for some $\alpha \in (0, 1]$. Our Assumption **A3** is on each variable through the entries of the true covariance Σ while (24) imposes such a condition on the edge variables $Y_{(j,k)} = X_j X_k - \mathrm{E}(X_j X_k)$, resulting in a vector ℓ_1-norm restriction on a much larger matrix Γ, which can be more restrictive for large p. More specifically, condition (24) arises in Ravikumar et al. (2011) to tackle the analysis of the $\log\det\Omega$ term in the graphical lasso problem. By contrast, in our setting the parameterization in terms of L means that the $\log\det$ term is simply a sum of log terms on diagonal elements and is thus easier to deal with, leading to the milder irrepresentable assumption. Another difference is that they require the sample size $n > c\kappa_\Gamma^2 d^2 \log p$ for some constant c. The quantity d measures the maximum number of non-zero elements in each row of the true Σ, which in our case is $2K+1$, and $\kappa_\Gamma = \left\| \left(\Gamma_{\mathcal{S}\mathcal{S}} \right)^{-1} \right\|_\infty$ can be much larger than κ^2. Thus, comparing to (21), one finds that their sample size requirement is much more restrictive. A similar comparison could also be made with the lasso penalized D-trace estimator (Zhang and Zou, 2014), whose irrepresentable condition involves $\Gamma = (\Sigma \otimes I + I \otimes \Sigma)/2 \in \mathbb{R}^{p^2 \times p^2}$. Of course, the results in both Ravikumar et al. (2011) and Zhang and Zou (2014) apply to estimators invariant to permutation of variables; additionally, the random vector only needs to satisfy an exponential-type tail condition.

4.3 Precision Matrix Estimation Consistency

Although our primary target of interest is L, the parameterization $\Omega = L^T L$ makes it natural for us to try to connect our results of estimating L with the vast literature in directly estimating Ω, which is the standard estimation target when the known ordering is not available. In this section, we consider the estimation consistency of Ω using the results we obtained for L. The following theorem gives results of how well $\hat{\Omega} = \hat{L}^T \hat{L}$ performs in estimating the true precision matrix $\Omega = L^T L$ in terms of various matrix norm criteria.

Theorem 4 *Let $\theta = \max_r \theta_r$, $K = \max_r K_r$ and $s = \sum_r K_r$ denote the total number of non-zero off-diagonal elements in L. Define $\zeta_\Sigma = \frac{8\sqrt{2\theta}}{\alpha}\left(4 \max_r \left\| \left(\Sigma_{\mathcal{I}_r \mathcal{I}_r} \right)^{-1} \right\|_\infty + 5\kappa^2\right)$. Under the assumptions in Theorem 3, the following deviation bounds hold with probability greater than $1 - cp^{-1}$ for some constant c independent of n and p:*

$$\begin{aligned}
\left\| \hat{\Omega} - \Omega \right\|_\infty &\leq 2\zeta_\Sigma |||L|||_\infty \sqrt{\frac{\log p}{n}} + \zeta_\Sigma^2 (K+1) \frac{\log p}{n}, \\
\left\| \left\| \hat{\Omega} - \Omega \right\| \right\|_\infty &\leq 2\zeta_\Sigma |||L|||_\infty (K+1) \sqrt{\frac{\log p}{n}} + \zeta_\Sigma^2 (K+1)^2 \frac{\log p}{n}, \\
\left\| \left\| \hat{\Omega} - \Omega \right\| \right\|_2 &\leq 2\zeta_\Sigma |||L|||_\infty (K+1) \sqrt{\frac{\log p}{n}} + \zeta_\Sigma^2 (K+1)^2 \frac{\log p}{n}, \\
\left\| \hat{\Omega} - \Omega \right\|_F &\leq 2\kappa\zeta_\Sigma \sqrt{\frac{(s+p)\log p}{n}} + \zeta_\Sigma^2 (K+1) \sqrt{s+p} \frac{\log p}{n}.
\end{aligned}$$

When the quantities ζ_Γ, $|||L|||_\infty$, and κ are treated as constants, these bounds can be summarized more succinctly as follows:

Proof See Appendix H. ■

Corollary 5 *Using the notation and conditions in Theorem 4, if ζ_Γ, $|||L|||_\infty$, and κ remain constant, then the scaling $(K+1)^2 \log p = o(n)$ is sufficient to guarantee the following estimation error bounds:*

$$\begin{aligned}
\left\| \hat{\Omega} - \Omega \right\|_\infty &= \mathcal{O}_P\left(\sqrt{\frac{\log p}{n}} \right), \\
\left\| \left\| \hat{\Omega} - \Omega \right\| \right\|_\infty &= \mathcal{O}_P\left((K+1) \sqrt{\frac{\log p}{n}} \right), \\
\left\| \left\| \hat{\Omega} - \Omega \right\| \right\|_2 &= \mathcal{O}_P\left((K+1) \sqrt{\frac{\log p}{n}} \right), \\
\left\| \hat{\Omega} - \Omega \right\|_F &= \mathcal{O}_P\left(\sqrt{\frac{(s+p)\log p}{n}} \right).
\end{aligned}$$

The conditions for these deviation bounds to hold are those required for support recovery as in Theorem 3. In many cases where estimation consistency is more of interest than support recovery, we can still deliver the desired error rate in Frobenius norm, matching the rate derived in Rothman et al. (2008). In particular, we can drop the strong irrepresentable assumption (**A3**) and weaken the Gaussian assumption (**A1**) to the following marginal sub-Gaussian assumption:

A5 *Marginal sub-Gaussian assumption*: The sample matrix $\mathbf{X} \in \mathbb{R}^{n\times p}$ has n independent rows with each row drawn from the distribution of a zero-mean random vector $X = (X_1, \cdots, X_p)^T$ with covariance Σ and sub-Gaussian marginals, i.e.,

$$\mathrm{E}\exp\left(tX_j/\sqrt{\Sigma_{jj}}\right) \leq \exp\left(Ct^2\right)$$

for all $j = 1, \ldots, p$, $t \geq 0$ and for some constant $C > 0$ that does not depend on j.

Theorem 6 *Under Assumption **A2**, **A4** and **A5**, with tuning parameter λ of scale $\sqrt{\frac{\log p}{n}}$ and weights as in (7), the scaling $(s+p)\log p = o(n)$ is sufficient for the following estimation error bounds in Frobenius norm to hold:*

$$\left\|\hat{L} - L\right\|_F = \mathcal{O}_P\left(\sqrt{\frac{(s+p)\log p}{n}}\right),$$
$$\left\|\hat{\Omega} - \Omega\right\|_F = \mathcal{O}_P\left(\sqrt{\frac{(s+p)\log p}{n}}\right).$$

Proof See Appendix I. ■

The rates in Corollary 5 (and Theorem 6) essentially match the rates obtained in methods that directly estimate Ω (e.g., the graphical lasso estimator, studied in Rothman et al. 2008, Ravikumar et al. 2011, and the column-by-column methods as in Cai et al. 2011, Liu and Wang 2012, and Sun and Zhang 2013). However, the exact comparison in rates with these methods is not straightforward. First, the targets of interest are different. In the setting where the variables have a known ordering, we are more interested in the structural information among variables that is expressed in L, and thus accurate estimation of L is more important. When such ordering is not available as considered in Rothman et al. (2008); Cai et al. (2011); Liu and Wang (2012) and so on, however, the conditional dependence structure encoded by the sparsity pattern in Ω is more of interest, and the accuracy of directly estimating Ω is the focus. Moreover, deviation bounds of different methods are built upon assumptions that treat different quantities as constants. Quantities that are assumed to remain constant in the analysis of one method might actually be allowed to scale with ambient dimension in a nontrivial manner in another method, which makes direct rate comparison among different methods complicated and less illuminating.

Our analysis can be extended to the unweighted version of our estimator, i.e., with weight $w_{\ell m} = 1$, but under more restrictive conditions and with slower rates of convergence. Specifically, Assumption **A3** becomes $\max_{\ell\in\mathcal{I}_r^c}\left\|\Sigma_{\ell\mathcal{I}_r}\left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1}\right\|_1 \leq (1-\alpha)/K_r$ for each

$r = 2, \ldots, p$. With the same tuning parameter choice (13) and (20), the terms of K_r and K in sample size requirements (14) and (21) are replaced with K_r^2 and K^2, respectively. The estimation error bounds in all norms are multiplied by an extra factor of K. All of the above indicates that in highly sparse situations (in which K is very small), the unweighted estimator has very similar theoretical performance to the weighted estimator.

