

problem from Equation (1) becomes

$$\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}\in\boldsymbol{\Phi}} \mathcal{L}(\boldsymbol{\phi}) \quad \text{such that} \quad \text{supp}(q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})) \subseteq \text{supp}(p(\boldsymbol{\theta} \mid \mathbf{x})). \tag{3}$$

We explicitly include this constraint because we have not specified the form of the variational approximation; we must ensure that $q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})$ stays within the support of the posterior.

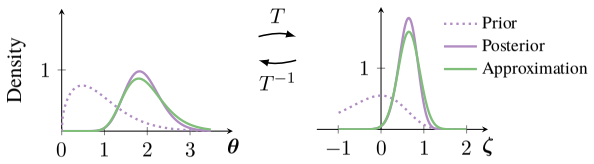
The support of the posterior, however, may also be unknown. So, we further assume that the support of the posterior equals that of the prior, $\text{supp}(p(\boldsymbol{\theta} \mid \mathbf{x})) = \text{supp}(p(\boldsymbol{\theta}))$. This is a benign assumption, which holds for most models considered in machine learning. In detail, it holds when the likelihood does not constrain the prior; i.e., the likelihood must be positive over the sample space for any $\boldsymbol{\theta}$ drawn from the prior.

Our recipe for automating VI. The traditional way of solving Equation (3) is difficult. We begin by choosing a variational family $q(\boldsymbol{\theta}\,;\,\boldsymbol{\phi})$ that, by definition, satisfies the support matching constraint. We compute the expectations in the ELBO, either analytically or through approximation. We then decide on a strategy to maximize the ELBO. For instance, we might use coordinate ascent by iteratively updating the components of $\boldsymbol{\phi}$. Or, we might follow gradients of the ELBO with respect to $\boldsymbol{\phi}$ while staying within $\boldsymbol{\Phi}$. Finally, we implement, test, and debug software that performs the above. Each step requires expert thought and analysis in the service of a single algorithm for a single model.

In contrast, our approach allows a user to define any differentiable probability model for which we automate the process of developing a corresponding VI algorithm. Our recipe for automating VI has three ingredients. First, we automatically transform the support of the latent variables $\boldsymbol{\theta}$ to the real coordinate space (Section 2.3); this lets us choose from a variety of variational distributions q without worrying about the support matching constraint (Section 2.4). Second, we compute the ELBO for any model using Monte Carlo (MC) integration, which only requires being able to sample from the variational distribution (Section 2.5). Third, we employ stochastic gradient ascent to maximize the ELBO and use automatic differentiation to compute gradients without any user input (Section 2.6). With these tools, we can develop a generic method that automatically solves the variational optimization problem for a large class of models.

2.3 Automatic Transformation of Constrained Variables

We begin by transforming the support of the latent variables $\boldsymbol{\theta}$ such that they live in the real coordinate space $\mathbb{R}^K$. Once we transform the joint density, we can choose the variational approximation independent of the model.



Define a one-to-one differentiable function

$$T : \text{supp}(p(\boldsymbol{\theta})) \to \mathbb{R}^K, \tag{4}$$

and identify the transformed variables as $\boldsymbol{\zeta} = T(\boldsymbol{\theta})$. The transformed joint density $p(\mathbf{x}, \boldsymbol{\zeta})$ is a function of $\boldsymbol{\zeta}$; it has the representation

$$p(\mathbf{x}, \boldsymbol{\zeta}) = p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|,$$

where $p(\mathbf{x}, \boldsymbol{\theta} = T^{-1}(\boldsymbol{\zeta}))$ is the joint density in the original latent variable space, and $J_{T^{-1}}(\boldsymbol{\zeta})$ is the Jacobian of the inverse of T. Transformations of continuous probability densities require a Jacobian; it accounts for how the transformation warps unit volumes and ensures that the transformed density integrates to one (Olive, 2014). (See Appendix A.)

(a) Latent variable space **(b)** Real coordinate space

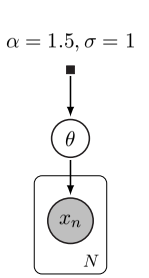
Figure 1: Transforming the latent variable to real coordinate space. The purple line is the posterior. The green line is the approximation. **(a)** The latent variable space is $\mathbb{R}_{>0}$. **(a→b)** T transforms the latent variable space to $\mathbb{R}$. **(b)** The variational approximation is a Gaussian in real coordinate space.

Consider again our Weibull-Poisson example from Section 2.1. The latent variable θ lives in $\mathbb{R}_{>0}$. The logarithm $\zeta = T(\theta) = \log(\theta)$ transforms $\mathbb{R}_{>0}$ to the real line $\mathbb{R}$. Its Jacobian adjustment is the derivative of the inverse of the logarithm $\left|\det J_{T^{-1}(\zeta)}\right| = \exp(\zeta)$. The transformed density is

$$p(x, \zeta) = \text{Poisson}(x \mid \exp(\zeta)) \times \text{Weibull}(\exp(\zeta) \mid 1.5, 1) \times \exp(\zeta).$$

Figures 1a and 1b depict this transformation.

As we describe in the introduction, we implement our algorithm in Stan (Stan Development Team, 2016). Stan maintains a library of transformations and their corresponding Jacobians. Specifically, it provides various transformations for upper and lower bounds, simplex and ordered vectors, and structured matrices such as covariance matrices and Cholesky factors. With Stan, we can automatically transform the joint density of any differentiable probability model to one with real-valued latent variables. (See Figure 2.)



2.4 Variational Approximations in Real Coordinate Space

After the transformation, the latent variables $\boldsymbol{\zeta}$ have support in the real coordinate space $\mathbb{R}^K$. We have a choice of variational approximations in this space. Here, we consider Gaussian distributions (Figure 1b); these implicitly induce non-Gaussian variational distributions in the original latent variable space (Figure 1a).

Mean-field Gaussian. One option is to posit a factorized (mean-field) Gaussian variational approximation

$$q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) = \text{Normal}\left(\boldsymbol{\zeta} \mid \boldsymbol{\mu}, \text{diag}(\boldsymbol{\sigma}^2)\right) = \prod_{k=1}^{K} \text{Normal}\left(\zeta_k \mid \mu_k, \sigma_k^2\right),$$

where the vector $\boldsymbol{\phi} = (\mu_1, \cdots, \mu_K, \sigma_1^2, \cdots, \sigma_K^2)$ concatenates the mean and variance of each Gaussian factor. Since the variance parameters must always be positive, the variational parameters live in the set $\boldsymbol{\Phi} = \{\mathbb{R}^K, \mathbb{R}^K_{>0}\}$. Re-parameterizing the mean-field Gaussian removes this constraint. Consider the logarithm of the standard deviations, $\boldsymbol{\omega} = \log(\boldsymbol{\sigma})$, applied element-wise. The support of $\boldsymbol{\omega}$ is now the real coordinate space and $\boldsymbol{\sigma}$ is always positive. The mean-field Gaussian becomes $q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) = \text{Normal}\left(\boldsymbol{\zeta} \mid \boldsymbol{\mu}, \text{diag}(\exp(\boldsymbol{\omega})^2)\right)$, where the vector $\boldsymbol{\phi} = (\mu_1, \cdots, \mu_K, \omega_1, \cdots, \omega_K)$ concatenates the mean and logarithm of the standard deviation of each factor. Now, the variational parameters are unconstrained in $\mathbb{R}^{2K}$.

```

  // likelihood
  for (n in 1:N)
    x[n] ~ poisson(theta);
}
```

Figure 2: Specifying a simple nonconjugate probability model in Stan.

Full-rank Gaussian. Another option is to posit a full-rank Gaussian variational approximation

$$q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) = \text{Normal}\left(\boldsymbol{\zeta} \mid \boldsymbol{\mu}, \boldsymbol{\Sigma}\right),$$

where the vector $\boldsymbol{\phi} = (\boldsymbol{\mu}, \boldsymbol{\Sigma})$ concatenates the mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. To ensure that $\boldsymbol{\Sigma}$ always remains positive semidefinite, we re-parameterize the covariance matrix using a Cholesky factorization, $\boldsymbol{\Sigma} = \mathbf{L}\mathbf{L}^\top$. We use the non-unique definition of the Cholesky factorization where the diagonal elements of $\mathbf{L}$ need not be positively constrained (Pinheiro and Bates, 1996). Therefore $\mathbf{L}$ lives in the unconstrained space of lower-triangular matrices with $K(K+1)/2$ real-valued entries. The full-rank Gaussian becomes $q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) = \text{Normal}\left(\boldsymbol{\zeta} \mid \boldsymbol{\mu}, \mathbf{L}\mathbf{L}^\top\right)$, where the variational parameters $\boldsymbol{\phi} = (\boldsymbol{\mu}, \mathbf{L})$ are unconstrained in $\mathbb{R}^{K+K(K+1)/2}$.

The full-rank Gaussian generalizes the mean-field Gaussian approximation. The off-diagonal terms in the covariance matrix $\boldsymbol{\Sigma}$ capture posterior correlations across latent random variables.[4] This leads to a more accurate posterior approximation than the mean-field Gaussian; however, it comes at a computational cost. Various low-rank approximations to the covariance matrix reduce this cost, yet limit its ability to model complex posterior correlations (Seeger, 2010; Challis and Barber, 2013).

The choice of a Gaussian. Choosing a Gaussian distribution may call to mind the Laplace approximation technique, where a second-order Taylor expansion around the maximum-a-posteriori estimate gives a Gaussian approximation to the posterior. However, using a Gaussian variational approximation is not equivalent to the Laplace approximation (Opper and Archambeau, 2009). Our approach is distinct in another way: the posterior approximation in the original latent variable space (Figure 1a) is non-Gaussian.

The implicit variational density. The transformation T from Equation (4) maps the support of the latent variables to the real coordinate space. Thus, its inverse T^{-1} maps back to the support of the latent variables. This implicitly defines the variational approximation in the original latent variable space as $q\left(T(\boldsymbol{\theta})\,;\,\boldsymbol{\phi}\right)\left|\det J_T(\boldsymbol{\theta})\right|$. The transformation ensures that the support of this approximation is always bounded by that of the posterior in the original latent variable space.

Sensitivity to T. There are many ways to transform the support a variable to the real coordinate space. The form of the transformation directly affects the shape of the variational approximation in the original latent variable space. We study sensitivity to the choice of transformation in Section 3.3.

4. This is a form of structured mean-field variational inference (Wainwright and Jordan, 2008; Barber, 2012).

2.5 The Variational Problem in Real Coordinate Space

Here is the story so far. We began with a differentiable probability model $p(\mathbf{x}, \boldsymbol{\theta})$. We transformed the latent variables into $\boldsymbol{\zeta}$, which live in the real coordinate space. We defined variational approximations in the transformed space. Now, we consider the variational optimization problem.

Write the variational objective function, the ELBO, in real coordinate space as

$$\mathcal{L}(\boldsymbol{\phi}) = \mathbb{E}_{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})}\left[\log p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) + \log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right] + \mathbb{H}\big[q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})\big]. \tag{5}$$

The inverse of the transformation T^{-1} appears in the joint model, along with the determinant of the Jacobian adjustment. The ELBO is a function of the variational parameters $\boldsymbol{\phi}$ and the entropy $\mathbb{H}$, both of which depend on the variational approximation. (Derivation in Appendix B.)

Now, we can freely optimize the ELBO in the real coordinate space without worrying about the support matching constraint. The optimization problem from Equation (3) becomes

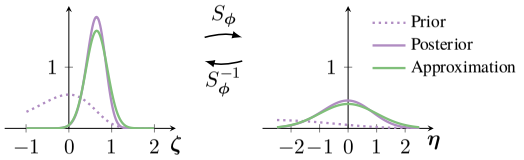
$$\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}} \mathcal{L}(\boldsymbol{\phi}) \tag{6}$$

where the parameter vector $\boldsymbol{\phi}$ lives in some appropriately dimensioned real coordinate space. This is an unconstrained optimization problem that we can solve using gradient ascent. Traditionally, this would require manual computation of gradients. Instead, we develop a stochastic gradient ascent algorithm that uses automatic differentiation to compute gradients and MC integration to approximate intractable expectations.

We cannot directly use automatic differentiation on the ELBO. This is because the ELBO involves an intractable expectation. However, we can automatically differentiate the functions inside the expectation. (The model p and transformation T are both easy to represent as computer functions (Baydin et al., 2015).) To apply automatic differentiation, we want to push the gradient operation inside the expectation. To this end, we employ one final transformation: elliptical standardization[5] (Härdle and Simar, 2012).

Elliptical standardization. Consider a transformation $S_{\boldsymbol{\phi}}$ that absorbs the variational parameters $\boldsymbol{\phi}$; this converts the Gaussian variational approximation into a standard Gaussian. In the mean-field case, the standardization is $\boldsymbol{\eta} = S_{\boldsymbol{\phi}}(\boldsymbol{\zeta}) = \operatorname{diag}\left(\exp\left(\boldsymbol{\omega}\right)\right)^{-1}\left(\boldsymbol{\zeta} - \boldsymbol{\mu}\right)$. In the full-rank Gaussian, the standardization is $\boldsymbol{\eta} = S_{\boldsymbol{\phi}}(\boldsymbol{\zeta}) = \mathbf{L}^{-1}(\boldsymbol{\zeta} - \boldsymbol{\mu})$.

In both cases, the standardization encapsulates the variational parameters; in return it gives a fixed variational density



$$q(\boldsymbol{\eta}) = \text{Normal}\left(\boldsymbol{\eta} \mid \mathbf{0}, \mathbf{I}\right) = \prod_{k=1}^{K} \text{Normal}\left(\eta_k \mid 0, 1\right),$$

as shown in Figures 3a and 3b.

The standardization transforms the variational problem from Equation (5) into

$$\boldsymbol{\phi}^* = \arg\max_{\boldsymbol{\phi}} \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta}\,;\,\mathbf{0},\mathbf{I})}\left[\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right] + \mathbb{H}\big[q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})\big].$$

5. Also known as a "coordinate transformation" (Rezende et al., 2014), an "invertible transformation" (Titsias and Lázaro-Gredilla, 2014), and the "re-parameterization trick" (Kingma and Welling, 2014).

(a) Real coordinate space **(b)** Standardized space

Figure 3: Elliptical standardization. The purple line is the posterior. The green line is the approximation. **(a)** The variational approximation is a Gaussian in real coordinate space. **(a→b)** $S_{\boldsymbol{\phi}}$ absorbs the parameters of the Gaussian. **(b)** We maximize the ELBO in the standardized space, with a fixed approximation. The green line is a standard Gaussian.

The expectation is now in terms of a standard Gaussian density. The Jacobian of elliptical standardization evaluates to one, because the Gaussian distribution is a member of the location-scale family: standardizing a Gaussian gives another Gaussian distribution. (See Appendix A.)

We do not need to transform the entropy term as it does not depend on the model or the transformation; we have a simple analytic form for the entropy of a Gaussian and its gradient. We implement these once and reuse for all models.

2.6 Stochastic Optimization

We now reach the final step: stochastic optimization of the variational objective function.

Computing gradients. Since the expectation is no longer dependent on $\boldsymbol{\phi}$, we can directly calculate its gradient. Push the gradient inside the expectation and apply the chain rule to get

$$\nabla_{\boldsymbol{\mu}}\mathcal{L} = \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta})}\left[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta}) \nabla_{\boldsymbol{\zeta}} T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}} \log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right]. \tag{7}$$

We obtain gradients with respect to $\boldsymbol{\omega}$ (mean-field) and $\mathbf{L}$ (full-rank) in a similar fashion

$$\nabla_{\boldsymbol{\omega}}\mathcal{L} = \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta})}\left[\left(\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta}) \nabla_{\boldsymbol{\zeta}} T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}} \log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right) \boldsymbol{\eta}^\top \operatorname{diag}(\exp(\boldsymbol{\omega}))\right] + \mathbf{1} \tag{8}$$

$$\nabla_{\mathbf{L}}\mathcal{L} = \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta})}\left[\left(\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, \boldsymbol{\theta}) \nabla_{\boldsymbol{\zeta}} T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}} \log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right) \boldsymbol{\eta}^\top\right] + (\mathbf{L}^{-1})^\top. \tag{9}$$

(Derivations in Appendix C.)

We can now compute the gradients inside the expectation with automatic differentiation. The only thing left is the intractable expectation. MC integration provides a simple approximation: draw samples from the standard Gaussian and evaluate the empirical mean of the gradients within the expectation (Appendix D). In practice a single sample suffices. (We study this in detail in Section 3.2 and in the experiments in Section 4.)

This gives noisy unbiased gradients of the ELBO for any differentiable probability model. We can use these gradients in a stochastic optimization routine to automate variational inference.

Stochastic gradient ascent. Equipped with noisy unbiased gradients of the ELBO, ADVI implements stochastic gradient ascent (Algorithm 1). This algorithm is guaranteed to converge to a local maximum of the ELBO under certain conditions on the step-size sequence.[6] Stochastic gradient ascent falls

6. This is also called a *learning rate* or *schedule* in the machine learning community.

Algorithm 1: Automatic differentiation variational inference (ADVI)

Input: Dataset $\mathbf{x} = x_{1:N}$, model $p(\mathbf{x}, \boldsymbol{\theta})$.
Set iteration counter $i = 1$.
Initialize $\boldsymbol{\mu}^{(1)} = \mathbf{0}$.
Initialize $\boldsymbol{\omega}^{(1)} = \mathbf{0}$ (mean-field) or $\mathbf{L}^{(1)} = \mathbf{I}$ (full-rank).
Determine η via a search over finite values.
while *change in* ELBO *is above some threshold* **do**
  Draw M samples $\boldsymbol{\eta}_m \sim \text{Normal}(\mathbf{0}, \mathbf{I})$ from the standard multivariate Gaussian.
  Approximate $\nabla_{\boldsymbol{\mu}}\mathcal{L}$ using MC integration (Equation (7)).
  Approximate $\nabla_{\boldsymbol{\omega}}\mathcal{L}$ or $\nabla_{\mathbf{L}}\mathcal{L}$ using MC integration (Equations (8) and (9)).
  Calculate step-size $\boldsymbol{\rho}^{(i)}$ (Equation (10)).
  Update $\boldsymbol{\mu}^{(i+1)} \longleftarrow \boldsymbol{\mu}^{(i)} + \text{diag}(\boldsymbol{\rho}^{(i)})\nabla_{\boldsymbol{\mu}}\mathcal{L}$.
  Update $\boldsymbol{\omega}^{(i+1)} \longleftarrow \boldsymbol{\omega}^{(i)} + \text{diag}(\boldsymbol{\rho}^{(i)})\nabla_{\boldsymbol{\omega}}\mathcal{L}$ or $\mathbf{L}^{(i+1)} \longleftarrow \mathbf{L}^{(i)} + \text{diag}(\boldsymbol{\rho}^{(i)})\nabla_{\mathbf{L}}\mathcal{L}$.
  Increment iteration counter.
end
Return $\boldsymbol{\mu}^* \longleftarrow \boldsymbol{\mu}^{(i)}$.
Return $\boldsymbol{\omega}^* \longleftarrow \boldsymbol{\omega}^{(i)}$ or $\mathbf{L}^* \longleftarrow \mathbf{L}^{(i)}$.

under the class of stochastic approximations, where Robbins and Monro (1951) established a pair of conditions that ensure convergence. Many sequences satisfy these criteria, but their specific forms impact the success of stochastic gradient ascent in practice. We describe an adaptive step-size sequence for ADVI below.

Adaptive step-size sequence. Adaptive step-size sequences retain (possibly infinite) memory about past gradients and adapt to the high-dimensional curvature of the ELBO optimization space (Amari, 1998; Duchi et al., 2011; Ranganath et al., 2013; Kingma and Adam, 2015). These sequences enjoy theoretical bounds on their convergence rates. However, in practice, they can be slow to converge. The empirically justified RMSPROP sequence (Tieleman and Hinton, 2012) converges quickly in practice but lacks any convergence guarantees. We propose a new step-size sequence which effectively combines both approaches.

Consider the step-size $\boldsymbol{\rho}^{(i)}$ and a gradient vector $\mathbf{g}^{(i)}$ at iteration i. We define the kth element of $\boldsymbol{\rho}^{(i)}$ as

$$\rho_k^{(i)} = \eta \times i^{-1/2+\epsilon} \times \left(\tau + \sqrt{s_k^{(i)}}\right)^{-1}, \tag{10}$$

where we apply the following recursive update

$$s_k^{(i)} = \alpha g_k^{2(i)} + (1-\alpha)s_k^{(i-1)}, \tag{11}$$

with an initialization of $s_k^{(1)} = g_k^{2(1)}$.

The first factor $\eta \in \mathbb{R}_{>0}$ controls the scale of the step-size sequence. It mainly affects the beginning of the optimization. We adaptively tune η by searching over $\eta \in \{0.01, 0.1, 1, 10, 100\}$ using a subset of the data and selecting the value that leads to the fastest convergence (Bottou, 2012).

The middle term $i^{-1/2+\epsilon}$ decays as a function of the iteration i. We set $\epsilon = 10^{-16}$, a small value that guarantees that the step-size sequence satisfies the Robbins and Monro (1951) conditions.

The last term adapts to the curvature of the ELBO optimization space. Memory about past gradients are processed in Equation (11). The weighting factor $\alpha \in (0, 1)$ defines a compromise of old and new gradient information, which we set to 0.1. The quantity s_k converges to a non-zero constant. Without the previous decaying term, this would lead to possibly large oscillations around a local optimum of the ELBO. The additional perturbation $\tau > 0$ prevents division by zero and down-weights early iterations. In practice the step-size is not sensitive to this value (Hoffman et al., 2013), so we set $\tau = 1$.

Complexity and data subsampling. ADVI has complexity $\mathcal{O}(NMK)$ per iteration, where N is the number of data points, M is the number of MC samples (typically between 1 and 10), and K is the number of latent variables. Classical VI which hand-derives a coordinate ascent algorithm has complexity $\mathcal{O}(NK)$ per pass over the dataset. The added complexity of automatic differentiation over analytic gradients is roughly constant (Carpenter et al., 2015; Baydin et al., 2015).

We scale ADVI to large datasets using stochastic optimization with data subsampling (Hoffman et al., 2013; Titsias and Lázaro-Gredilla, 2014). The adjustment to Algorithm 1 is simple: sample a minibatch of size $B \ll N$ from the dataset and scale the likelihood of the model by N/B (Hoffman et al., 2013). The stochastic extension of ADVI has a per-iteration complexity $\mathcal{O}(BMK)$.

In Sections 4.3 and 4.4, we apply this stochastic extension to analyze datasets with hundreds of thousands to millions of observations.

2.7 Related Work

ADVI is an automatic variational inference algorithm, implemented within the Stan probabilistic programming system. This draws on two major themes.

Probabilistic programming. The first theme is probabilistic programming. One class of systems focuses on probabilistic models where the user specifies a joint probability distribution. Some examples are BUGS (Spiegelhalter et al., 1995), JAGS (Plummer, 2003), and Stan (Stan Development Team, 2016). Another class of systems allows the user to directly specify probabilistic programs that may not admit a closed form probability distribution. Some examples are Church (Goodman et al., 2008), Figaro (Pfeffer, 2009), Venture (Mansinghka et al., 2014), Anglican (Wood et al., 2014), and WebPPL (Goodman and Stuhlmüller, 2014). Both classes primarily rely on various forms of MCMC sampling for inference.

Variational inference. The second is a body of work that generalizes variational inference. Ranganath et al. (2014) and Salimans and Knowles (2014) propose a black box technique that only requires computing gradients of the variational approximating family. Kingma and Welling (2014) and Rezende et al. (2014) describe a reparameterization of the variational problem that simplifies optimization. Titsias and Lázaro-Gredilla (2014) leverage the gradient of the model for a class of real-valued models. Rezende and Mohamed (2015), Ranganath et al. (2016) and Tran et al. (2016b) improve the accuracy of black box variational approximations. Here we build on and extend these ideas to

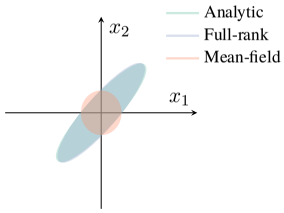
automate variational inference; we highlight technical connections as we study the properties of ADVI in Section 3.

Some notable work crosses both themes. Bishop et al. (2002) present an automated variational algorithm for graphical models with conjugate exponential relationships between all parent-child pairs. Winn and Bishop (2005) and Minka et al. (2014) extend this to graphical models with non-conjugate relationships by either using custom approximations or sampling. ADVI automatically supports a more comprehensive class of nonconjugate models; see Section 2.1. Wingate and Weber (2013) study a more general setting, where the variational approximation itself is a probabilistic program.

Automatic differentiation. Automatic differentiation and machine learning enjoy a colorful and intertwined history (Baydin et al., 2015). For example, the backpropagation algorithm, rediscovered independently many times, is a form of automatic differentiation for neural network weights (Widrow and Lehr, 1990). Similarly, researchers have applied automatic differentiation to specific models, such as extended Kalman filters (Meyer et al., 2003) and computer vision models (Pock et al., 2007). Automatic differentiation also appears in recent variational inference research. For instance, the Bayes-by-backprop algorithm is a specific application of automatic differentiation to variational inference in Bayesian neural networks (Blundell et al., 2015). Many of the methods described above could, if applicable, use automatic differentiation to compute gradients of the model and the variational approximating families.

Software. ADVI can also be implemented in other general-purpose software frameworks, such as autograd (Maclaurin et al., 2015), Theano (Theano Development Team, 2016) and TensorFlow (Abadi et al., 2016). These frameworks offer features such as symbolic or automatic differentiation and abstractions for parallel computation. Two other implementations of ADVI are available, at the time of publication. The first is in PyMC3 (Salvatier et al., 2016), a probabilistic programming package, that implements ADVI in Python using Theano. The second is in Edward (Tran et al., 2016a), a Python library for probabilistic modeling, inference, and criticism, that implements ADVI in Python using TensorFlow.

3. Properties of Automatic Differentiation Variational Inference



Automatic differentiation variational inference (ADVI) extends classical variational inference techniques in a few directions. In this section, we use simulated data to study three aspects of ADVI: the accuracy of mean-field and full-rank approximations, the variance of the ADVI gradient estimator, and the sensitivity to the transformation T.

3.1 Accuracy

We begin by considering three models that expose how the mean-field approximation affects the accuracy of ADVI.

Two-dimensional Gaussian. We first study a simple model that does not require approximate inference. Consider a multivariate Gaussian likelihood $\text{Normal}(\mathbf{y} \mid \boldsymbol{\mu}, \boldsymbol{\Sigma})$ with fixed, yet highly correlated, covariance $\boldsymbol{\Sigma}$; our goal is to estimate the mean $\boldsymbol{\mu}$. If we place a multivariate Gaussian prior on $\boldsymbol{\mu}$ then the posterior is also a Gaussian that we can compute analytically (Bernardo and Smith, 2009).

We draw 1000 datapoints from the model and run both variants of ADVI, mean-field and full-rank, until convergence. Figure 4 compares the ADVI methods to the exact posterior. Both procedures correctly identify the mean of the analytic posterior. However, the shape of the mean-field approximation is incorrect. This is because the mean-field approximation ignores off-diagonal terms of the Gaussian covariance. ADVI minimizes the KL divergence from the approximation to the exact posterior; this leads to a systemic underestimation of marginal variances (Bishop, 2006).

	Analytic	Full-rank	Mean-field
Variance along x_1	0.28	0.28	0.13
Variance along x_2	0.31	0.31	0.14

Figure 4: Comparison of mean-field and full-rank ADVI on a two-dimensional Gaussian model. The figure shows the accuracy of the full-rank approximation. Ellipses correspond to two-sigma level sets of the Gaussian. The table quantifies the underestimation of marginal variances by the mean-field approximation.

Logistic regression. We now study a model for which we need approximate inference. Consider logistic regression, a generalized linear model with a binary response y, covariates $\mathbf{x}$, and likelihood $\text{Bern}(y \mid \text{logit}^{-1}(\mathbf{x}^\top \boldsymbol{\beta}))$; our goal is to estimate the coefficients $\boldsymbol{\beta}$. We place an independent Gaussian prior on each regression coefficient.

We simulated 9 random covariates from the prior distribution (plus a constant intercept) and drew 1000 datapoints from the likelihood. We estimated the posterior of the coefficients with ADVI and Stan's default MCMC technique, the no-U-turn sampler (NUTS) (Hoffman and Gelman, 2014). Figure 5 shows the marginal posterior densities obtained from each approximation. MCMC and ADVI perform similarly in their estimates of the posterior mean. The mean-field approximation, as expected, underestimates marginal posterior variances on most of the coefficients. The full-rank approximation, once again, better matches the posterior.

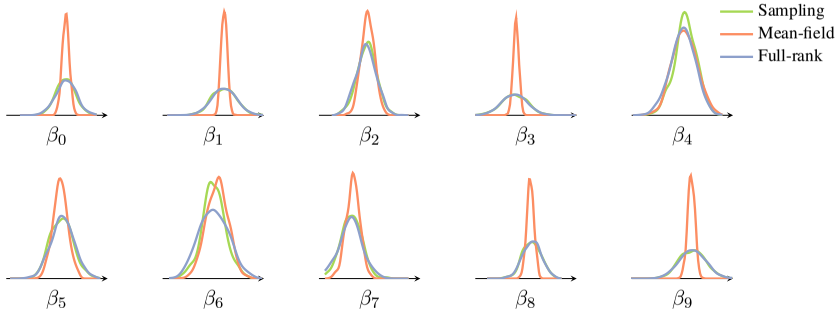


Figure 5: Comparison of marginal posterior densities for a logistic regression model. Each plot shows kernel density estimates for the posterior of each coefficient using 1000 samples. Mean-field ADVI underestimates variances for most of the coefficients.

Stochastic volatility time-series model. Finally, we study a model where the data are not exchangeable. Consider an autoregressive process to model how the latent volatility (i.e., variance) of an economic asset changes over time (Kim et al., 1998); our goal is to estimate the sequence of volatilities. We expect these posterior estimates to be correlated, especially when the volatilities trend away from their mean value.

In detail, the price data exhibit latent volatility as part of the variance of a zero-mean Gaussian

$$y_t \sim \text{Normal}\left(0, \exp(h_t/2)\right)$$

where the log volatility follows an auto-regressive process

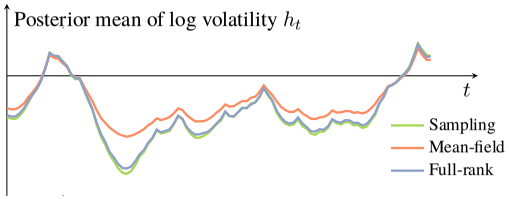
$$h_t \sim \text{Normal}\left(\mu + \phi(h_{t-1} - \mu), \sigma\right) \quad \text{with initialization} \quad h_1 \sim \text{Normal}\left(\mu, \frac{\sigma}{\sqrt{1-\phi^2}}\right).$$

We place the following priors on the latent variables

$$\mu \sim \text{Cauchy}(0, 10), \quad \phi \sim \text{Unif}(-1, 1), \quad \text{and} \quad \sigma \sim \text{Lognormal}(0, 10).$$

We set $\mu = -1.025$, $\phi = 0.9$ and $\sigma = 0.6$, and simulate a dataset of 500 time-steps from the generative model above. Figure 6 plots the posterior mean of the log volatility h_t as a function of time. Mean-field ADVI struggles to describe the mean of the posterior, particularly when the log volatility drifts far away from μ. This is expected behavior for a mean-field approximation to a time-series model (Turner and Sahani, 2008). In contrast, full-rank ADVI matches the estimates obtained from sampling.

We further investigate this by studying posterior correlations of the log volatility sequence. We draw $S = 1000$ samples of 500-dimensional log volatility sequences $\{\mathbf{h}^{(s)}\}_1^S$. Figure 7 shows the empirical posterior covariance matrix, $1/S-1 \sum_s (\mathbf{h}^{(s)} - \overline{\mathbf{h}})(\mathbf{h}^{(s)} - \overline{\mathbf{h}})^\top$ for each method. The mean-field covariance (fig. 7a) fails to capture the locally correlated structure of the full-rank and sampling covariance matrices (figs. 7b and 7c). All covariance matrices exhibit a blurry spread due to finite sample size.



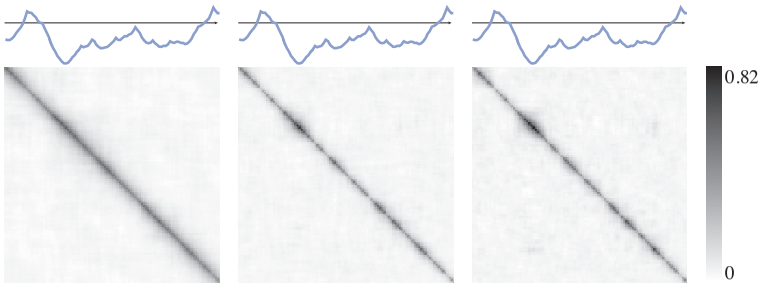


Figure 6: Comparison of posterior mean estimates of volatility h_t. Mean-field ADVI underestimates h_t, especially when it moves far away from its mean μ. Full-rank ADVI matches the accuracy of sampling.

The regions where the local correlation is strongest correspond to the regions where mean-field underestimates the log volatility. To help identify these regions, we overlay the sampling mean log volatility estimate from Figure 6 above each matrix. Both full-rank ADVI and sampling results exhibit correlation where the log volatility trends away from its mean value.

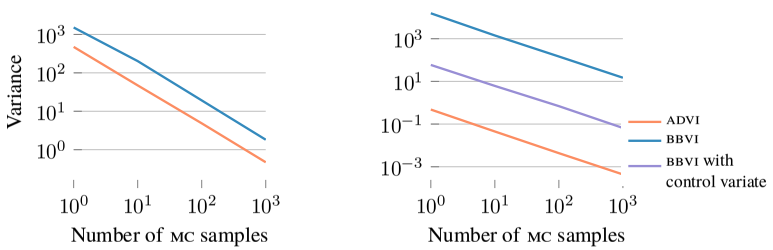
(a) Mean-field **(b)** Full-rank **(c)** Sampling

Figure 7: Comparison of empirical posterior covariance matrices. The mean-field ADVI covariance matrix fails to capture the local correlation structure seen in the full-rank ADVI and sampling results. All covariance matrices exhibit a blurry spread due to finite sample size.

Recommendations. How to choose between full-rank and mean-field ADVI? Scientists interested in posterior variances and covariances should use the full-rank approximation. Full-rank ADVI captures posterior correlations, in turn producing more accurate marginal variance estimates. For large data, however, full-rank ADVI can be prohibitively slow.

Scientists interested in prediction should initially rely on the mean-field approximation. Mean-field ADVI offers a fast algorithm for approximating the posterior mean. In practice, accurate posterior mean estimates dominate predictive accuracy; underestimated marginal variances matters less.

3.2 Variance of the Stochastic Gradients



ADVI uses Monte Carlo integration to approximate gradients of the ELBO, and then uses these gradients in a stochastic optimization algorithm (Section 2). The speed of ADVI hinges on the variance of the gradient estimates. When a stochastic optimization algorithm suffers from high-variance gradients, it must repeatedly recover from poor parameter estimates.

ADVI is not the only way to compute Monte Carlo approximations of the gradient of the ELBO. Black box variational inference (BBVI) takes a different approach (Ranganath et al., 2014). The BBVI gradient estimator uses the gradient of the variational approximation and avoids using the gradient of the model. For example, the following BBVI estimator

$$\nabla_{\boldsymbol{\mu}}^{\text{BBVI}} \mathcal{L} = \mathbb{E}_{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})}\left[\nabla_{\boldsymbol{\mu}} \log q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \left\{\log p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) + \log \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right| - \log q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})\right\}\right]$$

and the ADVI gradient estimator in Equation (7) both lead to unbiased estimates of the exact gradient. While BBVI is more general—it does not require the gradient of the model and thus applies to more settings—its gradients can suffer from high variance.

Figure 8 empirically compares the variance of both estimators for two models. Figure 8a shows the variance of both gradient estimators for a simple univariate model, where the posterior is a Gamma$(10, 10)$. We estimate the variance using ten thousand re-calculations of the gradient $\nabla_\phi \mathcal{L}$, across an increasing number of MC samples M. The ADVI gradient has lower variance; in practice, a single sample suffices. (See the experiments in Section 4.)

(a) Univariate Model **(b)** Multivariate Nonlinear Regression Model

Figure 8: Comparison of gradient estimator variances. The ADVI gradient estimator exhibits lower variance than the BBVI estimator. Moreover, it does not require control variate variance reduction, which is not available in univariate situations.

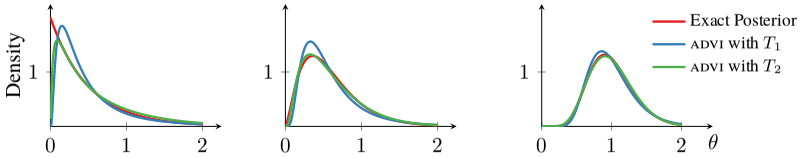
Figure 8b shows the same calculation for a 100-dimensional nonlinear regression model with likelihood $\text{Normal}(\mathbf{y} \mid \tanh(\mathbf{x}^\top \boldsymbol{\beta}), \mathbf{I})$ and a Gaussian prior on the regression coefficients $\boldsymbol{\beta}$. Because this is a multivariate example, we also show the BBVI gradient with a variance reduction scheme using control variates described in Ranganath et al. (2014). In both cases, the ADVI gradient is more sample efficient.

3.3 Sensitivity to Transformations

ADVI uses a transformation T from the unconstrained space to the constrained space. We now study how the choice of this transformation affects the non-Gaussian posterior approximation in the original latent variable space.

Consider a posterior density in the Gamma family, with support over $\mathbb{R}_{>0}$. Figure 9 shows three configurations of the Gamma, ranging from $\text{Gamma}(1, 2)$, which places most of its mass close to $\theta = 0$, to $\text{Gamma}(10, 10)$, which is centered at $\theta = 1$. Consider two transformations T_1 and T_2

$$T_1 : \theta \mapsto \log(\theta) \quad \text{and} \quad T_2 : \theta \mapsto \log(\exp(\theta) - 1),$$



both of which map $\mathbb{R}_{>0}$ to $\mathbb{R}$. ADVI can use either transformation to approximate the Gamma posterior. Which one is better?

Figures 9a to 9c show the ADVI approximation under both transformations. Table 2 reports the corresponding KL divergences. Both graphical and numerical results prefer T_2 over T_1. A quick analysis corroborates this. T_1 is the logarithm, which flattens out for large values. However, T_2 is almost linear for large values of θ. Since both the Gamma (the posterior) and the Gaussian (the ADVI approximation) densities are light-tailed, T_2 is the preferable transformation.

Is there an optimal transformation? Without loss of generality, we consider fixing a standard Gaussian distribution in the real coordinate space.[7] The optimal transformation is then

$$T^* = \Phi^{-1} \circ P(\boldsymbol{\theta} \mid \mathbf{x})$$

7. For two transformations T_1 and T_2 from latent variable space to real coordinate space, there always exists a transformation T_3 within the real coordinate space such that $T_1(\theta) = T_3(T_2(\theta))$.

(a) $\text{Gamma}(1, 2)$ **(b)** $\text{Gamma}(2.5, 4.2)$ **(c)** $\text{Gamma}(10, 10)$

Figure 9: ADVI approximations to Gamma densities under two different transformations.

	$\text{Gamma}(1, 2)$	$\text{Gamma}(2.5, 4.2)$	$\text{Gamma}(10, 10)$
KL $(q \parallel p)$ with T_1	8.1×10^{-2}	3.3×10^{-2}	8.5×10^{-3}
KL $(q \parallel p)$ with T_2	1.6×10^{-2}	3.6×10^{-3}	7.7×10^{-4}

Table 2: KL divergence of ADVI approximations to Gamma densities for two transformations.

where P is the cumulative density function of the posterior and Φ^{-1} is the inverse cumulative density function of the standard Gaussian. P maps the posterior to a uniform distribution and Φ^{-1} maps the uniform distribution to the standard Gaussian. The optimal choice of transformation enables the Gaussian variational approximation to be exact. Sadly, estimating the optimal transformation requires estimating the cumulative density function of the posterior $P(\boldsymbol{\theta} \mid \mathbf{x})$; this is just as hard as the original goal of estimating the posterior density $p(\boldsymbol{\theta} \mid \mathbf{x})$.

This observation motivates pairing transformations with Gaussian variational approximations; there is no need for more complex variational families. ADVI takes the approach of using a library and a model compiler. This is not the only option. For example, Knowles (2015) posits a factorized Gamma density for positively constrained latent variables. In theory, this is equivalent to a mean-field Gaussian density paired with the transformation $T = P_{\text{Gamma}}$, the cumulative density function of the Gamma. (In practice, P_{Gamma} is difficult to compute.) Challis and Barber (2012) study Fourier transform techniques for location-scale variational approximations beyond the Gaussian. Another option is to learn the transformation during optimization. We discuss recent approaches in this direction in Section 5.

4. ADVI in Practice

We now apply ADVI to an array of nonconjugate probability models. With simulated and real data, we study linear regression with automatic relevance determination, hierarchical logistic regression, several variants of non-negative matrix factorization, mixture models, and probabilistic principal component analysis. We compare mean-field ADVI to two MCMC sampling algorithms: Hamiltonian Monte Carlo (HMC) (Neal, 2011) and the no-U-turn sampler (NUTS) (Hoffman and Gelman, 2014). NUTS is an adaptive extension of HMC and the default sampler in Stan.

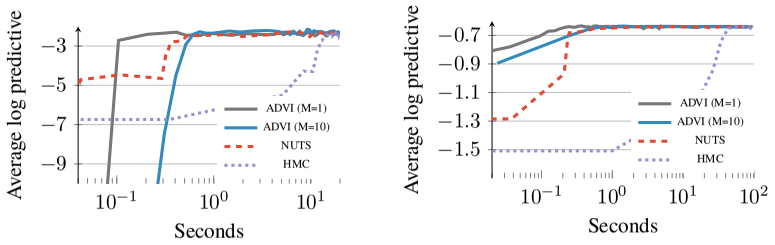
To place ADVI and MCMC on a common scale, we report predictive likelihood on held-out data as a function of computation time. Specifically, we estimate the predictive likelihood

$$p(\mathbf{x}_{\text{held-out}} \mid \mathbf{x}) = \int p(\mathbf{x}_{\text{held-out}} \mid \boldsymbol{\theta}) p(\boldsymbol{\theta} \mid \mathbf{x}) \, \mathrm{d}\boldsymbol{\theta}$$

using Monte Carlo estimation. With MCMC, we run the chain and plug in each sample to estimate the integral above; with ADVI, we draw a sample from the variational approximation at every iteration.

We conclude with a case study: an exploratory analysis of over a million taxi rides. Here we show how a scientist might use ADVI in practice.

4.1 Hierarchical Regression Models



We begin with two nonconjugate regression models: linear regression with automatic relevance determination (ARD) (Bishop, 2006) and hierarchical logistic regression (Gelman and Hill, 2006).

Linear regression with ARD. This is a linear regression model with a hierarchical prior structure that leads to sparse estimates of the coefficients. (Details in Appendix F.1.) We simulate a dataset with 250 regressors such that half of the regressors have no predictive power. We use 10 000 data points for training and withhold 1000 for evaluation.

Logistic regression with a spatial hierarchical prior. This is a hierarchical logistic regression model from political science. The prior captures dependencies, such as states and regions, in a polling dataset from the United States 1988 presidential election (Gelman and Hill, 2006). The model is nonconjugate and would require some form of approximation to derive a classical VI algorithm. (Details in Appendix F.2.)

The dataset includes 145 regressors, with age, education, and state and region indicators. We use 10 000 data points for training and withhold 1536 for evaluation.

Results. Figure 10 plots average log predictive accuracy as a function of time. For these simple models, all methods reach the same predictive accuracy. We study ADVI with two settings of M, the number of MC samples used to estimate gradients. A single sample per iteration is sufficient; it is also the fastest. (We set $M = 1$ from here on.)

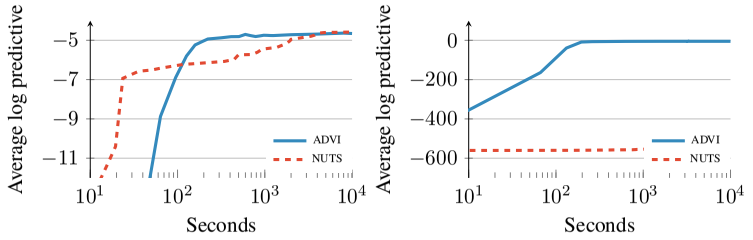
(a) Linear regression with ARD

(b) Hierarchical logistic regression

Figure 10: Held-out predictive accuracy results | hierarchical generalized linear models on simulated and real data.

4.2 Non-negative Matrix Factorization

We continue by exploring two nonconjugate non-negative matrix factorization models (Lee and Seung, 1999): a constrained Gamma Poisson model (Canny, 2004) and a Dirichlet Exponential Poisson model. Here, we show how easy it is to explore new models using ADVI. In both models, we use the



Frey Faces dataset, which contains 1956 frames (28×20 pixels) of facial expressions extracted from a video sequence.

Constrained Gamma Poisson. This is a Gamma Poisson matrix factorization model with an ordering constraint: each row of one of the Gamma factors goes from small to large values. (Details in Appendix F.3.)

Dirichlet Exponential Poisson. This is a nonconjugate Dirichlet Exponential factorization model with a Poisson likelihood. (Details in Appendix F.4.)

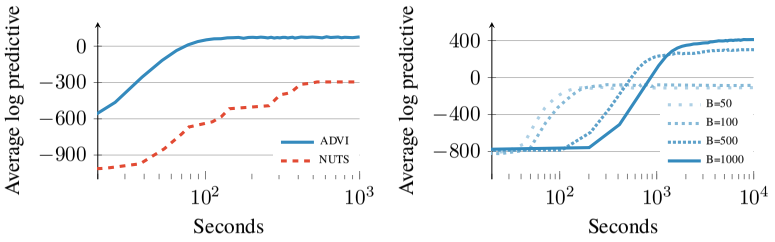
Results. Figure 11 shows average log predictive accuracy as well as ten factors recovered from both models. ADVI provides an order of magnitude speed improvement over NUTS (Figure 11a). NUTS struggles with the Dirichlet Exponential model (Figure 11b). In both cases, HMC does not produce any useful samples within a budget of one hour; we omit HMC from here on.

The Gamma Poisson model (Figure 11c) appears to pick significant frames out of the dataset. The Dirichlet Exponential factors (Figure 11d) are sparse and indicate components of the face that move, such as eyebrows, cheeks, and the mouth.

(a) Gamma Poisson predictive likelihood

(b) Dirichlet exponential predictive likelihood

(c) Gamma Poisson factors



(d) Dirichlet exponential factors

Figure 11: Held-out predictive accuracy results | two non-negative matrix factorization models applied to the Frey Faces dataset.

4.3 Gaussian Mixture Model

This is a nonconjugate Gaussian mixture model (GMM) applied to color image histograms. We place a Dirichlet prior on the mixture proportions, a Gaussian prior on the component means, and a lognormal prior on the standard deviations. (Details in Appendix F.5.) We explore the imageCLEF dataset, which has 250 000 images (Villegas et al., 2013). We withhold 10 000 images for evaluation.

In Figure 12a we randomly select 1000 images and train a model with 10 mixture components. ADVI quickly finds a good solution. NUTS struggles to find an adequate solution and HMC fails altogether

(a) Subset of 1000 images **(b)** Full dataset of 250 000 images

Figure 12: Held-out predictive accuracy results | GMM of the imageCLEF image histogram dataset. **(a)** ADVI outperforms NUTS (Hoffman and Gelman, 2014). **(b)** ADVI scales to large datasets by subsampling minibatches of size B from the dataset at each iteration (Hoffman et al., 2013).

(not shown). This is likely due to label switching, which can affect HMC-based algorithms in mixture models (Stan Development Team, 2016).

Figure 12b shows ADVI results on the full dataset. We increase the number of mixture components to 30. Here we use ADVI, with additional stochastic subsampling of minibatches from the data (Hoffman et al., 2013). With a minibatch size of 500 or larger, ADVI reaches high predictive accuracy. Smaller minibatch sizes lead to suboptimal solutions, an effect also observed in Hoffman et al. (2013). ADVI converges in about two hours; NUTS cannot handle such large datasets.

4.4 A Case Study: Exploring Millions of Taxi Trajectories

How might a scientist use ADVI in practice? How easy is it to develop and revise new models? To answer these questions, we apply ADVI to a modern exploratory data analysis task: analyzing traffic patterns. In this section, we demonstrate how ADVI enables a scientist to quickly develop and revise complex hierarchical models.

The city of Porto has a centralized taxi system of 442 cars. When serving customers, each taxi reports its spatial location at 15 second intervals; this sequence of (x, y) coordinates describes the trajectory and duration of each trip. A dataset of trajectories is publicly available: it contains all 1.7 million taxi rides taken during the year 2014 (European Conference of Machine Learning, 2015).

To gain insight into this dataset, we wish to cluster the trajectories. The first task is to process the raw data. Each trajectory has a different length: shorter trips contain fewer (x, y) coordinates than longer ones. The average trip is approximately 13 minutes long, which corresponds to 50 coordinates. We want to cluster independent of length, so we interpolate all trajectories to 50 coordinate pairs. This converts each trajectory into a point in $\mathbb{R}^{100}$.

The trajectories have structure; for example, major roads and highways appear frequently. This motivates an approach where we first identify a lower-dimensional representation of the data to capture aggregate features, and then we cluster the trajectories in this representation. This is easier than clustering them in the original data space.

We begin with simple dimension reduction: probabilistic principal component analysis (PPCA) (Bishop, 2006). This is a Bayesian generalization of classical principal component analysis, which

is easy to write in Stan. However, like its classical counterpart, PPCA does not identify how many principal components to use for the subspace. To address this, we propose an extension: PPCA with automatic relevance determination (ARD).

PPCA with ARD identifies the latent dimensions that are most effective at explaining variation in the data. The strategy is similar to that in Section 4.1. We assume that there are 100 latent dimensions (i.e., the same dimension as the data) and impose a hierarchical prior that encourages sparsity. Consequently, the model only uses a subset of the latent dimensions to describe the data. (Details in Appendix F.6.)

We randomly subsample ten thousand trajectories and use ADVI to infer a subspace. Figure 13 plots the progression of the ELBO. ADVI converges in approximately an hour and finds an eleven-dimensional subspace. We omit sampling results as both HMC and NUTS struggle with the model; neither produce useful samples within an hour.

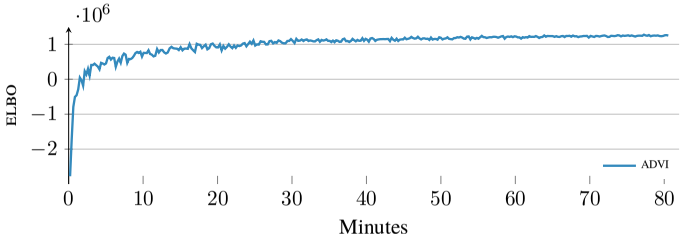


Figure 13: ELBO of PPCA model with ARD. ADVI converges in approximately an hour.

Equipped with this eleven-dimensional subspace, we turn to analyzing the full dataset of 1.7 million taxi trajectories. We first project all trajectories into the subspace. We then use the GMM from Section 4.3 ($K = 30$) components to cluster the trajectories. ADVI takes less than half an hour to converge.

Figure 14 shows a visualization of fifty thousand randomly sampled trajectories. Each color represents the set of trajectories that associate with a particular Gaussian mixture. The clustering is geographical: taxi trajectories that are close to each other are bundled together. The clusters identify frequently taken taxi trajectories.

When we processed the raw data, we interpolated each trajectory to an equal length. This discards all duration information. What if some roads are particularly prone to traffic? Do these roads lead to longer trips?

Supervised probabilistic principal component analysis (SUP-PPCA) is one way to model this. The idea is to regress the durations of each trip onto a subspace that also explains variation in a response variable, in this case, the duration. SUP-PPCA is a simple extension of PPCA (Murphy, 2012). We further extend it using the same ARD prior as before. (Details in Appendix F.7.)

ADVI enables a quick repeat of the above analysis, this time with SUP-PPCA. With ADVI, we find another set of GMM clusters in less than two hours. These clusters, however, are more informative.

Figure 15 shows two clusters that identify particularly busy roads: the bridges of Porto that cross the Duoro river. Figure 15a shows a group of short trajectories that use the two old bridges near the city center. Figure 15b show a group of longer trajectories that use the two newer bridges connecting highways that circumscribe the city.

Figure 14: A visualization of fifty thousand randomly sampled taxi trajectories. The colors represent thirty Gaussian mixtures and the trajectories associated with each.

(a) Trajectories that take the inner bridges. **(b)** Trajectories that take the outer bridges.

Figure 15: Two clusters using SUP-PPCA subspace clustering.

Analyzing these taxi trajectories illustrates how exploratory data analysis is an iterative effort: we want to rapidly evaluate models and modify them based on what we learn. ADVI, which provides automatic and fast inference, enables effective exploration of massive datasets.

5. Discussion

We presented automatic differentiation variational inference (ADVI), a variational inference algorithm that works "out of the box" for a large class of modern probabilistic models. The main idea is to transform the latent variables into a common space. Solving the variational inference problem in this

common space solves it for all models in the class. We studied ADVI using ten different probability models and deployed it as part of Stan, a probabilistic programming system.

There are several avenues for research.

Accuracy. As we showed in Section 3.3, ADVI can be sensitive to the transformations that map the constrained parameter space to the real coordinate space. Dinh et al. (2014) and Rezende and Mohamed (2015) use a cascade of simple transformations to improve accuracy. Tran et al. (2016b) place a Gaussian process to learn the optimal transformation and prove its expressiveness as a universal approximator. Hierarchical variational models (Ranganath et al., 2016) develop rich approximations for non-differentiable latent variable models.

Optimization. ADVI uses first-order automatic differentiation to implement stochastic gradient ascent. Higher-order gradients may enable faster convergence; however computing higher-order gradients comes at a computational cost (Fan et al., 2015). ADVI works with unbiased gradient estimators; introducing some bias to reduce variance could also improve convergence speed (Ruiz et al., 2016a,b). Optimization using line search could also improve convergence robustness (Mahsereci and Hennig, 2015), as well as natural gradient approaches for nonconjugate models (Khan et al., 2015).

Practical heuristics. Two things affect ADVI convergence: initialization and step-size scaling. We initialize ADVI in the real coordinate space as a standard Gaussian. A better heuristic could adapt to the model and dataset based on moment matching. We adaptively tune the scale of the step-size sequence using a finite search. A better heuristic could avoid this additional computation.

Probabilistic programming. We designed and deployed ADVI with Stan in mind. Thus, we focused on the class of differentiable probability models. How can we extend ADVI to discrete latent variables? One approach would be to adapt ADVI to use the black box gradient estimator for these variables (Ranganath et al., 2014). This requires some care as these gradients will exhibit higher variance than the gradients with respect to the differentiable latent variables. (See Section 3.2.) With support for discrete latent variables, modified versions of ADVI could be extended to more general probabilistic programming systems, such as Church (Goodman et al., 2008), Figaro (Pfeffer, 2009), Venture (Mansinghka et al., 2014), Anglican (Wood et al., 2014), WebPPL (Goodman and Stuhlmüller, 2014), and Edward (Tran et al., 2016a).

Before we conclude, we offer some general advice. ADVI, like all of variational inference, is an approximate inference technique. As such, we recommend carefully studying its accuracy for new models. While Section 3.1 indicates a potential shortcoming, the quality of ADVI's posterior approximation will differ from model to model. We recommend validating ADVI for new models by running "fake data" checks (Cook et al., 2006). One of the advantages of ADVI is that its speed of convergence gives more opportunity for such checking in practice.

In summary, ADVI is a first step towards an automated variational inference algorithm that works well for a large class of practical models on modern real-world datasets. Each step of the recipe for ADVI highlights key design decisions: automating transformation of latent variables using a compiler, choosing a variational family that leads to low-variance gradient estimators of the variational objective, and developing an adaptive stochastic optimization step-size sequence that works not only in theory, but also in practice. ADVI enables scientists to easily build, explore, and revise complex probabilistic models with large data.

Appendix A. Transformations of Continuous Probability Densities

We present a brief summary of transformations, largely based on (Olive, 2014).

Consider a scalar (univariate) random variable X with probability density function $f_X(x)$. Let $\mathcal{X} = \text{supp}(f_X(x))$ be the support of X. Now consider another random variable Y defined as $Y = T(X)$. Let $\mathcal{Y} = \text{supp}(f_Y(y))$ be the support of Y.

If T is a one-to-one and differentiable function from $\mathcal{X}$ to $\mathcal{Y}$, then Y has probability density function

$$f_Y(y) = f_X\left(T^{-1}(y)\right) \left| \frac{\mathrm{d}T^{-1}(y)}{\mathrm{d}y} \right|.$$

Let us sketch a proof. Consider the cumulative density function Y. If the transformation T is increasing, we directly apply its inverse to the cdf of Y. If the transformation T is decreasing, we apply its inverse to one minus the cdf of Y. The probability density function is the derivative of the cumulative density function. These things combined give the absolute value of the derivative above.

The extension to multivariate variables $\mathbf{X}$ and $\mathbf{Y}$ requires a multivariate version of the absolute value of the derivative of the inverse transformation. This is the absolute determinant of the Jacobian, $|\det J_{T^{-1}}(\mathbf{Y})|$ where the Jacobian is

$$J_{T^{-1}}(\mathbf{Y}) = \begin{pmatrix} \frac{\partial T_1^{-1}}{\partial y_1} & \cdots & \frac{\partial T_1^{-1}}{\partial y_K} \\ \vdots & & \vdots \\ \frac{\partial T_K^{-1}}{\partial y_1} & \cdots & \frac{\partial T_K^{-1}}{\partial y_K} \end{pmatrix}.$$

Intuitively, the Jacobian describes how a transformation warps unit volumes across spaces. This matters for transformations of random variables, since probability density functions must always integrate to one.

Appendix B. Transformation of the Evidence Lower Bound

Recall that $\boldsymbol{\zeta} = T(\boldsymbol{\theta})$ and that the variational approximation in the real coordinate space is $q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})$.

We begin with the ELBO in the original latent variable space. We then transform the latent variable space to the real coordinate space.

$$\begin{aligned}
\mathcal{L}(\boldsymbol{\phi}) &= \int q(\boldsymbol{\theta}) \log \left[\frac{p(\mathbf{x}, \boldsymbol{\theta})}{q(\boldsymbol{\theta})} \right] \mathrm{d}\boldsymbol{\theta} \\
&= \int q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \log \left[\frac{p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|}{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})} \right] \mathrm{d}\boldsymbol{\zeta} \\
&= \int q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \log \left[p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right| \right] \mathrm{d}\boldsymbol{\zeta} - \int q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \log \left[q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \right] \mathrm{d}\boldsymbol{\zeta} \\
&= \mathbb{E}_{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})} \left[\log p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) + \log \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right| \right] - \mathbb{E}_{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})} \left[\log q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi}) \right] \\
&= \mathbb{E}_{q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})} \left[\log p\left(\mathbf{x}, T^{-1}(\boldsymbol{\zeta})\right) + \log \left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right| \right] + \mathbb{H}\big[q(\boldsymbol{\zeta}\,;\,\boldsymbol{\phi})\big].
\end{aligned}$$

Appendix C. Gradients of the Evidence Lower Bound

First, consider the gradient with respect to the $\boldsymbol{\mu}$ parameter. We exchange the order of the gradient and the integration through the dominated convergence theorem (Çınlar, 2011). The rest is the chain

rule for differentiation.

$$\begin{aligned}
\nabla_{\boldsymbol{\mu}}\mathcal{L} &= \nabla_{\boldsymbol{\mu}}\Big\{\mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right] + \mathbb{H}\big[q(\boldsymbol{\zeta};\boldsymbol{\phi})\big]\Big\} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\nabla_{\boldsymbol{\mu}}\left\{\log p\left(\mathbf{x}, T^{-1}(S^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S^{-1}(\boldsymbol{\eta})\right)\right|\right\}\right] \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\left(\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right)\nabla_{\boldsymbol{\mu}}S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right] \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right]
\end{aligned}$$

Then, consider the gradient with respect to the mean-field $\boldsymbol{\omega}$ parameter.

$$\begin{aligned}
\nabla_{\boldsymbol{\omega}}\mathcal{L} &= \nabla_{\boldsymbol{\omega}}\Big\{\mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right] \\
&\qquad + \frac{K}{2}(1+\log(2\pi)) + \sum_{k=1}^{K}\log(\exp(\omega_k))\Big\} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\nabla_{\boldsymbol{\omega}}\left\{\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right\}\right] + \mathbf{1} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\left(\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right)\nabla_{\boldsymbol{\omega}}S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right] + \mathbf{1} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\left(\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right)\boldsymbol{\eta}^{\top}\mathrm{diag}(\exp(\boldsymbol{\omega}))\right] + \mathbf{1}.
\end{aligned}$$

Finally, consider the gradient with respect to the full-rank $\mathbf{L}$ parameter.

$$\begin{aligned}
\nabla_{\mathbf{L}}\mathcal{L} &= \nabla_{\mathbf{L}}\Big\{\mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right] \\
&\qquad + \frac{K}{2}(1+\log(2\pi)) + \frac{1}{2}\log\left|\det(\mathbf{L}\mathbf{L}^{\top})\right|\Big\} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\nabla_{\mathbf{L}}\left\{\log p\left(\mathbf{x}, T^{-1}(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta}))\right) + \log\left|\det J_{T^{-1}}\left(S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right)\right|\right\}\right] \\
&\qquad + \nabla_{\mathbf{L}}\frac{1}{2}\log\left|\det(\mathbf{L}\mathbf{L}^{\top})\right| \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\left(\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right)\nabla_{\mathbf{L}}S_{\boldsymbol{\phi}}^{-1}(\boldsymbol{\eta})\right] + (\mathbf{L}^{-1})^{\top} \\
&= \mathbb{E}_{\mathrm{N}(\boldsymbol{\eta};\mathbf{0},\mathbf{I})}\left[\left(\nabla_{\boldsymbol{\theta}}\log p(\mathbf{x},\boldsymbol{\theta})\nabla_{\boldsymbol{\zeta}}T^{-1}(\boldsymbol{\zeta}) + \nabla_{\boldsymbol{\zeta}}\log\left|\det J_{T^{-1}}(\boldsymbol{\zeta})\right|\right)\boldsymbol{\eta}^{\top}\right] + (\mathbf{L}^{-1})^{\top}
\end{aligned}$$

Appendix D. Automating Expectations: Monte Carlo Integration

Expectations of continuous random variables are integrals. We can use MC integration to approximate them (Robert and Casella, 1999). All we need are samples from q.

$$\mathbb{E}_{q(\boldsymbol{\eta})}\big[f(\boldsymbol{\eta})\big] = \int f(\boldsymbol{\eta})q(\boldsymbol{\eta})\,\mathrm{d}\boldsymbol{\eta} \approx \frac{1}{S}\sum_{s=1}^{S} f(\boldsymbol{\eta}_s) \text{ where } \boldsymbol{\eta}_s \sim q(\boldsymbol{\eta}).$$

MC integration provides noisy, yet unbiased, estimates of the integral. The standard deviation of the estimates decrease as $\mathcal{O}(1/\sqrt{s})$.

Appendix E. Running ADVI in Stan

Visit `http://mc-stan.org/` to download the latest version of Stan. Follow instructions on how to install Stan. You are then ready to use ADVI.

Stan offers multiple interfaces. We describe the command line interface (`cmdStan`) below.

```
./myModel  variational
           grad_samples=M              ( M = 1 default )
           data file=myData.data.R
           output file=output_advi.csv
           diagnostic_file=elbo_advi.csv
```

Figure 16: Syntax for using ADVI via `cmdStan`.

Here, `myData.data.R` is the dataset stored in the R language `Rdump` format. `output_advi.csv` contains samples from the posterior and `elbo_advi.csv` reports the ELBO.

Appendix F. Details of Studied Models

F.1 Linear Regression with Automatic Relevance Determination

Linear regression with ARD is a high-dimensional sparse regression model (Bishop, 2006; Drugowitsch, 2013). This sort of regression model is sometimes referred to as an *hierarchical* or *multilevel* regression model. We describe the model below. The Stan program is in Figure 17.

The inputs are $\mathbf{x} = x_{1:N}$ where each x_n is D-dimensional. The outputs are $\mathbf{y} = y_{1:N}$ where each y_n is 1-dimensional. The weights vector $\mathbf{w}$ is D-dimensional. The likelihood

$$p(\mathbf{y} \mid \mathbf{x}, \mathbf{w}, \sigma) = \prod_{n=1}^{N} \mathrm{Normal}\left(y_n \mid \mathbf{w}^{\top}\mathbf{x}_n\,,\ \sigma\right)$$

describes measurements corrupted by iid Gaussian noise with unknown standard deviation σ.

The ARD prior and hyper-prior structure is as follows

$$\begin{aligned}
p(\mathbf{w}, \sigma, \boldsymbol{\alpha}) &= p(\mathbf{w}, \sigma \mid \boldsymbol{\alpha})p(\boldsymbol{\alpha}) \\
&= \mathrm{Normal}\left(\mathbf{w} \mid 0\,,\ \sigma\left(\mathrm{diag}\sqrt{\boldsymbol{\alpha}}\right)^{-1}\right)\mathrm{InvGamma}(\sigma \mid a_0, b_0)\prod_{i=1}^{D}\mathrm{Gamma}(\alpha_i \mid c_0, d_0)
\end{aligned}$$

where $\boldsymbol{\alpha}$ is a D-dimensional hyper-prior on the weights, where each component gets its own independent Gamma prior.

We simulate data such that only half the regressors have predictive power. The results in Figure 10a use $a_0 = b_0 = c_0 = d_0 = 1$ as hyper-parameters for the Gamma priors.

F.2 Hierarchical Logistic Regression

Hierarchical logistic regression is an intuitive way to model structured classification problems. We study a model of voting preferences, republican or democrat, from the 1988 United States presidential election. Chapter 14.1 of (Gelman and Hill, 2006) motivates the model and explains the dataset in

detail. We also briefly describe the model below. The Stan program is in Figure 18, based on (Stan Development Team, 2016).

$$\Pr(y_n = 1) = \text{sigmoid}\Big(\beta^0 + \beta^{\text{female}} \cdot \text{female}_n + \beta^{\text{black}} \cdot \text{black}_n + \beta^{\text{female.black}} \cdot \text{female.black}_n + \alpha^{\text{age}}_{k[n]} + \alpha^{\text{edu}}_{l[n]} + \alpha^{\text{age.edu}}_{k[n],l[n]} + \alpha^{\text{state}}_{j[n]}\Big)$$

$$\alpha^{\text{state}}_j \sim \text{Normal}\left(\alpha^{\text{region}}_{m[j]} + \beta^{\text{v.prev}} \cdot \text{v.prev}_j\,,\ \sigma_{\text{state}}\right).$$

The hierarchical variables are

$$\begin{aligned}
\alpha^{\text{age}}_k &\sim \text{Normal}\left(0\,,\ \sigma_{\text{age}}\right) \text{ for } k = 1, \ldots, K \\
\alpha^{\text{edu}}_l &\sim \text{Normal}\left(0\,,\ \sigma_{\text{edu}}\right) \text{ for } l = 1, \ldots, L \\
\alpha^{\text{age.edu}}_{k,l} &\sim \text{Normal}\left(0\,,\ \sigma_{\text{age.edu}}\right) \text{ for } k = 1, \ldots, K, l = 1, \ldots, L \\
\alpha^{\text{region}}_m &\sim \text{Normal}\left(0\,,\ \sigma_{\text{region}}\right) \text{ for } m = 1, \ldots, M.
\end{aligned}$$

The regression coefficient β has a Normal(0, 10) prior and all standard deviation latent variables have half Normal(0, 10) priors.

F.3 Non-negative Matrix Factorization: Constrained Gamma Poisson Model

The Gamma Poisson factorization model describes discrete data matrices (Canny, 2004; Cemgil, 2009).

Consider a $U \times I$ matrix of observations. We find it helpful to think of $u = \{1, \cdots, U\}$ as users and $i = \{1, \cdots, I\}$ as items, as in a recommendation system setting. The generative process for a Gamma Poisson model with K factors is

1. For each user u in $\{1, \cdots, U\}$:
   - For each component k, draw $\theta_{uk} \sim \text{Gamma}(a_0, b_0)$.
2. For each item i in $\{1, \cdots, I\}$:
   - For each component k, draw $\beta_{ik} \sim \text{Gamma}(c_0, d_0)$.
3. For each user and item:
   - Draw the observation $y_{ui} \sim \text{Poisson}(\boldsymbol{\theta}_u^\top \boldsymbol{\beta}_i)$.

A potential downfall of this model is that it is not uniquely identifiable: swapping rows and columns of $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$ give the same inner product. One way to contend with this is to constrain either vector to be an ordered vector during inference. We constrain each $\boldsymbol{\theta}_u$ vector in our model in this fashion. The Stan program is in Figure 19. We set $K = 10$ and all the Gamma hyper-parameters to 1 in our experiments.

F.4 Non-negative Matrix Factorization: Dirichlet Exponential Poisson Model

Another model for discrete data is a Dirichlet Exponential model. The Dirichlet enforces uniqueness while the exponential promotes sparsity. This is a non-conjugate model that does not appear to have been studied before.

The generative process for a Dirichlet Exponential model with K factors is

1. For each user u in $\{1, \cdots, U\}$:
   - Draw the K-vector $\boldsymbol{\theta}_u \sim \text{Dirichlet}(\boldsymbol{\alpha}_0)$.
2. For each item i in $\{1, \cdots, I\}$:
   - For each component k, draw $\beta_{ik} \sim \text{Exponential}(\lambda_0)$.
3. For each user and item:
   - Draw the observation $y_{ui} \sim \text{Poisson}(\boldsymbol{\theta}_u^\top \boldsymbol{\beta}_i)$.

The Stan program is in Figure 20. We set $K = 10$, $\alpha_0 = 1000$ for each component, and $\lambda_0 = 0.1$. With this configuration of hyper-parameters, the factors $\boldsymbol{\beta}_i$ appear sparse.

F.5 Gaussian Mixture Model

The Gaussian mixture model (GMM) is a versatile probability model (Bishop, 2006), often used for density estimation and clustering. Here we use it to group a dataset of natural images based on their color histograms. We build a high-dimensional GMM with a Gaussian prior for the mixture means, a lognormal prior for the mixture standard deviations, and a Dirichlet prior for the mixture components.

Represent the images as $\mathbf{y} = y_{1:N}$ where each y_n is D-dimensional and there are N observations. The likelihood for the images is

$$p(\mathbf{y} \mid \boldsymbol{\theta}, \boldsymbol{\mu}, \boldsymbol{\sigma}) = \prod_{n=1}^{N} \sum_{k=1}^{K} \theta_k \prod_{d=1}^{D} \text{Normal}(y_{nd} \mid \mu_{kd}, \sigma_{kd})$$

with a Dirichlet prior for the mixture proportions

$$p(\boldsymbol{\theta}) = \text{Dirichlet}(\boldsymbol{\theta}\,;\, \boldsymbol{\alpha}_0),$$

a Gaussian prior for the mixture means

$$p(\boldsymbol{\mu}) = \prod_{k=1}^{D} \prod_{d=1}^{D} \text{Normal}(\mu_{kd}\,;\, 0, 1)$$

and a lognormal prior for the mixture standard deviations

$$p(\boldsymbol{\sigma}) = \prod_{k=1}^{D} \prod_{d=1}^{D} \text{Lognormal}(\sigma_{kd}\,;\, 0, 1).$$

The dimension of the color histograms in the imageCLEF dataset is $D = 576$. This is a concatenation of three 192-length histograms, one for each color channel (red, green, blue) of the images.

We scale the image histograms to have zero mean and unit variance. Setting α_0 to a small value encourages the model to use fewer components to explain the data. Larger values of α_0 encourage the model to use all K components. We set $\alpha_0 = 1\,000$ in our experiments.

The Stan program is in Figure 21. The stochastic data subsampling version of the code is in Figure 22.

F.6 Probabilistic Principal Component Analysis with Automatic Relevance Determination

Probabilistic principal component analysis (PPCA) is a Bayesian extension of classical principal component analysis (Bishop, 2006). Consider a dataset of $\mathbf{x} = x_{1:N}$ where each x_n is D-dimensional. Let $M < D$ be the dimension of the subspace we will use for analysis.

First define a set of latent variables $\mathbf{z} = z_{1:N}$ where each z_n is M-dimensional. Draw each z_n from a standard normal

$$p(\mathbf{z}) = \prod_{n=1}^{N} \text{Normal}(z_n \,;\, \mathbf{0}, \mathbf{I}).$$

Then define a set of principal components $\mathbf{w} = w_{1:D}$ where each w_d is M-dimensional. Similarly, draw the principal components from a standard normal

$$p(\mathbf{w}) = \prod_{d=1}^{D} \text{Normal}(w_d \,;\, \mathbf{0}, \mathbf{I}).$$

Finally define the likelihood through an inner product as

$$p(\mathbf{x} \mid \mathbf{w}, \mathbf{z}, \sigma) = \prod_{n=1}^{N} \text{Normal}(x_n \,;\, \mathbf{w}^\top z_n, \sigma\mathbf{I}).$$

The standard deviation σ is also a latent variable. Place a lognormal prior on it as

$$p(\sigma) = \text{Lognormal}(\sigma \,;\, 0, 1).$$

We extend PPCA by adding an ARD hierarchical prior. The extended model introduces a M-dimensional vector $\boldsymbol{\alpha}$ which chooses which principal components to retain. ($M < D$ now represents the maximum number of principal components to consider.) This extends the above by

$$\begin{aligned}
p(\boldsymbol{\alpha}) &= \prod_{m=1}^{M} \text{InvGamma}(\alpha_m \,;\, 1, 1) \\
p(\mathbf{w} \mid \boldsymbol{\alpha}) &= \prod_{d=1}^{D} \text{Normal}(w_d \,;\, \mathbf{0}, \sigma\text{diag}(\boldsymbol{\alpha})) \\
p(\mathbf{x} \mid \mathbf{w}, \mathbf{z}, \sigma) &= \prod_{n=1}^{N} \text{Normal}(x_n \,;\, \mathbf{w}z_n, \sigma\mathbf{I}).
\end{aligned}$$

The Stan program that implements PPCA is in Figure 23.

F.7 Supervised Probabilistic Principal Component Analysis with Automatic Relevance Determination

Supervised probabilistic principal component analysis (SUP-PPCA) augments PPCA by regressing a vector of observed random variables y onto the principal component subspace. The idea is to not only find a set of principal components that describe variation in the dataset $\mathbf{x}$, but to also predict y. The complete model is

$$\begin{aligned}
p(\mathbf{z}) &= \prod_{n=1}^{N} \text{Normal}(z_n \,;\, \mathbf{0}, \mathbf{I}) \\
p(\sigma) &= \text{Lognormal}(\sigma \,;\, 0, 1) \\
p(\boldsymbol{\alpha}) &= \prod_{m=1}^{M} \text{InvGamma}(\alpha_m \,;\, 1, 1) \\
p(\mathbf{w}_\mathbf{x} \mid \boldsymbol{\alpha}) &= \prod_{d=1}^{D} \text{Normal}(w_d \,;\, \mathbf{0}, \sigma\text{diag}(\boldsymbol{\alpha})) \\
p(w_y \mid \boldsymbol{\alpha}) &= \text{Normal}(w_y \,;\, \mathbf{0}, \sigma\text{diag}(\boldsymbol{\alpha})) \\
p(\mathbf{x} \mid \mathbf{w}_\mathbf{x}, \mathbf{z}, \sigma) &= \prod_{n=1}^{N} \text{Normal}(x_n \,;\, \mathbf{w}_\mathbf{x} z_n, \sigma\mathbf{I}) \\
p(y \mid w_y, \mathbf{z}, \sigma) &= \prod_{n=1}^{N} \text{Normal}(y_n \,;\, w_y z_n, \sigma).
\end{aligned}$$

The Stan program that implements SUP-PPCA is in Figure 24.

Editor: Russ Greiner

Abstract

Tuning the regularisation and kernel hyperparameters is a vital step in optimising the generalisation performance of kernel methods, such as the support vector machine (SVM). This is most often performed by minimising a resampling/cross-validation based model selection criterion, however there seems little practical guidance on the most suitable form of resampling. This paper presents the results of an extensive empirical evaluation of resampling procedures for SVM hyperparameter selection, designed to address this gap in the machine learning literature. We tested 15 different resampling procedures on 121 binary classification data sets in order to select the best SVM hyperparameters. We used three very different statistical procedures to analyse the results: the standard multi-classifier/multi-data set procedure proposed by Demšar, the confidence intervals on the excess loss of each procedure in relation to 5-fold cross validation, and the Bayes factor analysis proposed by Barber. We conclude that a 2-fold procedure is appropriate to select the hyperparameters of an SVM for data sets for 1000 or more datapoints, while a 3-fold procedure is appropriate for smaller data sets.

Keywords: Hyperparameters; SVM; resampling; cross-validation; k-fold; bootstrap

1. Introduction

The support vector machine (SVM) (Boser et al., 1992; Cortes and Vapnik, 1995) is a powerful machine learning algorithm for statistical pattern recognition tasks, with strong theoretical foundations (Vapnik, 1998) and excellent performance in a range of real-world applications (e.g. Joachims, 1998; Furey et al., 2000; Fernández-Delgado et al., 2014). Perhaps the most common variant of the SVM uses the radial basis function (RBF) kernel, as recommended as a default approach in a popular guide to SVM (Hsu et al., 2010). The application of the RBF SVM to a classification problem requires the selection of appropriate values for two hyperparameters: a regularisation parameter, C, and a parameter governing the sensitivity of the kernel, γ. Given values for these two hyperparameters and the training data, an SVM solver, such as libSVM (Chang and Lin, 2011), can find the unique solution of the constrained quadratic optimization problem defining the SVM formulation and return a classifier. We assume that the reader is familiar with the theory of SVMs and in particular of the SVM with the RBF (also known as Gaussian) kernel.

Unfortunately, the situation is less straightforward for model selection; there is no similarly principled means of optimising the hyperparameters. The simplest approach is to divide the data set into training and testing sets, and for each C and γ from a suitable set, select the pair that result in the SVM that when trained on the training set has lowest error rate over the corresponding test set. More commonly, resampling approaches, such as *cross-validation*, use multiple test/training sets in order to form a better model selection criterion from the available data.

This paper presents an empirical investigation of the effects of different resampling approaches to hyperparameter tuning on the generalisation performance of the final classifier. The investigation is focussed primarily on the SVM with an RBF kernel, but the main conclusions are repeated and validated for the linear and polynomial kernel SVM, as discussed in Section 5.

1.1 Resampling Approaches to Performance Evaluation

Performance evaluation is a key component of model selection procedures typically used in practical applications of support vector machines. Assume we have a sample of data, $\mathcal{G} = \{z_i = (\boldsymbol{x}_i, y_i)\}_{i=1}^n$, where $\boldsymbol{x}_i \in \mathcal{X} \subset \mathbb{R}^d$ is a vector of attributes describing the i^{th} example and y_i is the corresponding class label; for binary classification tasks, $y_i \in \{-1, +1\}$. Resampling procedures provide a performance estimate based on repeatedly dividing $\mathcal{G}$ to form a *training set* and a *test set* (sometimes known as a *validation set*). More formally, in the i^{th} iteration of the resampling procedure, TR_i represents the training set and TE_i is the test set, such that

$$TR_i \cap TE_i = \emptyset \quad \text{and} \quad TR_i \cup TE_i \subseteq \mathcal{G}.$$

Let $\epsilon(\mathcal{B} \mid \mathcal{A}, C, \gamma)$ represent the error rate of an SVM trained on the training sample $\mathcal{A}$, using hyperparameter values C and γ, evaluated on the test set $\mathcal{B}$. The performance estimate provided by resampling methods is then typically the mean of the error rates obtained on the test set in each fold, i.e.

$$\text{Error}(C, \gamma) = \frac{1}{N} \sum_{i=1}^{N} \epsilon(\, TE_i \mid \, TR_i, C, \gamma),$$

where N is the number of iterations, or *folds*, of the resampling procedure. Different resampling *procedures*, such as *k-fold cross-validation*, *bootstrap* and *leave-one-out cross-validation* differ only in the way in which the data are partitioned to form TR_i and TE_i in each fold. Some common resampling procedures include:

- *k-fold cross-validation*: Partition $\mathcal{G}$ to form k disjoint sets F_j of approximately similar size, such that $\bigcup_j F_j = \mathcal{G}$. Then in each of the k iterations, a different set is used for testing and the others for training, i.e. $TE_i = F_i$ and $TR_i = \bigcup_{j \neq i} F_j$. In *stratified* cross-validation, $\mathcal{G}$ is partitioned such that each subset has a similar proportion of patterns belonging to each class. In repeated k-fold cross-validation, this procedure is performed repeatedly, with a different initial partitioning in each iteration.

License: CC-BY 4.0, see https://creativecommons.org/licenses/by/4.0/. Attribution requirements are provided at http://jmlr.org/papers/v18/16-174.html.

- *Leave one out cross-validation*: This is the most extreme form of k-fold cross-validation, in which each set F_i consists of a single training pattern, i.e. $TE_i = \{z_i\}$ and $TR_i = \mathcal{G} \setminus \{z_i\}$.

- *Hold-out*: A single training set, TR_1, is defined, with size $p \times n$, and $TE_1 = \mathcal{G} \setminus TR_1$, where $p \in [0,\ 1]$. In stratified hold-out, the partitioning is performed such that TE_1 and TR_1 have a similar proportion of patterns of each class. In repeated hold-out resampling, this procedure is performed repeatedly with different random partitions of $\mathcal{G}$.

- *Bootstrap:* In each iteration, TR_i is obtained by sampling n items, with replacement from $\mathcal{G}$, and $TE_i = \mathcal{G} \setminus TR_i$.

- *Subsampling*: A hold-out resampling procedure where $TR_i \cup TE_i \subset \mathcal{G}$, that is, where only a subset of the available data set is used in each iteration. This is useful where a very large amount of data is provided.

Unfortunately, the names of these procedures are not well standardised. Appendix A discusses alternative names used for the concepts and procedures discussed in this paper.

Finally, resampling should be contrasted with *resubstitution*, a performance estimation method that uses the same set for both training the SVM and measuring its error rate. There are variations on the resubstitution procedure, where the data used to measure the error rate is the same data used in training, but they are given different weights (Braga-Neto and Dougherty, 2004).

1.2 Model Selection

The process of *model selection*, in the case of kernel learning methods, refers to the tuning of the kernel and regularisation hyperparameters in order to maximise generalisation performance. The generalisation error of a classifier can be expressed as an expectation over random samples, $\boldsymbol{z}$, drawn from the distribution $\mathcal{D}$ from which the training set was obtained,

$$\check{\epsilon}(C, \gamma) = \mathbb{E}_{z \sim \mathcal{D}} \left[\epsilon(z \mid \mathcal{G}, C, \gamma) \right]$$

Ideally we would like to choose the hyperparameters C and γ so that $\check{\epsilon}$ is minimized, that is:

$$C^*, \gamma^* = \underset{C,\gamma}{\operatorname{argmin}}\ \check{\epsilon}(C, \gamma) \tag{1}$$

Unfortunately, the distribution giving rise to the data is generally unknown, and so we are unable to evaluate or directly optimise $\check{\epsilon}$. The solution is to optimise instead an *estimate*, $\tilde{\epsilon}$, of the true generalisation error, $\check{\epsilon}$. By far the most common approach is to optimise a resampling-based estimate. The estimate, $\tilde{\epsilon}$, of $\check{\epsilon}$ for a particular resampling procedure rs is defined as:

$$\tilde{\epsilon}_{rs}(C, \gamma) = \frac{1}{N} \sum_{i=1}^{N} \epsilon(TE_i \mid TR_i, C, \gamma).$$

Given that a particular resampling procedure (rs) was selected, the choice of the SVM hyperparameters is governed by:

$$C^*_{rs}, \gamma^*_{rs} = \underset{C,\gamma}{\operatorname{argmin}}\ \tilde{\epsilon}_{rs}(C, \gamma).$$

It would be computationally infeasible to evaluate every possible combination of the hyperparameters, C and γ, so in general the search evaluates combinations from a finite set $\mathcal{S}$.

$$C^*_{rs}, \gamma^*_{rs} = \underset{C,\gamma \in \mathcal{S}}{\operatorname{argmin}}\ \tilde{\epsilon}_{rs}(C, \gamma). \tag{2}$$

Different model selection procedures adopt different methods to generate the set $\mathcal{S}$; they can be specified a-priori, as in the case of grid-search or random search, or successive elements of $\mathcal{S}$ can be generated according to the results obtained from evaluating existing elements, as in the case of Nelder-Mead simplex (Nelder and Mead, 1965), gradient descent (Chapelle et al., 2002) or other non-convex methods (Friedrichs and Igel, 2005; De Souza et al., 2006).

The choice of resampling procedure depends on two possibly conflicting criteria: firstly we would like to maximise generalisation performance, and secondly reduce computational expense. The error of a resampling estimate of generalisation consists of two components, *bias* and *variance*. The bias component represents the degree to which the estimate differs *on average* from the true value, over a large number of datasets of the same size as $\mathcal{G}$ sampled from the same underlying distribution, $\mathcal{D}$. The generalisation performance of classifiers tends to improve as the size of the training set increases. Resampling estimates therefore tend to have a pessimistic bias, systematically underestimating the generalisation performance of a classifier trained on $\mathcal{G}$, as in each fold a classifier is trained on only a subset of $\mathcal{G}$. The optimal hyperparameters for an SVM, particularly the regularisation parameter (C), can also demonstrate some degree of dependence on the size of the training set, which also leads to a bias in the hyperparameter estimates from resampling based model selection procedures. The variance component reflects the difference between the estimated and true values due to the particular sample of data on which the estimate was computed (and also due the random partitioning of the sample). As the model selection procedure directly minimises the resampling estimate, the presence of a non-negligible variance component introduces a risk of over-fitting in model selection (Cawley and Talbot, 2010), which results in suboptimal hyperparameter selection. Let us define the *true* excess loss (el) of a resampling procedure rs, as

$$el(rs) = \mathbb{E}_{\boldsymbol{z} \sim \mathcal{D}} \left[\epsilon(\boldsymbol{z} \mid \mathcal{G}, C^*_{rs}, \gamma^*_{rs}) - \epsilon(\boldsymbol{z} \mid \mathcal{G}, C^*, \gamma^*) \right],$$

where C^* and γ^* are the choices of optimal hyperparameters defined in Equation 1. The first important consideration in the choice of procedure is then to minimise the excess loss.

Unfortunately, the true excess loss is unknowable: Firstly we do not know the true values of γ^* and C^*, i.e. the values minimizing the generalisation error (1), indeed if these values were known, model selection using resampling methods (2) would be entirely redundant. Secondly, we do not know the true distribution of the data, $\mathcal{D}$, so we cannot perform the expectation involved in evaluating the generalisation error (1). The best we can do is to estimate the generalisation error using a finite test sample and compare the performance obtained using model selection based on a given resampling method against model selection

using some sensible baseline method, such as five-fold cross-validation. We therefore define the excess loss relative to five-fold cross-validation as the observed difference in the error rate on a fixed test set for classifiers trained with hyper-parameters adjusted so as to minimise a given resampling based performance estimate and so as to minimise the five-fold cross-validation estimate. This gives a relative indication of the improvement in generalisation performance due to the resampling method used to tune the hyper-parameters.

The second consideration in the choice of resampling procedure is the computational cost. The different resampling procedures have very different computational costs for the hyperparameter search. For example, for each possible pair of values C and γ, 10-fold cross-validation will require the fitting of 10 separate SVM classifiers, each with a training set of $0.9 \times |\mathcal{G}|$. For 5-fold cross validation, for each pair of hyperparameters, there will be 5 classifiers trained, each with a training set of size $0.8 \times |\mathcal{G}|$ — not only fewer support vector machines need be constructed, but each is fitted to a smaller training sample, with lower computational expense. If one is using a batch SVM solver, such as SVMlight (Joachims, 1999) or libSVM (Chang and Lin, 2011), one can assume that the learning time is at least quadratic in relation to the training size (Bottou and Lin, 2007).

A trade-off between these two criteria must be reached in selecting a suitable resampling estimator. We would like to minimise the number of folds to reduce computational expense, however the variance of resampling estimators is generally reduced by increasing the number of folds, resulting in improved hyperparameter estimates. Again, we would like to reduce the size of the training set to reduce training time, but this also tends to increase the variance of the estimator. If the training set is made smaller, the uncertainty in estimating the model parameters will be greater, and hence the test set error more variable. However this leaves more data available for the test set, which tends to reduce the variance of the estimator. In reaching a compromise, we must ensure that the training and test sets are both sufficiently large, and a sufficient number of folds are used, for the estimator to have a suitably low variance, whilst at the same time limiting computational expense so that the procedure remains practical. The goal of this research is to understand the balance of these two conflicting considerations.

We must point out that this paper evaluates different *fixed* resampling procedures, as opposed to adaptive resampling (Kuhn, 2014; Krueger et al., 2015) to select the SVM hyperparameters. Fixed resampling will use the same resampling procedure for each of the possible hyperparameter combinations being tested, by far the most common procedure. However there has been some recent work on adaptive resampling where, for example, the full resampling procedure is not performed for some of the hyperparameter combination if the results for tests sets so far indicate that one can be sure that the results are suboptimal (Kuhn, 2014), or where a small subsampling is used first for all hyperparameter combinations and as one becomes increasingly sure that some of the combinations have better results than others, subsampling with increasing larger training sets are tested (Krueger et al., 2015).

1.3 Related Literature

The problems of the computational cost of hyperparameter selection for the SVM, and the generalisation performance of the resulting classifier, have been discussed in the literature in

many forms. There are in general three alternatives to improve hyperparameter selection, which will be discussed separately:

- Use a different metric derived from the training set, typically a lower bound on generalisation performance, such as Xi-alpha, span and radius/margin bounds to select the hyperparameters (e.g. Vapnik and Chapelle, 2000; Keerthi, 2002; Joachims, 2000; Wahba, 1999).
- Use different search/optimisation procedures such as random search, Nelder-Mead simplex, non-convex optimization procedures, to select the combinations of C and γ to be evaluated during model selection (e.g. Bergstra and Bengio, 2012; Huang et al., 2007; Friedrichs and Igel, 2005; De Souza et al., 2006).
- Use different resampling procedures to estimate $\tilde{\epsilon}$ (e.g. Anguita et al., 2005, 2012).

The first approach, given above, optimises an alternative metric, rather than the error rate, ϵ, i.e.:

$$C^*, \gamma^* = \underset{C,\gamma \in \mathcal{S}}{\operatorname{argmin}}\ \phi(\mathcal{G}, C, \gamma)$$

The metric, ϕ, is sometimes called an *internal metric* or a model selection criterion and they are computed from the training set alone. Internal metrics, proposed in the literature include: the span bound (Vapnik and Chapelle, 2000); the radius/margin bound (Keerthi, 2002); the Xi-Alpha bound (Joachims, 2000); GACV (Wahba, 1999); and maximal discrepancy (Anguita et al., 2005). Duan et al. (2003) compare 5-fold cross-validation with some internal metrics, such as Xi-alpha and GACV as methods to select SVM hyperparameters on five data sets and find that the 5-fold has lower excess loss. Anguita et al. (2005) compare many cross-validation procedures and some internal metrics (maximal discrepancy and compression bound) for hyperparameter selection on 13 data sets, and find that cross-validation based procedures have lower excess loss than the internal metrics.

The second approach to improving the hyperparameter selection procedure usually fixes a particular model selection criterion, say 10-fold cross-validation, and proposes different means by which the C, γ are selected from the $\mathcal{S}$ set, and more generally, how the $\mathcal{S}$ set is dynamically computed given the error for the previously selected pairs C, γ. We will call this approach, the *hyperparameter search procedure*. Most search procedures are based on the fact that the error response surface, that is the error for each value of C and γ, is generally non-convex, and thus methods based on gradient descent can only be *guaranteed* to find a local minima. The standard, or most common search procedure is a simple *grid search*, where the set $\mathcal{S}$ is predefined, usually a geometrically spaced grid in both C and γ, i.e. the $\mathcal{S}$ points are taken from a uniform 2-dimensional grid in the $\log C \times \log \gamma$ space. This is the search procedure used in this research. Bergstra and Bengio (2012) propose a random search in the space $\log C \times \log \gamma$. Huang et al. (2007) propose selecting from fixed points in the $\log C \times \log \gamma$ space following the principles of uniform design (Fang et al., 2000). Keerthi and Lin (2003) discuss the asymptotic behaviour of the error surface for an SVM in the $\log C \times \log \gamma$ space and proposes a method by which the C is optimized in a 1D grid search for the *linear* SVM problem, which yields a $\hat{C}$ value, and the C and γ for the RBF SVM is selected using a 1D grid search on the line that satisfies $\log \gamma = \log C - \log \hat{C}$. Davenport et al. (2010) propose that one should see the non-convexity of

the error surface for different C and γ as a noisy convex surface, and proposes a filtered coordinate descent search where the "true value" of the error at a particular point C, γ is a Gaussian filtered value of the error rate in a neighbourhood of C, γ. Keerthi et al. (2007) define an approximation to the gradient of the error surface and proposes that a gradient descent search should be performed to select the optimal C and γ. Finally, many researchers have proposed the use of non-convex optimization procedures to select the optimal hyperparameters, including evolutionary algorithms (Friedrichs and Igel, 2005), and particle swarm optimisation (De Souza et al., 2006; Li and Tan, 2010)

The third approach, selection of different resampling procedures, is the one explored in this paper. We know of few papers that discuss relative merits of resampling procedures and the selection of hyperparameters: The closest to this research is Anguita et al. (2005). Anguita et al. (2005) compare 9-fold cross-validation (kf9), 10-fold cv (kf10), 10 repetitions of the bootstrap procedure (10xboot), 100 repetitions of the bootstrap (100xboot), leave-one-out (loo), and 70/30 hold-out on 13 data sets (along with two internal metrics) for hyperparameter selection. They use a different experimental procedure — a fixed test set (in our notation a fixed $\mathcal{F}$ data set) and thus they can estimate $\epsilon(\mathcal{F} \mid \mathcal{G}, C^*, \gamma^*)$ and the excess loss using the fixed test set. They average the relative excess loss across the data sets (for each procedure). They report that the k-fold procedures have lower relative excess loss, followed by the 100xboot, the 10xboot, the loo and the 70/30 in that order. They did not include any discussion on whether the differences can be considered negligible. Another result reported in the paper is that 100xboot has the lower estimate error for $\epsilon(\mathcal{F} \mid \mathcal{G}, C^*, \gamma^*)$, followed by loo, 10xboot, 70/30, and last kf.

2. Methods and data

This paper describes an experimental evaluation of different resampling-based model selection criteria, using 121 different data sets (described in detail in Section 2.2). The error rate of the SVM trained with the choice of hyperparameters selected using the different resampling procedures (discussed in Section 2.1) are evaluated using a 2-fold cross-validation. That is, each data set is divided into two halves, the different resampling procedures are used to select the hyperparameters using the first half, the SVM is trained in this first half and its error rate evaluated for the second half. The procedure is repeated using the second half as training set and the first half as test set. The estimate of the error rate for the resampling procedure (or more precisely the error rate of the SVM with hyperparameters selected by the resampling procedure) is the average of the two measured error rates. If i denotes a data set, i_a and i_b two halves of the data set, then the estimated error rate for a resampling procedure rs is

$$eer(rs, i) = \frac{\epsilon(i_b \mid i_a, C^*_{rs,a}, \gamma^*_{rs,a}) + \epsilon(i_a \mid i_b, C^*_{rs,b}, \gamma^*_{rs,b})}{2} \tag{3}$$

where $C^*_{rs,a}$ and $\gamma^*_{rs,a}$ are computed as described in Equation 2, where the i_a half of the data set i corresponds to $\mathcal{G}$ (we discuss the candidate set $\mathcal{S}$ below).

For the 112 smallest data sets, we used three different statistical methods to compare the estimated error rate for each resampling procedure with that of a baseline procedure, in this case the 5-fold cross-validation (details of the comparison methods in Section 3). We

used the 9 remaining large data sets, for which the experiments above would require too much computational time, to verify the conclusions derived from the experiments on the smaller data sets.

The time required to perform hyperparameter selection for each procedure, for each data set, was also recorded and the ratio with 5-fold cross-validation calculated. The time ratio was also averaged over all procedures to compute an "expected time ratio" of the resampling procedures in relation to that of 5-fold cross-validation.

For all procedures and data sets, the hyperparameter search procedure used an 11×10 grid search (the $\mathcal{S}$ set) following the ranges and steps popularized by `libsvm` (Hsu et al., 2010) i.e. $C = \{2^{-5}, 2^{-3}, \ldots, 2^{15}\}$, and $\gamma = \{2^{-15}, 2^{-13}, \ldots, 2^{3}\}$.

2.1 Resampling Procedures

The following resampling procedures are investigated:

1. 2-fold cross-validation (kf2)
2. 3-fold cross-validation (kf3)
3. 5-fold cross-validation (kf5)
4. 10-fold cross-validation (kf10)
5. 2 times repeated 5-fold (2xkf5)
6. 2 times repeated 10-fold (2xkf10)
7. 5, 10, and 20 times repeated bootstrap (5xboot, 10xboot, 20xboot)
8. 80/20 hold-out (80/20) — a training set of size approximately 80% of the original data, and test set of 20%, with similar proportion of classes
9. resubstitution (resub), training and testing in the whole data set
10. inverted 5-fold (invkf5): learning on a single fold, and testing on the remaining.
11. 20/20 hold out (20/20) — training and test sets of 20%
12. 5 times repeated 20/20 hold out (5x20/20)
13. 20/10 holdout (20/10)
14. 10/10 hold out (10/10)
15. 5 times repeated 10/10 hold out (5x10/10)

We describe procedures 3 to 8 as *large-training set* resampling procedures. If n is the size of the $\mathcal{G}$ set ($n = |\mathcal{G}|$) then the large-training procedures will perform training on sets ranging from $0.8 \times n$ for the kf5, 2xkf5, 80/20, to n for the bootstrap[1]. The 3-fold and 2-fold (item

1. Technically the size of the training set for the bootstrap depends on the details of the implementation. The set TR_i has size n, but some of the data are necessarily repeated. If one uses a naive implementation, the training set has size n, but if one makes use of weights for each data point to account for the repetition of the data, then the training size for the bootstrap is on average $0.632n$.

1 and 2 in the list) will be called *medium-training set* procedures, since they will perform training on $0.67n$ to $0.5n$ data points. The other procedures are called *small-training set* procedures, since the training size ranges from $0.1n$ (10/10 and others) to $0.2n$ (20/20 and others). Somewhat counter-intuitively, the *small-training set* procedures are more useful for *large* data sets, When it is the case that a small fraction of G can represent the underlying data-generating distribution, such resampling procedures can obtain good accuracy at a tiny fraction of the computational cost of resampling procedures that build larger training sets.

2.2 Data sets

The 121 data sets used in this study were collected from the UCI repository (Lichman, 2013), processed and converted by the authors of Fernández-Delgado et al. (2014) into a unified format. The data is derived from the 165 available at UCI repository in March 2013. From this set, they discarded 56, mainly because they were too large (number of data and/or number of features), or because they were not in a "common UCI format". Four further data sets were added to those from the UCI repository, and finally some data sets that had two or more definitions of "classes" were converted into different problems. For example the data set *cardiotocography* defined two classification problems, one with 3 classes and the other with 10 classes — each became a different data set. The names of the data sets are a simplification of the original UCI name. For each data set, categorical features were converted to numerical data, and each feature was *standardised* to have a mean of zero and unit standard deviation. No further pre-processing or feature selection was performed by Fernández-Delgado et al. (2014). We used the data generated by the authors of Fernández-Delgado et al. (2014), downloaded in November 2014. In 19 data sets the data were divided into a training and test set, but the test set was not standardized (in the data available in Nov 2014). In these cases we standardized the test set (independently of the training set) and joined the two into a single data set. Some of the 121 original data sets are multi-class. Since the SVM is essentially a binary classification procedure, we converted the multi-class problems into binary problems by ordering each of the original classes according to their names and alternately assigned the original classes to the new positive and negative classes. Finally, we used all the data sets with less than 10,000 data for the experiments, and used the 9 data sets with more than 10,000 data to verify the conclusions from the experiments.

The characteristics of all data sets used are reported in Appendix B. The tables report the size of each half of the data set. The average data set size is 2250 patterns (median 341.5, max 65030); the average number of features is 30 (median 17, max 263). The proportion of samples belonging to the positive class is displayed in the histogram in Figure 6 in Appendix B. The proportions are approximately normally distributed with mean 0.60 and standard deviation of 0.17.

3. Metrics and statistical procedures

We perform three different statistical analyses of the results. The first is the standard multi-classifier/multiple-data set comparison procedure proposed by Demšar (2006), where the multiple resampling procedures play the part of the multiple classifiers. The second

analysis computes confidence intervals for the excess loss of different resampling procedures in relation to kf5, and verify whether this interval is within a range of equivalence. If the confidence interval on the excess loss is smaller than a threshold the error rates of the two different resampling procedures are considered to be "equivalent". This second analysis addresses some of the general criticism of procedures based on the "null hypothesis significance test" (NHST) framework and is in consonance of what is usually referred to in the medical literature as "practical significance" (as opposed to mere "statistical significance"). The final form of analysis is the Bayes factor test proposed by (Barber, 2012, chapter 12).

3.1 Demšar procedure

Demšar (2006) proposed a method to determine whether a statistically significant difference exists in the performance of multiple classifiers on many data sets. In our case, the different resampling procedures used in hyperparameter optimisation play the role of the different classifiers. Demšar suggests using the Friedman test as an omnibus nonparametric paired test (the pairing is each data set). This test computes the p-value based on the null hypothesis that all classifiers are "equivalent" in terms of their true rankings. If the p-value is low enough one would reject the claim that the classifiers are "equivalent" and should proceed to determine *which* differences are "statistically significant" or not. In the case that all classifiers are being compared on an equal basis, Demšar (2006) proposes the Nemeyi post-hoc test. In our case, we are not interested in comparing all pairs of procedures, but only in comparing each resampling procedure with the baseline provided by kf5. In this case, Demšar (2006) proposes pairwise Wilcoxon signed-rank tests (the paired version of the non-parametric Wilcoxon test), but with the correction to the resulting p-values due to the multiple comparison. He proposes either the Bonferroni-Dunn procedure, or one of the step-up/down procedures of Holm, Hochberg, or Hommel.

3.2 Confidence interval on the excess loss

The Demšar's procedure falls under the null hypothesis significance testing framework, that is, one assumes that there are no differences among the resampling procedures and declare that there is a "statistically significant" difference if the probability of a difference in mean rankings at least as large as that actually observed is below a pre-determined threshold (usually 0.05). However, even if a "statistically significant" difference exists, the effect size may be sufficiently small that it is of no relevance to practical applications. For example, it may be that the difference between one procedure and another is a decrease of (say) 0.0001 in the error rate. This difference could be "statistically significant" but would be unlikely to be "practically significant" (Kirk, 1996). One possible way of determining if there is a practically significant variation between a resampling procedure and kf5 (for instance) for selecting SVM hyperparameters would be to determine a confidence interval for the excess loss and show that (with 95% confidence) the excess loss exceeds a *threshold of equivalence*.

The important aspect of the confidence interval procedure is the definition of a "equivalence" threshold — above what level of excess loss should a difference be considered a "practically relevant" change in the error rate? In this paper we will propose a method to determine this threshold of equivalence. Besides the resampling procedures described in Section 2.1, we also evaluated another procedure which was a repetition of the kf5 procedure

but with different folds; we call it the kf5bis procedure. The difference between the kf5 and kf5bis procedure was the random generator seed, and thus the "luck/bad luck" the experimenter has in creating the folds. Thus, in some sense the excess loss of the kf5bis procedure is a limit of equivalence, not necessarily because it is small, but because it is an excess loss one cannot further reduce, since it represents the effect of "luck" in the resampling procedure for selecting the hyperparameter. Thus, in this paper we use the mean excess loss of the kf5bis procedure as the threshold of equivalence. Table 2 in Section 4.2 reports among the other resampling procedures, the mean excess loss of the kf5bis procedure as -0.0031. Thus in this paper we will consider excess loss within the range $[-0.0031, 0.0031]$ as irrelevant. Simplifying, the NHST approach would compute the confidence interval for the excess loss and declare that the excess loss is statistically significant if the confidence interval does not cross the zero. A "practical significance" approach computes the same confidence interval for the excess loss, but declares that the excess loss is "irrelevant" if the interval is fully contained in the $[-0.0031, 0.0031]$ range.

3.3 Bayes factor

The third method to compare error rates across different data sets is the Bayesian analysis proposed by Barber (2012, chapter 12). The excess loss analysis above is based solely on the value of the error rate. The Bayesian method is based on both the magnitude of the error rate and the number of samples used in evaluating that error rate. For example, one will be more willing to assume that a classifier a which made 50 errors over 500 samples is equivalent to a classifier b that made 55 errors in 500, than if the first made 700 errors in 7000 samples, while the second made 770. Although the change in error rate is the same in both cases (0.10 versus 0.11), nevertheless, because of the larger test set, one is less sure that the two classifiers are equivalent in the second scenario. The Bayesian analysis measures the ratio between the probability that the classifiers are the equivalent versus the probability that they are not equivalent (given the data), and this *Bayes factor* should be much lower in the second scenario.

Given two classifiers evaluated on the same data set (or in our case the classifiers based on the different choices of hyperparameters derived using different resampling procedures), the method computes "How much evidence is there that the two samples of correct and incorrect predictions in the test set comes from independent multinomial distributions?" which is a possible rephrasing of the question "How much evidence is there supporting the contention that the two classifiers are performing differently?" Let us assume that classifier a when applied to the test set results in $e_a = \langle c_a, i_a \rangle$ where c_a is the number of correct predictions, and i_a the number of incorrect predictions, and similarly for classifier b. $P(H_{\text{same}} \mid e_a, e_b)$ is the posterior probability that the pairs of correct and incorrect results e_a and e_b come from the same (unknown) binomial distribution, which would indicate that both classifiers are equivalent. $P(H_{\text{indep}} \mid e_a, e_b)$ is the posterior probability that they came from independent distributions and therefore that the two classifiers are not equivalent (more precisely, it will be very unlikely that the two independent distributions are the same). The Bayes factor (BF) is the ratio of these two probabilities:

$$BF = \frac{P(H_{\text{same}} \mid e_a, e_b)}{P(H_{\text{indep}} \mid e_a, e_b)} \tag{4}$$

The larger the Bayes factor, the higher is the evidence towards the hypothesis that the two classifiers are equivalent. If $Z(x)$ is the beta function of a pair, and $u = \langle 1, 1 \rangle$, then the BF is calculated as

$$BF = \frac{Z(u)Z(u + e_a + e_b)}{Z(u + e_a)Z(u + e_b)} \tag{5}$$

Appendix C contains the derivation of this formula. In our case, we will consider 5-fold cross-validation as the baseline, and we will compare all other procedures to it, and thus we will calculate for each resampling procedure its Bayes factor in relation to 5-fold cross-validation.

We will report the $2 \log_e BF$ as defined in Equation 4. The reason to use the log is that the BF is a multiplicative factor, and for the mean and confidence interval calculations we need an additive factor. The use of the constant 2 is to follow the table of Kass and Raftery (1995) regarding the interpretation of strength of the evidence in favour of one or the other hypothesis, which is based on $2 \log_e$.

3.4 Computational Expense

Considering the time consumed for hyperparameter selection via the different resampling procedures, we ran all of the procedures for a single data set in sequence on a single core (of a multiple core machine). Different data sets were distributed to different cores of the same machine. We collected the total time to perform the resampling procedure to select the hyperparameters — the time to learn the final classifier with the optimal hyperparameters and to apply it to the other half of the data set was not included in the time measure. Again we use 5-fold cross-validation as baseline, and report the ratio of the execution time of each procedure and the 5-fold cross-validation execution time. The statistical calculations are performed with the log of the time ratio, which was then converted back to report the mean and confidence interval.

3.5 Statistical procedure

Besides the statistical tests performed by the Demšar procedure, we are interested in estimation of the mean excess loss, the log BF, and the ratio of execution time for each resampling procedure, in relation to the 5-fold. To evaluate the confidence interval of the mean of each of these measures, we use a bootstrap procedure with the "BCA" (bias- corrected and accelerated) evaluation method for the confidence interval (Efron, 1987). We use a 95% confidence level and $5,000$ replications of the bootstrap procedure.

3.6 Reproducibility

The 121 data sets, the program used to run the hyperparameter search, the raw results for each resampling procedure and data set, the program to analyse the results and generate the figures in this paper are available at `https://dx.doi.org/10.6084/m9.figshare.1359901`.

4. Results

In this section we report the results obtained from all experiments using the 112 smallest data sets, for which the experiments were computationally feasible.

4.1 Demšar procedure

We performed the Friedman test (as implemented in the libraries of the R programming language) with the following results: Friedman $\chi^2 = 382.8071$, d.f. $= 17$, p-value $<$ 2.2e-16. Thus, we reject the hypothesis that all resampling procedures are equivalent. We then performed the Wilcoxon signed-rank test for each procedure against kf5. The resulting p-values are given in Table 1. The first column is the average rank of each resampling procedure. The table includes kf5 as the first entry. The results indicate that there is no clear winner among the different resampling procedures. Notice that all average ranks for the medium and large training set procedures are similar (around 7) with the exception of the resubstitution (average rank of 15.2). Note that the average rank for the kf5 procedure itself is 7.2; thus procedures with average rank less than 7.2 are "better" then kf5, while a larger average rank indicates "worse" resampling procedures.

The second column of Table 1 displays the original p-value (from the Wilcoxon test) without any correction for multiple comparisons. The third column shows the result of Holm's correction, followed by the results of the Hochberg, Hommel, and Bonferroni-Dunn corrections, where p-values below 0.05 (which indicates a 95% confidence) are in bold. Again the results of these tests suggest that resubstitution, and the *small training set* procedures (except 5x20/20) are inferior to kf5, and the other methods are statistically equivalent, or more precisely, we cannot show that the other methods are statistically dissimilar. Table 1 shows that besides resub, all other large and medium training procedure are not statistically significantly different from kf5.

4.2 Excess loss

Table 2 reports the mean and 95% confidence interval of the excess losses for each of the resampling procedures. Figure 1 repeats the excess loss data of Table 2, removing the resubstitution data. The result of the mean excess loss for the kf5bis is -0.0031. As discussed, the absolute value of that excess loss is our threshold of equivalence; excess losses with absolute value lower than 0.0031 are considered in this paper as irrelevant.

4.3 Bayes factor

Table 3 reports the results of the Bayes factor calculations. Most of the results for the log BF are within the range from 5.5 to 6.1 in favour of the hypothesis that the error rate of each of the resampling procedures are the same as kf5. Following the scale of interpretation given by Kass and Raftery (1995), if the $2\log_e$ of the Bayes factor is in the range from 2 to 6, the evidence should be considered "positive", and from 6 to 10 "strong". Thus most of the results are in the direction of a positive evidence in favour that the resampling procedures results are the same as the 5-fold results.

A more specific threshold is derived from the kf5 and kf5bis results (first two lines in Table 3). kf5 is the result of calculating the Bayes factor for the kf5 procedure itself, so we

procedure	mean rank	original	Holm	Hochberg	Hommel	Bonferroni
kf5	7.2					
kf5bis	6.7	0.08	0.51	0.51	0.40	1.00
kf2	6.8	0.66	1.00	0.78	0.78	1.00
kf3	6.3	0.04	0.39	0.36	0.30	0.74
2xkf5	6.2	0.23	0.99	0.71	0.68	1.00
kf10	6.5	0.04	0.39	0.36	0.30	0.76
5xboot	7.2	0.78	1.00	0.78	0.78	1.00
10xboot	5.8	0.20	0.99	0.71	0.60	1.00
20xboot	5.8	0.06	0.41	0.41	0.35	0.99

Table 1: The result of the Demšar procedure comparing the resampling procedures. First column names the procedure, second display the average rank. The following columns display the p-value of the Wilcoxon signed rank test when compared with kf5: the original p-value, and then after the Holm, Hochberg, Hommel, and Bonferroni corrections

are sure that both procedures have exactly the same expected generalization error, and yet for this case, the log Bayes factor is on average 5.89. Thus, 5.89 is the mean theoretical maximum of the log Bayes factor for the data sets used in the experiment. Thus, the results in Table 3 are very close to the mean maximum. The kf5bis provides a limit to what is a "relevant" certainty. By design, the kf5bis results should be irrelevantly different than their kf5 counterpart — it could be that for one data set, the kf5bis result is sufficiently different to the kf5 result, but we are averaging over 112 data sets. So, we would like to make the claim that Bayes factor above 5.70, which is the average of the kf5bis, show that the differences are irrelevant to this problem. Figure 2 repeats the Bayes factor data Table 3 for data points around the 5.70 threshold above which one should consider that there is enough evidence that the resampling procedure is equivalent to the 5-fold.

4.4 Computational Expense

Table 4 reports the mean and confidence interval of the ratio of the time required for each resampling procedure and that for kf5. We would like to point out some anomalies or

unexpected results regarding the computational expense. The first one is that resubstitution is slower than kf5. A second one is that the 5-times repeated 20/20 and 10/10 are only three times as expensive as the corresponding non-repeated procedure. We do not know how to explain these results, but it is possible that they are also due to interference between different runs; as discussed in Section 3.4 the many cores of the machines were executing the experiments in different data sets at the same time.

5. Discussion

The results for the medium-training procedures (kf2 and kf3) are a welcome surprise. The Demšar analysis shows that they are not significantly different to those obtained using kf5. Furthermore, the excess loss confidence interval shows that their excess loss is mostly within the irrelevance threshold, and the Bayes factor indicates that there is good evidence that their performances are equivalent to that of kf5. However, these two procedures select the SVM hyperparameters in 33% and 55% of the time of the kf5 procedure — a useful computational saving.

Most of the large-training procedures have a negative mean excess loss, that is, they select hyperparameters that result in slightly lower error rates for the future data. The two

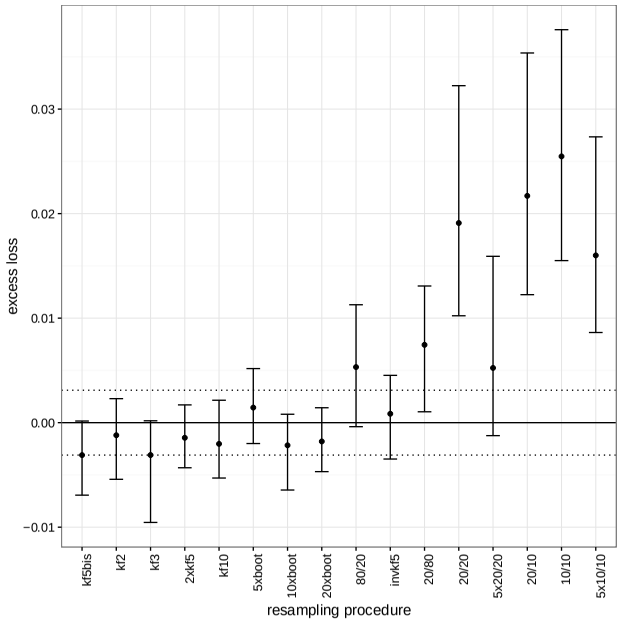

Figure 1: Excess loss in relation to kf5 for the resampling procedures (resubstitution not included). The dotted line indicates the limit for what is considered an irrelevant change in the loss.

exceptions are the 80/20 and the resub procedures discussed below. But for all procedures that result in a better selection of the hyperparameters the mean excess loss it is still within our range of equivalence to kf5. That is, even using computationally more expensive procedures such as 20- and 10-times bootstrap, 2 times repeated 5-fold, on average it is not likely that there will be relevant changes in the final error rate of the classifier. This result is consistent with the Demšar analysis, which show no statistically significant differences between these procedures and kf5. The two large-training resampling procedures that have positive excess loss are the 20% hold-out (80/20) and the resubstitution estimator. The result for resubstitution is widely known—the use of the same data for training and testing causes severe overfitting—but we have shown that the overfitting is also severe in regards to hyperparameter selection.

The small-training procedures all incur positive excess losses, to varying extents, and thus are in general "worse" than kf5, but the inverse-kf5 and the 20/80 holdout have the lowest mean excess loss. The excess loss for the 20/20 procedures (sample 20% for training and 20% for testing), and for the 20/10 and 10/10 procedures are very significant. We

Table 3: $2\log_e$ of the Bayes factor of the hypothesis that the resampling procedure results are the same as the kf5 results versus the hypothesis that they are independent. The numbers in the table are the mean difference of the log of the Bayes factor between the procedures indicated in the left column and the kf5. The last two columns are the 95% confidence interval for the mean.

conclude from these observations, that there seems to be no real gain in using resampling procedures more costly than 5-fold cross-validation. On the other hand, the kf2 and kf3 procedures seem to achieve a similar result to kf5, with lower computational costs.

An important issue is whether the results for the equivalence, for practical purposes, of the kf2, kf3 and kf5 procedures carries forward to larger and higher dimensional data. We tested the kf2 and kf3 on the 9 largest data sets. The results are in Table 5. The table shows the excess loss in relation to kf5, the log BF of both procedures and the kf5 log BF (which indicates the maximum value) and the time ratios in relation to kf5. With the exception of the nursery data set, all excess losses are within our limit or irrelevance, and the BF are close to the maximum, a very strong evidence that these procedures perform equally well for larger size data sets. Figures 3 and 4 show the values of the excess loss as a function of the data set size and the number of dimensions of the data. For data sets with sizes beyond the examples tested, one can look at the trend of excess loss as a function of the data set size in Figures 3 and 4: there is a compelling trend of diminishing excess loss as the data set size increase. Therefore we are very confident that one can safely use kf2 or kf3 to tune

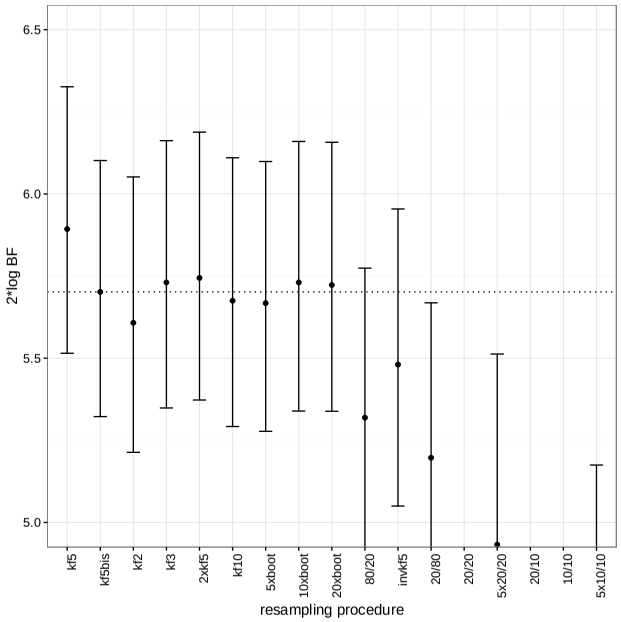

Figure 2: Bayes factor of the ratio of the probabilities that the resampling procedure and the 5-fold are equivalent. Data around the 5.7 threshold, above which one should consider that there is enough evidence to claim the equivalence.

SVM hyperparameters in large data sets. Note that as the size of the dataset increases, the bias and variance of most resampling procedures tend to decrease, so this is entirely in accord with a-priori intuition.

The evidence of a decreasing trend for larger dimensionality is less compelling for the kf2 than it is for the kf3. For one data set with larger dimensionality, the excess loss of kf2 is outside our range of irrelevance, but that is not true for the kf3. It should be noted though that the RBF kernel is often unsuitable for high-dimensional datasets and a linear kernel is often preferable in such cases (Hsu et al., 2010).

Another important issue is whether the practical equivalence of the kf2 and kf3 to kf5 is also valid for an SVM with other kernels. We evaluated the excess loss of kf2 and kf3 on the 112 smallest datasets on SVM with polynomial and linear kernels. The results are displayed in Table 6. The data are also displayed in Figure 5. The results are not too different than the excess loss for the RBF SVM, with the exception of a somewhat higher excess loss for the kf2 for linear SVM. So we believe that the conclusions of practical equivalence of the kf2

and kf3 resampling procedures in relation to the kf5 resampling to select hyperparameters are also valid for the linear and polynomial SVM.

5.1 Limits of this research

The strength of the conclusions of this research rests on the assumption that the set of 121 data set used are a good sample of "real life" data sets. There are limits to this assumption. Fernández-Delgado et al. (2014) did not include large data sets (large number of data points

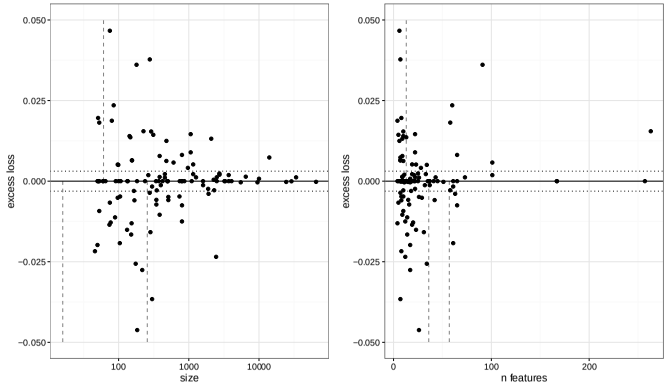

Figure 3: The excess loss of the kf2 procedure in relation to the dataset size and dimensionality. The dotted horizontal line is our threshold of irrelevance. The dashed transparent vertical line indicates that there is a data point at that position that was clipped from the graph.

Kernel	procedure	mean	min	max
Polynomial	kf2	**0.006**	0.002	0.010
	kf3	0.001	-0.003	0.004
Linear	kf2	0.002	0.000	0.005
	kf3	0.002	0.000	0.007

Table 6: Excess loss for the kf2 and kf3 procedures on SVm with Polynomial and Linear kernels.

or large number of features). Thus, our sample does not reflect large data sets (especially text-classification datasets which also have a high dimensionality). Practitioners working with these kinds of data sets are advised to check our conclusions before following them.

It has been suggested that the outer 2-fold procedure to estimate $\check{\epsilon}$ was probably too noisy since kf2 is a high variance estimator. Appendix E shows that even using a 5xkf2 (on the 42 data sets with at most 400 data) the results do not change significantly — but the confidence intervals are somewhat reduced. Therefore, even if a lower variance estimator of $\check{\epsilon}$ was used, we do not believe the results would change substantively.

This research assumed that kf5 was the "standard" resampling procedure for hyperparameter selection, and compared all other procedures against kf5. The many results in the paper show, among others, kf2 and kf3 are equivalent from a practical point of view to kf5. But that might not be the case for more costly, low variance procedures such as kf10 or 20xboot. Appendix F shows the result of the Nemenyi test for comparing all resampling

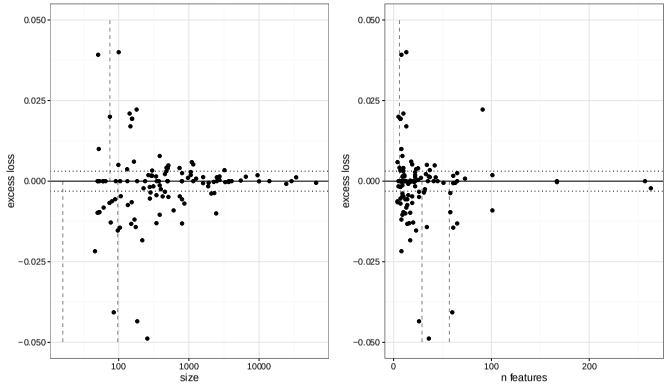

Figure 4: The excess loss of the kf3 procedure in relation to the dataset size and dimensionality. The dotted horizontal line is our threshold of irrelevance. The dashed transparent vertical line indicates that there is a data point at that position that was clipped from the graph.

procedures against each other. None of the large-training and medium-training procedures are statistically significantly different from each other, with the exception of 80/20 and resub which were also not equivalent to kf5.

5.2 Methodological discussion

We believe that besides the important result of a strong suggestion of using 2-fold or 3-fold cross validation to select the hyperparameters of an SVM this research also opens an important methodological discussion on at least three topics. The first is the use of a Bayesian framework for the comparison of classifiers. The second is the use of concepts of "practical irrelevance" or "practical equivalence" in machine learning, and in particular the use of the kf5bis to discover the threshold of equivalence. The final issue, is whether it is methodologically sound to average excess losses. The Bayes factor approach resulted in a metric that is not very sensitive. Most of the results in Table 3 are similar to each other and almost all are in the range of positive evidence, but as we have shown using the results of kf5, this seems to be the strongest evidence possible in this problem. Our decisions regarding the BF should be reviewed by future researchers in search of a more sensitive metric. For example, we used only the number of correct and incorrect predictions in the Bayesian calculations. Barber (2012) implicitly suggest both these measures and also using the 4-tuple of true positives, true negatives, false positives, and false negatives.

We must explain why we used two other analysis procedures beyond the usual Demšar proposal. As we discussed, the Demšar (2006) procedure falls within the NHST framework, and other empirical sciences realized that NHST are rarely the correct tool to analyse data

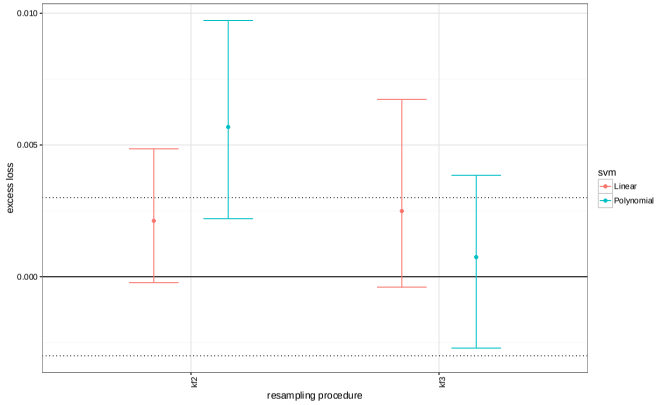

Figure 5: The excess loss of the kf2 and kf3 procedures for Linear and Polynomial SVM, measured on the 112 smallest dataset. The dotted line is the threshold of practical equivalence.

(Gardner and Altman, 1986; Thompson, 2002; Woolston, 2015). Significance tests can tell us that two samples are different enough that it is unlikely that they came from the same population, but not whether the difference matters for any practical purpose. Alternatively, significance tests can tell us that there is not enough evidence to make the claim that the two samples came from the same population, which in no way means that the two samples are "the same." Our proposal of using a confidence interval on an effect size and a measure of practical equivalence is one possible direction, as is our usage of Barber (2012) Bayesian analysis.

Another methodological proposal was to use the kf5bis (a different random selection for the kf5) as a way of determining a threshold of equivalence. The differences between kf5 and kf5bis should on average over many data sets be irrelevant, either because they are too small to matter or because there is no way to reduce them.

The final discussion is whether computing the mean (and confidence interval) of a excess loss is a sound procedure. An argument against it is that error rates (and therefore differences in error rates) cannot be compared across different data sets. One can argue that an improvement of 0.05 in the error rate would be a substantial improvement if the error rate was originally 0.08; however an improvement of 0.05, where the original error rate was 0.28, is rather less significant. The same number (0.05) seems to mean different things in these two situations, and therefore adding those two numbers (to compute the average) does not seems a reasonable operation. We believe that the source of this problem is that the variance of the error rates across different resampling procedures, for example, varies as a function of the error rate itself. If the variance of error rates for low error rates is low, then 0.05 is a considerable magnitude (in standard deviations) for an error rate of 0.08. The

variance should be much larger for an error rate of 0.28, which in turn means that 0.05 is not such a large change in that case. But as Appendix D shows, the variance of the excess loss (for all procedures) does not increase as the error rate (for the kf5 procedure) increases. In fact the variance can be seen as constant across the different error rates, and that would allow one to compute the average of the excess losses.

6. Conclusions

This research has evaluated the impact of different resampling procedures in the selection of SVM hyperparameters, by comparing 17 different procedures in 121 data sets. The conclusion is that the 2-fold procedure should be used in data sets with more than 1000 points. In these cases the user may expect a difference of -0.0031 to 0.0031 in the error rate of the classifier if a 5-fold procedure was used, which we believe is the limit of what one should consider an irrelevant change in the classifier error rate. For smaller data sets, we could not detect any significant difference (on average) between 5-fold and computationally more costly procedures such as 10-fold, 5 to 20 times repeated bootstrap, or 2 times repeated 5-fold. We believe that a 3-fold is appropriate for smaller data sets.

Acknowledgments

The authors would like to thank the anonymous reviewers and the editor for their detailed and constructive comments that have significantly improved this paper, and Nicola Talbot for her careful proof-reading and copy-editing. The first author would like to thank a Microsoft Azure Research Award that allowed to run some of the experiments in this research in the Azure cloud.

Appendix A. Terminology

resampling vs cross-validation. What we called *resampling* is frequently called *cross-validation*. We decided to use *resampling* instead of the most common term *cross-validation*, because we understand that the "cross" term in *cross validation* implies a subset that is used in training and then again in testing, as in the k-fold procedure. That is not necessarily true for the bootstrap procedure — there is no subset that is by construction used in the training and then in the testing. Resampling procedures are also called *out-of-sample* techniques (Anguita et al., 2012).

k-fold also known as *k-fold cross validation* or *cross-validation* by itself (Kuhn et al., 2014).

hold out is sometimes called *leave group out* (Kuhn et al., 2014) or *split sample* (Molinaro et al., 2005).

model selection (Cawley and Talbot, 2010) is also called *selection of hyperparameters* or *hyperparameter optimization* (Bergstra and Bengio, 2012) or *hyperparameter tuning* (Duan et al., 2003)

bootstrap: in the version of bootstrap described here the error rate is measured solely on the test set which contains only the data not included in the training set. Two other variations of bootstrap are commonly used: the .632-bootstrap (Efron, 1983) and the .632+-bootstrap (Efron and Tibshirani, 1997). For these methods the error estimate is calculated using not only the test set, but also the error rate of the training set itself.

Appendix B. Data sets

Table 7 lists the characteristics of all data sets, ordered by size. The name of the data set is the same as those used in Fernández-Delgado et al. (2014). The size refers to one half of the data set (please refer to section 2 regarding the methodology to compute the excess log loss). The *nfeat* column is the number of features or number of dimensions of the data in the data sets; *ndata* the number of patterns; *prop* the proportion of data in the positive class. *Notes* has the following values:

- r the data set was removed from all analysis because all cross validation tests have less than 5 examples of a particular class
- s some of the experiments did not run because their test sets had less than 5 examples of a particular class
- m the data set describes a multiclass problem, and so was converted to a binary problem using the procedure discussed in section 2
- l the data set has more than 5000 patterns so it was used in the large data set validation.
- t the data set was originally divided into a test and train set, where the test set was not standardized (see section 2).

Figure 6 displays the histogram of the proportion of the positive class.

Appendix C. Derivation of the Bayes factor formula

The derivation below is taken from chapter 12 of Barber (2012) by fixing the data for each classification (e_i) to be a pair number-of-correct-predictions and number-of-incorrect-predictions, and by computing the BF as $\frac{p(H_{\text{same}}|e_a,e_b)}{p(H_{\text{indep}}|e_a,e_b)}$ instead of $\frac{p(h_{\text{indep}}|e_a,e_b)}{p(h_{\text{same}}|e_a,e_b)}$. Let us assume that classifier a when running on the test set results in $e_a = \langle c_a, i_a \rangle$ where c_a is the number of correct predictions, and i_a the number of incorrect predictions, and similarly for classifier b. The standard Bayesian model selection method is to calculate:

$$\frac{P(H_1 \mid e_a, e_b)}{P(H_2 \mid e_a, e_b)} = \frac{P(e_a, e_b \mid H_1)}{P(e_a, e_b \mid H_2)} \frac{P(H_1)}{P(H_2)}.$$

In this case, H_1 is the hypothesis that the two data e_a and e_b come from independent multinomial distributions (H_{indep}) and H_2 that they come from the same distribution (H_{same}). Also let us assume that there is no prior preference for choosing any of these two hypothesis, and thus $P(H_{\text{indep}}) = P(H_{\text{same}})$.

For both hypothesis we will assume that the two values c_i and i_i are sampled from a multinomial distribution, $P(\langle c_a, i_a \rangle = \langle a_1, a_2 \rangle \mid \alpha = \rangle \alpha_1, \alpha_2 \rangle) = \alpha_1^{a_1} \alpha_2^{a_2}$, with an unknown α. α is sampled from a Dirichlet distribution:

$$P(\alpha) = \frac{1}{Z(u)} \alpha_1^{u_1 - 1} \alpha_2^{u_2 - 1},$$

where $Z(u)$ is the normalizing constant

$$Z(u) = \frac{\Gamma(u_1)\Gamma(u_2)}{\Gamma(u_1 + u_2)},$$

$\Gamma(.)$ is the gamma function and $u = \langle u_1, u_2 \rangle$ is the parameters of the Dirichelet distribution. $u = \langle 1, 1 \rangle$ results in a uniform distribution over the possible values of α_1 and α_2. The same is assumed for c_b and i_b.

For the independent hypothesis, we assume that the two data e_a and e_b comes from independent distributions, with independent α and β, that is

$$\begin{aligned} P(e_a, e_b \mid H_{\text{indep}}) &= \int P(e_a, e_b \mid \alpha, \beta, H_{\text{indep}}) P(\alpha, \beta \mid H_{\text{indep}}) d\alpha d\beta, \\ &= \int P(e_a \mid \alpha, H_{\text{indep}}) P(\alpha \mid H_{\text{indep}}) d\alpha \int P(e_b \mid \beta, H_{\text{indep}}) P(\beta \mid H_{\text{indep}}) d\beta, \\ &= \frac{Z(u+e_a)}{Z(u)} \frac{Z(u+e_b)}{Z(u)}. \end{aligned}$$

For the same hypothesis, we assume that both e_a and e_b were sampled from the same (unknown) multinomial distribution:

$$\begin{aligned} P(e_a, e_b \mid H_{\text{same}}) &= \int P(e_a, e_b \mid \alpha, H_{\text{same}}) P(\alpha, \mid H_{\text{same}}) d\alpha, \\ &= \int P(e_a \mid \alpha, H_{\text{same}}) P(e_b \mid \alpha, H_{\text{same}}) P(\alpha \mid H_{\text{same}}) d\alpha, \\ &= \frac{Z(u+e_a+e_b)}{Z(u)}. \end{aligned}$$

Thus, the Bayes factor is:

$$BF = \frac{p(H_{\text{same}} \mid e_a, e_b)}{p(H_{\text{indep}} \mid e_a, e_b)} = \frac{Z(u) Z(u+e_a+e_b)}{Z(u+e_a) Z(u+e_b)}. \tag{6}$$

Appendix D. Variance of the excess loss

Figure 7 is a scatter plot of all excess losses for all procedures as a function of the kf5 error rate. The figure seems to indicate that the variance ~~is~~ does not increase as the error rate increases, as discussed in the text. Figure 8 computes the variance of the excess losses for all procedures for different kf5 error rates. The kf5 error rate was divided into 20 equal ranges, and the variance of the excess loss was computed for each range. The figure places the variance at the mean kf5 error rate for each range. Not all ranges are represented in the figure because 3 of them fall between the last two kf5 error rates.

Appendix E. The outer loop

The outer loop in the experiments is a 2-fold, that is we run the experiments in half of the data set and measure the error rate in the second half, then we change the train and test halves, and average the two measures. But kf2 is a high variance estimation. To evaluate the consequence of this choice, we ran an experiment where the outer loop is a 5xkf2, a 5-times repeated kf2, for all data sets with less than 400 points. The results are reported in Figure 9. The figure plots the mean and confidence intervals for the original experiment with a kf2 outer loop and the 5xkf2 experiment, for 42 data sets with less than 400 data. The results show that there was a reduction in the confidence interval for the large- and mid-training procedures, but no systematic difference in the mean excess loss. For the small training procedures there seems to be a small decrease in the mean excess loss, and usually

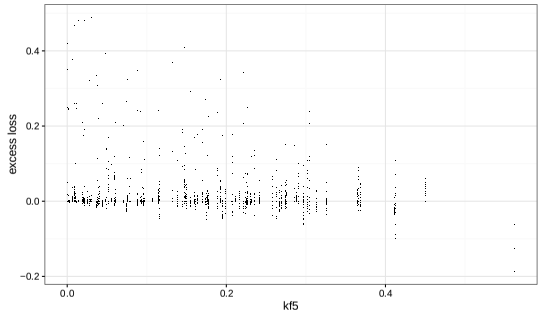

Figure 7: Scatter plot of all excess losses (for all procedures) as a function of the kf5 error rate.

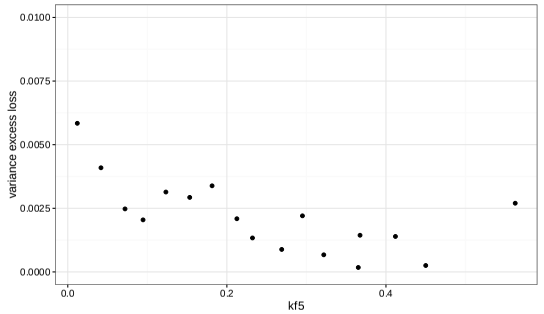

Figure 8: Variance of all excess losses for different kf5 error rates.

a small decrease in the confidence intervals, but not for all procedures. These differences should diminish as the data set increases in size. Thus had we used a repeated kf2 in the outer loop, the results would likely be similar, with maybe a small reduction on the sizes of the confidence intervals.

Abstract

Binary classification is the problem of predicting the class a given sample belongs to. To achieve a good prediction performance, it is important to find a suitable model for a given dataset. However, it is often time consuming and impractical for practitioners to try various classification models because each model employs a different formulation and algorithm. The difficulty can be mitigated if we have a unified formulation and an efficient universal algorithmic framework for various classification models to expedite the comparison of performance of different models for a given dataset. In this paper, we present a unified formulation of various classification models (including C-SVM, ℓ_2-SVM, ν-SVM, MM-FDA, MM-MPM, logistic regression, distance weighted discrimination) and develop a general optimization algorithm based on an accelerated proximal gradient (APG) method for the formulation. We design various techniques such as backtracking line search and adaptive restarting strategy in order to speed up the practical convergence of our method. We also give a theoretical convergence guarantee for the proposed fast APG algorithm. Numerical experiments show that our algorithm is stable and highly competitive to specialized algorithms designed for specific models (e.g., sequential minimal optimization (SMO) for SVM).

Keywords: restarted accelerated proximal gradient method, binary classification, minimum norm problem, vector projection computation, support vector machine

1. Introduction

Binary classification is one of the most important problems in machine learning. Among the wide variety of binary classification models which have been proposed to date, the most popular ones include support vector machines (SVMs) (Cortes and Vapnik, 1995; Schölkopf et al., 2000) and logistic regression (Cox, 1958). To achieve a good prediction performance, it is often important for the user to find a suitable model for a given dataset. However, the task of finding a suitable model is often time consuming and tedious as different classification models generally employ different formulations and algorithms. Moreover, the user might have to change not only the optimization algorithms but also solvers/software in order to solve different models. The goal of this paper is to present a unified formulation for various classification models and also to design a fast universal algorithmic framework for solving different models. By doing so, one can simplify and speed up the process of finding the best classification model for a given dataset. We can also compare various classification methods in terms of computation time and prediction performance in the same platform.

In this paper, we first propose a unified classification model which can express various models including C-SVM (Cortes and Vapnik, 1995), ν-SVM (Schölkopf et al., 2000), ℓ_2-SVM, logistic regression (Cox, 1958), MM-FDA, MM-MPM (Nath and Bhattacharyya, 2007), distance weighted discrimination (Marron et al., 2007). The unified model is first formulated as an unconstrained ℓ_2-regularized loss minimization problem, which is further transformed into the problem of minimizing a convex objective function (quadratic function, plus additional terms only for logistic regression) over a simple feasible region such as the intersection of a box and a hyperplane, truncated simplex, unit ball, and so on. Taking different loss functions (correspondingly different feasible regions in the transformed problem) will lead to different classification models. For example, when the feasible region is given by the intersection of a box and a hyperplane, the unified formulation coincides with the well-known C-SVM or logistic regression, and when the region is given by a truncated simplex, the problem is the same as the ν-SVM.

It is commonly acknowledged that there is "no free lunch" in supervised learning in the sense that no single algorithm can outperform all other algorithms in all cases. Therefore, there can be no single "best" software for binary classification. However, by taking advantage of the above-mentioned unified formulation, we can design an efficient algorithm which is applicable to the various existing models mentioned in the last paragraph. Our proposed algorithm is based on the accelerated proximal gradient (APG) method (Beck and Teboulle, 2009; Nesterov, 2005) and during the algorithm, only the procedure for computing the projection onto the associated feasible region differs for different models. In other words, by changing the computation of the projection, our algorithm can be applied to arbitrary classification models (i.e., arbitrary feasible region) without changing the optimization algorithmic framework. The great advantage of our algorithm is that most existing models have simple feasible regions, which make the computation of the projection easy and efficient.

The APG method is known to be one of the most efficient first-order methods theoretically. In order to make our APG based method practically efficient, we further employ various techniques such as backtracking line search (Beck and Teboulle, 2009; Scheinberg et al., 2014) and adaptive restarting strategies (O'Donoghue and Candès, 2015) to speed up the convergence of the algorithm. Our method incorporates several speed-up strategies while guaranteeing its convergence even for a general non-strongly convex function. Since our method is a further improvement of the standard APG method, we will call it as fast accelerated proximal gradient (FAPG) method. Our FAPG method improves several other restarting schemes (Nesterov, 2013; Lin and Xiao, 2015; Su et al., 2014) which have guaranteed convergence in the case when the objective function is strongly convex. To make our method even more efficient in practice, we simplify some steps in the implementation

of our FAPG algorithm, though we can no longer ensure its theoretical convergence. To summarize, while our method has extensive generality, numerical experiments show that it performs stably and is highly competitive to specialized algorithms designed for specific classification models. Indeed, our method solved SVMs with a linear kernel substantially faster than LIBSVM (Chang and Lin, 2011) which implemented the SMO (Platt, 1998) and SeDuMi (Sturm, 1999) which implemented an interior-point method. Moreover, our FAPG method often run faster than the highly optimized LIBLINEAR (Fan et al., 2008) especially for large-scale datasets with feature dimension $n > 2000$. The FAPG method can be applied not only to the unified classification model but also to the general convex composite optimization problem such as ℓ_1-regularized classification models, which are solved faster than LIBLINEAR in most cases. It may be better to think of a stochastic variant of our method for further improvement and we leave it as a future research topic. We focus here on the deterministic one as the first trial to provide an efficient unified algorithm which is applicable to all well-known existing classification models.

The rest of this paper is organized as follows. Section 2 introduces some preliminary definitions and results on binary classification models and the APG method. Section 3 presents a unified formulation of binary classification models. In Section 4, we provide solution methods for the unified formulation. We develop efficient algorithms for computing projections which are used in the APG method. Then we design our FAPG method combined with various techniques to speed-up its practical convergence. The iteration complexity of $O\big((\log k/k)^2\big)$ of our algorithm is also established, where k is the iteration counter. Numerical experiments are presented in Section 5.

2. Preliminaries

In this section, we introduce some preliminary definitions on binary classification models and the APG method.

2.1 Binary Classification Models

Let $\mathcal{X} \subset \mathbb{R}^n$ be the input domain and $\{+1, -1\}$ be the set of the binary labels. Suppose that we have samples,

$$(\boldsymbol{x}_1, y_1), \ldots, (\boldsymbol{x}_m, y_m) \in \mathcal{X} \times \{+1, -1\}.$$

Define $M := \{1, \ldots, m\}$, $M_+ := \{i \in M \mid y_i = +1\}$, and $M_- := \{i \in M \mid y_i = -1\}$. Let $m_+ = |M_+|$ and $m_- = |M_-|$.

We compute $(\boldsymbol{w}, b)$ for a decision function $h(\boldsymbol{x}) = \boldsymbol{w}^\top \boldsymbol{x} - b$ using these samples and use $h(\boldsymbol{x})$ to predict the label for a new input point $\hat{\boldsymbol{x}} \in \mathcal{X}$. If $h(\hat{\boldsymbol{x}})$ is positive (resp. negative), then the label of $\hat{\boldsymbol{x}}$ is predicted to be $+1$ (resp. -1). Here we focus on linear learning models by using linear functions $h(\boldsymbol{x})$, but the discussions in this paper can be directly applied to non-linear kernel models (Schölkopf and Smola, 2002) using nonlinear maps $\phi(\boldsymbol{x})$ mapping $\boldsymbol{x}$ from the original space to a high dimensional space.

There are various binary classification models to compute $(\boldsymbol{w}, b)$ such as the support vector machines (SVMs), e.g. (Cortes and Vapnik, 1995; Schölkopf et al., 2000; Schölkopf and Smola, 2002), the margin maximized minimax probability machine (MM-MPM) (Nath and Bhattacharyya, 2007), the model based on Fisher's discriminant analysis (MM-FDA) (Bhattacharyya, 2004; Takeda et al., 2013), and the logistic regression (Cox, 1958).

Many binary classification models have the following formulation which consists of the sum of loss of each sample and a regularization term:

$$\min_{\boldsymbol{w},b} \sum_{i=1}^{m} \ell\big(y_i(\boldsymbol{w}^\top \boldsymbol{x}_i - b)\big) + \frac{1}{C}\|\boldsymbol{w}\|_p^p, \tag{1}$$

where $\ell : \mathbb{R} \to \mathbb{R}$ is a proper, closed, and convex function; $C > 0$ is a parameter; and $\|\cdot\|_p$ is the p-norm with $p \in [1, \infty]$.

2.2 Accelerated Proximal Gradient Method

In this section, we first introduce the accelerated proximal gradient (APG) method (Beck and Teboulle, 2009) which is designed for the following problem:

$$\min_{\boldsymbol{\alpha} \in \mathbb{R}^d} F(\boldsymbol{\alpha}) := f(\boldsymbol{\alpha}) + g(\boldsymbol{\alpha}). \tag{2}$$

Note that one can express a minimization problem constrained over a set S in the form of (2) by setting $g = \delta_S$, where

$$\delta_S(\boldsymbol{\alpha}) = \begin{cases} 0 & (\boldsymbol{\alpha} \in S) \\ +\infty & (\boldsymbol{\alpha} \notin S) \end{cases}$$

is the indicator function of the set S.

To apply the APG method to (2), we need to assume the following conditions:

1. $g : \mathbb{R}^d \to \mathbb{R} \cup \{+\infty\}$ is a proper, closed, and convex function which is possibly nonsmooth. Its effective domain $\mathrm{dom}(g) = \{\boldsymbol{\alpha} \in \mathbb{R}^d \mid g(\boldsymbol{\alpha}) < +\infty\}$ is closed and convex.

2. $f : \mathbb{R}^d \to \mathbb{R}$ is a proper, closed, convex, and continuously differentiable function, and its gradient $\nabla f(\cdot)$ is Lipschitz continuous on $\mathbb{R}^d$,[1] i.e., there exists a constant $L > 0$ such that
$$\|\nabla f(\boldsymbol{\alpha}) - \nabla f(\boldsymbol{\beta})\|_2 \le L\|\boldsymbol{\alpha} - \boldsymbol{\beta}\|_2 \quad \forall \boldsymbol{\alpha}, \boldsymbol{\beta} \in \mathbb{R}^d. \tag{3}$$
The minimum value of such L is referred to as the Lipschitz constant L_f of $\nabla f(\cdot)$.

3. The problem (2) is solvable, i.e., the optimal value is finite and an optimal solution $\boldsymbol{\alpha}^*$ exists.

Let $L \ge L_f$. We define an approximate function $Q_L : \mathbb{R}^d \to \mathbb{R}$ of $f(\boldsymbol{\alpha})$ around $\boldsymbol{\beta}$ and a mapping $T_L(\boldsymbol{\alpha}) : \mathbb{R}^d \to \mathbb{R}^d$ as follows:

$$Q_L(\boldsymbol{\alpha}; \boldsymbol{\beta}) = f(\boldsymbol{\beta}) + \langle \nabla f(\boldsymbol{\beta}), \boldsymbol{\alpha} - \boldsymbol{\beta} \rangle + \frac{L}{2}\|\boldsymbol{\alpha} - \boldsymbol{\beta}\|_2^2 + g(\boldsymbol{\alpha})$$
$$T_L(\boldsymbol{\beta}) = \operatorname*{argmin}_{\boldsymbol{\alpha} \in \mathbb{R}^d} Q_L(\boldsymbol{\alpha}; \boldsymbol{\beta}).$$

1. It is sufficient if $\nabla f(\cdot)$ is Lipschitz continuous on a neighborhood of $\mathrm{dom}(g)$: the convex hull of $\mathrm{dom}(g) \cup \{\boldsymbol{\beta}^k \mid k = 1, 2, \ldots\}$, where $\boldsymbol{\beta}^k$ $(k = 1, 2, \ldots)$ are points generated at Step 3 of the APG method. Obviously, however, it is not possible to know the points a priori.

The basic proximal gradient (PG) method generates a sequence $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$ by

$$\boldsymbol{\alpha}^{k+1} = T_L(\boldsymbol{\alpha}^k) \;=\; \operatorname*{argmin}_{\boldsymbol{\alpha}\in\mathbb{R}^d} \Big\{ g(\boldsymbol{\alpha}) + \frac{L}{2}\Big\|\boldsymbol{\alpha} - \Big(\boldsymbol{\alpha}^k - \frac{1}{L}\nabla f(\boldsymbol{\alpha}^k)\Big)\Big\|_2^2 \Big\}$$
$$= \operatorname{prox}_{g,L}\Big(\boldsymbol{\alpha}^k - \frac{1}{L}\nabla f(\boldsymbol{\alpha}^k)\Big),$$

where $\operatorname{prox}_{g,L}(\bar{\boldsymbol{\alpha}}) := \operatorname{argmin}_{\boldsymbol{\alpha}\in\mathbb{R}^d}\Big\{g(\boldsymbol{\alpha}) + \frac{L}{2}\|\boldsymbol{\alpha}-\bar{\boldsymbol{\alpha}}\|_2^2\Big\}$ is the proximal operator of g. If $g = \delta_S$, then $\operatorname{prox}_{g,L_k} = P_S$, where $P_S(\bar{\boldsymbol{\alpha}}) = \operatorname{argmin}_{\boldsymbol{\alpha}\in S}\|\boldsymbol{\alpha}-\bar{\boldsymbol{\alpha}}\|_2$ is the orthogonal projection of $\bar{\boldsymbol{\alpha}}$ onto the set S. In this case, the above PG method coincides with the gradient projection method. If $g(\cdot) = \|\cdot\|_1$, then $\big(\operatorname{prox}_{g,L}(\boldsymbol{\alpha})\big)_i = \operatorname{sign}(\alpha_i)\max\{0, |\alpha_i| - L\}$ $(i = 1, 2, \ldots, d)$ which is known as the soft-thresholding operator. Other analytical computations of the proximal operators of various g can be found in (Parikh and Boyd, 2014, Section 6).

It is known that the PG method has the iteration complexity such that $F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \le O(1/k)$, where $\boldsymbol{\alpha}^*$ is an optimal solution of (2). The APG method (Beck and Teboulle, 2009), which is also known as *FISTA*, is an acceleration of the PG method. It generates two sequences $\{\boldsymbol{\beta}^k\}_{k=1}^{\infty}$ and $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$. For an arbitrary initial point $\boldsymbol{\beta}^1 = \boldsymbol{\alpha}^0 \in \mathbb{R}^d$ and $t_1 = 1$, the APG method solves (2) through the following steps $(k = 1, 2, \ldots)$:

Accelerated Proximal Gradient Method

Step 1. Compute
$$\boldsymbol{\alpha}^k = T_L(\boldsymbol{\beta}^k) = \operatorname{prox}_{g,L}\Big(\boldsymbol{\beta}^k - \frac{1}{L}\nabla f(\boldsymbol{\beta}^k)\Big).$$

Step 2. Compute $t_{k+1} = \frac{1+\sqrt{1+4t_k^2}}{2}$.

Step 3. Compute $\boldsymbol{\beta}^{k+1} = \boldsymbol{\alpha}^k + \frac{t_k - 1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$.

For the APG method, the iteration complexity result such that $F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \le O(1/k^2)$ is known (see (Beck and Teboulle, 2009, Theorem 4.4)). The second term $\frac{t_k-1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$ in Step 3 can be seen as the *momentum* of the sequence $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$. It enlarges the moving distance of the sequences $\{\boldsymbol{\alpha}\}_{k=0}^{\infty}, \{\boldsymbol{\beta}\}_{k=1}^{\infty}$ which may lead them closer to the optimum $\boldsymbol{\alpha}^*$ more quickly. While various other APG methods (e.g, (Nesterov, 2013; Monteiro et al., 2016; Su et al., 2014)) are proposed, the above APG (namely, FISTA) is used in many applications because it is simpler to implement.

It is known that $\boldsymbol{\alpha}^*$ is an optimal solution of (2) if and only if $\boldsymbol{\alpha}^* = T_L(\boldsymbol{\alpha}^*)$. More specifically, the necessary and sufficient optimality condition for $\boldsymbol{\alpha}^*$ to be an optimal solution of (2) is

$$\exists \gamma_\alpha \in \partial g(\boldsymbol{\alpha}^*) \quad \text{s.t.} \quad \langle \nabla f(\boldsymbol{\alpha}^*) + \gamma_\alpha,\ \boldsymbol{\alpha} - \boldsymbol{\alpha}^* \rangle \ge 0, \quad \forall \boldsymbol{\alpha} \in \mathbb{R}^d. \tag{4}$$

On the other hand, from the definition of $T_L(\boldsymbol{\beta})$, we have

$$\exists \gamma_\beta \in \partial g(T_L(\boldsymbol{\beta})) \quad \text{s.t.} \quad \langle \nabla f(T_L(\boldsymbol{\beta})) + L\big(T_L(\boldsymbol{\beta}) - \boldsymbol{\beta}\big) + \gamma_\beta,\ \boldsymbol{\alpha} - T_L(\boldsymbol{\beta}) \rangle \ge 0, \quad \forall \boldsymbol{\alpha} \in \mathbb{R}^d, \tag{5}$$

for any $\boldsymbol{\beta} \in \mathbb{R}^d$. The term $L\big(T_L(\boldsymbol{\beta}) - \boldsymbol{\beta}\big)$ in (5) can be seen as the residual of the optimality condition (4). Thus it would be a natural criterion to terminate the APG if $L\|T_L(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k\|_2 < \epsilon$ with a small constant $\epsilon > 0$.

Despite having a strong iteration complexity result, the APG method may still not be efficient enough for practical purpose. In the following, we describe several well-known strategies to make the APG method practically efficient.

2.2.1 Backtracking Strategy

We assume that L is greater than or equals to the Lipschitz constant L_f of $\nabla f(\boldsymbol{\alpha})$. However it is advantageous to use a smaller value for L whenever possible since the constant L plays the role of a step size as in a gradient descent method; fixing L to be the Lipschitz constant L_f is usually too conservative (see Table 5 in Section 5). Thus we adopt the following backtracking strategy (Beck and Teboulle, 2009) after Step 1 with arbitrary given constants $\eta_u > 1$ and $L_0 > 0$:

'bt': While
$$F(\boldsymbol{\alpha}^k) > Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k), \tag{6}$$
update $L_k \leftarrow \eta_u L_k$ and $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k)$. Set $L_{k+1} \leftarrow L_k$.

The inequality (6) in 'bt' ensures that the complexity result $F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \le O(1/k^2)$ still holds. We note that the inequality $F(\boldsymbol{\alpha}^k) \le Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k)$ is satisfied if $L_k \ge L_f$, i.e., it is a weaker condition than (3).

2.2.2 Decreasing Strategy for L_k

Beck and Teboulle (2009) designed the backtracking strategy 'bt' so that the values of L_k is non-decreasing. In fact, the convergence analysis of (Beck and Teboulle, 2009) requires the value of L_k to be non-decreasing. However, it is advantageous to decrease the value of L_k whenever possible since the constant $\frac{1}{L_k}$ gives a larger step size.

To allow L_k to decrease, Scheinberg et al. (2014) modifies the APG method so that $\{t_k\}_{k=1}^{\infty}$ satisfies $t_k/L_k \ge t_{k+1}(t_{k+1} - 1)/L_{k+1}$ $(\forall k \ge 1)$ and the sequences $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$ and $\{\boldsymbol{\beta}^k\}_{k=1}^{\infty}$ are generated along with $\{t_k\}_{k=1}^{\infty}$. To be specific, let us introduce the following simple step to decrease the value of L_k, where $\eta_d > 1$ is a given constant.

'dec': Set $L_{k+1} \leftarrow L_k/\eta_d$.

The modified APG of (Scheinberg et al., 2014) can be described as in Algorithm 1. It differs from the original APG in that the updates of t_k and $\boldsymbol{\beta}^k$ are added to 'bt' and Step 2 is modified. The convergence of Algorithm 1 is shown as follows.

Proposition 1 (from Scheinberg et al., 2014) *Let S^* be the set of optimal solutions of (2). For any $\boldsymbol{\alpha}^* \in S^*$, the sequence $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$ generated by Algorithm 1 satisfies the following inequality:*

$$F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \le \frac{2\eta_u L_f \|\boldsymbol{\alpha}^0 - \boldsymbol{\alpha}^*\|_2^2}{k^2}, \quad \forall k \ge 1.$$

Algorithm 1 An Accelerated Proximal Gradient Method with Non-Monotonic Backtracking

Input: f, ∇f, g, $\mathrm{prox}_{g,L}$, $\epsilon > 0$, $L_1 = L_0 > 0$, $\eta_u > 1$, $\eta_d > 1$, $k_{max} > 0$, $\boldsymbol{\beta}^1 = \boldsymbol{\alpha}^0$
Output: $\boldsymbol{\alpha}^k$
Initialize: $t_1 \leftarrow 1,\ t_0 \leftarrow 0$
for $k = 1, \ldots, k_{max}$ **do**
  $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) = \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L_k}\nabla f(\boldsymbol{\beta}^k)\right)$ # Step 1
  while $F(\boldsymbol{\alpha}^k) > Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k)$ **do**
    $L_k \leftarrow \eta_u L_k$ # 'bt'
    $t_k \leftarrow \frac{1+\sqrt{1+4(L_k/L_{k-1})t_{k-1}^2}}{2}$
    $\boldsymbol{\beta}^k \leftarrow \boldsymbol{\alpha}^{k-1} + \frac{t_{k-1}-1}{t_k}(\boldsymbol{\alpha}^{k-1} - \boldsymbol{\alpha}^{k-2})$
    $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) = \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L_k}\nabla f(\boldsymbol{\beta}^k)\right)$
  end while
  if $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\| < \epsilon$ **then**
    break
  end if
  $L_{k+1} \leftarrow L_k/\eta_d$ # 'dec'
  $t_{k+1} \leftarrow \frac{1+\sqrt{1+4(L_{k+1}/L_k)t_k^2}}{2}$ # Step 2'
  $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^k + \frac{t_k-1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$ # Step 3
end for

2.2.3 Restarting Strategy

The value $\frac{t_k-1}{t_{k+1}} \in [0,1)$ in Step 3 determines the amount of *momentum* in $\frac{t_k-1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$. When the value $\frac{t_k-1}{t_{k+1}}$ is close to 1, i.e., the momentum is high, the sequences of solutions $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty}$ and $\{\boldsymbol{\beta}^k\}_{k=1}^{\infty}$ would overshoot and oscillate around the optimal solution $\boldsymbol{\alpha}^*$. In order to avoid the oscillation and further speed up the convergence, O'Donoghue and Candès (2015) introduced an adaptive restarting strategy:

're': If $\nabla f(\boldsymbol{\beta}^k)^\top(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}) + g(\boldsymbol{\alpha}^k) - g(\boldsymbol{\alpha}^{k-1}) > 0$,
then update $t_{k+1} \leftarrow 1$, $t_k \leftarrow 0$, $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^{k-1}$, and $\boldsymbol{\alpha}^k \leftarrow \boldsymbol{\alpha}^{k-1}$.

Roughly, the APG method resets the momentum back to zero and restarts from the previous point $\boldsymbol{\alpha}^{k-1}$ if the direction of motion $\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}$ seems to cause the (approximated) objective value to increase, which may be a sign of overshooting. Note that the computational cost of 're' is inexpensive since $\nabla f(\boldsymbol{\beta}^k)$ has already been computed at Step 1. O'Donoghue and Candès (2015) also provided a heuristic convergence analysis for their restarting scheme ('re') when f is a strongly convex (i.e., there exists a constant $\mu > 0$ such that $f(\boldsymbol{\alpha}) - \frac{\mu}{2}\|\boldsymbol{\alpha} - \boldsymbol{\alpha}^*\|_2^2$ is convex) quadratic function and $g = 0$. However, the convergence of 're' for a general strongly convex objective function is unknown (not to mention for the general non-strongly convex function in our problem).

There are several other restarting schemes (Nesterov, 2013; Lin and Xiao, 2015; Su et al., 2014). They have guaranteed convergence in the case that f is strongly convex.

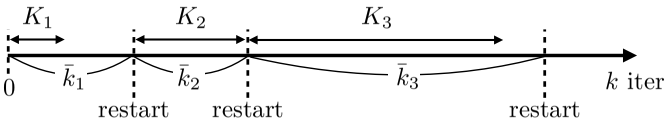

Figure 1: Illustration of Maintaining Top-Speed Strategy ('mt'). A prohibition period of restart for K_i iteration are imposed after the i-th restart occurs. If the condition $\nabla f(\boldsymbol{\beta}^k)^\top(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}) < 0$ is satisfied after the period passed, then the $(i+1)$-th restart occurs. The next prohibition period is doubled, i.e., $K_{i+1} = 2K_i$. $\bar{k}_i (\geq K_i)$ denotes the number of iteration taken between the $(i-1)$-th and i-th restart, which will be used to convergence analysis in Section 4.2.

Nesterov (2013) proposed a restarting method, which has asymptotic linear convergence if g is strongly convex. Lin and Xiao (2015) showed that a similar restart technique can achieve the same convergence rate as Nesterov's scheme if f is strongly convex. Su et al. (2014) modeled the APG method as a second-order ordinary differential equation (ODE). They provided a *speed restarting* framework that ensures a linear convergence of the ODE with respect to time in the case that f is strongly convex and $g = 0$. To the best of our knowledge, none of the restarting schemes have convergence guarantees for a general non-strongly convex function.

2.2.4 Maintaining Top-Speed Strategy

The restarting strategy cancels out high momentum and prevents overshooting. In the neighborhood of an optimum, however, maintaining high momentum may be effective rather than restarting APG (see Figures 6 and 8 in Section 5), because large overshooting may not occur. Thus we put a prohibition period of restart for K_i iteration after the i-th restart occurs, where K_i increases as $K_i = 2K_{i-1}$ $(i = 2, 3, \ldots)$ and $K_1 \geq 2$. See Figure 1 for illustration. Precisely, letting $k = k_{re}$ be the iteration count at which the last restart occurs, we introduce the following step:

'mt': If $k \leq k_{re} + K_i$, then skip 're'. If restart occurs, then update $k_{re} \leftarrow k$, $K_{i+1} \leftarrow 2K_i$, and $i \leftarrow i + 1$.

While a similar strategy is taken in the experiment of (Monteiro et al., 2016), its convergence analysis is not provided. One of our contributions in this paper is to show that in fact the modification 'mt' of the restarting strategy can ensure the convergence rate of $O\big((\log k/k)^2\big)$ under a mild assumption. We will elaborate it in Section 4.2.

3. New Unified Formulation

In this paper, we focus on the following ℓ_2-regularized loss minimization problem:

$$\min_{\boldsymbol{w},b}\ \mathcal{L}(\widetilde{A}^\top \boldsymbol{w} - \boldsymbol{a}b) + \frac{1}{2C}\|\boldsymbol{w}\|_2^2, \tag{7}$$

where $\mathcal{L} : \mathbb{R}^m \to \mathbb{R}$ is a proper, closed, and convex function; $\widetilde{A} \in \mathbb{R}^{n\times l}$, $\boldsymbol{a} \in \mathbb{R}^l$, and $C > 0$ is a parameter. We will later show examples such that

- $l = m, \quad \widetilde{A} = \widetilde{X} := [y_1\boldsymbol{x}_1, y_2\boldsymbol{x}_2, \ldots, y_m\boldsymbol{x}_m], \quad \boldsymbol{a} = \boldsymbol{y}, \quad$ and
- $l = n, \quad \widetilde{A} = I, \quad \boldsymbol{a} = \boldsymbol{0}.$

Our algorithm to be described later can be applied to a more general loss-regularized model with $p \in (1, \infty)$:

$$\min_{\boldsymbol{w},b} \left\{ \mathcal{L}(\widetilde{A}^\top \boldsymbol{w} - \boldsymbol{a}b) \mid \|\boldsymbol{w}\|_p \le \lambda \right\}, \tag{8}$$

where $\lambda > 0$ is a parameter. We note that the condition $p \in (1, \infty)$ is required for our unified classification algorithm because the smoothness of the dual norm of $\|\cdot\|_p$ is required to apply the APG method to the dual problem of (8). However, if $p \in \{1, \infty\}$ and $\mathcal{L}$ is smooth, the APG method can be applied to the primal problem (8). See Appendix D for ℓ_1-regularized problems, i.e., the case of $p = 1$.

3.1 Dual Formulation

The dual problems of (7) is given by

$$\min_{\boldsymbol{\alpha}} \left\{ \mathcal{L}^*(-\boldsymbol{\alpha}) + \frac{C}{2}\|\widetilde{A}\boldsymbol{\alpha}\|_2^2 \mid \boldsymbol{\alpha}^\top \boldsymbol{a} = 0 \right\}, \tag{9}$$

where $\mathcal{L}^*(\boldsymbol{\alpha}) = \sup_{\boldsymbol{z}}\{\boldsymbol{\alpha}^\top \boldsymbol{z} - \mathcal{L}(\boldsymbol{z})\}$ is the convex conjugate of $\mathcal{L}$.

The dual problem of (8) is

$$\min_{\boldsymbol{\alpha}} \ \{ \mathcal{L}^*(-\boldsymbol{\alpha}) + \lambda\|\widetilde{A}\boldsymbol{\alpha}\|_p^* \mid \boldsymbol{\alpha}^\top \boldsymbol{a} = 0 \}, \tag{10}$$

where $\|\boldsymbol{z}\|_p^* = \sup_{\|\boldsymbol{w}\|_p \le 1}\{\boldsymbol{z}^\top \boldsymbol{w}\}$ is the dual norm of $\|\cdot\|_p$. It is known that $\|\cdot\|_p^* = \|\cdot\|_q$, where $q = p/(p-1)$. The problem (10) can be seen as the Fenchel dual of (8), whose derivation is shown in Appendix A. We note that the norms $\|\cdot\|_p$ and $\|\cdot\|_q^*$ are smooth for $p \in (1, \infty)$.

As shown later, in all classification models, $\mathcal{L}^*$ is the sum of a smooth function and an indicator function of a simple set S for which the projection P_S can be computed efficiently. Thus we can apply the APG method as an acceleration of the gradient projection method to the dual problems (9) and (10). By this construction, we can ensure the fast convergence rate of $F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \le O(1/k^2)$ for various classification models in a unified way. In other word, the APG method can obtain a solution with desired accuracy $\epsilon > 0$ in $O(1/\sqrt{\epsilon})$ iteration.

There is an existing work (Zhou et al., 2010) which applies the APG method to the primal C-SVM, i.e., (7) with the hinge loss function. However, their method requires $O(1/\epsilon)$ iteration to obtain a solution with the desired accuracy $\epsilon > 0$ because it approximates the hinge loss by a smoothed function and making the approximation tighter requires extra iterations (Nesterov, 2005).

3.2 Relation to Existing Binary Classification Models

In this section, we show some specific examples of $\mathcal{L}$ and $\mathcal{L}^*$.