5. Simulation Study

In this section we study the empirical performance of our estimators (both with weights as in (7) and with no weights, i.e., $w_{\ell m} = 1$) on simulated data. For comparison, we include two other sparse precision matrix estimators designed for the ordered-variable case:

- **Non-Adaptive Banding** (Bickel and Levina, 2008): This method estimates L as a lower-triangular matrix with a fixed bandwidth K applying across all rows. The regularization parameter used in this method is the fixed bandwidth K.
- **Nested Lasso** (Levina et al., 2008): This method yields an adaptive banded structure by solving a set of penalized least-squares problems (both the loss function and the nested-lasso penalty are non-convex). The regularization parameter controls the amount of penalty and thus the sparsity level of the resulting estimate.

All simulations are run at a sample size of $n = 100$, where each sample is drawn independently from the p-dimensional normal distribution $N(\mathbf{0}, (L^TL)^{-1})$. We compare the performance of our estimators with the methods above both in terms of support recovery (in Section 5.1) and in terms of how well $\hat{L}$ estimates L (in Section 5.2). For support recovery, we consider $p = 200$ and for estimation accuracy, we consider $p = 50, 100, 200$, which corresponds to settings where $p < n$, $p = n$, and $p > n$, respectively.

We simulate under the following models for L. We adapt the parameterization $L = D^{-1}T$ as in Khare et al. (2016), where D is a diagonal matrix with diagonal elements drawn randomly from a uniform distribution on the interval $[2, 5]$, and T is a lower-triangular matrix with ones on its diagonal and off-diagonal elements defined as follows:

- **Model 1**: Model 1 is at one extreme of bandedness of the Cholesky factor L, in which we take the lower triangular matrix $L \in \mathbb{R}^{p\times p}$ to have a strictly banded structure, with each row having the same bandwidth $K_r = K = 1$ for all r. Specifically, we take $T_{r,r} = 1$, $T_{r,r-1} = 0.8$ and $T_{r,j} = 0$ for $j < r - 1$.
- **Model 2**: Model 2 is at the other extreme, in which we allow K_r to vary with r. We take T to be a block diagonal matrix with 5 blocks, each of size $p/5$. Within each block, with probability 0.5 each row r is assigned with a non-zero bandwidth that is randomly drawn from a uniform distribution on $\{1, \ldots, r-1\}$ (for $r > 1$). Each non-zero element in T is then drawn independently from a uniform distribution on the interval $[0.1, 0.4]$, and is assigned with a positive/negative sign with probability 0.5.
- **Model 3**: Model 3 is a denser and thus more challenging version of Model 2, with T a block diagonal matrix with only 2 blocks. Each of the blocks is of size $p/2$ but is otherwise generated as in Model 2.

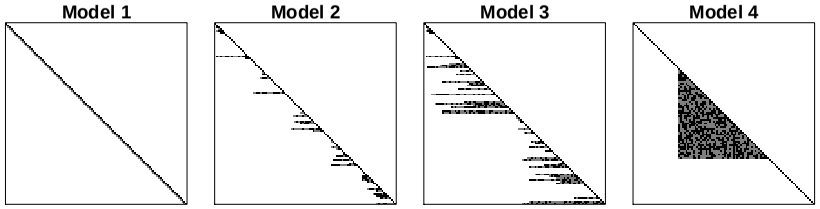

Figure 3: Schematic of four simulation scenarios with $p = 100$: (from left to right) Model 1 is strictly banded, Model 2 has small variable bandwidth, Model 3 has large variable bandwidth, and Model 4 is block-diagonal. Black, gray, and white stand for positive, negative, and zero entries, respectively. The proportion of elements that are non-zero is 4%, 6%, 15%, and 26%, respectively.

- **Model 4**: Model 4 is a dense block diagonal model. The matrix T has a completely dense lower-triangular block from the $p/4$-th row to the $3p/4$-th row and is zero everywhere else. Within this block, all off-diagonal elements are drawn uniformly from $[0.1, 0.2]$, and positive/negative signs are then assigned with probability 0.5.