3.2.1 C-SVM

Let $\widetilde{A} = \widetilde{X}$ and $\boldsymbol{a} = \boldsymbol{y}$ in (7). Let $\ell(z) = \max\{0, 1 - z\}$ be the hinge loss and $\mathcal{L}(\boldsymbol{z}) = \sum_{i=1}^m \ell(z_i)$. Then the primal problem (7) is known as the standard C-SVM (Cortes and Vapnik, 1995). Since

$$\mathcal{L}^*(-\boldsymbol{\alpha}) = \sum_{i=1}^m \ell^*(-\alpha_i), \quad \text{where} \quad \ell^*(-\alpha) = \begin{cases} -\alpha & \text{if } \alpha \in [0,1] \\ +\infty & \text{otherwise,} \end{cases}$$

the dual problem (9) can be reduced to

$$\min_{\boldsymbol{\alpha}} \ \frac{C}{2}\|\widetilde{X}\boldsymbol{\alpha}\|_2^2 - \boldsymbol{\alpha}^\top \boldsymbol{e} + \delta_{S_C}(\boldsymbol{\alpha}), \tag{11}$$

where $S_C = \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0, \ \boldsymbol{0} \le \boldsymbol{\alpha} \le \boldsymbol{e}\}$.

3.2.2 ℓ_2-SVM

Let $\widetilde{A} = \widetilde{X}$ and $\boldsymbol{a} = \boldsymbol{y}$ in (7). Let $\ell(z) = (\max\{0, 1 - z\})^2$ be the truncated squared loss and $\mathcal{L}(\boldsymbol{z}) = \sum_{i=1}^m \ell(z_i)$. Then the primal problem (7) is known as the ℓ_2-SVM. Since

$$\mathcal{L}^*(-\boldsymbol{\alpha}) = \sum_{i=1}^m \ell^*(-\alpha_i), \quad \text{where} \quad \ell^*(-\alpha) = \begin{cases} \frac{\alpha^2}{4} & \text{if } \alpha \ge 0 \\ +\infty & \text{otherwise,} \end{cases}$$

the dual problem (9) can be reduced to

$$\min_{\boldsymbol{\alpha}} \ \frac{C}{2}\|\widetilde{X}\boldsymbol{\alpha}\|_2^2 + \frac{\|\boldsymbol{\alpha}\|_2^2}{4} + \delta_{S_{\ell_2}}(\boldsymbol{\alpha}), \tag{12}$$

where $S_{\ell_2} = \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0, \ \boldsymbol{\alpha} \ge \boldsymbol{0}\}$.

3.2.3 Logistic regression

Let $\widetilde{A} = \widetilde{X}$ and $\boldsymbol{a} = \boldsymbol{y}$ in (7). Let $\ell(z) = \log(1 + \exp(-z))$ be the logistic loss and $\mathcal{L}(\boldsymbol{z}) = \sum_{i=1}^m \ell(z_i)$. Then the primal problem (7) is the logistic regression (Cox, 1958). Since

$$\mathcal{L}^*(-\boldsymbol{\alpha}) = \sum_{i=1}^m \ell^*(-\alpha_i), \quad \text{where} \quad \ell^*(-\alpha) = \begin{cases} \alpha\log(\alpha) + (1-\alpha)\log(1-\alpha) & (0 < \alpha < 1) \\ 0 & (\alpha = 0, 1) \\ +\infty & \text{otherwise,} \end{cases}$$

the dual problem (9) can be reduced to

$$\min_{\boldsymbol{\alpha}} \ \frac{C}{2}\|\widetilde{X}\boldsymbol{\alpha}\|_2^2 + \sum_{i:\alpha_i > 0} \alpha_i \log(\alpha_i) + \sum_{i:\alpha_i < 1} (1-\alpha_i)\log(1-\alpha_i) + \delta_{S_{\mathrm{LR}}}(\boldsymbol{\alpha}), \tag{13}$$

where $S_{\mathrm{LR}} = \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0, \ \boldsymbol{0} \le \boldsymbol{\alpha} \le \boldsymbol{e}\}$.

We should note that the gradient of the second and third terms in (13) is not Lipschitz continuous on S_{LR} and not defined at $\alpha_i = 0, 1$ $(i \in M)$. However, since it is known that

its optimal solution $\boldsymbol{\alpha}^*$ satisfies $\mathbf{0} < \boldsymbol{\alpha}^* < \boldsymbol{e}$ (Yu et al., 2011), we can instead solve (13) by replacing $S_{\rm LR}$ by $S_{\rm LR}(\xi) := \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \xi \boldsymbol{e} \le \boldsymbol{\alpha} \le (1-\xi)\boldsymbol{e}\}$, where $\xi > 0$ is a small constant. The second and third terms in (13) are differentiable over $S_{\rm LR}(\xi)$. We will later show numerically that the resulting decision hyperplane is robust to a small deviation of ξ (see Table 6 in Section 5).

3.2.4 ν-SVM

Let $\widetilde{A} = \widetilde{X}$ and $\boldsymbol{a} = \boldsymbol{y}$ in (7). Let

$$\mathcal{L}(\boldsymbol{z}) = \min_{\rho} \Big\{ -\rho + \frac{1}{m\nu} \sum_{i=1}^{m} \max\{\rho - z_i, 0\} \Big\},$$

where $\nu \in (0, 1]$ is a given parameter. The function $\mathcal{L}(\boldsymbol{z})$, known as the conditional value-at-risk (CVaR) (Rockafellar and Uryasev, 2000), is the expected value of the upper ν-tail distribution. Gotoh and Takeda (2005) pointed out that minimizing CVaR is equivalent to ν-SVM (Schölkopf et al., 2000), which is also known to be equivalent to C-SVM.

Since

$$\mathcal{L}^*(-\boldsymbol{\alpha}) = \begin{cases} 0 & \Big(\boldsymbol{e}^\top \boldsymbol{\alpha} = 1 \text{ and } \boldsymbol{\alpha} \in \Big[0, \frac{1}{m\nu}\Big]^m\Big) \\ +\infty & \text{otherwise,} \end{cases}$$

the dual problem is given by

$$\min_{\boldsymbol{\alpha}} \ \frac{C}{2} \|\widetilde{X}\boldsymbol{\alpha}\|_2^2 + \delta_{S_\nu}(\boldsymbol{\alpha}), \tag{14}$$

where $S_\nu = \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \boldsymbol{\alpha}^\top \boldsymbol{e} = 1,\ \mathbf{0} \le \boldsymbol{\alpha} \le \frac{1}{m\nu}\boldsymbol{e}\}$ is the intersection of the hyperplane $\{\boldsymbol{\alpha} \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0\}$ and the truncated simplex $\{\boldsymbol{\alpha} \mid \boldsymbol{\alpha}^\top \boldsymbol{e} = 1,\ \mathbf{0} \le \boldsymbol{\alpha} \le \frac{1}{m\nu}\boldsymbol{e}\}$. Note that any positive value for C does not change the optimal solution of (14), and therefore, we can set $C = 1$. There exists a valid range $(\nu_{min}, \nu_{max}] \subseteq (0, 1]$ for ν, where ν_{min} is the infimum of $\nu > 0$ such that $\widetilde{X}\boldsymbol{\alpha}^* \neq \mathbf{0}$, and $\nu_{max} := \frac{2\max\{m_+, m_-\}}{m}$ is the maximum of $\nu \le 1$ for which $S_\nu \neq \phi$. Since the parameter ν takes a value in the finite range $(\nu_{min}, \nu_{max}]$, choosing the parameter value for ν-SVM is often easier than that for C-SVM.

3.2.5 Distance Weighted Discrimination (DWD)

Let $\widetilde{A} = \widetilde{X}$, $\boldsymbol{a} = \boldsymbol{y}$, $\lambda = 1$ and $p = 2$ in (8). For a positive parameter ν, let $\ell(z)$ be the function defined by

$$\begin{aligned} \ell(z) &= \min_{\rho} \Big\{ \frac{1}{\rho} + \frac{1}{m\nu}(\rho - z) \mid \rho \ge z,\ \rho \ge \sqrt{m\nu} \Big\} \\ &= \begin{cases} \frac{1}{z} & \text{if } z \ge \sqrt{m\nu} \\ \frac{2\sqrt{m\nu} - z}{m\nu} & \text{otherwise} \end{cases}. \end{aligned}$$

Consider $\mathcal{L}(\boldsymbol{z}) = \sum_{i=1}^m \ell(z_i)$. This loss function is used in the distance weighted discrimination (DWD) (Marron et al., 2007) which is proposed as an alternative to ν-SVM. Since we have

$$\mathcal{L}^*(-\boldsymbol{\alpha}) = \sum_{i=1}^m \ell^*(-\alpha_i), \quad \text{where} \quad \ell^*(-\alpha) = \begin{cases} -2\sqrt{\alpha} & \big(0 \le \alpha \le \frac{1}{m\nu}\big) \\ +\infty & \text{otherwise,} \end{cases}$$

the dual problem (9) can be equivalently reduced to

$$\min_{\boldsymbol{\alpha}} \Big\{ \|\widetilde{X}\boldsymbol{\alpha}\|_2 - 2\sum_{i=1}^m \sqrt{\alpha_i} + \delta_{S_{\rm DWD}}(\boldsymbol{\alpha}) \Big\}, \tag{15}$$

where $S_{\rm DWD} = \big\{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \mathbf{0} \le \boldsymbol{\alpha} \le \frac{1}{m\nu}\boldsymbol{e}\big\}$.

As in the case of the logistic regression, the second term in (15) is not differentiable at $\alpha_i = 0$ ($i \in M$). However, since it is known that there exists an optimal solution $\boldsymbol{\alpha}^*$ such that $\alpha_i^* > 0$ ($i \in M$), we can solve (15) by replacing $S_{\rm DWD}$ by $S_{\rm DWD}(\xi) = \big\{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \xi\boldsymbol{e} \le \boldsymbol{\alpha} \le \frac{1}{m\nu}\boldsymbol{e}\big\}$ where $\xi > 0$ is a small constant. The second term in (15) is differentiable over $S_{\rm DWD}(\xi)$.

3.2.6 Extended Fisher's discriminant analysis (MM-FDA)

The well-known Fisher's discriminant analysis (FDA) uses a decision function to maximize the ratio of the variance between the classes to the variance within the classes. Let $\bar{\boldsymbol{x}}_o$ and Σ_o, $o \in \{+, -\}$, be the mean vectors and the positive definite covariance matrices of $\boldsymbol{x}_i$, $i \in M_o$, respectively. Then FDA is formulated as follows:

$$\max_{\boldsymbol{w}} \ \frac{\big(\boldsymbol{w}^\top(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-)\big)^2}{\boldsymbol{w}^\top(\Sigma_+ + \Sigma_-)\boldsymbol{w}}.$$

Its optimal solution is given by

$$\boldsymbol{w}^* = (\Sigma_+ + \Sigma_-)^{-1}(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-).$$

Let $\widetilde{A} = I$ and $\boldsymbol{a} = \mathbf{0}$ in (7). Here we consider the mean-standard deviation type of risk corresponding to FDA:

$$\mathcal{L}(\boldsymbol{w}) = -\boldsymbol{w}^\top(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + \kappa\sqrt{\boldsymbol{w}^\top(\Sigma_+ + \Sigma_-)\boldsymbol{w}},$$

where $\kappa > 0$ is a parameter. Since

$$\begin{aligned} \mathcal{L}^*(-\boldsymbol{\alpha}) &= \sup_{\boldsymbol{w}} \Big\{ -\boldsymbol{\alpha}^\top \boldsymbol{w} + \boldsymbol{w}^\top(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) - \kappa\sqrt{\boldsymbol{w}^\top(\Sigma_+ + \Sigma_-)\boldsymbol{w}} \Big\} \\ &= \sup_{\boldsymbol{w}} \min_{\|\boldsymbol{u}\|_2 \le \kappa} \Big\{ -\boldsymbol{\alpha}^\top \boldsymbol{w} + \boldsymbol{w}^\top(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + \boldsymbol{w}^\top(\Sigma_+ + \Sigma_-)^{1/2}\boldsymbol{u} \Big\} \\ &= \min_{\boldsymbol{u}} \big\{ \delta_{S_{\rm FDA}}(\boldsymbol{u}) \mid \boldsymbol{\alpha} = (\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + (\Sigma_+ + \Sigma_-)^{1/2}\boldsymbol{u} \big\}, \end{aligned}$$

where $S_{\rm FDA} = \big\{\boldsymbol{u} \in \mathbb{R}^n \mid \|\boldsymbol{u}\|_2 \le \kappa\big\}$, the dual problem (9) can be reduced to

$$\min_{\boldsymbol{\alpha}, \boldsymbol{u}} \Big\{ \delta_{S_{\rm FDA}}(\boldsymbol{u}) + \frac{C}{2}\|\boldsymbol{\alpha}\|_2^2 \mid \boldsymbol{\alpha} = (\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + (\Sigma_+ + \Sigma_-)^{1/2}\boldsymbol{u} \Big\},$$

which is equivalent to

$$\min_{\boldsymbol{u}} \left\{ \delta_{S_{\mathrm{FDA}}}(\boldsymbol{u}) + \left\| (\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + (\Sigma_+ + \Sigma_-)^{1/2}\boldsymbol{u} \right\|_2^2 \right\}. \tag{16}$$

Takeda et al. (2013) showed that

$$\kappa_{\max} := \left| \begin{array}{ll} \inf_{\boldsymbol{u},\kappa} & \kappa \\ \text{s.t.} & \min_{\boldsymbol{u}} \left\{ \left\| (\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + (\Sigma_+ + \Sigma_-)^{1/2}\boldsymbol{u} \right\|_2 + \delta_{S_{\mathrm{FDA}}}(\boldsymbol{u}) \right\} = 0 \end{array} \right.$$

is equivalent to FDA. Hence (16) can be seen as an extension of FDA. We will refer it as MM-FDA in this paper.

3.2.7 Maximum Margin Minimax Probability Machine (MM-MPM)

Let $\widetilde{A} = I$ and $\boldsymbol{a} = \boldsymbol{0}$ in (7). We consider a class-wise mean-standard deviation type of risk:

$$\mathcal{L}(\boldsymbol{w}) = \Big(-\boldsymbol{w}^\top \bar{\boldsymbol{x}}_+ + \kappa \sqrt{\boldsymbol{w}^\top \Sigma_+ \boldsymbol{w}} \Big) - \Big(-\boldsymbol{w}^\top \bar{\boldsymbol{x}}_- + \kappa \sqrt{\boldsymbol{w}^\top \Sigma_- \boldsymbol{w}} \Big).$$

Similar to MM-FDA, we have

$$\begin{aligned} \mathcal{L}^*(\boldsymbol{w}) &= \sup_{\boldsymbol{w}} \Big\{ -\boldsymbol{\alpha}^\top \boldsymbol{w} + \Big(\boldsymbol{w}^\top \bar{\boldsymbol{x}}_+ - \kappa \sqrt{\boldsymbol{w}^\top \Sigma_+ \boldsymbol{w}} \Big) - \Big(\boldsymbol{w}^\top \bar{\boldsymbol{x}}_- - \kappa \sqrt{\boldsymbol{w}^\top \Sigma_- \boldsymbol{w}} \Big) \Big\} \\ &= \sup_{\boldsymbol{w}} \min_{\substack{\|\boldsymbol{u}_+\|_2 \le \kappa \\ \|\boldsymbol{u}_-\|_2 \le \kappa}} \Big\{ -\boldsymbol{\alpha}^\top \boldsymbol{w} + \big(\boldsymbol{w}^\top \bar{\boldsymbol{x}}_+ + \boldsymbol{w}^\top \Sigma_+^{1/2} \boldsymbol{u}_+ \big) - \big(\boldsymbol{w}^\top \bar{\boldsymbol{x}}_- + \boldsymbol{w}^\top \Sigma_-^{1/2} \boldsymbol{u}_- \big) \Big\} \\ &= \min_{\boldsymbol{u}_+, \boldsymbol{u}_-} \left\{ \delta_{S_{\mathrm{MPM}}}(\boldsymbol{u}_+, \boldsymbol{u}_-) \mid \boldsymbol{\alpha} = \big(\bar{\boldsymbol{x}}_+ + \Sigma_+^{1/2} \boldsymbol{u}_+ \big) - \big(\bar{\boldsymbol{x}}_- + \Sigma_-^{1/2} \boldsymbol{u}_- \big) \right\}, \end{aligned}$$

where $S_{\mathrm{MPM}} = \big\{ (\boldsymbol{u}_+, \boldsymbol{u}_-) \in \mathbb{R}^n \times \mathbb{R}^n \mid \|\boldsymbol{u}_+\|_2 \le \kappa,\ \|\boldsymbol{u}_-\|_2 \le \kappa \big\}$. Thus the dual problem (9) can be reduced to

$$\min_{\boldsymbol{\alpha}, \boldsymbol{u}_+, \boldsymbol{u}_-} \Big\{ \delta_{S_{\mathrm{MPM}}}(\boldsymbol{u}_+, \boldsymbol{u}_-) + \frac{C}{2} \|\boldsymbol{\alpha}\|_2^2 \mid \boldsymbol{\alpha} = \big(\bar{\boldsymbol{x}}_+ + \Sigma_+^{1/2} \boldsymbol{u}_+ \big) - \big(\bar{\boldsymbol{x}}_- + \Sigma_-^{1/2} \boldsymbol{u}_- \big) \Big\},$$

which is equivalent to

$$\min_{\boldsymbol{u}_+, \boldsymbol{u}_-} \left\{ \delta_{S_{\mathrm{MPM}}}(\boldsymbol{u}_+, \boldsymbol{u}_-) + \left\| \big(\bar{\boldsymbol{x}}_+ + \Sigma_+^{1/2} \boldsymbol{u}_+ \big) - \big(\bar{\boldsymbol{x}}_- + \Sigma_-^{1/2} \boldsymbol{u}_- \big) \right\|_2^2 \right\}. \tag{17}$$

The last problem (17) is equivalent to the dual of the maximum margin minimax probability machine (MM-MPM) (Nath and Bhattacharyya, 2007).

4. A Fast APG method for Unified Binary Classification

In this section, we first provide an efficient vector projection computation in order to apply the APG method to the unified formulation of the binary classification models. After that, we develop a fast APG (FAPG) method and show its convergence.

4.1 Vector Projection Computation

When applying the APG method to a constrained optimization problem over S, the projection P_S onto S appears at Step 1. We need to change the computation of the projection P_S depending on the definition of S. In this section, we provide efficient projection computations for S_C, S_{ℓ_2}, $S_{\mathrm{LR}}(\xi)$, S_ν, $S_{\mathrm{DWD}}(\xi)$, S_{MPM}, and S_{FDA}.

4.1.1 Bisection Method for Projection

Many models shown in Section 3 have a linear equality and box constraints. Here we consider the set $S = \{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{e} = r,\ l \le \alpha_i \le u\ (\forall i \in M)\}$ and provide an efficient algorithm for computing the projection $P_S(\bar{\boldsymbol{\alpha}})$:

$$\min_{\boldsymbol{\alpha}} \Big\{ \frac{1}{2} \|\boldsymbol{\alpha} - \bar{\boldsymbol{\alpha}}\|_2^2 \mid \boldsymbol{\alpha}^\top \boldsymbol{e} = r, \quad l \le \alpha_i \le u, \quad (i \in M) \Big\}. \tag{18}$$

We assume that (18) is feasible. One way to solve (18) is to use breakpoint search algorithms (e.g., (Helgason et al., 1980; Kiwiel, 2008; Duchi et al., 2008)). They are exact algorithms and have linear time complexity of $O(m)$. Helgason et al. (1980); Kiwiel (2008) developed the breakpoint search algorithms for the continuous quadratic knapsack problem (CQKP) which involves the projection (18) as a special case. By integrating the breakpoint search algorithm and the red-black tree data structure, Duchi et al. (2008) developed an efficient update algorithm of the gradient projection method when the gradient is sparse.

In this paper, we provide a numerical algorithm for (18). Although its worst case complexity is $O\Big(m \log\big(\frac{\bar{\alpha}_{\max} - \bar{\alpha}_{\min}}{\epsilon'}\big)\Big)$, where $\bar{\alpha}_{\max} = \max\{\bar{\alpha}_i \mid i \in M\}$ and $\bar{\alpha}_{\min} = \min\{\bar{\alpha}_i \mid i \in M\}$, it often requires less time to compute a solution $\hat{\boldsymbol{\alpha}}$ such that $\|\hat{\boldsymbol{\alpha}} - P_S(\bar{\boldsymbol{\alpha}})\|_\infty < \epsilon' = u$ in practice, where $u \approx 2.22 \times 10^{-16}$ is the IEEE 754 double precision. Note that the error u can occur even when using the breakpoint search algorithm because u is the supremum of the relative error due to rounding in the floating point number system. Thus, it is sufficient to choose $\epsilon' = u$ as the stopping tolerance for our algorithm in practice. [2]

The difference between the algorithms is that the breakpoint search algorithms use binary search, whereas our algorithm uses bisection to solve an equation. It is known that the projection (18) can be reduced to finding the root of an one dimensional monotone function.

Lemma 2 (e.g. Helgason et al., 1980) *Suppose that the problem* (18) *is feasible. Let*

$$\alpha_i(\theta) = \min\Big\{ \max\{l, \bar{\alpha}_i - \theta\}, u \Big\}, \quad i \in M$$

and let

$$h(\theta) = \sum_{i \in M} \alpha_i(\theta).$$

The following statements hold:

2. Another practical way is to decrease ϵ', i.e., to improve the accuracy of the projection progressively, as APG iterates. The APG method with the inexact computation also share the same iteration complexity $O(1/k^2)$ as the exact counterpart, as shown in (Jiang et al., 2012).

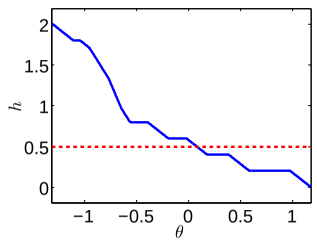

Figure 2: Illustration of the function $h(\theta) := \sum_{i\in M} \alpha_i(\theta)$. The function h is piecewise linear.

1. *$h(\theta)$ is a continuous, non-increasing, and piecewise linear function which has breakpoints at $\bar{\alpha}_i - u$ and $\bar{\alpha}_i - l$ $(i \in M)$.*

2. *There exists $\theta^* \in (\bar{\alpha}_{\min} - \frac{r}{m}, \bar{\alpha}_{\max} - \frac{r}{m})$ such that $h(\theta^*) = r$.*

3. *Let $\hat{\alpha}_i = \alpha_i(\theta^*)$, $i \in M$. Then $\hat{\boldsymbol{\alpha}}$ is an optimal solution of* (18).

An example of $h(\theta)$ is illustrated in Figure 2. To solve $h(\theta) = r$, the breakpoint search uses the binary search to find two adjacent breakpoints that contain a solution θ^* between them. Then the exact solution θ^* can be obtained by linear interpolation of the two breakpoints.

Instead of binary search, we employ the bisection method to solve the equation $h(\theta) = r$.

Bisection Algorithm for Projection

Step 1. Set $\theta^u = \bar{\alpha}_{\max} - \frac{r}{m}$ and $\theta^l = \bar{\alpha}_{\min} - \frac{r}{m}$.

Step 2. Set $\hat{\theta} = (\theta^u + \theta^l)/2$

Step 3. Compute $h(\hat{\theta})$.

Step 4. If $h(\hat{\theta}) = r$, then terminate with $\hat{\theta}^* = \hat{\theta}$.
Else if $h(\hat{\theta}) < r$, then set $\theta^u = \hat{\theta}$.
Else if $h(\hat{\theta}) > r$, then set $\theta^l = \hat{\theta}$.

Step 5. If $|\theta^u - \theta^l| < \epsilon'$, then terminate with $\hat{\theta}^* = \hat{\theta}$. Else, go to Step 2.

All steps require at most $O(m)$ operations and the maximum number of iteration is $\lceil \log(\frac{\bar{\alpha}_{\max} - \bar{\alpha}_{\min}}{\epsilon'}) \rceil$. Thus, the computational complexity of the bisection algorithm is at most $O\big(m \log(\frac{\bar{\alpha}_{\max} - \bar{\alpha}_{\min}}{\epsilon'})\big)$.

As the bisection method narrows the interval (θ^l, θ^u), some of the terms $\alpha_i(\theta)$, $i \in M$, can be set to l, $\bar{\alpha}_i - \theta$, or u for $\theta \in (\theta^l, \theta^u)$. By exploiting the property of $\alpha_i(\theta)$, we can refine the computation of $h(\hat{\theta})$ in Step 3 by avoiding recalculation of certain sums. Moreover, we can often obtain an exact solution. Let us divide M into the following three disjoint sets

for given θ^l and θ^u satisfying $\theta^l < \theta^u$:

$$\begin{aligned} U &:= \{i \in M \mid \bar{\alpha}_i - \theta^u \geq u \quad (\text{i.e., } \alpha_i(\theta) = u, \quad \forall \theta \in [\theta^l, \theta^u])\} \\ L &:= \{i \in M \mid \bar{\alpha}_i - \theta^l \leq l \quad (\text{i.e., } \alpha_i(\theta) = l, \quad \forall \theta \in [\theta^l, \theta^u])\} \\ I &:= M \backslash (U \cup L). \end{aligned}$$

If $\bar{\alpha}_i - \theta^u \geq l$ and $\bar{\alpha}_i - \theta^l \leq u$ $\forall i \in I$, then

$$\theta = \Big(|U|u + |L|l + \sum_{i\in I} \alpha_i - r\Big)/|I| \tag{19}$$

is an exact solution. If $I \neq \phi$, then we also divide I into the following three disjoint sets for given $\hat{\theta} \in (\theta^l, \theta^u)$:

$$\begin{aligned} I^U &= \{i \in I \mid \bar{\alpha}_i - \hat{\theta} \geq u, \quad (\text{i.e., } \alpha_i(\theta) = u \quad \forall \theta \in [\theta^l, \hat{\theta}])\} \\ I^L &= \{i \in I \mid \bar{\alpha}_i - \hat{\theta} \leq l, \quad (\text{i.e., } \alpha_i(\theta) = l \quad \forall \theta \in [\hat{\theta}, \theta^u])\} \\ I^C &= I \backslash (I^U \cup I^L) \end{aligned}$$

Then we have

$$h(\hat{\theta}) = \sum_{i\in M} \alpha_i(\hat{\theta}) = \underbrace{|U|u}_{s_u} + \underbrace{|I^U|u}_{\Delta s_u} + \underbrace{|L|l}_{s_l} + \underbrace{|I^L|l}_{\Delta s_l} + \underbrace{\sum_{i\in I^C} \alpha_i}_{s_c} - |I^C|\hat{\theta}.$$

By storing the value of each terms, we can reduce the number of additions. The resulting algorithm can be described as Algorithm 2.

Compared to the existing breakpoint search algorithms, our bisection method can avoid the computation of breakpoints and the comparison between them. In many cases, our algorithm can obtain the exact solution by (19). It is often faster than the breakpoint search algorithms in practice (see Table 2 in Section 5).

Remark 3 *Mimicking (Kiwiel, 2008), we can divide the set M more finely and reduce the recalculation of certain sums as shown in Appendix B. However, Algorithm 2 allows for simpler implementation and runs faster on our computer systems.*

In the followings, we use Algorithm 2 to compute the projection onto S_C, S_{ℓ_2}, $S_{\mathrm{LR}}(\xi)$, $S_{\mathrm{DWD}}(\xi)$ and S_ν.

4.1.2 Projection for C-SVM, Logistic Regression, ℓ_2-SVM, DWD

The projection for C-SVM, logistic regression, ℓ_2-SVM, and DWD can be formulated as follows:

$$\min_{\boldsymbol{\alpha}} \Big\{ \frac{1}{2}\|\boldsymbol{\alpha} - \bar{\boldsymbol{\alpha}}\|_2^2 \mid \boldsymbol{y}^\top \boldsymbol{\alpha} = 0, \quad l \leq \alpha_i \leq u \quad (i \in M) \Big\}, \tag{20}$$

where $(l, u) = (0, 1)$ for C-SVM, $(l, u) = (0, \infty)$ for ℓ_2-SVM, $(l, u) = (\xi, 1 - \xi)$ for logistic regression, and $(l, u) = \big(\xi, \frac{1}{m\nu}\big)$ for DWD. By transforming the variable $\boldsymbol{\alpha}$ and the vector $\bar{\boldsymbol{\alpha}}$ to

$$\beta_i = \begin{cases} \alpha_i & \text{if } y_i = 1 \\ -\alpha_i + l + u & \text{otherwise} \end{cases} \quad \text{and} \quad \bar{\beta}_i = \begin{cases} \bar{\alpha}_i & \text{if } y_i = 1 \\ -\bar{\alpha}_i + l + u & \text{otherwise,} \end{cases}$$

Algorithm 2 Bisection Algorithm for (18)

INPUT: $\bar{\boldsymbol{\alpha}},\ r,\ \boldsymbol{l},\ \boldsymbol{u},\ \epsilon' > 0$ OUTPUT: $\boldsymbol{\alpha}$

INITIALIZE: $I \leftarrow M,\ s_u \leftarrow s_l \leftarrow s_c \leftarrow 0,\ \theta^u \leftarrow \bar{\alpha}_{\max} - \frac{r}{m},\ \theta^l \leftarrow \bar{\alpha}_{\min} - \frac{r}{m}$ # Step 1

while $|\theta^u - \theta^l| > \epsilon'$ **do**

  $\hat{\theta} \leftarrow \frac{\theta^u + \theta^l}{2}$ # Step 2

  $\hat{u} \leftarrow u + \hat{\theta}, \quad \hat{l} \leftarrow l + \hat{\theta}$

  $I^U \leftarrow \{i \in I \mid \bar{\alpha}_i \geq \hat{u}\}, \quad I^L \leftarrow \{i \in I \mid \bar{\alpha}_i \leq \hat{l}\}$ # Step 3

  $I^C \leftarrow I \backslash (I^U \cup I^L)$

  $\Delta s_u \leftarrow |I^U| u, \quad \Delta s_l \leftarrow |I^L| l, \quad s_c \leftarrow \sum_{i \in I^C} \alpha_i$

  $val \leftarrow s_u + \Delta s_u + s_l + \Delta s_l + s_c - |I^C| \hat{\theta}$

  if $val < r$ **then** # Step 4

    $\theta^u \leftarrow \hat{\theta}, \quad I \leftarrow I^C \cup I^L$

    $s_u \leftarrow s_u + \Delta s_u$

  else if $val > r$ **then**

    $\theta^l \leftarrow \hat{\theta}, \quad I \leftarrow I^C \cup I^U$

    $s_l \leftarrow s_l + \Delta s_l$

  else

    break

  end if

  if $\bar{\alpha}_i - \theta^u \geq l$ and $\bar{\alpha}_i - \theta^l \leq u \quad \forall i \in I$ **then**

    $\hat{\theta} \leftarrow (s_u + s_l + s_c - r)/|I|$

    break

  end if

end while

$\alpha_i \leftarrow \alpha_i(\hat{\theta}),\ \forall i \in M$ # Step 5

respectively, the problem (20) can be reduced to

$$\min_{\boldsymbol{\beta}} \Big\{ \frac{1}{2} \|\boldsymbol{\beta} - \bar{\boldsymbol{\beta}}\|_2^2 \mid \boldsymbol{e}^\top \boldsymbol{\beta} = (l+u) m_-, \quad l \leq \beta_i \leq u \quad (i \in M) \Big\}.$$

The last problem can be solved by Algorithm 2.

4.1.3 Projection for ν-SVM

In applying the APG method to ν-SVM, we shall be concerned with the projection $P_{S_\nu}(\bar{\boldsymbol{\alpha}})$:

$$\min_{\boldsymbol{\alpha}} \Big\{ \frac{1}{2} \|\boldsymbol{\alpha} - \bar{\boldsymbol{\alpha}}\|_2^2 \ \Big|\ \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \boldsymbol{\alpha}^\top \boldsymbol{e} = 1,\ \boldsymbol{0} \leq \boldsymbol{\alpha} \leq \frac{1}{m\nu} \boldsymbol{e} \Big\}. \tag{21}$$

Let $\boldsymbol{\alpha}_+$ and $\boldsymbol{\alpha}_-$ be the subvectors of $\boldsymbol{\alpha}$ corresponding to the label $+1$ and -1, respectively. Let $\boldsymbol{e}_+$ and $\boldsymbol{e}_-$ be subvectors of $\boldsymbol{e}$ with size m_+ and m_-. From the fact that the conditions $\boldsymbol{\alpha}^\top \boldsymbol{y} = 0$ and $\boldsymbol{\alpha}^\top \boldsymbol{e} = 1$ are equivalent to $\boldsymbol{\alpha}_o^\top \boldsymbol{e}_o = \frac{1}{2}$ $(o \in \{+,-\})$, the problem (21) can be decomposed into the following two problems:

$$\min_{\boldsymbol{\alpha}_o} \Big\{ \frac{1}{2} \|\boldsymbol{\alpha}_o - \bar{\boldsymbol{\alpha}}_o\|_2^2 \ \Big|\ \boldsymbol{e}_o^\top \boldsymbol{\alpha} = \frac{1}{2},\ \boldsymbol{0} \leq \boldsymbol{\alpha}_o \leq \frac{1}{m\nu} \boldsymbol{e}_o \Big\},\ o \in \{+,-\}. \tag{22}$$

Then, Algorithm 2 can be applied to solve (22).

4.1.4 Projection for MM-MPM and MM-FDA

The projection $P_{S_{\rm FDA}}(\bar{\boldsymbol{\alpha}})$ of $\bar{\boldsymbol{\alpha}}$ onto $S_{\rm FDA} = \big\{ \boldsymbol{\alpha} \in \mathbb{R}^n \mid \|\boldsymbol{\alpha}\|_2 \leq \kappa \big\}$ is easy to compute; We have

$$P_{S_{\rm FDA}}(\bar{\boldsymbol{\alpha}}) = \min \Big\{ 1, \frac{\kappa}{\|\bar{\boldsymbol{\alpha}}\|_2} \Big\} \bar{\boldsymbol{\alpha}}.$$

Similarly, the projection $P_{S_{\rm MPM}}(\bar{\boldsymbol{\alpha}}_+, \bar{\boldsymbol{\alpha}}_-)$ for MM-MPM can be computed as follows:

$$P_{S_{\rm MPM}}(\bar{\boldsymbol{\alpha}}_+, \bar{\boldsymbol{\alpha}}_-) = \Big(\min \Big\{ 1, \frac{\kappa}{\|\bar{\boldsymbol{\alpha}}_+\|_2} \Big\} \bar{\boldsymbol{\alpha}}_+, \min \Big\{ 1, \frac{\kappa}{\|\bar{\boldsymbol{\alpha}}_-\|_2} \Big\} \bar{\boldsymbol{\alpha}}_- \Big).$$

4.2 Convergence Analysis of a Fast APG Method with Speed-up Strategies

We have shown several strategies to speed-up the APG method in Section 2. While the convergence proof has been shown for the backtracking 'bt' and decreasing 'dec' strategy, the convergence for the restart 're' and maintaining top-speed 'mt' strategy is unknown. In this section, we develop a fast APG (FAPG) method by combining all these techniques and show its convergence.

4.2.1 A Fast APG with Stabilization

In addition to the techniques in Section 2, we also employ the following practical stabilization strategy, where it does *not* affect our convergence analysis.

Decreasing L ('dec') and restarting strategies ('re') shown in Section 2 are effective to speed-up the practical convergence of the APG method, especially in early iterations and near the optimal solution, respectively (see Figures 6 and 10 in Section 5). However, they have opposing effects. Decreasing L_k enlarges the stepsize $\frac{1}{L_k}$, which extends $\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}$.

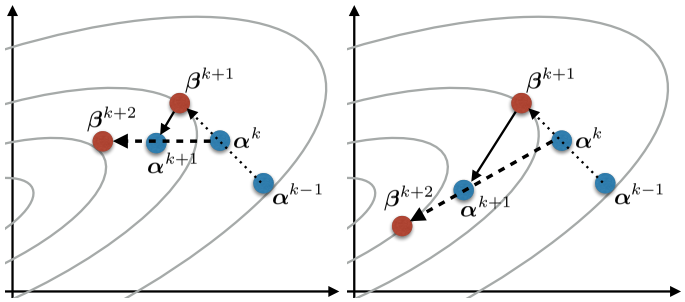

Figure 3: Effects of the value of L_k to the momentum $\frac{t_k-1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$ (left: L_k is large, right: L_k is small). A smaller value of L_k gives a larger step size at Step 1 as illustrated by the solid lines. This results in high momentum at Step 3 as illustrated by the dashed lines.

This inherently induces high momentum (as illustrated in Figure 3). On the other hand, the restarting strategy cancels out high momentum. Hence combining them triggers the restart frequently and makes the APG method unstable. In order to avoid the instability, it would be necessary to reduce the η_d (rate of decreasing L_k) near the optimum. The restart would occur when the sequences approach the optimum. Therefore we take the following strategy to reduce the value of η_d with a constant $\delta \in (0, 1)$:

'st': Update $\eta_d \leftarrow \delta \cdot \eta_d + (1 - \delta) \cdot 1$ when the restart occurs.

Algorithm 3 is our FAPG method which combines these strategies. The difference from Algorithm 1 is the "if block" after Step 3.

4.2.2 Convergence Analysis

Let $\bar{k}_i$ denotes the number of iteration taken between the $(i-1)$-th and the i-th restart (see Figure 1 for illustration). In the followings, we denote $\boldsymbol{\alpha}^k$ as $\boldsymbol{\alpha}^{(j,k_{j+1})}$ if $k = \sum_{i=1}^{j} \bar{k}_i + k_{j+1}$ ($\bar{k}_{j+1} \geq k_{j+1} \geq 0$). In other word, $\boldsymbol{\alpha}^{(i,k_{i+1})}$ denotes a point obtained at the k_{i+1}-th iteration counting from the i-th restart. Note that $\boldsymbol{\alpha}^{(i+1,0)} = \boldsymbol{\alpha}^{(i,\bar{k}_{i+1}-1)}$ ($\forall i \geq 0$). We will frequently switch the notations $\boldsymbol{\alpha}^k$ and $\boldsymbol{\alpha}^{(i,k_{i+1})}$ for notational convenience.

The following lemma is useful to evaluate the function F.

Lemma 4 (from Beck and Teboulle, 2009) *If $F(T_L(\boldsymbol{\beta})) \leq Q_L(T_L(\boldsymbol{\beta}); \boldsymbol{\beta})$, then*

$$F(T_L(\boldsymbol{\beta})) - F(\boldsymbol{\alpha}) \leq \frac{L}{2}\{\|\boldsymbol{\beta} - \boldsymbol{\alpha}\|_2^2 - \|T_L(\boldsymbol{\beta}) - \boldsymbol{\alpha}\|_2^2\}, \quad \forall \boldsymbol{\alpha} \in \mathbb{R}^d.$$

Using Lemma 4, we obtain the following key lemma.

Algorithm 3 A Fast Accelerated Proximal Gradient (FAPG) Method with Speeding-Up Strategies

Input: f, ∇f, g, $\mathrm{prox}_{g,L}$, $\epsilon > 0$, $L_1 = L_0 > 0$, $\eta_u > 1$, $\eta_d > 1$, $k_{max} > 0$, $\boldsymbol{\beta}^1 = \boldsymbol{\alpha}^0 = \boldsymbol{\alpha}^{-1}$, $K_1 \geq 2$, $\delta \in (0, 1)$
Output: $\boldsymbol{\alpha}^k$
Initialize: $t_1 \leftarrow 1$, $t_0 \leftarrow 0$, $i \leftarrow 1$, $k_{re} \leftarrow 0$
for $k = 1, \ldots, k_{max}$ **do**
  $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) = \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L_k}\nabla f(\boldsymbol{\beta}^k)\right)$ # Step 1
  while $F(\boldsymbol{\alpha}^k) > Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k)$ **do**
    $L_k \leftarrow \eta_u L_k$ # 'bt'
    $t_k \leftarrow \frac{1+\sqrt{1+4(L_k/L_{k-1})t_{k-1}^2}}{2}$
    $\boldsymbol{\beta}^k \leftarrow \boldsymbol{\alpha}^{k-1} + \frac{t_{k-1}-1}{t_k}(\boldsymbol{\alpha}^{k-1} - \boldsymbol{\alpha}^{k-2})$
    $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) = \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L_k}\nabla f(\boldsymbol{\beta}^k)\right)$
  end while
  if $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\| < \epsilon$ **then**
    break
  end if
  $L_{k+1} \leftarrow L_k/\eta_d$ # 'dec'
  $t_{k+1} \leftarrow \frac{1+\sqrt{1+4(L_{k+1}/L_k)t_k^2}}{2}$ # Step 2'
  $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^k + \frac{t_k-1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$ # Step 3
  if $k > k_{re} + K_i$ and $\langle \nabla f(\boldsymbol{\beta}^k), \boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}\rangle + g(\boldsymbol{\alpha}^k) - g(\boldsymbol{\alpha}^{k-1}) > 0$ **then**
    $k_{re} \leftarrow k$, $K_{i+1} \leftarrow 2K_i$, $i \leftarrow i+1$ # 'mt'
    $\eta_d \leftarrow \delta \cdot \eta_d + (1-\delta) \cdot 1$ # 'st'
    $t_{k+1} \leftarrow 1$, $t_k \leftarrow 0$, $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^{k-1}$, $\boldsymbol{\alpha}^k \leftarrow \boldsymbol{\alpha}^{k-1}$ # 're'
  end if
end for

Lemma 5 *Let the sequence* $\{\boldsymbol{\alpha}^k\}_{k=1}^{\infty} (\equiv \{\boldsymbol{\alpha}^{(i,k_{i+1})}\})$ *be generated by Algorithm 3. The following inequality holds:*

$$F(\boldsymbol{\alpha}^k) \leq F(\boldsymbol{\alpha}^0), \quad \forall k \geq 1.$$

Moreover,

$$F(\boldsymbol{\alpha}^{(i,k_{i+1})}) \leq F(\boldsymbol{\alpha}^{(i,0)}), \quad \forall i \geq 0 \quad \textit{and} \quad \forall k_{i+1} \in \{0, 1, 2, \ldots, \bar{k}_{i+1}\},$$

and

$$F(\boldsymbol{\alpha}^{(i+1,0)}) \leq F(\boldsymbol{\alpha}^{(i,0)}), \quad \forall i \geq 0.$$

Proof First, assume that the restart does not occur (i.e., the steps 're', 'st', and 'mt' are not executed) until the k-th iteration. From Lemma 4, we have

$$F(\boldsymbol{\alpha}^1) - F(\boldsymbol{\alpha}^0) \leq \frac{L_1}{2}\{\|\boldsymbol{\beta}^1 - \boldsymbol{\alpha}^0\|_2^2 - \|\boldsymbol{\alpha}^1 - \boldsymbol{\alpha}^0\|_2^2\} = -\frac{L_1}{2}\|\boldsymbol{\alpha}^1 - \boldsymbol{\alpha}^0\|_2^2 \leq 0. \tag{23}$$

For all $n = 1, 2, \ldots$, we also have

$$\begin{aligned} F(\boldsymbol{\alpha}^{n+1}) - F(\boldsymbol{\alpha}^n) &\leq \frac{L_{n+1}}{2}\{\|\boldsymbol{\beta}^{n+1} - \boldsymbol{\alpha}^n\|_2^2 - \|\boldsymbol{\alpha}^{n+1} - \boldsymbol{\alpha}^n\|_2^2\} \\ &= \frac{L_{n+1}}{2}\Big\{\Big(\frac{t_n - 1}{t_{n+1}}\Big)^2\|\boldsymbol{\alpha}^n - \boldsymbol{\alpha}^{n-1}\|_2^2 - \|\boldsymbol{\alpha}^{n+1} - \boldsymbol{\alpha}^n\|_2^2\Big\}. \end{aligned}$$

Summing over $n = 1, 2, \ldots, k-1$, we obtain

$$\begin{aligned} &F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^1) \\ &\leq \frac{1}{2}\left\{L_2\Big(\frac{t_1 - 1}{t_2}\Big)^2\|\boldsymbol{\alpha}^1 - \boldsymbol{\alpha}^0\|_2^2 + \sum_{n=2}^{k-1}\Big(L_{n+1}\Big(\frac{t_n - 1}{t_{n+1}}\Big)^2 - L_n\Big)\|\boldsymbol{\alpha}^n - \boldsymbol{\alpha}^{n-1}\|_2^2 - L_k\|\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}\|_2^2\right\}. \end{aligned}$$

Note that $t_1 - 1 = 0$ and $\Big(L_{n+1}\Big(\frac{t_n - 1}{t_{n+1}}\Big)^2 - L_n\Big) \leq 0$ for all $n \geq 1$ because

$$\frac{t_n - 1}{t_{n+1}} = \frac{2(t_n - 1)}{1 + \sqrt{1 + 4(L_{n+1}/L_n)t_n^2}} \leq \frac{2(t_n - 1)}{\sqrt{4(L_{n+1}/L_n)t_n^2}} = \sqrt{\frac{L_n}{L_{n+1}}}\frac{t_n - 1}{t_n}.$$

Thus we have

$$F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^1) \leq 0.$$

Similarly, since the restart does not occur from $\boldsymbol{\alpha}^{(i,0)}$ to $\boldsymbol{\alpha}^{(i,\bar{k}_{i+1})}$ $(\forall i \geq 0)$, we have

$$F(\boldsymbol{\alpha}^{(i,k_{i+1})}) \leq F(\boldsymbol{\alpha}^{(i,0)}), \quad \forall k_{i+1} \in \{0, 1, \ldots, \bar{k}_{i+1}\},$$

and hence by definition,

$$F(\boldsymbol{\alpha}^{(i+1,0)}) = F(\boldsymbol{\alpha}^{(i,\bar{k}_{i+1}-1)}) \leq F(\boldsymbol{\alpha}^{(i,0)}).$$

■

Lemma 5 states that the initial function value $F(\boldsymbol{\alpha}^{(i,0)})$ of each outer iteration gives an upper bound of the subsequent function values and hence the sequence $\{F(\boldsymbol{\alpha}^{(i,0)})\}_{i=1}^{\infty}$ is non-increasing as illustrated in Figure 4.

Now we are ready to show the convergence result of Algorithm 3.

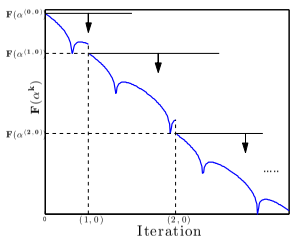

Figure 4: Illustration of the sequence $\{F(\boldsymbol{\alpha}^k)\}_{k=0}^{\infty}$ generated by Algorithm 3. Lemma 5 ensures that the function values $F(\boldsymbol{\alpha}^{(i,0)})$ at restarted points are non-increasing and gives upper bounds of the subsequent function values.

Theorem 6 *Consider the sequence* $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty} (\equiv \{\boldsymbol{\alpha}^{(i,k_{i+1})}\})$ *generated by Algorithm 3. Let* S^* *be the set of optimal solutions and* $B := \{\boldsymbol{\alpha} \mid F(\boldsymbol{\alpha}) \leq F(\boldsymbol{\alpha}^0)\}$ *be the level set. Assume that there exists a finite* R *such that*

$$R \geq \sup_{\boldsymbol{\alpha}^* \in S^*}\sup_{\boldsymbol{\alpha} \in B}\|\boldsymbol{\alpha} - \boldsymbol{\alpha}^*\|_2.$$

Then we have

$$F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \leq 2\eta_u L_f R^2\Big(\frac{\log_2(k+2)}{k - \log_2(k+2)}\Big)^2, \quad \forall k \geq 3.$$

Proof From Lemma 5, we have $\boldsymbol{\alpha}^k \in B$ for all $k \geq 1$. Let $\boldsymbol{\alpha}^k = \boldsymbol{\alpha}^{(j,k_{j+1})}$. We assume $k_{j+1} \geq 1$ without loss of generality. From Proposition 1, we have

$$F(\boldsymbol{\alpha}^{(j,k_{j+1})}) - F(\boldsymbol{\alpha}^*) \leq \frac{2\eta_u L_f\|\boldsymbol{\alpha}^{(j,0)} - \boldsymbol{\alpha}^*\|_2^2}{k_{j+1}^2}$$

Moreover, for all $1 \leq i \leq j$, Lemma 5 leads to

$$\begin{aligned} F(\boldsymbol{\alpha}^{(j,k_{j+1})}) - F(\boldsymbol{\alpha}^*) &\leq F(\boldsymbol{\alpha}^{(j,0)}) - F(\boldsymbol{\alpha}^*) \\ &\leq F(\boldsymbol{\alpha}^{(i,0)}) - F(\boldsymbol{\alpha}^*) \\ &= F(\boldsymbol{\alpha}^{(i-1,\bar{k}_i-1)}) - F(\boldsymbol{\alpha}^*) \\ &\leq \frac{2\eta_u L_f\|\boldsymbol{\alpha}^{(i-1,0)} - \boldsymbol{\alpha}^*\|_2^2}{(\bar{k}_i - 1)^2} \\ &\leq \frac{2\eta_u L_f R^2}{(\bar{k}_i - 1)^2}. \end{aligned}$$

Note that $\bar{k}_i \geq K_i \geq 2$. Thus we obtain

$$F(\boldsymbol{\alpha}^{(j,k_{j+1})}) - F(\boldsymbol{\alpha}^*) \leq \frac{2\eta_u L_f R^2}{(\max\{\bar{k}_1 - 1, \bar{k}_2 - 1, \ldots, \bar{k}_j - 1, k_{j+1}\})^2} \leq \frac{2\eta_u L_f R^2}{(\max\{\bar{k}_1, \bar{k}_2, \ldots, \bar{k}_j, k_{j+1}\} - 1)^2}$$

From

$$k \geq \sum_{i=1}^{j} K_i = \frac{K_1(2^j - 1)}{2 - 1} \geq 2^{j+1} - 2,$$

the number of restart j is at most $\log_2(k+2) - 1$. Hence we have

$$\max\{\bar{k}_1, \bar{k}_2, \ldots, \bar{k}_j, k_{j+1}\} \geq \frac{k}{j+1} \geq \frac{k}{\log_2(k+2)}, \tag{24}$$

which leads to

$$F(\boldsymbol{\alpha}^{(j,k_{j+1})}) - F(\boldsymbol{\alpha}^*) \leq 2\eta_u L_f R^2 \Big(\frac{\log_2 k}{k - \log_2(k+2)}\Big)^2, \quad \forall k \geq 3.$$

■

The above theorem ensures the convergence of Algorithm 3 for C-SVM, ν-SVM, MM-MPM, MM-FDA, and ℓ_2-SVM because the level set B is bounded for any initial point $\boldsymbol{\alpha}^0 \in \mathrm{dom}(g)$ since S_C, S_ν, S_{FDA}, and S_{MPM} are bounded and the objective function of ℓ_2-SVM is strongly convex. Similarly, the algorithm is convergent for the logistic regression problem (13) if S_{LR} is replaced by $\{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \xi \boldsymbol{e} \leq \boldsymbol{\alpha} \leq \boldsymbol{e}\}$ for some small constant $\xi > 0$. To guarantee the convergence of Algorithm 3 for the distance weighted discrimination problem (15), we need to replace S_{DWD} by $S_{\mathrm{DWD}}(\xi) := \big\{\boldsymbol{\alpha} \in \mathbb{R}^m \mid \boldsymbol{\alpha}^\top \boldsymbol{y} = 0,\ \xi \boldsymbol{e} \leq \boldsymbol{\alpha} \leq \frac{1}{m\nu}\boldsymbol{e}\big\}$ for some small constant $\xi > 0$ and make the assumption that $\|\widetilde{X}\boldsymbol{\alpha}\|_2 > 0$ for all $\boldsymbol{\alpha} \in S_{\mathrm{DWD}}(\xi)$.

The iteration complexity $O\big((\log(k)/k)^2\big)$ shown in Theorem 6 can be improved to $O\big((W(k)/k)^2\big)$ by finding a better lower bound of (24), where the Lambert's W function $W(\cdot)$ (Corless et al., 1996) is the inverse function of $x\exp(x)$ and diverges slower than $\log(\cdot)$.

Theorem 7 *Consider the sequence $\{\boldsymbol{\alpha}^k\}_{k=0}^{\infty} (\equiv \{\boldsymbol{\alpha}^{(i,k_{i+1})}\})$ generated by Algorithm 3. Let S^* be the set of optimal solutions and $B := \{\boldsymbol{\alpha} \mid F(\boldsymbol{\alpha}) \leq F(\boldsymbol{\alpha}^0)\}$ be the level set. Assume that there exists a finite R such that*

$$R \geq \sup_{\boldsymbol{\alpha}^* \in S^*} \sup_{\boldsymbol{\alpha} \in B} \|\boldsymbol{\alpha} - \boldsymbol{\alpha}^*\|_2.$$

Then we have

$$F(\boldsymbol{\alpha}^k) - F(\boldsymbol{\alpha}^*) \leq 2\eta_u L_f R^2 \Big(\frac{W(2k\ln 2)}{k\ln 2 - W(2k\ln 2)}\Big)^2, \quad \forall k \geq 3.$$

Proof See Appendix C. ■

4.3 A Practical FAPG

In this section, we develop a practical version of the FAPG method which reduces the computation cost of FAPG at each iterations.

4.3.1 Heuristic Backtracking Procedure

Although the APG method of (Scheinberg et al., 2014), which is employed in Algorithm 1 and modified in Algorithm 3, can guarantee the convergence, its principal drawback is the extra computational cost at the backtracking step. Recall that

$$Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k) = f(\boldsymbol{\beta}^k) + \langle \nabla f(\boldsymbol{\beta}^k),\ \boldsymbol{\alpha}^k - \boldsymbol{\beta}^k \rangle + \frac{L_k}{2}\|\boldsymbol{\alpha}^k - \boldsymbol{\beta}^k\|_2^2 + g(\boldsymbol{\alpha}^k).$$

To check the condition $F(\boldsymbol{\alpha}^k) \leq Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k)$, we need to recompute $f(\boldsymbol{\beta}^k)$ and $\nabla f(\boldsymbol{\beta}^k)$ since $\boldsymbol{\beta}^k$ is updated at each loop of the backtracking.

On the other hand, since the original APG of (Beck and Teboulle, 2009) does not update $\boldsymbol{\beta}^k$ during the backtracking step, we can reduce the computation cost by storing the value of $f(\boldsymbol{\beta}^k)$ and $\nabla f(\boldsymbol{\beta}^k)$. Hence we follow the strategy of (Beck and Teboulle, 2009), i.e., we remove the steps for updating t_k and $\boldsymbol{\beta}^k$ subsequent to 'bt' from Algorithm 3 and restore Step 2 as $t_{k+1} \leftarrow \frac{1+\sqrt{1+4t_k^2}}{2}$.

4.3.2 Skipping Extra Computations

The backtracking step ('bt') involves extra computation of the function value $F(\boldsymbol{\alpha}^k)$. Checking the termination criteria $L_k\|T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k\|_2 < \epsilon$ also involves the extra computation of $\nabla f(\boldsymbol{\alpha}^k)$ which is needed for $T_{L_k}(\boldsymbol{\alpha}^k)$. These computation costs can be significant (see Tables 3 and 9 in Section 5). Thus we compute the 'bt' and $L_k\|T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k\|_2$ in every 10 and 100 iterations, respectively.

Instead of checking the condition $L_k\|T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k\|_2 < \epsilon$, we check whether $L_k\|\boldsymbol{\alpha}^k - \boldsymbol{\beta}^k\|_2 < \epsilon$ at each iteration. The reason for doing so is that computing $L_k\|\boldsymbol{\alpha}^k - \boldsymbol{\beta}^k\|_2$ is much cheaper than computing $T_{L_k}(\boldsymbol{\alpha}^k)$. It follows from (4) and (5) that if $\boldsymbol{\alpha}^k = \boldsymbol{\beta}^k$, then $\boldsymbol{\alpha}^k$ is an optimal solution. Moreover, $L_k(\boldsymbol{\alpha}^k - \boldsymbol{\beta}^k)$ represents a residual of a sufficient optimality condition for $\boldsymbol{\alpha}^k$ (and necessary and sufficient optimality condition for $\boldsymbol{\beta}^k$).

Finally, our practical FAPG is described as in Algorithm 4. We note that FAPG can be applied not only to the unified formulation shown in Section 3, but also to the optimization problem of the form (2). See Appendix D in which we demonstrate the performance of FAPG for ℓ_1-regularized classification models.

4.4 Computation of Primal Solution from Dual Solution

Various classification models can be solved in a unified way by applying the vector projection method and the FAPG method to the dual formulation (9) or (10). However, the primal solution $(\boldsymbol{w}, b)$ of (7) or (8) is still required to do classification tasks. In this section, we provide a method to compute the primal solution $(\hat{\boldsymbol{w}}, \hat{b})$ which corresponds to the dual solution $\hat{\boldsymbol{\alpha}}$.

Algorithm 4 A Practical Fast Accelerated Proximal Gradient Method

Input: f, ∇f, g, $\mathrm{prox}_{g,L}$, $\epsilon > 0$, $L > 0$, $\eta_u > 1$, $\eta_d > 1$ $\delta \in (0,1)$, $k_{max} > 0$, $K_1 \geq 2$, $\boldsymbol{\beta}^1 = \boldsymbol{\alpha}^0$
Output: $\boldsymbol{\alpha}^k$
Initialize: $t_1 \leftarrow 1$, $i \leftarrow 1$, $k_{re} \leftarrow 0$
for $k = 1, \ldots, k_{max}$ **do**
  $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) = \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L}\nabla f(\boldsymbol{\beta}^k)\right)$ # Step 1
  if k mod 10 == 1 **then**
    while $F(\boldsymbol{\alpha}^k) > Q_{L_k}(\boldsymbol{\alpha}^k; \boldsymbol{\beta}^k)$ **do**
      $L_k \leftarrow \eta L_k$; $\boldsymbol{\alpha}^k \leftarrow T_{L_k}(\boldsymbol{\beta}^k) \leftarrow \mathrm{prox}_{g,L_k}\left(\boldsymbol{\beta}^k - \frac{1}{L_k}\nabla f(\boldsymbol{\beta}^k)\right)$ # 'bt'
    end while
  end if
  if $\|L(\boldsymbol{\alpha}^k - \boldsymbol{\beta}^k)\| < \epsilon$ or ((k mod 100 == 1) and ($\|L(T_L(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\| < \epsilon$)) **then**
    break
  end if
  $L_{k+1} \leftarrow L_k/\eta_d$ # 'dec'
  $t_{k+1} \leftarrow \frac{1+\sqrt{1+4t_k^2}}{2}$ # Step 2
  $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^k + \frac{t_k - 1}{t_{k+1}}(\boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1})$ # Step 3
  if $k > k_{re} + K_i$ and $\langle \nabla f(\boldsymbol{\beta}^k),\ \boldsymbol{\alpha}^k - \boldsymbol{\alpha}^{k-1}\rangle + g(\boldsymbol{\alpha}^k) - g(\boldsymbol{\alpha}^{k-1}) > 0$ **then**
    $k_{re} \leftarrow k$, $K_{i+1} \leftarrow 2K_i$, $i \leftarrow i+1$. # 'mt'
    $\eta_d \leftarrow \delta \cdot \eta_d + (1-\delta)\cdot 1$. # 'st'
    $t_{k+1} \leftarrow 1$, $\boldsymbol{\beta}^{k+1} \leftarrow \boldsymbol{\alpha}^{k-1}$, $\boldsymbol{\alpha}^k \leftarrow \boldsymbol{\alpha}^{k-1}$ # 're'
  end if
end for

4.4.1 Computation of $\boldsymbol{w}$

The primal vector $\hat{\boldsymbol{w}}$ in (8) corresponding to the dual solution $\hat{\boldsymbol{\alpha}}$ (and $\hat{\boldsymbol{u}}$ for MM-FDA and MM-MPM) can be obtained as

$$\hat{\boldsymbol{w}} = \underset{\|\boldsymbol{w}\|_p \leq 1}{\mathrm{argmax}}\, \boldsymbol{w}^\top \boldsymbol{z}, \quad \text{with} \quad \hat{w}_i = \frac{\mathrm{sign}(z_i)|z_i|^{q-1}}{\|\boldsymbol{z}\|_q^{q-1}} \quad \forall\, i \in M, \tag{25}$$

where $q = p/(p-1)$ and $\boldsymbol{z} = \widetilde{A}\hat{\boldsymbol{\alpha}}$ (i.e., $\boldsymbol{z} = \widetilde{X}\hat{\boldsymbol{\alpha}}$ for C-SVM, ℓ_2-SVM, ν-SVM, logistic regression, and DWD; $\boldsymbol{z} = \hat{\boldsymbol{\alpha}} = (\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_-) + (\Sigma_+ + \Sigma_-)^{1/2}\hat{\boldsymbol{u}}$ for MM-FDA; and $\boldsymbol{z} = \hat{\boldsymbol{\alpha}} = (\bar{\boldsymbol{x}}_+ + \Sigma_+^{1/2}\hat{\boldsymbol{u}}_+) - (\bar{\boldsymbol{x}}_- + \Sigma_-^{1/2}\hat{\boldsymbol{u}}_-)$ for MM-MPM).

4.4.2 Computation of b

There are some issues on computing an optimal bias term b. For C-SVM, ℓ_2-SVM, ν-SVM, DWD, and logistic regression, the bias term b is derived from the Lagrange multiplier corresponding to the constraint $\boldsymbol{\alpha}^\top \boldsymbol{y} = 0$. However, it is often difficult to compute the corresponding Lagrange multiplier. In addition, MM-FDA and MM-MPM does not provide a specific way to compute the bias term. Thus we need to estimate an appropriate value of b.

One of the efficient ways is to estimate b as the minimum solution of training error under a given $\hat{\boldsymbol{w}}$, i.e.,

$$\hat{b} \in \underset{b}{\mathrm{argmin}}\ \rho(b) := \sum_{i=1}^{m} \ell\big(y_i(\boldsymbol{x}_i^\top \hat{\boldsymbol{w}} - b)\big), \quad \text{where} \quad \ell(z) = \begin{cases} 1 & (z < 0) \\ 0 & (\text{otherwise}). \end{cases} \tag{26}$$

Let $\zeta_i = \boldsymbol{x}_i^\top \hat{\boldsymbol{w}}$ $(i = 1, 2, \ldots, m)$. Let σ be the permutation such that $\zeta_{\sigma(1)} \leq \zeta_{\sigma(2)} \leq \ldots \leq \zeta_{\sigma(m)}$. If $b < \zeta_{\sigma(1)}$, then $\boldsymbol{x}_i^\top \hat{\boldsymbol{w}} - b > 0$ $(\forall i \in M)$, i.e., all samples are predicted as positive $\hat{y} = +1$. Then we have m_- misclassified samples and thus $\rho(b) = m_-$. If $b \in (\zeta_{\sigma(1)}, \zeta_{\sigma(2)})$, then only $\boldsymbol{x}_{\sigma(1)}$ is predicted as negative $\hat{y} = -1$. Thus we have $\rho(b) = m_- + y_{\sigma(1)}$. Similarly, if $b \in (\zeta_{\sigma(k)}, \zeta_{\sigma(k+1)})$, then we have $\rho(b) = m_- + \sum_{i=1}^{k} y_{\sigma(i)}$. Thus, by letting $k^* \in \mathrm{argmin}_k \sum_{i=1}^{k} y_{\sigma(i)}$, an arbitrary constant $\hat{b} \in (\zeta_{\sigma(k^*)}, \zeta_{\sigma(k^*+1)})$ is an optimal solution of the problem (26). The minimization algorithm is as follows:

Step 1. Compute $\zeta_i = \hat{\boldsymbol{w}}^\top \boldsymbol{x}_i$ $(i = 1, 2, \ldots, m)$.

Step 2. Sort ζ_i as $\zeta_{\sigma(1)} \leq \zeta_{\sigma(2)} \leq \ldots \leq \zeta_{\sigma(m)}$.

Step 3. Find $k^* = \mathrm{argmin}_k \sum_{i=1}^{k} y_{\sigma(i)}$.

Step 4. Compute $\hat{b} = (\zeta_{(k^*)} + \zeta_{(k^*+1)})/2$.

Its computational complexity is $O\big(m(n + \log m)\big)$.

4.4.3 Duality Gap

The component b obtained above is not necessarily the primal optimal solution. Moreover, $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{u}}$ are close to optimal, but may not be exactly optimal due to e.g., numeric overflow.

We still obtain a primal solution $(\hat{\boldsymbol{w}}, \hat{b})$ with some optimality gap guarantee. Since $(\hat{\boldsymbol{w}}, \hat{b})$ and $\hat{\boldsymbol{\alpha}}$ are the primal and dual feasible solutions, respectively, we can obtain the duality gap by

$$\left\{\mathcal{L}(\widetilde{A}^\top \hat{\boldsymbol{w}} - \boldsymbol{a}\hat{b}) + \frac{1}{2C}\|\hat{\boldsymbol{w}}\|_2^2)\right\} - \left\{\mathcal{L}^*(-\hat{\boldsymbol{\alpha}}) + \frac{C}{2}\|\widetilde{A}\hat{\boldsymbol{\alpha}}\|_2^2\right\}$$

for the formulations of (7) and (9); and

$$\mathcal{L}(\widetilde{A}^\top \hat{\boldsymbol{w}} - \boldsymbol{a}\hat{b}) - \left\{\mathcal{L}^*(-\hat{\boldsymbol{\alpha}}) + \lambda\|\widetilde{A}\hat{\boldsymbol{\alpha}}\|_p^*\right\}$$

for the formulations of (8) and (10). Therefore, the obtained primal solution $(\hat{\boldsymbol{w}}, \hat{b})$ has a guarantee that the gap between its objective value and the optimal value is at most the duality gap.

5. Numerical Experiment

In this section we demonstrate the performance of our proposed FAPG algorithm. We run the numerical experiments on a Red Hat Enterprise Linux Server release 6.4 (Santiago) with Intel Xeon Processor E5-2680 (2.7GHz) and 64 GB of physical memory. We implemented the practical FAPG method (Algorithm 4) in MATLAB R2013a and the bisection method (Algorithm 2) in C++. The C++ code was called from MATLAB via MEX files.

We conducted the experiments using artificial datasets and benchmark datasets from LIBSVM Data (Chang and Lin, 2011). The artificial datasets were generated as follows. Positive samples $\{\boldsymbol{x}_i \in \mathbb{R}^n \mid i \in M_+\}$ and negative samples $\{\boldsymbol{x}_i \in \mathbb{R}^n \mid i \in M_-\}$ were distributed with n-dimensional standard normal distributions $\mathcal{N}_n(\boldsymbol{0}, I_n)$ and $\mathcal{N}_n(\frac{10}{\sqrt{n}}\boldsymbol{e}, SS^\top)$, respectively, where the elements of the $n \times n$ matrix S are i.i.d. random variables following the standard normal distribution $\mathcal{N}(0,1)$. The marginal probability of the label was assumed to be same, i.e. $P(y=+1) = P(y=-1) = \frac{1}{2}$. After generating the samples, we scaled them so that each input vector $\boldsymbol{x}_i$ $(\forall i \in M)$ was in $[-1,1]^n$ for the purpose of computational stability, following LIBSVM (Chang and Lin, 2011). On the other hand, we scaled the benchmark datasets, that are not scaled by Chang and Lin (2011), so that $\boldsymbol{x}_i \in [0,1]^n$, $(\forall i \in [m])$ in order to leverage their sparsity. The details of benchmark datasets are shown in Table 1.

5.1 Projection Algorithms

Before presenting the performance of our practical FAPG algorithm, we compared the performance of our bisection algorithm (Algorithm 2) against the breakpoint search algorithm (Kiwiel, 2008, Algorithm 3.1) with random pivoting. Both algorithms were implemented in C++. We generated $\mathbb{R}^n$-valued random vectors $\tilde{\boldsymbol{\alpha}}$ with uniformly distributed elements and computed the projections $P_{S_\nu}(\tilde{\boldsymbol{\alpha}})$ of $\tilde{\boldsymbol{\alpha}}$ onto S_ν, where $S_\nu := \left\{\boldsymbol{\alpha} \mid \boldsymbol{e}_o^\top \boldsymbol{\alpha}_o = \frac{1}{2},\ o \in \{+,-\},\ \boldsymbol{0} \le \boldsymbol{\alpha} \le \frac{1}{m\nu}\boldsymbol{e}\right\}$ with $\nu = 0.5$. The bisection algorithm used the accuracy of $\epsilon' \approx 2.22 \times 10^{-16}$ (i.e., IEEE 754 double precision). Table 2 reports the average and standard deviation of the computation times and the number of iterations of 20 trials. As we can see from Table 2, the bisection method was faster and more stable (in the sense that the deviations are smaller) than the breakpoint search algorithm. This explains why we

Table 2: Runtime of Projection Algorithms

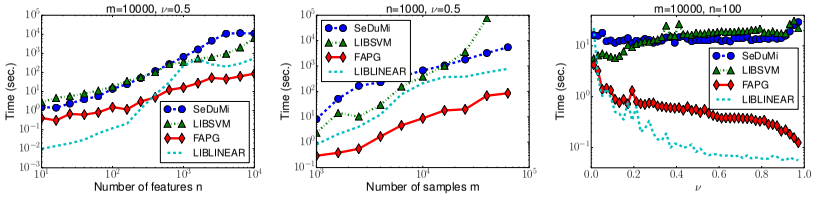

Figure 5: Computation Time for ν-SVM

have chosen to use the bisection methods in Section 4.1 to perform the projection steps in Algorithm 4.

5.2 ν-SVM

As mentioned in Section 3.2, the standard C-SVM (11) and ν-SVM (14) are equivalent. Here we chose ν-SVM to solve because choosing the parameter of ν-SVM is easier than that of C-SVM. We solved the ν-SVM (14) via our FAPG method, SeDuMi (Sturm, 1999), and LIBSVM (Chang and Lin, 2011). SeDuMi is a general purpose optimization solver implementing an interior point method for large-scale second-order cone problems such as (14). LIBSVM implements the sequential minimal optimization (SMO) (Platt, 1998) which is specialized for learning ν-SVM. For reference, we also compared the FAPG method with LIBLINEAR (Fan et al., 2008) which implements a highly optimized stochastic dual coordinate descent method (Hsieh et al., 2008) for C-SVM[3] (Cortes and Vapnik, 1995) and is known to be quite an efficient method; we note that it may not be a fair comparison because LIBLINEAR omits the bias term b of C-SVM from the calculations, [4] i.e., it solves a less complex model than the ν-SVM (14) in order to speed up the computation.

We terminate the algorithms if the violation of the KKT optimality condition is less than $\epsilon = 10^{-6}$. The heuristic option in LIBSVM was set to "off" in order to speed up its convergence for large datasets. In the FAPG method, (η_u, η_d, δ) were set to $(1.1, 1.1, 0.8)$. L_0 was set to the maximum value in the diagonal elements of $\widetilde{X}^\top \widetilde{X}$ (i.e., the coefficient matrix of the quadratic form). The initial point $\boldsymbol{\alpha}^0$ was set to the *center* $\boldsymbol{\alpha}^c$ of S_ν, i.e. $\alpha^c_i = \frac{1}{2m_o}$, $i \in M_o$, $o \in \{+, -\}$.

5.2.1 Scalability

First, we compare the computation time with respect to the size of the datasets and parameters using artificial datasets. The results are shown in Figure 5. The left panel shows the computation time with respect to the dimension n of the features for $m = 10000$ and $\nu = 0.5$. The FAPG method has a clear advantage when the dimension n is high, say

3. C-SVM (with the bias term b) is known to lead to the same decision function as ν-SVM if ν and C are set properly (Schölkopf et al., 2000). The value of C corresponding to ν can be computed by LIBSVM.
4. Although LIBLINEAR can virtually deal with the bias term b by augmenting the dimension of the samples, the best performance of the resulting model tends to be lower than the one of ν-SVM as reported in (Kitamura et al., 2014).

Function	% Time	Time	# Evals.	Time/Eval.
$\nabla f(\boldsymbol{\alpha})$	78.1%	14.909	1375	0.0108
$f(\boldsymbol{\alpha})$	10.8%	2.053	369	0.0056
$P_{S_\nu}(\boldsymbol{\alpha})$	6.9%	1.307	1453	0.0009
Total Runtime:		19.080		

Table 3: Runtime Breakdown of the FAPG Method (sec.)

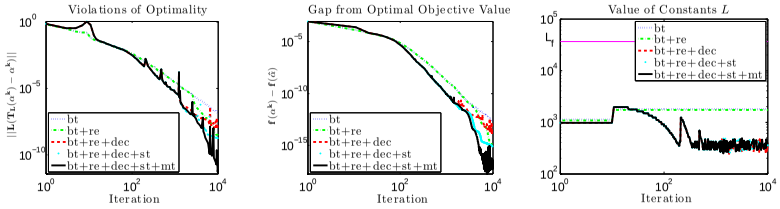

Figure 6: Effect of various acceleration strategies for the APG Method.

$n \geq 10^3$. The middle panel shows the computation time with respect to the number m of the samples for $n = 1000$ and $\nu = 0.5$. LIBSVM did not converge within a week for $m = 63000$. SeDuMi, LIBLINEAR, and the APG method were scalable for the increased number of samples m. The right panel illustrates the computation time with respect to the parameter ν for $m = 10000$ and $n = 100$. We may observe that the FAPG method (and LIBLINEAR) is very efficient when ν is larger than 0.1. This can be attributed to the fact that larger ν shrinks the feasible region S_ν and shorten the distance between the initial point $\boldsymbol{\alpha}^0 = \boldsymbol{\alpha}^c$ and the optimal solution $\boldsymbol{\alpha}^*$.

5.2.2 Runtime Breakdown

Table 3 shows the runtime breakdown of the FAPG method for the artificial dataset with $(m, n, \nu) = (10000, 1000, 0.5)$. The computation of the gradient $\nabla f(\boldsymbol{\alpha})$ and the function $f(\boldsymbol{\alpha})$ was the most time-consuming parts in the FAPG method. Since the computations of 'bt' (and $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\|$) involve the extra evaluation of $f(\boldsymbol{\alpha}^k)$ (and/or $\nabla f(\boldsymbol{\alpha}^k)$), computing them only every 100 iteration (and 10 iteration, respectively) as in Algorithm 4 would be effective to reduce the total runtime. Our projection algorithm was efficient enough in the sense that its runtime was marginal compared to the runtime of the other parts.

5.2.3 Effect of Each Acceleration Strategy

Figure 6 shows the running history of the FAPG method with various acceleration strategies for the artificial dataset with $(m, n, \nu) = (10000, 1000, 0.5)$.

The left panel depicts the violations of the optimality, i.e. the values of $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\|$. The FAPG method with 'bt+re' restarted at $k = 2594$, where the sharp decrease occurred. 'dec' was effective to reduce $L_k\|T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k\|$ in the early iterations. The FAPG method with 'bt+re+dec' seems to be unstable near the optimum (say $k \geq 10^3$), but

the one with 'bt+re+dec+st' converged stably. Moreover, 'bt+re+dec+st+mt' obtained much more accurate solution than others. We note that several spikes of the values occurred when using 'dec' because it sometimes leads a small value of L_k that violates the condition (6). However, the violation was swiftly recovered in every 10 iterations by 'bt' and did not affect the speed of convergence so much.

The middle panel illustrated the gap in objective value $f(\boldsymbol{\alpha}^k) - f(\hat{\boldsymbol{\alpha}})$ where we regarded $\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha}^{10000}$ of 'bt+re+dec+st+mt' as an optimal solution. The gap behaved similar to the violations of the optimality $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\|$. At $k = 1000$, the objective value $f(\boldsymbol{\alpha}^k)$ reached $f(\hat{\boldsymbol{\alpha}})$ within a relative error 0.0003% though the violation of optimality was greater than $\epsilon = 10^{-6}$. Thus, a larger tolerance, say $\epsilon = 10^{-5}$, may also lead to a reasonable solution in practice.

The right panel illustrated the value of constant L_k of the FAPG at each iteration and the value of Lipschitz constant L_f; L_f is known to be the largest eigenvalue of $\widetilde{X}^\top \widetilde{X}$. While $L_f = 3.61 \times 10^4$, the FAPG method with 'bt+re+dec+st+mt' leads to a much smaller average value of 3.68×10^2 for L_k, while the maximum value for L_k is 1.95×10^3.

5.2.4 Benchmark Results

We also conducted experiments using the benchmark datasets. C was set to 10. The computation time is shown in Table 4. When using linear kernel, the FAPG method outperformed LIBSVM and SeDuMi for large datasets where $m \geq 50000$. We indicated the smallest computation time among the three methods except for LIBLINEAR by boldface because the optimal solutions of LIBLINEAR are different from those of the other three methods (note that LIBLINEAR solves a simpler type of SVM, i.e., C-SVM without the bias term b). However, the FAPG method had an advantage over LIBLINEAR for many datasets where $n \geq 2000$.

When using the RBF kernel, SeDuMi broke down for datasets with $m \geq 10000$ as in the case of the artificial datasets. The FAPG method run out of memory for $m \geq 50000$ since it requires the $m \times m$ dense kernel matrix K to compute the gradient $\nabla f(\boldsymbol{\alpha})$. The FAPG can avoid the memory shortage by computing the elements of K on demand as LIBSVM does for large datasets. Although the current implementation has room for improvement, our practical FAPG method was still competitive with LIBSVM and had stable and good performance for datasets with large n.

We should remark that the number of iterations taken by the FAPG method with the RBF kernel tends to be smaller than the one with the linear kernel. However, when using the RBF kernel, the computational complexity of $\nabla f(\boldsymbol{\alpha})$ changes from $O(mn)$ to $O(m^2)$. Hence the total runtime tended to increase except for "gisette" whose n and m have the same order of magnitude.

In summary, the FAPG method showed better performance than specialized algorithms designed for learning SVM, such as LIBSVM and LIBLINEAR, in many datasets. Taking into account of the generality (i.e., applicability to other models) of FAPG, one could argue that it is a very efficient method.

Table 5 shows the values taken by the parameter L_k. We can see that our practical FAPG method (with backtracking strategy and decreasing strategy for L_k) keep the values of L_k to be much smaller than the Lipschitz constant L_f.

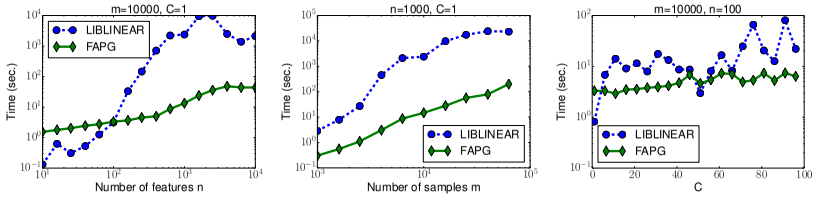

Figure 7: Computation Time for Logistic Regression.

5.3 Logistic Regression

We solved the dual logistic regression (13) via the FAPG method and LIBLINEAR (Fan et al., 2008). LIBLINEAR implements a highly optimized stochastic dual coordinate descent method (Yu et al., 2011) whose subproblems are solved by the Newton method. Note that, as in the case of SVM, LIBLINEAR omits the bias term b from the calculations, i.e., it solves a less complex model than (13). We terminate both algorithms if the violation of the KKT optimality condition is less than $\epsilon = 10^{-6}$. In the FAPG method, (η_u, η_d, δ) were set to $(1.1, 1.1, 0.8)$. L_0 was set to 1. The initial point $\boldsymbol{\alpha}^0$ was set to $\xi \boldsymbol{e}$.

5.3.1 Sensitivity to ξ

Since the gradient ∇f is not defined at $\alpha_i = 0, 1$ $(i \in M)$, we approximately solve the problem by using the constraints $\xi \leq \alpha_i \leq 1 - \xi$ $(i \in M)$, where $\xi > 0$. Table 6 shows the classification accuracy for $\xi = 10^{-2}, 10^{-3}, 10^{-4}$, and 10^{-5}. For all cases, the approximated logistic regression performed better than LIBLINEAR. The classification accuracy of FAPG was identical for $\xi \leq 10^{-3}$, and better than the accuracy with $\xi = 10^{-2}$. We employ $\xi = 10^{-4}$ in the following experiments.

5.3.2 Scalability

First, we compare the computation time with respect to the size of the datasets and parameter using artificial datasets. The results (for the linear kernel) are shown in Figure 7. The left panel shows the computation time with respect to the dimension n of the features for $m = 10000$ and $C = 10$. The FAPG method has a clear advantage when the dimension n is high, say $n \geq 10^2$. The middle panel shows the computation time with respect to the number m of the samples for $n = 1000$ and $C = 10$. The computation time of FAPG grew

Function	% Time	Time	# Evals.	Time/Eval.
$\nabla f(\boldsymbol{\alpha})$	85.4%	10.005	1452	6.89.E-03
$f(\boldsymbol{\alpha})$	12.3%	1.443	340	4.24.E-03
$P_{S_{\mathrm{LR}}}(\boldsymbol{\alpha})$	0.5%	0.058	1473	3.94.E-05
Total Runtime:		11.720		

Table 7: Runtime Breakdown of the FAPG Method (sec.)

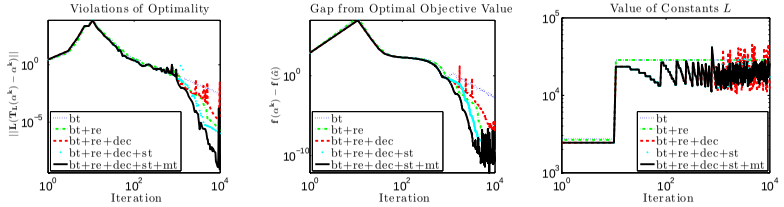

Figure 8: Effect of various acceleration strategies for the FAPG Method.

slower than the one of LIBLINEAR. The right panel illustrates the computation time with respect to the parameter C for $m = 10000$ and $n = 100$. Unlike ν-SVM, the computation time of the FAPG did not change so much depending on the parameter C because it does not affect the area of feasible region. We can observe that the FAPG method is numerically more stable than LIBLINEAR with respect to the changes of the parameter C.

5.3.3 Runtime Breakdown

Table 7 shows the runtime breakdown of the FAPG method for the artificial dataset with $(m, n, C) = (10000, 1000, 10)$. The computation of the gradient $\nabla f(\boldsymbol{\alpha})$ and the function $f(\boldsymbol{\alpha})$ was the most time-consuming parts as in the case of ν-SVM. Thus skipping backtracking step and evaluation of the optimality $\|L_k(\boldsymbol{\alpha}^k - T_{L_k}(\boldsymbol{\alpha}^k))\|$ reduce the computation time significantly because it can avoid the extra computation of f and ∇f.

5.3.4 Effect of Each Acceleration Strategy

Figure 8 shows the running history of the FAPG method with various acceleration strategies for the dataset 'a8a'. C was set to 10.

The left panel depicts the violations of the optimality, i.e. the values of $\|L_k(T_{L_k}(\boldsymbol{\alpha}^k) - \boldsymbol{\alpha}^k)\|$. 're' had effect on decreasing the values after $k = 762$ at which the first restart occur. 'bt+re+dec' just became unstable compared to 'bt+re' because the gradient of the logistic regression is intrinsically large near the boundary of the feasible region S_{LR}. However, 'bt+re+dec+st' could recover from the instability. It is remarkable that only 'bt+re+dec+st+mt' fell below 10^{-6} in 10000 iterations. Thus, one could argue that 'mt' had a significant effect on reducing the violation. The middle panel illustrated the gap in the objective value $f(\boldsymbol{\alpha}^k) - f(\hat{\boldsymbol{\alpha}})$ where we regarded $\hat{\boldsymbol{\alpha}} = \boldsymbol{\alpha}^{10000}$ of 'bt+re+dec+st+mt' as an optimal solution. 'bt+re+dec+st+mt' decreased the function value faster than others

and found the minimum solution while oscillation occurred at the end of iteration. The right panel illustrated the value of constant L_k of the FAPG at each iteration.

5.3.5 Benchmark Results

We measured computation time for the benchmark datasets. The parameter C was set to 10 throughout this experiment. The experimental results are shown in Table 8. LIBLINEAR was efficient because it solves a less complex model (without the bias term) than (13). In some cases, however, FAPG solved (13) faster than LIBLINEAR. The computation time and iteration count of FAPG was nearly proportional to the number of samples m. On the other hand, LIBLINEAR took much longer time for 'madeon' and 'splice' although they are relatively small datasets.

Taking these results and Figure 7 into account, one could argue that the FAPG method exhibits stable convergence empirically.