Model 1 is a stationary autoregressive model of order 1. By the regression interpretation (1), for each r, it can be verified that the autoregressive polynomial of the r-th row of Models 2, 3, and 4 has all roots outside the unit circle, which characterizes stationary autoregressive models of orders equal to the corresponding row-wise bandwidths. See Figure 3 for examples of the four sparsity patterns for $p = 100$. The non-adaptive banding method should benefit from Model 1 while the nested lasso and our estimators are expected to perform better in the other three models where each row has its own bandwidth.

For all four models and every value of p considered, we verified that Assumptions **A3** and **A4** hold and then simulated $n = 100$ observations according to each of the four models based on Assumption **A1**.

5.1 Support Recovery

We first study how well the different estimators identify zeros in the four models above. We generate $n = 100$ random samples from each model with $p = 200$. The tuning parameter $\lambda \geq 0$ in (5) measures the amount of regularization and determines the sparsity level of the estimator. We use 100 tuning parameter values for each estimator and repeat the simulation 10 times.

Figure 4 shows the sensitivity (fraction of true non-zeros that are correctly recovered) and specificity (fraction of true zeros that are correctly set to zero) of each method parameterized by its tuning parameter (in the case of non-adaptive banding, the parameter is the bandwidth itself, ranging from 0 to $p - 1$). Each set of 10 curves of the same color corresponds to the results of one estimator, and each curve within the set corresponds to

the result of one draw from 10 simulations. Curves closer to the upper-right corner indicate better classification performance (the $x + y = 1$ line corresponds to random guessing).

The sparsity level of the non-adaptive banding estimator depends only on the pre-specified bandwidth (which is the method's tuning parameter) and not on the data itself. Consequently, the sensitivity-specificity curves for the non-adaptive banding do not vary across replications when simulating from a particular underlying model. The sparsity levels of the nested lasso and our methods, by contrast, hinge on the data, thus giving a different curve for each replication.

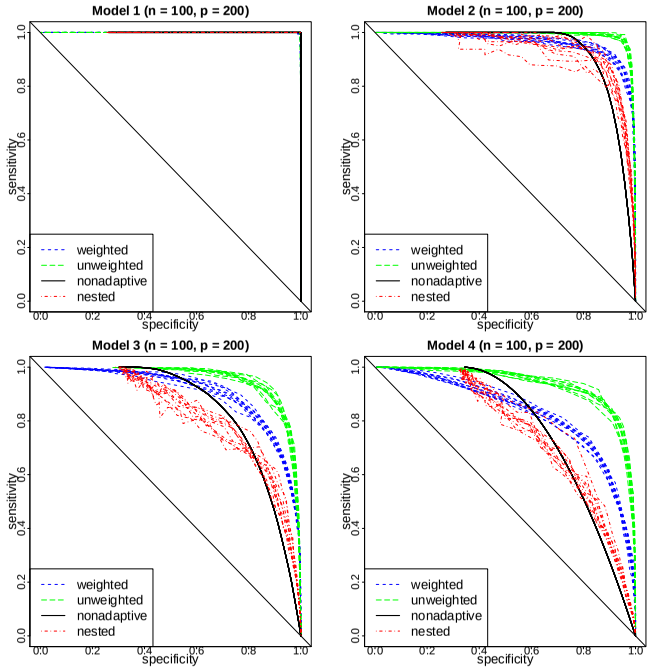

Figure 4: ROC curves showing support recovery when the true L (top-left) is strictly banded, (top-right) has small variable bandwidth, (bottom-left) has large variable bandwidth, and (bottom-right) is block-diagonal, over 10 replications.

In practice, we find that our methods and the nested lasso sometimes produce entries with very small, but non-zero, absolute values. To study support recovery, we set all estimates whose absolute values are below 10^{-10} to zero, both in our estimators and the nested lasso.

In Model 1, we observe that all methods considered attain perfect classification accuracy for some value of their tuning parameter. While the non-adaptive approach is guaranteed to do so in this scenario, it is reassuring to see that the more flexible methods can still perfectly recover this sparsity pattern.

In Model 2, we observe that our two methods outperform the nested lasso, which itself, as expected, outperforms the non-adaptive banding method. As the model becomes more challenging (from Model 2 to Model 4), the performances of all four methods start deteriorating. Interestingly, the nested lasso no longer retains its advantage over non-adaptive banding in Models 3 and 4, while the performance advantage of our methods become even more substantial.