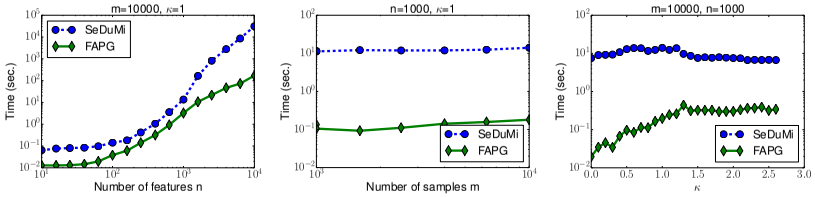

Figure 9: Computation Time for MM-MPM

5.4 MM-MPM

Next, we conducted experiments on MM-MPM (17). To the best of our knowledge, there are no specialized methods for MM-MPM. Thus, we compared the FAPG method only to SeDuMi (Sturm, 1999) which implements an interior point method for the large-scale second-order cone problems such as (17). We terminated the computations if the violation of KKT optimality is less than $\epsilon = 10^{-6}$. In the FAPG method, (η_u, η_d, δ) were set to $(1.1, 1.1, 0.8)$. The value of L_0 was set to the maximum value in the diagonal elements of $\widetilde{\Sigma}^\top\widetilde{\Sigma}$ (i.e., the coefficient matrix of the quadratic form), where $\widetilde{\Sigma} = [\Sigma_+^{1/2}, -\Sigma_-^{1/2}]$. The initial point $\boldsymbol{u}^0 = (\boldsymbol{u}_+^0, \boldsymbol{u}_-^0)$ was set to the origin $\mathbf{0}$.

5.4.1 Scalability

The computation time for the artificial datasets are shown in Figure 9. The left panel shows the results with respect to the number n of features for $m = 10000$ and $\kappa = 1$. The FAPG method has a clear advantage over SeDuMi for large n, say $n \geq 10^3$. The middle panel illustrates the computation time with respect to the number m of samples for $n = 2000$ and $\kappa = 1$. The computation time is nearly independent of the number m of samples because the sizes of matrices $\Sigma_o^{1/2}$ $(o \in \{+, -\})$, which are used for computing the function $f(\boldsymbol{u})$ and the gradient $\nabla f(\boldsymbol{u})$, are $n \times n$. The right panel shows the computation time with respect to the parameter κ for $m = 10000$ and $n = 2000$. We can observe that a larger value of κ leads to more computation time for the FAPG method although it is still far more efficient than SeDuMi. The effect of a larger κ on the FAPG method could be because it gives a larger feasible region $S_{\rm MPM}$, which in turns leads to a larger distance between the initial point $\boldsymbol{u}^0$ and the optimal solution $\boldsymbol{u}^*$ as in the case of ν-SVM (the right panel of Figure 5).

5.4.2 Runtime Breakdown

Table 9 shows the runtime breakdown of the FAPG method for the artificial dataset with $(m, n, \kappa) = (10000, 1000, 1)$. As in the case of ν-SVM (Table 3), the computations of the gradient $\nabla f(\boldsymbol{u})$ and the function value $f(\boldsymbol{u})$ are the most time-consuming parts. Thus, computing 'bt' and $L_k\|T_{L_k}(\boldsymbol{u}^k) - \boldsymbol{u}^k\|$ periodically, which involves the computations of $f(\boldsymbol{u}^k)$ and/or $\nabla f(\boldsymbol{u}^k)$, is effective to reduce the total runtime. The projection $P_{S_{\rm MPM}}(\boldsymbol{u})$ for MM-MPM shown in Section 4.1.4 can be computed highly efficiently.

Function	% Time	Time	# Evals.	Time/Eval.
$\nabla f(\boldsymbol{u})$	75.9%	0.836	339	2.47.E-03
$f(\boldsymbol{u})$	14.2%	0.157	119	1.32.E-03
$P_{S_{\rm MPM}}(\boldsymbol{u})$	3.1%	0.034	383	8.88.E-05
Total Runtime:		1.102		

Table 9: Runtime Breakdown of FAPG Method for MM-MPM (sec.)

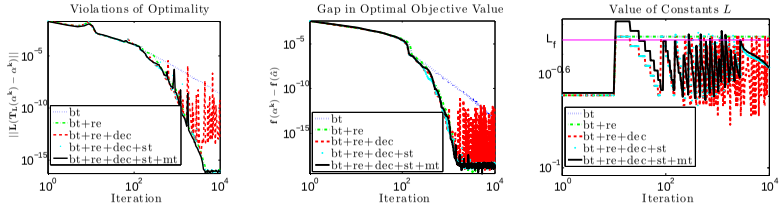

Figure 10: Effect of Each Strategy for the APG Method.

5.4.3 Effect of Each Strategy

Figure 10 illustrates the running history of FAPG with various practical strategies for the artificial dataset with $(m, n, \kappa) = (10000, 1000, 1)$. As in the case of ν-SVM, 're' is effective in reducing the violation of optimality $L_k\|T_{L_k}(\boldsymbol{u}^k) - \boldsymbol{u}^k\|$ and the value of $f(\boldsymbol{u}^k) - f(\hat{\boldsymbol{\alpha}})$. 'dec' seems to make the FAPG method to be unstable, but 'st' can stabilize it. 'bt+re+dec+st' and 'bt+re+dec+st+mt' decreased $L\|T_L(\boldsymbol{u}^k) - \boldsymbol{u}^k\|$ and $f(\boldsymbol{u}^k) - f(\hat{\boldsymbol{\alpha}})$ slightly faster than 'bt+re'.

In the right panel, we can see that the APG method uses values smaller than L_f for L_k in most iterations, where the Lipschitz constant L_f of the gradient $\nabla f(\boldsymbol{u}) = \widetilde{\Sigma}^\top(\bar{\boldsymbol{x}}_+ - \bar{\boldsymbol{x}}_- + \widetilde{\Sigma}\boldsymbol{u})$ is known to be the largest eigenvalue of the matrix $\widetilde{\Sigma}^\top\widetilde{\Sigma}$ (recall that $\widetilde{\Sigma} = [\Sigma_+^{1/2}, -\Sigma_-^{1/2}]$ and $\boldsymbol{u} = (\boldsymbol{u}_+, \boldsymbol{u}_-)$).

5.4.4 Benchmark Results

Table 10 shows the computational results for the benchmark datasets. We did the experiments by setting $\kappa = \kappa_{max}/2$, but MM-MPM could not be solved for $n \geq 20000$ because the sizes of the $n \times n$ matrices $\Sigma_o^{1/2}$ $(o \in \{+, -\})$ are extremely large.

The FAPG method was much faster than SeDuMi especially when the dimension is high, say $n \geq 2000$. Unlike for ν-SVM (Table 5), the FAPG method for MM-MPM sometimes led to larger values of L_k than the Lipschitz constant L_f. However, the average of the values of L_k is still smaller than L_f.

5.5 Classification Ability

Using the benchmark datasets, we compared the classification ability of classification models: ν-SVM, logistic regression, MM-MPM, and MM-FDA. Each dataset was randomly partitioned into 10 disjoint sets. We investigated the averages of the test accuracy using

Table 11: Average Performance of Each Classification Model. The best results are indicated by boldface. '–' means that the cross-validation could not be done within 36000 sec. '**' means that it had run out of memory.

cross-validation over the 10 disjoint sets. We found the best parameter of the each classification model using grid search with cross-validation. The results are reported in Table 11. The model that shows the best performance varies with datasets. This implies the importance of finding a suitable classification model to a dataset in order to achieve a high prediction performance. Our algorithm is useful for the purpose; it provides a unified and efficient framework for solving various classification models.

6. Conclusion

In this work, we presented a unified classification model and provided a general algorithm for the model. We designed a fast accelerated proximal gradient (FAPG) method based on the original APG method in (Beck and Teboulle, 2009) to the model by devising efficient projection computations and effective heuristic acceleration strategies. Our unified

algorithm makes it easy to compare various models, because we can use the same algorithmic framework for the models by only changing the computation of projections. Thus, it provides a practical and useful tool for practitioners who are looking for the best model for a given dataset. Numerical experiments demonstrate the efficiency of our algorithm for large datasets. Indeed, our method often run faster than LIBLINEAR (Fan et al., 2008) especially for large-scale datasets such that $n > 2000$.

In this paper we showed a convergence property of our method for a general non-strongly convex function because our examples are mostly non-strongly convex. As a future work, we would like to see if the linear convergence for FAPG can be established for μ-strongly convex function and provide an adaptive parameter selection scheme even when μ is positive but unknown. In addition, we would like to investigate stochastic variants of our method. Recently, large scale learning has motivated researchers to develop stochastic gradient descent (SGD) methods. SGD approximates the gradient $\nabla\mathcal{L}(\cdot)$ of a loss function by a computationally inexpensive random variable whose expectation coincides with $\nabla\mathcal{L}(\cdot)$. More precisely, it assumes that the loss function is defined as the sum of loss of each sample, i.e., $\mathcal{L}(\widetilde{X}^\top \boldsymbol{w} - \boldsymbol{y}b) = \sum_{i=1}^m \ell(y_i(\boldsymbol{w}^\top \boldsymbol{x}_i - b))$, and approximates the *full* gradient $\nabla\mathcal{L}(\widetilde{X}^\top \boldsymbol{w} - \boldsymbol{y}b)$ by the gradient $\nabla\ell(y_i(\boldsymbol{w}^\top \boldsymbol{x}_i - b))$ of loss of a randomly chosen sample. PG and APG methods can be adapted in SGD, e.g., as (Nitanda, 2014; Defazio et al., 2014) and references there in. In particular, the stochastic dual coordinate ascent (SDCA) method (Shalev-Shwartz and Zhang, 2013, 2016) is a stochastic APG applied to the dual formulation, which is closely related to our unified classification model. While its framework would be useful to develop a stochastic variant of our FAPG presented in this paper, it cannot be directly applied to the unified classification model because ν-SVM, MM-MPM, and MM-FDA do not satisfy the assumption on $\mathcal{L}(\cdot)$: the loss function is defined as the sum of loss of each sample. It is an important future work to relax the assumption for stochastic methods and extend our FAPG to stochastic ones in order to solve even larger scale problems.

Acknowledgments

We would like to express our warm thanks to the reviewers, whose insightful comments have led to many substantial improvements.

Appendix

Appendix A. Derivation of the Dual Problem (10)

The primal problem (8) can be transformed as follows:

$$\begin{aligned}
&\min_{\boldsymbol{w},b}\{\mathcal{L}(\widetilde{A}^\top \boldsymbol{w} - b\boldsymbol{a}) \mid \|\boldsymbol{w}\|_p \le \lambda\} \\
&= \min_{\boldsymbol{w},b,\boldsymbol{z}}\{\mathcal{L}(\boldsymbol{z}) \mid \|\boldsymbol{w}\|_p \le \lambda,\ \boldsymbol{z} = \widetilde{A}^\top \boldsymbol{w} - b\boldsymbol{a}\} \\
&= \min_{\|\boldsymbol{w}\|_p \le \lambda, b, \boldsymbol{z}} \max_{\boldsymbol{\alpha}}\{\mathcal{L}(\boldsymbol{z}) + \boldsymbol{\alpha}^\top(\boldsymbol{z} - \widetilde{A}^\top \boldsymbol{w} + b\boldsymbol{a})\}.
\end{aligned}$$

Its dual problem (10) is derived as follows:

$$\begin{aligned}
&\max_{\boldsymbol{\alpha}} \min_{\|\boldsymbol{w}\|_p \le \lambda, b, \boldsymbol{z}}\{\mathcal{L}(\boldsymbol{z}) + \boldsymbol{\alpha}^\top(\boldsymbol{z} - \widetilde{A}^\top \boldsymbol{w} + b\boldsymbol{a})\} \\
&= -\min_{\boldsymbol{\alpha}}\Big\{\max_{\boldsymbol{z}}\big\{-\boldsymbol{\alpha}^\top \boldsymbol{z} - \mathcal{L}(\boldsymbol{z})\big\} + \max_{\|\boldsymbol{w}\|_p \le \lambda}\big\{\boldsymbol{\alpha}^\top \widetilde{A}^\top \boldsymbol{w}\big\} + \max_{b}\big\{\boldsymbol{\alpha}^\top \boldsymbol{a} b\big\}\Big\} \\
&= -\min_{\boldsymbol{\alpha}}\{\mathcal{L}^*(-\boldsymbol{\alpha}) + \lambda\|\widetilde{A}\boldsymbol{\alpha}\|_p^* \mid \boldsymbol{\alpha}^\top \boldsymbol{a} = 0\}.
\end{aligned}$$

Appendix B. Refined Bisection Algorithm

The computational cost of $h(\hat{\theta})$ in Algorithm 2 can be reduced by dividing the indices set M more finely as in (Kiwiel, 2008). Here we divide M into the following four disjoint sets for given θ^l and θ^u satisfying $\theta^l < \theta^u$:

$$\begin{aligned}
U &:= \{i \in M \mid \bar{\alpha}_i - \theta^u \ge u && \text{(i.e., } \alpha_i(\theta) = u, && \forall\theta \in [\theta^l, \theta^u])\} \\
L &:= \{i \in M \mid \bar{\alpha}_i - \theta^l \le l && \text{(i.e., } \alpha_i(\theta) = l, && \forall\theta \in [\theta^l, \theta^u])\} \\
C &:= \{i \in M \mid \bar{\alpha}_i - \theta^l < u,\ \bar{\alpha}_i - \theta^u > l && \text{(i.e., } \alpha_i(\theta) = \bar{\alpha}_i - \theta, && \forall\theta \in [\theta^l, \theta^u])\} \\
I &:= M\backslash(U \cup C \cup L) && \text{(}[\theta^l, \theta^u] \text{ contains a breakpoint of } \alpha_i(\theta)) &.
\end{aligned}$$

If $I = \phi$, then solving

$$\theta = \Big(|U|u + |L|l + \sum_{i \in C} \bar{\alpha}_i - r\Big)/|C|$$

obtains an exact solution. If $I \neq \phi$, then we also divide I into the following five disjoint sets for given $\hat{\theta} \in (\theta^l, \theta^u)$:

$$\begin{aligned}
I^U &= \{i \in I \mid \bar{\alpha}_i - \hat{\theta} \ge u, && \text{(i.e., } \alpha_i(\theta) = u && \forall\theta \in [\theta^l, \hat{\theta}])\} \\
I^L &= \{i \in I \mid \bar{\alpha}_i - \hat{\theta} \le l, && \text{(i.e., } \alpha_i(\theta) = l && \forall\theta \in [\hat{\theta}, \theta^u])\} \\
I^{C_u} &= \{i \in I \mid \bar{\alpha}_i - \theta^l < u,\ \bar{\alpha}_i - \hat{\theta} > l, && \text{(i.e., } \alpha_i(\theta) = \bar{\alpha}_i - \theta && \forall\theta \in [\theta^l, \hat{\theta}])\} \\
I^{C_l} &= \{i \in I \mid \bar{\alpha}_i - \hat{\theta} < u,\ \bar{\alpha}_i - \theta^u > l, && \text{(i.e., } \alpha_i(\theta) = \bar{\alpha}_i - \theta && \forall\theta \in [\hat{\theta}, \theta^u])\} \\
I^I &= I\backslash(I^U \cup I^{C_u} \cup I^{C_l} \cup I^L)
\end{aligned}$$

Then we have

$$\begin{aligned}
h(\hat{\theta}) = \sum_{i \in M} \alpha_i(\hat{\theta}) = &\underbrace{|U|u}_{s_u} + \underbrace{|I^U|u}_{\Delta s_u} + \underbrace{|L|l}_{s_l} + \underbrace{|I^L|l}_{\Delta s_l} \\
&+ \underbrace{\sum_{i \in I^C} \alpha_i}_{s_c} + \underbrace{\sum_{i \in I^{C_u}} \alpha_i}_{\Delta s_{c_u}} + \underbrace{\sum_{i \in I^{C_l}} \alpha_i}_{\Delta s_{c_l}} + \sum_{i \in I^I} \alpha_i - |C \cup I^{C_u} \cup I^{C_l} \cup I^I|\hat{\theta}.
\end{aligned}$$

By leveraging on the structure of h, the refined bisection method for (18) can be described as Algorithm 5.

Algorithm 5 Refined Bisection Algorithm for (18)

INPUT: $\bar{\boldsymbol{\alpha}}$, r, $\boldsymbol{l}$, $\boldsymbol{u}$, $\epsilon' > 0$ OUTPUT: $\boldsymbol{\alpha}$

INITIALIZE: $I \leftarrow M$, $s_u \leftarrow s_l \leftarrow s_c \leftarrow 0$, $\theta^u \leftarrow \bar{\alpha}_{\max} - \frac{r}{m}$, $\theta^l \leftarrow \bar{\alpha}_{\min} - \frac{r}{m}$ # Step 1

while $|\theta^u - \theta^l| > \epsilon'$ **do**

$\hat{\theta} \leftarrow \frac{\theta^u + \theta^l}{2}$ # Step 2

$\hat{u} \leftarrow u + \hat{\theta}, \quad \hat{l} \leftarrow l + \hat{\theta}$

$I^U \leftarrow \{i \in I \mid \bar{\alpha}_i \geq \hat{u}\}, \quad I^L \leftarrow \{i \in I \mid \bar{\alpha}_i \leq \hat{l}\}$ # Step 3

$u^u \leftarrow u + \theta^u, \quad l^l \leftarrow l + \theta^l$

$I^{C_u} \leftarrow \{i \in I \mid \bar{\alpha}_i > l^l,\ \bar{\alpha}_i < \hat{u}\}, \quad I^{C_l} \leftarrow \{i \in I \mid \bar{\alpha}_i < u^u,\ \bar{\alpha}_i > \hat{l}\}$

$I^I \leftarrow I \backslash (I^U \cup I^{C_u} \cup I^{C_l} \cup I^L)$

$\Delta s_u \leftarrow |I^U| u, \quad \Delta s_l \leftarrow |I^L| l$

$\Delta s_{c_u} \leftarrow \sum_{i \in I^{C_u}} \alpha_i, \quad \Delta s_{c_l} \leftarrow \sum_{i \in I^{C_l}} \alpha_i$

$val \leftarrow s_u + \Delta s_u + s_l + \Delta s_l + s_c + \Delta s_{c_u} + \Delta s_{c_l} + \sum_{i \in I^I} \alpha_i - |C \cup I^{C_u} \cup I^{C_l} \cup I^I| \hat{\theta}$

if $val < r$ **then** # Step 4

$\theta^u \leftarrow \hat{\theta}, \quad I \leftarrow I^I \cup I^{C_l} \cup I^L$

$s_u \leftarrow s_u + \Delta s_u, \quad s_c \leftarrow s_c + \Delta s_{c_u}$

else if $val > r$ **then**

$\theta^l \leftarrow \hat{\theta}, \quad I \leftarrow I^I \cup I^{C_u} \cup I^U$

$s_l \leftarrow s_l + \Delta s_l, \quad s_c \leftarrow s_c + \Delta s_{c_l}$

else

break

end if

if $I == \phi$ **then**

$\hat{\theta} \leftarrow (s_u + s_l + s_c - r)/|C|$

break

end if

end while

$\alpha_i \leftarrow \alpha_i(\hat{\theta}),\ \forall i \in M$ # Step 5

Appendix C. Proof of Theorem 7

We show the iteration complexity $O\big((W(k)/k)^2\big)$ of Algorithm 3, where $W(z)$ is the inverse function of $f(x) = x\exp(x)$ and called Lambert's W function (Corless et al., 1996). $W(z)$ is single-valued for $z \geq 0$, but multi-valued for $z < 0$. For $z \geq 0$, $W(z)$ is monotonically increasing, but diverges slower than $\log(z)$. It is known that $W(z)$ cannot be expressed in terms of elementary functions.

Here we improve the lower bound (24) of

$$\max\{\bar{k}_1, \bar{k}_2, \ldots, \bar{k}_j, k_{j+1}\}.$$

Since $\bar{k}_i \geq K_i \geq 2^i$ for all $i \in \{1, 2, \ldots, j\}$, we have

$$\max\{\bar{k}_1, \bar{k}_2, \ldots, \bar{k}_j, k_{j+1}\} \geq \max\Big\{\frac{k}{j+1}, 2^j\Big\}.$$

$\frac{k}{j+1}$ is monotonically decreasing and 2^j is monotonically increasing with respect to j. Thus the right-hand side is minimized at $j = \hat{j}$ such that

$$\frac{k}{\hat{j}+1} = 2^{\hat{j}}.$$

The above equation implies that

$$\begin{aligned}
&\frac{2k}{\hat{j}+1} = \exp\big((\hat{j}+1)\ln 2\big) \\
&\Rightarrow 2k\ln 2 = (\hat{j}+1)\ln 2 \exp\big((\hat{j}+1)\ln 2\big) \\
&\Rightarrow W(2k\ln 2) = (\hat{j}+1)\ln 2 \\
&\Rightarrow \hat{j} = \frac{W(2k\ln 2)}{\ln 2} - 1,
\end{aligned}$$

which yields

$$\max\Big\{\frac{k}{j+1}, 2^j\Big\} \geq \frac{k\ln 2}{W(2k\ln 2)}.$$

This leads to

$$F(\boldsymbol{\alpha}^{(j,k_{j+1})}) - F(\boldsymbol{\alpha}^*) \leq 2\eta_u L_f R^2 \Big(\frac{W(2k\ln 2)}{k\ln 2 - W(2k\ln 2)}\Big)^2, \quad \forall k \geq 3.$$

Appendix D. Application of FAPG to ℓ_1-regularized models

The ℓ_1-regularized logistic regression:

$$\min_{\boldsymbol{w}} C\sum_{i=1}^m \log(1 + \exp(-y_i \boldsymbol{w}^\top \boldsymbol{x}_i)) + \|\boldsymbol{w}\|_1 \tag{27}$$

and the ℓ_1-regularized ℓ_2-loss SVM:

$$\min_{\boldsymbol{w}} C\sum_{i=1}^m \big(\max\{0, 1 - y_i \boldsymbol{w}^\top \boldsymbol{x}_i\}\big)^2 + \|\boldsymbol{w}\|_1 \tag{28}$$

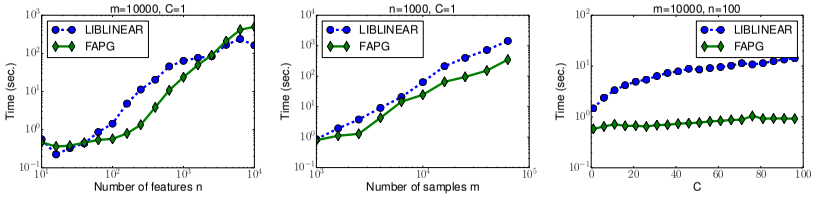

Figure 11: Computation Time for ℓ_1-regularized Logistic Regression (27).

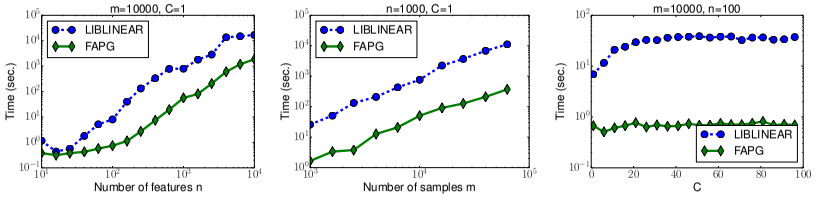

Figure 12: Computation Time for ℓ_1-regularized ℓ_2-loss SVM (28).

have the form of (2), where $C > 0$ is a hyperparameter. Letting $g(\cdot) = \|\cdot\|_1$, we have $\left(\mathrm{prox}_{g,L}(\boldsymbol{w})\right)_i = \mathrm{sign}(w_i)\max\{0, |w_i| - L\}$ $(i = 1, 2, \ldots, m)$ which is known as the soft-thresholding operator.

We applied the practical FAPG (Algorithm 4) and LIBLINEAR (Fan et al., 2008) to (27) and (28) using the artificial datasets which is generated as described in Section 5. We set the initial point $\boldsymbol{w}^0$ to the origin $\mathbf{0}$ and the tolerance ϵ to 10^{-6}. For all datasets, FAPG found solutions with better objective value than LIBLINEAR does. Figures 11 and 12 show the computation time of FAPG and LIBLINEAR. FAPG was highly competitive to and numerically more stable than LIBLINEAR with respect to the changes of the hyperparameter C.

Abstract

`imbalanced-learn` is an open-source python toolbox aiming at providing a wide range of methods to cope with the problem of imbalanced dataset frequently encountered in machine learning and pattern recognition. The implemented state-of-the-art methods can be categorized into 4 groups: (i) under-sampling, (ii) over-sampling, (iii) combination of over- and under-sampling, and (iv) ensemble learning methods. The proposed toolbox depends only on `numpy`, `scipy`, and `scikit-learn` and is distributed under MIT license. Furthermore, it is fully compatible with `scikit-learn` and is part of the `scikit-learn-contrib` supported project. Documentation, unit tests as well as integration tests are provided to ease usage and contribution. Source code, binaries, and documentation can be downloaded from `https://github.com/scikit-learn-contrib/imbalanced-learn`.

Keywords: Imbalanced Dataset, Over-Sampling, Under-Sampling, Ensemble Learning, Machine Learning, Python.

1. Introduction

Real world datasets commonly show the particularity to have a number of samples of a given class under-represented compared to other classes. This imbalance gives rise to the "class imbalance" problem (Prati et al., 2009) (or "curse of imbalanced datasets") which is the problem of learning a concept from the class that has a small number of samples.

The class imbalance problem has been encountered in multiple areas such as telecommunication managements, bioinformatics, fraud detection, and medical diagnosis, and has been considered one of the top 10 problems in data mining and pattern recognition (Yang and Wu, 2006; Rastgoo et al., 2016). Imbalanced data substantially compromises the learning process, since most of the standard machine learning algorithms expect balanced class distribution or an equal misclassification cost (He and Garcia, 2009). For this reason, several approaches have been specifically proposed to handle such datasets. Some of these methods have been implemented mainly in R language (Torgo, 2010; Kuhn, 2015; Dal Pozzolo et al., 2013). Up to our knowledge, there is no python toolbox allowing such processing while cutting edge machine learning toolboxes are available (Pedregosa et al., 2011; Sonnenburg et al., 2010).

In this paper, we present the `imbalanced-learn` API, *a python toolbox to tackle the curse of imbalanced datasets in machine learning*. The following sections present the project vision, a snapshot of the API, an overview of the implemented methods, and finally, we conclude this work by including future functionalities for the `imbalanced-learn` API.

2. Project management

Quality assurance In order to ensure code quality, a set of unit tests is provided leading to a coverage of 99 % for the release 0.2 of the toolbox. Furthermore, the code consistency is ensured by following `PEP8` standards and each new contribution is automatically checked through landscape, which provides metrics related to code quality.
Continuous integration To allow both the user and the developer to either use or contribute to this toolbox, Travis CI is used to easily integrate new code and ensure back-compatibility.
Community-based development All the development is performed in a collaborative manner. Tools such as git, GitHub, and gitter are used to ease collaborative programming, issue tracking, code integration, and idea discussions.
Documentation A consistent API documentation is provided using `sphinx` and `numpydoc`. An additional installation guide and examples are also provided and centralized on GitHub[1].
Project relevance At the edition time, the repository is visited no less than 2,000 times per week, attracting about 300 unique visitors per week. Additionally, the toolbox is supported by `scikit-learn` through the `scikit-learn-contrib` projects.

3. Implementation design

```python
from sklearn.datasets import make_classification
from sklearn.decomposition import PCA
from imblearn.over_sampling import SMOTE

# Generate the dataset
X, y = make_classification(n_classes=2, weights=[0.1, 0.9],
                           n_features=20, n_samples=5000)

# Apply the SMOTE over-sampling
sm = SMOTE(ratio='auto', kind='regular')
X_resampled, y_resampled = sm.fit_sample(X, y)
```

Listing 1: Code snippet to over-sample a dataset using SMOTE.

The implementation relies on `numpy`, `scipy`, and `scikit-learn`. Each sampler class implements three main methods inspired from the `scikit-learn` API: (i) `fit` computes several statistics which are later needed to resample the data into a balanced set; (ii)

`sample` performs the sampling and returns the data with the desired balancing ratio; and (iii) `fit_sample` is equivalent to calling the method `fit` followed by the method `sample`. A class `Pipeline` is inherited from the `scikit-learn` toolbox to automatically combine `samplers`, `transformers`, and `estimators`. Additionally, we provide some specific state-of-the-art metrics to evaluate classification performance.

4. Implemented methods

The `imbalanced-learn` toolbox provides four different strategies to tackle the problem of imbalanced dataset: (i) under-sampling, (ii) over-sampling, (iii) a combination of both, and (iv) ensemble learning. The following subsections give an overview of the techniques implemented.

4.1 Notation and background

Let χ be an imbalanced dataset with χ_{min} and χ_{maj} being the subset of samples belonging to the minority and majority class, respectively. The balancing ratio of the dataset χ is defined as:

$$r_\chi = \frac{|\chi_{min}|}{|\chi_{maj}|} \ , \tag{1}$$

where $|\cdot|$ denotes the cardinality of a set. The balancing process is equivalent to resample χ into a new dataset χ_{res} such that $r_\chi > r_{\chi_{res}}$.

Under-sampling Under-sampling refers to the process of reducing the number of samples in χ_{maj}. The implemented methods can be categorized into 2 groups: (i) fixed under-sampling and (ii) cleaning under-sampling. *Fixed under-sampling* refer to the methods which perform under-sampling to obtain the appropriate balancing ratio $r_{\chi_{res}}$. Contrary to the previous methods, *cleaning under-sampling* do not allow to reach specifically the balancing ratio $r_{\chi_{res}}$, but rather clean the feature space based on some empirical criteria.

Over-sampling Contrary to under-sampling, data balancing can be performed by over-sampling such that new samples are generated in χ_{min} to reach the balancing ratio $r_{\chi_{res}}$.

Combination of over- and under-sampling Over-sampling can lead to over-fitting which can be avoided by applying cleaning under-sampling methods (Prati et al., 2009).

Ensemble learning Under-sampling methods imply that samples of the majority class are lost during the balancing procedure. Ensemble methods offer an alternative to use most of the samples. In fact, an ensemble of balanced sets is created and used to later train any classifier.

5. Future plans and conclusion

In this paper, we shortly presented the foundations of the `imbalanced-learn` toolbox vision and API. As avenues for future works, additional methods based on prototype/instance selection, generation, and reduction will be added as well as additional user guides.

Abstract

We present a canonical way to turn any smooth parametric family of probability distributions on an arbitrary search space X into a continuous-time black-box optimization method on X, the *information-geometric optimization* (IGO) method. Invariance as a major design principle keeps the number of arbitrary choices to a minimum. The resulting *IGO flow* is the flow of an ordinary differential equation conducting the natural gradient ascent of an adaptive, time-dependent transformation of the objective function. It makes no particular assumptions on the objective function to be optimized.

The IGO method produces explicit IGO algorithms through time discretization. It naturally recovers versions of known algorithms and offers a systematic way to derive new ones. In continuous search spaces, IGO algorithms take a form related to natural evolution strategies (NES). The cross-entropy method is recovered in a particular case with a large time step, and can be extended into a smoothed, parametrization-independent maximum likelihood update (IGO-ML). When applied to the family of Gaussian distributions on $\mathbb{R}^d$, the IGO framework recovers a version of the well-known CMA-ES algorithm and of xNES. For the family of Bernoulli distributions on $\{0,1\}^d$, we recover the seminal PBIL algorithm and cGA. For the distributions of restricted Boltzmann machines, we naturally obtain a novel algorithm for discrete optimization on $\{0,1\}^d$. All these algorithms are natural instances of, and unified under, the single information-geometric optimization framework.

The IGO method achieves, thanks to its intrinsic formulation, maximal invariance properties: invariance under reparametrization of the search space X, under a change of parameters of the probability distribution, and under increasing transformation of the function to be optimized. The latter is achieved through an adaptive, quantile-based formulation of the objective.

Theoretical considerations strongly suggest that IGO algorithms are essentially characterized by a minimal change of the distribution over time. Therefore they have minimal loss in diversity through the course of optimization, provided the initial diversity is high. First experiments using restricted Boltzmann machines confirm this insight. As a simple consequence, IGO seems to provide, from information theory, an elegant way to simultaneously explore several valleys of a fitness landscape in a single run.

1. Introduction

Optimization problems are at the core of many disciplines. Given an objective function $f : X \to \mathbb{R}$, to be optimized on some space X, the goal of black-box optimization is to find solutions $x \in X$ with small (in the case of minimization) value $f(x)$, using the least number of calls to the function f. In a *black-box* scenario, knowledge about the function f is restricted to the handling of a device (e.g., a simulation code) that delivers the value $f(x)$ for any input $x \in X$. The search space X may be finite, discrete infinite, or continuous. However, optimization algorithms are often designed for a specific type of search space, exploiting its specific structure.

One major design principle in general and in optimization in particular is related to *invariance*. Invariance extends performance observed on a single function to an entire associated invariance class, that is, it generalizes from a single problem to a class of problems. Thus it hopefully provides better robustness w.r.t. changes in the presentation of a problem. For continuous search spaces, invariance under translation of the coordinate system is standard in optimization. Invariance under general affine-linear changes of the coordinates has been—we believe—one of the keys to the success of the Nelder-Mead *Downhill Simplex method* (Nelder and Mead, 1965), of quasi-Newton methods (Deuflhard, 2011) and of the *covariance matrix adaptation evolution strategy*, CMA-ES (Hansen and Ostermeier, 2001; Hansen and Auger, 2014). While these relate to transformations in the search space, another important invariance concerns the application of monotonically increasing transformations to f, so that it is indifferent whether the function f, f^3 or $f \times |f|^{-2/3}$ is minimized. This way some non-convex or non-smooth functions can be as "easily" optimised as convex ones. Invariance under f-transformation is not uncommon, e.g., for evolution strategies (Schwefel, 1995) or pattern search methods (Hooke and Jeeves, 1961; Torczon, 1997; Nelder and Mead, 1965); however it has not always been recognized as an attractive feature.

Many stochastic optimization methods have been proposed to tackle black-box optimization. The underlying (often hidden) principle of these stochastic methods is to iteratively update a probability distribution P_θ defined on X, parametrized by a set of parameters θ. At a given iteration, the distribution P_θ represents, loosely speaking, the current belief about where solutions with the smallest values of the function f may lie. Over time, P_θ is expected to concentrate around the minima of f. The update of the distribution involves querying the function with points sampled from the current probability distribution P_θ. Although implicit in the presentation of many stochastic optimization algorithms, this is the explicit setting for the wide family of *estimation of distribution algorithms* (EDA) (Larranaga and Lozano, 2002; Baluja and Caruana, 1995; Pelikan et al., 2002). Updates of the probability distribution often rely on heuristics (nevertheless in Toussaint 2004 the possible interest of information geometry to exploit the structure of probability distributions for designing better grounded heuristics is pointed out). In addition, in the EDA setting we can distinguish two theoretically founded approaches to update P_θ.

First, the *cross-entropy* method consists in taking θ minimizing the Kullback–Leibler divergence between P_θ and the indicator of the best points according to f (de Boer et al., 2005).

Second, one can transfer the objective function f to the space of parameters θ by taking the average of f under P_θ, seen as a function of θ. This average is a new function from an Euclidian space to $\mathbb{R}$ and is minimal when P_θ is concentrated on minima of f. Consequently, θ can be updated by following a gradient descent of this function with respect to θ. This has been done in various situations such as $X = \{0,1\}^d$ and the family of Bernoulli measures (Berny, 2000a) or of Boltzmann machines (Berny, 2002), or on $X = \mathbb{R}^d$ for the family of Gaussian distributions (Berny, 2000b; Gallagher and Frean, 2005) or the exponential family also using second order information (Zhou and Hu, 2014; E. Zhou, 2016).

However, taking the ordinary gradient with respect to θ depends on the precise way a parameter θ is chosen to represent the distribution P_θ, and does not take advantage of the Riemannian metric structure of families of probability distributions. In the context of machine learning, Amari noted the shortcomings of the ordinary gradient for families of probability distributions (Amari, 1998) and proposed instead to use the natural gradient with respect to the Fisher metric (Rao, 1945; Jeffreys, 1946; Amari and Nagaoka, 2000). In the context of optimization, this natural gradient has been used for exponential families on $X = \{0,1\}^d$ (Malagò et al., 2008, 2011) and for the family of Gaussian distributions on $X = \mathbb{R}^d$ with so-called natural evolution strategies (NES, Wierstra et al. 2008; Sun et al. 2009; Glasmachers et al. 2010; Wierstra et al. 2014).

However, none of the previous attempts using gradient updates captures the invariance under increasing transformations of the objective function, which is instead, in some cases, enforced *a posteriori* with heuristic arguments.

Building on these ideas, this paper overcomes the invariance problem of previous attempts and provides a consistent, unified picture of optimization on arbitrary search spaces via invariance principles. More specifically, we consider an arbitrary search space X, either discrete or continuous, and a black-box optimization problem on X, that is, a function $f : X \to \mathbb{R}$ to be minimized. We assume that a family of probability distributions P_θ on X depending on a continuous multicomponent parameter $\theta \in \Theta$ has been chosen. A classical example is to take $X = \mathbb{R}^d$ and to consider the family of all Gaussian distributions P_θ on $\mathbb{R}^d$, with $\theta = (m, C)$ the mean and covariance matrix. Another simple example is $X = \{0,1\}^d$ equipped with the family of Bernoulli measures: $\theta = (\theta_i)_{1 \leqslant i \leqslant d}$ and $P_\theta(x) = \prod \theta_i^{x_i}(1-\theta_i)^{1-x_i}$ for $x = (x_i) \in X$.

From this setting, *information-geometric optimization* (IGO) can be defined in a natural way. At each (continuous) time t, we maintain a value θ^t of the parameter of the distribution. The function f to be optimized is transferred to the parameter space Θ by means of a suitable time-dependent transformation based on the P_{θ^t}*-levels* of f (Definition 3). The *IGO flow*, introduced in Definition 4, follows the natural gradient of the expected value of this function of θ^t in the parameter space Θ, where the natural gradient derives from the Fisher information metric. The IGO flow is thus the flow of an ordinary differential equation in space Θ. This continuous-time gradient flow is turned into a family of explicit *IGO algorithms* by taking an Euler time discretization of the differential equation and approximating the distribution P_{θ^t} by using samples. From the start, the IGO flow is invariant under strictly increasing transformations of f (Proposition 17); we also prove that the sampling procedure

is consistent (Theorem 6). IGO algorithms share their final algebraic form with the *natural evolution strategies* (NES) introduced in the Gaussian setting (Wierstra et al., 2008; Sun et al., 2009; Glasmachers et al., 2010; Wierstra et al., 2014); the latter are thus recovered in the IGO framework as an Euler approximation to a well-defined flow, without heuristic arguments.

The IGO method also has an equivalent description as an *infinitesimal maximum likelihood update* (Theorem 10); this reveals a new property of the natural gradient and does not require a smooth parametrization by θ anymore. This also establishes a specific link (Theorem 12) between IGO, the natural gradient, and the *cross-entropy method* (de Boer et al., 2005).

When we instantiate IGO using the family of Gaussian distributions on $\mathbb{R}^d$, we naturally obtain versions of the well-known *covariance matrix adaptation evolution strategy* (CMA-ES, Hansen and Ostermeier 2001; Hansen and Kern 2004; Jastrebski and Arnold 2006) and of *natural evolution strategies*. With Bernoulli measures on the discrete cube $\{0,1\}^d$, we recover (Proposition 14) the well-known *population-based incremental learning* (PBIL, Baluja and Caruana 1995; Baluja 1994) and the *compact genetic algorithm* (cGA, Harik et al. 1999); this derivation of PBIL or cGA as a natural gradient ascent appears to be new, and emphasizes the common ground between continuous and discrete optimization.

From the IGO framework, it is (theoretically) immediate to build new optimization algorithms using more complex families of distributions than Gaussian or Bernoulli. As an illustration, distributions associated with restricted Boltzmann machines (RBMs) provide a new but natural algorithm for discrete optimization on $\{0,1\}^d$ which is able to handle dependencies between the bits (see also Berny 2002). The probability distributions associated with RBMs are multimodal; combined with the specific information-theoretic properties of IGO that guarantee minimal change in diversity over time, this allows IGO to reach multiple optima at once in a natural way, at least in a simple experimental setup (Appendix B).

The IGO framework is built to achieve maximal *invariance properties*. First, the IGO flow is invariant under reparametrization of the family of distributions P_θ, that is, it only depends on P_θ and not on the way we write the parameter θ (Proposition 18). This invariance under θ-reparametrization is the main idea behind *information geometry* (Amari and Nagaoka, 2000). For instance, for Gaussian measures it should not matter whether we use the covariance matrix or its inverse or a Cholesky factor as the parameter. This limits the influence of encoding choices on the behavior of the algorithm. Second, the IGO flow is invariant under a change of coordinates in the search space X, provided that this change of coordinates globally preserves the family of distributions P_θ (Proposition 19). For instance, for Gaussian distributions on $\mathbb{R}^d$, this includes all affine changes of coordinates. This means that the algorithm, apart from initialization, does not depend on the precise way the data is presented. Last, the IGO flow and IGO algorithms are invariant under applying a strictly increasing function to f (Proposition 17). Contrary to previous formulations using natural gradients (Wierstra et al., 2008; Glasmachers et al., 2010; Akimoto et al., 2010), this invariance is achieved from the start. Such invariance properties mean that we deal with *intrinsic* properties of the objects themselves, and not with the way we encode them as collections of numbers in $\mathbb{R}^d$. It also means, most importantly, that we make a minimal number of arbitrary choices.

In Section 2, we define the IGO flow and the IGO algorithm. We begin with standard facts about the definition and basic properties of the natural gradient, and its connection with Kullback–Leibler divergence and diversity. We then proceed to the detailed description of the algorithm.

In Section 3, we state some first mathematical properties of IGO. These include monotone improvement of the objective function, invariance properties, and the form of IGO for exponential families of probability distributions.

In Section 4 we explain the theoretical relationships between IGO, maximum likelihood estimates and the cross-entropy method. In particular, IGO is uniquely characterized by a weighted log-likelihood maximization property (Theorem 10).

In Section 5, we apply the IGO framework to explicit families of probability distributions. Several well-known optimization algorithms are recovered this way. These include PBIL (Sec. 5.1) using Bernoulli distributions, and versions of CMA-ES and other evolutionary algorithms such as EMNA and xNES (Sec. 5.2) using Gaussian distributions.

Appendix A discusses further aspects, perspectives and implementation matters of the IGO framework. In Appendix B, we illustrate how IGO can be used to design new optimization algorithms, by deriving the IGO algorithm associated with restricted Boltzmann machines. We illustrate experimentally, on a simple bimodal example, the specific influence of the Fisher information matrix on the optimization trajectories, and in particular on the diversity of the optima obtained. Appendix C details a number of further mathematical properties of IGO (such as its invariance properties or the case of noisy objective functions). Appendix D contains the previously omitted proofs of the mathematical statements.

2. Algorithm Description

We now present the outline of the algorithm. Each step is described in more detail in the sections below.

The IGO flow can be seen as an *estimation of distribution algorithm*: at each time t, we maintain a probability distribution P_{θ^t} on the search space X, where $\theta^t \in \Theta$. The value of θ^t will evolve so that, over time, P_{θ^t} gives more weight to points x with better values of the function $f(x)$ to optimize.

A straightforward way to proceed is to transfer f from x-space to θ-space: define a function $F(\theta)$ as the P_θ-average of f and then do a gradient descent for $F(\theta)$ in space Θ (Berny, 2000a, 2002, 2000b; Gallagher and Frean, 2005). This way, θ will converge to a point such that P_θ yields a good average value of f. We depart from this approach in two ways:

- At each time, we replace f with an adaptive transformation of f representing how good or bad observed values of f are *relative to other observations*. This provides invariance under all monotone transformations of f.

- Instead of the vanilla gradient for θ, we use the so-called *natural gradient* given by the Fisher information matrix. This reflects the intrinsic geometry of the space of probability distributions, as introduced by Rao and Jeffreys (Rao, 1945; Jeffreys, 1946) and later elaborated upon by Amari and others (Amari and Nagaoka, 2000). This provides invariance under reparametrization of θ and, importantly, minimizes the change of diversity of P_θ.

The algorithm is constructed in two steps: we first give an "ideal" version, namely, a version in which time t is continuous so that the evolution of θ^t is given by an ordinary differential equation in Θ. Second, the actual algorithm is a time discretization using a finite time step and Monte Carlo sampling instead of exact P_θ-averages.

2.1 The Natural Gradient on Parameter Space

We recall suitable definitions of the vanilla and the natural gradient and motivate using the natural gradient in the context of optimization.

2.1.1 About Gradients and the Shortest Path Uphill

Let g be a smooth function from $\mathbb{R}^d$ to $\mathbb{R}$, to be maximized. We first recall the interpretation of gradient ascent as "the shortest path uphill".

Let $y \in \mathbb{R}^d$. Define the vector z by

$$z = \lim_{\varepsilon \to 0} \arg\max_{z,\, \|z\| \leqslant 1} g(y + \varepsilon z) \ . \tag{1}$$

Then one can check that z is the normalized gradient of g at y: $z_i = \frac{\partial g/\partial y_i}{\|\partial g/\partial y\|}$. (This holds only at points y where the gradient of g does not vanish.)

This shows that, for small δt, the well-known gradient ascent of g given by

$$y_i^{t+\delta t} = y_i^t + \delta t \, \frac{\partial g}{\partial y_i}$$

realizes the largest increase of the value of g, for a given step size $\|y^{t+\delta t} - y^t\|$.

The relation (1) depends on the choice of a norm $\|\cdot\|$ (the gradient of g is given by $\partial g/\partial y_i$ only in an orthonormal basis). If we use, instead of the standard metric $\|y - y'\| = \sqrt{\sum (y_i - y'_i)^2}$ on $\mathbb{R}^d$, a metric $\|y - y'\|_A = \sqrt{\sum A_{ij}(y_i - y'_i)(y_j - y'_j)}$ defined by a positive definite matrix A_{ij}, then the gradient of g with respect to this metric is given by $\sum_j A^{-1}_{ij} \frac{\partial g}{\partial y_i}$. This follows from the textbook definition of gradients by $g(y+\varepsilon z) = g(y) + \varepsilon \langle \nabla g, z \rangle_A + O(\varepsilon^2)$ with $\langle \cdot, \cdot \rangle_A$ the scalar product associated with the matrix A_{ij} (Schwartz, 1992).

It is possible to write the analogue of (1) using the A-norm. We then find that the gradient ascent associated with metric A is given by

$$y^{t+\delta t} = y^t + \delta t \, A^{-1} \, \frac{\partial g}{\partial y}$$

for small δt and maximizes the increment of g for a given A-distance $\|y^{t+\delta t} - y^t\|_A$—it realizes the steepest A-ascent. Maybe this viewpoint clarifies the relationship between gradient and metric: this steepest ascent property can actually be used as a definition of gradients.

In our setting we want to use a gradient ascent in the parameter space Θ of our distributions P_θ. The "vanilla" gradient $\frac{\partial}{\partial \theta_i}$ is associated with the metric $\|\theta - \theta'\| = \sqrt{\sum (\theta_i - \theta'_i)^2}$ and clearly depends on the choice of parametrization θ. Thus this metric, and the direction pointed by this gradient, are not intrinsic, in the sense that they do not depend only on the *distribution* P_θ. A metric depending on θ only through the distributions P_θ can be defined as follows.

2.1.2 Fisher Information and the Natural Gradient on Parameter Space

Let $\theta, \theta' \in \Theta$ be two values of the distribution parameter. A widely used way to define a "distance" between two generic distributions[1] P_θ and $P_{\theta'}$ is the *Kullback–Leibler divergence* from information theory, defined (Kullback, 1997) as

$$\mathrm{KL}(P_{\theta'} \,\|\, P_\theta) = \int_x \ln \frac{P_{\theta'}(\mathrm{d}x)}{P_\theta(\mathrm{d}x)}\, P_{\theta'}(\mathrm{d}x) \ .$$

When $\theta' = \theta + \delta\theta$ is close to θ, under mild smoothness assumptions we can expand the Kullback–Leibler divergence at second order in $\delta\theta$. This expansion defines the Fisher information matrix I at θ (Kullback, 1997):

$$\mathrm{KL}(P_{\theta+\delta\theta} \,\|\, P_\theta) = \frac{1}{2} \sum I_{ij}(\theta)\, \delta\theta_i \delta\theta_j + O(\delta\theta^3) \ . \tag{2}$$

An equivalent definition of the Fisher information matrix is by the usual formulas (Cover and Thomas, 2006)

$$I_{ij}(\theta) = \int_x \frac{\partial \ln P_\theta(x)}{\partial\theta_i} \frac{\partial \ln P_\theta(x)}{\partial\theta_j}\, P_\theta(\mathrm{d}x) = -\int_x \frac{\partial^2 \ln P_\theta(x)}{\partial\theta_i\, \partial\theta_j}\, P_\theta(\mathrm{d}x) \ .$$

The Fisher information matrix defines a (Riemannian) metric on Θ: the distance, in this metric, between two very close values of θ is given by the square root of twice the Kullback–Leibler divergence. Since the Kullback–Leibler divergence depends only on P_θ and not on the parametrization of θ, this metric is intrinsic.

If $g : \Theta \to \mathbb{R}$ is a smooth function on the parameter space, its *natural gradient* (Amari, 1998) at θ is defined in accordance with the Fisher metric as

$$(\widetilde{\nabla}_\theta\, g)_i = \sum_j I^{-1}_{ij}(\theta)\, \frac{\partial g(\theta)}{\partial\theta_j}$$

or more synthetically

$$\widetilde{\nabla}_\theta\, g = I^{-1}\, \frac{\partial g}{\partial\theta} \ .$$

From now on, we will use $\widetilde{\nabla}_\theta$ to denote the natural gradient and $\frac{\partial}{\partial\theta}$ to denote the vanilla gradient.

By construction, the natural gradient descent is intrinsic: it does not depend on the chosen parametrization θ of P_θ, so that it makes sense to speak of the natural gradient ascent of a function $g(P_\theta)$. The Fisher metric is essentially the only way to obtain this property (Amari and Nagaoka, 2000, Section 2.4).

Given that the Fisher metric comes from the Kullback–Leibler divergence, the "shortest path uphill" property of gradients mentioned above translates as follows (see also Amari 1998, Theorem 1):

1. Throughout the text we do not distinguish a probability distribution P, seen as a measure, and its density with respect to some unspecified reference measure $\mathrm{d}x$, and so will write indifferently $P(\mathrm{d}x)$ or $P(x)\mathrm{d}x$. The measure-theoretic viewpoint allows for a unified treatment of the discrete and continuous case.

Proposition 1 *The natural gradient ascent points in the direction $\delta\theta$ achieving the largest change of the objective function, for a given distance between P_θ and $P_{\theta+\delta\theta}$ in Kullback–Leibler divergence. More precisely, let g be a smooth function on the parameter space Θ. Let $\theta \in \Theta$ be a point where $\widetilde{\nabla} g(\theta)$ does not vanish. Then, if*

$$\delta\theta = \frac{\widetilde{\nabla} g(\theta)}{\|\widetilde{\nabla} g(\theta)\|}$$

is the direction of the natural gradient of g (with $\|\cdot\|$ the Fisher norm), we have

$$\delta\theta = \lim_{\varepsilon\to 0} \frac{1}{\varepsilon} \operatorname*{arg\,max}_{\substack{\delta\theta' \text{ such that} \\ \mathrm{KL}(P_{\theta+\delta\theta'} \,\|\, P_\theta) \leqslant \varepsilon^2/2}} g(\theta + \delta\theta').$$

Here we have implicitly assumed that the parameter space Θ is such that no two points $\theta \in \Theta$ define the same probability distribution, and the mapping $P_\theta \mapsto \theta$ is smooth.

2.1.3 Why Use the Fisher Metric Gradient for Optimization? Relationship to Diversity

The first reason for using the natural gradient is its reparametrization invariance, which makes it the only gradient available in a general abstract setting (Amari and Nagaoka, 2000). Practically, this invariance also limits the influence of encoding choices on the behavior of the algorithm (Appendix C.1). The Fisher matrix can be also seen as an *adaptive learning rate* for different components of the parameter vector θ_i: components i with a high impact on P_θ will be updated more cautiously.

Another advantage comes from the relationship with Kullback–Leibler distance in view of the "shortest path uphill" (see also Amari 1998). To minimize the value of some function $g(\theta)$ defined on the parameter space Θ, the naive approach follows a gradient descent for g using the "vanilla" gradient

$$\theta_i^{t+\delta t} = \theta_i^t + \delta t \tfrac{\partial g}{\partial\theta_i}$$

and, as explained above, this maximizes the increment of g for a given increment $\|\theta^{t+\delta t} - \theta^t\|$. On the other hand, the Fisher gradient

$$\theta_i^{t+\delta t} = \theta_i^t + \delta t I^{-1} \tfrac{\partial g}{\partial\theta_i}$$

maximizes the increment of g for a given Kullback–Leibler distance $\mathrm{KL}(P_{\theta^{t+\delta t}} \,\|\, P_{\theta^t})$.

In particular, if we choose an initial value θ^0 such that P_{θ^0} covers the whole space X uniformly (or a wide portion, in case X is unbounded), the Kullback–Leibler divergence between P_{θ^t} and P_{θ^0} is the Shannon entropy of the uniform distribution minus the Shannon entropy of P_{θ^t}, and so this divergence measures the loss of diversity of P_{θ^t} with respect to the uniform distribution.

Proposition 2 *Let $g : \Theta \to \mathbb{R}$ be a regular function of θ and let θ^0 such that P_{θ^0} is the uniform distribution on a finite space X. Let $(\theta^t)_{t\geqslant 0}$ be the trajectory of the gradient ascent of g using the natural gradient. Then for small t we have*

$$\theta^t = \arg\max_\theta \{t \cdot g(\theta) + \mathrm{Ent}(P_\theta)\} + o(t) \tag{3}$$

where Ent *is the Shannon entropy.*

(We have stated the proposition over a finite space to have a well-defined uniform distribution. A short proof, together with the regularity conditions on g, is given in Appendix D.)

So following the natural gradient of a function g, starting at or close to the uniform distribution, amounts to optimizing the function g with *minimal loss of diversity, provided the initial diversity is large.* (This is valid, of course, only at the beginning; once one gets too far from uniform, a better interpretation is minimal *change* of diversity.) On the other hand, the vanilla gradient descent does not satisfy Proposition 2: it optimizes g with minimal change in the numerical values of the parameter θ, which is of little interest.

So arguably this method realizes the best trade-off between optimization and loss of diversity. (Though, as can be seen from the detailed algorithm description below, maximization of diversity occurs only greedily at each step, and so there is no guarantee that after a given time, IGO will provide the highest possible diversity for a given objective function value.)

An experimental confirmation of the positive influence of the Fisher matrix on diversity is given in Appendix B below.

2.2 IGO: Information-Geometric Optimization

We now introduce a quantile-based rewriting of the objective function. From applying the natural gradient on the rewritten objective we derive *information-geometric optimization*.

2.2.1 Quantile Rewriting of f

Our original problem is to minimize a function $f : X \to \mathbb{R}$. A simple way to turn f into a function on Θ is to use the expected value $-\mathbb{E}_{P_\theta} f$ (Berny, 2000a; Wierstra et al., 2008), but expected values can be unduly influenced by extreme values and using them can be rather unstable (Whitley, 1989); moreover $-\mathbb{E}_{P_\theta} f$ is not invariant under increasing transformation of f (this invariance implies we can only *compare* f-values, not sum them up).

Instead, we take an adaptive, quantile-based approach by first replacing the function f with a monotone rewriting $W^f_{\theta^t}$, depending on the current parameter value θ^t, and then following the gradient of $\mathbb{E}_{P_\theta} W^f_{\theta^t}$, seen as a function of θ. A due choice of $W^f_{\theta^t}$ allows to control the range of the resulting values and achieves the desired invariance. Because the rewriting $W^f_{\theta^t}$ depends on θ^t, it might be viewed as an *adaptive* f-transformation.

The monotone rewriting entails that if $f(x)$ is "small" then $W^f_\theta(x) \in \mathbb{R}$ is "large" and vice versa. The quantitative meaning of "small" or "large" depends on $\theta \in \Theta$. To obtain the value of $W^f_\theta(x)$ we compare $f(x)$ to the quantiles of f under the current distribution, as measured by the P_θ-level fraction in which the value of $f(x)$ lies.

Definition 3 *The lower and upper P_θ-f-levels of $x \in X$ are defined as*

$$\begin{aligned} q^<_\theta(x) &= \Pr_{x' \sim P_\theta}(f(x') < f(x)) \\ q^\leqslant_\theta(x) &= \Pr_{x' \sim P_\theta}(f(x') \leqslant f(x)) \ . \end{aligned} \tag{4}$$

Let $w : [0;1] \to \mathbb{R}$ be a non-increasing function, the selection scheme.

The transform $W^f_\theta(x)$ of an objective function $f : X \to \mathbb{R}$ is defined as a function of the P_θ-f-level of x as

$$W^f_\theta(x) = \begin{cases} w(q^\leqslant_\theta(x)) & \text{if } q^\leqslant_\theta(x) = q^<_\theta(x), \\ \frac{1}{q^\leqslant_\theta(x) - q^<_\theta(x)} \int_{q=q^<_\theta(x)}^{q=q^\leqslant_\theta(x)} w(q)\,\mathrm{d}q & \text{otherwise.} \end{cases} \tag{5}$$

The level functions $q : X \to [0,1]$ reflect the probability to sample a better value than $f(x)$. They are monotone in f (if $f(x_1) \leqslant f(x_2)$ then $q^<_\theta(x_1) \leqslant q^<_\theta(x_2)$, and likewise for $q^\leqslant$) and invariant under strictly increasing transformations of f.

A typical choice for w is $w(q) = \mathbb{1}_{q \leqslant q_0}$ for some fixed value q_0, the *selection quantile*. In what follows, we suppose that a selection scheme (weighting scheme) w has been chosen once and for all.

As desired, the definition of W^f_θ is invariant under a strictly increasing transformation of f. For instance, the P_θ-median of f gets remapped to $w(\frac{1}{2})$.

Note that $\mathbb{E}_{x \sim P_\theta} W^f_\theta(x)$ is always equal to $\int_0^1 w$, independently of f and θ: indeed, by definition, the P_θ inverse-quantile of a random point under P_θ is uniformly distributed in $[0;1]$. In the following, our objective will be to maximize the expected value of $W^f_{\theta^t}$ over θ, that is, to maximize

$$\mathbb{E}_{P_\theta} W^f_{\theta^t} = \int W^f_{\theta^t}(x)\, P_\theta(\mathrm{d}x) \tag{6}$$

over θ, where θ^t is fixed at a given step but will adapt over time.

Importantly, $W^f_\theta(x)$ can be estimated in practice: indeed, the P_θ-f-levels $\Pr_{x' \sim P_\theta}(f(x') < f(x))$ can be estimated by taking samples of P_θ and ordering the samples according to the value of f (see below). The estimate remains invariant under strictly increasing f-transformations.

2.2.2 The IGO Gradient Flow

At the most abstract level, IGO is a continuous-time gradient flow in the parameter space Θ, which we define now. In practice, discrete time steps (a.k.a. iterations) are used, and P_θ-integrals are approximated through sampling, as described in the next section.

Let θ^t be the current value of the parameter at time t, and let $\delta t \ll 1$. We define $\theta^{t+\delta t}$ in such a way as to increase the P_θ-weight of points where f is small, while not going too far from P_{θ^t} in Kullback–Leibler divergence. We use the adaptive weights $W^f_{\theta^t}$ as a way to measure which points have large or small values. In accordance with (6), this suggests taking the gradient ascent

$$\theta^{t+\delta t} = \theta^t + \delta t\, \widetilde{\nabla}_\theta \int W^f_{\theta^t}(x)\, P_\theta(\mathrm{d}x) \tag{7}$$

where the natural gradient is suggested by Proposition 1.

Note again that we use $W^f_{\theta^t}$ and not W^f_θ in the integral. So the gradient $\widetilde{\nabla}_\theta$ does not act on the adaptive objective $W^f_{\theta^t}$. If we used W^f_θ instead, we would face a paradox: right after a move, previously good points do not seem so good any more since the distribution has improved. More precisely, $\int W^f_\theta(x)\, P_\theta(\mathrm{d}x)$ is constant and always equal to the average weight $\int_0^1 w$, and so the gradient would always vanish.

Using the log-likelihood trick $\widetilde{\nabla} P_\theta = P_\theta \, \widetilde{\nabla} \ln P_\theta$ (assuming P_θ is smooth), we get an equivalent expression of the update above as an integral under the current distribution P_{θ^t}; this is important for practical implementation. This leads to the following definition.

Definition 4 (IGO flow) *The IGO flow is the set of continuous-time trajectories in space Θ, defined by the ordinary differential equation*

$$\frac{\mathrm{d}\theta^t}{\mathrm{d}t} = \widetilde{\nabla}_\theta \int W^f_{\theta^t}(x)\, P_\theta(x) \mathrm{d}x \tag{8}$$

$$= \int W^f_{\theta^t}(x)\, \frac{\widetilde{\nabla}_\theta P_\theta(x)}{P_{\theta^t}(x)} P_{\theta^t}(x) \mathrm{d}x$$

$$= \int W^f_{\theta^t}(x)\, \widetilde{\nabla}_\theta \ln P_\theta(x)\, P_{\theta^t}(\mathrm{d}x) \tag{9}$$

$$= I^{-1}(\theta^t) \int W^f_{\theta^t}(x)\, \frac{\partial \ln P_\theta(x)}{\partial \theta}\, P_{\theta^t}(\mathrm{d}x) \ . \tag{10}$$

where the gradients are taken at point $\theta = \theta^t$, and I is the Fisher information matrix.

Natural evolution strategies (NES, Wierstra et al. 2008; Glasmachers et al. 2010; Sun et al. 2009; Wierstra et al. 2014) feature a related gradient *descent* with $f(x)$ instead of $W^f_{\theta^t}(x)$. The associated flow would read

$$\frac{\mathrm{d}\theta^t}{\mathrm{d}t} = -\widetilde{\nabla}_\theta \int f(x)\, P_\theta(\mathrm{d}x) \ , \tag{11}$$

where the gradient is taken at θ^t (in the sequel when not explicitly stated, gradients in θ are taken at $\theta = \theta^t$). However, in the end NESs always implement algorithms using sample quantiles (via "nonlinear *fitness shaping*"), as if derived from the gradient ascent of $W^f_{\theta^t}(x)$.

The update (9) is a weighted average of "intrinsic moves" increasing the log-likelihood of some points. We can slightly rearrange the update as

$$\frac{\mathrm{d}\theta^t}{\mathrm{d}t} = \int \overbrace{W^f_{\theta^t}(x)}^{\text{preference weight}} \underbrace{\widetilde{\nabla}_\theta \ln P_\theta(x)}_{\text{intrinsic move to reinforce } x} \overbrace{P_{\theta^t}(\mathrm{d}x)}^{\text{current sample distribution}} \tag{12}$$

$$= \widetilde{\nabla}_\theta \int \underbrace{W^f_{\theta^t}(x) \ln P_\theta(x)}_{\text{weighted log-likelihood}} P_{\theta^t}(\mathrm{d}x) \ , \tag{13}$$

which provides an interpretation for the IGO gradient flow as a gradient ascent optimization of the weighted log-likelihood of the "good points" of the current distribution. In the sense of Theorem 10 below, IGO is in fact the "best" way to increase this log-likelihood.

For exponential families of probability distributions, we will see later that the IGO flow rewrites as a nice derivative-free expression (21).

2.2.3 IGO Algorithms: Time Discretization and Sampling

The above is a mathematically well-defined continuous-time flow in parameter space. Its practical implementation involves three approximations depending on two parameters N and δt:

- the integral under P_{θ^t} is approximated using N samples taken from P_{θ^t};
- the value $W^f_{\theta^t}$ is approximated for each sample taken from P_{θ^t};
- the time derivative $\frac{\mathrm{d}\theta^t}{\mathrm{d}t}$ is approximated by a δt time increment: instead of the continuous-time IGO flow (8) we use its Euler approximation scheme $\theta^{t+\delta t} \approx \theta^t + \delta t \frac{\mathrm{d}\theta^t}{\mathrm{d}t}$, so that the time t of the flow is discretized with a step size δt, which thus becomes the learning rate of the algorithm. (See Corollary 21 for an interpretation of δt as a number of bits of information introduced in the distribution P_{θ^t} at each step.)

We also assume that the Fisher information matrix $I(\theta)$ and $\frac{\partial \ln P_\theta(x)}{\partial \theta}$ can be computed (see discussion below if $I(\theta)$ is unknown).

At each step, we draw N samples $x_1, \dots, x_N$ under P_{θ^t}. To approximate $W^f_{\theta^t}$, we rank the samples according to the value of f. Define $\mathrm{rk}(x_i) = \#\{j \,|\, f(x_j) < f(x_i)\}$ and let the estimated weight of sample x_i be

$$\widehat{w}_i = \frac{1}{N}\, w\left(\frac{\mathrm{rk}(x_i) + 1/2}{N}\right), \tag{14}$$

using the non-increasing selection scheme function w introduced in Definition 3 above. (This is assuming there are no ties in our sample; in case several sample points have the same value of f, we define $\widehat{w}_i$ by averaging the above over all possible rankings of the ties[2].)

Then we can approximate the IGO flow as follows.

Definition 5 (IGO algorithms) *The* IGO algorithm *associated with parametrization θ, sample size N and step size δt is the following update rule for the parameter θ^t. At each step, N sample points $x_1, \dots, x_N$ are drawn according to the distribution P_{θ^t}. The parameter is updated according to*

$$\theta^{t+\delta t} = \theta^t + \delta t \sum_{i=1}^N \widehat{w}_i \ \widetilde{\nabla}_\theta \ln P_\theta(x_i)\Big|_{\theta=\theta^t} \tag{16}$$

$$= \theta^t + \delta t\, I^{-1}(\theta^t) \sum_{i=1}^N \widehat{w}_i \ \frac{\partial \ln P_\theta(x_i)}{\partial \theta}\Big|_{\theta=\theta^t} \tag{17}$$

where $\widehat{w}_i$ is the weight (14) *obtained from the ranked values of the objective function f.*

Equivalently one can fix the weights $w_i = \frac{1}{N}\, w\left(\frac{i-1/2}{N}\right)$ once and for all and rewrite the update as

$$\theta^{t+\delta t} = \theta^t + \delta t\, I^{-1}(\theta^t) \sum_{i=1}^N w_i \ \frac{\partial \ln P_\theta(x_{i:N})}{\partial \theta}\Big|_{\theta=\theta^t} \tag{18}$$

2. A mathematically neater but less intuitive version would be

$$\widehat{w}_i = \frac{1}{\mathrm{rk}^{\leqslant}(x_i) - \mathrm{rk}^{<}(x_i)} \int_{u=\mathrm{rk}^{<}(x_i)/N}^{u=\mathrm{rk}^{\leqslant}(x_i)/N} w(u)\mathrm{d}u \tag{15}$$

with $\mathrm{rk}^{<}(x_i) = \#\{j \,|\, f(x_j) < f(x_i)\}$ and $\mathrm{rk}^{\leqslant}(x_i) = \#\{j \,|\, f(x_j) \leqslant f(x_i)\}$.

where $x_{i:N}$ denotes the sampled point ranked i^{th} according to f, i.e. $f(x_{1:N}) < \ldots < f(x_{N:N})$ (assuming again there are no ties). Note that $\{x_{i:N}\} = \{x_i\}$ and $\{w_i\} = \{\widehat{w}_i\}$.

As will be discussed in Section 5, this update applied to multivariate normal distributions or Bernoulli measures allows us to neatly recover versions of some well-established algorithms, in particular CMA-ES and PBIL. Actually, in the Gaussian context updates of the form (17) have already been introduced (Glasmachers et al., 2010; Akimoto et al., 2010), though not formally derived from a continuous-time flow with inverse quantiles.

When $N \to \infty$, the IGO algorithm using samples approximates the continuous-time IGO gradient flow, see Theorem 6 below. Indeed, the IGO algorithm, with $N = \infty$, is simply the Euler approximation scheme for the ordinary differential equation defining the IGO flow (8). The latter result thus provides a sound mathematical basis for currently used rank-based updates.

2.2.4 IGO Flow versus IGO Algorithms

The IGO *flow* (8) is a well-defined continuous-time set of trajectories in the space of probability distributions P_θ, depending only on the objective function f and the chosen family of distributions. It does not depend on the chosen parametrization for θ (Proposition 18).

On the other hand, there are several IGO *algorithms* associated with this flow. Each IGO algorithm approximates the IGO flow in a slightly different way. An IGO algorithm depends on three further choices: a sample size N, a time discretization step size δt, and a choice of parametrization for θ in which to implement (17).

If δt is small enough, and N large enough, the influence of the parametrization θ disappears and all IGO algorithms are approximations of the "ideal" IGO flow trajectory. However, the larger δt, the poorer the approximation gets.

So for large δt, different IGO algorithms for the same IGO flow may exhibit different behaviors. We will see an instance of this phenomenon for Gaussian distributions: both CMA-ES and the maximum likelihood update (EMNA) can be seen as IGO algorithms, but the latter with $\delta t = 1$ is known to exhibit premature loss of diversity (Section 5.2).

Still, if δt is sufficiently small, two IGO algorithms for the same IGO flow will differ less from each other than from a non-IGO algorithm: at each step the difference is only $O(\delta t^2)$ (Appendix C.1). On the other hand, for instance, the difference between an IGO algorithm and the vanilla gradient ascent is, generally, not smaller than $O(\delta t)$ at each step, i.e., it can be roughly as big as the steps themselves.

2.2.5 Unknown Fisher Matrix

The algorithm presented so far assumes that the Fisher matrix $I(\theta)$ is known as a function of θ. This is the case for Gaussian or Bernoulli distributions. However, for restricted Boltzmann machines as considered below, no analytical form is known. Yet, provided the quantity $\frac{\partial}{\partial\theta} \ln P_\theta(x)$ can be computed or approximated, it is possible to approximate the integral

$$I_{ij}(\theta) = \int_x \frac{\partial \ln P_\theta(x)}{\partial \theta_i} \frac{\partial \ln P_\theta(x)}{\partial \theta_j} \, P_\theta(\mathrm{d}x)$$

using P_θ-Monte Carlo samples for x. These samples may or may not be the same as those used in the IGO update (17): in particular, it is possible to use as many Monte Carlo samples as necessary to approximate I_{ij}, at no additional cost in terms of the number of calls to the black-box function f to optimize.

Note that each Monte Carlo sample x will contribute $\frac{\partial \ln P_\theta(x)}{\partial \theta_i} \frac{\partial \ln P_\theta(x)}{\partial \theta_j}$ to the Fisher matrix approximation. This is a rank-1 non-negative matrix[3]. So, for the approximated Fisher matrix to be invertible, the number of (distinct) samples x needs to be at least equal to, and ideally much larger than, the number of components of the parameter θ: $N_{\text{Fisher}} \geqslant \dim \Theta$.

For exponential families of distributions, the IGO update has a particular form (21) which simplifies this matter somewhat (Section 3.3). In Appendix B this is examplified using restricted Boltzmann machines.

3. First Properties of IGO

In this section we derive some basic properties of IGO and present the IGO flow for exponential families.

3.1 Consistency of Sampling

The first property to check is that when $N \to \infty$, the update rule using N samples converges to the IGO update rule. This is *not* a straightforward application of the law of large numbers, because the estimated weights $\widehat{w}_i$ depend (non-continuously) on the *whole* sample $x_1, \ldots, x_N$, and not only on x_i.

Theorem 6 (Consistency) *When $N \to \infty$, the N-sample IGO update rule* (17)*:*

$$\theta^{t+\delta t} = \theta^t + \delta t \, I^{-1}(\theta^t) \sum_{i=1}^{N} \widehat{w}_i \left. \frac{\partial \ln P_\theta(x_i)}{\partial \theta} \right|_{\theta=\theta^t}$$

converges with probability 1 *to the update rule* (7)*:*

$$\theta^{t+\delta t} = \theta^t + \delta t \, \widetilde{\nabla}_\theta \int W_{\theta^t}^f(x) \, P_\theta(\mathrm{d}x) \ .$$

The proof is given in Appendix D, under mild regularity assumptions. In particular we do not require that w is continuous. Unfortunately, the proof does not provide an explicit sample size above which the IGO algorithm would be guaranteed to stay close to the IGO flow with high probability; presumably such a size would be larger than the typical sample sizes used in practice.

This theorem may clarify previous claims (Wierstra et al., 2008; Akimoto et al., 2010) where rank-based updates similar to (7), such as in NES or CMA-ES, were derived from optimizing the expected value $-\mathbb{E}_{P_\theta} f$. The rank-based weights $\widehat{w}_i$ were then introduced *after* the derivation as a useful heuristic to improve stability. Theorem 6 shows that, for large N, CMA-ES and NES actually follow the gradient flow of the quantity $\mathbb{E}_{P_\theta} W_{\theta^t}^f$: the update can be rigorously derived from optimizing the expected value of the inverse-quantile-rewriting $W_{\theta^t}^f$.

3. The alternative, equivalent formula $I_{ij}(\theta) = -\int_x \frac{\partial^2 \ln P_\theta(x)}{\partial \theta_i \, \partial \theta_j} \, P_\theta(\mathrm{d}x)$ for the Fisher matrix will not necessarily yield non-negative matrices through Monte Carlo sampling.

3.2 Monotonicity: Quantile Improvement

Gradient descents come with a guarantee that the fitness value decreases over time. Here, since we work with probability distributions on X, we need to define a "fitness" of the distribution P_{θ^t}. An obvious choice is the expectation $\mathbb{E}_{P_{\theta^t}} f$, but it is not invariant under f-transformation and moreover may be sensitive to extreme values.

It turns out that the monotonicity properties of the IGO gradient flow depend on the choice of the selection scheme w. For instance, if $w(u) = \mathbb{1}_{u \leqslant 1/2}$, then the median of f under P_{θ^t} improves over time.

Proposition 7 (Quantile improvement) *Consider the IGO flow* (8)*, with the weight* $w(u) = \mathbb{1}_{u \leqslant q}$ *where* $0 < q < 1$ *is fixed. Then the value of the* q*-quantile of* f *improves over time: if* $t_1 \leqslant t_2$ *then* $Q^q_{P_{\theta^{t_2}}}(f) \leqslant Q^q_{P_{\theta^{t_1}}}(f)$*. Here the* q*-quantile value* $Q^q_P(f)$ *of* f *under a probability distribution* P *is defined as the largest number* m *such that* $\Pr_{x\sim P}(f(x) \geqslant m) \geqslant 1 - q$*.*

Assume moreover that the objective function f *has no plateau, i.e. for any* $v \in \mathbb{R}$ *and any* $\theta \in \Theta$ *we have* $\Pr_{x\sim P_\theta}(f(x) = v) = 0$*. Then for* $t_1 < t_2$ *either* $\theta^{t_1} = \theta^{t_2}$ *or* $Q^q_{P_{\theta^{t_2}}}(f) < Q^q_{P_{\theta^{t_1}}}(f)$*.*

The proof is given in Appendix D, together with the necessary regularity assumptions. Note that on a discrete search space, the objective function has only plateaus, and the q-quantile will evolve by successive jumps even as θ evolves continuously.

This property is proved here only for the IGO gradient flow (8) with $N = \infty$ and $\delta t \to 0$. For an IGO algorithm with finite N, the dynamics is random and one cannot expect monotonicity. Still, Theorem 6 ensures that, with high probability, trajectories of a large enough finite population stay close to the infinite-population limit trajectory.

In Akimoto and Ollivier (2013) this result was extended to finite time steps instead of infinitesimal δt, using the IGO-ML framework from Section 4 below.

3.3 The IGO Flow for Exponential Families

The expressions for the IGO update simplify somewhat if the family P_θ happens to be an exponential family of probability distributions (see also Malagò et al. 2008, 2011 for optimization using the natural gradient for exponential families). This covers, for instance, Gaussian or Bernoulli distributions.

Suppose that P_θ can be written as

$$P_\theta(\mathrm{d}x) = \frac{1}{Z(\theta)} \exp\left(\sum \theta_i T_i(x)\right) H(\mathrm{d}x)$$

where $T_1, \dots, T_k$ is a finite family of functions on X, $H(\mathrm{d}x)$ is an arbitrary reference measure on X, and $Z(\theta)$ is the normalization constant. It is well-known (Amari and Nagaoka, 2000, (2.33)) that

$$\frac{\partial \ln P_\theta(x)}{\partial \theta_i} = T_i(x) - \mathbb{E}_{P_\theta} T_i \tag{19}$$

so that (Amari and Nagaoka, 2000, (3.59))

$$I_{ij}(\theta) = \mathrm{Cov}_{P_\theta}(T_i, T_j) \ . \tag{20}$$

By plugging this into the definition of the IGO flow (10) we find:

Proposition 8 *Let* P_θ *be an exponential family parametrized by the natural parameters* θ *as above. Then the IGO flow is given by*

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \mathrm{Cov}_{P_\theta}(T, T)^{-1} \, \mathrm{Cov}_{P_\theta}(T, W^f_\theta) \tag{21}$$

where $\mathrm{Cov}_{P_\theta}(T, W^f_\theta)$ *denotes the vector* $(\mathrm{Cov}_{P_\theta}(T_i, W^f_\theta))_i$*, and* $\mathrm{Cov}_{P_\theta}(T, T)$ *the matrix* $(\mathrm{Cov}_{P_\theta}(T_i, T_j))_{ij}$*.*

Note that the right-hand side does not involve derivatives w.r.t. θ any more. This result makes it easy to simulate the IGO flow using, e.g., a Gibbs sampler for P_θ: both covariances in (21) may be approximated by sampling, so that neither the Fisher matrix nor the gradient term need to be known in advance, and no derivatives are involved.

The values of the variables $\bar{T}_i = \mathbb{E}T_i$, namely the expected value of T_i under the current distribution, can often be used as an alternative parametrization for an exponential family (e.g. for a one-dimensional Gaussian, these are the mean μ and the second moment $\mu^2 + \sigma^2$). The IGO flow (9) may be rewritten using these variables, using the relation $\widetilde{\nabla}_{\theta_i} = \frac{\partial}{\partial \bar{T}_i}$ for the natural gradient of exponential families (Proposition 29 in Appendix D). One finds:

Proposition 9 *With the same setting as in Proposition 8, the expectation variables* $\bar{T}_i = \mathbb{E}_{P_\theta} T_i$ *satisfy the following evolution equation under the IGO flow*

$$\frac{\mathrm{d}\bar{T}_i}{\mathrm{d}t} = \mathrm{Cov}(T_i, W^f_\theta) = \mathbb{E}(T_i \, W^f_\theta) - \bar{T}_i \, \mathbb{E}W^f_\theta \ . \tag{22}$$

The proof is given in Appendix D, in the proof of Theorem 12. We shall further exploit this fact in Section 4.

3.3.1 Exponential Families with Latent Variables.

Similar formulas hold when the distribution $P_\theta(x)$ is the marginal of an exponential distribution $P_\theta(x, h)$ over a "hidden" or "latent" variable h, such as the restricted Boltzmann machines of Appendix B.

Namely, with $P_\theta(x) = \frac{1}{Z(\theta)} \sum_h \exp(\sum_i \theta_i T_i(x, h)) \, H(\mathrm{d}x, \mathrm{d}h)$ we have

$$\frac{\partial \ln P_\theta(x)}{\partial \theta_i} = U_i(x) - \mathbb{E}_{P_\theta} U_i \tag{23}$$

where

$$U_i(x) = \mathbb{E}_{P_\theta}(T_i(x, h)|x)$$

is the expectation of $T_i(x, h)$ knowing x. Then the Fisher matrix is

$$I_{ij}(\theta) = \mathrm{Cov}_{P_\theta}(U_i, U_j) \tag{24}$$

and consequently, the IGO flow takes the form

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \mathrm{Cov}_{P_\theta}(U, U)^{-1} \, \mathrm{Cov}_{P_\theta}(U, W^f_\theta) \ . \tag{25}$$

3.4 Further Mathematical Properties of IGO

IGO enjoys a number of other mathematical properties that are expanded upon in Appendix C.

- By its very construction, the IGO flow is invariant under a number of transformations of the original problem. First, replacing the objective function f with a strictly increasing function of f does not change the IGO flow (Proposition 17 in Appendix C.1).

  Second, changing the parameterization θ used for the family P_θ (e.g., letting θ be a variance or a standard deviation) results in unchanged trajectories for the distributions P_θ under the IGO flow (Proposition 18 in Appendix C.1).

  Finally, the IGO flow is insensitive to transformations of the original problem by a change of variable in the search space X itself, provided this transformation can be reflected in the family of distributions P_θ (Proposition 19 in Appendix C.1); this covers, for instance, optimizing $f(Ax)$ instead of $f(x)$ in $\mathbb{R}^d$ using Gaussian distributions, where A is any invertible matrix.

  These latter two invariances are specifically due to the natural gradient and are not satisfied by a vanilla gradient descent. f-invariance and X-invariance are directly inherited from the IGO flow by IGO algorithms, but this is only approximately true of θ-invariance, as discussed in Appendix C.1.

- The speed of the IGO flow is bounded by the variance of the weight function w on $[0; 1]$ (Appendix C.2, Proposition 20). This implies that the parameter δt in the IGO flow is not a meaningless variable but is related to the maximal number of bits introduced in P_θ at each step (Appendix C.2, Corollary 21).

- IGO algorithms still make sense when the objective function f is noisy, that is, when each call to f returns a non-deterministic value. This can be accounted for without changing the framework: we prove in Proposition 22 (Appendix C.3) that IGO for noisy f is equivalent to IGO for a non-noisy $\tilde{f}$ defined on a larger space $X \times \Omega$ with distributions $\tilde{P}_\theta$ that are uniform over Ω. Consequently, theorems such as consistency of sampling immediately transfer to the noisy case.

- The IGO flow can be computed explicitly in the simple case of linear functions on $\mathbb{R}^d$ using Gaussian distributions, and its convergence can be proven for linear functions on $\{0, 1\}^d$ with Bernoulli distributions (Appendix C.4).

3.5 Implementation Remarks

We conclude this section by a few practical remarks when implementing IGO algorithms.

3.5.1 Influence of the Selection Scheme w

The selection scheme w directly affects the update rule (18).

A natural choice is $w(u) = \mathbb{1}_{u \leqslant q}$. This results, as shown in Proposition 7, in an improvement of the q-quantile over the course of optimization. Taking $q = 1/2$ springs to mind (giving positive weights to the better half of the samples); however, this is often

not selective enough, and both theory and experiments confirm that for the Gaussian case, efficient optimization requires $q < 1/2$ (see Section 5.2). According to Beyer (2001), on the sphere function $f(x) = \sum_i x_i^2$, the optimal q is about 0.27 if sample size N is not larger than the search space dimension d, and even smaller otherwise (Jebalia and Auger, 2010).

Second, replacing w with $w + c$ for some constant c clearly has no influence on the IGO continuous-time flow (7), since the gradient will cancel out the constant. However, this is not the case for the update rule (18) with a finite sample of size N.

Indeed, adding a constant c to w adds a quantity $c\frac{1}{N}\sum \widetilde{\nabla}_\theta \ln P_\theta(x_i)$ to the update. In expectation, this quantity vanishes because the P_θ-expected value of $\widetilde{\nabla}_\theta \ln P_\theta$ is 0 (because $\int (\widetilde{\nabla}_\theta \ln P_\theta)\, P_\theta = \int \widetilde{\nabla} P_\theta = \widetilde{\nabla} 1 = 0$). So adding a constant to w does not change the expected value of the update, but it may change, e.g., its variance. The empirical average of $\widetilde{\nabla}_\theta \ln P_\theta(x_i)$ in the sample will be $O(1/\sqrt{N})$. So translating the weights results in a $O(1/\sqrt{N})$ change in the update. See also Section 4 in Sun et al. (2009).

Thus, one may be tempted to introduce a well chosen value of c so as to reduce the variance of the update. However, determining an optimal value for c is difficult: the optimal value minimizing the variance actually depends on possible correlations between $\widetilde{\nabla}_\theta \ln P_\theta$ and the function f. The only general result is that one should shift w such that 0 lies within its range. Assuming independence, or dependence with enough symmetry, the optimal shift is when the weights average to 0.

3.5.2 Complexity

The complexity of the IGO algorithm depends much on the computational cost model. In optimization, it is fairly common to assume that the objective function f is very costly compared to any other calculations performed by the algorithm (Moré et al., 1981; Dolan and Moré, 2002). Then the cost of IGO in terms of number of f-calls is N per iteration, and the cost of using inverse quantiles and computing the natural gradient is negligible.