The fact that the unweighted version of our method outperforms the weighted version stems from the fact that all models are comparatively sparse for $p = 200$, and so the heavier penalty on each row delivered by the unweighted approach recovers the support more easily than the weighted version.

5.2 Estimation Accuracy

We proceed by comparing the estimators in terms of how far $\hat{L}$ is from L. To this end, we generate $n = 100$ random samples from the four models with $p = 50$, $p = 100$, and $p = 200$. Each method is computed with its tuning parameter selected to maximize the Gaussian likelihood on the validation data in a 5-fold cross-validation. For comparison, we report the estimation accuracy of each estimate in terms of the scaled Frobenius norm $\frac{1}{p}\left\|\hat{L} - L\right\|_F^2$, the matrix infinity norm $\left\|\left\|\hat{L} - L\right\|\right\|_\infty$, the spectral norm $\left\|\left\|\hat{L} - L\right\|\right\|_2$, and the (scaled) Kullback-Leibler loss $\frac{1}{p}\left[\mathrm{tr}(\Omega^{-1}\hat{\Omega}) - \log\det(\Omega^{-1}\hat{\Omega}) - p\right]$ (Levina et al., 2008).

The simulation is repeated 50 times, and the results are summarized in Figure 5 through Figure 8. Each figure corresponds to a model, and consists of a 4-by-3 panel layout. Each row corresponds to an error measure, and each column corresponds to a value of p.

As expected, the non-adaptive banding estimator does better than the other estimators in Model 1. In Models 2, 3, and 4, where bandwidths vary with row, our estimators and the nested lasso outperform non-adaptive banding.

A similar pattern is observed as in support recovery. As the model becomes more complex and p gets larger, the performance of the nested lasso degrades and gradually becomes worse than non-adaptive banding. By contrast, as the estimation problem becomes more difficult, the advantage in performance of our methods becomes more obvious.

We again observe that the unweighted estimator performs better than the weighted one. As shown in Section 4, the overall performance of our method hinges on the underlying model complexity (measured in terms of $\max_r K_r$) as well as the relative size of n and p. When n is relatively small, usually a more constrained method (like the unweighted estimator) is preferred over a more flexible method (like the weighted estimator). So in our simulation setting, it is reasonable to observe that the unweighted method works better. Note that as the underlying L becomes denser (from Model 1 to Model 4), the performance difference between the weighted and the unweighted estimator diminishes. This corroborates our discussion in the end of Section 4 that the performance of the unweighted estimator becomes worse when the underlying model is dense.