Setting the cost of f aside, the complexity of the IGO algorithm depends mainly on the computation of the (inverse) Fisher matrix. Assume an analytical expression for this matrix is known. Then, with $p = \dim \Theta$ the number of parameters, the cost of storage of the Fisher matrix is $O(p^2)$ per iteration, and its inversion typically costs $O(p^3)$ per iteration. However, depending on the situation and on possible algebraic simplifications, strategies exist to reduce this cost (e.g., Le Roux et al. 2007 in a learning context). For instance, for CMA-ES the cost is $O(Np)$ (Suttorp et al., 2009). More generally, parametrization by expectation parameters (see above), when available, may reduce the cost to $O(Np)$ as well.

If no analytical form of the Fisher matrix is known and Monte Carlo estimation is required, then complexity depends on the particular situation at hand and is related to the best sampling strategies available for a particular family of distributions. For Boltzmann machines, for instance, a host of such strategies are available (Ackley et al., 1985; Salakhutdinov and Murray, 2008; Salakhutdinov, 2009; Desjardins et al., 2010). Still, in such a situation, IGO may be competitive if the objective function f is costly.

3.5.3 Recycling Old Samples

To compute the ranks of samples in (14), it might be advisable to re-use samples from previous iterations, so that a smaller number of samples is necessary, see e.g. Sun et al. (2009).

For $N = 1$, this is indispensable. In order to preserve sampling consistency (Theorem 6) the old samples need to be reweighted using the ratio of their likelihood under the current versus old distribution, as in importance sampling.

In evolutionary computation, elitist selection (also called plus-selection) is a common approach where the all-time best samples are taken into account in each iteration. Elitist selection can be modelled in the IGO framework by using the current all-time best samples in addition to samples from P_θ. Specifically, in the $(\mu + \lambda)$-selection scheme, we set $N = \mu + \lambda$ and let $x_1, \ldots, x_\mu$ be the current all-time μ best points. Then we sample λ new points, $x_{\mu+1}, \ldots, x_N$, from the current distribution P_θ and apply (16) with $w(q) = (N/\mu)\mathbb{1}_{q \leq \mu/N}$.

3.5.4 Initialization

As with other distribution-based optimization algorithms, it is usually a good idea to initialize in such a way as to cover a wide portion of the search space, i.e. θ^0 should be chosen so that P_{θ^0} has large diversity. For IGO algorithms this is particularly effective, since, as explained above, the natural gradient provides minimal change of diversity (greedily at each step) for a given change in the objective function.

4. IGO, Maximum Likelihood, and the Cross-Entropy Method

In this section we generalize the IGO update for settings where the natural gradient may not exist. This generalization reveals a unique IGO algorithm for finite step-sizes δt and a natural link to the cross-entropy method.

4.1 IGO as a Smooth-time Maximum Likelihood Estimate

The IGO flow turns out to be the only way to maximize a *weighted* log-likelihood, where points of the current distribution are slightly reweighted according to f-preferences.

This relies on the following interpretation of the natural gradient as a weighted maximum likelihood update with infinitesimal learning rate. This result singles out, in yet another way, the *natural* gradient among all possible gradients. The proof is given in Appendix D.

Theorem 10 (Natural gradient as ML with infinitesimal weights) *Let $\varepsilon > 0$ and $\theta_0 \in \Theta$. Let $W(x)$ be a function of x and let θ be the solution of*

$$\theta = \arg\max_\theta \left\{ (1-\varepsilon) \underbrace{\int \ln P_\theta(x)\, P_{\theta_0}(\mathrm{d}x)}_{= \text{const} - \mathrm{KL}(P_{\theta_0} \| P_\theta),\ \text{maximal for } \theta = \theta_0} + \varepsilon \int \ln P_\theta(x) \overbrace{W(x)}^{\text{preference weight biasing } P_{\theta_0}} P_{\theta_0}(\mathrm{d}x) \right\} \ . \tag{26}$$

Then, when $\varepsilon \to 0$ we have

$$\theta = \theta_0 + \varepsilon \int \widetilde{\nabla}_\theta \ln P_\theta(x)\ W(x)\, P_{\theta_0}(\mathrm{d}x) + O(\varepsilon^2) \ . \tag{27}$$

Likewise for discrete samples: with $x_1, \ldots, x_N \in X$, let θ be the solution of

$$\theta = \arg\max_\theta \left\{ (1-\varepsilon) \int \ln P_\theta(x)\, P_{\theta_0}(\mathrm{d}x) + \varepsilon \sum_i W(x_i)\ \ln P_\theta(x_i) \right\} \ . \tag{28}$$

Then when $\varepsilon \to 0$ we have

$$\theta = \theta_0 + \varepsilon \sum_i W(x_i)\ \widetilde{\nabla}_\theta \ln P_\theta(x_i) + O(\varepsilon^2) \ . \tag{29}$$

So if $W(x) = W^f_{\theta_0}(x)$ is the weight of the points according to quantilized f-preferences, the weighted maximum log-likelihood necessarily is the IGO flow (9) using the natural gradient—or the IGO update (17) when using samples.

Thus the IGO flow is the unique flow that, continuously in time, slightly changes the distribution to maximize the log-likelihood of points with good values of f. (In addition, IGO continuously updates the weight $W^f_{\theta^t}(x)$ depending on f and on the current distribution, so that we keep optimizing.)

This theorem suggests a way to approximate the IGO flow by enforcing this interpretation for a given non-infinitesimal step size δt, as follows.

Definition 11 (IGO-ML algorithm) *The* IGO-ML algorithm *with step size δt updates the value of the parameter θ^t according to*

$$\theta^{t+\delta t} = \arg\max_\theta \left\{ (1 - \delta t \sum_i \widehat{w}_i) \int \ln P_\theta(x)\, P_{\theta^t}(\mathrm{d}x) \ + \ \delta t \sum_i \widehat{w}_i \ln P_\theta(x_i) \right\} \tag{30}$$

where $x_1, \ldots, x_N$ are sample points drawn according to the distribution P_{θ^t}, and $\widehat{w}_i$ is the weight (14) *obtained from the ranked values of the objective function f.*

The IGO-ML algorithm is obviously independent of the parametrization θ: indeed it only depends on P_θ itself. Furthermore, the IGO-ML update (30) does not even require a smooth parametrization of the distribution anymore (though in this case, a small δt will likely result in stalling: $\theta^{t+\delta t} = \theta^t$ if the set of possible values for θ is discrete).

Like the cross-entropy method below, the IGO-ML algorithm can be applied only when the argmax can be computed.

It turns out that for exponential families, IGO-ML is just the IGO algorithm in a particular parametrization (see Theorem 12).

4.2 The Cross-Entropy Method

Taking $\delta t = 1$ in (30) above corresponds to a full maximum likelihood update; when using the truncation selection scheme w, this is the *cross-entropy method* (CEM). The cross-entropy method can be defined in an optimization setting as follows (de Boer et al., 2005). Like IGO, it depends on a family of probability distributions P_θ parametrized by $\theta \in \Theta$, and a number of samples N at each iteration. Let also $N_e = \lceil qN \rceil$ $(0 < q < 1)$ be a number of *elite* samples.

At each step, the cross-entropy method for optimization samples N points $x_1, \ldots, x_N$ from the current distribution P_{θ^t}. Let $\widehat{w}_i$ be $1/N_e$ if x_i belongs to the N_e samples with the best value of the objective function f, and $\widehat{w}_i = 0$ otherwise. Then the *cross-entropy method* or *maximum likelihoood* update (CEM/ML) for optimization is (de Boer et al., 2005, Algorithm 3.1)

$$\theta^{t+1} = \arg\max_\theta \sum \widehat{w}_i \ln P_\theta(x_i) \tag{31}$$

(assuming the argmax is tractable). This corresponds to $\delta t = 1$ in (30).

A commonly used version of CEM with a smoother update depends on a step size parameter $0 < \alpha \leqslant 1$ and is given (de Boer et al., 2005) by

$$\theta^{t+1} = (1-\alpha)\theta^t + \alpha \arg\max_\theta \sum \widehat{w}_i \ln P_\theta(x_i). \tag{32}$$

The standard CEM/ML update is $\alpha = 1$. For $\alpha = 1$, the standard cross-entropy method is independent of the parametrization θ, whereas for $\alpha < 1$ this is not the case.

Note the difference between the IGO-ML algorithm (30) and the smoothed CEM update (32) with step size $\alpha = \delta t$: the smoothed CEM update performs a weighted average of the parameter value *after* taking the maximum likelihood estimate, whereas IGO-ML uses a weighted average of current and previous likelihoods, *then* takes a maximum likelihood estimate. In general, these two rules can greatly differ, as they do for Gaussian distributions (Section 5.2).

This swapping of averaging makes IGO-ML parametrization-independent whereas the smoothed CEM update is not.

Yet, for exponential families of probability distributions, there exists one particular parametrization θ in which the IGO algorithm and the smoothed CEM update coincide. We now proceed to this construction.

4.3 IGO for Expectation Parameters and Maximum Likelihood

The particular form of IGO for exponential families has an interesting consequence if the parametrization chosen for the exponential family is the set of *expectation parameters*. Let $P_\theta(x) = \frac{1}{Z(\theta)} \exp\left(\sum \theta_j T_j(x)\right) H(\mathrm{d}x)$ be an exponential family as above. The *expectation parameters* are $\bar{T}_j = \bar{T}_j(\theta) = \mathbb{E}_{P_\theta} T_j$, (denoted η_j in Amari and Nagaoka 2000, Eq. 3.56). The notation $\bar{T}$ will denote the collection $(\bar{T}_j)$. We shall use the notation $P_{\bar{T}}$ to denote the probability distribution P parametrized by the expectation parameters.

It is well-known that, in this parametrization, the maximum likelihood estimate for a sample of points $x_1, \ldots, x_N$ is just the empirical average of the expectation parameters over that sample:

$$\arg\max_{\bar{T}} \frac{1}{N} \sum_{i=1}^N \ln P_{\bar{T}}(x_i) = \frac{1}{N} \sum_{i=1}^N T(x_i) \ . \tag{33}$$

In the discussion above, one main difference between IGO and smoothed CEM was whether we took averages before or after taking the maximum log-likelihood estimate. For the expectation parameters $\bar{T}_i$, we see that these operations commute. (One can say that these expectation parameters "linearize maximum likelihood estimates".) After some work we get the following result.

Theorem 12 (IGO, CEM and maximum likelihood) *Let*

$$P_\theta(\mathrm{d}x) = \frac{1}{Z(\theta)} \exp\left(\sum \theta_j T_j(x)\right) H(\mathrm{d}x)$$

be an exponential family of probability distributions, where the T_j are functions of x and H is some reference measure. Let us parametrize this family by the expected values $\bar{T}_j = \mathbb{E} T_j$.

Let us assume the chosen weights $\widehat{w}_i$ sum to 1. For a sample $x_1, \ldots, x_N$, let

$$T_j^* = \sum_i \widehat{w}_i T_j(x_i).$$

Then the IGO update (17) *in this parametrization reads*

$$\bar{T}_j^{t+\delta t} = (1-\delta t)\, \bar{T}_j^t + \delta t\, T_j^*. \tag{34}$$

Moreover these three algorithms coincide:

- *The IGO-ML algorithm* (30).
- *The IGO algorithm* (17) *written in the parametrization $\bar{T}_j$* (34).
- *The smoothed CEM algorithm* (32) *written in the parametrization $\bar{T}_j$, with $\alpha = \delta t$.*

Corollary 13 *For exponential families, the standard CEM/ML update* (31) *coincides with the IGO algorithm in parametrization $\bar{T}_j$ with $\delta t = 1$.*

Beware that the expectation parameters $\bar{T}_j$ are not always the most obvious parameters (Amari and Nagaoka, 2000, Section 3.5). For example, for 1-dimensional Gaussian distributions, the expectation parameters are the mean μ and the second moment $\mu^2 + \sigma^2$, not the mean and variance. When expressed back in terms of mean and variance, the update (34) boils down to $\mu \leftarrow (1-\delta t)\mu + \delta t \mu^*$ and $\sigma^2 \leftarrow (1-\delta t)\sigma^2 + \delta t (\sigma^*)^2 + \delta t (1-\delta t)(\mu^* - \mu)^2$, where μ^* and σ^* denote the mean and standard deviation of the samples x_i.

On the other hand, when using smoothed CEM with mean and variance as parameters, the new variance is $(1-\delta t)\sigma^2 + \delta t (\sigma^*)^2$, which can be significantly smaller for $\delta t \in (0,1)$. This proves, in passing, that the smoothed CEM update in other parametrizations is generally *not* an IGO algorithm (because it can differ at first order in δt).

The case of Gaussian distributions is further exemplified in Section 5.2 below: in particular, smoothed CEM in the (μ, σ) parametrization almost invariably exhibits a reduction of variance, often leading to premature convergence.

For these reasons we think that the IGO-ML algorithm is the sensible way to define an interpolated ML estimate for $\delta t < 1$ in a parametrization-independent way (see however the analysis of a critical δt in Section 5.2). In Appendix A we further discuss IGO and CEM and sum up the differences and relative advantages.

Taking $\delta t = 1$ is a bold approximation choice: the "ideal" continuous-time IGO flow itself, after time 1, does not coincide with the maximum likelihood update of the best points in the sample. Since the maximum likelihood algorithm is known to converge prematurely in some instances (Section 5.2), using the parametrization by expectation parameters with large δt may not be desirable.

The considerable simplification of the IGO update in these coordinates reflects the duality of coordinates $\bar{T}_i$ and θ_i. More precisely, the natural gradient ascent w.r.t. the parameters $\bar{T}_i$ is given by the vanilla gradient w.r.t. the parameters θ_i:

$$\widetilde{\nabla}_{\bar{T}_i} = \frac{\partial}{\partial \theta_i}$$

(Proposition 29 in Appendix D).

5. CMA-ES, NES, EDAs and PBIL from the IGO Framework

In this section we investigate the IGO algorithms for Bernoulli measures and for multivariate normal distributions, and show the correspondence to well-known algorithms. Restricted Boltzmann machines are given as a third, novel example. In addition, we discuss the influence of the parametrization of the distributions.

5.1 PBIL and cGA as IGO Algorithms for Bernoulli Measures

Let us consider on $X = \{0,1\}^d$ a family of Bernoulli measures $P_\theta(x) = p_{\theta_1}(x_1) \times \ldots \times p_{\theta_d}(x_d)$ with $p_{\theta_i}(x_i) = \theta_i^{x_i}(1-\theta_i)^{1-x_i}$, with each $\theta_i \in [0;1]$. As this family is a product of probability measures $p_{\theta_i}(x_i)$, the different components of a random vector y following P_θ are independent and all off-diagonal terms of the Fisher information matrix are zero. Diagonal terms are given by $\frac{1}{\theta_i(1-\theta_i)}$. Therefore the inverse of the Fisher matrix is a diagonal matrix with diagonal entries equal to $\theta_i(1-\theta_i)$. In addition, the partial derivative of $\ln P_\theta(x)$ w.r.t. θ_i is computed in a straightforward manner resulting in

$$\frac{\partial \ln P_\theta(x)}{\partial \theta_i} = \frac{x_i}{\theta_i} - \frac{1-x_i}{1-\theta_i} \ .$$

Let $x_1, \ldots, x_N$ be N samples at step t with distribution P_{θ^t} and let $x_{1:N}, \ldots, x_{N:N}$ be the samples ranked according to f value. The natural gradient update (18) with Bernoulli measures is then

$$\theta_i^{t+\delta t} = \theta_i^t + \delta t\, \theta_i^t(1-\theta_i^t) \sum_{j=1}^N w_j \left(\frac{[x_{j:N}]_i}{\theta_i^t} - \frac{1-[x_{j:N}]_i}{1-\theta_i^t} \right) \tag{35}$$

where $w_j = w((j-1/2)/N)/N$ and $[y]_i$ denotes the i^{th} coordinate of $y \in X$. The previous equation simplifies to

$$\theta_i^{t+\delta t} = \theta_i^t + \delta t \sum_{j=1}^N w_j \left([x_{j:N}]_i - \theta_i^t \right) \ , \tag{36}$$

or, denoting $\bar{w}$ the sum of the weights $\sum_{j=1}^N w_j$,

$$\theta_i^{t+\delta t} = (1 - \bar{w}\delta t)\, \theta_i^t + \delta t \sum_{j=1}^N w_j \, [x_{j:N}]_i \ . \tag{37}$$

The algorithm so obtained coincides with the so-called *population-based incremental learning* algorithm (PBIL, Baluja and Caruana 1995) for $N =$ `NUMBER_SAMPLES` and the appropriate (usually non-negative) weights w_j, as well as with the *compact genetic algorithm* (cGA, Harik et al. 1999) for $N = 2$ and $w_1 = -w_2$. Different variants of PBIL correspond to different choices of the selection scheme w. In cGA, components for which both samples have the same value are unchanged, because $w_1 + w_2 = 0$. We have thus proved the following.

Proposition 14 *The IGO algorithm on $\{0,1\}^d$ using Bernoulli measures parametrized by θ as above, coincides with the* compact Genetic Algorithm *(cGA) when $N = 2$ and $w_1 = -w_2$.*

Moreover, it coincides with Population-Based Incremental Learning *(PBIL) with the following correspondence of parameters. The PBIL algorithm using the μ best solutions, see Baluja and Caruana (1995, Figure 4), is recovered*[4] *using $\delta t =$ LR, $w_j = (1-\text{LR})^{j-1}$ for $j = 1, \ldots, \mu$, and $w_j = 0$ for $j = \mu+1, \ldots, N$.*

If the selection scheme of IGO is chosen as $w_1 = 1$, $w_j = 0$ for $j = 2, \ldots, N$, IGO recovers the PBIL/EGA algorithm with update rule towards the best solution (Baluja, 1994, Figure 4), with $\delta t =$ LR (the learning rate of PBIL) and MUT_PROBABILITY $= 0$ *(no random mutation of θ).*

Interestingly, the parameters θ_i are the expectation parameters described in Section 4: indeed, the expectation of x_i is θ_i. So the formulas above are particular cases of (34). Thus, by Theorem 12, PBIL is both a smoothed CEM in these parameters and an IGO-ML algorithm.

Let us now consider another, so-called "logit" representation, given by the logistic function $P(x_i = 1) = \frac{1}{1+\exp(-\tilde{\theta}_i)}$. This $\tilde{\theta}$ is the exponential parametrization of Section 3.3. We find that

$$\frac{\partial \ln P_{\tilde{\theta}}(x)}{\partial \tilde{\theta}_i} = (x_i - 1) + \frac{\exp(-\tilde{\theta}_i)}{1+\exp(-\tilde{\theta}_i)} = x_i - \mathbb{E} x_i \tag{38}$$

(cf. Eq. 19) and that the diagonal elements of the Fisher information matrix are given by $\exp(-\tilde{\theta}_i)/(1+\exp(-\tilde{\theta}_i))^2 = \operatorname{Var} x_i$ (as per Eq. 20). So the natural gradient update (18) with Bernoulli measures in parametrization $\tilde{\theta}$ reads

$$\tilde{\theta}_i^{t+\delta t} = \tilde{\theta}_i^t + \delta t (1+\exp(\tilde{\theta}_i^t)) \left(-\bar{w} + (1+\exp(-\tilde{\theta}_i^t)) \sum_{j=1}^N w_j [x_{j:N}]_i \right) \ . \tag{39}$$

To better compare the update with the previous representation, note that $\theta_i = \frac{1}{1+\exp(-\tilde{\theta}_i)}$ and thus we can rewrite

$$\tilde{\theta}_i^{t+\delta t} = \tilde{\theta}_i^t + \frac{\delta t}{\theta_i^t(1-\theta_i^t)} \sum_{j=1}^N w_j \left([x_{j:N}]_i - \theta_i^t \right) \ . \tag{40}$$

So the direction of the update is the same as before and is given by the proportion of bits set to 0 or 1 in the best samples, compared to its expected value under the current distribution. The magnitude of the update is different since the parameter $\tilde{\theta}$ ranges from $-\infty$ to $+\infty$ instead of from 0 to 1. We did not find this algorithm in the literature.

These updates also illustrate the influence of setting the sum of weights to 0 or not (Section 3.5). If, at some time, the first bit is equal to 1 both for a majority of good points and for a majority of bad points, then the original PBIL will increase the probability of setting the first bit to 1, which is counterintuitive. If the weights w_i are chosen to sum to 0 this noise effect disappears; otherwise, it disappears only on average.

4. Note that the pseudocode for the algorithm in Baluja and Caruana (1995, Figure 4) is slightly erroneous since it gives smaller weights to better individuals. The error can be fixed by updating the probability in reversed order, looping from `NUMBER_OF_VECTORS_TO_UPDATE_FROM` to 1. This was confirmed by S. Baluja in personal communication. We consider here the corrected version of the algorithm.

5.2 Multivariate Normal Distributions (Gaussians)

Evolution strategies (Rechenberg, 1973; Schwefel, 1995; Beyer and Schwefel, 2002) are black-box optimization algorithms for the continuous search domain, $X \subseteq \mathbb{R}^d$ (for simplicity we assume $X = \mathbb{R}^d$ in the following), which use multivariate normal distributions to sample new solutions. In the context of continuous black-box optimization, *Natural Evolution Strategies* (NES) introduced the idea of using a natural gradient update of the distribution parameters (Wierstra et al., 2008; Sun et al., 2009; Glasmachers et al., 2010; Wierstra et al., 2014). Surprisingly, the well-known *Covariance Matrix Adaption Evolution Strategy* (CMA-ES, Hansen and Ostermeier 1996, 2001; Hansen et al. 2003; Hansen and Kern 2004; Jastrebski and Arnold 2006) also turns out to conduct a natural gradient update of distribution parameters (Akimoto et al., 2010; Glasmachers et al., 2010).

Let $x \in \mathbb{R}^d$. As the most prominent example, we use mean vector $m = \mathbb{E}x$ and covariance matrix $C = \mathbb{E}(x-m)(x-m)^\mathsf{T} = \mathbb{E}(xx^\mathsf{T}) - mm^\mathsf{T}$ to parametrize a normal distribution via $\theta = (m, C)$. The IGO update in (17) or (18) in this parametrization can now be entirely formulated without the (inverse) Fisher matrix, similarly to (34) or (22). The complexity of the update is linear in the number of parameters (size of $\theta = (m, C)$, where $(d^2 - d)/2$ parameters are redundant).

Let us discuss known algorithms that implement updates of this kind.

5.2.1 CMA-ES.

The rank-μ-update CMA-ES implements the equations[5]

$$m^{t+1} = m^t + \eta_\mathrm{m} \sum_{i=1}^{N} \widehat{w}_i (x_i - m^t) \tag{41}$$

$$C^{t+1} = C^t + \eta_\mathrm{c} \sum_{i=1}^{N} \widehat{w}_i ((x_i - m^t)(x_i - m^t)^\mathsf{T} - C^t) \tag{42}$$

where $\widehat{w}_i$ are the weights based on ranked f-values, see (14) and (17).

Proposition 15 *The IGO update* (17) *for Gaussian distributions in the parametrization by mean and covariance matrix* (m, C)*, coincides with the CMA-ES update equations* (41) *and* (42) *with* $\eta_\mathrm{c} = \eta_\mathrm{m}$.

This result is essentially due to Akimoto et al. (2010) and Glasmachers et al. (2010), who showed that the CMA-ES update with $\eta_\mathrm{c} = \eta_\mathrm{m}$ is a natural gradient update[6].

However, in deviation from the IGO algorithm, the learning rates η_m and η_c are assigned different values if $N \ll \dim \Theta$ in CMA-ES[7]. Note that the Fisher information matrix is block-diagonal in m and C (Akimoto et al., 2010), so that application of the different learning rates and of the inverse Fisher matrix commute. Moreover, CMA-ES uses a *path cumulation* method to adjust the step sizes, which is not covered by the IGO framework (see Appendix A).

5. The CMA-ES implements these equations given the parameter setting $c_1 = 0$ and $c_\sigma = 0$ (or $d_\sigma = \infty$, see e.g. Hansen 2009) that disengages the effect of the rank-one update and of step size control and therefore of both so-called evolution paths.

6. In these articles the result has been derived for $\theta \leftarrow \theta + \eta \widetilde{\nabla}_\theta \mathbb{E}_{P_\theta} f$, see (11), leading to $f(x_i)$ in place of $\widehat{w}_i$. No assumptions on f have been used besides that it does not depend on θ. Consequently, by replacing f with $W^f_{\theta^t}$, where θ^t is fixed, the derivation holds equally well for $\theta \leftarrow \theta + \eta \widetilde{\nabla}_\theta \mathbb{E}_{P_\theta} W^f_{\theta^t}$.

7. Specifically, let $\sum |\widehat{w}_i| = 1$, then the settings are $\eta_\mathrm{m} = 1$ and $\eta_\mathrm{c} \approx 1/(d^2 \sum \widehat{w}_i^2)$ (Hansen, 2006b).

5.2.2 Convenient Reparametrizations Over Time.

For practical purposes, at each step it is convenient to work in a representation of θ in which the diagonal Fisher matrix $I(\theta^t)$ has a simple form, e.g., diagonal with simple diagonal entries. It is generally not possible to obtain such a representation for all θ simultaneously. Still it is always possible to find a transformation achieving a diagonal Fisher matrix at a single parameter θ^t, in multiple ways (it amounts to choosing a basis of parameter space which is orthogonal in the Fisher metric). Such a representation is never unique and not intrinsic, yet it still provides a convenient way to write the algorithms.

For CMA-ES, one such representation can be found by sending the current covariant matrix C^t to the identity, e.g., by representing the mean and covariance matrix by $((C^t)^{-1/2} m, (C^t)^{-1/2} C (C^t)^{-1/2})$ instead of (m, C). Then the Fisher matrix $I(\theta^t)$ at (m^t, C^t) becomes diagonal. The next algorithm we discuss, xNES (Glasmachers et al., 2010), exploits this possibility in a logarithmic representation of the covariance matrix.

5.2.3 Natural Evolution Strategies.

Natural evolution strategies (NES, Wierstra et al. 2008; Sun et al. 2009) implement (41) as well, while using a Cholesky decomposition of C as the parametrization for the update of the variance parameters. The resulting update that replaces (42) is neither particularly elegant nor numerically efficient. The more recent xNES (Glasmachers et al., 2010) chooses an "exponential" parametrization that naturally depends on the current parameters. This leads to an elegant formulation where the additive update in exponential parametrization becomes a multiplicative update for C. With $C = AA^\mathsf{T}$, the matrix update reads

$$A \leftarrow A \times \exp\left(\frac{\eta_\mathrm{c}}{2} \sum_{i=1}^{N} \widehat{w}_i \times (z_i z_i^\mathsf{T} - \mathrm{I}_d) \right) \tag{43}$$

where $z_i = A^{-1}(x_i - m)$ and I_d is the identity matrix. From (43) the updated covariance matrix is $C \leftarrow A \times \exp\left(\eta_\mathrm{c} \sum_{i=1}^{N} \widehat{w}_i \times (z_i z_i^\mathsf{T} - \mathrm{I}_d)\right) \times A^\mathsf{T}$.

Compared to (42), the update has the advantage that also negative weights, $\widehat{w}_i < 0$, always lead to a feasible covariance matrix. By default, xNES sets $\eta_\mathrm{m} \neq \eta_\mathrm{c}$ in the same circumstances as in CMA-ES, but contrary to CMA-ES the past evolution path is not taken into account (Glasmachers et al., 2010).

When $\eta_\mathrm{c} = \eta_\mathrm{m}$, xNES is consistent with the IGO flow (8), and implements an IGO algorithm (17) slightly generalized in that it uses a θ^t-dependent parametrization, which represents the current covariance matrix by 0. Namely, we have:

Proposition 16 (exponential IGO update of Gaussians) *Let* (m^t, C^t) *be the current mean and covariance matrix. Let* $C^t = AA^\mathsf{T}$*. Let* θ *be the time-dependent parametrization of the space of Gaussian distributions, which parametrizes the Gaussian distribution* (m, C) *by*

$$\theta = (m, R), \qquad R = \ln(A^{-1} C (A^\mathsf{T})^{-1})$$

where ln *is the logarithm of positive matrices. (Note that the current value* C^t *of* C *is represented as* $R = 0$*.)*

Then the IGO update (17) *in the parametrization* θ *is as follows: the mean* m *is updated as in CMA-ES* (41)*, and the parameter* R *is updated as*

$$R \leftarrow \delta t \sum_{i=1}^{N} \widehat{w}_i \times (A^{-1}(x_i - m)(x_i - m)^\mathsf{T}(A^\mathsf{T})^{-1} - \mathrm{I}_d) \tag{44}$$

thus resulting in the same update as (43) *(with* $\eta_\mathrm{c} = \delta t$*) for the covariance matrix:* $C \leftarrow A \exp(R) A^\mathsf{T}$.

Proof Indeed, by basic differential geometry, if parametrization $\theta' = \varphi(\theta)$ is used, the IGO update for θ' is $D\varphi(\theta^t)$ applied to the IGO update for θ, where $D\varphi$ is the differential of φ. Here, given the update (42) for C, to find the update for R we have to compute the differential of the map $C \mapsto \ln(A^{-1}C(A^\mathsf{T})^{-1})$ taken at $C = AA^\mathsf{T}$: for any matrix M we have $\ln(A^{-1}(AA^\mathsf{T} + \varepsilon M)(A^\mathsf{T})^{-1}) = \varepsilon\, A^{-1}M(A^\mathsf{T})^{-1} + O(\varepsilon^2)$. So to find the update for the variable R we have to apply $A^{-1} \dots (A^\mathsf{T})^{-1}$ to the update (42) for C. ■

5.2.4 Cross-Entropy Method and EMNA

Estimation of distribution algorithms (EDA) and the *cross-entropy method* (CEM, Rubinstein 1999; Rubinstein and Kroese 2004) estimate a new distribution from a censored sample. Generally, the new parameter value can be written as

$$\begin{aligned} \theta_\mathrm{maxLL} &= \arg\max_\theta \sum_{i=1}^{N} \widehat{w}_i \ln P_\theta(x_i) \\ &\longrightarrow_{N\to\infty} \arg\max_\theta \mathbb{E}_{P_{\theta^t}} W^f_{\theta^t} \ln P_\theta \end{aligned} \tag{45}$$

by Theorem 6. Here, the weights $\widehat{w}_i$ are equal to $1/\mu$ for the μ best points (censored or elitist sample) and 0 otherwise. This θ_maxLL maximizes the weighted log-likelihood of $x_1, \dots, x_N$; equivalently, it minimizes the cross-entropy and the Kullback–Leibler divergence to the distribution of the best μ samples[8].

For Gaussian distributions, Equation (45) can be explicitly written in the form

$$m^{t+1} = m^* = \sum_{i=1}^{N} \widehat{w}_i x_i \tag{46}$$

$$C^{t+1} = C^* = \sum_{i=1}^{N} \widehat{w}_i (x_i - m^*)(x_i - m^*)^\mathsf{T} \tag{47}$$

the empirical mean and variance of the elite sample.

8. Let P_w denote the distribution of the weighted samples: $\Pr(x = x_i) = \widehat{w}_i$ and $\sum_i \widehat{w}_i = 1$. Then the cross-entropy between P_w and P_θ reads $\sum_i P_w(x_i) \ln 1/P_\theta(x_i)$ and the KL divergence reads $\mathrm{KL}(P_w \,\|\, P_\theta) = \sum_i P_w(x_i) \ln 1/P_\theta(x_i) - \sum_i P_w(x_i) \ln 1/P_w(x_i)$. Minimization of both terms in θ result in θ_maxLL.

Equations (46) and (47) also define the simplest continuous domain EDA, the *estimation of multivariate normal algorithm* ($\mathrm{EMNA}_\mathrm{global}$, Larranaga and Lozano 2002). Interestingly, (46) and (47) only differ from (41) and (42) (with $\eta_\mathrm{m} = \eta_\mathrm{c} = 1$) in that the new mean m^{t+1} is used instead of m^t in the covariance matrix update (Hansen, 2006b).

The smoothed CEM (32) in this parametrization thus writes

$$m^{t+\delta t} = (1 - \delta t) m^t + \delta t m^* \tag{48}$$

$$C^{t+\delta t} = (1 - \delta t) C^t + \delta t C^* \ . \tag{49}$$

Note that *this is not an IGO algorithm* (i.e., there is no parametrization of the family of Gaussian distributions in which the IGO algorithm coincides with update Eq. 49): indeed, all IGO algorithms coincide at first order in δt when $\delta t \to 0$ (because they recover the IGO flow), while this update for $C^{t+\delta t}$ does not coincide with (42) in this limit, due to the use of m^* instead of m^t. This does not contradict Theorem 12: smoothed CEM is an IGO algorithm only if smoothed CEM is written in the expectation parametrization, which (m, C) is not.

5.2.5 CMA-ES, Smoothed CEM, and IGO-ML

Let us compare IGO-ML (30), rank-μ CMA (41)–(42), and smoothed CEM (48)–(49) in the parametrization with mean and covariance matrix. These algorithms all update the distribution mean in the same way, while the update of the covariance matrix depends on the algorithm. With learning rate δt, these updates are computed to be

$$\begin{aligned} m^{t+1} &= (1 - \delta t)\, m^t + \delta t\, m^* \\ C^{t+1} &= (1 - \delta t)\, C^t + \delta t\, C^* + \delta t (1 - \delta t)^j\, (m^* - m^t)(m^* - m^t)^\mathsf{T} \ , \end{aligned} \tag{50}$$

for different values of j, where m^* and C^* are the mean and covariance matrix computed over the elite sample (with positive weights $\widehat{w}_i$ summing to one) as above. The rightmost term of (50) is reminiscent of the so-called rank-one update in CMA-ES (not included in Eq. 42).

For $j = 0$ we recover the rank-μ CMA-ES update (42), for $j = 1$ we recover IGO-ML, and for $j = \infty$ we recover smoothed CEM (the rightmost term is absent). The case $j = 2$ corresponds to an update that uses m^{t+1} instead of m^t in (42) (with $\eta_\mathrm{m} = \eta_\mathrm{c} = \delta t$). For $0 < \delta t < 1$, the larger j, the smaller C^{t+1}. For $\delta t = 1$, IGO-ML and smoothed CEM/EMNA realize θ_maxLL from (45)–(47).

For $\delta t \to 0$, the update is independent of j at first order in δt if $j < \infty$: this reflects compatibility with the IGO flow of CMA-ES and of IGO-ML, but not of smoothed CEM.

In the default (full) CMA-ES (as opposed to rank-μ CMA-ES), the coefficient preceeding $(m^* - m^t)(m^* - m^t)^\mathsf{T}$ in (50) reads approximately $3\delta t$, where the additional $2\delta t$ originate from the so-called rank-one update and are moreover modulated by a "cumulated path" up to a factor of about $\sqrt{d}$ (Hansen and Auger, 2014).

5.2.6 Critical δt

Let us assume that $\mu < N$ weights are set to $\widehat{w}_i = 1/\mu$ and the remaining weights to zero, so that the selection ratio is $q = \mu/N$.

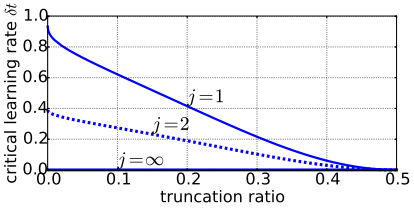

Figure 1: Critical δt versus selection truncation ratio q for three values of j in (50). With δt above the critical δt, the variance decreases systematically when optimizing a linear function, indicating failure of the algorithm. For CMA-ES/NES where $j = 0$, the critical δt for $q < 0.5$ is infinite.

Then there is a critical value of δt depending on this ratio q, such that above this critical δt the algorithms given by IGO-ML and smoothed CEM are prone to premature convergence. Indeed, let f be a linear function on $\mathbb{R}^d$, and consider the variance in the direction of the gradient of f. Assuming further $N \to \infty$ and $q \leq 1/2$, then the variance C^* of the elite sample is smaller than the current variance C^t, by a constant factor. Depending on the precise update for C^{t+1}, if δt is too large, the variance C^{t+1} is going to be smaller than C^t by a constant factor as well. This implies that the algorithm is going to stall, i.e., the variance will go to 0 before the optimum is reached. (On the other hand, the continuous-time IGO flow corresponding to $\delta t \to 0$ does not stall, see Appendix C.4.)

We now study the critical δt (in the limit $N \to \infty$) below which the algorithm does not stall (this is done similarly to the analysis in Appendix C.4 for linear functions). For IGO-ML, ($j = 1$ in Eq. 50, or equivalently for the smoothed CEM in the expectation parameters $(m, C + mm^\mathsf{T})$, see Section 4), the variance increases if and only if δt is smaller than the critical value $\delta t_{\text{crit}} = qb\sqrt{2\pi}e^{b^2/2}$ where b is the percentile function of q, i.e. b is such that $q = \int_b^\infty e^{-x^2/2}/\sqrt{2\pi}$. This value δt_{crit} is plotted as a solid line in Fig. 1. For $j = 2$, δt_{crit} is smaller, related to the above by $\delta t_{\text{crit}} \leftarrow \sqrt{1 + \delta t_{\text{crit}}} - 1$ and plotted as a dashed line in Fig. 1. For CEM ($j = \infty$), the critical δt is zero (reflecting the non-IGO behavior of CEM in this parametrization). For CMA-ES ($j = 0$), the critical δt is infinite for $q < 1/2$. When the selection ratio q is above $1/2$, for all algorithms the critical δt becomes zero.

5.2.7 Gaussian Distributions with Restricted Parametrization

When considering a restricted parametrization of multivariate normal distributions, IGO recovers other known algorithms. In particular for sep-CMA-ES (Ros and Hansen, 2008) and SNES (Schaul et al., 2011), the update has been restricted to the diagonal of the covariance matrix.

5.3 IGO for Restricted Boltzmann Machines, and Multimodal Optimization

As a third example after Bernoulli and Gaussian distributions, we have applied IGO to restricted Boltzmann machines (RBMs, Smolensky 1986; Ackley et al. 1985), which are

families of distributions on the search space $X = \{0, 1\}^d$ extending Bernoulli distributions to allow for dependencies between the bits (see, e.g., Berny 2002 for Boltzmann machines used in an optimization setting). The details are given in Appendix B. We chose this example for two reasons.

First, it illustrates how to obtain a novel algorithm from a family of probability distributions in the IGO framework, in a case when there is no fully explicit expression for the Fisher information matrix.

Second, it illustrates the influence of the natural gradient on diversity and its relevance to multimodal optimization. The RBM probability distributions on $\{0, 1\}^d$ are multimodal, contrary to Bernoulli distributions. Thus, in principle, IGO on such distributions could reach several optima simultaneously. This allows for a simple testing of the entropy-maximizing property of the IGO flow (Proposition 2). Accordingly, for a given improvement on the objective function, we would expect IGO to favor preserving the diversity of P_θ. Indeed on a simple objective function with two optima, we find that the IGO flow converges to a distribution putting weight on both optima, while a descent using the vanilla gradient always only concentrates around one optimum. This might be relevant for multimodal optimization, where simultaneous handling of multiple hypotheses is seen as useful for optimization (Sareni and Krähenbühl, 1998; Das et al., 2011), or in situations in which several valleys appear equally good at first but only one of them contains the true optimum.

We refer to Appendix B for a reminder about Boltzmann machines, for how IGO rolls out in this case, and for the detailed experimental setup for studying the influence of IGO in a multimodal situation.

6. Summary and Conclusion

We sum up:

- The information-geometric optimization (IGO) framework derives from invariance principles the uniquely defined IGO flow (Definition 4), and allows, via discretization in time and space, to build optimization algorithms from any family of distributions on any search space. In some instances (Gaussian distributions on $\mathbb{R}^d$ or Bernoulli distributions on $\{0, 1\}^d$) it recovers versions of known algorithms (PBIL, CMA-ES, cGA, NES); in other instances (restricted Boltzmann machine distributions) it produces new, hopefully efficient optimization algorithms.

- The use of a quantile-based, time-dependent transform of the objective function, Equation (5), provides a rigorous derivation of rank-based update rules, frequently used in current optimization algorithms. Theorem 6 uniquely identifies the infinite-population limit of these update rules.

- The IGO flow is singled out by its equivalent description as an infinitesimal weighted maximum log-likelihood update (Theorem 10). In a particular parametrization and with a step size of 1, IGO recovers the cross-entropy method (Corollary 13). This reveals a connection between CEM and the natural gradient, and allows to define a new, fully parametrization-invariant smoothed maximum likelihood update, the IGO-ML.

- Theoretical arguments suggest that the IGO flow minimizes the change of diversity in the course of optimization. As diversity usually decreases in the course of optimization, IGO algorithms tend to exhibit minimal diversity loss for the observed improvement. In particular, starting with high diversity and using multimodal distributions may allow simultaneous exploration of multiple optima of the objective function. Preliminary experiments with restricted Boltzmann machines confirm this effect in a simple situation.

Thus, the IGO framework provides sound theoretical foundations to optimization algorithms based on probability distributions. In particular, this viewpoint helps to bridge the gap between continuous and discrete optimization.

The invariance properties, which reduce the number of arbitrary choices, together with the relationship between natural gradient and diversity, may contribute to a theoretical explanation of the good practical performance of those currently used algorithms, such as CMA-ES, which can be interpreted as instantiations of IGO.

We hope that invariance properties will acquire in computer science the importance they have in mathematics, where intrinsic thinking is the first step for abstract linear algebra or differential geometry, and in modern physics, where the notions of invariance w.r.t. the coordinate system and so-called gauge invariance play a central role.

Acknowledgments

The authors would like to thank Michèle Sebag for the acronym and for helpful comments. We also thank Youhei Akimoto for helpful feedback and inspiration. Y. O. would like to thank Cédric Villani and Bruno Sévennec for helpful discussions on the Fisher metric. A. A. and N. H. would like to acknowledge the Dagstuhl Seminar No 10361 on the Theory of Evolutionary Computation (`http://www.dagstuhl.de/10361`) for crucially inspiring this paper, their work on natural gradients and beyond. This work was partially supported by the ANR-2010-COSI-002 grant (SIMINOLE) of the French National Research Agency.

Appendix A. Further Discussion and Perspectives

This appendix touches upon further aspects and perspectives of the IGO framework and its implementations.

A.1 A Single Framework for Optimization on Arbitrary Spaces

A strength of the IGO viewpoint is to automatically provide a distinct and arguably in some sense optimal optimization algorithm from any family of probability distributions on any given space, discrete or continuous. IGO algorithms feature desired invariance properties and thereby make fewer arbitrary choices.

In particular, IGO describes several well-known optimization algorithms within a single framework. For Bernoulli distributions, to the best of our knowledge, PBIL or cGA have never been identified as a natural gradient ascent in the literature[9]. For Gaussian distributions, algorithms of the same form (17) had been developed previously (Hansen and Ostermeier, 2001; Wierstra et al., 2008) and their close relationship with a natural gradient ascent had been recognized (Akimoto et al., 2010; Glasmachers et al., 2010). These works, however, also strongly suggest that IGO algorithms may need to be complemented with further heuristics to achieve efficient optimization algorithms. In particular, learning rate settings and diversity control (step-size) deviate from the original framework. These deviations mostly stem from time discretization and the choice of a finite sample size, both necessary to derive an IGO *algorithm* from the IGO *flow*. Further work is needed to fully understand this from a theoretical viewpoint.

The wide applicability of natural gradient approaches seems not to be widely known in the optimization community (though see Malagò et al. 2008).

A.2 About Invariance

The role of invariance is two-fold. First, invariance breaks otherwise arbitrary choices in the algorithm design. Second, and more importantly, invariance implies generalization of behavior from single problem instances to entire problem classes (with the caveat to choose the initial state of the algorithm accordingly), thereby making the outcome of optimization more predictable.

Optimization problems faced in reality—and algorithms used in practice—are often far too complex to be amenable to a rigorous mathematical analysis. Consequently, the judgement of algorithms in practice is to a large extent based in empirical observations, either on artificial benchmarks or on the experience with real-world problems. Invariance, as a guarantee of generalization, has an immediate impact on the relevance of any such empirical observations and, in the same line of reasoning, can be interpreted as a notion of robustness.

A.3 About Quantiles

The IGO flow in (8) has, to the best of our knowledge, never been defined before. The introduction of the quantile-rewriting (5) of the objective function provides the first rigorous

9. Thanks to Jonathan Shapiro for giving an early argument confirming this property (personal communication).

derivation of quantile- or rank- or comparison-based optimization from a gradient ascent in θ-space.

NES and CMA-ES have been claimed to maximize $-\mathbb{E}_{P_\theta} f$ via natural gradient ascent (Wierstra et al., 2008; Akimoto et al., 2010). However, we have proved that the NES and CMA-ES updates actually converge to the IGO flow, not to the similar flow with the gradient of $\mathbb{E}_{P_\theta} f$ (Theorem 6). So we find that in reality these algorithms maximize $\mathbb{E}_{P_\theta} W^f_{\theta^t}$, where $W^f_{\theta^t}$ is a decreasing transformation of the f-quantiles under the current sample distribution.

Moreover, in practice, maximizing $-\mathbb{E}_{P_\theta} f$ tends to be a rather unstable procedure and has been discouraged, see for example Whitley (1989) and Sun et al. (2009).

A.4 About Choice of P_θ: Learning a Model of Good Points

The choice of the family of probability distributions P_θ plays a double role.

First, it is analogous to choosing the variation operators (namely *mutation* or *recombination*) as seen in evolutionary algorithms: indeed, P_θ encodes possible moves according to which new sample points are explored.

Second, optimization algorithms using distributions can be interpreted as learning a probabilistic model of where the points with good values lie in the search space. With this point of view, P_θ describes *richness of this model*: for instance, restricted Boltzmann machines with h hidden units can describe distributions with up to 2^h modes, whereas the Bernoulli distribution is unimodal. This influences, for instance, the ability to explore several valleys and optimize multimodal functions in a single run.

More generally, the IGO framework makes it tempting to use more complex models of where good points lie, inspired, e.g., from machine learning, and adapt them for optimization. The restricted Boltzmann machines of Appendix B are a first step in this direction. The initial idea behind these machines is that each hidden unit controls a block of coordinates of the search space (a block of features), so that the optimization algorithm hopefully builds a good model of which features must be activated or de-activated together to obtain good values of f. This is somewhat reminiscent of a crossover operator: if observation of good points shows that a block of features go together, this information is stored in the RBM structure and this block may be later activated as a whole, thus effectively transferring blocks of features from one good solution to another. Inspired by models of deep learning (Bengio et al., 2012), one might be tempted to stack such models on top of each other, so that optimization would operate on a more and more abstract representation of the problem. IGO and the natural gradient might help in exploiting the added expressivity that comes with richer models: in our simple experiment, the vanilla gradient ignores the additional expressivity of RBMs with respect to Bernoulli distributions (Appendix B). The downside of a richer model is that either the sample size N must be increased or the learning rate δt must be decreased to obtain a stable algorithm (a situation analogous to overfitting in machine learning: richer models will be quicker to concentrate too much around a few observed good samples).

A.5 Natural Gradient and Parametrization Invariance

Central to IGO is the use of the natural gradient, which follows from θ-invariance (parametrization invariance) and makes sense on any search space, discrete or continuous.

While the IGO flow is exactly θ-invariant, for any practical implementation of an IGO algorithm, a parametrization choice has to be made. Different parametrizations lead to different algorithms and larger values of δt are likely to result in more differing algorithms. Still, since all IGO algorithms approximate the IGO flow, two parametrizations in combination with IGO will differ less than the same two parametrizations in combination with another algorithm (such as the vanilla gradient or the smoothed CEM method)—at least if the learning rate δt is not too large. The chosen parametrization becomes more relevant as the step size δt increases.

On the other hand, natural evolution strategies have not emphasized θ-invariance: the chosen parametrization (Cholesky, exponential) has been considered as a defining feature. We believe the term "natural evolution strategy" should rather be used independently of the chosen parameterization, thereby referring to the usage of the natural gradient as the main principle for the update of distribution parameters.

A.6 IGO, Maximum Likelihood and Cross-Entropy

The cross-entropy method (CEM, de Boer et al. 2005) can be used to produce optimization algorithms given a family of probability distributions on an arbitrary space, by performing a jump to a maximum likelihood estimate of the parameters.

We have seen (Corollary 13) that the standard CEM is an IGO algorithm *in a particular parametrization*, with a learning rate δt equal to 1. However, it is well-known, both theoretically and experimentally (Branke et al., 2007; Hansen, 2006b; Wagner et al., 2004), that standard CEM loses diversity too fast in many situations. The usual solution (de Boer et al., 2005) is to reduce the learning rate (smoothed CEM, Equation 32), but this breaks the reparametrization invariance of non-smoothed CEM.

On the other hand, the IGO flow can be seen as a *maximum likelihood update with infinitesimal learning rate* (Theorem 10). This interpretation allows to define a particular IGO algorithm, the IGO-ML (Definition 11): it performs a maximum likelihood update with an arbitrary learning rate, and keeps the reparametrization invariance. It coincides with CEM when the learning rate is set to 1, but it differs from smoothed CEM by the exchange of the order of argmax and averaging (compare Equations 30 and 32), and coincides with the IGO flow for small learning rates. We argue that this new, fully invariant algorithm is the conceptually better way to reduce the learning rate and achieve smoothing in CEM.

Standard CEM with rate 1 can lose diversity, yet is a particular case of an IGO algorithm: this illustrates the fact that reasonable values of the learning rate δt depend on the parametrization. We have studied this phenomenon in detail for various Gaussian IGO algorithms (Section 5.2).

Why would a smaller learning rate perform better than a large one in an optimization setting? It might seem more efficient to jump directly to the maximum likelihood estimate of currently known good points, instead of performing an iterated gradient ascent towards this maximum. Due to having only a limited number of samples, however, optimization faces a "moving target", contrary to a learning setting in which the example distribution is often stationary. Currently known good points heavily depend on the current distribution and are likely not to indicate the *position* at which the optimum lies, but, rather, the broad

direction in which the optimum is to be found. After each update, the next elite sample points are going to be located somewhere new.

A.7 Diversity and Multiple Optima

The IGO framework emphasizes the relation of natural gradient and diversity: we argued that IGO provides minimal diversity change for a given objective function improvement. In particular, provided the initial diversity is large, diversity is kept at a maximum after the upate. This theoretical relationship can be observed experimentally for restricted Boltzmann machines (Appendix B).

On the other hand, using the vanilla gradient does not lead to a balanced distribution between the two optima in our experiments. Using the vanilla gradient introduces hidden arbitrary choices between those points (more exactly between moves in Θ-space). This results in unnecessary and unwelcome loss of diversity, and might also be detrimental at later stages in the optimization. This may reflect the fact that the Euclidean metric on the space of parameters, implicitly used in the vanilla gradient, becomes less and less meaningful for gradient descent on complex distributions.

IGO and the natural gradient are certainly relevant to the well-known problem of exploration-exploitation balance: as we have seen, arguably the natural gradient realizes the largest improvement in the objective with the least possible change of diversity in the distribution.

More generally, like other distribution-based optimization algorithms, IGO tries to learn a model of where the good points are. This is typical of machine learning, one of the contexts for which the natural gradient was studied. The conceptual relationship of IGO and IGO-like optimization algorithms with machine learning is still to be explored and exploited.

We now present some ideas which we believe would be worth exploring.

A.8 Adaptive Learning Rate

Comparing consecutive updates to evaluate a learning rate or step size is an effective measure. For example, in back-propagation, the update sign has been used to adapt the learning rate of each single weight in an artificial neural network (Silva and Almeida, 1990). In CMA-ES, a step size is adapted depending on whether recent steps tended to move in a consistent direction or to backtrack. This is measured by considering the changes of the mean m of the Gaussian distribution.

For a probability distribution P_θ on an arbitrary search space, in general no notion of mean may be defined. However, it is still possible to define "backtracking" in the evolution of θ as follows.

Consider two successive updates $\delta\theta^t = \theta^t - \theta^{t-\delta t}$ and $\delta\theta^{t+\delta t} = \theta^{t+\delta t} - \theta^t$. Their scalar product in the Fisher metric $I(\theta^t)$ is

$$\langle \delta\theta^t, \delta\theta^{t+\delta t} \rangle = \sum_{ij} I_{ij}(\theta^t)\, \delta\theta^t_i\, \delta\theta^{t+\delta t}_j \quad .$$

Dividing by the associated norms will yield the cosine $\cos\alpha$ of the angle between $\delta\theta^t$ and $\delta\theta^{t+\delta t}$.

If this cosine is positive, the learning rate δt may be increased. If the cosine is negative, the learning rate probably needs to be decreased. Various schemes for the change of δt can be devised; for instance, inspired by step size updates commonly used in evolution strategies, one can multiply δt by $\exp(\beta(\cos\alpha))$ or $\exp(\beta\,\mathrm{sign}(\cos\alpha))$, where $\beta \approx \min(N/\dim\Theta, 1/2)$. As this cosine can be quite noisy, cumulation over several time steps might be advisable.

As before, this scheme is constructed to be robust w.r.t. reparametrization of θ, thanks to the use of the Fisher metric. However, for large learning rates δt, in practice the parametrization might well become relevant.

A.9 Geodesic Parametrization

While the IGO flow is fully invariant under θ-reparametrization, an IGO algorithm does depend on the choice of parametrization for θ, even if for small δt the difference between two IGO algorithms is $O(\delta t^2)$, one order of magnitude smaller than between IGO and vanilla gradient in general.

So one can wonder how to discretize time in the IGO flow in a fully intrinsic way, not depending at all on a parametrization for θ. A first possibility is given by the IGO-ML algorithm (Definition 11)—this means, for exponential families, that we can decide to single out the parametrization by expectation parameters.

Another, more geometric solution is to use *geodesics* on the statistical manifold. This means we approximate the trajectories of the IGO flow by successive geodesic segments of length δt in the Fisher metric, where the initial direction of each segment is given by the direction of the IGO flow (16). This defines an approximation to the IGO flow that depends on the step size δt and sample size N, but *not* on any choice of parametrization. This approach is fully developed in Bensadon (2015).

A.10 Finite Sample Size and Noisy IGO Flow

The IGO flow is an ideal model of the IGO algorithms. But the IGO flow is deterministic while IGO algorithms are stochastic, depending on a finite number N of random samples. This might result in important differences in their behavior and one can wonder if there is a way to reflect stochasticity directly in the definition of the IGO flow.

The IGO update (16) is a stochastic update

$$\theta^{t+\delta t} = \theta^t + \delta t \sum_{i=1}^{N} \widehat{w}_i\ \widetilde{\nabla}_\theta \ln P_\theta(x_i)\Big|_{\theta=\theta^t}$$

because the term $\sum_{i=1}^N \widehat{w}_i\ \widetilde{\nabla}_\theta \ln P_\theta(x_i)\Big|_{\theta=\theta^t}$ involves a random sample. As such, this term has an expectation and a variance. So for a fixed N and δt, this random update is a weak approximation with step size δt (Kloeden and Platen, 1992, Chapter 9.7) of a stochastic differential equation on θ, whose drift is the expectation of the IGO update (which tends to the IGO flow when $N \to \infty$), and whose noise term is $\sqrt{\delta t}$ times the square root of the covariance matrix of the update applied to a normal random vector.

Such a stochastic differential equation, defining a *noisy IGO flow*, might be a better theoretical object with which to compare the actual behavior of IGO algorithms, than the ideal noiseless IGO flow.

For instance, this strongly suggests that if we have $\delta t \to 0$ while N is kept fixed in an IGO algorithm, noise will disappear (compare Remark 2 in Akimoto et al. 2012).

Second, for large N, one expects the variance of the IGO update to scale like $1/N$, so that the noise term will scale like $\sqrt{\delta t/N}$. This formally suggests that, within reasonable bounds, multiplying or dividing both N and δt by the same factor should result in similar behavior of the algorithm, so that for instance it should be reasonable to reset δt to $10\delta t/N$ and N to 10. (Note that the cost in terms of f-calls of these two algorithms is similar.)

This dependency is reflected in evolution strategies in several ways, provided N is smaller than the search space dimension. First, theoretical results for large search space dimension on the sphere function, $f(x) = \|x\|^2$, indicate that the optimal step size δt for the mean vector is proportional to N, provided the weighting function w is either truncation selection with a fixed truncation ratio (Beyer, 2001) or optimal weights (Arnold, 2006). Second, the learning rate δt of the covariance matrix in CMA-ES is chosen proportional to $\left(\sum_{i=1}^N \widehat{w}_i\right)^2 / \sum_{i=1}^N \widehat{w}_i^2$ which is again proportional to N (Hansen and Kern, 2004). For small enough N, the progress per f-call is then in both cases rather independent of the choice of N.

These results suggest that in implementations, N can be chosen rather freely, whereas δt will be set to $\text{const} \cdot N$. The constant is chosen small enough to ensure stability, but as large as possible to maximize speed; still, $\delta t \leq 1$ is another constraint for (very) large N.

A.11 Influence of the Fisher Geometry of the Statistical Manifold

The global Riemannian geometry of the statistical manifold P_θ might have a bearing on the behavior of stochastic algorithms exploring this manifold. For instance, the Fisher metric identifies the set of 1-dimensional normal distributions $\mathcal{N}(m, \sigma^2)$ with the two-dimensional hyperbolic plane. The latter has negative curvature. The sign of curvature has a strong influence on the behavior of random walks in a Riemannian manifold: in particular, in negative curvature, successive random errors tend to not compensate as much as in the Euclidean case (because geodesics diverge more quickly); this might be relevant to the settings of a stochastic optimization algorithm, suggesting to use larger sample size or smaller steps when curvature is negative; Bensadon (2015) provides first observations in this direction, associated with negative curvature in the space of Gaussians. This is speculative and remains to be explored.

Appendix B. Implementing an IGO Algorithm with a New Family of Probability Distributions: Restricted Boltzmann Machines

In this appendix we show how to apply IGO to restricted Boltzmann machines (RBMs, Smolensky 1986; Ackley et al. 1985), a family of probability distributions on the discrete hypercube that extends Bernoulli distributions and can represent correlations between variables.

This first illustrates how to set up an IGO algorithm from a family of probability distributions for which no fully explicit expression for the Fisher information matrix is available.

Second, we test the relationship between IGO and diversity of p_θ, in view of the entropy-maximizing property of the IGO flow (Proposition 2). We consider a simple function with

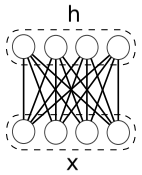

Figure 2: The RBM architecture with the observed ($\mathbf{x}$) and latent ($\mathbf{h}$) variables. In our experiments, a single hidden unit was used.

two optima, and compare the behavior of the IGO flow with that of a vanilla gradient flow. The latter always converges to a single optimum, even though RBMs allow for multimodal distributions. On the other hand, IGO seems to always converge to both optima at once, taking advantage of RBM multimodality.

Finally we interpret this observations by pointing out a non-obvious breach of symmetry between 0 and 1 on $\{0,1\}^d$ for the vanilla gradient of RBMs; the natural gradient automatically compensates for this.

B.1 Restricted Boltzmann Machines.

RBMs first define a joint distribution on $\mathbf{x} \in \{0,1\}^d$ together with a *hidden* or *latent* variable $\mathbf{h} \in \{0,1\}^{d_h}$ (Ghahramani, 2004). Summation over $\mathbf{h}$ provides the distribution over $\mathbf{x}$. The probability associated with an observation $\mathbf{x} = (x_i) \in \{0,1\}^d$ and latent variable $\mathbf{h} = (h_j) \in \{0,1\}^{d_h}$ is

$$P_\theta(\mathbf{x}, \mathbf{h}) = \frac{e^{-E(\mathbf{x},\mathbf{h})}}{\sum_{\mathbf{x}',\mathbf{h}'} e^{-E(\mathbf{x}',\mathbf{h}')}}\,, \qquad P_\theta(\mathbf{x}) = \sum_{\mathbf{h}} P_\theta(\mathbf{x}, \mathbf{h}), \tag{51}$$

where the *energy function* E is

$$E(\mathbf{x}, \mathbf{h}) = -\sum_i a_i x_i - \sum_j b_j h_j - \sum_{i,j} w_{ij} x_i h_j \tag{52}$$

(compare Section 3.3). The distribution is parametrized by $\theta = (\mathbf{a}, \mathbf{b}, \mathbf{w})$. The "biases" $\mathbf{a}$ and $\mathbf{b}$ can be subsumed into the weights $\mathbf{w}$ by introducing variables x_0 and h_0 always equal to one, which we implicitly do from now on.

The hidden variable $\mathbf{h}$ introduces correlations between the components of $\mathbf{x}$ (see Figure 2). For instance, with $d_h = 1$, the distribution on $\mathbf{x}$ is the sum of two Bernoulli distributions with $\mathbf{h}$ acting as a "switch".

B.2 IGO for RBMs.

RBMs constitute an exponential family with latent variables (with the statistics $T(\mathbf{x}, \mathbf{h})$ being all the $x_i h_j$). So the IGO flow (10) is given by (25) where the first contribution is the Fisher matrix (24) and the second contribution is the log-probability derivatives weighted

by the objective function values. However, these expressions are not explicit due to the expectations under P_θ. Still, these expectations can be replaced with Monte Carlo sampling; this is what we will do.

Actually, when applying IGO to such distributions to optimize an objective function $f(\mathbf{x})$, we have two choices. The first is to see the objective function $f(\mathbf{x})$ as a function of $(\mathbf{x}, \mathbf{h})$ where $\mathbf{h}$ is a dummy variable; then we can use the IGO algorithm to optimize over $(\mathbf{x}, \mathbf{h})$ using the distributions $P_\theta(\mathbf{x}, \mathbf{h})$. A second possibility is to marginalize $P_\theta(\mathbf{x}, \mathbf{h})$ over the hidden units $\mathbf{h}$ as in (51), to define the distribution $P_\theta(\mathbf{x})$; then we can use the IGO algorithm to optimize f over $\mathbf{x}$ using $P_\theta(\mathbf{x})$.

These two approaches yield slightly different algorithms. The Fisher matrix for the distributions $P_\theta(\mathbf{x}, \mathbf{h})$ is given by (20) (exponential families) whereas the one for the distributions $P_\theta(\mathbf{x})$ is given by (24) (exponential families with latent variables). For instance, with $I_{w_{ij} w_{i'j'}}$ denoting the entry of the Fisher matrix corresponding to the components w_{ij} and $w_{i'j'}$ of the parameter θ, from (20) we get

$$I_{w_{ij} w_{i'j'}}(\theta) = \mathrm{Cov}_{P_\theta}(x_i h_j, x_{i'} h_{j'}) = \mathbb{E}_{P_\theta}[x_i h_j x_{i'} h_{j'}] - \mathbb{E}_{P_\theta}[x_i h_j] \, \mathbb{E}_{P_\theta}[x_{i'} h_{j'}] \tag{53}$$

whereas from (24) we get the same expression in which each h_j is replaced with its expectation $\bar{h}_j$ knowing $\mathbf{x}$ namely $\bar{h}_j = \mathbb{E}_{P_\theta}[h_j|\mathbf{x}] = \left(1 + e^{-b_j - \sum_i x_i w_{ij}}\right)^{-1}$ and likewise for $h_{j'}$.

Both versions were tested on a small instance and found to be viable. However the version using $(\mathbf{x}, \mathbf{h})$ is numerically more stable and requires fewer samples to get a reliable (in particular, invertible) estimate of the Fisher matrix, both in practice and theory[10]. For this reason we selected the first approach: we optimize f as a function of $(\mathbf{x}, \mathbf{h})$ using IGO for the probability distributions $P_\theta(\mathbf{x}, \mathbf{h})$.

A practical IGO update is thus obtained from (21) by replacing the expectations with Monte Carlo samples $(\mathbf{x}, \mathbf{h})$ from P_θ. A host of strategies are available to sample from RBMs (Ackley et al., 1985; Salakhutdinov and Murray, 2008; Salakhutdinov, 2009; Desjardins et al., 2010); we simply used Gibbs sampling (Hinton., 2002). So the IGO update reads

$$\theta^{t+\delta t} = \theta^t + \delta t \, \widehat{\mathrm{Cov}}(T, T)^{-1} \, \widehat{\mathrm{Cov}}(T, W^f_{\theta^t}) \tag{54}$$

where T denotes the vector of all statistics $T_{ij}(\mathbf{x}, \mathbf{h}) = x_i h_j$ corresponding to the component w_{ij} of the parameter θ, and where $\widehat{\mathrm{Cov}}$ denotes the empirical covariance over a set of Monte Carlo samples $(\mathbf{x}, \mathbf{h})$ taken from $P_{\theta^t}(\mathbf{x}, \mathbf{h})$. Thus $\hat{I} = \widehat{\mathrm{Cov}}(T, T)$ is the estimated Fisher matrix, a matrix of size $\dim(\theta)^2$ as in (53). $\widehat{\mathrm{Cov}}(T, W^f_{\theta^t})$ is a vector of size $\dim(\theta)$ giving the correlation, in the Monte Carlo sample, between the statistics T_{ij} and the ranked values $W^f_{\theta^t}$ of the objective function of the points $(\mathbf{x}, \mathbf{h})$ in the sample: this vector is the sum of weighted log-probability derivatives in the IGO update (17), thanks to (19).

Different sample sizes N_{Fish} and N can be used to evaluate $\widehat{\mathrm{Cov}}(T, T)$ and $\widehat{\mathrm{Cov}}(T, W^f_{\theta^t})$. The sample size for $\widehat{\mathrm{Cov}}(T, W^f_{\theta^t})$ is just the IGO parameter N, the number of points on which the objective function has to be evaluated; it is typically kept small especially if f is costly. On the other hand it is important to obtain a reliable (in particular, invertible) estimate of the Fisher matrix: invertibility requires a number of samples at least, and ideally much larger than, $\dim(\theta)$, because each point in the sample contributes a rank-1 term to the empirical covariance matrix $\widehat{\mathrm{Cov}}(T, T)$. Increasing N_{Fish} does not require additional f-calls.

10. Indeed, if $I_1(\theta)$ is the Fisher matrix at θ in the first approach and $I_2(\theta)$ in the second approach, we always have $I_1(\theta) \geqslant I_2(\theta)$ in the sense of positive-definite matrices. This is because probability distributions on the pair $(\mathbf{x}, \mathbf{h})$ carry more information than their projections on $\mathbf{x}$ only, and so the Kullback–Leibler distances will always be larger. In particular, there exist values of θ for which the Fisher matrix I_2 is not invertible whereas I_1 is.

B.3 An Experiment with Two Optima: IGO, Diversity, and Multimodal Optimization.

We tested the resulting IGO trajectories on a simple objective function with two optima on $\{0, 1\}^d$, namely, the *two-min function based at* $\mathbf{y}$ defined as

$$f_{\mathbf{y}}(\mathbf{x}) = \min\left(\sum_i |x_i - y_i| \, , \sum_i |(1 - x_i) - y_i|\right) \tag{55}$$

which, as a function of $\mathbf{x}$, has two optima, one at $\mathbf{x} = \mathbf{y}$ and the other at its binary complement $\mathbf{x} = \bar{\mathbf{y}}$. The value of the base point $\mathbf{y}$ was randomized for each independent run.

We ran both the IGO algorithm as described above, and a version using the vanilla gradient instead of the natural gradient (that is, omitting the Fisher matrix in the IGO update).

The dimension was $d = 40$ and we used an RBM with only one latent variable ($d_h = 1$). Therefore $\dim(\theta) = 81$. We used a large sample size of $N = 10,000$ for Monte Carlo sampling, so as to be close to the theoretical IGO flow behavior. We also tested a smaller, more realistic sample size of $N = 10$ (still keeping $N_{\text{Fish}} = 10,000$), with similar but noisier results. The selection scheme (Section 2.2) was $w(q) = \mathbb{1}_{q \leqslant 1/5}$ (cf. Rechenberg 1994) so that the best 20% points in the sample are given weight 1 for the update.

The RBM was initialized so that at startup, the distribution P_{θ^0} is close to uniform on $(\mathbf{x}, \mathbf{h})$, in line with Proposition 2. Explicitly we set $w_{ij} \leftarrow \mathcal{N}(0, \frac{1}{d.d_h})$ and then $b_j \leftarrow -\sum_i \frac{w_{ij}}{2}$ and $a_i \leftarrow -\sum_j \frac{w_{ij}}{2} + \mathcal{N}(0, \frac{0.01}{d^2})$ which ensure a close-to-uniform initial distribution.

Full experimental details, including detailed setup and additional results, can be found in a previous version of this article (Ollivier et al., 2011, Section 5). (In particular, IGO runs are frozen when the estimated Fisher matrix becomes singular or unreliable.) The code used for these experiments can be found at `http://www.ludovicarnold.com/projects:igocode` .

The results show that, most of the time, with IGO the distribution P_{θ^t} converges to a distribution giving positive mass to both optima; on the other hand, over 300 independent runs, the same algorithm using the vanilla gradient only converges to one optimum at the expense at the other, so that the vanilla gradient *never* exploited the possibility offered by the RBM to create a bimodal probability distribution on $\{0, 1\}^d$. Figure 3 shows ten random runs (out of 300 in our experiments) of the two algorithms: for each of the two optima we plot its distance to the nearest of the points drawn from P_{θ^t}, as a function of time t.[11]

11. Note that the value of δt is not directly comparable between the natural and vanilla gradients. Theory suggests that at startup the IGO trajectory with δt is most comparable to the vanilla gradient trajectory with $4\delta t$, because from (53) most of the diagonal terms of the Fisher matrix are equal to $1/4$ and most off-diagonal terms are 0 at startup. The experiments confirm that this yields roughly comparable convergence speeds.

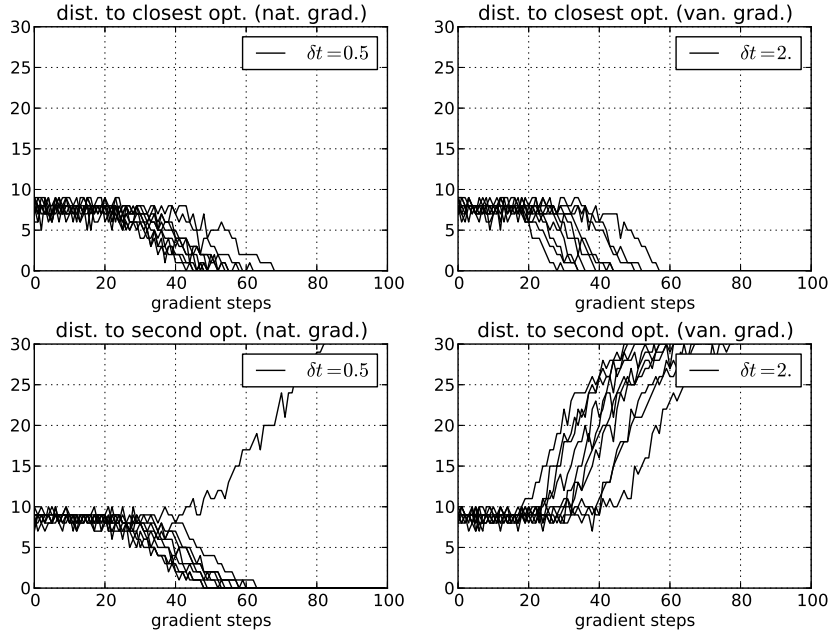

Figure 3: Distance to the two optima during 10 IGO optimization runs and 10 vanilla gradient runs. For each optimum, we plot its distance to the nearest point among the samples from P_{θ^t} found at each step.

This is even clearer when looking at the hidden variable $\mathbf{h}$. With $d_h = 1$ the two possible values $h = 0$ and $h = 1$ can create a sum of two Bernoulli distributions on $\mathbf{x}$. Figure 4 plots the average value of h in the sample for IGO and for the vanilla gradient. As can be seen, over IGO optimization the balance between the two modes is preserved, whereas using vanilla gradient optimization the zero mode is lost.

We interpret this as an illustration of Proposition 2: for a given improvement on the objective function, IGO will favor preserving the diversity (entropy) of P_θ. Using more richly multimodal distributions (e.g., RBMs with $d_h > 1$), this might be useful for multimodal optimization or for optimization situations in which there are several almost equally deep valleys only one of which contains the true optimum.

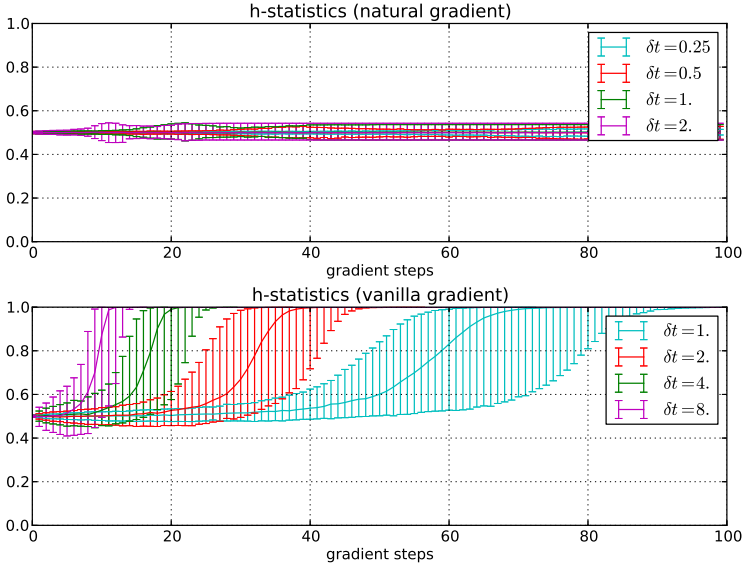

Figure 4: Median over 300 runs of the average of h in the sample, for IGO and vanilla gradient optimization. Error bars indicate the 16th and 84th quantile over the runs.

B.4 Breach of Symmetry by the Vanilla Gradient.

This experiment reveals that, curiously, the vanilla gradient loses multimodality by always setting the hidden variable h to 1, not to 0 (Figure 4). So the vanilla gradient for RBMs seems to favor $h = 1$.

Of course, exchanging the values 0 and 1 for the hidden variables in a restricted Boltzmann machine still gives a distribution of another Boltzmann machine. Changing h_j into $1 - h_j$ is equivalent to resetting $a_i \leftarrow a_i + w_{ij}$, $b_j \leftarrow -b_j$, and $w_{ij} \leftarrow -w_{ij}$.

IGO and the natural gradient are impervious to such a change by Proposition 19. But the vanilla gradient implicitly relies on the Euclidean norm on parameter space, as explained in Section 2.1. For this norm, the distance between the RBM distributions (a_i, b_j, w_{ij}) and (a'_i, b'_j, w'_{ij}) is $\sum_i |a_i - a'_i|^2 + \sum_j \left|b_j - b'_j\right|^2 + \sum_{ij} \left|w_{ij} - w'_{ij}\right|^2$. However, the change of variables $a_i \leftarrow a_i + w_{ij}$, $b_j \leftarrow -b_j$, $w_{ij} \leftarrow -w_{ij}$ does *not* preserve this Euclidean metric. Thus, exchanging 0 and 1 for the hidden variables will result in two different vanilla gradient ascents. The observed asymmetry on h is a consequence of this implicit asymmetry.

Of course it is possible to use parametrizations for which the vanilla gradient will be more symmetric: for instance, using $-1/1$ instead of $0/1$ for the variables, or rewriting the

energy as

$$E(\mathbf{x},\mathbf{h}) = -\sum_i A_i(x_i - \tfrac{1}{2}) - \sum_j B_j(h_j - \tfrac{1}{2}) - \sum_{i,j} W_{ij}(x_i - \tfrac{1}{2})(h_j - \tfrac{1}{2}) \qquad (56)$$

with "bias-free" parameters A_i, B_j, W_{ij} related to the usual parametrization by $w_{ij} = W_{ij}$, $a_i = A_i - \frac{1}{2}\sum_j w_{ij}$, and $b_j = B_j - \frac{1}{2}\sum_i w_{ij}$. The vanilla gradient might perform better in this parametrization.

However, we adopted the approach of using a family of probability distributions found in the literature, with the parametrization commonly found in the literature. We then used the vanilla gradient and the natural gradient on these distributions—and indeed the vanilla gradient, or an approximation thereof, is routinely applied to RBMs in the literature to optimize the log-likelihood of data (Hinton., 2002; Hinton et al., 2006; Bengio et al., 2007). It was not obvious a priori (at least for us) that the vanilla gradient ascent favors $h = 1$. Since the first version of this article was written, this phenomenon has been recognized for Boltzmann machines (Montavon and Müller, 2012).

This directly illustrates the specific influence of the chosen gradient (the two implementations only differ by the inclusion of the Fisher matrix): the natural gradient offers a systematic way to recover symmetry from a non-symmetric gradient update.

Symmetry alone does not explain why IGO reaches the two optima simultaneously: a symmetry-preserving stochastic algorithm could as well end up on either single optimum with 50% probability in each run. The diversity-preserving property of IGO (Proposition 2) offers a reasonable interpretation of why this does not happen.

Appendix C. Further Mathematical Properties of the IGO Flow

This appendix provides further mathematical properties of the IGO flow in general and in specific scenarios.

C.1 Invariance Properties

Here we formally state the invariance properties of the IGO flow under various reparametrizations. Since these results follow from the very construction of the algorithm, the proofs are omitted.

Proposition 17 (f-invariance) *Let $\varphi : \mathbb{R} \to \mathbb{R}$ be a strictly increasing function. Then the trajectories of the IGO flow when optimizing the functions f and $\varphi(f)$ are the same.*

The same is true for the discretized algorithm with population size N and step size $\delta t > 0$.

Proposition 18 (θ-invariance) *Let $\theta' = \varphi(\theta)$ be a smooth bijective function of θ and let $P'_{\theta'} = P_{\varphi^{-1}(\theta')}$. Let θ^t be the trajectory of the IGO flow when optimizing a function f using the distributions P_θ, initialized at θ^0. Then the IGO flow trajectory $(\theta')^t$ obtained from the optimization of the function f using the distributions $P'_{\theta'}$, initialized at $(\theta')^0 = \varphi(\theta^0)$, is the same, namely $(\theta')^t = \varphi(\theta^t)$.*

For the algorithm with finite N and $\delta t > 0$, invariance under reparametrization of θ is only true approximately, in the limit when $\delta t \to 0$. As mentioned above, the IGO update

(17), with $N = \infty$, is simply the Euler approximation scheme for the ordinary differential equation (8) defining the IGO flow. At each step, the Euler scheme is known to make an error $O(\delta t^2)$ with respect to the true flow. This error actually depends on the parametrization of θ.

So the IGO updates for different parametrizations coincide at first order in δt, and may, in general, differ by $O(\delta t^2)$. For instance the difference between the CMA-ES and xNES updates is indeed $O(\delta t^2)$, see Section 5.2.

For comparison, using the vanilla gradient results in a divergence of $O(\delta t)$ at each step between different parametrizations, so this divergence could be of the same magnitude as the steps themselves.

In that sense, one can say that IGO algorithms are "more parametrization-invariant" than other algorithms. This stems from their origin as a discretization of the IGO flow.

However, if the map φ is affine then this phenomenon disappears: parametrizations that differ by an affine map on θ yield the same IGO algorithm.

The next proposition states that, for example, if one uses a family of distributions on $\mathbb{R}^d$ which is invariant under affine transformations, then IGO algorithms optimize equally well a function and its image under any affine transformation (up to an obvious change in the initialization). This proposition generalizes the well-known corresponding property of CMA-ES (Hansen and Auger, 2014, Proposition 9).

This invariance under X-transformations only holds provided the X-transformation preserves the "shape" of the family of probability distributions P_θ, as follows.

Let us define, as usual, the image (*pushforward*) of a probability distribution P by a transformation $\varphi : X \to X$ as the probability distribution P' such that $P'(Y) = P(\varphi^{-1}(Y))$ for any subset $Y \subset X$ (Schilling, 2005, Chapter 7). In the continuous domain, the density of the new distribution P' is obtained by the usual change of variable formula involving the Jacobian of φ (Schilling, 2005, Chapter 15).

We say that a transformation $\varphi : X \to X$ *globally preserves* a family of probability distributions (P_θ), if the image of any P_θ by φ is equal to some distribution $P_{\theta'}$ in the same family, and if moreover the correspondence $\theta \mapsto \theta'$ is locally a diffeomorphism.

Proposition 19 (X-invariance) *Let $\varphi : X \to X$ be a one-to-one transformation of the search space which globally preserves the family of measures P_θ. Let θ^t be the IGO flow trajectory for the optimization of function f, initialized at P_{θ^0}. Let $(\theta')^t$ be the IGO flow trajectory for optimization of $f \circ \varphi^{-1}$, initialized at the image of P_{θ^0} by φ. Then $P_{(\theta')^t}$ is the image of P_{θ^t} by φ.*

For the discretized algorithm with population size N and step size $\delta t > 0$, the same is true up to an error of $O(\delta t^2)$ per iteration. This error disappears if the action of the map φ on Θ by pushforward is affine.

The latter case of affine transforms is well exemplified by CMA-ES: here, using the variance and mean as the parametrization of Gaussians, the new mean and variance after an affine transform of the search space are an affine function of the old mean and variance; specifically, for the affine transformation $A : x \mapsto Ax + b$ we have $(m, C) \mapsto (Am + b, ACA^\mathsf{T})$. Another example, on the discrete search space $X = \{0,1\}^d$, is the exchange of 0 and 1: for reasonable choices of the family P_θ, the IGO flow and IGO algorithms will be invariant under such a change in the way the data is presented.

C.2 Speed of the IGO Flow

Proposition 20 *The speed of the IGO flow, i.e. the norm of $\frac{\mathrm{d}\theta^t}{\mathrm{d}t}$ in the Fisher metric, is at most $\sqrt{\int_0^1 w^2 - (\int_0^1 w)^2}$ where w is the selection scheme.*

The proof is given in Appendix D.

A bounded speed means that the IGO flow will not explode in finite time, or go out-of-domain if the Fisher metric on the statistical manifold Θ is complete (for instance, the IGO flow on Gaussian distributions will not yield non-positive or degenerate covariance matrices). Due to the approximation terms $O(\delta t^2)$, this may not be true of IGO algorithms.

This speed can be monitored in practice in at least two ways. The first is just to compute the Fisher norm of the increment $\theta^{t+\delta t} - \theta^t$ using the Fisher matrix; for small δt this is close to $\delta t \| \frac{\mathrm{d}\theta}{\mathrm{d}t} \|$ with $\| \cdot \|$ the Fisher metric. The second is as follows: since the Fisher metric coincides with the Kullback–Leibler divergence up to a factor $1/2$, we have $\mathrm{KL}(P_{\theta^{t+\delta t}} \,\|\, P_{\theta^t}) \approx \frac{1}{2} \delta t^2 \| \frac{\mathrm{d}\theta}{\mathrm{d}t} \|^2$ at least for small δt. Since it is relatively easy to estimate $\mathrm{KL}(P_{\theta^{t+\delta t}} \,\|\, P_{\theta^t})$ by comparing the new and old log-likelihoods of points in a Monte Carlo sample, one can obtain an estimate of $\| \frac{\mathrm{d}\theta}{\mathrm{d}t} \|$.

Corollary 21 *Consider an IGO algorithm with selection scheme w, step size δt and sample size N. Then, with probability* 1*,*

$$\frac{\mathrm{KL}(P_{\theta^{t+\delta t}} \,\|\, P_{\theta^t})}{\delta t^2} \leqslant \frac{1}{2} \mathrm{Var}_{[0,1]}\, w + o(1)_{(\delta t, N) \to (0,\infty)} \ .$$

For instance, with $w(q) = \mathbb{1}_{q \leqslant q_0}$ and neglecting the error terms, an IGO algorithm introduces at most $\frac{1}{2} \delta t^2\, q_0 (1 - q_0)$ bits of information (in base e) per iteration into the probability distribution P_θ. The proof is given in Appendix D.

Thus, the time discretization parameter δt is not just an arbitrary variable: it has an intrinsic interpretation related to a number of bits introduced at each step of the algorithm. This kind of relationship suggests, more generally, to use the Kullback–Leibler divergence as an external and objective way to measure learning rates in those optimization algorithms which use probability distributions.

The result above is only an upper bound. Maximal speed can be achieved only if all "good" points point in the same direction. If the various good points in the sample suggest moves in inconsistent directions, then the IGO update will be much smaller. While non-consistent moves are generally to be expected if $N < \dim \Theta$, it may also be a sign that the signal is noisy, or that the family of distributions P_θ is not well suited to the problem at hand and should be enriched.

As an example, using a family of Gaussian distributions with unkown mean and fixed identity variance on $\mathbb{R}^d$, one checks that for the optimization of a linear function on $\mathbb{R}^d$, with the weight $w(u) = \mathbb{1}_{u<1/2}$, the IGO flow moves at constant speed $1/\sqrt{2\pi} \approx 0.4$, whatever the dimension d. On a rapidly varying sinusoidal function, the moving speed will be much slower because there are "good" and "bad" points in all directions.

This may suggest ways to design the selection scheme w to achieve maximal speed in some instances. Indeed, looking at the proof of the proposition, which involves a Cauchy–Schwarz inequality, one can see that the maximal speed is achieved only if there is a linear relationship

between the weights $W_\theta^f(x)$ and the gradient $\widetilde{\nabla}_\theta \ln P_\theta(x)$. For instance, for the optimization of a linear function on $\mathbb{R}^d$ using Gaussian measures of known variance, the maximal speed will be achieved when the selection scheme $w(u)$ is the inverse of the Gaussian cumulative distribution function. (In particular, $w(u)$ tends to $+\infty$ when $u \to 0$ and to $-\infty$ when $u \to 1$.) This is in accordance with known results: the expected value of the i-th order statistic of N standard Gaussian variates is the optimal $\widehat{w}_i$ value for Gaussians on the sphere function, $f(x) = \sum_i x_i^2$, where $d \to \infty$ (Beyer, 2001; Arnold, 2006). For $N \to \infty$, this order statistic converges to the inverse Gaussian cumulative distribution function.

C.3 Noisy Objective Functions

Suppose that the objective function f is non-deterministic: each time we ask for the value of f at a point $x \in X$, we get a random result. In this setting we may write the random value $f(x)$ as $f(x) = \tilde{f}(x, \omega)$ where ω is an unseen random seed, and $\tilde{f}$ is a deterministic function of x and ω. Without loss of generality, up to a change of variables we can assume that ω is uniformly distributed in $[0, 1]$.

We can still use the IGO algorithm without modification in this context. One might wonder which properties (consistency of sampling, etc.) still apply when f is not deterministic. Actually, IGO algorithms for noisy functions fit very nicely into the IGO framework: the following proposition allows to transfer any property of IGO to the case of noisy functions.

Proposition 22 (Noisy IGO) *Let f be a random function of $x \in X$, namely, $f(x) = \tilde{f}(x, \omega)$ where ω is a random variable uniformly distributed in $[0, 1]$, and $\tilde{f}$ is a deterministic function of x and ω. Then the two following algorithms coincide:*

- *The IGO algorithm* (16)*, using a family of distributions P_θ on space X, applied to the noisy function f, and where the samples are ranked according to the random observed value of f (here we assume that, for each sample, the noise ω is independent from everything else);*
- *The IGO algorithm on space $X \times [0, 1]$, using the family of distributions $\tilde{P}_\theta = P_\theta \otimes U_{[0,1]}$, applied to the deterministic function $\tilde{f}$. Here $U_{[0,1]}$ denotes the uniform law on $[0, 1]$.*

The (easy) proof is given in the Appendix D.

This proposition states that noisy optimization can be modeled as ordinary distribution-based optimization with a component of the distribution being independent of the control parameter θ. Conversely, any component of the search space in which a distribution-based optimization algorithm cannot perform selection or specialization will effectively act as a random noise on the objective function.

As a consequence of this result, all properties of IGO can be transferred to the noisy case. Consider, for instance, consistency of sampling (Theorem 6). The N-sample IGO update rule for the noisy case is identical to the non-noisy case (17):

$$\theta^{t+\delta t} = \theta^t + \delta t\, I^{-1}(\theta^t) \sum_{i=1}^{N} \widehat{w}_i \ \frac{\partial \ln P_\theta(x_i)}{\partial \theta}\bigg|_{\theta=\theta^t}$$

where each weight $\widehat{w}_i$ computed from (14) now incorporates noise from the objective function because the rank of x_i is computed on the random function, or equivalently on the deterministic function $\tilde{f}$: $\mathrm{rk}(x_i) = \#\{j, \tilde{f}(x_j, \omega_j) < \tilde{f}(x_i, \omega_i)\}$.

Consistency of sampling (Theorem 6) thus takes the following form through Proposition 22: When $N \to \infty$, the N-sample IGO update rule on the noisy function f converges with probability 1 to the update rule

$$\begin{aligned}\theta^{t+\delta t} &= \theta^t + \delta t\, \widetilde{\nabla}_\theta \int_0^1 \int W^{\tilde{f}}_{\theta^t}(x,\omega)\, P_\theta(\mathrm{d}x)\, \mathrm{d}\omega \\ &= \theta^t + \delta t\, \widetilde{\nabla}_\theta \int \bar{W}^f_{\theta^t}(x)\, P_\theta(\mathrm{d}x) \end{aligned} \tag{57}$$

where $\bar{W}^f_\theta(x) = \mathbb{E}_\omega W^{\tilde{f}}_\theta(x,\omega)$. Thus when $N \to \infty$ the update becomes deterministic as the effects of noise get averaged, as could be expected.

Thus, applying the IGO algorithm to noisy objective functions as in Proposition 22 requires defining the IGO flow for noisy objective functions as

$$\frac{\mathrm{d}\theta^t}{\mathrm{d}t} = \widetilde{\nabla}_\theta \int \bar{W}^f_{\theta^t}(x)\, P_\theta(\mathrm{d}x) \tag{58}$$

where $\bar{W}^f_\theta(x) = \mathbb{E}_\omega W^{\tilde{f}}_\theta(x,\omega)$ is the *average* weight of x over the values $f(x)$. Thus, the effects of noise remain visible even for $N \to \infty$, as $\bar{W}$ is in general flatter than W.

Note that there is another possible way to define the IGO flow for noisy objective functions. The flow (58) amounts to taking a point x, computing a (random) value $f(x)$, computing the level $q^<_\theta(x) = \Pr_{x'\sim P_\theta}(f(x') < f(x))$ of this random value $f(x)$, applying the selection scheme w, and then averaging. In this approach the value $q^<_\theta(x)$ is a random variable depending on the value of $f(x)$. Alternatively, we could define the value $q_\theta(x)$ by applying Definition 3 unchanged, namely, $q^<_\theta(x) = \Pr_{x'\sim P_\theta}(f(x') < f(x))$ in which $f(x)$ itself is treated as a random variable under the probability Pr, so that $q^<_\theta(x)$ is deterministic and takes into account all possible values for $f(x)$. Then we could apply the selection scheme w to this value $q^<_\theta(x)$ as in Definition 3 and define the IGO flow accordingly. The value of $q^<_\theta(x)$ in this second version is the expected value of $q^<_\theta(x)$ in the first version.

When the selection scheme w is affine, these two approaches coincide; however this is not the case in general, as the second version averages the q-values while the first version averages the weights $w(q)$. The second version would be the $N \to \infty$ limit of a slightly more complex algorithm using several evaluations of f for each sample x_i in order to compute noise-free average ranks and quantiles. The first version has the advantage of leaving the algorithm unchanged and of inheriting properties from the deterministic case via Proposition 22.

C.4 The IGO Flow for Linear Functions on $\{0,1\}^d$ and $\mathbb{R}^d$

In this section we take a closer look at the IGO differential equation solutions of (8) for some simple examples of objective functions, for which it is possible to obtain exact information about these IGO trajectories.

We start with the discrete search space $X = \{0,1\}^d$ and linear functions (to be minimized) defined as $f(x) = c - \sum_{i=1}^d \alpha_i x_i$ with $\alpha_i > 0$. (So maximization of the classical onemax function $f_{\mathrm{onemax}}(x) = \sum_{i=1}^d x_i$ is covered by setting $\alpha_i = 1$.) The differential equation of

the IGO flow (8) for the Bernoulli measures $P_\theta(x) = p_{\theta_1}(x_1)\dots p_{\theta_d}(x_d)$ defined on X is the $\delta t \to 0$ limit of the IGO-PBIL update (36):

$$\frac{\mathrm{d}\theta^t_i}{\mathrm{d}t} = \int W^f_{\theta^t}(x)(x_i - \theta^t_i) P_{\theta^t}(\mathrm{d}x) =: g_i(\theta^t)\ . \tag{59}$$

Although finding the analytical solution of the differential equation (59) for any initial condition seems a bit intricate, we show that the solution of (59) converges to $(1,\dots,1)$ starting from any initial $\theta \in (0,1]^d$. Note that starting with $\theta_i = 0$ for some i prevents IGO (and PBIL) from sampling any 1 for component i, so that the components of θ that are equal to 0 at startup will always stay so; in that case the IGO flow effectively works as in a smaller-dimensional space.

To prove convergence to $(1,\dots,1)$, we establish the following result:

Lemma 23 *Assume that the selection scheme $w : [0,1] \to \mathbb{R}$ is bounded, that w is a nonincreasing function and that there exists $q_0, q_1 \in (0,1)$ such that $w(q_0) \neq w(q_1)$. On $f(x) = c - \sum_{i=1}^d \alpha_i x_i$, the solution of (59) satisfies $\sum_{i=1}^d \alpha_i \frac{\mathrm{d}\theta^t_i}{\mathrm{d}t} \geqslant 0$; moreover $\sum \alpha_i \frac{\mathrm{d}\theta^t_i}{\mathrm{d}t} = 0$ if and only $\theta \in \{0,1\}^d$.*

Proof We compute $\sum_{i=1}^d \alpha_i g_i(\theta^t)$ and find that

$$\begin{aligned}\sum_{i=1}^d \alpha_i \frac{\mathrm{d}\theta^t_i}{\mathrm{d}t} &= \int W^f_{\theta^t}(x) \left(\sum_{i=1}^d \alpha_i x_i - \sum_{i=1}^d \alpha_i \theta^t_i\right) P_{\theta^t}(\mathrm{d}x) \\ &= \int W^f_{\theta^t}(x)(f(\theta^t) - f(x)) P_{\theta^t}(\mathrm{d}x) \\ &= \mathbb{E}[W^f_{\theta^t}(x)]\,\mathbb{E}[f(x)] - \mathbb{E}[W^f_{\theta^t}(x) f(x)] \end{aligned}$$

where the expectations are taken under P_{θ^t}. Using Lemma 24 below, we have that $\mathbb{E}[W^f_{\theta^t}(x)]\,\mathbb{E}[f(x)] - \mathbb{E}[W^f_{\theta^t}(x) f(x)] \geqslant 0$ and in addition $\mathbb{E}[W^f_{\theta^t}(x)]\,\mathbb{E}[f(x)] - \mathbb{E}[W^f_{\theta^t}(x) f(x)] = 0$ if and only if $\theta^t \in \{0,1\}^d$. ∎

Lemma 24 *Under the assumptions of Lemma 23*

$$\mathbb{E}[-W^f_{\theta^t}(x) f(x)] \geqslant \mathbb{E}[-W^f_{\theta^t}(x)]\mathbb{E}[f(x)] \tag{60}$$

with equality if and only if $\theta^t \in \{0,1\}^d$. Here the expectations are taken under $x \sim P_{\theta^t}$.

Proof We want to prove that $\mathrm{Cov}[-W^f_{\theta^t}(x), f(x)] \geqslant 0$ with equality if and only if $\theta^t \in \{0,1\}^d$. Let us define the random variable $Z = f(x)$ when $x \sim P_{\theta^t}$. Remark that $W^f_{\theta^t}(x) = \mathscr{G}(Z)$ where

$$\mathscr{G}(z) = \frac{1}{F^\leqslant_{\theta^t}(z) - F^<_{\theta^t}(z)} \int_{F^<_{\theta^t}(z)}^{F^\leqslant_{\theta^t}(z)} w(q)dq\ , \tag{61}$$

where $F^\leqslant_{\theta^t}(z) = \Pr_{x'\sim P_{\theta^t}}(f(x') \leqslant z)$ and $F^<_{\theta^t}(z) = \Pr_{x'\sim P_{\theta^t}}(f(x') < z)$. That is $\mathscr{G}$ is the average of w on the interval $(F^<_{\theta^t}(z), F^\leqslant_{\theta^t}(z))$. Since w is nonincreasing, the function $\mathscr{G}$ is also nonincreasing. We have the following equality

$$\mathrm{Cov}[-W^f_{\theta^t}(x), f(x)] = \mathrm{Cov}[-\mathscr{G}(Z), Z]$$

where $-\mathscr{G}$ is nondecreasing. Following (Thorisson, 2000, Chapter 1), we write

$$\mathrm{Cov}[-\mathscr{G}(Z), Z] = \frac{1}{2}\mathrm{Cov}[-\mathscr{G}(Z) + \mathscr{G}(Z'), Z - Z']$$

where Z and Z' are independent following the distribution P_{θ^t}. Given that both the mean of $-\mathscr{G}(Z) + \mathscr{G}(Z')$ and $Z - Z'$ are zero

$$\mathrm{Cov}[-\mathscr{G}(Z), Z] = \frac{1}{2}E[(-\mathscr{G}(Z) + \mathscr{G}(Z'))(Z - Z')] = \frac{1}{2}E[|-\mathscr{G}(Z) + \mathscr{G}(Z')||Z - Z'|] \geqslant 0 \ ,$$

where the last equality holds because $-\mathscr{G}$ is nondecreasing. This proves the main statement of the lemma.

We will now show that if $\theta^t \notin \{0,1\}^d$, then $E[|-\mathscr{G}(Z) + \mathscr{G}(Z')||Z - Z'|] > 0$ and thus consequently $\mathrm{Cov}[-W^f_{\theta^t}(x), f(x)] > 0$. We simply need to show that Z can take with strictly positive probabilities p_1 and p_2 two distinct values z_1 and z_2 such that $\mathscr{G}(z_1)$ and $\mathscr{G}(z_2)$ are distinct. We will then have

$$E[|-\mathscr{G}(Z) + \mathscr{G}(Z')||Z - Z'|] \geqslant (|-\mathscr{G}(z_1) + \mathscr{G}(z_2)||z_1 - z_2|)\, p_1 p_2 > 0 \ .$$

Let us assume that one single θ_i belongs to $(0,1)$ and all the others are either 0 or 1. We can assume without loss of generality that $\theta_1 \in (0,1)$. Then $f(x)$ takes (only) two distinct values with positive probability; let z_1 be the one associated with $x_1 = 1$ and z_2 with $x_1 = 0$. Then $z_1 < z_2$ thanks to the definition of f and because $\alpha_i > 0$. Moreover, unravelling the definitions we find $\mathscr{G}(z_1) = \frac{1}{\theta_1}\int_0^{\theta_1} w(q)dq$ and $\mathscr{G}(z_2) = \frac{1}{1-\theta_1}\int_{\theta_1}^1 w(q)dq$.

The assumption states that there exists $q_0, q_1 \in (0,1)$ such that $w(q_0) \neq w(q_1)$. Assume without loss of generality that $q_0 < q_1$ and $w(q_0) > w(q_1)$. Either $w(q_1) \geqslant w(\theta_1)$ or $w(q_1) < w(\theta_1)$. In the first case, then $\theta_1 > q_0$ and

$$\frac{1}{\theta_1}\int_0^{\theta_1} w(q)dq = \frac{1}{\theta_1}\left(\int_0^{q_0} w(q)dq + \int_{q_0}^{\theta_1} w(q)dq\right) > \frac{1}{\theta_1}\left(w(q_0)q_0 + w(\theta_1)(\theta_1 - q_0)\right) > w(\theta_1) \ ,$$

Meanwhile, $\mathscr{G}(z_2) = \frac{1}{1-\theta_1}\int_{\theta_1}^1 w(q)dq \leqslant w(\theta_1)$ and thus

$$\mathscr{G}(z_1) > \mathscr{G}(z_2) \ .$$

If $w(q_1) < w(\theta_1)$, then $q_1 > \theta_1$ and

$$\begin{aligned}\mathscr{G}(z_2) = \frac{1}{1-\theta_1}\int_{\theta_1}^1 w(q)dq &= \frac{1}{1-\theta_1}\left(\int_{\theta_1}^{q_1} w(q)dq + \int_{q_1}^1 w(q)dq\right) \\ &\leqslant \frac{1}{1-\theta_1}(w(\theta_1)(q_1 - \theta_1) + w(q_1)(1 - q_1)) < w(\theta_1) \quad (62)\end{aligned}$$

and thus $\mathscr{G}(z_2) < w(\theta_1) \leqslant \mathscr{G}(z_1)$ as well.

In the case where we have not only two but l distinct fitnesses that can be sampled with strictly positive probabilities, say $z_1 < \ldots < z_l$, we can show similarly that $\mathscr{G}(z_1) > \mathscr{G}(z_l)$. ■

We are now ready to state the convergence of the trajectories of IGO-PBIL (and cGA) update in the limit of $\delta t \to 0$.

Proposition 25 *Assume that the selection scheme $w : [0,1] \to \mathbb{R}$ is bounded, that w is a nonincreasing function and that there exists $q_0, q_1 \in (0,1)$ such that $w(q_0) \neq w(q_1)$. On the linear functions $f(x) = c - \sum_{i=1}^d \alpha_i x_i$, the critical point $\theta = (1, \ldots, 1)$ of the IGO-PBIL differential equation* (59) *is stable and for any initial condition $\theta \in (0;1]^d$, the continuous-time trajectory solving* (59) *converges to* $(1, \ldots, 1)$.

Proof Remark first that if we start at $\theta^0 \in [\varepsilon, 1]^d$, then the solution of (59) stays in $[\varepsilon, 1]^d$. Indeed, the trajectory cannot go out of $[0,1]^d$ and, in addition, for $\theta \in [\varepsilon, 1)^d$ we have $g_i(\theta) \geqslant 0$ so that the trajectory of (59) cannot go out of $[\varepsilon, 1]^d$. The proof that $g_i(\theta) \geqslant 0$ for $\theta \in [\varepsilon, 1)^d$ is similar to the proof that $\mathrm{Cov}[-W^f_{\theta^t}(x), f(x)] \geqslant 0$ in Lemma 24: namely, we can write $g_i(\theta) = \int \mathbb{E}[W^f_{\theta^t}(x)|x_i](x_i - \theta_i)p_{\theta_i}(x_i)dx_i = \theta_i(1-\theta_i)[h(1) - h(0)]$ where $h(x_i) = \mathbb{E}[W^f_{\theta^t}(x)|x_i] = \mathbb{E}[\mathscr{G}(f(x))|x_i]$ where $\mathscr{G}$ is defined in (61). Then $h(1) \geqslant h(0)$ comes from the increase of $\mathscr{G}$ when going to better function values.

Consider now on $[\varepsilon, 1]^d$, the non-negative function $V(\theta) = \sum_{i=1}^d \alpha_i - \sum_{i=1}^d \alpha_i \theta_i$. Then $V^*(\theta) := \nabla V(\theta) \cdot g(\theta) \leqslant 0$, and $V^*(\theta)$ equals zero only for $\theta \in \{0,1\}^d$ according to Lemma 23. Hence for $\theta \in [\varepsilon, 1]^d$, the function V is a Lyapunov function (Khalil, 1996; Agarwal and O'Regan, 2008), which is minimal at $(1, \ldots, 1)$ and such that $V^*(\theta) < 0$ except at $(1, \ldots, 1)$. Therefore the trajectory of (59) will converge to $(1, \ldots, 1)$ as t goes to infinity (the proof is similar to that of (Khalil, 1996, Theorem 4.1)). Given that this holds for any $\varepsilon > 0$, we can conclude that the trajectory of (59) converges to $(1, \ldots, 1)$ starting from any $\theta \in (0,1]^d$. ■

We now consider on $\mathbb{R}^d$ the family of multivariate normal distributions $P_\theta = \mathcal{N}(m, \sigma^2 I_d)$ with covariance matrix equal to $\sigma^2 I_d$. The parameter θ thus has $d+1$ components $\theta = (m, \sigma) \in \mathbb{R}^d \times \mathbb{R}$. The natural gradient update using this family was derived in Glasmachers et al. (2010); from this we can derive the IGO differential equation which reads:

$$\frac{\mathrm{d}m^t}{\mathrm{d}t} = \int_{\mathbb{R}^d} W^f_{\theta^t}(x)(x - m^t)P_{\mathcal{N}(m^t, (\sigma^t)^2 I_d)}(x)\mathrm{d}x \quad (63)$$

$$\frac{\mathrm{d}\tilde{\sigma}^t}{\mathrm{d}t} = \int_{\mathbb{R}^d} \frac{1}{2d}\left\{\sum_{i=1}^d \left(\frac{x_i - m_i^t}{\sigma^t}\right)^2 - 1\right\} W^f_{\theta^t}(x)P_{\mathcal{N}(m^t, (\sigma^t)^2 I_d)}(x)\mathrm{d}x \quad (64)$$

where σ^t and $\tilde{\sigma}^t$ are linked via $\sigma^t = \exp(\tilde{\sigma}^t)$ or $\tilde{\sigma}^t = \ln(\sigma^t)$. Denoting $\mathcal{N}$ a random vector following a centered multivariate normal distribution with identity covariance matrix we can rewrite the gradient flow as

$$\frac{\mathrm{d}m^t}{\mathrm{d}t} = \sigma^t \mathbb{E}\left[W^f_{\theta^t}(m^t + \sigma^t\mathcal{N})\mathcal{N}\right] \quad (65)$$

$$\frac{\mathrm{d}\tilde{\sigma}^t}{\mathrm{d}t} = \mathbb{E}\left[\frac{1}{2}\left(\frac{\|\mathcal{N}\|^2}{d} - 1\right) W^f_{\theta^t}(m^t + \sigma^t\mathcal{N})\right] \ . \quad (66)$$

Let us analyze the solution of the previous system on linear functions. Without loss of generality (thanks to invariance) we can consider the linear function $f(x) = x_1$. We have

$$W^f_{\theta^t}(x) = w(\Pr(m_1^t + \sigma^t Z_1 < x_1))$$

where Z_1 follows a standard one-dimensional normal distribution and thus

$$W^f_{\theta^t}(m^t + \sigma^t \mathcal{N}) = w(\mathrm{Pr}_{Z_1 \sim \mathcal{N}(0,1)}(Z_1 < \mathcal{N}_1)) \tag{67}$$
$$= w(\mathcal{F}(\mathcal{N}_1)) \tag{68}$$

with $\mathcal{F}$ the cumulative distribution of a standard normal distribution, and $\mathcal{N}_1$ the first component of $\mathcal{N}$. The differential equation thus simplifies into

$$\frac{\mathrm{d}m^t}{\mathrm{d}t} = \sigma^t \begin{pmatrix} \mathbb{E}\left[w(\mathcal{F}(\mathcal{N}_1))\mathcal{N}_1\right] \\ 0 \\ \vdots \\ 0 \end{pmatrix} \tag{69}$$

$$\frac{\mathrm{d}\tilde{\sigma}^t}{\mathrm{d}t} = \frac{1}{2d}\mathbb{E}\left[(|\mathcal{N}_1|^2 - 1)w(\mathcal{F}(\mathcal{N}_1))\right] \ . \tag{70}$$

Consider, for example, the truncation selection function, i.e. $w(q) = 1_{q \leqslant q_0}$ where $q_0 \in (0, 1)$. (Within the IGO algorithm, this results in so-called *intermediate recombination* of the $q_0 \times N$ best samples.) We find that

$$\frac{\mathrm{d}m^t_1}{\mathrm{d}t} = \sigma^t \mathbb{E}[\mathcal{N}_1 1_{\{\mathcal{N}_1 \leqslant \mathcal{F}^{-1}(q_0)\}}] =: \sigma^t \beta \tag{71}$$

$$\frac{\mathrm{d}\tilde{\sigma}^t}{\mathrm{d}t} = \frac{1}{2d}\left(\int_0^{q_0} \mathcal{F}^{-1}(u)^2 \mathrm{d}u - q_0\right) =: \alpha \ . \tag{72}$$

The solution of the IGO flow for the linear function $f(x) = x_1$ is thus given by

$$m^t_1 = m^0_1 + \frac{\sigma^0 \beta}{\alpha}\exp(\alpha t) \tag{73}$$

$$\sigma^t = \sigma^0 \exp(\alpha t) \ . \tag{74}$$

The coefficient β is negative for any $q_0 < 1$. The coefficient α is positive if and only if $q_0 < 1/2$ by a simple calculus argument[12]; this corresponds to selecting less than half of the sampled points in an ES. In this case the step size σ^t grows exponentially fast to infinity and the mean vector moves along the gradient direction towards minus ∞ at the same rate. If more than half of the points are selected, $q_0 \geqslant 1/2$, the step size will decrease to zero exponentially fast and the mean vector will get stuck (compare also Grahl et al. 2005; Hansen 2006a; Pošík 2008).

For an analysis of the solutions of the system of differential equations (65) and (66) on more complex functions, namely convex-quadratic functions and twice continuously differentiable functions, we refer to Akimoto et al. (2012).

12. Indeed $\alpha = \frac{1}{2d\sqrt{2\pi}} \int_{-\infty}^{\mathcal{F}^{-1}(q_0)} (x^2 - 1)\exp(-x^2/2)\mathrm{d}x = \frac{1}{2d\sqrt{2\pi}} g(\mathcal{F}^{-1}(q_0))$ where $g(y) = \int_{-\infty}^{y} (x^2 - 1)\exp(-x^2/2)\mathrm{d}x$. Using $g(0) = 0$ and $\lim_{y \to \pm\infty} g(y) = 0$, and studying the sign of $g'(y)$, we find that g is positive for $y < 0$ and negative for $y > 0$. Since $\mathcal{F}^{-1}(q_0) < 0$ if and only if $q_0 < 1/2$, we find that $\alpha = \frac{1}{2d\sqrt{2\pi}} g(\mathcal{F}^{-1}(q_0))$ is positive if and only if $q_0 < 1/2$.

Appendix D. Proofs

This final appendix provides longer proofs of propositions and theorems of the paper.

D.1 Proof of Proposition 2

We begin with a calculus lemma which will also be used for the proof of Theorem 10. The proof is omitted and amounts to writing the maximum of a quadratic function obtained by the second-order Taylor expansion of f.

Lemma 26 *Let f be real-valued function on a finite-dimensional vector space E equipped with a positive definite quadratic form $\|\cdot\|^2$. Assume f is smooth and has at most quadratic growth at infinity. Then, for any $x \in E$, we have*

$$\nabla f(x) = \lim_{\varepsilon \to 0} \frac{1}{\varepsilon} \arg\max_h \left\{ f(x + h) - \frac{1}{2\varepsilon}\|h\|^2 \right\}$$

where ∇ is the gradient associated with the norm $\|\cdot\|$. Equivalently,

$$\arg\max_y \left\{ f(y) - \frac{1}{2\varepsilon}\|y - x\|^2 \right\} = x + \varepsilon \nabla f(x) + O(\varepsilon^2)$$

when $\varepsilon \to 0$.

Proposition 2 follows by taking the Fisher information metric at θ^0 for the metric $\|\cdot\|^2$, and using the relation $\mathrm{KL}(P \,\|\, Q) = -\mathrm{Ent}(P) + \log \# X$ if Q is the uniform distribution on a finite space X.

D.2 Proof of Theorem 6 (Convergence of Empirical Means and Quantiles)

Let us give a more precise statement including the necessary regularity conditions.

Proposition 27 *Let $\theta \in \Theta$. Assume that the derivative $\frac{\partial \ln P_\theta(x)}{\partial \theta}$ exists for P_θ-almost all $x \in X$ and that $\mathbb{E}_{P_\theta}\left|\frac{\partial \ln P_\theta(x)}{\partial \theta}\right|^2 < +\infty$. Assume that the function w is non-decreasing and bounded.*

Let $(x_i)_{i \in \mathbb{N}}$ be a sequence of independent samples of P_θ. Then with probability 1, as $N \to \infty$ we have

$$\frac{1}{N}\sum_{i=1}^{N} \widehat{W}^f(x_i) \frac{\partial \ln P_\theta(x_i)}{\partial \theta} \to \int W^f_\theta(x) \frac{\partial \ln P_\theta(x)}{\partial \theta} P_\theta(\mathrm{d}x)$$

where

$$\widehat{W}^f(x_i) = w\left(\frac{\mathrm{rk}_N(x_i) + 1/2}{N}\right)$$

with $\mathrm{rk}_N(x_i) = \#\{1 \leqslant j \leqslant N,\ f(x_j) < f(x_i)\}$. (When there are f-ties in the sample, $\widehat{W}^f(x_i)$ is defined as the average of $w((r + 1/2)/N)$ over the possible rankings r of x_i.)

Proof Let $g : X \to \mathbb{R}$ be any function with $\mathbb{E}_{P_\theta} g^2 < \infty$. We will show that $\frac{1}{N}\sum \widehat{W}^f(x_i)g(x_i) \to \int W_\theta^f(x)g(x)\,P_\theta(\mathrm{d}x)$. Applying this with g equal to the components of $\frac{\partial \ln P_\theta(x)}{\partial\theta}$ will yield the result.

Let us decompose

$$\frac{1}{N}\sum \widehat{W}^f(x_i)g(x_i) = \frac{1}{N}\sum W_\theta^f(x_i)g(x_i) + \frac{1}{N}\sum(\widehat{W}^f(x_i) - W_\theta^f(x_i))g(x_i).$$

Each summand in the first term involves only one sample x_i (contrary to $\widehat{W}^f(x_i)$ which depends on the whole sample). So by the strong law of large numbers, almost surely $\frac{1}{N}\sum W_\theta^f(x_i)g(x_i)$ converges to $\int W_\theta^f(x)g(x)\,P_\theta(\mathrm{d}x)$. So we have to show that the second term converges to 0 almost surely.

By the Cauchy–Schwarz inequality, we have

$$\left|\frac{1}{N}\sum(\widehat{W}^f(x_i) - W_\theta^f(x_i))g(x_i)\right|^2 \leqslant \left(\frac{1}{N}\sum(\widehat{W}^f(x_i) - W_\theta^f(x_i))^2\right)\left(\frac{1}{N}\sum g(x_i)^2\right)$$

By the strong law of large numbers, the second term $\frac{1}{N}\sum g(x_i)^2$ converges to $\mathbb{E}_{P_\theta} g^2$ almost surely. So we have to prove that the first term $\frac{1}{N}\sum(\widehat{W}^f(x_i) - W_\theta^f(x_i))^2$ converges to 0 almost surely.

Since w is bounded by assumption, we can write

$$\begin{aligned}(\widehat{W}^f(x_i) - W_\theta^f(x_i))^2 &\leqslant 2B\left|\widehat{W}^f(x_i) - W_\theta^f(x_i)\right| \\ &= 2B\left|\widehat{W}^f(x_i) - W_\theta^f(x_i)\right|_+ + 2B\left|\widehat{W}^f(x_i) - W_\theta^f(x_i)\right|_-\end{aligned}$$

where B is the bound on $|w|$. We will bound each of these terms.

Let us abbreviate $q_i^< = \Pr_{x'\sim P_\theta}(f(x') < f(x_i))$, $q_i^\leqslant = \Pr_{x'\sim P_\theta}(f(x') \leqslant f(x_i))$, $r_i^< = \#\{j \leqslant N,\, f(x_j) < f(x_i)\}$, $r_i^\leqslant = \#\{j \leqslant N,\, f(x_j) \leqslant f(x_i)\}$.

By definition of $\widehat{W}^f$ we have

$$\widehat{W}^f(x_i) = \frac{1}{r_i^\leqslant - r_i^<}\sum_{k=r_i^<}^{r_i^\leqslant - 1} w((k+1/2)/N)$$

and moreover $W_\theta^f(x_i) = w(q_i^<)$ if $q_i^< = q_i^\leqslant$ or $W_\theta^f(x_i) = \frac{1}{q_i^\leqslant - q_i^<}\int_{q_i^<}^{q_i^\leqslant} w$ otherwise.

The Glivenko–Cantelli theorem (Billingsley, 1995, Theorem 20.6) implies that $\sup_i \left|q_i^\leqslant - r_i^\leqslant/N\right|$ tends to 0 almost surely, and likewise for $\sup_i |q_i^< - r_i^</N|$. So let N be large enough so that these errors are bounded by ε.

Since w is non-increasing, we have $w(q_i^<) \leqslant w(r_i^</N - \varepsilon)$. In the case $q_i^< \neq q_i^\leqslant$, we decompose the interval $[q_i^<; q_i^\leqslant]$ into $(r_i^\leqslant - r_i^<)$ subintervals. The average of w over each such subinterval is compared to a term in the sum defining $w^N(x_i)$: since w is non-increasing, the average of w over the k^{th} subinterval is at most $w((r_i^< + k)/N - \varepsilon)$. So we get

$$W_\theta^f(x_i) \leqslant \frac{1}{r_i^\leqslant - r_i^<}\sum_{k=r_i^<}^{r_i^\leqslant - 1} w(k/N - \varepsilon)$$

so that

$$W_\theta^f(x_i) - \widehat{W}^f(x_i) \leqslant \frac{1}{r_i^\leqslant - r_i^<}\sum_{k=r_i^<}^{r_i^\leqslant - 1}(w(k/N - \varepsilon) - w((k+1/2)/N)).$$

Let us sum over i, remembering that there are $(r_i^\leqslant - r_i^<)$ values of j for which $f(x_j) = f(x_i)$. Taking the positive part, we get

$$\frac{1}{N}\sum_{i=1}^N \left|W_\theta^f(x_i) - \widehat{W}^f(x_i)\right|_+ \leqslant \frac{1}{N}\sum_{k=0}^{N-1}(w(k/N - \varepsilon) - w((k+1/2)/N)).$$

Since w is non-increasing we have

$$\frac{1}{N}\sum_{k=0}^{N-1} w(k/N - \varepsilon) \leqslant \int_{-\varepsilon - 1/N}^{1-\varepsilon-1/N} w$$

and

$$\frac{1}{N}\sum_{k=0}^{N-1} w((k+1/2)/N) \geqslant \int_{1/2N}^{1+1/2N} w$$

(we implicitly extend the range of w so that $w(q) = w(0)$ for $q < 0$ and likewise for $q > 1$). So we have

$$\frac{1}{N}\sum_{i=1}^N \left|W_\theta^f(x_i) - \widehat{W}^f(x_i)\right|_+ \leqslant \int_{-\varepsilon-1/N}^{1/2N} w - \int_{1-\varepsilon-1/N}^{1+1/2N} w \leqslant (2\varepsilon + 3/N)B$$

where B is the bound on $|w|$.

Reasoning symmetrically with $w(k/N + \varepsilon)$ and the inequalities reversed, we get a similar bound for $\frac{1}{N}\sum\left|W_\theta^f(x_i) - \widehat{W}^f(x_i)\right|_-$. This ends the proof. ∎

D.3 Proof of Proposition 7 (Quantile Improvement)

Let us use the weight $w(u) = \mathbb{1}_{u\leqslant q}$. Let m be the value of the q-quantile of f under P_{θ^t}. We want to show that the value of the q-quantile of f under $P_{\theta^{t+\delta t}}$ is less than m, unless the gradient vanishes and the IGO flow is stationary.

Let $p_- = \Pr_{x\sim P_{\theta^t}}(f(x) < m)$, $p_m = \Pr_{x\sim P_{\theta^t}}(f(x) = m)$ and $p_+ = \Pr_{x\sim P_{\theta^t}}(f(x) > m)$. By definition of the quantile value we have $p_- + p_m \geqslant q$ and $p_+ + p_m \geqslant 1 - q$. Let us assume that we are in the more complicated case $p_m \neq 0$ (for the case $p_m = 0$, simply remove the corresponding terms).

We have $W_{\theta_t}^f(x) = 1$ if $f(x) < m$, $W_{\theta_t}^f(x) = 0$ if $f(x) > m$ and $W_{\theta_t}^f(x) = \frac{1}{p_m}\int_{p_-}^{p_- + p_m} w(u)\mathrm{d}u = \frac{q - p_-}{p_m}$ if $f(x) = m$.

Using the same notation as above, let $g_t(\theta) = \int W_{\theta^t}^f(x)\,P_\theta(\mathrm{d}x)$. Decomposing this integral on the three sets $f(x) < m$, $f(x) = m$ and $f(x) > m$, we get that $g_t(\theta) = \Pr_{x\sim P_\theta}(f(x) < m) + \Pr_{x\sim P_\theta}(f(x) = m)\frac{q - p_-}{p_m}$. In particular, $g_t(\theta^t) = q$.

Since we follow a gradient ascent of g_t, for δt small enough we have $g_t(\theta^{t+\delta t}) > g_t(\theta^t)$ unless the gradient vanishes. If the gradient vanishes we have $\theta^{t+\delta t} = \theta^t$ and the quantiles are the same. Otherwise we get $g_t(\theta^{t+\delta t}) > g_t(\theta^t) = q$.

Since $\frac{q-p_-}{p_m} \leqslant \frac{(p_-+p_m)-p_-}{p_m} = 1$, we have $g_t(\theta) \leqslant \Pr_{x\sim P_\theta}(f(x) < m) + \Pr_{x\sim P_\theta}(f(x) = m) = \Pr_{x\sim P_\theta}(f(x) \leqslant m)$.

So $\Pr_{x\sim P_{\theta^{t+\delta t}}}(f(x) \leqslant m) \geqslant g_t(\theta^{t+\delta t}) > q$. This implies, by definition, that the q-quantile value of $P_{\theta^{t+\delta t}}$ is at most m. Moreover, if the objective function has no plateau then $\Pr_{x\sim P_{\theta^{t+\delta t}}}(f(x) = m) = 0$ and so $\Pr_{x\sim P_{\theta^{t+\delta t}}}(f(x) < m) > q$ which implies that the q-quantile of $P_{\theta^{t+\delta t}}$ is stricly less than m.

D.4 Proof of Theorem 10 (Natural Gradient as ML with Infinitesimal Weights)

The proof of Theorem 10 will use Lemma 26. Let W be a function of x, and fix some θ_0 in Θ.

We need some regularity assumptions: we assume that no two points $\theta \in \Theta$ define the same probability distribution and that the map $P_\theta \mapsto \theta$ is continuous. We also assume that the map $\theta \mapsto P_\theta$ is smooth enough, so that $\int \ln P_\theta(x)\, W(x)\, P_{\theta_0}(\mathrm{d}x)$ is a smooth function of θ. (These are restrictions on θ-regularity: this does not mean that W has to be continuous as a function of x.)

The two statements of Theorem 10 using a sum and an integral have similar proofs, so we only include the first. For $\varepsilon > 0$, let θ be the solution of

$$\theta = \arg\max \left\{ (1-\varepsilon) \int \ln P_\theta(x)\, P_{\theta_0}(\mathrm{d}x) + \varepsilon \int \ln P_\theta(x)\, W(x)\, P_{\theta_0}(\mathrm{d}x) \right\}.$$

Then we have

$$\begin{aligned}
\theta &= \arg\max \left\{ \int \ln P_\theta(x)\, P_{\theta_0}(\mathrm{d}x) + \varepsilon \int \ln P_\theta(x)\, (W(x)-1)\, P_{\theta_0}(\mathrm{d}x) \right\} \\
&= \arg\max \left\{ \int \ln P_\theta(x)\, P_{\theta_0}(\mathrm{d}x) - \int \ln P_{\theta_0}(x)\, P_{\theta_0}(\mathrm{d}x) + \varepsilon \int \ln P_\theta(x)\, (W(x)-1)\, P_{\theta_0}(\mathrm{d}x) \right\}
\end{aligned}$$

(because the added term does not depend on θ)

$$\begin{aligned}
&= \arg\max \left\{ -\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta) + \varepsilon \int \ln P_\theta(x)\, (W(x)-1)\, P_{\theta_0}(\mathrm{d}x) \right\} \\
&= \arg\max \left\{ -\frac{1}{\varepsilon}\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta) + \int \ln P_\theta(x)\, (W(x)-1)\, P_{\theta_0}(\mathrm{d}x) \right\}
\end{aligned}$$

When $\varepsilon \to 0$, the first term exceeds the second one if $\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta)$ is too large (because W is bounded), and so $\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta)$ tends to 0. So we can assume that θ is close to θ_0.

When $\theta = \theta_0 + \delta\theta$ is close to θ_0, we have

$$\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta) = \frac{1}{2} \sum I_{ij}(\theta_0)\, \delta\theta_i\, \delta\theta_j + O(\delta\theta^3)$$

with $I_{ij}(\theta_0)$ the Fisher matrix at θ_0. (This actually holds both for $\mathrm{KL}(P_{\theta_0} \,\|\, P_\theta)$ and $\mathrm{KL}(P_\theta \,\|\, P_{\theta_0})$.)

Thus, we can apply Lemma 26 using the Fisher metric $\sum I_{ij}(\theta_0)\, \delta\theta_i\, \delta\theta_j$, and working on a small neighborhood of θ_0 in θ-space (which can be identified with $\mathbb{R}^{\dim\Theta}$). The lemma states that the argmax above is attained at

$$\theta = \theta_0 + \varepsilon \widetilde{\nabla}_\theta \int \ln P_\theta(x)\, (W(x)-1)\, P_{\theta_0}(\mathrm{d}x)$$

up to $O(\varepsilon^2)$, with $\widetilde{\nabla}$ the natural gradient.

Finally, the gradient cancels the constant -1 because $\int (\widetilde{\nabla} \ln P_\theta)\, P_{\theta_0} = 0$ at $\theta = \theta_0$. This proves Theorem 10.

D.5 Proof of Theorem 12 (IGO, CEM and IGO-ML)

Let P_θ be a family of probability distributions of the form

$$P_\theta(\mathrm{d}x) = \frac{1}{Z(\theta)} \exp\left(\sum \theta_i T_i(x)\right)\, H(\mathrm{d}x)$$

where $T_1, \dots, T_k$ is a finite family of functions on X and $H(\mathrm{d}x)$ is some reference measure on X. We assume that the family of functions $(T_i)_i$ together with the constant function $T_0(x) = 1$, are linearly independent. This prevents redundant parametrizations where two values of θ describe the same distribution; this also ensures, by elementary linear algebra, that the Fisher matrix $\mathrm{Cov}(T_i, T_j)$ is invertible.

The IGO update (17) in the parametrization $\bar{T}_i$ is a sum of terms of the form

$$\widetilde{\nabla}_{\bar{T}_i} \ln P(x).$$

So we will compute the natural gradient $\widetilde{\nabla}_{\bar{T}_i}$ in those coordinates.

Let us start with a proposition giving an expression for the Fisher scalar product between two tangent vectors δP and $\delta' P$ of a statistical manifold of exponential distributions. It is one way to express the duality between the coordinates θ_i and $\bar{T}_i$ (compare (Amari and Nagaoka, 2000, (3.30) and Section 3.5)).

Proposition 28 *Let $\delta\theta_i$ and $\delta'\theta_i$ be two small variations of the parameters θ_i. Let $\delta P(x)$ and $\delta' P(x)$ be the resulting variations of the probability distribution P, and $\delta\bar{T}_i$ and $\delta'\bar{T}_i$ the resulting variations of $\bar{T}_i$. Then the scalar product, in Fisher information metric, between the tangent vectors δP and $\delta' P$, is*

$$\langle \delta P, \delta' P \rangle = \sum_i \delta\theta_i\, \delta'\bar{T}_i = \sum_i \delta'\theta_i\, \delta\bar{T}_i.$$

Proof

First, let us prove that $\frac{\partial \bar{T}_i}{\partial \theta_j} = I_{ij}$, the Fisher matrix for θ. Indeed, $\frac{\partial \bar{T}_i}{\partial \theta_j} = \int_x T_i(x) \frac{\partial P(x)}{\partial \theta_j} = \int_x T_i(x) P(x) \frac{\partial \ln P(x)}{\partial \theta_j} = \int_x T_i(x) P(x) (T_j(x) - \bar{T}_j)$ by (19); this is equal to $\mathrm{Cov}(T_i, T_j)$ which is I_{ij} by (20).

Then, by definition of the Fisher metric we have $\langle \delta P, \delta' P\rangle = \sum_{i,j} I_{ij}\, \delta\theta_i\, \delta'\theta_j$ but $\sum_j I_{ij}\delta'\theta_j$ is equal to $\delta'\bar{T}_i$ by the above, because $\delta'\bar{T}_i = \sum_j \frac{\partial \bar{T}_i}{\partial \theta_j}\delta'\theta_j$. Thus we find $\langle \delta P, \delta' P\rangle = \sum_i \delta\theta_i \delta'\bar{T}_i$ as needed. ∎

Proposition 29 *Let f be a function on the statistical manifold of an exponential family as above. Then the components of the natural gradient w.r.t. the expectation parameters are given by the vanilla gradient w.r.t. the natural parameters:*

$$\widetilde{\nabla}_{\bar{T}_i} f = \frac{\partial f}{\partial \theta_i} \tag{75}$$

and conversely

$$\widetilde{\nabla}_{\theta_i} f = \frac{\partial f}{\partial \bar{T}_i} \ . \tag{76}$$

(Beware this does *not* mean that the gradient ascent in any of those parametrizations is the vanilla gradient ascent.)

We could not find a reference for this result, though we think it is known (as a consequence of Amari and Nagaoka 2000, Eq. 3.32).

Proof We saw above that $\frac{\partial \bar{T}}{\partial \theta} = I$. Since $\widetilde{\nabla}_\theta f = I^{-1}\frac{\partial f}{\partial \theta}$, this proves (76) by substituting $\frac{\partial f}{\partial \theta} = \left(\frac{\partial \bar{T}}{\partial \theta}\right)^{\mathsf{T}} \frac{\partial f}{\partial \bar{T}}$.

For the first statement (75) (the one needed for Theorem 12) we have to derive the Fisher matrix for the variables $\bar{T}$. It follows from Proposition 28 that the Fisher matrix in these variables is I^{-1}, by considering the Fisher metric $\sum \delta\theta_i.\delta'\bar{T}_i$ and substituting $I^{-1}\delta\bar{T}$ for $\delta\theta$. Then (75) is proved along the same lines as (76). ∎

Back to the proof of Theorem 12. We can now compute the desired terms:

$$\widetilde{\nabla}_{\bar{T}_i} \ln P(x) = \frac{\partial \ln P(x)}{\partial \theta_i} = T_i(x) - \bar{T}_i$$

by (19). This proves the first statement (34) in Theorem 12 about the form of the IGO update in these parameters.

The other statements follow easily from this together with the additional fact (33) that, for any set of (positive or negative) weights a_i with $\sum a_i = 1$, the value $T^* = \sum_i a_i T(x_i)$ maximizes $\sum_i a_i \ln P(x_i)$.

D.6 Proof of Proposition 20 and Corollary 21 (Speed of IGO)

Lemma 30 *Let X be a centered L^2 random variable with values in $\mathbb{R}^d$ and let A be a real-valued L^2 random variable. Then*

$$\|\mathbb{E}(AX)\| \leqslant \sqrt{\lambda \operatorname{Var} A}$$

where λ is the largest eigenvalue of the covariance matrix of X expressed in an orthonormal basis.

Proof Let v be any vector in $\mathbb{R}^d$; its norm satisfies

$$\|v\| = \sup_{w,\, \|w\|\leqslant 1} (v \cdot w)$$

and in particular

$$\begin{aligned}
\|\mathbb{E}(AX)\| &= \sup_{w,\, \|w\|\leqslant 1} (w \cdot \mathbb{E}(AX)) \\
&= \sup_{w,\, \|w\|\leqslant 1} \mathbb{E}(A\,(w \cdot X)) \\
&= \sup_{w,\, \|w\|\leqslant 1} \mathbb{E}((A - \mathbb{E}A)\,(w \cdot X)) \quad \text{since } (w \cdot X) \text{ is centered} \\
&\leqslant \sup_{w,\, \|w\|\leqslant 1} \sqrt{\operatorname{Var} A}\, \sqrt{\mathbb{E}((w \cdot X)^2)}
\end{aligned}$$

by the Cauchy–Schwarz inequality.

Now, in an orthonormal basis we have

$$(w \cdot X) = \sum_i w_i X_i$$

so that

$$\begin{aligned}
\mathbb{E}((w \cdot X)^2) &= \mathbb{E}\left((\textstyle\sum_i w_i X_i)(\sum_j w_j X_j)\right) \\
&= \textstyle\sum_i \sum_j \mathbb{E}(w_i X_i w_j X_j) \\
&= \textstyle\sum_i \sum_j w_i w_j \mathbb{E}(X_i X_j) \\
&= \textstyle\sum_i \sum_j w_i w_j C_{ij}
\end{aligned}$$

with C_{ij} the covariance matrix of X. The latter expression is the scalar product $(w \cdot Cw)$. Since C is a symmetric positive-semidefinite matrix, $(w \cdot Cw)$ is at most $\lambda\|w\|^2$ with λ the largest eigenvalue of C. ∎

For the IGO flow we have $\frac{\mathrm{d}\theta^t}{\mathrm{d}t} = \mathbb{E}_{x\sim P_\theta} W_\theta^f(x) \tilde{\nabla}_\theta \ln P_\theta(x)$.

So applying the lemma, we get that the norm of $\frac{\mathrm{d}\theta}{\mathrm{d}t}$ is at most $\sqrt{\lambda \operatorname{Var}_{x\sim P_\theta} W_\theta^f(x)}$ where λ is the largest eivengalue of the covariance matrix of $\tilde{\nabla}_\theta \ln P_\theta(x)$ (expressed in a coordinate system where the Fisher matrix at the current point θ is the identity).

By construction of the quantiles, we have $\operatorname{Var}_{x\sim P_\theta} W_\theta^f(x) \leqslant \operatorname{Var}_{[0,1]} w$ (with equality unless there are ties). Indeed, for a given x, let $\mathcal{U}$ be a uniform random variable in $[0,1]$ independent from x and define the random variable $Q = q^<(x) + (q^\leqslant(x) - q^<(x))\mathcal{U}$. Then Q is uniformly distributed between the upper and lower quantiles $q^\leqslant(x)$ and $q^<(x)$ and thus we can rewrite $W_\theta^f(x)$ as $\mathbb{E}(w(Q)|x)$. By the Jensen inequality we have $\operatorname{Var} W_\theta^f(x) = \operatorname{Var} \mathbb{E}(w(Q)|x) \leqslant \operatorname{Var} w(Q)$. In addition when x is taken under P_θ, Q is uniformly distributed in $[0,1]$ and thus $\operatorname{Var} w(Q) = \operatorname{Var}_{[0,1]} w$, i.e., $\operatorname{Var}_{x\sim P_\theta} W_\theta^f(x) \leqslant \operatorname{Var}_{[0,1]} w$.

Besides, consider the tangent space in Θ-space at point θ^t, and let us choose an orthonormal basis in this tangent space for the Fisher metric. Then, in this basis we have $\tilde{\nabla}_i \ln P_\theta(x) =$

$\partial_i \ln P_\theta(x)$. So the covariance matrix of $\tilde{\nabla} \ln P_\theta(x)$ is $\mathbb{E}_{x\sim P_\theta}(\partial_i \ln P_\theta(x) \partial_j \ln P_\theta(x))$, which is equal to the Fisher matrix by definition. So this covariance matrix is the identity, whose largest eigenvalue is 1. This proves Proposition 20.

For Corollary 21, by the relationship (2) between Fisher matrix and Kullback–Leibler divergence, if v is the speed of the IGO flow then the Kullback–Leibler divergence between P_{θ^t} and $P_{\theta^{t+\delta t}}$ (where $P_{\theta^{t+\delta t}}$ is the trajectory of the IGO flow after a time δt) is equal to the square norm of $\delta t.v$ in Fisher metric up to an $O(\|\delta t.v\|^3)$ term. Now if $P_{\theta^{t+\delta t}}$ is obtained by a finite-population IGO *algorithm*, by Theorem 6 the actual v from the IGO algorithm differs from the speed of the IGO flow by an $o(1)_{N\to\infty}$ term. Collecting terms, we find the expression in Corollary 21.

D.7 Proof of Proposition 22 (Noisy IGO)

On the one hand, let P_θ be a family of distributions on X. The IGO algorithm (16) applied to a random function $f(x) = \tilde{f}(x, \omega)$ where ω is a random variable uniformly distributed in $[0, 1]$ reads

$$\theta^{t+\delta t} = \theta^t + \delta t \sum_{i=1}^{N} \hat{w}_i \widetilde{\nabla}_\theta \ln P_\theta(x_i) \tag{77}$$

where $x_i \sim P_\theta$ and $\hat{w}_i$ is according to (14) where ranking is applied to the values $\tilde{f}(x_i, \omega_i)$, with ω_i uniform variables in $[0, 1]$ independent from x_i and from each other.

On the other hand, for the IGO algorithm using $P_\theta \otimes U_{[0,1]}$ and applied to the deterministic function $\tilde{f}$, $\hat{w}_i$ is computed using the ranking according to the $\tilde{f}$ values of the sampled points $\tilde{x}_i = (x_i, \omega_i)$, and thus coincides with the one in (77).

Besides,

$$\partial_\theta \ln P_{\theta\otimes U_{[0,1]}}(\tilde{x}_i) = \partial_\theta \ln P_\theta(x_i) + \underbrace{\partial_\theta \ln U_{[0,1]}(\omega_i)}_{=0}$$

and thus, both the vanilla gradients and the Fisher matrix I (given by the tensor square of the vanilla gradients) coincide. This proves that the IGO algorithm update on space $X \times [0, 1]$, using the family of distributions $\tilde{P}_\theta = P_\theta \otimes U_{[0,1]}$, applied to the deterministic function $\tilde{f}$, coincides with (77).

Abstract

We consider neural networks with a single hidden layer and non-decreasing positively homogeneous activation functions like the rectified linear units. By letting the number of hidden units grow unbounded and using classical non-Euclidean regularization tools on the output weights, they lead to a convex optimization problem and we provide a detailed theoretical analysis of their generalization performance, with a study of both the approximation and the estimation errors. We show in particular that they are adaptive to unknown underlying linear structures, such as the dependence on the projection of the input variables onto a low-dimensional subspace. Moreover, when using sparsity-inducing norms on the input weights, we show that high-dimensional non-linear variable selection may be achieved, without any strong assumption regarding the data and with a total number of variables potentially exponential in the number of observations. However, solving this convex optimization problem in infinite dimensions is only possible if the non-convex subproblem of addition of a new unit can be solved efficiently. We provide a simple geometric interpretation for our choice of activation functions and describe simple conditions for convex relaxations of the finite-dimensional non-convex subproblem to achieve the same generalization error bounds, even when constant-factor approximations cannot be found. We were not able to find strong enough convex relaxations to obtain provably polynomial-time algorithms and leave open the existence or non-existence of such tractable algorithms with non-exponential sample complexities.

Keywords: Neural networks, non-parametric estimation, convex optimization, convex relaxation.

1. Introduction

Supervised learning methods come in a variety of ways. They are typically based on local averaging methods, such as k-nearest neighbors, decision trees, or random forests, or on optimization of the empirical risk over a certain function class, such as least-squares regression, logistic regression or support vector machine, with positive definite kernels, with model selection, structured sparsity-inducing regularization, or boosting (see, e.g., Györfi and Krzyzak, 2002; Hastie et al., 2009; Shalev-Shwartz and Ben-David, 2014, and references therein).

Most methods assume either explicitly or implicitly a certain class of models to learn from. In the non-parametric setting, the learning algorithms may adapt the complexity of the models as the number of observations increases: the sample complexity (i.e., the number of observations) to adapt to any particular problem is typically large. For example, when learning Lipschitz-continuous functions in $\mathbb{R}^d$, at least $n = \Omega(\varepsilon^{-\max\{d,2\}})$ samples are needed to learn a function with excess risk ε (von Luxburg and Bousquet, 2004, Theorem 15). The exponential dependence on the dimension d is often referred to as the *curse of dimensionality*: without any restrictions, exponentially many observations are needed to obtain optimal generalization performances.

At the other end of the spectrum, parametric methods such as linear supervised learning make strong assumptions regarding the problem and generalization bounds based on estimation errors typically assume that the model is well-specified, and the sample complexity to attain an excess risk of ε grows as $n = \Omega(d/\varepsilon^2)$, for linear functions in d dimensions and Lipschitz-continuous loss functions (Shalev-Shwartz and Ben-David, 2014, Chapter 9). While the sample complexity is much lower, when the assumptions are not met, the methods underfit and more complex models would provide better generalization performances.

Between these two extremes, there are a variety of models with structural assumptions that are often used in practice. For input data in $x \in \mathbb{R}^d$, prediction functions $f : \mathbb{R}^d \to \mathbb{R}$ may for example be parameterized as:

(a) *Affine functions*: $f(x) = w^\top x + b$, leading to potential severe underfitting, but easy optimization and good (i.e., non exponential) sample complexity.

(b) *Generalized additive models*: $f(x) = \sum_{j=1}^d f_j(x_j)$, which are generalizations of the above by summing functions $f_j : \mathbb{R} \to \mathbb{R}$ which may not be affine (Hastie and Tibshirani, 1990; Ravikumar et al., 2008; Bach, 2008a). This leads to less strong underfitting but cannot model interactions between variables, while the estimation may be done with similar tools than for affine functions (e.g., convex optimization for convex losses).

(c) *Nonparametric ANOVA models*: $f(x) = \sum_{A \in \mathcal{A}} f_A(x_A)$ for a set $\mathcal{A}$ of subsets of $\{1, \dots, d\}$, and non-linear functions $f_A : \mathbb{R}^A \to \mathbb{R}$. The set $\mathcal{A}$ may be either given (Gu, 2013) or learned from data (Lin and Zhang, 2006; Bach, 2008b). Multi-way interactions are explicitly included but a key algorithmic problem is to explore the $2^d - 1$ non-trivial potential subsets.

(d) *Single hidden-layer neural networks*: $f(x) = \sum_{j=1}^k \sigma(w_j^\top x + b_j)$, where k is the number of units in the hidden layer (see, e.g., Rumelhart et al., 1986; Haykin, 1994). The activation function σ is here assumed to be fixed. While the learning problem may be cast as a (sub)differentiable optimization problem, techniques based on gradient descent may not find the global optimum. If the number of hidden units is fixed, this is a parametric problem.

(e) *Projection pursuit* (Friedman and Stuetzle, 1981): $f(x) = \sum_{j=1}^k f_j(w_j^\top x)$ where k is the number of projections. This model combines both (b) and (d); the only difference with neural networks is that the non-linear functions $f_j : \mathbb{R} \to \mathbb{R}$ are learned from data. The optimization is often done sequentially and is harder than for neural networks.

(e) *Dependence on a unknown k-dimensional subspace*: $f(x) = g(W^\top x)$ with $W \in \mathbb{R}^{d\times k}$, where g is a non-linear function. A variety of algorithms exist for this problem (Li, 1991; Fukumizu et al., 2004; Dalalyan et al., 2008). Note that when the columns of W are assumed to be composed of a single non-zero element, this corresponds to *variable selection* (with at most k selected variables).

In this paper, our main aim is to answer the following question: **Is there a *single* learning method that can deal *efficiently* with all situations above with *provable adaptivity*?** We consider single-hidden-layer neural networks, with non-decreasing homogeneous activation functions such as

$$\sigma(u) = \max\{u, 0\}^\alpha = (u)_+^\alpha,$$

for $\alpha \in \{0, 1, \ldots\}$, with a particular focus on $\alpha = 0$ (with the convention that $0^0 = 0$), that is $\sigma(u) = 1_{u>0}$ (a threshold at zero), and $\alpha = 1$, that is, $\sigma(u) = \max\{u, 0\} = (u)_+$, the so-called *rectified linear unit* (Nair and Hinton, 2010; Krizhevsky et al., 2012). We follow the convexification approach of Bengio et al. (2006); Rosset et al. (2007), who consider potentially infinitely many units and let a sparsity-inducing norm choose the number of units automatically. This leads naturally to incremental algorithms such as forward greedy selection approaches, which have a long history for single-hidden-layer neural networks (see, e.g., Breiman, 1993; Lee et al., 1996).

We make the following contributions:

- We provide in Section 2 a review of functional analysis tools used for learning from continuously infinitely many basis functions, by studying carefully the similarities and differences between L_1- and L_2-penalties on the output weights. For L_2-penalties, this corresponds to a positive definite kernel and may be interpreted through random sampling of hidden weights. We also review incremental algorithms (i.e., forward greedy approaches) to learn from these infinite sets of basis functions when using L_1-penalties.

- The results are specialized in Section 3 to neural networks with a single hidden layer and activation functions which are positively homogeneous (such as the rectified linear unit). In particular, in Sections 3.2, 3.3 and 3.4, we provide simple geometric interpretations to the non-convex problems of additions of new units, in terms of separating hyperplanes or Hausdorff distance between convex sets. They constitute the core potentially hard computational tasks in our framework of learning from continuously many basis functions.

- In Section 4, we provide a detailed theoretical analysis of the approximation properties of (single hidden layer) convex neural networks with monotonic homogeneous activation functions, with explicit bounds. We relate these new results to the extensive literature on approximation properties of neural networks (see, e.g., Pinkus, 1999, and references therein) in Section 4.7, and show that these neural networks are indeed adaptive to linear structures, by replacing the exponential dependence in dimension by an exponential dependence in the dimension of the subspace of the data can be projected to for good predictions.

	Functional form	Generalization bound
No assumption		$n^{-1/(d+3)} \log n$
Affine function	$w^\top x + b$	$d^{1/2} \cdot n^{-1/2}$
Generalized additive model	$\sum_{j=1}^k f_j(w_j^\top x)$, $w_j \in \mathbb{R}^d$	$kd^{1/2} \cdot n^{-1/4} \log n$
Single-layer neural network	$\sum_{j=1}^k \eta_j (w_j^\top x + b_j)_+$	$kd^{1/2} \cdot n^{-1/2}$
Projection pursuit	$\sum_{j=1}^k f_j(w_j^\top x)$, $w_j \in \mathbb{R}^d$	$kd^{1/2} \cdot n^{-1/4} \log n$
Dependence on subspace	$f(W^\top x)$, $W \in \mathbb{R}^{d\times s}$	$d^{1/2} \cdot n^{-1/(s+3)} \log n$

Table 1: Summary of generalization bounds for various models. The bound represents the expected excess risk over the best predictor in the given class. When no assumption is made, the dependence in n goes to zero with an exponent proportional to $1/d$ (which leads to sample complexity exponential in d), while making assumptions removes the dependence of d in the exponent.

- In Section 5, we study the generalization properties under a standard supervised learning set-up, and show that these convex neural networks are adaptive to all situations mentioned earlier. These are summarized in Table 1 and constitute the main statistical results of this paper. When using an ℓ_1-norm on the input weights, we show in Section 5.3 that high-dimensional non-linear variable selection may be achieved, that is, the number of input variables may be much larger than the number of observations, without any strong assumption regarding the data (note that we do not present a polynomial-time algorithm to achieve this).

- We provide in Section 5.5 simple conditions for convex relaxations to achieve the same generalization error bounds, even when constant-factor approximation cannot be found (e.g., because it is NP-hard such as for the threshold activation function and the rectified linear unit). We present in Section 6 convex relaxations based on semi-definite programming, but we were not able to find strong enough convex relaxations (they provide only a provable sample complexity with a polynomial time algorithm which is exponential in the dimension d) and leave open the existence or non-existence of polynomial-time algorithms that preserve the non-exponential sample complexity.

2. Learning from Continuously Infinitely Many Basis Functions

In this section we present the functional analysis framework underpinning the methods presented in this paper, which learn for a potential continuum of features. While the formulation from Sections 2.1 and 2.2 originates from the early work on the approxima-

tion properties of neural networks (Barron, 1993; Kurkova and Sanguineti, 2001; Mhaskar, 2004), the algorithmic parts that we present in Section 2.5 have been studied in a variety of contexts, such as "convex neural networks" (Bengio et al., 2006), or ℓ_1-norm with infinite dimensional feature spaces (Rosset et al., 2007), with links with conditional gradient algorithms (Dunn and Harshbarger, 1978; Jaggi, 2013) and boosting (Rosset et al., 2004).

In the following sections, note that there will be two different notions of *infinity*: infinitely many inputs x and infinitely many basis functions $x \mapsto \varphi_v(x)$. Moreover, two orthogonal notions of *Lipschitz-continuity* will be tackled in this paper: the one of the prediction functions f, and the one of the loss ℓ used to measure the fit of these prediction functions.

2.1 Variation Norm

We consider an arbitrary measurable input space $\mathcal{X}$ (this will a sphere in $\mathbb{R}^{d+1}$ starting from Section 3), with a set of *basis functions* (a.k.a. *neurons* or *units*) $\varphi_v : \mathcal{X} \to \mathbb{R}$, which are parameterized by $v \in \mathcal{V}$, where $\mathcal{V}$ is a compact topological space (typically a sphere for a certain norm on $\mathbb{R}^d$ starting from Section 3). We assume that for any given $x \in \mathcal{X}$, the functions $v \mapsto \varphi_v(x)$ are continuous. These functions will be the hidden neurons in a single-hidden-layer neural network, and thus $\mathcal{V}$ will be $(d+1)$-dimensional for inputs of dimension d (to represent any affine function). Throughout Section 2, these features will be left unspecified as most of the tools apply more generally.

In order to define our space of functions from $\mathcal{X} \to \mathbb{R}$, we need real-valued Radon measures, which are continuous linear forms on the space of continuous functions from $\mathcal{V}$ to $\mathbb{R}$, equipped with the uniform norm (Rudin, 1987; Evans and Gariepy, 1991). For a continuous function $g : \mathcal{V} \to \mathbb{R}$ and a Radon measure μ, we will use the standard notation $\int_{\mathcal{V}} g(v) d\mu(v)$ to denote the action of the measure μ on the continuous function g. The norm of μ is usually referred to as its *total variation* (such finite total variation corresponds to having a continuous linear form on the space of continuous functions), and we denote it as $|\mu|(\mathcal{V})$, and is equal to the supremum of $\int_{\mathcal{V}} g(v) d\mu(v)$ over all continuous functions with values in $[-1, 1]$. As seen below, when μ has a density with respect to a probability measure, this is the L_1-norm of the density.

We consider the space $\mathcal{F}_1$ of functions f that can be written as

$$f(x) = \int_{\mathcal{V}} \varphi_v(x) d\mu(v),$$

where μ is a signed Radon measure on $\mathcal{V}$ with finite total variation $|\mu|(\mathcal{V})$.

When $\mathcal{V}$ is finite, this corresponds to

$$f(x) = \sum_{v \in \mathcal{V}} \mu_v \varphi_v(x),$$

with total variation $\sum_{v \in \mathcal{V}} |\mu_v|$, where the proper formalization for infinite sets $\mathcal{V}$ is done through measure theory.

The infimum of $|\mu|(\mathcal{V})$ over all decompositions of f as $f = \int_{\mathcal{V}} \varphi_v d\mu(v)$, turns out to be a norm γ_1 on $\mathcal{F}_1$, often called the *variation* norm of f with respect to the set of basis functions (see, e.g., Kurkova and Sanguineti, 2001; Mhaskar, 2004).

Given our assumptions regarding the compactness of $\mathcal{V}$, for any $f \in \mathcal{F}_1$, the infimum defining $\gamma_1(f)$ is in fact attained by a signed measure μ, as a consequence of the compactness of measures for the weak topology (see Evans and Gariepy, 1991, Section 1.9).

In the definition above, if we assume that the signed measure μ has a density with respect to a fixed *probability* measure τ with full support on $\mathcal{V}$, that is, $d\mu(v) = p(v) d\tau(v)$, then, the variation norm $\gamma_1(f)$ is also equal to the infimal value of

$$|\mu|(\mathcal{V}) = \int_{\mathcal{V}} |p(v)| d\tau(v),$$

over all integrable functions p such that $f(x) = \int_{\mathcal{V}} p(v) \varphi_v(x) d\tau(v)$. Note however that not all measures have densities, and that the two infimums are the same as all Radon measures are limits of measures with densities. Moreover, the infimum in the definition above is not attained in general (for example when the optimal measure is singular with respect to $d\tau$); however, it often provides a more intuitive definition of the variation norm, and leads to easier comparisons with Hilbert spaces in Section 2.3.

Finite number of neurons. If $f : \mathcal{X} \to \mathbb{R}$ is decomposable into k basis functions, that is, $f(x) = \sum_{j=1}^k \eta_j \varphi_{v_j}(x)$, then this corresponds to $\mu = \sum_{j=1}^k \eta_j \delta(v = v_j)$, and the total variation of μ is equal to the ℓ_1-norm $\|\eta\|_1$ of η. Thus the function f has variation norm less than $\|\eta\|_1$ or equal. This is to be contrasted with the number of basis functions, which is the ℓ_0-pseudo-norm of η.

2.2 Representation from Finitely Many Functions

When minimizing any functional J that depends only on the function values taken at a subset $\hat{\mathcal{X}}$ of values in $\mathcal{X}$, over the ball $\{f \in \mathcal{F}_1, \ \gamma_1(f) \leqslant \delta\}$, then we have a "representer theorem" similar to the reproducing kernel Hilbert space situation, but also with significant differences, which we now present.

The problem is indeed simply equivalent to minimizing a functional on functions restricted to $\mathcal{X}$, that is, to minimizing $J(f_{|\hat{\mathcal{X}}})$ over $f_{|\hat{\mathcal{X}}} \in \mathbb{R}^{\hat{\mathcal{X}}}$, such that $\gamma_{1|\hat{\mathcal{X}}}(f_{|\hat{\mathcal{X}}}) \leqslant \delta$, where

$$\gamma_{1|\hat{\mathcal{X}}}(f_{|\hat{\mathcal{X}}}) = \inf_{\mu} |\mu|(\mathcal{V}) \text{ such that } \forall x \in \hat{\mathcal{X}}, \ f_{|\hat{\mathcal{X}}}(x) = \int_{\mathcal{V}} \varphi_v(x) d\mu(v);$$

we can then build a function defined over all $\mathcal{X}$, through the optimal measure μ above.

Moreover, by Carathéodory's theorem for cones (Rockafellar, 1997), if $\hat{\mathcal{X}}$ is composed of only n elements (e.g., n is the number of observations in machine learning), the optimal function $f_{|\hat{\mathcal{X}}}$ above (and hence f) may be decomposed into at most n functions φ_v, that is, μ is supported by at most n points in $\mathcal{V}$, among a potential continuum of possibilities.

Note however that the identity of these n functions is not known in advance, and thus there is a significant difference with the representer theorem for positive definite kernels and Hilbert spaces (see, e.g., Shawe-Taylor and Cristianini, 2004), where the set of n functions are known from the knowledge of the points $x \in \hat{\mathcal{X}}$ (i.e., kernel functions evaluated at x).

2.3 Corresponding Reproducing Kernel Hilbert Space (RKHS)

We have seen above that if the real-valued measures μ are restricted to have density p with respect to a fixed probability measure τ with full support on $\mathcal{V}$, that is, $d\mu(v) = p(v) d\tau(v)$,

then, the norm $\gamma_1(f)$ is the infimum of the total variation $|\mu|(\mathcal{V}) = \int_{\mathcal{V}} |p(v)| d\tau(v)$, over all decompositions $f(x) = \int_{\mathcal{V}} p(v)\varphi_v(x) d\tau(v)$.

We may also define the infimum of $\int_{\mathcal{V}} |p(v)|^2 d\tau(v)$ over the same decompositions (squared L_2-norm instead of L_1-norm). It turns out that it defines a squared norm γ_2^2 and that the function space $\mathcal{F}_2$ of functions with finite norm happens to be a reproducing kernel Hilbert space (RKHS). When $\mathcal{V}$ is finite, then it is well-known (see, e.g., Berlinet and Thomas-Agnan, 2004, Section 4.1) that the infimum of $\sum_{v \in \mathcal{V}} \mu_v^2$ over all vectors μ such that $f = \sum_{v \in V} \mu_v \varphi_v$ defines a squared RKHS norm with positive definite kernel $k(x,y) = \sum_{v \in V} \varphi_v(x)\varphi_v(y)$.

We show in Appendix A that for any compact set $\mathcal{V}$, we have defined a squared RKHS norm γ_2^2 with positive definite kernel $k(x,y) = \displaystyle\int_{\mathcal{V}} \varphi_v(x)\varphi_v(y) d\tau(v)$.

Random sampling. Note that such kernels are well-adapted to approximations by sampling several basis functions φ_v sampled from the probability measure τ (Neal, 1995; Rahimi and Recht, 2007). Indeed, if we consider m i.i.d. samples $v_1, \dots, v_m$, we may define the approximation $\hat{k}(x,y) = \frac{1}{m} \sum_{i=1}^m \varphi_{v_i}(x)\varphi_{v_i}(y)$, which corresponds to an explicit feature representation. In other words, this corresponds to sampling units v_i, using prediction functions of the form $\frac{1}{m} \sum_{i=1}^m \eta_i \varphi_{v_i}(x)$ and then penalizing by the ℓ_2-norm of η.

When m tends to infinity, then $\hat{k}(x,y)$ tends to $k(x,y)$ and random sampling provides a way to work efficiently with explicit m-dimensional feature spaces. See Rahimi and Recht (2007) for a analysis of the number of units needed for an approximation with error ε, typically of order $1/\varepsilon^2$. See also Bach (2017) for improved results with a better dependence on ε when making extra assumptions on the eigenvalues of the associated covariance operator.

Relationship between $\mathcal{F}_1$ and $\mathcal{F}_2$. The corresponding RKHS norm is always greater than the variation norm (because of Jensen's inequality), and thus the RKHS $\mathcal{F}_2$ is included in $\mathcal{F}_1$. However, as shown in this paper, the two spaces $\mathcal{F}_1$ and $\mathcal{F}_2$ have very different properties; e.g., γ_2 may be computed easily in several cases, while γ_1 does not; also, learning with $\mathcal{F}_2$ may either be done by random sampling of sufficiently many weights or using kernel methods, while $\mathcal{F}_1$ requires dedicated convex optimization algorithms with potentially non-polynomial-time steps (see Section 2.5).

Moreover, for any $v \in \mathcal{V}$, $\varphi_v \in \mathcal{F}_1$ with a norm $\gamma_1(\varphi_v) \leqslant 1$, while in general $\varphi_v \notin \mathcal{F}_2$. This is a simple illustration of the fact that $\mathcal{F}_2$ is too small and thus will lead to a lack of adaptivity that will be further studied in Section 5.4 for neural networks with certain activation functions.

2.4 Supervised Machine Learning

Given some distribution over the pairs $(x,y) \in \mathcal{X} \times \mathcal{Y}$, a loss function $\ell : \mathcal{Y} \times \mathbb{R} \to \mathbb{R}$, our aim is to find a function $f : \mathcal{X} \to \mathbb{R}$ such that the functional $J(f) = \mathbb{E}[\ell(y, f(x))]$ is small, given some i.i.d. observations (x_i, y_i), $i = 1, \dots, n$. We consider the empirical risk minimization framework over a space of functions $\mathcal{F}$, equipped with a norm γ (in our situation, $\mathcal{F}_1$ and $\mathcal{F}_2$, equipped with γ_1 or γ_2). The empirical risk $\hat{J}(f) = \frac{1}{n} \sum_{i=1}^n \ell(y_i, f(x_i))$, is minimized either (a) by constraining f to be in the ball $\mathcal{F}^\delta = \{f \in \mathcal{F},\ \gamma(f) \leqslant \delta\}$ or (b) regularizing the empirical risk by $\lambda\gamma(f)$. Since this paper has a more theoretical nature, we focus on constraining, noting that in practice, penalizing is often more robust (see, e.g., Harchaoui et al., 2013) and leaving its analysis in terms of learning rates for future work. Since the functional $\hat{J}$ depends only on function values taken at finitely many points, the results from Section 2.2 apply and we expect the solution f to be spanned by only n functions $\varphi_{v_1}, \dots, \varphi_{v_n}$ (but we ignore in advance which ones among all φ_v, $v \in \mathcal{V}$, and the algorithms in Section 2.5 will provide approximate such representations with potentially less or more than n functions).

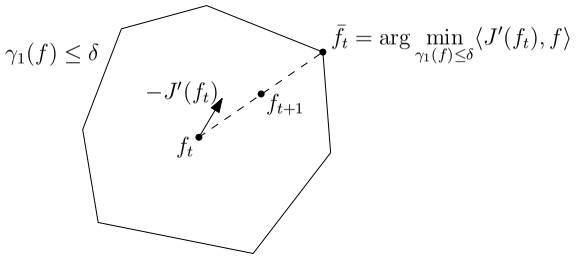

Figure 1: Conditional gradient algorithm for minimizing a smooth functional J on $\mathcal{F}_1^\delta = \{f \in \mathcal{F}_1,\ \gamma_1(f) \leqslant \delta\}$: going from f_t to f_{t+1}; see text for details.

Approximation error vs. estimation error. We consider an ε-approximate minimizer of $\hat{J}(f) = \frac{1}{n} \sum_{i=1}^n \ell(y_i, f(x_i))$ on the convex set $\mathcal{F}^\delta$, that is a certain $\hat{f} \in \mathcal{F}^\delta$ such that $\hat{J}(\hat{f}) \leqslant \varepsilon + \inf_{f \in \mathcal{F}^\delta} \hat{J}(f)$. We thus have, using standard arguments (see, e.g., Shalev-Shwartz and Ben-David, 2014):

$$J(\hat{f}) - \inf_{f \in \mathcal{F}} J(f) \leqslant \left[\inf_{f \in \mathcal{F}^\delta} J(f) - \inf_{f \in \mathcal{F}} J(f) \right] + 2 \sup_{f \in \mathcal{F}^\delta} |\hat{J}(f) - J(f)| + \varepsilon,$$

that is, the excess risk $J(\hat{f}) - \inf_{f \in \mathcal{F}} J(f)$ is upper-bounded by a sum of an *approximation error* $\inf_{f \in \mathcal{F}^\delta} J(f) - \inf_{f \in \mathcal{F}} J(f)$, an *estimation error* $2 \sup_{f \in \mathcal{F}^\delta} |\hat{J}(f) - J(f)|$ and an *optimization error* ε (see also Bottou and Bousquet, 2008). In this paper, we will deal with all three errors, starting from the optimization error which we now consider for the space $\mathcal{F}_1$ and its variation norm.

2.5 Incremental Conditional Gradient Algorithms

In this section, we review algorithms to minimize a smooth functional $J : L_2(d\rho) \to \mathbb{R}$, where ρ is a probability measure on $\mathcal{X}$. This may typically be the expected risk or the empirical risk above. When minimizing $J(f)$ with respect to $f \in \mathcal{F}_1$ such that $\gamma_1(f) \leqslant \delta$, we need algorithms that can efficiently optimize a convex function over an infinite-dimensional space of functions. Conditional gradient algorithms allow to incrementally build a set of elements of $\mathcal{F}_1^\delta = \{f \in \mathcal{F}_1,\ \gamma_1(f) \leqslant \delta\}$; see, e.g., Frank and Wolfe (1956); Dem'yanov and Rubinov (1967); Dudik et al. (2012); Harchaoui et al. (2013); Jaggi (2013); Bach (2015).

Conditional gradient algorithm. We assume the functional J is convex and L-smooth, that is for all $h \in L_2(d\rho)$, there exists a gradient $J'(h) \in L_2(d\rho)$ such that for all $f \in L_2(d\rho)$,

$$0 \leqslant J(f) - J(h) - \langle f - h, J'(h) \rangle_{L_2(d\rho)} \leqslant \frac{L}{2} \|f - h\|^2_{L_2(d\rho)}.$$

When $\mathcal{X}$ is finite, this corresponds to the regular notion of smoothness from convex optimization (Nesterov, 2004).

The conditional gradient algorithm (a.k.a. Frank-Wolfe algorithm) is an iterative algorithm, starting from any function $f_0 \in \mathcal{F}_1^\delta$ and with the following recursion, for $t \geqslant 0$:

$$\begin{aligned} \bar{f}_t &\in \arg\min_{f \in \mathcal{F}_1^\delta} \langle f, J'(f_t) \rangle_{L_2(d\rho)} \\ f_{t+1} &= (1 - \rho_t) f_t + \rho_t \bar{f}_t. \end{aligned}$$

See an illustration in Figure 1. We may choose either $\rho_t = \frac{2}{t+1}$ or perform a line search for $\rho_t \in [0, 1]$. For all of these strategies, the t-th iterate is a convex combination of the functions $\bar{f}_0, \dots, \bar{f}_{t-1}$, and is thus an element of $\mathcal{F}_1^\delta$. It is known that for these two strategies for ρ_t, we have the following convergence rate (see, e.g. Jaggi, 2013):

$$J(f_t) - \inf_{f \in \mathcal{F}_1^\delta} J(f) \leqslant \frac{2L}{t+1} \sup_{f, g \in \mathcal{F}_1^\delta} \|f - g\|^2_{L_2(d\rho)}.$$

When, $r^2 = \sup_{v \in \mathcal{V}} \|\varphi_v\|^2_{L_2(d\rho)}$ is finite, we have $\|f\|^2_{L_2(d\rho)} \leqslant r^2 \gamma_1(f)^2$ and thus we get a convergence rate of $\frac{2Lr^2\delta^2}{t+1}$.

Moreover, the basic Frank-Wolfe (FW) algorithm may be extended to handle the regularized problem as well (Harchaoui et al., 2013; Bach, 2013; Zhang et al., 2012), with similar convergence rates in $O(1/t)$. Also, the second step in the algorithm, where the function f_{t+1} is built in the segment between f_t and the newly found extreme function, may be replaced by the optimization of J over the convex hull of all functions $\bar{f}_0, \dots, \bar{f}_t$, a variant which is often referred to as *fully corrective*. Moreover, in our context where $\mathcal{V}$ is a space where local search techniques may be considered, there is also the possibility of "fine-tuning" the vectors v as well (Bengio et al., 2006), that is, we may optimize the function $(v_1, \dots, v_t, \alpha_1, \dots, \alpha_t) \mapsto J(\sum_{i=1}^t \alpha_i \varphi_{v_i})$, through local search techniques, starting from the weights (α_i) and points (v_i) obtained from the conditional gradient algorithm.

Adding a new basis function. The conditional gradient algorithm presented above relies on solving at each iteration the "Frank-Wolfe step":

$$\max_{\gamma(f) \leqslant \delta} \langle f, g \rangle_{L_2(d\rho)}.$$

for $g = -J'(f_t) \in L_2(d\rho)$. For the norm γ_1 defined through an L_1-norm, we have for $f = \int_{\mathcal{V}} \varphi_v d\mu(v)$ such that $\gamma_1(f) = |\mu|(\mathcal{V})$:

$$\begin{aligned} \langle f, g \rangle_{L_2(d\rho)} &= \int_{\mathcal{X}} f(x) g(x) d\rho(x) = \int_{\mathcal{X}} \left(\int_{\mathcal{V}} \varphi_v(x) d\mu(v) \right) g(x) d\rho(x) \\ &= \int_{\mathcal{V}} \left(\int_{\mathcal{X}} \varphi_v(x) g(x) d\rho(x) \right) d\mu(v) \\ &\leqslant \gamma_1(f) \cdot \max_{v \in \mathcal{V}} \left| \int_{\mathcal{X}} \varphi_v(x) g(x) d\rho(x) \right|, \end{aligned}$$

with equality if and only if $\mu = \mu_+ - \mu_-$ with μ_+ and μ_- two non-negative measures, with μ_+ (resp. μ_-) supported in the set of maximizers v of $|\int_{\mathcal{X}} \varphi_v(x) g(x) d\rho(x)|$ where the value is positive (resp. negative).

This implies that:

$$\max_{\gamma_1(f) \leqslant \delta} \langle f, g \rangle_{L_2(d\rho)} = \delta \max_{v \in \mathcal{V}} \left| \int_{\mathcal{X}} \varphi_v(x) g(x) d\rho(x) \right|, \tag{1}$$

with the maximizers f of the first optimization problem above (left-hand side) obtained as δ times convex combinations of φ_v and $-\varphi_v$ for maximizers v of the second problem (right-hand side).

A common difficulty in practice is the hardness of the Frank-Wolfe step, that is, the optimization problem above over $\mathcal{V}$ may be difficult to solve. See Section 3.2, 3.3 and 3.4 for neural networks, where this optimization is usually difficult.

Finitely many observations. When $\mathcal{X}$ is finite (or when using the result from Section 2.2), the Frank-Wolfe step in Eq. (1) becomes equivalent to, for some vector $g \in \mathbb{R}^n$:

$$\sup_{\gamma_1(f) \leqslant \delta} \frac{1}{n} \sum_{i=1}^n g_i f(x_i) = \delta \max_{v \in \mathcal{V}} \left| \frac{1}{n} \sum_{i=1}^n g_i \varphi_v(x_i) \right|, \tag{2}$$

where the set of solutions of the first problem is in the convex hull of the solutions of the second problem.

Non-smooth loss functions. In this paper, in our theoretical results, we consider non-smooth loss functions for which conditional gradient algorithms do not converge in general. One possibility is to smooth the loss function, as done by Nesterov (2005): an approximation error of ε may be obtained with a smoothness constant proportional to $1/\varepsilon$. By choosing ε as $1/\sqrt{t}$, we obtain a convergence rate of $O(1/\sqrt{t})$ after t iterations. See also Lan (2013).

Approximate oracles. The conditional gradient algorithm may deal with approximate oracles; however, what we need in this paper is not the additive errors situations considered by Jaggi (2013), but multiplicative ones on the computation of the dual norm (similar to ones derived by Bach (2013) for the regularized problem).

Indeed, in our context, we minimize a function $J(f)$ on $f \in L_2(d\rho)$ over a norm ball $\{\gamma_1(f) \leqslant \delta\}$. A multiplicative approximate oracle outputs for any $g \in L_2(d\rho)$, a vector $\hat{f} \in L_2(d\rho)$ such that $\gamma_1(\hat{f}) = 1$, and

$$\langle \hat{f}, g \rangle \leqslant \max_{\gamma_1(f) \leqslant 1} \langle f, g \rangle \leqslant \kappa \langle \hat{f}, g \rangle,$$

for a fixed $\kappa \geqslant 1$. In Appendix B, we propose a modification of the conditional gradient algorithm that converges to a certain $h \in L_2(d\rho)$ such that $\gamma_1(h) \leqslant \delta$ and for which $\inf_{\gamma_1(f) \leqslant \delta} J(f) \leqslant J(h) \leqslant \inf_{\gamma_1(f) \leqslant \delta/\kappa} J(f)$.

Such approximate oracles are not available in general, because they require uniform bounds over all possible values of $g \in L_2(d\rho)$. In Section 5.5, we show that a weaker form of oracle is sufficient to preserve our generalization bounds from Section 5.

Approximation of any function by a finite number of basis functions. The Frank-Wolfe algorithm may be applied in the function space $\mathcal{F}_1$ with $J(f) = \frac{1}{2}\mathbb{E}[(f(x)-g(x))^2]$, we get a function f_t, supported by t basis functions such that $\mathbb{E}[(f_t(x) - g(x))^2] = O(\gamma(g)^2/t)$. Hence, any function in $\mathcal{F}_1$ may be approximated with averaged error ε with $t = O([\gamma(g)/\varepsilon]^2)$ units. Note that the conditional gradient algorithm is one among many ways to obtain such approximation with ε^{-2} units (Barron, 1993; Kurkova and Sanguineti, 2001; Mhaskar, 2004). See Section 4.1 for a (slightly) better dependence on ε for convex neural networks.

3. Neural Networks with Non-decreasing Positively Homogeneous Activation Functions

In this paper, we focus on a specific family of basis functions, that is, of the form

$$x \mapsto \sigma(w^\top x + b),$$

for specific activation functions σ. We assume that σ is non-decreasing and positively homogeneous of some integer degree, i.e., it is equal to $\sigma(u) = (u)_+^\alpha$, for some $\alpha \in \{0, 1, \dots\}$. We focus on these functions for several reasons:

- Since they are not polynomials, linear combinations of these functions can approximate any measurable function (Leshno et al., 1993).
- By homogeneity, they are invariant by a change of scale of the data; indeed, if all observations x are multiplied by a constant, we may simply change the measure μ defining the expansion of f by the appropriate constant to obtain exactly the same function. This allows us to study functions defined on the unit-sphere.
- The special case $\alpha = 1$, often referred to as the *rectified linear unit*, has seen considerable recent empirical success (Nair and Hinton, 2010; Krizhevsky et al., 2012), while the case $\alpha = 0$ (hard thresholds) has some historical importance (Rosenblatt, 1958).

The goal of this section is to specialize the results from Section 2 to this particular case and show that the "Frank-Wolfe" steps have simple geometric interpretations.

We first show that the positive homogeneity of the activation functions allows to transfer the problem to a unit sphere.

Boundedness assumptions. For the theoretical analysis, we assume that our data inputs $x \in \mathbb{R}^d$ are almost surely bounded by R in ℓ_q-norm, for some $q \in [2, \infty]$ (typically $q = 2$ and $q = \infty$). We then build the augmented variable $z \in \mathbb{R}^{d+1}$ as $z = (x^\top, R)^\top \in \mathbb{R}^{d+1}$ by appending the constant R to $x \in \mathbb{R}^d$. We therefore have $\|z\|_q \leqslant \sqrt{2}R$. By defining the vector $v = (w^\top, b/R)^\top \in \mathbb{R}^{d+1}$, we have:

$$\varphi_v(x) = \sigma(w^\top x + b) = \sigma(v^\top z) = (v^\top z)_+^\alpha,$$

which now becomes a function of $z \in \mathbb{R}^{d+1}$.

Without loss of generality (and by homogeneity of σ), we may assume that the ℓ_p-norm of each vector v is equal to $1/R$, that is $\mathcal{V}$ will be the $(1/R)$-sphere for the ℓ_p-norm, where $1/p + 1/q = 1$ (and thus $p \in [1, 2]$, with corresponding typical values $p = 2$ and $p = 1$).

This implies by Hölder's inequality that $\varphi_v(x)^2 \leqslant 2^\alpha$. Moreover this leads to functions in $\mathcal{F}_1$ that are bounded everywhere, that is, $\forall f \in \mathcal{F}_1$, $f(x)^2 \leqslant 2^\alpha \gamma_1(f)^2$. Note that the functions in $\mathcal{F}_1$ are also Lipschitz-continuous for $\alpha \geqslant 1$.

Since all ℓ_p-norms (for $p \in [1, 2]$) are equivalent to each other with constants of at most $\sqrt{d}$ with respect to the ℓ_2-norm, all the spaces $\mathcal{F}_1$ defined above are equal, but the norms γ_1 are of course different and they differ by a constant of at most $d^{\alpha/2}$—this can be seen by computing the dual norms like in Eq. (2) or Eq. (1).

Homogeneous reformulation. In our study of approximation properties, it will be useful to consider the the space of function $\mathcal{G}_1$ defined for z in the unit sphere $\mathbb{S}^d \subset \mathbb{R}^{d+1}$ of the Euclidean norm, such that $g(z) = \int_{\mathbb{S}^d} \sigma(v^\top z) d\mu(v)$, with the norm $\gamma_1(g)$ defined as the infimum of $|\mu|(\mathbb{S}^d)$ over all decompositions of g. Note the slight overloading of notations for γ_1 (for norms in $\mathcal{G}_1$ and $\mathcal{F}_1$) which should not cause any confusion.

In order to prove the approximation properties (with unspecified constants depending only on d), we may assume that $p = 2$, since the norms $\|\cdot\|_p$ for $p \in [1, \infty]$ are equivalent to $\|\cdot\|_2$ with a constant that grows at most as $d^{\alpha/2}$ with respect to the ℓ_2-norm. We thus focus on the ℓ_2-norm in all proofs in Section 4.

We may go from $\mathcal{G}_1$ (a space of real-valued functions defined on the unit ℓ_2-sphere in $d+1$ dimensions) to the space $\mathcal{F}_1$ (a space of real-valued functions defined on the ball of radius R for the ℓ_2-norm) as follows (this corresponds to sending a ball in $\mathbb{R}^d$ into a spherical cap in dimension $d+1$, as illustrated in Figure 2).

- Given $g \in \mathcal{G}_1$, we define $f \in \mathcal{F}_1$, with $f(x) = \left(\frac{\|x\|_2^2}{R^2} + 1\right)^{\alpha/2} g\left(\frac{1}{\sqrt{\|x\|_2^2 + R^2}} \begin{pmatrix} x \\ R \end{pmatrix}\right)$. If g may be represented as $\int_{\mathbb{S}^d} \sigma(v^\top z) d\mu(v)$, then the function f that we have defined may be represented as

$$\begin{aligned} f(x) &= \left(\frac{\|x\|_2^2}{R^2} + 1\right)^{\alpha/2} \int_{\mathbb{S}^d} \left(v^\top \frac{1}{\sqrt{\|x\|_2^2 + R^2}} \begin{pmatrix} x \\ R \end{pmatrix}\right)_+^\alpha d\mu(v) \\ &= \int_{\mathbb{S}^d} \left(v^\top \begin{pmatrix} x/R \\ 1 \end{pmatrix}\right)_+^\alpha d\mu(v) = \int_{\mathbb{S}^d} \sigma(w^\top x + b) d\mu(Rw, b), \end{aligned}$$

  that is $\gamma_1(f) \leqslant \gamma_1(g)$, because we have assumed that $(w^\top, b/R)^\top$ is on the $(1/R)$-sphere.

- Conversely, given $f \in \mathcal{F}_1$, for $z = (t^\top, a)^\top \in \mathbb{S}^d$, we define $g(z) = g(t, a) = f(\frac{Rt}{a}) a^\alpha$, which we define as such on the set of $z = (t^\top, a)^\top \in \mathbb{R}^d \times \mathbb{R}$ (of unit norm) such that $a \geqslant \frac{1}{\sqrt{2}}$. Since we always assume $\|x\|_2 \leqslant R$, we have $\sqrt{\|x\|_2^2 + R^2} \leqslant \sqrt{2}R$, and the value of $g(z, a)$ for $a \geqslant \frac{1}{\sqrt{2}}$ is enough to recover f from the formula above.

  On that portion $\{a \geqslant 1/\sqrt{2}\}$ of the sphere $\mathbb{S}^d$, this function exactly inherits the differentiability properties of f. That is, (a) if f is bounded by 1 and f is $(1/R)$-Lipschitz-continuous, then g is Lipschitz-continuous with a constant that only depends on d and α and (b), if all derivatives of order less than k are bounded by R^{-k}, then all derivatives of the same order of g are bounded by a constant that only depends on d and α. Precise notions of differentiability may be defined on the sphere, using

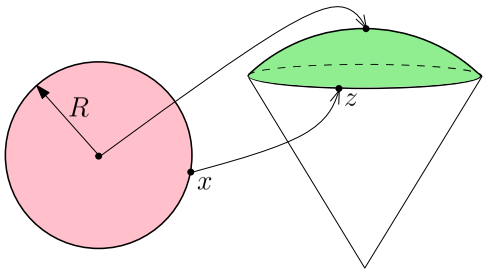

Figure 2: Sending a ball to a spherical cap.

the manifold structure (see, e.g., Absil et al., 2009) or through polar coordinates (see, e.g., Atkinson and Han, 2012, Chapter 3). See these references for more details.

The only remaining important aspect is to define g on the entire sphere, so that (a) its regularity constants are controlled by a constant times the ones on the portion of the sphere where it is already defined, (b) g is either even or odd (this will be important in Section 4). Ensuring that the regularity conditions can be met is classical when extending to the full sphere (see, e.g., Whitney, 1934). Ensuring that the function may be chosen as odd or even may be obtained by multiplying the function g by an infinitely differentiable function which is equal to one for $a \geqslant 1/\sqrt{2}$ and zero for $a \leqslant 0$, and extending by $-g$ or g on the hemi-sphere $a < 0$.

In summary, we may consider in Section 4 functions defined on the sphere, which are much easier to analyze. In the rest of the section, we specialize some of the general concepts reviewed in Section 2 to our neural network setting with specific activation functions, namely, in terms of corresponding kernel functions and geometric reformulations of the Frank-Wolfe steps.

3.1 Corresponding Positive-definite Kernels

In this section, we consider the ℓ_2-norm on the input weight vectors w (that is $p = 2$). We may compute for $x, x' \in \mathbb{R}^d$ the kernels defined in Section 2.3:

$$k_\alpha(x, x') = \mathbb{E}[(w^\top x + b)_+^\alpha (w^\top x' + b)_+^\alpha],$$

for (Rw, b) distributed uniformly on the unit ℓ_2-sphere $\mathbb{S}^d$, and $x, x' \in \mathbb{R}^{d+1}$. Given the angle $\varphi \in [0, \pi]$ defined through $\frac{x^\top x'}{R^2} + 1 = (\cos\varphi)\sqrt{\frac{\|x\|_2^2}{R^2} + 1}\sqrt{\frac{\|x'\|_2^2}{R^2} + 1}$, we have explicit expressions (Le Roux and Bengio, 2007; Cho and Saul, 2009):

$$\begin{aligned} k_0(z, z') &= \frac{1}{2\pi}(\pi - \varphi) \\ k_1(z, z') &= \frac{\sqrt{\frac{\|x\|_2^2}{R^2} + 1}\sqrt{\frac{\|x'\|_2^2}{R^2} + 1}}{2(d+1)\pi}((\pi - \varphi)\cos\varphi + \sin\varphi) \end{aligned}$$

$$k_2(z, z') = \frac{\left(\frac{\|x\|_2^2}{R^2} + 1\right)\left(\frac{\|x'\|_2^2}{R^2} + 1\right)}{2\pi[(d+1)^2 + 2(d+1)]}(3\sin\varphi\cos\varphi + (\pi - \varphi)(1 + 2\cos^2\varphi)).$$

There are key differences and similarities between the RKHS $\mathcal{F}_2$ and our space of functions $\mathcal{F}_1$. The RKHS is smaller than $\mathcal{F}_1$ (i.e., the norm in the RKHS is larger than the norm in $\mathcal{F}_1$); this implies that approximation properties of the RKHS are transferred to $\mathcal{F}_1$. In fact, our proofs rely on this fact.

However, the RKHS norm does not lead to any adaptivity, while the function space $\mathcal{F}_1$ does (see more details in Section 5). This may come as a paradox: both the RKHS $\mathcal{F}_2$ and $\mathcal{F}_1$ have similar properties, but one is adaptive while the other one is not. A key intuitive difference is as follows: given a function f expressed as $f(x) = \int_{\mathcal{V}} \varphi_v(x) p(v) d\tau(v)$, then $\gamma_1(f) = \int_{\mathcal{V}} |p(v)| d\tau(v)$, while the squared RKHS norm is $\gamma_2(f)^2 = \int_{\mathcal{V}} |p(v)|^2 d\tau(v)$. For the L_1-norm, the measure $p(v)d\tau(v)$ may tend to a singular distribution with a bounded norm, while this is not true for the L_2-norm. For example, the function $(w^\top x + b)_+^\alpha$ is in $\mathcal{F}_1$, while it is not in $\mathcal{F}_2$ in general.

3.2 Incremental Optimization Problem for $\alpha = 0$

We consider the problem in Eq. (2) for the special case $\alpha = 0$. For $z_1, \dots, z_n \in \mathbb{R}^{d+1}$ and a vector $y \in \mathbb{R}^n$, the goal is to solve (as well as the corresponding problem with y replaced by $-y$):

$$\max_{v \in \mathbb{R}^{d+1}} \sum_{i=1}^n y_i 1_{v^\top z_i > 0} = \max_{v \in \mathbb{R}^{d+1}} \sum_{i \in I_+} |y_i| 1_{v^\top z_i > 0} - \sum_{i \in I_-} |y_i| 1_{v^\top z_i > 0},$$

where $I_+ = \{i, y_i \geqslant 0\}$ and $I_- = \{i, y_i < 0\}$. As outlined by Bengio et al. (2006), this is equivalent to finding an hyperplane parameterized by v that minimizes a weighted misclassification rate (when doing linear classification). Note that the norm of v has no effect.

NP-hardness. This problem is NP-hard in general. Indeed, if we assume that all y_i are equal to -1 or 1 and with $\sum_{i=1}^n y_i = 0$, then we have a balanced binary classification problem (we need to assume n even). The quantity $\sum_{i=1}^n y_i 1_{v^\top z_i > 0}$ is then $\frac{n}{2}(1 - 2e)$ where e is the corresponding classification error for a problem of classifying at positive (resp. negative) the examples in I_+ (resp. I_-) by thresholding the linear classifier $v^\top z$. Guruswami and Raghavendra (2009) showed that for all (ε, δ), it is NP-hard to distinguish between instances (i.e., configurations of points x_i), where a halfspace with classification error at most ε exists, and instances where all half-spaces have an error of at least $1/2 - \delta$. Thus, it is NP-hard to distinguish between instances where there exists $v \in \mathbb{R}^{d+1}$ such that $\sum_{i=1}^n y_i 1_{v^\top z_i > 0} \geqslant \frac{n}{2}(1 - 2\varepsilon)$ and instances where for all $v \in \mathbb{R}^{d+1}$, $\sum_{i=1}^n y_i 1_{v^\top z_i > 0} \leqslant n\delta$. Thus, it is NP-hard to distinguish instances where $\max_{v \in \mathbb{R}^{d+1}} \sum_{i=1}^n y_i 1_{v^\top z_i > 0} \geqslant \frac{n}{2}(1 - 2\varepsilon)$ and ones where it is less than $\frac{n}{2}\delta$. Since this is valid for all δ and ε, this rules out a constant-factor approximation.

Convex relaxation. Given linear binary classification problems, there are several algorithms to approximately find a good half-space. These are based on using convex surrogates (such as the hinge loss or the logistic loss). Although some theoretical results do exist regarding the classification performance of estimators obtained from convex surrogates (Bartlett et al., 2006), they do not apply in the context of linear classification.

3.3 Incremental Optimization Problem for $\alpha = 1$

We consider the problem in Eq. (2) for the special case $\alpha = 1$. For $z_1, \dots, z_n \in \mathbb{R}^{d+1}$ and a vector $y \in \mathbb{R}^n$, the goal is to solve (as well as the corresponding problem with y replaced by $-y$):

$$\max_{\|v\|_p \leqslant 1} \sum_{i=1}^n y_i (v^\top z_i)_+ = \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} (v^\top |y_i| z_i)_+ - \sum_{i \in I_-} (v^\top |y_i| z_i)_+,$$

where $I_+ = \{i, y_i \geqslant 0\}$ and $I_- = \{i, y_i < 0\}$. We have, with $t_i = |y_i| z_i \in \mathbb{R}^{d+1}$, using convex duality:

$$\begin{aligned}
\max_{\|v\|_p \leqslant 1} \sum_{i=1}^n y_i (v^\top z_i)_+ &= \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} (v^\top t_i)_+ - \sum_{i \in I_-} (v^\top t_i)_+ \\
&= \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} \max_{b_i \in [0,1]} b_i v^\top t_i - \sum_{i \in I_-} \max_{b_i \in [0,1]} b_i v^\top t_i \\
&= \max_{b_+ \in [0,1]^{I_+}} \max_{\|v\|_p \leqslant 1} \min_{b_- \in [0,1]^{I_-}} v^\top [T_+^\top b_+ - T_-^\top b_-] \\
&= \max_{b_+ \in [0,1]^{I_+}} \min_{b_- \in [0,1]^{I_-}} \max_{\|v\|_p \leqslant 1} v^\top [T_+^\top b_+ - T_-^\top b_-] \text{ by Fenchel duality,} \\
&= \max_{b_+ \in [0,1]^{I_+}} \min_{b_- \in [0,1]^{I_-}} \|T_+^\top b_+ - T_-^\top b_-\|_q,
\end{aligned}$$

where $T_+ \in \mathbb{R}^{n_+ \times d}$ has rows t_i, $i \in I_+$ and $T_- \in \mathbb{R}^{n_- \times d}$ has rows t_i, $i \in I_-$, with $v \in \arg\max_{\|v\|_p \leqslant 1} v^\top (T_+^\top b_+ - T_-^\top b_-)$. The problem thus becomes

$$\max_{b_+ \in [0,1]^{n_+}} \min_{b_- \in [0,1]^{n_-}} \|T_+^\top b_+ - T_-^\top b_-\|_q.$$

For the problem of maximizing $|\sum_{i=1}^n y_i (v^\top z_i)_+|$, then this corresponds to

$$\max \left\{ \max_{b_+ \in [0,1]^{n_+}} \min_{b_- \in [0,1]^{n_-}} \|T_+^\top b_+ - T_-^\top b_-\|_q, \max_{b_- \in [0,1]^{n_-}} \min_{b_+ \in [0,1]^{n_+}} \|T_+^\top b_+ - T_-^\top b_-\|_q \right\}.$$

This is exactly the Hausdorff distance between the two convex sets $\{T_+^\top b_+,\ b_+ \in [0,1]^{n_+}\}$ and $\{T_-^\top b_-,\ b_- \in [0,1]^{n_-}\}$ (referred to as zonotopes, see below).

Given the pair (b_+, b_-) achieving the Hausdorff distance, then we may compute the optimal v as $v = \arg\max_{\|v\|_p \leqslant 1} v^\top (T_+^\top b_+ - T_-^\top b_-)$. Note this has not changed the problem at all, since it is equivalent. It is still NP-hard in general (König, 2014). But we now have a geometric interpretation with potential approximation algorithms. See below and Section 6.

Zonotopes. A *zonotope* A is the Minkowski sum of a finite number of segments from the origin, that is, of the form

$$A = [0, t_1] + \cdots + [0, t_r] = \left\{ \sum_{i=1}^r b_i t_i,\ b \in [0,1]^r \right\},$$

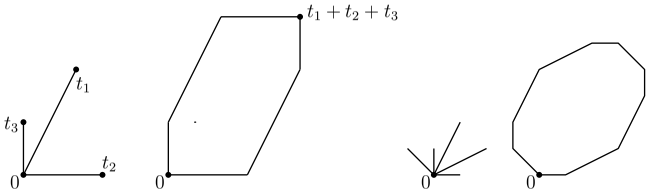

Figure 3: Two zonotopes in two dimensions: (left) vectors, and (right) their Minkowski sum (represented as a polygone).

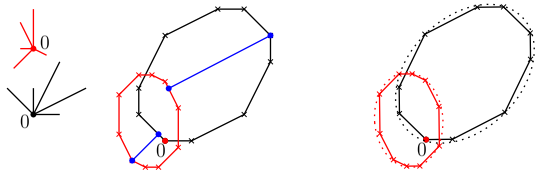

Figure 4: Left: two zonotopes (with their generating segments) and the segments achieving the two sides of the Haussdorf distance. Right: approximation by ellipsoids.

for some vectors t_i, $i = 1, \dots, r$ (Bolker, 1969). See an illustration in Figure 3. They appear in several areas of computer science (Edelsbrunner, 1987; Guibas et al., 2003) and mathematics (Bolker, 1969; Bourgain et al., 1989). In machine learning, they appear naturally as the affine projection of a hypercube; in particular, when using a higher-dimensional distributed representation of points in $\mathbb{R}^d$ with elements in $[0,1]^r$, where r is larger than d (see, e.g., Hinton and Ghahramani, 1997), the underlying polytope that is modelled in $\mathbb{R}^d$ happens to be a zonotope.

In our context, the two convex sets $\{T_+^\top b_+,\ b_+ \in [0,1]^{n_+}\}$ and $\{T_-^\top b_-,\ b_- \in [0,1]^{n_-}\}$ defined above are thus zonotopes. See an illustration of the Hausdorff distance computation in Figure 4 (middle plot), which is the core computational problem for $\alpha = 1$.

Approximation by ellipsoids. Centrally symmetric convex polytopes (w.l.o.g. centered around zero) may be approximated by ellipsoids. In our set-up, we could use the minimum volume enclosing ellipsoid (see, e.g. Barvinok, 2002), which can be computed exactly when the polytope is given through its vertices, or up to a constant factor when the polytope is such that quadratic functions may be optimized with a constant factor approximation. For zonotopes, the standard semi-definite relaxation of Nesterov (1998) leads to such constant-factor approximations, and thus the minimum volume inscribed ellipsoid may be computed up to a constant. Given standard results (see, e.g. Barvinok, 2002), a $(1/\sqrt{d})$-scaled version of the ellipsoid is inscribed in this polytope, and thus the ellipsoid is a provably good approximation of the zonotope with a factor scaling as $\sqrt{d}$. However, the approximation

ratio is not good enough to get any relevant bound for our purpose (see Section 5.5), as for computing the Haussdorff distance, we care about potentially vanishing differences that are swamped by constant factor approximations.

Nevertheless, the ellipsoid approximation may prove useful in practice, in particular because the ℓ_2-Haussdorff distance between two ellipsoids may be computed in polynomial time (see Appendix E).

NP-hardness. Given the reduction of the case $\alpha = 1$ (rectified linear units) to $\alpha = 0$ (exact thresholds) (Livni et al., 2014), the incremental problem is also NP-hard, so as obtaining a constant-factor approximation. However, this does not rule out convex relaxations with non-constant approximation ratios (see Section 6 for more details).

3.4 Incremental Optimization Problem for $\alpha \geqslant 2$

We consider the problem in Eq. (2) for the remaining cases $\alpha \geqslant 2$. For $z_1, \dots, z_n \in \mathbb{R}^{d+1}$ and a vector $y \in \mathbb{R}^n$, the goal is to solve (as well as the corresponding problem with y replaced by $-y$):

$$\max_{\|v\|_p \leqslant 1} \frac{1}{\alpha} \sum_{i=1}^n y_i (v^\top z_i)_+^\alpha = \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} \frac{1}{\alpha} (v^\top |y_i|^{1/\alpha} z_i)_+^\alpha - \sum_{i \in I_-} \frac{1}{\alpha} (v^\top |y_i|^{1/\alpha} z_i)_+^\alpha,$$

where $I_+ = \{i, y_i \geqslant 0\}$ and $I_- = \{i, y_i < 0\}$. We have, with $t_i = |y_i|^{1/\alpha} z_i \in \mathbb{R}^{d+1}$, and $\beta \in (1, 2]$ defined by $1/\beta + 1/\alpha = 1$ (we use the fact that the function $u \mapsto u^\alpha/\alpha$ and $v \mapsto v^\beta/\beta$ are Fenchel-dual to each other):

$$\begin{aligned}
\max_{\|v\|_p \leqslant 1} \frac{1}{\alpha} \sum_{i=1}^n y_i (v^\top z_i)_+^\alpha &= \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} \frac{1}{\alpha} (v^\top t_i)_+^\alpha - \sum_{i \in I_-} \frac{1}{\alpha} (v^\top t_i)_+^\alpha \\
&= \max_{\|v\|_p \leqslant 1} \sum_{i \in I_+} \max_{b_i \geqslant 0} \Big\{ b_i v_i^\top t_i - \frac{1}{\beta} b_i^\beta \Big\} - \sum_{i \in I_-} \max_{b_i \geqslant 0} \Big\{ b_i v^\top t_i - \frac{1}{\beta} b_i^\beta \Big\} \\
&= \max_{b_+ \in \mathbb{R}_+^{I_+}} \min_{b_- \in \mathbb{R}_+^{I_-}} \max_{\|v\|_p \leqslant 1} v^\top [T_+^\top b_+ - T_-^\top b_-] - \frac{1}{\beta} \|b_+\|_\beta^\beta + \frac{1}{\beta} \|b_-\|_\beta^\beta \\
&\qquad \text{by Fenchel duality,} \\
&= \max_{b_+ \in [0,1]^{I_+}} \min_{b_- \in [0,1]^{I_-}} \|T_+^\top b_+ - T_-^\top b_-\|_q - \frac{1}{\beta} \|b_+\|_\beta^\beta + \frac{1}{\beta} \|b_-\|_\beta^\beta, \quad (3)
\end{aligned}$$

where $T_+ \in \mathbb{R}^{n_+ \times d}$ has rows t_i, $i \in I_+$ and $T_- \in \mathbb{R}^{n_- \times d}$ has rows t_i, $i \in I_-$, with $v \in \arg\max_{\|v\|_p \leqslant 1} (T_+^\top b_+ - T_-^\top b_-)^\top v$. Contrary to the case $\alpha = 1$, we do not obtain exactly a formulation as a Hausdorff distance. However, if we consider the convex sets $K_\lambda^+ = \{T_+^\top b_+,\ b_+ \geqslant 0,\ \|b_+\|_\beta \leqslant \lambda\}$ and $K_\mu^- = \{T_-^\top b_-,\ b_- \geqslant 0,\ \|b_-\|_\beta \leqslant \mu\}$, then, a solution of Eq. (3) may be obtained from Hausdorff distance computations between K_λ^+ and K_μ^-, for certain λ and μ.

Note that, while for $\alpha = 1$ we can use the identity $2u_+ = u + |u|$ to replace the rectified linear unit by the absolute value and obtain the same function space, this is not possible for $\alpha = 2$, as $(u_+)^2$ and u^2 do not differ by a linear function. This implies that the results from Livni et al. (2014), which state that for the quadratic activation function, the incremental problems is equivalent to an eigendecomposition (and hence solvable in polynomial time), do not apply.

4. Approximation Properties

In this section, we consider the approximation properties of the set $\mathcal{F}_1$ of functions defined on $\mathbb{R}^d$. As mentioned earlier, the norm used to penalize input weights w or v is irrelevant for approximation properties as all norms are equivalent. Therefore, we focus on the case $q = p = 2$ and ℓ_2-norm constraints.

Because we consider homogeneous activation functions, we start by studying the set $\mathcal{G}_1$ of functions defined on the unit ℓ_2-sphere $\mathbb{S}^d \subset \mathbb{R}^{d+1}$. We denote by τ_d the uniform probability measure on $\mathbb{S}^d$. The set $\mathcal{G}_1$ is defined as the set of functions on the sphere such that $g(z) = \int_{\mathbb{S}^d} \sigma(v^\top z) p(z) d\tau_d(z)$, with the norm $\gamma_1(g)$ equal to the smallest possible value of $\int_{\mathbb{S}^d} |p(z)| d\tau_d(z)$. We may also define the corresponding squared RKHS norm by the smallest possible value of $\int_{\mathbb{S}^d} |p(z)|^2 d\tau_d(z)$, with the corresponding RKHS $\mathcal{G}_2$.

In this section, we first consider approximation properties of functions in $\mathcal{G}_1$ by a finite number of neurons (only for $\alpha = 1$). We then study approximation properties of functions on the sphere by functions in $\mathcal{G}_1$. It turns out that all our results are based on the approximation properties of the corresponding RKHS $\mathcal{G}_2$: we give sufficient conditions for being in $\mathcal{G}_2$, and then approximation bounds for functions which are not in $\mathcal{G}_2$. Finally we transfer these to the spaces $\mathcal{F}_1$ and $\mathcal{F}_2$, and consider in particular functions which only depend on projections on a low-dimensional subspace, for which the properties of $\mathcal{G}_1$ and $\mathcal{G}_2$ (and of $\mathcal{F}_1$ and $\mathcal{F}_2$) differ. This property is key to obtaining generalization bounds that show adaptivity to linear structures in the prediction functions (as done in Section 5).

Approximation properties of neural networks with finitely many neurons have been studied extensively (see, e.g., Petrushev, 1998; Pinkus, 1999; Makovoz, 1998; Burger and Neubauer, 2001). In Section 4.7, we relate our new results to existing work from the literature on approximation theory, by showing that our results provide an explicit control of the various weight vectors which are needed for bounding the estimation error in Section 5.

4.1 Approximation by a Finite Number of Basis Functions

A key quantity that drives the approximability by a finite number of neurons is the variation norm $\gamma_1(g)$. As shown in Section 2.5, any function g such that $\gamma_1(g)$ is finite, may be approximated in $L_2(\mathbb{S}^d)$-norm with error ε with $n = O(\gamma_1(g)^2 \varepsilon^{-2})$ units. For $\alpha = 1$ (rectified linear units), we may improve the dependence in ε, through the link with zonoids and zonotopes, as we now present.

If we decompose the signed measure μ as $\mu = \mu_+ - \mu_-$ where μ_+ and μ_- are positive measures, then, for $g \in \mathcal{G}_1$, we have $g(z) = \int_{\mathbb{S}^d} (v^\top z)_+ d\mu_+(v) - \int_{\mathbb{S}^d} (v^\top z)_+ d\mu_-(v) = g_+(z) - g_-(z)$, which is a decomposition of g as a difference of positively homogenous convex functions.

Positively homogenous convex functions h may be written as the *support function* of a compact convex set K (Rockafellar, 1997), that is, $h(z) = \max_{y \in K} y^\top z$, and the set K characterizes the function h. The functions g_+ and g_- defined above are not *any* convex positively homogeneous functions, as we now describe.

If the measure μ_+ is supported by finitely many points, that is, $\mu_+(v) = \sum_{i=1}^r \eta_i \delta(v - v_i)$ with $\eta \geqslant 0$, then $g_+(z) = \sum_{i=1}^t \eta_i (v_i^\top z)_+ = \sum_{i=1}^t (\eta_i v_i^\top z)_+ = \sum_{i=1}^t (t_i^\top z)_+$ for $t_i = \eta_i v_i$. Thus the corresponding set K_+ is the *zonotope* $[0, t_1] + \cdots + [0, t_r] = \{ \sum_{i=1}^r b_i t_i, \ b \in [0,1]^r \}$ already defined in Section 3.3. Thus the functions $g_+ \in \mathcal{G}_1$ and $g_- \in \mathcal{G}_1$ for finitely supported measures μ are support functions of zonotopes.

When the measure μ is not constrained to have finite support, then the sets K_+ and K_- are limits of zonotopes, and thus, by definition, *zonoids* (Bolker, 1969), and thus functions in $\mathcal{G}_1$ are differences of support functions of zonoids. Zonoids are a well-studied set of convex bodies. They are centrally symmetric, and in two dimensions, all centrally symmetric compact convexs sets are (up to translation) zonoids, which is not true in higher dimensions (Bolker, 1969). Moreover, the problem of approximating a zonoid by a zonotope with a small number of segments (Bourgain et al., 1989; Matoušek, 1996) is essentially equivalent to the approximation of a function g by finitely many neurons. The number of neurons directly depends on the norm γ_1, as we now show.

Proposition 1 (Number of units - $\alpha = 1$) *Let $\varepsilon \in (0, 1/2)$. For any function g in $\mathcal{G}_1$, there exists a measure μ supported on at most r points in $\mathcal{V}$, so that for all $z \in \mathbb{S}^d$. $|g(z) - \int_{\mathbb{S}^d} (v^\top z)_+ d\mu(v)| \leqslant \varepsilon \gamma_1(g)$, with $r \leqslant C(d) \varepsilon^{-2d/(d+3)}$, for some constant $C(d)$ that depends only on d.*

Proof Without loss of generality, we assume $\gamma(g) = 1$. It is shown by Matoušek (1996) that for any probability measure μ (positive and with finite mass) on the sphere $\mathbb{S}^d$, there exists a set of r points $v_1, \dots, v_r$, so that for all $z \in \mathbb{S}^d$,

$$\left| \int_{\mathbb{S}^d} |v^\top z| d\mu(v) - \frac{1}{r} \sum_{i=1}^r |v_i^\top z| \right| \leqslant \varepsilon, \tag{4}$$

with $r \leqslant C(d) \varepsilon^{-2+6/(d+3)} = C(d) \varepsilon^{-2d/(d+3)}$, for some constant $C(d)$ that depends only on d. We may then simply write

$$g(z) = \int_{\mathbb{S}^d} (v^\top z)_+ d\mu(v) = \frac{1}{2} \int_{\mathbb{S}^d} (v^\top z) d\mu(v) + \frac{\mu_+(\mathbb{S}^d)}{2} \int_{\mathbb{S}^d} |v^\top z| \frac{d\mu_+(v)}{\mu_+(\mathbb{S}^d)} - \frac{\mu_-(\mathbb{S}^d)}{2} \int_{\mathbb{S}^d} |v^\top z| \frac{d\mu_-(v)}{\mu_-(\mathbb{S}^d)},$$

and approximate the last two terms with error $\varepsilon \mu_\pm(\mathbb{S}^d)$ with r terms, leading to an approximation of $\varepsilon \mu_+(\mathbb{S}^d) + \varepsilon \mu_-(\mathbb{S}^d) = \varepsilon \gamma_1(g) = \varepsilon$, with a remainder that is a linear function $q^\top z$ of z, with $\|q\|_2 \leqslant 1$. We may then simply add two extra units with vectors $q/\|q\|_2$ and weights $-\|q\|_2$ and $\|q\|_2$. We thus obtain, with $2r + 2$ units, the desired approximation result.

Note that Bourgain et al. (1989, Theorem 6.5) showed that the scaling in ε in Eq. (4) is not improvable, if the measure is allowed to have non equal weights on all points and the proof relies on the non-approximability of the Euclidean ball by centered zonotopes. This results does not apply here, because we may have different weights $\mu_-(\mathbb{S}^d)$ and $\mu_+(\mathbb{S}^d)$. ■

Note that the proposition above is slightly improved in terms of the scaling of the number of neurons with respect to the approximation error ε (improved exponent), compared to conditional gradient bounds (Barron, 1993; Kurkova and Sanguineti, 2001). Indeed, the simple use of conditional gradient leads to $r \leqslant \varepsilon^{-2} \gamma_1(g)^2$, with a better constant (independent of d) but a worse scaling in ε—also with a result in $L_2(\mathbb{S}^d)$-norm and not uniformly on the ball $\{\|x\|_q \leqslant R\}$. Note also that the conditional gradient algorithm gives a constructive way of building the measure. Moreover, the proposition above is related to the result from Makovoz (1998, Theorem 2), which applies for $\alpha = 0$ but with a number of neurons growing as $\varepsilon^{-2d/(d+1)}$, or to the one of Burger and Neubauer (2001, Example 3.1), which applies to a piecewise affine sigmoidal function but with a number of neurons growing as $\varepsilon^{-2(d+1)/(d+3)}$ (both slightly worse than ours).

Finally, the number of neurons needed to express a function with a bound on the γ_2-norm can be estimated from general results on approximating reproducing kernel Hilbert space described in Section 2.3, whose kernel can be expressed as an expectation. Indeed, Bach (2017) shows that with k neurons, one can approximate a function in $\mathcal{F}_2$ with unit γ_2-norm with an error measured in L_2 of $\varepsilon = k^{-(d+3)/(2d)}$. When inverting the relationship between k and ε, we get a number of neurons scaling as $\varepsilon^{-2d/(d+3)}$, which is the same as in Prop. 1 but with an error in L_2-norm instead of L^∞-norm.

4.2 Sufficient Conditions for Finite Variation

In this section and the next one, we study more precisely the RKHS $\mathcal{G}_2$ (and thus obtain similar results for $\mathcal{G}_1 \supset \mathcal{G}_2$). The kernel $k(x, y) = \int_{\mathbb{S}^d} (v^\top x)_+ (v^\top y)_+ d\tau_d(v)$ defined on the sphere $\mathbb{S}^d$ belongs to the family of dot-product kernels (Smola et al., 2001) that only depends on the dot-product $x^\top y$, although in our situation, the function is not particularly simple (see formulas in Section 3.1). The analysis of these kernels is similar to one of translation-invariant kernels; for $d = 1$, i.e., on the 2-dimensional sphere, it is done through Fourier series; while for $d > 1$, *spherical harmonics* have to be used as the expansion of functions in series of spherical harmonics make the computation of the RKHS norm explicit (see a review of spherical harmonics in Appendix D.1 with several references therein). Since the calculus is tedious, all proofs are put in appendices, and we only present here the main results. In this section, we provide simple sufficient conditions for belonging to $\mathcal{G}_2$ (and hence $\mathcal{G}_1$) based on the existence and boundedness of derivatives, while in the next section, we show how any Lipschitz-function may be approximated by functions in $\mathcal{G}_2$ (and hence $\mathcal{G}_1$) with precise control of the norm of the approximating functions.

The derivatives of functions defined on $\mathbb{S}^d$ may be defined in several ways, using the manifold structure (see, e.g., Absil et al., 2009) or through polar coordinates (see, e.g., Atkinson and Han, 2012, Chapter 3). For $d = 1$, the one-dimensional sphere $\mathbb{S}^1 \subset \mathbb{R}^2$ may be parameterized by a single angle and thus the notion of derivatives and the proof of the following result is simpler and based on Fourier series (see Appendix C.2). For the general proof based on spherical harmonics, see Appendix D.2.

Proposition 2 (Finite variation on the sphere) *Assume that $g : \mathbb{S}^d \to \mathbb{R}$ is such that all i-th order derivatives exist and are upper-bounded in absolute value by η for $i \in \{0, \dots, s\}$, where s is an integer such that $s \geqslant (d-1)/2 + \alpha + 1$. Assume g is even if α is odd (and vice-versa); then $g \in \mathcal{G}_2$ and $\gamma_2(g) \leqslant C(d, \alpha) \eta$, for a constant $C(d, \alpha)$ that depends only on d and α.*

We can make the following observations:

– *Tightness of conditions*: as shown in Appendix D.5, there are functions g, which have bounded first s derivatives and do not belong to $\mathcal{G}_2$ while $s \leqslant \frac{d}{2} + \alpha$ (at least when $s - \alpha$ is even). Therefore, when $s - \alpha$ is even, the scaling in $(d-1)/2 + \alpha$ is optimal.

– *Dependence on α*: for any d, the higher the α, the stricter the sufficient condition. Given that the estimation error grows slowly with α (see Section 5.1), low values of α would be preferred in practice.

– *Dependence on d*: a key feature of the sufficient condition is the dependence on d, that is, as d increases the number of derivatives has to increase in $d/2$—like for Sobolev spaces in dimension d (Adams and Fournier, 2003). This is another instantiation of the curse of dimensionality: only very smooth functions in high dimensions are allowed.

– *Special case $d = 1$, $\alpha = 0$*: differentiable functions on the sphere in $\mathbb{R}^2$, with bounded derivatives, belong to $\mathcal{G}_2$, and thus all Lipschitz-continuous functions, because Lipschitz-continuous functions are almost everywhere differentiable with bounded derivative (Adams and Fournier, 2003).

4.3 Approximation of Lipschitz-continuous Functions

In order to derive generalization bounds for target functions which are not sufficiently differentiable (and may not be in $\mathcal{G}_2$ or $\mathcal{G}_1$), we need to approximate any Lipschitz-continuous function, with a function $g \in \mathcal{G}_2$ with a norm $\gamma_2(g)$ that will grow as the approximation gets tighter. We give precise rates in the proposition below. Note the requirement for parity of the function g. The result below notably shows the density of $\mathcal{G}_1$ in uniform norm in the space of Lipschitz-continuous functions of the given parity, which is already known since our activation functions are not polynomials (Leshno et al., 1993).

Proposition 3 (Approximation of Lipschitz-continuous functions on the sphere) *For δ greater than a constant depending only on d and α, for any function $g : \mathbb{S}^d \to \mathbb{R}$ such that for all $x, y \in \mathbb{S}^d$, $g(x) \leqslant \eta$ and $|g(x) - g(y)| \leqslant \eta \|x - y\|_2$, and g is even if α is odd (and vice-versa), there exists $h \in \mathcal{G}_2$, such that $\gamma_2(h) \leqslant \delta$ and*

$$\sup_{x \in \mathbb{S}^d} |h(x) - g(x)| \leqslant C(d, \alpha) \eta \Big(\frac{\delta}{\eta} \Big)^{-1/(\alpha + (d-1)/2)} \log \Big(\frac{\delta}{\eta} \Big).$$

This proposition is shown in Appendix C.3 for $d = 1$ (using Fourier series) and in Appendix D.4 for all $d \geqslant 1$ (using spherical harmonics). We can make the following observations:

– *Dependence in δ and η*: as expected, the main term in the error bound $(\delta/\eta)^{-1/(\alpha+(d-1)/2)}$ is a decreasing function of δ/η, that is when the norm $\gamma_2(h)$ is allowed to grow, the approximation gets tighter, and when the Lipschitz constant of g increases, the approximation is less tight.

– *Dependence on d and α*: the rate of approximation is increasing in d and α. In particular the approximation properties are better for low α.

– *Special case $d = 1$ and $\alpha = 0$*: up to the logarithmic term we recover the result of Prop. 2, that is, the function g is in $\mathcal{G}_2$.

– *Tightness*: in Appendix D.5, we provide a function which is not in the RKHS and for which the tightest possible approximation scales as $\delta^{-2/(d/2+\alpha-2)}$. Thus the linear scaling of the rate as $d/2 + \alpha$ is not improvable (but constants are).

4.4 Linear Functions

In this section, we consider a linear function on $\mathbb{S}^d$, that is $g(x) = v^\top x$ for a certain $v \in \mathbb{S}^d$, and compute its norm (or upper-bound thereof) both for $\mathcal{G}_1$ and $\mathcal{G}_2$, which is independent of v and finite. In the following propositions, the notation $\approx$ means asymptotic equivalents when $d \to \infty$.

Proposition 4 (Norms of linear functions on the sphere) *Assume that $g : \mathbb{S}^d \to \mathbb{R}$ is such $g(x) = v^\top x$ for a certain $v \in \mathbb{S}^d$. If $\alpha = 0$, then $\gamma_1(g) \leqslant \gamma_2(g) = \frac{2d\pi}{d-1} \approx 2\pi$. If $\alpha = 1$, then $\gamma_1(g) \leqslant 2$, and for all $\alpha \geqslant 1$, $\gamma_1(g) \leqslant \gamma_2(g) = \frac{d}{d-1} \frac{4\pi}{\alpha} \frac{\Gamma(\alpha/2 + d/2 + 1)}{\Gamma(\alpha/2)\Gamma(d/2+1)} \approx C d^{\alpha/2}$.*

We see that for $\alpha = 1$, the γ_1-norm is less than a constant, and is much smaller than the γ_2-norm (which scales as $\sqrt{d}$). For $\alpha \geqslant 2$, we were not able to derive better bounds for γ_1 (other than the value of γ_2).

4.5 Functions of Projections

If $g(x) = \varphi(w^\top x)$ for some unit-norm $w \in \mathbb{R}^{d+1}$ and φ a function defined on the real-line, then the value of the norms γ_2 and γ_1 differ significantly. Indeed, for γ_1, we may consider a new variable $\tilde{x} \in \mathbb{S}^1 \subset \mathbb{R}^2$, with its first component $\tilde{x}_1 = w^\top x$, and the function $\tilde{g}(\tilde{x}) = \varphi(\tilde{x}_1)$. We may then apply Prop. 2 to $\tilde{g}$ with $d = 1$. That is, if φ is $(\alpha+1)$-times differentiable with bounded derivatives, there exists a decomposition $\tilde{g}(\tilde{x}) = \int_{\mathbb{S}^1} \tilde{\mu}(\tilde{v}) \sigma(\tilde{v}^\top \tilde{x}) d\tilde{\mu}$, with $\gamma_1(\tilde{g}) = |\tilde{\mu}|(\mathbb{S}^1)$, which is *not* increasing in d. If we consider any vector $t \in \mathbb{R}^{d+1}$ which is orthogonal to w in $\mathbb{R}^{d+1}$, then, we may define a measure μ supported in the circle defined by the two vectors w and t and which is equal to $\tilde{\mu}$ on that circle. The total variation of μ is the one of $\tilde{\mu}$ while g can be decomposed using μ and thus $\gamma_1(g) \leqslant \gamma_1(\tilde{g})$. Similarly, Prop. 3 could also be applied (and will for obtaining generalization bounds), also our reasoning works for any low-dimensional projections: the dependence on a lower-dimensional projection allows to reduce smoothness requirements.

However, for the RKHS norm γ_2, this reasoning does not apply. For example, a certain function φ exists, which is s-times differentiable, as shown in Appendix D.5, for $s \leqslant \frac{d}{2} + \alpha$ (when $s - \alpha$ is even), and is not in $\mathcal{G}_2$. Thus, given Prop. 2, the dependence on a uni-dimensional projection does not make a difference regarding the level of smoothness which is required to belong to $\mathcal{G}_2$.

4.6 From the Unit-sphere $\mathbb{S}^d$ to $\mathbb{R}^{d+1}$

We now extend the results above to functions defined on $\mathbb{R}^d$, to be approximated by functions in $\mathcal{F}_1$ and $\mathcal{F}_2$. More precisely, we first extend Prop. 2 and Prop. 3, and then consider norms of linear functions and functions of projections.

Proposition 5 (Finite variation) *Assume that $f : \mathbb{R}^d \to \mathbb{R}$ is such that all i-th order derivatives exist and are upper-bounded on the ball $\{\|x\|_q \leqslant R\}$ by η/R^i for $i \in \{0, \dots, k\}$, where s is the smallest integer such that $s \geqslant (d-1)/2 + \alpha + 1$; then $f \in \mathcal{F}_2$ and $\gamma_2(f) \leqslant C(d,\alpha)\eta$, for a constant $C(d,\alpha)$ that depends only on d and α.*

Proof By assumption, the function $x \mapsto f(Rx)$ has all its derivatives bounded by a constant times η. Moreover, we have defined $g(t,a) = f(\frac{Rt}{a})a^\alpha$ so that all derivatives are bounded by η. The result then follows immediately from Prop. 2. ■

Proposition 6 (Approximation of Lipschitz-continuous functions) *For δ larger than a constant that depends only on d and α, for any function $f : \mathbb{R}^d \to \mathbb{R}$ such that for all x, y such that $\|x\|_q \leqslant R$ and $\|y\|_q \leqslant R$, $|f(x)| \leqslant \eta$ and $|f(x) - f(y)| \leqslant \eta R^{-1}\|x - y\|_q$, there exists $g \in \mathcal{F}_2$ such that $\gamma_2(g) \leqslant \delta$ and*

$$\sup_{\|x\|_q \leqslant R} |f(x) - g(x)| \leqslant C(d,\alpha)\eta\Big(\frac{\delta}{\eta}\Big)^{-1/(\alpha+(d-1)/2)} \log\Big(\frac{\delta}{\eta}\Big).$$

Proof With the same reasoning as above, we obtain that g is Lipschitz-continuous with constant η, we thus get the desired approximation error from Prop. 3. ■

Linear functions. If $f(x) = w^\top x + b$, with $\|w\|_2 \leqslant \eta$ and $b \leqslant \eta R$, then for $\alpha = 1$, it is straightforward that $\gamma_1(f) \leqslant 2R\eta$. Moreover, we have $\gamma_2(f) \sim CR\eta$. For other values of α, we also have γ_1-norms less than a constant (depending *only* of α) times $R\eta$. The RKHS norms are bit harder to compute since linear functions for f leads to linear functions for g only for $\alpha = 1$.

Functions of projections. If $f(x) = \varphi(w^\top x)$ where $\|w\|_2 \leqslant \eta$ and $\varphi : \mathbb{R} \to \mathbb{R}$ is a function, then the norm of f is the same as the norm of the function φ on the interval $[-R\eta, R\eta]$, and it thus does not depend on d. This is a consequence of the fact that the total mass of a Radon measure remains bounded even when the support has measure zero (which might not be the case for the RKHS defined in Section 2.3). For the RKHS, there is no such results and it is in general not adaptive.

More generally, if $f(x) = \Phi(W^\top x)$ for $W \in \mathbb{R}^{d\times s}$ with the largest singular value of W less than η, and Φ a function from $\mathbb{R}^s$ to $\mathbb{R}$, then for $\|x\|_2 \leqslant R$, we have $\|W^\top x\|_2 \leqslant R\eta$, and thus we may apply our results for $d = s$.

ℓ_1-penalty on input weights (p=1). When using an ℓ_1-penalty on input weights instead of an ℓ_2-penalty, the results in Prop. 5 and 6 are unchanged (only the constants that depend on d are changed). Moreover, when $\|x\|_\infty \leqslant 1$ almost surely, functions of the form $f(x) = \varphi(w^\top x)$ where $\|w\|_1 \leqslant \eta$ and $\varphi : \mathbb{R} \to \mathbb{R}$ is a function, will also inherit from properties of φ (without any dependence on dimension). Similarly, for functions of the form $f(x) = \Phi(W^\top x)$ for $W \in \mathbb{R}^{d\times s}$ with all columns of ℓ_1-norm less than η, we have $\|W^\top x\|_\infty \leqslant R\eta$ and we can apply the s-dimensional result.

4.7 Related Work

In this section, we show how our results from the previous sections relate to existing work on neural network approximation theory.

Approximation of Lipschitz-continuous functions with finitely many neurons. In this section, we only consider the case $\alpha = 1$, for which we have two approximation bounds: Prop. 6 which approximates any η-Lipschitz-continuous function by a function with finite γ_1-norm less than δ and uniform error less than $\eta(\delta/\eta)^{-2/(d+1)}\log(\delta/\eta)$, and Prop. 1 which shows that a function with γ_1-norm less than δ, may be approximated with r neurons with uniform error $\delta r^{-(d+3)/(2d)}$.

Thus, given r neurons, we get an approximation of the original function with uniform error

$$\eta(\delta/\eta)^{-2/(d+1)}\log(\delta/\eta) + \delta r^{-(d+3)/(2d)}.$$

We can optimize over δ, and use $\delta = \eta n^{(d+1)/(2d)}$, to obtain a uniform approximation bound proportional to $\eta(\log n)n^{-1/d}$, for approximating an η-Lipschitz-continuous function with n neurons.

Approximation by ridge functions. The approximation properties of single hidden layer neural networks have been studied extensively, where they are often referred to as "ridge function" approximations. As shown by Pinkus (1999, Corollary 6.10)—based on a result from Petrushev (1998), the approximation order of $n^{-1/d}$ for the rectified linear unit was already known, but only in L_2-norm (and without the factor $\log n$), and without any constraints on the input and output weights. In this paper, we provide an explicit control of the various weights, which is needed for computing estimation errors. Moreover, while the two proof techniques use spherical harmonics, the proof of Petrushev (1998) relies on quadrature formulas for the associated Legendre polynomials, while ours relies on the relationship with the associated positive definite kernels, is significantly simpler, and offers additional insights into the problem (relationship with convex neural networks and zonoids). Maiorov (2006, Theorem 2.3) also derives a similar result, but in L_2-norm (rather than uniform norm), and for sigmoidal activation functions (which are bounded). Note finally, that the order $O(n^{-1/d})$ cannot be improved (DeVore et al., 1989, Theorem 4.2). Also, Maiorov and Meir (2000, Theorem 5) derive similar upper and lower bounds based on a random sampling argument which is close to using random features in the RKHS setting described in Section 2.3.

Relationship to hardness results for Boolean-valued functions. In this paper, we consider a particular view of the curse of dimensionality and ways of circumventing it, that is, our distribution over inputs is arbitrary, but our aim is to approximate a real-valued function. Thus, all hardness results depending on functions with values in $\{0,1\}$ do not apply there directly—see, e.g., Shalev-Shwartz and Ben-David (2014, Chapter 20), for the need of exponentially many hidden units for approximating most of the functions from $\{0,1\}^d$ to $\{0,1\}$.

Our approximation bounds show that, without any assumption beyond Lipschitz-continuity of the target function, it sufficient to have a number of hidden units which is still exponential in dimension (hence we also suffer from the curse of dimensionality), but a soon as the target function depends on linear low-dimensional structure, then we lose this exponential

dependence. It would be interesting to study an extension to $\{0,1\}$-valued functions, and also to relate our results to the number of linear regions delimited by neural networks with rectified linear units (Montufar et al., 2014).

5. Generalization Bounds

Our goal is to derive the generalization bounds outlined in Section 2.4 for neural networks with a single hidden layer. The main results that we obtain are summarized in Table 2 and show adaptivity to assumptions that avoid the curse of dimensionality.

More precisely, given some distribution over the pairs $(x,y) \in \mathcal{X} \times \mathcal{Y}$, a loss function $\ell : \mathcal{Y} \times \mathbb{R} \to \mathbb{R}$, our aim is to find a function $f : \mathbb{R}^d \to \mathbb{R}$ such that $J(f) = \mathbb{E}[\ell(y, f(x))]$ is small, given some i.i.d. observations (x_i, y_i), $i = 1, \dots, n$. We consider the empirical risk minimization framework over a space of functions $\mathcal{F}$, equipped with a norm γ (in our situations, $\mathcal{F}_1$ and $\mathcal{F}_2$, equipped with γ_1 or γ_2). The empirical risk $\hat{J}(f) = \frac{1}{n}\sum_{i=1}^n \ell(y_i, f(x_i))$, is minimized by constraining f to be in the ball $\mathcal{F}^\delta = \{f \in \mathcal{F},\ \gamma(f) \leqslant \delta\}$.

We assume that almost surely, $\|x\|_q \leqslant R$, that for all y the function $u \mapsto \ell(y,u)$ is G-Lipschitz-continuous on $\{|u| \leqslant \sqrt{2}\delta\}$, and that almost surely, $\ell(y,0) \leqslant G\delta$. As before z denotes $z = (x^\top, R)^\top$ so that $\|z\|_q \leqslant \sqrt{2}R$. This corresponds to the following examples:

- Logistic regression and support vector machines: we have $G = 1$.
- Least-squares regression: we take $G = \max\{\sqrt{2}\delta + \|y\|_\infty, \frac{\|y\|_\infty^2}{\sqrt{2}\delta}\}$.

Approximation errors $\inf_{f\in\mathcal{F}^\delta} J(f) - \inf_{f\in\mathcal{F}} J(f)$ will be obtained from the approximation results from Section 4 by assuming that the optimal target function f_* has a specific form. Indeed, we have:

$$\inf_{f\in\mathcal{F}^\delta} J(f) - J(f_*) \leqslant G \inf_{f\in\mathcal{F}^\delta} \Big\{ \sup_{\|x\|_q \leqslant R} |f(x) - f_*(x)| \Big\}.$$

We now deal with estimation errors $\sup_{f\in\mathcal{F}^\delta} |\hat{J}(f) - J(f)|$ using Rademacher complexities.

5.1 Estimation Errors and Rademacher Complexity

The following proposition bounds the uniform deviation between J and its empirical counterpart $\hat{J}$. This result is standard (see, e.g., Koltchinskii, 2001; Bartlett and Mendelson, 2003) and may be extended in bounds that hold with high-probability.

Proposition 7 (Uniform deviations) *We have the following bound on the expected uniform deviation:*

$$\mathbb{E}\Big[\sup_{\gamma_1(f)\leqslant\delta} |J(f) - \hat{J}(f)|\Big] \leqslant 4\frac{G\delta}{\sqrt{n}} C(p,d,\alpha),$$

with the following constants:

- *for $\alpha \geqslant 1$, $C(p,d,\alpha) \leqslant \alpha\sqrt{2\log(d+1)}$ for $p = 1$ and $C(p,d,\alpha) \leqslant \frac{\alpha}{\sqrt{p-1}}$ for $p \in (1,2]$*
- *for $\alpha = 0$, $C(p,d,\alpha) \leqslant C\sqrt{d+1}$, where C is a universal constant.*

Proof We use the standard framework of Rademacher complexities and get:

$$\begin{aligned}
&\mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} |J(f) - \hat{J}(f)| \\
\leqslant\ & 2\mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i \ell(y_i, f(x_i))\Big| \text{ using Rademacher random variables } \tau_i, \\
\leqslant\ & 2\mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i \ell(y_i, 0)\Big| + 2\mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i [\ell(y_i, f(x_i)) - \ell(y_i,0)]\Big| \\
\leqslant\ & 2\frac{G\delta}{\sqrt{n}} + 2G\mathbb{E}\sup_{\gamma(f)\leqslant\delta} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i f(x_i)\Big| \text{ using the Lipschitz-continuity of the loss,} \\
\leqslant\ & 2\frac{G\delta}{\sqrt{n}} + 2G\delta\mathbb{E}\sup_{\|v\|_p\leqslant 1/R} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i (v^\top z_i)_+^\alpha\Big| \text{ using Eq. (2).}
\end{aligned}$$

We then take different routes for $\alpha \geqslant 1$ and $\alpha = 0$.

For $\alpha \geqslant 1$, we have the upper-bound

$$\begin{aligned}
\mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} |J(f) - \hat{J}(f)| &\leqslant 2\frac{G\delta}{\sqrt{n}} + 2G\delta\alpha\mathbb{E}\sup_{\|v\|_p\leqslant 1/R} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i v^\top z_i\Big| \\
&\qquad \text{using the } \alpha\text{-Lipschitz-cont. of } (\cdot)_+^\alpha \text{ on } [-1,1], \\
&\leqslant 2\frac{G\delta}{\sqrt{n}} + 2\frac{G\alpha\delta}{Rn}\mathbb{E}\Big\|\sum_{i=1}^n \tau_i z_i\Big\|_q.
\end{aligned}$$

From Kakade et al. (2009), we get the following bounds on Rademacher complexities:

- If $p \in (1,2]$, then $q \in [2,\infty)$, and $\mathbb{E}\|\sum_{i=1}^n \tau_i z_i\|_q \leqslant \sqrt{q-1}R\sqrt{n} = \frac{1}{\sqrt{p-1}}R\sqrt{n}$
- If $p = 1$, then $q = \infty$, and $\mathbb{E}\|\sum_{i=1}^n \tau_i z_i\|_q \leqslant R\sqrt{n}\sqrt{2\log(d+1)}$.

Overall, we have $\mathbb{E}\|\sum_{i=1}^n \tau_i z_i\|_q \leqslant \sqrt{n}RC(p,d)$ with $C(p,d)$ defined above, and thus

$$\mathbb{E}\sup_{\gamma(f)\leqslant\delta} |J(f) - \hat{J}(f)| \leqslant 2\frac{G\delta}{\sqrt{n}}(1 + \alpha C(p,d)) \leqslant 4\frac{G\delta\alpha}{\sqrt{n}} C(p,d).$$

For $\alpha = 0$, we can simply go through the VC-dimension of half-hyperplanes, which is equal to d, and Theorem 6 from Bartlett and Mendelson (2003), that shows that $\mathbb{E}\sup_{v\in\mathbb{R}^{d+1}} \Big|\frac{1}{n}\sum_{i=1}^n \tau_i 1_{v^\top z_i}\Big| \leqslant C\frac{\sqrt{d+1}}{\sqrt{n}}$, where C is a universal constant.

Note that using standard results from Rademacher complexities, we have, with probability greater than $1-u$, $\sup_{\gamma_1(f)\leqslant\delta} |J(f) - \hat{J}(f)| \leqslant \mathbb{E}\sup_{\gamma_1(f)\leqslant\delta} |J(f) - \hat{J}(f)| + \frac{2G\delta}{\sqrt{n}}\sqrt{\log\frac{2}{u}}$. ■

5.2 Generalization Bounds for ℓ_2-norm Constraints on Input Weights ($p = 2$)

We now provide generalization bounds for the minimizer of the empirical risk given the contraint that $\gamma_1(f) \leqslant \delta$ for a well chosen δ, that will depend on the assumptions regarding the target function f_*, listed in Section 1. In this section, we consider an ℓ_2-norm on input weights w, while in the next section, we consider the ℓ_1-norm. The two situations are summarized and compared in Table 2, where we consider that $\|x\|_\infty \leqslant r$ almost surely, which implies that our bound R will depend on dimension as $R \leqslant r\sqrt{d}$.

Our generalization bounds are expected values of the excess expected risk for a our estimator (where the expectation is taken over the data).

Affine functions. We assume $f_*(x) = w^\top x + b$, with $\|w\|_2 \leqslant \eta$ and $|b| \leqslant R\eta$. Then, as seen in Section 4.6, $f_* \in \mathcal{F}_1$ with $\gamma_1(f_*) \leqslant C(\alpha)\eta R$ (the constant is independent of d because we approximate an affine function). From Prop. 7, we thus get a generalization bound proportional to $\frac{GR\eta}{\sqrt{n}}$ times a constant (that may depend on α), which is the same as assuming directly that we optimize over linear predictors only. The chosen δ is then a constant times $R\eta$, and does not grow with n, like in parametric estimation (although we do use a non-parametric estimation procedure).

Projection pursuit. We assume $f_*(x) = \sum_{j=1}^k f_j(w_j^\top x)$, with $\|w_j\|_2 \leqslant \eta$ and each f_j bounded by ηR and 1-Lipschitz continuous. From Prop. 6, we may approach each $x \mapsto f_j(w_j^\top x)$ by a function with γ_1-norm less than $\delta\eta R$ and uniform approximation $C(\alpha)\eta R\delta^{-1/\alpha}\log\delta$. This leads to a total approximation error of $kC(\alpha)G\eta R\delta^{-1/\alpha}\log\delta$ for a norm less than $k\delta\eta R$ (the constant is independent of d because we approximate a function of one-dimensional projection).

For $\alpha \geqslant 1$, from Prop. 7, the estimation error is $\frac{kGR\eta\delta}{\sqrt{n}}$, with an overall bound of $C(\alpha)kGR\eta(\frac{\delta}{\sqrt{n}}+\delta^{-1/\alpha}\log\delta)$. With $\delta = n^{\alpha/2(\alpha+1)}$ (which grows with n), we get an optimized generalization bound of $C(\alpha)kGR\eta\frac{\log n}{n^{1/(2\alpha+2)}}$, with a scaling independent of the dimension d (note however that R typically grow with $\sqrt{d}$, i.e., $r\sqrt{d}$, if we have a bound in ℓ_∞-norm for all our inputs x).

For $\alpha = 0$, from Prop. 5, the target function belongs to $\mathcal{F}_1$ with a norm less than $kGR\eta$, leading to an overall generalization bound of $\frac{kGR\eta\sqrt{d}}{\sqrt{n}}$.

Note that when the functions f_j are exactly the activation functions, the bound is better, as these functions directly belong to the space $\mathcal{F}_1$.

Multi-dimensional projection pursuit. We extend the situation above, by assuming $f_*(x) = \sum_{j=1}^k F_j(W_j^\top x)$ with each $W_j \in \mathbb{R}^{d\times s}$ having all singular values less than η and each F_j bounded by ηR and 1-Lipschitz continuous. From Prop. 6, we may approach each $x \mapsto F_j(W_j^\top x)$ by a function with γ_1-norm less than $\delta\eta R$ and uniform approximation $C(\alpha,s)\eta R\delta^{-1/(\alpha+(s-1)/2)}\log\delta$. This leads to a total approximation error of $kC(\alpha,s)G\eta R\delta^{-1/(\alpha+(s-1)/2)}\log\delta$.

For $\alpha \geqslant 1$, the estimation error is $kGR\eta\delta/\sqrt{n}$, with an overall bound of $C(\alpha,s)kGR\eta(\delta/\sqrt{n}+\delta^{-1/(\alpha+(s-1)/2)}\log\delta)$. With $\delta = n^{(\alpha+(s-1)/2)/(2\alpha+s-1)}$, we get an optimized bound of $\frac{C(\alpha,s)kGR\eta}{n^{1/(2\alpha+s+1)}}\log n$.

For $\alpha = 0$, we have an overall bound of $C(s)kGR\eta(\delta^{-2/(s-1)}\log\delta + \frac{\delta\sqrt{d}}{\sqrt{n}})$, and with $\delta = (n/d)^{(s-1)/(s+1)}$, we get a generalization bound scaling as $\frac{C(s)kGR\eta}{(n/d)^{1/(s+1)}}\log(n/d)$.

function space	$\|\cdot\|_2$, $\alpha \geqslant 1$	$\|\cdot\|_1$, $\alpha \geqslant 1$	$\alpha = 0$
$w^\top x + b$	$\frac{d^{1/2}}{n^{1/2}}$	$\sqrt{q}(\frac{\log d}{n})^{1/2}$	$\frac{(dq)^{1/2}}{n^{1/2}}$
$\sum_{j=1}^k f_j(w_j^\top x)$, $w_j \in \mathbb{R}^d$	$\frac{kd^{1/2}}{n^{1/(2\alpha+2)}}\log n$	$\frac{kq^{1/2}(\log d)^{1/(\alpha+1)}}{n^{1/(2\alpha+2)}}\log n$	$\frac{k(dq)^{1/2}}{n^{1/2}}$
$\sum_{j=1}^k f_j(W_j^\top x)$, $W_j \in \mathbb{R}^{d\times s}$	$\frac{kd^{1/2}}{n^{1/(2\alpha+s+1)}}\log n$	$\frac{kq^{1/2}(\log d)^{1/(\alpha+(s+1)/2)}}{n^{1/(2\alpha+s+1)}}\log n$	$\frac{(dq)^{1/2}d^{1/(s+1)}}{n^{1/(s+1)}}\log n$

Table 2: Summary of generalization bounds with different settings. See text for details.

Note that for $s = d$ and $k = 1$, we recover the usual Lipschitz-continuous assumption, with a rate of $\frac{C(\alpha,d)kGR\eta}{n^{1/(2\alpha+d+1)}}\log n$.

We can make the following observations:

- *Summary table*: when we know a bound r on all dimensions of x, then we may take $R = r\sqrt{d}$; this is helpful in comparisons in Table 2, where R is replaced by $r\sqrt{d}$ and the dependence in r is removed as it is the same for all models.
- *Dependence on d*: when making only a global Lipschitz-continuity assumption, the generalization bound has a bad scaling in n, i.e., as $n^{-1/(2\alpha+d+1)}$, which goes down to zero slowly when d increases. However, when making structural assumptions regarding the dependence on unknown lower-dimensional subspaces, the scaling in d disappears.
- *Comparing different values of α*: the value $\alpha = 0$ always has the best scaling in n, but constants are better for $\alpha \geqslant 1$ (among which $\alpha = 1$ has the better scaling in n).
- *Bounds for $\mathcal{F}_2$*: The simplest upper bound for the penalization by the space $\mathcal{F}_2$ depends on the approximation properties of $\mathcal{F}_2$. For linear functions and $\alpha = 1$, it is less than $\sqrt{d}\eta R$, with a bound $\frac{GR\eta\sqrt{d}}{\sqrt{n}}$. For the other values of α, there is a constant $C(d)$. Otherwise, there is no adaptivity and all other situations only lead to upper-bounds of $O(n^{-1/(2\alpha+d+1)})$. See more details in Section 5.4.
- *Sample complexity*: Note that the generalization bounds above may be used to obtain sample complexity results such as $d\varepsilon^{-2}$ for affine functions, $(\varepsilon k^{-1}d^{-1/2})^{-2\alpha-2}$ for projection pursuit, and $(\varepsilon k^{-1}d^{-1/2})^{-s-1-2\alpha}$ for the generalized version (up to logarithmic terms).
- *Relationship to existing work*: Maiorov (2006, Theorem 1.1) derives similar results for neural networks with sigmoidal activation functions (that tend to one at infinity) and the square loss only, and for a level of smoothness of the target function which grows with dimension (in this case, once can get easily rates of $n^{-1/2}$). Our result holds for problems where only bounded first-order derivatives are assumed, but by using Prop. 2, we would get similar rate by ensuring the target function belongs to $\mathcal{F}_2$ and hence to $\mathcal{F}_1$.

Lower bounds. In the sections above, we have only provided generalization bounds. Although interesting, deriving lower-bounds for the generalization performance when the target function belongs to certain function classes is out of the scope of this paper. Note however, that results from Sridharan (2012) suggest that the Rademacher complexities of the associated function classes provide such lower-bounds. For general Lipschitz-functions, these Rademacher complexities decreases as $n^{-\max\{d,2\}}$ (von Luxburg and Bousquet, 2004).

5.3 Generalization Bounds for ℓ_1-norm Constraints on Input Weights ($p = 1$)

We consider the same three situations, assuming that linear predictors have at most q non-zero elements. We assume that each component of x is almost surely bounded by r (i.e., a bound in ℓ_∞-norm).

Affine functions. We assume $f_*(x) = w^\top x + b$, with $\|w\|_2 \leqslant \eta$ and $|b| \leqslant R\eta$. Given that we have assumed that w has at most q non-zeros, we have $\|w\|_1 \leqslant \sqrt{q}\eta$.

Then, $f_* \in \mathcal{F}_1$ with $\gamma_1(f) \leqslant C(\alpha)\eta r\sqrt{q}$, with a constant that is independent of d because we have an affine function.

From Prop. 7, we thus get a rate of $\frac{Gr\eta\sqrt{q\log(d)}}{\sqrt{n}}$ times a constant (that may depend on α), which is the same as assuming directly that we optimize over linear predictors only (see, for example, Bühlmann and Van De Geer, 2011). We recover a high-dimensional phenomenon (although with a slow rate in $1/\sqrt{n}$), where d may be much larger than n, as long as $\log d$ is small compared to n. The chosen δ is then a constant times $r\eta\sqrt{q}$ (and does not grow with n).

Projection pursuit. We assume $f_*(x) = \sum_{j=1}^k f_j(w_j^\top x)$, with $\|w_j\|_2 \leqslant \eta$ (which implies $\|w_j\|_1 \leqslant \sqrt{q}\eta$ given our sparsity assumption) and each f_j bounded by $\eta r\sqrt{q}$ and 1-Lipschitz continuous. We may approach each $x \mapsto f_j(w_j^\top x)$ by a function with γ_1-norm less than $\delta\eta r\sqrt{q}$ and uniform approximation $C(\alpha)\eta r\sqrt{q}\delta^{-1/\alpha}\log\delta$, with a constant that is independent of d because we have a function of one-dimensional projection. This leads to a total approximation error of $kC(\alpha)G\eta r\sqrt{q}\delta^{-1/\alpha}\log\delta$ for a norm less than $k\delta\eta r\sqrt{q}$.

For $\alpha \geqslant 1$, the estimation error is $\frac{kGr\eta\delta\sqrt{q\log d}}{\sqrt{n}}$, with an overall bound of $C(\alpha)kGr\sqrt{q}\eta(\delta^{-1/\alpha}\log\delta + \frac{\delta\sqrt{\log d}}{\sqrt{n}})$. With $\delta = (n/\log d)^{\alpha/2(\alpha+1)}$, we get an optimized bound of $C(\alpha)kGr\sqrt{q}\eta\frac{\log n(\log d)^{1/(2\alpha+2)}}{n^{1/(2\alpha+2)}}$, with a scaling only dependent in d with a logarithmic factor.

For $\alpha = 0$, the target function belongs to $\mathcal{F}_1$ with a norm less than $kGr\sqrt{q}\eta$, leading to an overal bound of $\frac{kGr\eta\sqrt{q\log d}}{\sqrt{n}}$ (the sparsity is not helpful in this case).

Multi-dimensional projection pursuit. We assume $f_*(x) = \sum_{j=1}^k F_j(W_j^\top x)$ with each $W_j \in \mathbb{R}^{d\times s}$, having all columns with ℓ_2-norm less than η (note that this is a weaker requirement than having all singular values that are less than η). If we assume that each of these columns has at most q non-zeros, then the ℓ_1-norms are less than $r\sqrt{q}$ and we may use the approximation properties described at the end of Section 4.6. We also assume that each F_j is bounded by $\eta r\sqrt{q}$ and 1-Lipschitz continuous (with respect to the ℓ_2-norm).

We may approach each $x \mapsto F_j(W_j^\top x)$ by a function with γ_1-norm less than $\delta\eta r\sqrt{q}$ and uniform approximation $C(\alpha,s)\eta r\sqrt{q}\delta^{-1/(\alpha+(s-1)/2)}\log\delta$. This leads to a total approximation error of $kC(\alpha,s)G\eta r\sqrt{q}\delta^{-1/(\alpha+(s-1)/2)}\log\delta$.

For $\alpha \geqslant 1$, the estimation error is $kGr\sqrt{q}\eta\delta\sqrt{\log d}/\sqrt{n}$, with an overall bound which is equal to $C(\alpha,s)kGr\sqrt{q}\eta(\delta^{-1/(\alpha+(s-1)/2)}\log\delta + \frac{\delta\sqrt{\log d}}{\sqrt{n}})$. With $\delta = (n/\log d)^{(\alpha+(s-1)/2)/(2\alpha+s-1)}$, we get an optimized bound of $\frac{C(\alpha,s)kGr\sqrt{q}\eta(\log d)^{1/(2\alpha+s+1)}}{n^{1/(2\alpha+s+1)}}\log n$.

For $\alpha = 0$, we have the bound $\frac{C(s)kGr\sqrt{q}\eta}{(n/d)^{1/(s+1)}}\log(n/d)$, that is we cannot use the sparsity as the problem is invariant to the chosen norm on hidden weights.

We can make the following observations:

- *High-dimensional variable selection*: when $k = 1$, $s = q$ and W_1 is a projection onto q variables, then we obtain a bound proportional to $\frac{\sqrt{q}\eta(\log d)^{1/(2\alpha+s+1)}}{n^{1/(2\alpha+s+1)}}\log n$, which exhibits a high-dimensional scaling in a non-linear setting. Note that beyond sparsity, no assumption is made (in particular regarding correlations between input variables), and we obtain a high-dimensional phenomenon where d may be much larger than n.

- *Group penalties*: in this paper, we only consider ℓ_1-norm on input weights; when doing joint variable selection for all basis functions, it may be worth using a group penalty (Yuan and Lin, 2006; Bach, 2008a).

5.4 Relationship to Kernel Methods and Random Sampling

The results presented in the two sections above were using the space $\mathcal{F}_1$, with an L_1-norm on the outputs weights (and either an ℓ_1- or ℓ_2-norm on input weights). As seen in Sections 2.3 and 3.1, when using an L_2-norm on output weights, we obtain a reproducing kernel Hilbert space $\mathcal{F}_2$.

As shown in Section 6, the space $\mathcal{F}_2$ is significantly smaller than $\mathcal{F}_1$, and in particular is not adaptive to low-dimensional linear structures, which is the main advantage of the space $\mathcal{F}_1$. However, algorithms for $\mathcal{F}_2$ are significantly more efficient, and there is no need for the conditional gradient algorithms presented in Section 2.5. The first possibility is to use the usual RKHS representer theorem with the kernel functions computed in Section 3.1, leading to a computation complexity of $O(n^2)$. Alternatively, as shown by Rahimi and Recht (2007), one may instead sample m basis functions that is m different hidden units, keep the input weights fixed and optimize only the output layer with a squared ℓ_2-penalty. This will quickly (i.e., the error goes down as $1/\sqrt{m}$) approach the non-parametric estimator based on penalizing by the RKHS norm γ_2. Note that this argument of random sampling has been used to study approximation bounds for neural networks with finitely many units (Maiorov and Meir, 2000).

Given the usage of random sampling with L_2-penalties, it is thus tempting to sample weights, but now optimize an ℓ_1-penalty, in order to get the non-parametric estimator obtained from penalizing by γ_1. When the number of samples m tends to infinity, we indeed obtain an approximation that converges to γ_1 (this is simply a uniform version of the law of large numbers). However, the rate of convergence does depend on the dimension d, and in general exponentially many samples would be needed for a good approximation—see Bach (2013, Section 6) for a more precise statement in the related context of convex matrix factorizations.

5.5 Sufficient Condition for Polynomial-time Algorithms

In order to preserve the generalization bounds presented above, it is sufficient to be able to solve the following problem, for any $y \in \mathbb{R}^n$ and $z_1, \dots, z_n \in \mathbb{R}^{d+1}$:

$$\sup_{\|v\|_p=1} \left| \frac{1}{n} \sum_{i=1}^n y_i (v^\top z_i)_+^\alpha \right|, \tag{5}$$

up to a constant factor. That is, there exists $\kappa \geqslant 1$, such that for all y and z, we may compute $\hat{v}$ such that $\|\hat{v}\|_p = 1$ and

$$\left| \frac{1}{n} \sum_{i=1}^n y_i (\hat{v}^\top z_i)_+^\alpha \right| \geqslant \frac{1}{\kappa} \sup_{\|v\|_p=1} \left| \frac{1}{n} \sum_{i=1}^n y_i (v^\top z_i)_+^\alpha \right|.$$

This is provably NP-hard for $\alpha = 0$ (see Section 3.2), and for $\alpha = 1$ (see Section 3.3). If such an algorithm is available, the approximate conditional gradient presented in Section 2.5 leads to an estimator with the same generalization bound. Moreover, given the strong hardness results for improper learning in the situation $\alpha = 0$ (Klivans and Sherstov, 2006; Livni et al., 2014), a convex relaxation that would consider a larger set of predictors (e.g., by relaxing $vv^\top$ into a symmetric positive-definite matrix), and obtained a constant approximation guarantee, is also ruled out.

However, this is only a sufficient condition, and a simpler sufficient condition may be obtained. In the following, we consider $\mathcal{V} = \{v \in \mathbb{R}^{d+1}, \ \|v\|_2 = 1\}$ and basis functions $\varphi_v(z) = (v^\top z)_+^\alpha$ (that is we specialize to the ℓ_2-norm penalty on weight vectors). We consider a new variation norm $\hat{\gamma}_1$ which has to satisfy the following assumptions:

- *Lower-bound on* γ_1: It is defined from functions $\hat{\varphi}_{\hat{v}}$, for $\hat{v} \in \hat{\mathcal{V}}$, where for any $v \in \mathcal{V}$, there exists $\hat{v} \in \hat{\mathcal{V}}$ such that $\varphi_v = \hat{\varphi}_{\hat{v}}$. This implies that the corresponding space $\hat{\mathcal{F}}_1$ is larger than $\mathcal{F}_1$ and that if $f \in \mathcal{F}_1$, then $\hat{\gamma}_1(f) \leqslant \gamma_1(f)$.

- *Polynomial-time algorithm for dual norm*: The dual norm $\sup_{\hat{v} \in \hat{\mathcal{V}}} \left| \frac{1}{n} \sum_{i=1}^n y_i \hat{\varphi}_{\hat{v}}(z_i) \right|$ may be computed in polynomial time.

- *Performance guarantees for random direction*: There exists $\kappa > 0$, such that for any vectors $z_1, \dots, z_n \in \mathbb{R}^{d+1}$ with ℓ_2-norm less than R, and random standard Gaussian vector $y \in \mathbb{R}^n$,

$$\sup_{\hat{v} \in \hat{\mathcal{V}}} \left| \frac{1}{n} \sum_{i=1}^n y_i \hat{\varphi}_{\hat{v}}(x_i) \right| \leqslant \kappa \frac{R}{\sqrt{n}}. \tag{6}$$

  We may also replace the standard Gaussian vectors by Rademacher random variables.

We can then penalize by $\hat{\gamma}$ instead of γ. Since $\hat{\gamma}_1 \leqslant \gamma_1$, approximation properties are transferred, and because of the result above, the Rademacher complexity for $\hat{\gamma}_1$-balls scales as well as for γ_1-balls. In the next section, we show convex relaxations which cannot achieve these and leave the existence or non-existence of such norm $\hat{\gamma}_1$ as an open problem.

6. Convex Relaxations of the Frank-Wolfe Step

In this section, we provide approximation algorithms for the following problem of maximizing, for a given $y \in \mathbb{R}^n$ and vectors $z_1, \dots, z_n$:

$$\sup_{\|v\|_p=1} \frac{1}{n} \sum_{i=1}^n y_i (v^\top z_i)_+^\alpha$$

These approximation algorithms may be divided in three families, as they may be based on (a) geometric interpretations as linear binary classification or computing Haussdorff distances (see Section 3.2 and Section 3.3), (b) on direct relaxations, on (c) relaxations of sign vectors. For simplicity, we only focus on the case $p = 2$ (that is ℓ_2-constraint on weights) and on $\alpha = 1$ (rectified linear units). As described in Section 5.5, constant-factor approximation ratios are not possible, while approximation ratios that increases with n are possible (but as of now, we only obtain scalings in n that provide a provable sample complexity with a polynomial time algorithm which is exponential in the dimension d.

6.1 Semi-definite Programming Relaxations

We present two relaxations, which are of the form described in Section 5.5 (leading to potential generalization bounds) but do not attain the proper approximation scaling (as was checked empirically).

Note that all relaxations that end up being Lipschitz-continuous functions of z, will have at least the same scaling than the set of these functions. The Rademacher complexity of such functions is well-known, that is $1/\sqrt{n}$ for $d = 1$, $\sqrt{\frac{\log n}{n}}$ for $d = 2$ and $n^{-1/d}$ for larger d (von Luxburg and Bousquet, 2004). Unfortunately, the decay in n is too slow to preserve generalization bounds (which would require a scaling in $1/\sqrt{n}$).

d-dimensional relaxation. We denote $u_i = (v^\top z_i)_+ = \frac{1}{2} v^\top z_i + \frac{1}{2} |v^\top z_i|$. We may then use $2u_i - v^\top z_i = |v^\top z_i|$ and, for $\|v\|_2 = 1$, $\|vv^\top z_i\|_2 = |v^\top z_i| = \sqrt{z_i^\top vv^\top z_i}$. By denoting $V = vv^\top$, the constraint that $u_i = (v^\top z_i)_+ = \frac{1}{2} v^\top z_i + \frac{1}{2} |v^\top z_i|$ is equivalent to

$$\|Vz_i\|_2 \leqslant 2u_i - v^\top z_i \leqslant \sqrt{z_i^\top V z_i} \ \text{ and } \ V \succcurlyeq 0, \ \operatorname{tr} V = 1, \ \operatorname{rank}(V) = 1.$$

We obtain a convex relaxation when removing the rank constraint, that is

$$\sup_{V \succcurlyeq 0, \ \operatorname{tr} V = 1, \ u \in \mathbb{R}^n} u^\top y \ \text{ such that } \ \forall i \in \{1, \dots, n\}, \ \|Vz_i\|_2 \leqslant 2u_i - v^\top z_i \leqslant \sqrt{z_i^\top V z_i}.$$

$(n+d)$-dimensional relaxation. We may go further by also considering quadratic forms in $u \in \mathbb{R}^n$ defined above. Indeed, we have:

$$(2u_i - v^\top z_i)(2u_j - v^\top z_j) = |v^\top z_i| \cdot |v^\top z_j| = |v^\top z_i z_j^\top v| = |\operatorname{tr} V z_i z_j^\top|,$$

which leads to a convex program in $U = uu^\top$, $V = vv^\top$ and $J = uv^\top$, that is a semidefinite program with $d + n$ dimensions, with the constraints

$$4U_{ij} + x_j^\top V z_i - 2\delta_i^\top J z_j - 2\delta_j^\top J z_i \geqslant |\operatorname{tr} V z_i z_j^\top|,$$

and the usual semi-definite contraints $\begin{pmatrix} U & J \\ J^\top & V \end{pmatrix} \succcurlyeq \begin{pmatrix} u \\ v \end{pmatrix}\begin{pmatrix} u \\ v \end{pmatrix}^\top$, with the additional constraint that $4U_{ii} + z_i^\top V z_i - 4\delta_i^\top J z_i = \operatorname{tr} V z_i z_i^\top$.

If we add these constraints on top of the ones above, we obtain a tighter relaxation. Note that for this relaxation, we must have $[(2u_i - v^\top z_i) - (2u_j - v^\top z_j)]$ less than a constant times $\|z_i - z_j\|_2$. Hence, the result mentioned above regarding Lipschitz-continuous functions and the scaling of the upper-bound for random y holds (with the dependence on n which is not good enough to preserve the generalization bounds with a polynomial-time algorithm).

6.2 Relaxation of Sign Vectors

By introducing a sign vector $s \in \mathbb{R}^n$ such that $s_i \in \{-1, 1\}$ and $s_i v^\top x_i = |v^\top x_i|$, we have the following relaxation with $S = ss^\top$, $V = vv^\top$ and $J = sv^\top$:

- Usual semi-definite constraint: $\begin{pmatrix} S & J \\ J^\top & V \end{pmatrix} \succcurlyeq \begin{pmatrix} s \\ v \end{pmatrix}\begin{pmatrix} s \\ v \end{pmatrix}^\top$,
- Unit/trace constraints: $\operatorname{diag}(S) = 1$ and $\operatorname{tr} V = 1$,
- Sign constraint: $\delta_i^\top J x_i \geqslant \max_{j \neq i} |\delta_j^\top J x_i|$.
- Additional constraint: $(x_i^\top V x_i)^{1/2} \leqslant \delta_i^\top J x_i$.

We then need to maximize $\frac{1}{2n}\sum_{i=1}^n y_i \delta_i^\top J x_i + \frac{1}{2n}\sum_{i=1}^n y_i v^\top x_i$, which leads to a semidefinte program. Again empirically, it did not lead to the correct scaling as a function of n for random Gaussian vectors $y \in \mathbb{R}^n$.

7. Conclusion

In this paper, we have provided a detailed analysis of the generalization properties of convex neural networks with positively homogenous non-decreasing activation functions. Our main new result is the adaptivity of the method to underlying linear structures such as the dependence on a low-dimensional subspace, a setting which includes non-linear variable selection in presence of potentially many input variables.

All our current results apply to estimators for which no polynomial-time algorithm is known to exist and we have proposed sufficient conditions under which convex relaxations could lead to the same bounds, leaving open the existence or non-existence of such algorithms. Interestingly, these problems have simple geometric interpretations, either as binary linear classification, or computing the Haussdorff distance between two zonotopes.

In this work, we have considered a single real-valued output; the functional analysis framework readily extends to outputs in a finite-dimensional vector-space where vector-valued measures could be used, and then apply to multi-task or multi-class problems. However, the extension to multiple hidden layers does not appear straightforward as the units of the last hidden layers share the weights of the first hidden layers, which should require a new functional analysis framework.

The author also thanks Varun Kanade for pointing the NP-hardness linear classification result. The main part of this work was carried through while visiting the Centre de Recerca Matemàtica (CRM) in Barcelona.

Appendix A. Reproducing Kernel Hilbert Spaces for ℓ_2-norm Penalization

In this section, we consider a Borel probability measure τ on the compact space $\mathcal{V}$, and functions $\varphi_v : \mathcal{X} \to \mathbb{R}$ such that the functions $v \mapsto \varphi_v(x)$ are measurable for all $x \in \mathcal{X}$. We study the set $\mathcal{F}_2$ of functions f such that there exists a squared-integrable function $p : \mathcal{X} \to \mathbb{R}$ with $f(x) = \int_{\mathcal{V}} p(v)\varphi_v(x) d\tau(v)$ for all $x \in \mathcal{X}$. For $f \in \mathcal{F}_2$, we define $\gamma_2^2(f)$ as the infimum of $\int_{\mathcal{V}} p(v)^2 d\tau(v)$ over all decompositions of f. We now show that $\mathcal{F}_2$ is an RKHS with kernel $k(x, y) = \int_{\mathcal{V}} \varphi_v(x)\varphi_v(y) d\tau(v)$.

We follow the proof of Berlinet and Thomas-Agnan (2004, Section 4.1) and extend it to integrals rather than finite sums. We consider the linear mapping $T : L_2(d\tau) \to \mathcal{F}_2$ defined by $(Tp)(x) = \int_{\mathcal{V}} p(v)\varphi_v(x) d\tau(v)$, with null space $\mathcal{K}$. When restricted to the orthogonal complement $\mathcal{K}^\perp$, we obtain a bijection U from $\mathcal{K}^\perp$ to $\mathcal{F}_2$. We then define a dot-product on $\mathcal{F}_2$ as $\langle f, g\rangle = \int_{\mathcal{V}} (U^{-1}f)(v)(U^{-1}g)(v) d\tau(v)$.

We first show that this defines an RKHS with kernel k defined above. For this, we trivially have $k(\cdot, y) \in \mathcal{F}_2$ for all $y \in \mathcal{X}$. Moreover, for any $y \in \mathcal{X}$, we have with $p = U^{-1}k(\cdot, y) \in \mathcal{K}^\perp$ and $q : v \mapsto \varphi_v(y)$, $p - q \in \mathcal{K}$, which implies that $\langle f, k(\cdot, y)\rangle = \int_{\mathcal{V}} (U^{-1}f)(v) p(v) d\tau(v) = \int_{\mathcal{V}} (U^{-1}f)(v) q(v) d\tau(v) = \int_{\mathcal{V}} (U^{-1}f)(v)\varphi_v(y) d\tau(v) = T(U^{-1}f)(y) = f(y)$, hence the reproducing property is satisfied. Thus, $\mathcal{F}_2$ is an RKHS.

We now need to show that the RKHS norm which we have defined is actually γ_2. For any $f \in \mathcal{F}_2$ such that $f = Tp$, for $p \in L_2(d\tau)$, we have $p = U^{-1}f + q$, where $q \in \mathcal{K}$. Thus, $\int_{\mathcal{V}} p(v)^2 d\tau(v) = \|p\|^2_{L_2(d\tau)} = \|U^{-1}f\|^2_{L_2(d\tau)} + \|q\|^2_{L_2(d\tau)} = \|f\|^2 + \|q\|^2_{L_2(d\tau)}$. This implies that $\int_{\mathcal{V}} p(v)^2 d\tau(v) \geqslant \|f\|^2$ with equality if and only if $q = 0$. This shows that $\gamma_2(f) = \|f\|$.

Appendix B. Approximate Conditional Gradient with Multiplicative Oracle

In this section, we wish to minimize a smooth convex functional $J(h)$ on for h in a Hilbert-space over a norm ball $\{\gamma(h) \leqslant \delta\}$. A multiplicative approximate oracle outputs for any $g \in \mathbb{R}^n$, $\hat{h}$ such that $\gamma(\hat{h}) = 1$, and

$$\langle \hat{h}, g\rangle \leqslant \max_{\gamma(h) \leqslant 1} \langle h, g\rangle \leqslant \kappa \langle \hat{h}, g\rangle,$$

for a fixed $\kappa \geqslant 1$. We now propose a modification of the conditional gradient algorithm that converges to a certain h such that $\gamma(h) \leqslant \delta$ and for which $\inf_{\gamma(h) \leqslant \delta} J(h) \leqslant J(\hat{h}) \leqslant \inf_{\gamma(h) \leqslant \delta/\kappa} J(h)$.

We assume the smoothness of the function J with respect to the norm γ, that is, for a certain $L > 0$, for all h, h' such that $\gamma(h) \leqslant \delta$, then

$$J(h') \leqslant J(h) + \langle J'(h), h' - h \rangle + \frac{L}{2}\gamma(h - h')^2. \tag{7}$$

We consider the following recursion

$$\begin{aligned} \hat{h}_t &= -\delta \times \text{ output of approximate oracle at } -J'(h_t) \\ h_{t+1} &\in \arg\min_{\rho \in [0,1]} J((1-\rho)h_t + \rho \hat{h}_t). \end{aligned}$$

In the previous recursion, one may replace the minimization of J on the segment $[h_t, \hat{h}_t]$ with the minimization of its upper-bound of Eq. (7) taken at $h = h_t$. From the recursion, all iterates are in the γ-ball of radius δ. Following the traditional convergence proof for the conditional gradient method (Dunn and Harshbarger, 1978; Jaggi, 2013), we have, for any ρ in $[0, 1]$:

$$\begin{aligned} J(h_{t+1}) &\leqslant J(h_t) - \rho \langle J'(h_t), h_t - \hat{h}_t \rangle + 2L\rho^2\delta^2 \\ &= J(h_t) - \rho J'(h_t)^\top h_t + \kappa \langle J'(h_t), \frac{\hat{h}_t}{\kappa} \rangle + 2L\rho^2\delta^2 \\ &\leqslant J(h_t) - \rho J'(h_t)^\top h_t - \max_{\gamma(h) \leqslant \delta/\kappa} \{ - \langle J'(h_t), h \rangle \} + 2L\rho^2\delta^2. \end{aligned}$$

If we take h_* the minimizer of J on $\{\gamma(h) \leqslant \delta/\kappa\}$, we get:

$$J(h_{t+1}) \leqslant J(h_t) - \rho \langle J'(h_t), h_t - h_* \rangle + 2L\rho^2\delta^2.$$

Then, by using $J(h_t) \geqslant J(h_*) + \langle J'(h_t), h_* - h_t \rangle$, we get:

$$J(h_{t+1}) - J(h_*) \leqslant (1 - \rho)[J(h_t) - J(h_*)] + 2L\rho^2\delta^2.$$

This is valid for any $\rho \in [0, 1]$. If $J(h_t) - J(h_*) \leqslant 0$ for some t, then by taking $\rho = 0$ it remains the same of all greater t. Therefore, up to (the potentially never happening) point where $J(h_t) - J(h_*) \leqslant 0$, we can apply the regular proof of the conditional gradien to obtain: $J(h_t) \leqslant \inf_{\gamma(h) \leqslant \delta/\kappa} J(h) + \frac{4L\rho^2\delta^2}{t}$, which leads to the desired result. Note that a similar reasoning may be used for $\rho = 2/(t + 1)$.

Appendix C. Proofs for the 2-dimensional Sphere ($d = 1$)

In this section, we consider only the case $d = 1$, where the sphere $\mathbb{S}^d$ is isomorphic to $[0, 2\pi]$ (with periodic boundary conditions). We may then compute the norm γ_2 in closed form. Indeed, if we can decompose g as $g(\theta) = \frac{1}{2\pi}\int_0^{2\pi} p(\varphi)\sigma(\cos(\varphi - \theta))d\varphi$, then the decomposition of g into the k-th frequency elements (the combination of the two k-th elements of the Fourier series) is equal to, for $\sigma(u) = (u)_+^\alpha$, and for $k > 0$:

$$\begin{aligned} g_k(\theta) &= \frac{1}{\pi}\int_0^{2\pi} g(\eta)\cos k(\theta - \eta) d\eta \\ &= \frac{1}{\pi}\int_0^{2\pi} \frac{1}{2\pi}\Big(\int_0^{2\pi} p(\varphi)\sigma(\cos(\eta - \varphi))d\varphi\Big)\cos k(\theta - \eta) d\eta \text{ through the decomposition of } g, \\ &= \frac{1}{2\pi^2}\int_0^{2\pi} p(\varphi)\Big(\int_0^{2\pi} \sigma(\cos(\eta - \varphi))\cos k(\theta - \eta) d\eta\Big) d\varphi \\ &= \frac{1}{2\pi^2}\int_0^{2\pi} p(\varphi)\Big(\int_0^{2\pi} \sigma(\cos\eta)\cos k(\theta - \varphi - \eta) d\eta\Big) d\varphi \text{ by a change of variable,} \\ &= \frac{1}{2\pi^2}\int_0^{2\pi} p(\varphi)\Big(\cos k(\theta - \varphi)\int_0^{2\pi}\sigma(\cos\eta)\cos k\eta\, d\eta \\ &\qquad + \sin k(\theta - \varphi)\int_0^{2\pi}\sigma(\cos\eta)\sin k\eta\, d\eta\Big) d\varphi \text{ by expanding the cosine,} \\ &= \Big(\frac{1}{2\pi}\int_0^{2\pi}\sigma(\cos\eta)\cos k\eta\, d\eta\Big)\Big(\frac{1}{\pi}\int_0^{2\pi} p(\varphi)\cos k(\theta - \varphi)\Big) + 0 \text{ by a parity argument,} \\ &= \lambda_k p_k(\theta) \text{ with } \lambda_k = \frac{1}{2\pi}\int_0^{2\pi}\sigma(\cos\eta)\cos k\eta\, d\eta. \end{aligned}$$

For $k = 0$, the same equality holds (except that the two coefficients g_0 and p_0 are divided by 2π except of π).

Thus we may express $\|p\|^2_{L_2(\mathbb{S}^d)}$ as

$$\begin{aligned} \|p\|^2_{L_2(\mathbb{S}^d)} &= \sum_{k \geqslant 0}\|p_k\|^2_{L_2(\mathbb{S}^d)} = \sum_{\lambda_k \neq 0}\|p_k\|^2_{L_2(\mathbb{S}^d)} + \sum_{\lambda_k = 0}\|p_k\|^2_{L_2(\mathbb{S}^d)} \\ &= \sum_{\lambda_k \neq 0}\frac{1}{\lambda_k^2}\|g_k\|^2_{L_2(\mathbb{S}^d)} + \sum_{\lambda_k = 0}\|p_k\|^2_{L_2(\mathbb{S}^d)}. \end{aligned}$$

If we minimize over p, we thus need to have $\|p_k\|^2_{L_2(\mathbb{S}^d)} = 0$ for $\lambda_k = 0$, and we get

$$\gamma_2(g)^2 = \sum_{\lambda_k \neq 0}\frac{1}{\lambda_k^2}\|g_k\|^2_{L_2(\mathbb{S}^d)}. \tag{8}$$

We thus simply need to compute λ_k and its decay for all values of α, and then relate them to the smoothness properties of g, which is standard for Fourier series.

C.1 Computing λ_k

We now detail the computation of $\lambda_k = \frac{1}{2\pi}\int_0^{2\pi}\sigma(\cos\eta)\cos k\eta\, d\eta$ for the different functions $\sigma = (\cdot)_+^\alpha$. We have for $\alpha = 0$:

$$\frac{1}{2\pi}\int_0^{2\pi} 1_{\cos\eta \geqslant 0}\cos k\eta\, d\eta = \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}\cos k\eta\, d\eta = \frac{1}{\pi k}\sin\frac{k\pi}{2} \text{ if } k \neq 0.$$

For $k = 0$ it is equal to $\frac{1}{2}$. It is equal to zero for all other even k, and different from zero for all odd k, with λ_k going to zero as $1/k$.

We have for $\alpha = 1$:

$$\frac{1}{2\pi}\int_0^{2\pi}(\cos\eta)_+\cos k\eta\, d\eta = \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}\cos\eta\cos k\eta\, d\eta$$

$$
\begin{aligned}
&= \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}[\frac{1}{2}\cos(k+1)\eta + \frac{1}{2}\cos(k-1)\eta]\,d\eta \\
&= \frac{1}{4\pi}\left(\frac{2}{k+1}\sin(k+1)\frac{\pi}{2} + \frac{2}{k-1}\sin(k-1)\frac{\pi}{2}\right) \\
&= \frac{\cos\frac{k\pi}{2}}{2\pi}\left(\frac{1}{k+1} - \frac{1}{k-1}\right) = \frac{-\cos\frac{k\pi}{2}}{\pi(k^2-1)} \text{ for } k \neq 1.
\end{aligned}
$$

For $k=1$, it is equal to $1/4$. It is equal to zero for all other odd k, and different from zero for all even k, with λ_k going to zero as $1/k^2$.

For $\alpha = 2$, we have:

$$
\begin{aligned}
\frac{1}{2\pi}\int_0^{2\pi}(\cos\eta)_+^2\cos k\eta\,d\eta &= \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}(\cos\eta)^2\cos k\eta\,d\eta = \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}\frac{1+\cos 2\eta}{2}\cos k\eta\,d\eta \\
&= \frac{1}{2\pi}\int_{-\pi/2}^{\pi/2}[\frac{1}{2}\cos k\eta + \frac{1}{4}\cos(k+2)\eta + \frac{1}{4}\cos(k-2)\eta]\,d\eta \\
&= \frac{1}{4\pi}\left(\frac{2}{k}\sin k\frac{\pi}{2} + \frac{1}{k+2}\sin(k+2)\frac{\pi}{2} + \frac{1}{k-2}\sin(k-2)\frac{\pi}{2}\right) \\
&= \frac{\sin(k\frac{\pi}{2})}{4\pi}\left(\frac{2}{k} - \frac{1}{k+2} - \frac{1}{k-2}\right) \\
&= \frac{\sin(k\frac{\pi}{2})}{4\pi}\left(\frac{2k^2-8-k^2+2k-k^2-2k}{k(k^2-4)}\right) \\
&= \frac{-8\sin(k\frac{\pi}{2})}{4\pi k(k^2-4)} \text{ for } k \notin \{0,2\}.
\end{aligned}
$$

For $k=0$, it is equal to $1/4$, and for $k=2$, it is equal to $1/8$. It is equal to zero for all other even k, and different from zero for all odd k, with λ_k going to zero as $1/k^3$.

The general case for $\alpha \geqslant 2$ will be shown for for all d in Appendix D.2: for all $\alpha \in \mathbb{N}$, λ_k is different from zero for k having the opposite parity of α, with a decay as $1/k^{\alpha+1}$. All values from $k=0$ to α are also different from zero. All larger values with the same parity as α are equal to zero.

C.2 Proof of Prop. 2 for $d = 1$

We only consider the proof for $d=1$. For the proof for general d, see Appendix D.3.

Given the zero values of λ_k given above, if g has the opposite parity than α (that is, is even when α is odd, and vice-versa), then we may define p through its Fourier series, which is obtained by multiplying the one of g by a strictly positive sequence growing as $k^{\alpha+1}$.

Thus, if g is such that its $(\alpha+1)$-th order derivative is squared-integrable, then p defined above is squared-integrable, that is, $g \in \mathcal{G}_2$. Moreover, if all derivatives of order less than $(\alpha+1)$ are bounded by η, p is squared-integrable and $\|p\|^2_{L_2(\mathbb{S}^d)}$ is upper-bounded by a constant times η^2, i.e., $\gamma_2(g)^2 \leqslant C(\alpha)^2\eta^2$.

Note that we could relax the assumption that g is even (resp. odd) by adding all trigonometric polynomials of order less than α.

C.3 Proof of Prop. 3 for $d = 1$

Again, we only consider the proof for $d=1$. For the proof for general d, see Appendix D.4.

Without loss of generality, we assume that $\eta = 1$. For $d=1$, we essentially want to approximate a Lipschitz-continuous function by a function which is $(\alpha+1)$-times differentiable.

For $\alpha = 0$, then the function g is already in $\mathcal{G}_2$ with a norm less than one, because Lipschitz-continuous functions are almost everywhere differentiable with bounded derivative (Adams and Fournier, 2003). We thus now consider $\alpha > 0$.

Given λ_k defined above and $r \in (0,1)$, we define $\hat{p}$ through

$$
\hat{p}_k(\theta) = \sum_{k,\lambda_k \neq 0} \lambda_k^{-1} g_k(\theta) r^k.
$$

Our goal is to show that for r chosen close enough to 1, then the function $\hat{g}$ defined from $\hat{p}$ has small enough norm $\gamma_2(\hat{g}) \leqslant \|\hat{p}\|_{L_2(\mathbb{S}^d)}$, and is close to g.

Computation of norm. We have

$$
\|\hat{p}\|^2_{L_2(\mathbb{S}^d)} = \sum_{k,\lambda_k\neq 0} \lambda_k^{-2} r^{2k} \|g_k\|^2_{L_2(\mathbb{S}^d)}.
$$

Since g is 1-Lipschitz-continuous with constant 1, then it has a squared-integrable derivative $f = g'$ with norm less than 1 (Adams and Fournier, 2003), so that

$$
\|f\|^2_{L_2(\mathbb{S}^d)} = \sum_{k\geqslant 0} \|f_k\|^2_{L_2(\mathbb{S}^d)} \leqslant 1.
$$

This implies that using $\lambda_k^{-1} = O(k^{\alpha+1})$:

$$
\|\hat{p}\|^2_{L_2(\mathbb{S}^d)} \leqslant \lambda_0^{-2}\|g_0\|^2_{L_2(\mathbb{S}^d)} + \|g'\|^2_{L_2(\mathbb{S}^d)} \max_{k\geqslant 1,\lambda_k\neq 0} r^{2k}\lambda_k^{-2}k^{-2} \leqslant C + C\|g'\|^2_{L_2(\mathbb{S}^d)} \max_{k\geqslant 1} r^{2k}k^{2\alpha},
$$

because $\|g_0\|^2_{L_2(\mathbb{S}^d)}$ and $\|f\|^2_{L_2(\mathbb{S}^d)}$ are bounded by 1.

We may now compute the derivative of $k \mapsto r^{2k}k^{2\alpha}$ with respect to k (now considered a real number), that is $2\alpha k^{2\alpha-1}r^{2k} + k^{2\alpha}r^{2k}2\log r$, which is equal to zero for $\frac{\alpha}{k} = \log\frac{1}{r}$, that is $k = \frac{\alpha}{\log\frac{1}{r}}$, the maximum being then $e^{-2\alpha}(\frac{\alpha}{\log\frac{1}{r}})^{2\alpha} = O((1-r)^{-2\alpha})$, by using the concavity of the logarithm. Thus $\|\hat{p}\|_{L_2(\mathbb{S}^d)} \leqslant C(1-r)^{-\alpha}$. This defines $\hat{g}$ with $\gamma(\hat{g}) \leqslant C(1-r)^{-\alpha}$.

Computing distance between $\hat{g}$ and g. We have:

$$
\begin{aligned}
\hat{g}(\theta) &= \sum_{k\geqslant 0} g_k(\theta)r^k = \sum_{k>0}\frac{1}{\pi}\int_0^{2\pi} g(\eta)r^k\cos k(\theta-\eta)d\eta + \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta \\
&= \frac{1}{\pi}\int_0^{2\pi}\left(\sum_{k\geqslant 0} r^k\cos k(\theta-\eta)\right)g(\eta)d\eta - \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta \\
&= \frac{1}{\pi}\int_0^{2\pi}\mathrm{Real}\left(\frac{1}{1-re^{i(\theta-\eta)}}\right)g(\eta)d\eta - \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta
\end{aligned}
$$

$$
\begin{aligned}
&= \frac{1}{\pi}\int_0^{2\pi}\Big(\frac{1-r\cos(\theta-\eta)}{(1-r\cos(\theta-\eta))^2+r^2(\sin(\theta-\eta))^2}\Big)g(\eta)d\eta - \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta \\
&= \frac{1}{\pi}\int_0^{2\pi}\Big(\frac{1-r\cos(\theta-\eta)}{1+r^2-2r\cos(\theta-\eta)}\Big)g(\eta)d\eta - \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta \\
&= \frac{1}{2\pi}\int_0^{2\pi}\Big(\frac{1-r^2+1+r^2-2r\cos(\theta-\eta)}{1+r^2-2r\cos(\theta-\eta)}\Big)g(\eta)d\eta - \frac{1}{2\pi}\int_0^{2\pi} g(\eta)d\eta \\
&= \frac{1}{2\pi}\int_0^{2\pi}\Big(\frac{1-r^2}{1+r^2-2r\cos(\theta-\eta)}\Big)g(\eta)d\eta.
\end{aligned}
$$

We have, for any $\theta \in [0, 2\pi]$

$$
\begin{aligned}
|\hat{g}(\theta) - g(\theta)| &= \Big|\frac{1}{2\pi}\int_0^{2\pi}\Big(\frac{1-r^2}{1+r^2-2r\cos(\theta-\eta)}\Big)[g(\eta)-g(\theta)]d\eta\Big| \\
&\leqslant \frac{1}{2\pi}\int_0^{2\pi}\Big(\frac{1-r^2}{1+r^2-2r\cos(\theta-\eta)}\Big)|g(\eta)-g(\theta)|d\eta \\
&= \frac{1}{2\pi}\int_\pi^{\pi}\Big(\frac{1-r^2}{1+r^2-2r\cos\eta}\Big)|g(\theta)-g(\theta+\eta)|d\eta \ \text{ by periodicity,} \\
&= \frac{1}{\pi}\int_{\pi/2}^{\pi/2}\Big(\frac{1-r^2}{1+r^2-2r\cos\eta}\Big)|g(\theta)-g(\theta+\eta)|d\eta \ \text{ by parity of } g, \\
&\leqslant \frac{1}{\pi}\int_{\pi/2}^{\pi/2}\Big(\frac{1-r^2}{1+r^2-2r\cos\eta}\Big)\sqrt{2}|\sin\eta|d\eta \\
&\qquad \text{because the distance on the sphere is bounded by the sine,} \\
&\leqslant \frac{2}{\pi}\int_0^{\pi}\Big(\frac{1-r^2}{1+r^2-2r\cos\eta}\Big)\sin\eta\, d\eta \\
&= \frac{1}{\pi}\int_0^{1}\Big(\frac{1-r^2}{1+r^2-2rt}\Big)dt \ \text{ by the change of variable } t=\cos\theta, \\
&\leqslant C(1-r)\int_0^1\Big(\frac{1}{1+r^2-2rt}\Big)dt \\
&= C(1-r)\Big[\frac{-1}{2r}\log(1+r^2-2rt)\Big]_0^1 = C(1-r)\frac{1}{2r}\log\frac{1+r^2}{(1-r)^2}.
\end{aligned}
$$

It can be easily checked that for any $r \in (1/2, 1)$, the last function is less than a constant times $\frac{5}{2}C(1-r)\log\frac{1}{1-r}$. We thus get for δ large enough, by taking $r = 1-(C/\delta)^{1/\alpha} \in (1/2, 1)$, an error of

$$(C/\delta)^{1/\alpha}\log(C/\delta)^{-1/\alpha} = O(\delta^{-1/\alpha}\log\delta).$$

This leads to the desired result.

Appendix D. Approximations on the d-dimensional Sphere

In this appendix, we first review tools from spherical harmonic analysis, before proving the two main propositions regarding the approximation properties of the Hilbert space $\mathcal{G}_2$. Using spherical harmonics in our set-up is natural and is common in the analysis of ridge functions (Petrushev, 1998) and zonotopes (Bourgain and Lindenstrauss, 1988).

D.1 Review of Spherical Harmonics Theory

In this section, we review relevant concepts from spherical harmonics. See Frye and Efthimiou (2012); Atkinson and Han (2012) for more details. Spherical harmonics may be seen as extension of Fourier series to spheres in dimensions more than 2 (i.e., with our convention $d \geqslant 1$).

For $d \geqslant 1$, we consider the sphere $\mathbb{S}^d = \{x \in \mathbb{R}^{d+1},\ \|x\|_2 = 1\} \subset \mathbb{R}^{d+1}$, as well as its normalized rotation-invariant measure τ_d (with mass 1). We denote by $\omega_d = \frac{2\pi^{(d+1)/2}}{\Gamma((d+1)/2)}$ the surface area of the sphere $\mathbb{S}^d$.

Definition and links with Laplace-Beltrami operator. For any $k \geqslant 1$ (for $k = 0$, the constant function is the corresponding basis element), there is an orthonormal basis of spherical harmonics, $Y_{kj} : \mathbb{S}^d \to \mathbb{R}$, $1 \leqslant j \leqslant N(d,k) = \frac{2k+d-1}{k}\binom{k+d-2}{d-1}$. They are such $\langle Y_{ki}, Y_{si}\rangle_{\mathbb{S}^d} = \int_{\mathbb{S}^d} Y_{ki}(x)Y_{sj}d\tau_d(x) = \delta_{ij}\delta_{sk}$.

Each of these harmonics may be obtained from homogeneous polynomials in $\mathbb{R}^d$ with an Euclidean Laplacian equal to zero, that is, if we define a function $H_k(y) = Y_{ki}(y/\|y\|_2)\|y\|_2^k$ for $y \in \mathbb{R}^{d+1}$, then H_k is a homogeneous polynomial of degree k with zero Laplacian. From the relationship between the Laplacian in $\mathbb{R}^{d+1}$ and the Laplace-Beltrami operator Δ on $\mathbb{S}^d$, Y_{ki} is an eigenfunction of Δ with eigenvalue $-k(k+d-1)$. Like in Euclidean spaces, the Laplace-Beltrami operator may be used to characterize differentiability of functions defined on the sphere (Frye and Efthimiou, 2012; Atkinson and Han, 2012).

Legendre polynomials. We have the addition formula

$$\sum_{j=1}^{N(d,k)} Y_{kj}(x)Y_{kj}(y) = N(d,k)P_k(x^\top y),$$

where P_k is a Legendre polynomial of degree k and dimension $d+1$, defined as (Rodrigues' formula):

$$P_k(t) = (-1/2)^k\frac{\Gamma(d/2)}{\Gamma(k+d/2)}(1-t^2)^{(2-d)/2}\Big(\frac{d}{dt}\Big)^k(1-t^2)^{k+(d-2)/2}.$$

They are also referred to as Gegenbauer polynomials. For $d = 1$, P_k is the k-th Chebyshev polynomial, such that $P_k(\cos\theta) = \cos(k\theta)$ for all θ (and we thus recover the Fourier series framework of Appendix C). For $d = 2$, P_k is the usual Legendre polynomial.

The polynomial P_k is even (resp. odd) when k is even (resp. odd), and we have

$$\int_{-1}^1 P_k(t)P_j(k)(1-t^2)^{(d-2)/2}dt = \delta_{jk}\frac{\omega_d}{\omega_{d-1}}\frac{1}{N(d,k)}.$$

For small k, we have $P_0(t) = 1$, $P_1(t) = t$, and $P_2(t) = \frac{(d+1)t^2-1}{d}$.

The Hecke-Funk formula leads to, for any linear combination Y_k of Y_{kj}, $j \in \{1, \dots, N(d,k)\}$:

$$\int_{\mathbb{S}^d} f(x^\top y)Y_k(y)d\tau_d(y) = \frac{\omega_{d-1}}{\omega_d}Y_k(x)\int_{-1}^1 f(t)P_k(t)(1-t^2)^{(d-2)/2}dt.$$

Decomposition of functions in $L_2(\mathbb{S}^d)$. Any function $g : \mathbb{S}^d \to \mathbb{R}$, such that we have $\int_{\mathbb{S}^d} g(x) d\tau_d(x) = 0$ may be decomposed as

$$\begin{aligned} g(x) &= \sum_{k=1}^{\infty} \sum_{j=1}^{N(d,k)} \langle Y_{kj}, g\rangle Y_{kj}(x) = \sum_{k=1}^{\infty} \sum_{j=1}^{N(d,k)} \int_{\mathbb{S}^d} Y_{kj}(y) Y_{kj}(x) g(y) d\tau_d(y) \\ &= \sum_{k=1}^{\infty} g_k(x) \text{ with } g_k(x) = N(d,k) \int_{\mathbb{S}^d} g(y) P_k(x^\top y) d\tau_d(y). \end{aligned}$$

This is the decomposition in harmonics of degree k. Note that

$$g_1(x) = x^\top \Big[d \int_{\mathbb{S}^d} y g(y) d\tau_d(y) \Big]$$

is the linear part of g (i.e., if $g(x) = w^\top x$, $g_1 = g$). Moreover, if g does not have zero mean, we may define $g_0(x) = \int_{\mathbb{S}^d} g(y) d\tau_d(y)$ as the average value of g. Since the harmonics of different degrees are orthogonal to each other, we have the Parseval formula:

$$\|g\|^2_{\mathbb{S}^d} = \sum_{k \geqslant 0} \|g_k\|^2_{\mathbb{S}^d}.$$

Decomposition of functions of one-dimensional projections. If $g(x) = \varphi(x^\top v)$ for $v \in \mathbb{S}^d$ and $\varphi : [-1,1] \to \mathbb{R}$, then

$$\begin{aligned} g_k(x) &= N(d,k) \int_{\mathbb{S}^d} \varphi(v^\top y) P_k(x^\top y) d\tau(y) \\ &= N(d,k) \frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t) (1-t^2)^{(d-2)/2} dt \\ &= \Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t) (1-t^2)^{(d-2)/2} dt \Big) \sum_{j=1}^{N(d,k)} Y_{kj}(x) Y_{kj}(y), \end{aligned}$$

and

$$\begin{aligned} \|g_k\|^2_{L_2(\mathbb{S}^d)} &= \Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t) (1-t^2)^{(d-2)/2} dt \Big)^2 \sum_{j=1}^{N(d,k)} Y_{kj}(y)^2 \\ &= \Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t) (1-t^2)^{(d-2)/2} dt \Big)^2 N(d,k) P_k(1) \\ &= \Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t) (1-t^2)^{(d-2)/2} dt \Big)^2 N(d,k). \end{aligned}$$

D.2 Computing the RKHS Norm γ_2

Like for the case $d = 1$, we may compute the RKHS norm γ_2 of a function g in closed form given its decomposition in the basis of spherical harmonics $g = \sum_{k \geqslant 0} g_k$. If we can decompose $g(x) = \int_{\mathbb{S}^d} p(w) \sigma(w^\top x) d\tau_d(w)$ for a certain function $p : \mathbb{S}^d \to \mathbb{R}$, then we have, for $k \geqslant 0$:

$$\begin{aligned} g_k(x) &= N(d,k) \int_{\mathbb{S}^d} g(y) P_k(x^\top y) d\tau_d(y) \\ &= N(d,k) \int_{\mathbb{S}^d} \int_{\mathbb{S}^d} p(w) \sigma(w^\top y) P_k(x^\top y) d\tau_d(y) d\tau_d(w) \\ &= N(d,k) \int_{\mathbb{S}^d} p(w) \Big(\int_{\mathbb{S}^d} \sigma(w^\top y) P_k(x^\top y) d\tau_d(y) \Big) d\tau_d(w) \\ &= \frac{\omega_{d-1}}{\omega_d} N(d,k) \int_{\mathbb{S}^d} p(w) P_k(x^\top w) \Big(\int_{-1}^1 \sigma(t) P_k(t) (1-t^2)^{(d-2)/2} dt \Big) d\tau_d(w) \\ &\qquad \text{using the Hecke-Funk formula,} \\ &= \lambda_k p_k(x) \text{ with } \lambda_k = \frac{\omega_{d-1}}{\omega_d} \int_{-1}^1 \sigma(t) P_k(t) (1-t^2)^{(d-2)/2} dt. \end{aligned}$$

If $k \equiv \alpha \bmod 2$, then $\lambda_k \propto \frac{1}{2} \int_{-1}^1 t^\alpha P_k(t) (1-t^2)^{(d-2)/2} dt = 0$, for $k > \alpha$ since P_k is orthogonal to all polynomials of degree strictly less than k for that dot-product. Otherwise, $\lambda_k \neq 0$, since t^α may be decomposed as combination with non-zero coefficients of polynomials P_j for $j \equiv \alpha \bmod 2$, $j \leqslant \alpha$.

We now provide an explicit formula extending the proof technique (for $\alpha = 1$) of Schneider (1967) and Bourgain and Lindenstrauss (1988) to all values of α. See also Mhaskar (2006).

We have, by α successive integration by parts, for $k \geqslant \alpha + 1$:

$$\begin{aligned} &\int_0^1 t^\alpha \Big(\frac{d}{dt} \Big)^k (1-t^2)^{k+(d-2)/2} dt \\ &= (-1)^\alpha \alpha! \int_0^1 \Big(\frac{d}{dt} \Big)^{k-\alpha} (1-t^2)^{k+(d-2)/2} dt = -(-1)^\alpha \alpha! \Big(\frac{d}{dt} \Big)^{k-\alpha-1} (1-t^2)^{k+(d-2)/2} \Big|_{t=0} \\ &= -(-1)^\alpha \alpha! \Big(\frac{d}{dt} \Big)^{k-\alpha-1} \sum_{j \geqslant 0} \binom{k+(d-2)/2}{j} (-1)^j t^{2j} \Big|_{t=0} \text{ using the binomial formula,} \\ &= -(-1)^\alpha \alpha! \Big(\frac{d}{dt} \Big)^{k-\alpha-1} \binom{k+(d-2)/2}{j} (-1)^j t^{2j} \Big|_{t=0} \text{ for } 2j = k-\alpha-1, \\ &= -(-1)^\alpha \alpha! \binom{k+(d-2)/2}{j} (-1)^j (2j)! \text{ for } 2j = k-\alpha-1. \end{aligned}$$

Thus

$$\begin{aligned} \lambda_k &= -\frac{\omega_{d-1}}{\omega_d} (-1/2)^k \frac{\Gamma(d/2)}{\Gamma(k+d/2)} (-1)^\alpha \alpha! \binom{k+(d-2)/2}{j} (-1)^j (2j)! \text{ for } 2j = k-\alpha-1, \\ &= -\frac{\omega_{d-1}}{\omega_d} (-1/2)^k \frac{\Gamma(d/2)}{\Gamma(k+d/2)} (-1)^\alpha \alpha! \frac{\Gamma(k+\frac{d}{2})}{\Gamma(j+1)\Gamma(k+\frac{d}{2}-j)} (-1)^j \Gamma(2j+1) \\ &= -\frac{\omega_{d-1}}{\omega_d} (-1/2)^k \frac{\Gamma(d/2)}{\Gamma(k+d/2)} (-1)^\alpha \alpha! \frac{\Gamma(k+\frac{d}{2}) (-1)^{(k-\alpha-1)/2} \Gamma(k-\alpha)}{\Gamma(\frac{k}{2}-\frac{\alpha}{2}+\frac{1}{2}) \Gamma(\frac{k}{2}+\frac{d}{2}+\frac{\alpha}{2}+\frac{1}{2})} \\ &= \frac{d-1}{2\pi} \frac{\alpha! (-1)^{(k-\alpha-1)/2}}{2^k} \frac{\Gamma(d/2)\Gamma(k-\alpha)}{\Gamma(\frac{k}{2}-\frac{\alpha}{2}+\frac{1}{2}) \Gamma(\frac{k}{2}+\frac{d}{2}+\frac{\alpha}{2}+\frac{1}{2})}. \end{aligned}$$

By using Stirling formula $\Gamma(x) \approx x^{x-1/2}e^{-x}\sqrt{2\pi}$, we get an equivalent when k or d tends to infinity as a constant (that depends on α) times

$$d^{d/2+1/2}k^{k/2-\alpha/2+1/2}(k+d)^{-k/2-d/2-\alpha/2}.$$

Note that all exponential terms cancel out. Moreover, when k tends to infinity and d is considered constant, then we get the equivalent $k^{-d/2-\alpha-1/2}$, which we need for the following sections. Finally, when d tends to infinity and k is considered constant, then we get the equivalent $d^{-\alpha/2-k/2+1/2}$.

We will also need expressions of λ_k for $k=0$ and $k=1$. For $k=0$, we have:

$$\begin{aligned}\int_0^1 t^\alpha(1-t^2)^{d/2-1}dt &= \int_0^1 (1-u)^{\alpha/2}u^{d/2-1}\frac{du}{2\sqrt{1-u}} \text{ with } t=\sqrt{1-u},\\ &= \frac{1}{2}\int_0^1 (1-u)^{\alpha/2+1/2-1}u^{d/2-1}du = \frac{1}{2}\frac{\Gamma(\alpha/2+1/2)\Gamma(d/2)}{\Gamma(\alpha/2+1/2+d/2)},\end{aligned}$$

using the normalization factor of the Beta distribution. This leads to

$$\lambda_0 = \frac{\omega_{d-1}}{\omega_d}\frac{1}{2}\frac{\Gamma(\alpha/2+1/2)\Gamma(d/2)}{\Gamma(\alpha/2+1/2+d/2)} = \frac{d-1}{2\pi}\frac{1}{2}\frac{\Gamma(\alpha/2+1/2)\Gamma(d/2)}{\Gamma(\alpha/2+1/2+d/2)},$$

which is equivalent to $d^{1/2-\alpha/2}$ as d tends to infinity.

Moreover, for $k=1$, we have (for $\alpha>0$):

$$\begin{aligned}\int_0^1 t^\alpha\Big(\frac{d}{dt}\Big)(1-t^2)^{d/2}dt &= -\alpha\int_0^1 t^{\alpha-1}(1-t^2)^{d/2}dt = -\alpha\int_0^1 (1-u)^{\alpha/2-1/2}u^{d/2}\frac{du}{2\sqrt{1-u}}\\ &= -\alpha/2\int_0^1 (1-u)^{\alpha/2-1}u^{d/2+1-1}du = -\alpha/2\frac{\Gamma(\alpha/2)\Gamma(d/2+1)}{\Gamma(\alpha/2+d/2+1)}.\end{aligned}$$

This leads to, for $\alpha>0$:

$$\lambda_1 = (-1/2)\frac{2}{d}\frac{d-1}{2\pi}(-\alpha/2)\frac{\Gamma(\alpha/2)\Gamma(d/2+1)}{\Gamma(\alpha/2+d/2+1)} = \frac{d-1}{d}\frac{\alpha}{4\pi}\frac{\Gamma(\alpha/2)\Gamma(d/2+1)}{\Gamma(\alpha/2+d/2+1)},$$

which is equivalent to $d^{-\alpha/2}$ as d tends to infinity.

Finally, for $\alpha=0$, $\lambda_1 = \frac{d-1}{2d\pi}$. More generally, we have $|\lambda_k| \sim C(d)k^{-(d-1)/2-\alpha-1}$.

Computing the RKHS norm. Given g with the correct parity, then we have

$$\gamma_2(g)^2 = \sum_{k\geqslant 0}\lambda_k^{-2}\|g_k\|^2_{L_2(\mathbb{S}^d)}.$$

D.3 Proof of Prop. 2 for $d>1$

Given the expression of λ_k from the section above, the proof is essentially the same than for $d=1$ in Appendix C.3. If g is s-times differentiable with all derivatives bounded uniformly by η, then is equal to $g=\Delta^{s/2}f$ for a certain function f such that $\|f\|_{L_2(\mathbb{S}^d)}\leqslant\eta$ (where Δ is the Laplacian on the sphere) (Frye and Efthimiou, 2012; Atkinson and Han, 2012).

Moreover, since g has the correct parity,

$$\gamma_2(g)^2 \leqslant \|p\|^2_{L_2(\mathbb{S}^d)} \leqslant \sum_{k\geqslant 1,\lambda_k\neq 0}\lambda_k^{-2}\|g_k\|^2_{L_2(\mathbb{S}^d)}$$

Also, g_k are eigenfunctions of the Laplacian with eigenvalues $k(k+d-1)$. Thus, we have

$$\|g_k\|_2^2 \leqslant \|f_k\|^2_{L_2(\mathbb{S}^d)}\frac{1}{[k(k+d-1)]^s} \leqslant \|f_k\|^2_{L_2(\mathbb{S}^d)}/k^{2s},$$

leading to $\gamma_2(g)^2 \leqslant \max_{k\geqslant 2}\lambda_k^{-2}k^{-2s}\|f\|^2_{L_2(\mathbb{S}^d)} \leqslant \max_{k\geqslant 2}k^{d-1+2\alpha+2}k^{-2s}\|f\|^2_{L_2(\mathbb{S}^d)} \leqslant C(d)\eta^2$, if $s\geqslant (d-1)/2+\alpha+1$, which is the desired result.

D.4 Proof of Prop. 3 for $d>1$

Without loss of generality we assume that $\eta=1$, and we follow the same proof as for $d=1$ in Appendix C.3. We have assumed that for all $x,y\in\mathbb{S}^d$, $|g(x)-g(y)|\leqslant\eta\|x-y\|_2 = \eta\sqrt{2}\sqrt{1-x^\top y}$. Given the decomposition in the k-th harmonics, with

$$g_k(x) = N(d,k)\int_{\mathbb{S}^d} g(y)P_k(x^\top y)d\tau_d(y),$$

we may now define, for $r<1$:

$$\hat{p}(x) = \sum_{k,\lambda_k\neq 0}\lambda_k^{-1}r^k g_k(x),$$

which is always defined when $r\in(0,1)$ because the series is absolutely convergent. This defines a function $\hat{g}$ that will have a finite γ_2-norm and be close to g.

Computing the norm. Given our assumption regarding the Lipschitz-continuity of g, we have $g=\Delta^{1/2}f$ with $f\in L_2(\mathbb{S}^d)$ with norm less than 1 (Atkinson and Han, 2012). Moreover $\|g_k\|^2_{L_2(\mathbb{S}^d)}\leqslant Ck^2\|f_k\|^2_{L_2(\mathbb{S}^d)}$. We have

$$\begin{aligned}\|\hat{p}\|^2_{L_2(\mathbb{S}^d)} &= \sum_{k,\lambda_k\neq 0}\lambda_k^{-2}r^{2k}\|g_k\|^2_{L_2(\mathbb{S}^d)}\\ &\leqslant C(d,\alpha)\max_{k\geqslant 0}k^{d-1+2\alpha}r^{2k}\|f\|^2_{L_2(\mathbb{S}^d)} \text{ because } \lambda_k=\Omega(k^{-d/2-\alpha-1/2}),\\ &\leqslant C(d,\alpha)(1-r)^{-d+1-2\alpha} \text{ (see Appendix C.3).}\end{aligned}$$

The function $\hat{p}$ thus defines a function $\hat{g}\in\mathcal{G}_1$ by $\hat{g}_k=\lambda_k p_k$, for which $\gamma_2(g)\leqslant C(d,\alpha)(1-r)^{(-d+1)/2-\alpha}$.

Approximation properties. We now show that g and $\hat{g}$ are close to each other. Because of the parity of g, we have $\hat{g}_k=r^k g_k$. We have, using Theorem 4.28 from Frye and Efthimiou (2012):

$$\hat{g}(x) = \sum_{k\geqslant 0}r^k = \sum_{k\geqslant 0}r^k N(d,k)\int_{\mathbb{S}^d} g(y)P_k(x^\top y)d\tau_d(y)$$

$$= \int_{\mathbb{S}^d} g(y)\Big(\sum_{k\geqslant 0} r^k N(d,k) P_k(x^\top y)\Big) d\tau_d(y)$$
$$= \int_{\mathbb{S}^d} g(y) \frac{1-r^2}{(1+r^2-2r(x^\top y))^{(d+1)/2}} d\tau_d(y).$$

Moreover, following Bourgain and Lindenstrauss (1988), we have:

$$g(x)-\hat{g}(x) = \int_{\mathbb{S}^d} [g(x)-g(y)] \frac{1-r^2}{(1+r^2-2r(x^\top w))^{(d+1)/2}} d\tau_d(y)$$
$$= 2\int_{\mathbb{S}^d,\ y^\top x\geqslant 0} [g(x)-g(y)] \frac{1-r^2}{(1+r^2-2r(x^\top w))^{(d+1)/2}} d\tau_d(y) \text{ by parity of } g,$$
$$|g(x)-\hat{g}(x)| \leqslant \int_{\mathbb{S}^d,\ y^\top x\geqslant 0} \sqrt{2}\sqrt{1-x^\top y} \frac{1-r^2}{(1+r^2-2r(x^\top y))^{(d+1)/2}} d\tau_d(y).$$

As shown by Bourgain and Lindenstrauss (1988, Eq. (2.13)), this is less than a constant that depends on d times $(1-r)\log\frac{1}{1-r}$. We thus get for δ large enough, by taking $1-r = (C/\delta)^{1/(\alpha+(d-1)/2)} \in (0,1)$, an error of

$$(C/\delta)^{1/(\alpha+(d-1)/2)} \log(C/\delta)^{-1/(\alpha+(d-1)/2)}] = O(\delta^{1/(\alpha+(d-1)/2)} \log\delta),$$

which leads to the desired result.

D.5 Finding Differentiable Functions which are not in $\mathcal{G}_2$

In this section, we consider functions on the sphere which have the proper parity with respect to α, which are s-times differentiable with bounded derivatives, but which are not in $\mathcal{G}_2$. We then provide optimal approximation rates for these functions.

We assume that $s-\alpha$ is even, we consider $g(x) = (w^\top x)_+^s$ for a certain arbitrary $w \in \mathbb{S}^d$. As computed at the end of Appendix D.1, we have $\|g_k\|^2_{L_2(\mathbb{S}^d)} = \Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t)(1-t^2)^{(d-2)/2} dt\Big)^2 N(d,k)$. Given the computations from Appendix D.2, the squared norm equal to $\Big(\frac{\omega_{d-1}}{\omega_d} P_k(x^\top v) \int_{-1}^1 \varphi(t) P_k(t)(1-t^2)^{(d-2)/2} dt\Big)^2$ goes down to zero as $k^{-d-2s-1}$, while $N(d,k)$ grows as k^{d-1}. In order to use the computation of the RKHS norm derived in Appendix D.2, we need to make sure that g has the proper parity. This can de done by removing all harmonics with $k \leqslant s$ (note that these harmonics are also functions of $w^\top x$, and thus the function that we obtain is also a function of $w^\top x$). That function then has a squared RKHS norm equal to

$$\sum_{k\geqslant s, \lambda_k\neq 0} \|g_k\|^2_{L_2(\mathbb{S}^d)} \lambda_k^{-2}.$$

The summand has an asymptotic equivalent proportional to $k^{-d-2s-1} k^{d-1} k^{d+2\alpha+1}$ which is equal to $k^{d+2\alpha-2s-1}$. Thus if $d+2\alpha-2s \geqslant 0$, the series is divergent (the function is not in the RKHS), i.e., if $s \leqslant \alpha + \frac{d}{2}$.

Best approximation by a function in $\mathcal{G}_2$. The squared norm of the k-th harmonic $\|g_k\|^2_{L_2(\mathbb{S}^d)}$ goes down to zero as k^{-2s-2} and the squared RKHS norm of a h is equivalent to $\sum_{k\geqslant 0} \|h_k\|^2_{L_2(\mathbb{S}^d)} k^{d+2\alpha+1}$. Given δ, we may then find the function h such that $\gamma_2(h)^2 = \sum_{k\geqslant 0} \|h_k\|^2_{L_2(\mathbb{S}^d)} k^{d+2\alpha+1} \leqslant \delta^2$ with smallest $L_2(\mathbb{S}^d)$ norm distance to g, that is, $\sum_{k\geqslant 0} \|g_k - h_k\|^2_{L_2(\mathbb{S}^d)}$. The optimal approximation is $h_k = \alpha_k g_k$ for some $\alpha_k \in \mathbb{R}_+$, with error $\sum_{k\geqslant 0}(1-\alpha_k)^2 \|g_k\|^2_{L_2(\mathbb{S}^d)} \sim \sum_{k\geqslant 0}(1-\alpha_k)^2 k^{-2s-2}$ and squared γ_2-norm $\sum_{k\geqslant 0} \alpha_k^2 k^{d+2\alpha+1} k^{-2s-2} = \sum_{k\geqslant 0} \alpha_k^2 k^{d+2\alpha-2s-1}$. The optimal α_k is obtained by considering a Lagrange multiplier λ such that $(\alpha_k - 1)k^{-2s-2} + \lambda\alpha_k k^{d+2\alpha-2s-1} = 0$, that is, $\alpha_k = (k^{-2s-2} + \lambda k^{d+2\alpha-2s-1})^{-1} k^{-2s-2} = (1+\lambda k^{d+2\alpha+1})^{-1}$. We then have

$$\sum_{k\geqslant 0} \alpha_k^2 k^{d+2\alpha-2s-1} = \sum_{k\geqslant 0} (1+\lambda k^{d+2\alpha+1})^{-2} k^{d+2\alpha-2s-1}$$
$$\approx \int_0^\infty (1+\lambda t^{d+2\alpha+1})^{-2} t^{d+2\alpha-2s-1} dt \text{ by approximation by an integral,}$$
$$\propto \int_0^\infty (1+u)^{-2} d(t^{d+2\alpha-2s}) \text{ with the change of variable } u = \lambda t^{d+2\alpha+1}$$
$$\propto \lambda^{-(d+2\alpha-2s)/(d+2\alpha+1)} \text{ up to constants,}$$

which should be of order δ^2 (this gives the scaling of λ as a function of δ). Then the squared error is

$$\sum_{k\geqslant 0} (1-\alpha_k)^2 k^{-2s-2} = \sum_{k\geqslant 0} \frac{\lambda^2 t^{2d+4\alpha+2}}{(1+\lambda k^{d+2\alpha+1})^2} k^{-2s-2}$$
$$\approx \int_0^\infty \frac{\lambda^2 t^{2d+4\alpha-2s}}{(1+\lambda t^{d+2\alpha+1})^2} dt$$
$$\approx \lambda^2 \lambda^{-(2d+4\alpha-2s+1)/(d+2\alpha+1)} = \lambda^{-(2d+4\alpha-2s+1-2d-4\alpha-2)/(d+2\alpha+1)}$$
$$= \lambda^{(2s+1)/(d+2\alpha+1)} \approx \delta^{-2(2s+1)/(d+2\alpha-2s)},$$

and thus the (non-squared) approximation error scales as $\delta^{-(2s+1)/(d+2\alpha-2s)}$. For $s=1$, this leads to a scaling as $\delta^{-3/(d+2\alpha-2)}$.

D.6 Proof of Prop. 4

For $\alpha = 1$, by writing $v^\top x = (v^\top x)_+ - (-v^\top x)_+$ we obtain the upperbound $\gamma_1(g) \leqslant 2$. For all other situations, we may compute

$$\gamma_2(g)^2 = \sum_{k\geqslant 0} \frac{\|g_k\|^2_{L_2(\mathbb{S}^d)}}{\lambda_k^2}.$$

For g a linear function $g_k = 0$ except for $k=1$, for which, we have $g_1(x) = v^\top x$, and thus $\|g_k\|^2_{L_2(\mathbb{S}^d)} = \int_{\mathbb{S}^d} (v^\top x)^2 d\tau_d(x) = v^\top (\int_{\mathbb{S}^d} x x^\top \tau_d(x)) v = 1$. This implies that $\gamma_2(g) = \lambda_1^{-1}$. Given the expression (from Appendix D.2) $\lambda_1 = \frac{d-1}{d}\frac{\alpha}{4\pi}\frac{\Gamma(\alpha/2)\Gamma(d/2+1)}{\Gamma(\alpha/2+d/2+1)}$ for $\alpha > 1$ and $\lambda_1 = \frac{d-1}{2d\pi}$.

Appendix E. Computing ℓ_2-Haussdorff Distance between Ellipsoids

We assume that we are given two ellipsoids defined as $(x-a)^\top A^{-1}(x-a) \leqslant 1$ and $(x-b)^\top B^{-1}(x-b) \leqslant 1$ and we want to compute their Hausdorff distance. This leads to the two equivalent problems

$$\max_{\|w\|_2 \leqslant 1} w^\top (a-b) - \|B^{1/2} w\|_2 + \|A^{1/2} w\|_2,$$

$$\max_{\|u\|_2 \leqslant 1} \min_{\|v\|_2 \leqslant 1} \|a + A^{1/2} u - b - B^{1/2} v\|_2,$$

which are related by $w = a + A^{1/2}u - b - B^{1/2}v$. We first review classical methods for optimization of quadratic functions over the ℓ_2-unit ball.

Minimizing convex quadratic forms over the sphere. We consider the following convex optimization problem, with $Q \succcurlyeq 0$; we have by Lagrangian duality:

$$\begin{aligned}
&\min_{\|x\|_2 \leqslant 1} \frac{1}{2} x^\top Q x - q^\top x \\
&\max_{\lambda \geqslant 0} \min_{x \in \mathbb{R}^d} \frac{1}{2} x^\top Q x - q^\top x + \frac{\lambda}{2}(\|x\|_2^2 - 1) \\
&\max_{\lambda \geqslant 0} -\frac{1}{2} q^\top (Q + \lambda I)^{-1} q - \frac{\lambda}{2} \text{ with } x = (Q+\lambda I)^{-1} q.
\end{aligned}$$

If $\|Q^{-1}q\|_2 \leqslant 1$, then $\lambda = 0$ and $x = Q^{-1}q$. Otherwise, at the optimum, $\lambda > 0$ and $\|x\|_2^2 = q^\top (Q+\lambda I)^{-2} q = 1$, which implies $1 \leqslant \frac{1}{\lambda + \lambda_{\min}(Q)} q^\top Q^{-1} q$, which leads to $\lambda \leqslant q^\top Q^{-1} q - \lambda_{\min}(Q)$, which is important to reduce the interval of possible λ. The optimal λ may then be obtained by binary search (from a single SVD of Q).

Minimizing concave quadratic forms over the sphere. We consider the following non-convex optimization problem, with $Q \succcurlyeq 0$, for which strong Lagrangian duality is known to hold (Boyd and Vandenberghe, 2004):

$$\begin{aligned}
&\min_{\|x\|_2 \leqslant 1} -\frac{1}{2} x^\top Q x + q^\top x = \min_{\|x\|_2 = 1} -\frac{1}{2} x^\top Q x + q^\top x \\
&\max_{\lambda \geqslant 0} \min_{x \in \mathbb{R}^d} -\frac{1}{2} x^\top Q x + q^\top x + \frac{\lambda}{2}(\|x\|_2^2 - 1) \\
&\max_{\lambda \geqslant \lambda_{\max}(Q)} -\frac{1}{2} q^\top (\lambda I - Q)^{-1} q - \frac{\lambda}{2} \text{ with } x = (Q - \lambda I)^{-1} q.
\end{aligned}$$

At the optimum, we have $q^\top (\lambda I - Q)^{-2} q = 1$, which implies $1 \leqslant \frac{1}{[\lambda - \lambda_{\max}(Q)]^2} \|q\|_2^2$, which leads to $0 \leqslant \lambda - \lambda_{\max}(Q) \leqslant \|q\|_2$. We may perform binary search on λ from a single SVD of Q.

Computing the Haussdorff distance. We need to compute:

$$\max_{\|u\|_2 \leqslant 1} \min_{\|v\|_2 \leqslant 1} \frac{1}{2} \|a + A^{1/2}u - b - B^{1/2}v\|_2^2$$

$$\begin{aligned}
&= \max_{\|u\|_2 \leqslant 1} \max_{\lambda \geqslant 0} \min_{\|v\|_2 \leqslant 1} \frac{1}{2} \|a + A^{1/2}u - b - B^{1/2}v\|_2^2 + \frac{\lambda}{2}(\|v\|_2^2 - 1) \\
&= \max_{\|u\|_2 \leqslant 1} \max_{\lambda \geqslant 0} -\frac{\lambda}{2} + \frac{1}{2}\|a - b + A^{1/2}u\|^2 - \frac{1}{2}(a - b + A^{1/2}u)^\top B (B + \lambda I)^{-1} (a - b + A^{1/2}u) \\
&= \max_{\|u\|_2 \leqslant 1} \max_{\lambda \geqslant 0} -\frac{\lambda}{2} + \frac{\lambda}{2}(a - b + A^{1/2}u)^\top (B + \lambda I)^{-1} (a - b + A^{1/2}u)
\end{aligned}$$

with $v = (B + \lambda I)^{-1} B^{1/2} (a - b + A^{1/2}u)$. The interval in λ which is sufficient to explore is

$$\lambda \in [0, -\lambda_{\min}(B) + (\|a-b\|_2^2 + \lambda_{\max}(A^{1/2}))^2],$$

which are bounds that are independent of u.

Given $\lambda \geqslant 0$, we have the problem of

$$\begin{aligned}
&\min_{\mu \geqslant 0} \max_{u \in \mathbb{R}^d} \frac{\lambda}{2}(a - b + A^{1/2}u)^\top (B + \lambda I)^{-1} (a - b + A^{1/2}u) - \frac{\mu}{2}(\|u\|_2^2 - 1) - \frac{\lambda}{2} \\
&= \min_{\mu \geqslant 0} \max_{u \in \mathbb{R}^d} \frac{\lambda}{2}(a-b)^\top (B + \lambda I)^{-1}(a-b) + \frac{\mu - \lambda}{2} + \lambda u^\top A^{1/2} (B + \lambda I)^{-1} (a - b) \\
&\qquad\qquad - \frac{1}{2} u^\top (\mu I - \lambda A^{1/2} (B + \lambda I)^{-1} A^{1/2}) u \\
&= \min_{\mu \geqslant 0} \frac{\lambda}{2}(a-b)^\top (B + \lambda I)^{-1}(a-b) + \frac{\mu - \lambda}{2} \\
&\qquad + \lambda^2 (a-b)^\top (B + \lambda I)^{-1} A^{1/2} (\mu I - \lambda A^{1/2} (B + \lambda I)^{-1} A^{1/2})^{-1} A^{1/2} (B + \lambda I)^{-1} (a - b)
\end{aligned}$$

We have $u = (\frac{\mu}{\lambda} I - A^{1/2}(B + \lambda I)^{-1} A^{1/2})^{-1} A^{1/2} (B + \lambda I)^{-1} (a - b)$, leading to $w \propto (\lambda^{-1} B - \mu^{-1} A + I)(a - b)$. We need $\frac{\mu}{\lambda} \geqslant \lambda_{\max}(A^{1/2}(B + \lambda I)^{-1} A^{1/2})$. Moreover

$$0 \leqslant \frac{\mu}{\lambda} - \lambda_{\max}(A^{1/2}(B + \lambda I)^{-1} A^{1/2}) \leqslant \|A^{1/2}(B + \lambda I)^{-1}(a - b)\|.$$

This means that the ℓ_2-Haussdorff distance may be computed by solving in λ and μ, by exhaustive search with respect to λ and by binary search (or Newton's method) for μ. The complexity of each iteration is that of a singular value decomposition, that is $O(d^3)$. For more details on optimization of quadratic functions on the unit-sphere, see Forsythe and Golub (1965).

Abstract

Scaling kernel machines to massive data sets is a major challenge due to storage and computation issues in handling large kernel matrices, that are usually dense. Recently, many papers have suggested tackling this problem by using a low-rank approximation of the kernel matrix. In this paper, we first make the observation that the structure of shift-invariant kernels changes from low-rank to block-diagonal (without any low-rank structure) when varying the scale parameter. Based on this observation, we propose a new kernel approximation framework – Memory Efficient Kernel Approximation (MEKA), which considers both low-rank and clustering structure of the kernel matrix. We show that the resulting algorithm outperforms state-of-the-art low-rank kernel approximation methods in terms of speed, approximation error, and memory usage. As an example, on the covtype dataset with half a million samples, MEKA takes around 70 seconds and uses less than 80 MB memory on a single machine to achieve 10% relative approximation error, while standard Nyström approximation is about 6 times slower and uses more than 400MB memory to achieve similar approximation. We also present extensive experiments on applying MEKA to speed up kernel ridge regression.

Keywords: kernel approximation, Nyström method, kernel methods

1. Introduction

Kernel methods (Schölkopf and Smola, 2002) are a class of machine learning algorithms that first map samples from input space to a high-dimensional feature space. In the high-dimensional feature space, various methods can be applied depending on the machine learning task, for example, kernel support vector machine (SVM) (Cortes and Vapnik, 1995) (Hsieh, Si, and Dhillon, 2014a) and kernel ridge regression (Saunders, Gammerman, and Vovk, 1998). A key issue in scaling up kernel machines is the storage and computation of the kernel matrix, which is usually dense. Storing the dense matrix takes $O(n^2)$ space, while computing it requires $O(n^2 d)$ operations, where n is the number of data points and d is the dimension. A common approach to achieve scalability is to approximate the kernel matrix using limited memory storage. This approach not only resolves the memory issue, but also speeds up kernel machine solvers, because the time complexity for using the kernel is usually proportional to the amount of memory used to represent the kernel. Most kernel approximation methods aim to form a low-rank approximation $G \approx CC^T$ for the kernel matrix G, with $C \in \mathbb{R}^{n\times k}$ and rank $k \ll n$. Although it is well known that Singular Value Decomposition (SVD) yields the best rank-k approximation, it often cannot be applied as it requires the entire kernel matrix to be computed and stored. To overcome this issue, many methods have been proposed to approximate the best rank-k approximation of a kernel matrix, including Greedy basis selection techniques (Smola and Schölkopf, 2000), incomplete Cholesky decomposition (Fine and Scheinberg, 2001), and Nyström methods (Williams and Seeger, 2001).

However, it is unclear whether low-rank approximation is the most memory efficient way to approximate a kernel matrix. In this paper, we first make the observation that for practically used shift-invariant kernels, the kernel structure varies from low-rank to block-diagonal as the scaling parameter γ varies from 0 to ∞. This observation suggests that even the best rank-k approximation can have extremely large approximation error when γ is large, so it is worth exploiting the block structure of the kernel matrix. Based on this idea, we propose a Memory Efficient Kernel Approximation (MEKA) framework to approximate the kernel matrix. Our proposed framework considers and analyzes the use of clustering in the input space to efficiently exploit the block structure of shift-invariant kernels. We show that the individual blocks generated by kmeans clustering have low-rank structure, which motivates us to apply Nyström low-rank approximation to each block separately. Between-cluster blocks are then approximated in a memory-efficient manner. Our approach only needs $O(nk + (ck)^2)$ memory to store a rank-ck approximation(where $c \ll n$ is the number of clusters), while traditional low-rank methods need $O(nk)$ space to store a rank-k approximation. Therefore, using the same amount of storage, our method can achieve lower approximation error than the commonly used low-rank methods. Moreover, our proposed method takes less computation time than other low-rank methods to achieve a given approximation error.

Theoretically, we show that under the same amount of storage, the error bound of our approach can be better than standard Nyström if the gap between the $k+1$-st and $ck+1$-st singular values of G is larger than $\|\Delta\|_2$ where Δ consists of all between-cluster blocks. On real datasets, our proposed algorithm consumes less memory and computation time to achieve comparable reconstruction error. For example, on the covtype dataset with half million samples, MEKA takes around 70 seconds and uses less than 80 MB memory on a single machine to achieve 10% relative approximation error, while standard Nyström approximation takes more than 400 seconds and uses more than 400MB memory to achieve similar approximation. Also, MEKA is faster for kernel ridge regression compared with other state-of-the-art kernel approximation methods. As an example, on the mnist2m dataset with 2 million samples, our method takes 550 seconds on a single machine using less than 500 MBytes memory to achieve accuracy comparable with standard Nyström approximation,

which takes more than 2700 seconds and uses more than 2 GBytes memory on the same problem.

Parts of this paper have appeared previously in (Si, Hsieh, and Dhillon, 2014a). In this paper, we provide: (1) a more detailed survey of state-of-the-art methods; (2) much more comprehensive experimental comparisons; (3) thorough investigation of the influence of the parameters in our method; (4) the application of applying the block structure of kernel matrix to speed up kernel SVM; and (5) more discussion including how to achieve stable results and solve non-psd issues in MEKA.

The rest of the paper is outlined as follows. We first present related work in Section 2. We then explain the popular Nyström approximation method and present motivation for our framework in Section 3. We then show the block structure of kernel matrix and its application to speed up kernel SVM in Section 4. Our main kernel approximation algorithm MEKA is proposed and analyzed in Section 5. Experimental results are given in Section 6, and conclusion and discussion are provided in Section 7.

2. Related Research

To approximate the kernel matrix using limited memory, one common way is to use a low-rank approximation. The best rank-k approximation can be obtained by the SVD, but it is computationally prohibitive when n grows to tens of thousands. To address the scalability issue of SVD, approximate SVD solvers such as randomized SVD (Halko, Martinsson, and Tropp, 2011) have been widely used for large-scale data. To exploit the sparse structure of large-scale network data, an alternative is to apply CUR matrix decomposition (Mahoney and Drineas, 2009) that explicitly expresses the low-rank decomposition in terms of a small number of rows and columns of the original data matrix. Another way is building a hierarchical tree to initialize a block Lanczos algorithm to efficiently compute the spectral decomposition of large-scale graphs (Si, Shin, Dhillon, and Parlett, 2014b). Unfortunately, to approximate kernel matrices, all the above approaches need to compute the entire kernel matrix, so the time complexity is at least $O(dn^2)$.

Many algorithms have been proposed to overcome the prohibitive time and space complexity of SVD for approximating kernel matrices. They can be categorized into two classes: methods that explicitly approximate kernel matrices, and methods that approximate the kernel function.

Approximating the kernel matrix. The first class of approaches approximate the kernel matrix based on a subset of sampled elements; as a result, all of them are data dependent. The Nyström method (Williams and Seeger, 2001) is the most widely used technique to approximate the kernel matrix given a sampled subset of columns. To approximate a rank-k approximation, Nyström approximation requires $O(nk^2 + k^3)$ time to form the rank-k approximation. Many strategies have been proposed to improve over the basic Nyström approximation, including ensemble Nyström (Kumar, Mohri, and Talwalkar, 2009), Nyström with k-means to obtain benchmark points (Zhang, Tsang, and Kwok, 2008; Zhang and Kwok, 2010), randomized Nyström (Li, Kwok, and Lu, 2010), Nyström approximation with shift (Wang et al., 2014), adding "pseudo landmark points" to the Nyström approximation (Hsieh, Si, and Dhillon, 2014b), and fast-Nys that uses fast transform to generate structured landmark points to speed up Nyström approximation (Si, Hsieh, and Dhillon, 2016).

Different Nyström sampling strategies are analyzed and compared in (Kumar, Mohri, and Talwalkar, 2012; Gittens and Mahoney, 2013). Besides Nyström approximation, Fine and Scheinberg (2001) use the incomplete Cholesky decomposition with pivoting for approximating kernel matrices, which requires $O(nk^2 + nkd)$ time for computing a rank-k approximation. Bach and Jordan (2005) incorporate side information (labels) into the incomplete Cholesky decomposition, and show that the resulting problem can be solved with the same $O(nk^2 + nkd)$ time complexity. Finally, Achlioptas, McSherry, and Schölkopf (2001) propose a sampling and reweighted approach to obtain an unbiased estimator of the kernel-vector product, and use subspace iteration to approximate the top k eigenvectors.

Approximating the kernel function. The second class of methods is to directly approximate the kernel function without computing elements of the kernel matrix, so the approximation does not depend on the data. To approximate the kernel function, a typical approach is to find a feature mapping $Z : \mathbb{R}^d \to \mathbb{R}^k$ where the kernel function $K(\boldsymbol{x}, \boldsymbol{y})$ can be approximated by $Z(\boldsymbol{x})^T Z(\boldsymbol{y})$. Rahimi and Recht (2007, 2008) define the random feature map for shift invariant kernel functions based on the Fourier transform. In the resulting Random Kitchen Sinks (RKS) algorithm, the main computation turns out to be the matrix vector multiplication $W\boldsymbol{x}_i$ for each instance $\boldsymbol{x}_i$, where W is a Gaussian random matrix. To improve efficiency, Le, Sarlos, and Smola (2013) show that the computation of $W\boldsymbol{x}_i$ can be sped up by the fast Hadamard transform. On the other hand, Yang et al. (2014) propose to use a quasi Monte Carlo approach to improve the approximation performance of RKS. In addition to shift invariant kernels, Kar and Karnick (2012) construct the random feature map for polynomial kernels, and Hamid et al. (2014) propose the condensed random feature map to improve performance.

Besides the above approaches based on random feature maps, there are other methods that directly approximate the kernel function. Cotter, Keshet, and Srebro (2011) approximate the Gaussian kernel by the t-th order Taylor expansion, but it requires $O(d^t)$ features, which is computationally burdensome for large d or t. Chang et al. (2010) propose to use the kernel expansion for low-degree polynomial kernels. Recently, Yang et al. (2012) showed that the Nyström method has a better generalization error bound than the RKS approach if the gap in the eigen-spectrum of the kernel matrix is large.

Most of the above methods can be viewed as faster ways to find a rank-k approximation of the kernel matrix, so the approximation error is always worse than the top-k SVD when using $O(nk)$ memory. As we show in Section 3, the kernel matrix typically changes from low-rank to block structure as the scaling parameter γ increases. However, the block structure of the kernel matrix has *never* been considered in dense kernel approximation, although it has been studied for approximation of other types of matrices. For example, Savas and Dhillon (2011) applied Clustered Low Rank Approximation (CLRA) to approximate large and sparse social networks. CLRA applies spectral or graph clustering to the adjacency matrix of a social network, runs SVD on each diagonal block, and uses matrix projection to capture off-diagonal information. All these steps require storage of the entire matrix, thus they are infeasible for large-scale dense kernel matrices. For example, computing the entire kernel matrix of the mnist2m dataset would require about 8 TBytes of memory; moreover the time for computing the SVD and projection steps is prohibitive. On the same dataset

our proposed approach can obtain accurate results in 10 minutes with only 500 MBytes memory (as shown in Section 6). To achieve this, we need totally different algorithms than the ones in CLRA for clustering and approximating blocks to yield our memory-efficient scheme.

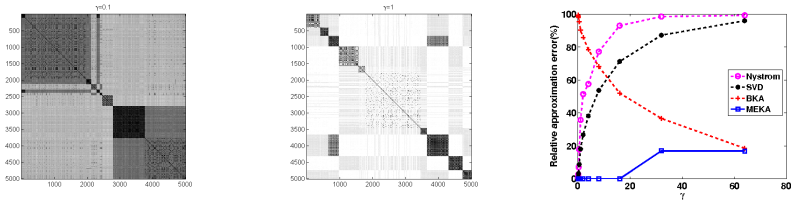
More specifically, CLRA was designed to approximate sparse adjacency matrices, but cannot be directly applied to large kernel matrices as that would require computation and storage of the entire kernel matrix at a cost of $O(n^2d)$ time and $O(n^2)$ space. To overcome this problem, we propose the following innovations: (1) We perform clustering, and then apply Nyström approximation to within-cluster blocks to avoid computing all within-block entries; (2) We theoretically justify the use of kmeans clustering to explore the block structure of the kernel; (3) We propose a sampling approach to capture between-block information; (4) We theoretically show the error bound of our method and compare it with the traditional Nyström approach.

3. Preliminaries and Motivation

Let $K(\cdot,\cdot)$ denote the kernel function, and $G \in \mathbb{R}^{n\times n}$ be the corresponding kernel matrix where $G_{ij} = K(\boldsymbol{x}_i, \boldsymbol{x}_j)$, and $\boldsymbol{x}_i$, $\boldsymbol{x}_j \in \mathbb{R}^d$ are data points. Computing and storing the kernel matrix G usually takes $O(n^2d)$ time and $O(n^2)$ space, which is prohibitive when there are millions of samples. One way to deal with these challenges is to approximate the dense kernel matrix G by a low-rank approximation $\tilde{G}$. By doing this, kernel machines are transformed to linear problems which can be solved efficiently. The best rank-k approximation of G is given by its singular value decomposition(SVD), i.e., $G \approx U_k\Sigma_k{U_k}^T$, where Σ_k is the diagonal matrix of largest k singular values and U_k contains the corresponding singular vectors.

However, computing the SVD of G is computationally prohibitive and memory intensive. Many fast kernel approximation algorithms have thus been proposed and studied. Nyström kernel approximation is a widely used approximation approach, which uses a sample of m data points and does not need to form the entire G explicitly to generate its low-rank approximation. In standard Nyström approximation (proposed in Williams and Seeger (2001)), we first uniformly at random sample m data points and assemble the corresponding m columns of G as the $n \times m$ matrix C. Let M be the $m \times m$ kernel matrix between the m sampled points, then the standard Nyström method generates a rank-k approximation to G as

$$G \approx \tilde{G} = CM_k^+C^T, \tag{1}$$



where M_k is the best rank-k approximation of M (by SVD) and M_k^+ is its pseudo-inverse. Various extensions to this Nyström based kernel approximation have been proposed. For example, k-means Nyström(Zhang, Tsang, and Kwok, 2008; Zhang and Kwok, 2010) uses clusters centroids as the landmark points to form C; ensemble Nyström(Kumar, Mohri, and Talwalkar, 2009) combines a collection of standard Nyström approximations. We will compare state-of-the-art Nyström based methods in Section 6.

We use the Gaussian kernel as an example to discuss the structure of the kernel matrix under different scale parameters. Given two samples $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$, the Gaussian kernel is given by $K(\boldsymbol{x}_i, \boldsymbol{x}_j) = e^{-\gamma\|\boldsymbol{x}_i-\boldsymbol{x}_j\|_2^2}$, where γ is a scale or width parameter; the corresponding kernel matrix entries are $G_{ij} = K(\boldsymbol{x}_i, \boldsymbol{x}_j)$. Low-rank approximation has been widely used

to obtain an approximation for kernel matrices. However, under different scale parameters, the kernel matrix has quite different structures, suggesting that different approximation strategies should be used for different γ.

Let us examine two extreme cases of the Gaussian kernel: when $\gamma \to 0$, $G \to \boldsymbol{e}\boldsymbol{e}^T$ where $\boldsymbol{e} = [1,\ldots,1]^T$. As a consequence, G is close to low-rank when γ is small. However, at the other extreme as $\gamma \to \infty$, G changes to the identity matrix, which has full rank with all eigenvalues equal to 1. In this case, G does not have a low-rank structure, but has a block/clustering structure. This observation motivates us to consider both low rank and clustering structure of the kernel matrix. Figures 1a and 1b give an example of the structure of a Gaussian kernel with different γ on a real dataset by randomly sampling 5000 samples from the covtype dataset.

Before discussing further details, we first contrast the use of block and low-rank approximations on the same dataset. We compare approximation errors for different methods when they use the same amount of memory in Figure 1c. Clearly, low-rank approximation methods work well only for very small γ values. Block Kernel Approximation (BKA), as proposed in Section 4.1, is a simple way to use clustering structure of G that is effective for large γ. Our proposed algorithm, MEKA, considers both block and low-rank structure of the kernel, and thus performs better than others under different γ values as seen in Figure 1c.

(a) The Gaussian kernel matrix with $\gamma = 0.1$ on covtype dataset

(b) The Gaussian kernel matrix with $\gamma = 1$ on covtype dataset

(c) Comparison of different kernel approximation methods for various γ.

Figure 1: (a) and (b) show that the structure of the Gaussian kernel matrix $K(\boldsymbol{x}, \boldsymbol{y}) = e^{-\gamma\|\boldsymbol{x}-\boldsymbol{y}\|^2}$ for the covtype data tends to become more block diagonal as γ increases(dark regions correspond to large values, while lighter regions correspond to smaller values). Plot (c) shows that low-rank approximations work only for small γ, and Block Kernel Approximation (BKA) works for large γ, while our proposed method MEKA works for small as well as large γ.

4. Block Kernel Approximation

In this section, we first introduce Block Kernel Approximation (BKA), a simple way to exploit the clustering structure of kernel matrices, and then show its application for speeding up kernel SVM.

4.1 Clustering Structure of Shift-invariant Kernel Matrices

There has been substantial research on approximating shift-invariant kernels (Rahimi and Recht, 2007). A kernel function $K(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is shift-invariant if the kernel value depends only on $\boldsymbol{x}_i - \boldsymbol{x}_j$, that is, $K(\boldsymbol{x}_i, \boldsymbol{x}_j) = f(\eta(\boldsymbol{x}_i - \boldsymbol{x}_j))$ where $f(\cdot)$ is a function that maps $\mathbb{R}^d$ to $\mathbb{R}$, and $\eta > 0$ is a constant to determine the "scale" of the data. η is very crucial to the performance of kernel machines and is usually chosen by cross-validation. We further define $g_{\boldsymbol{u}}(t) = f(\eta t \boldsymbol{u})$ to be a one variable function along $\boldsymbol{u}$'s direction where $\boldsymbol{u}$ is an unit vector. We assume the kernel function satisfies the following property:

Assumption 1 *$g_{\boldsymbol{u}}(t)$ is differentiable for all $t \neq 0$.*

Most of the practically used shift-invariant kernels satisfy the above assumption, for example, the Gaussian kernel ($K(\boldsymbol{x}, \boldsymbol{y}) = e^{-\gamma\|\boldsymbol{x}-\boldsymbol{y}\|_2^2}$), and the Laplacian kernel ($K(\boldsymbol{x}, \boldsymbol{y}) = e^{-\gamma\|\boldsymbol{x}-\boldsymbol{y}\|_1}$). It is clear that η^2 is equivalent to γ for the Gaussian kernel if written in the form of $K(\boldsymbol{x}, \boldsymbol{y}) = f(\eta(\boldsymbol{x} - \boldsymbol{y}))$. When η is large, off-diagonal blocks of shift-invariant kernel matrices will become small, and most of the information is concentrated in the diagonal blocks. To approximate the kernel matrix by exploiting this clustering structure, we first present a simple Block Kernel Approximation (BKA) as follows. Given a good partition $\mathcal{V}_1, \ldots, \mathcal{V}_c$ of the data points, where each $\mathcal{V}_s$ is a subset of $\{1, \ldots, n\}$, BKA approximates the kernel matrix as:

$$G \approx \tilde{G} \equiv \begin{bmatrix} G^{(1,1)} & 0 & \ldots & 0 \\ 0 & G^{(2,2)} & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & G^{(c,c)} \end{bmatrix}. \tag{2}$$

Here, $G^{(s,s)}$ denotes the kernel matrix for block $\mathcal{V}_s$ – note that this implies that diagonal blocks $\tilde{G}^{(s,s)} = G^{(s,s)}$ and all the off-diagonal blocks, $\tilde{G}^{(s,t)} = 0$ with $s \neq t$.

BKA is useful when η is large. By analyzing its approximation error, we now show that k-means in the input space can be used to capture the clustering structure for shift-invariant kernels. The approximation error equals $\|\tilde{G}-G\|_F^2 = \sum_{i,j} K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2 - \sum_{s=1}^c \sum_{i,j\in\mathcal{V}_s} K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2$. Since the first term is fixed, minimizing the error $\|\tilde{G} - G\|_F^2$ is the same with maximizing the second term, the sum of squared within-cluster entries $D = \sum_{s=1}^c \sum_{i,j\in\mathcal{V}_s} K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2$.

However, directly maximizing D will not give a useful partition – the maximizer will assign all the data into one cluster. The same problem occurs in graph clustering (Shi and Malik, 2000; von Luxburg, 2007). A common approach is to normalize D by each cluster's size $|\mathcal{V}_s|$. The resulting spectral clustering objective (also called ratio association) is:

$$D^{\text{kernel}}(\{\mathcal{V}_s\}_{s=1}^c) = \sum_{s=1}^{c} \frac{1}{|\mathcal{V}_s|} \sum_{i,j\in\mathcal{V}_s} K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2. \tag{3}$$

Maximizing (3) usually yields a balanced partition, but the computation is expensive because we have to compute all the entries in G. In the following theorem, we derive a lower bound for $D^{\text{kernel}}(\{\mathcal{V}_s\}_{s=1}^c)$:

Theorem 1 *For any shift-invariant kernel that satisfies Assumption 1,*

$$D^{kernel}(\{\mathcal{V}_s\}_{s=1}^c) \geq \bar{C} - \eta^2 R^2 D^{kmeans}(\{\mathcal{V}_s\}_{s=1}^c) \tag{4}$$

where $\bar{C} = \frac{nf(0)^2}{2}$, R is a constant depending on the kernel function, and $D^{kmeans} \equiv \sum_{s=1}^c \sum_{i\in\mathcal{V}_s} \|\boldsymbol{x}_i - \boldsymbol{m}_s\|_2^2$ is the k-means objective function, where $\boldsymbol{m}_s = (\sum_{i\in\mathcal{V}_s} \boldsymbol{x}_i)/|\mathcal{V}_s|$, $s = 1, \cdots, c$, are the cluster centers.

Proof We use $\boldsymbol{u}$ to denote the unit vector in the direction of $\boldsymbol{x}_i - \boldsymbol{x}_j$ ($\boldsymbol{x}_i \neq \boldsymbol{x}_j$). By the mean value theorem, we have

$$K(\boldsymbol{x}_i, \boldsymbol{x}_j) = g_{\boldsymbol{u}}(\eta\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2) = g_{\boldsymbol{u}}(0) + \eta g'_{\boldsymbol{u}}(s)\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2$$

for some $s \in (0, \eta\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2)$. By definition, $f(\boldsymbol{0}) = g_{\boldsymbol{u}}(0)$, so

$$f(\boldsymbol{0}) \leq K(\boldsymbol{x}_i, \boldsymbol{x}_j) + \eta R\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2, \tag{5}$$