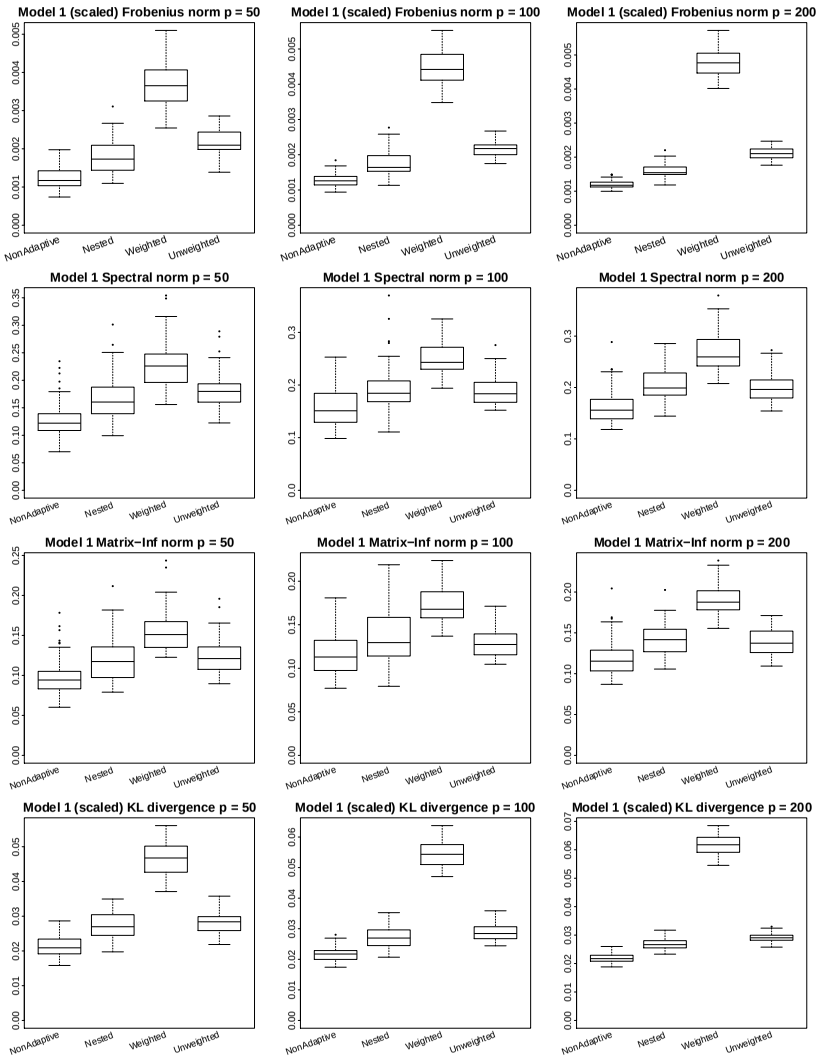

Figure 5: Estimation accuracy when data are generated from Model 1, which is strictly banded.

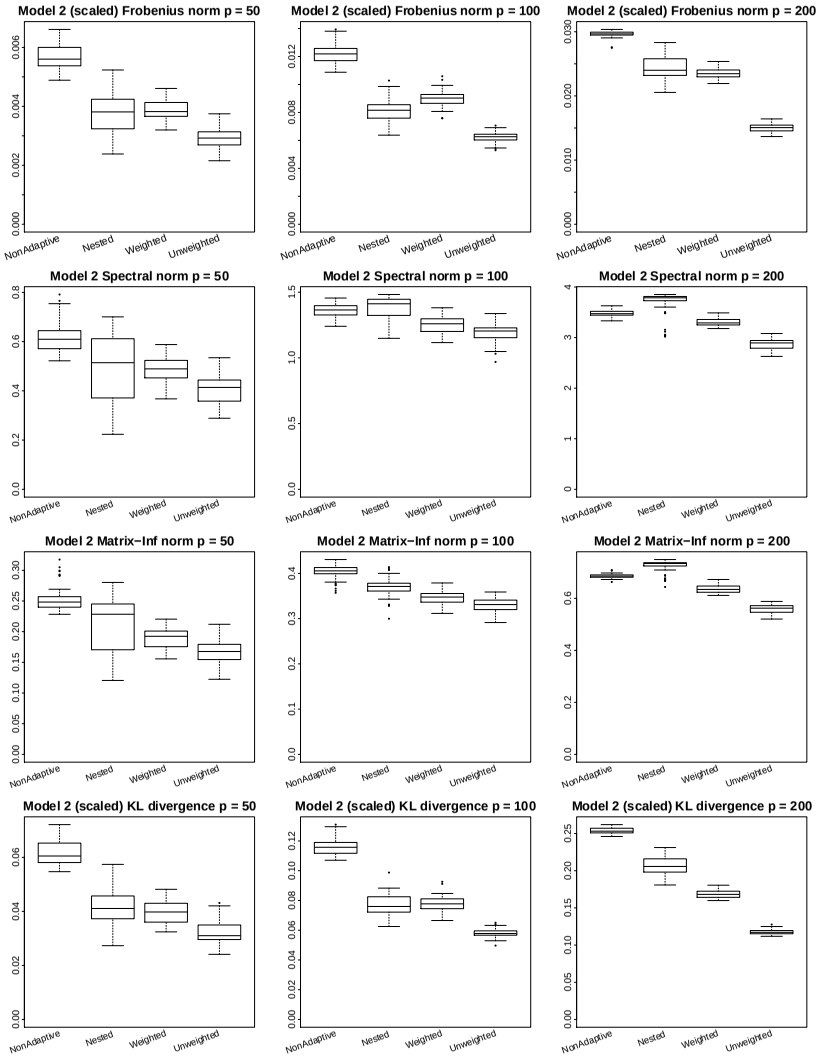

Figure 6: Estimation accuracy when data are generated from Model 2, which has small variable bandwidth.

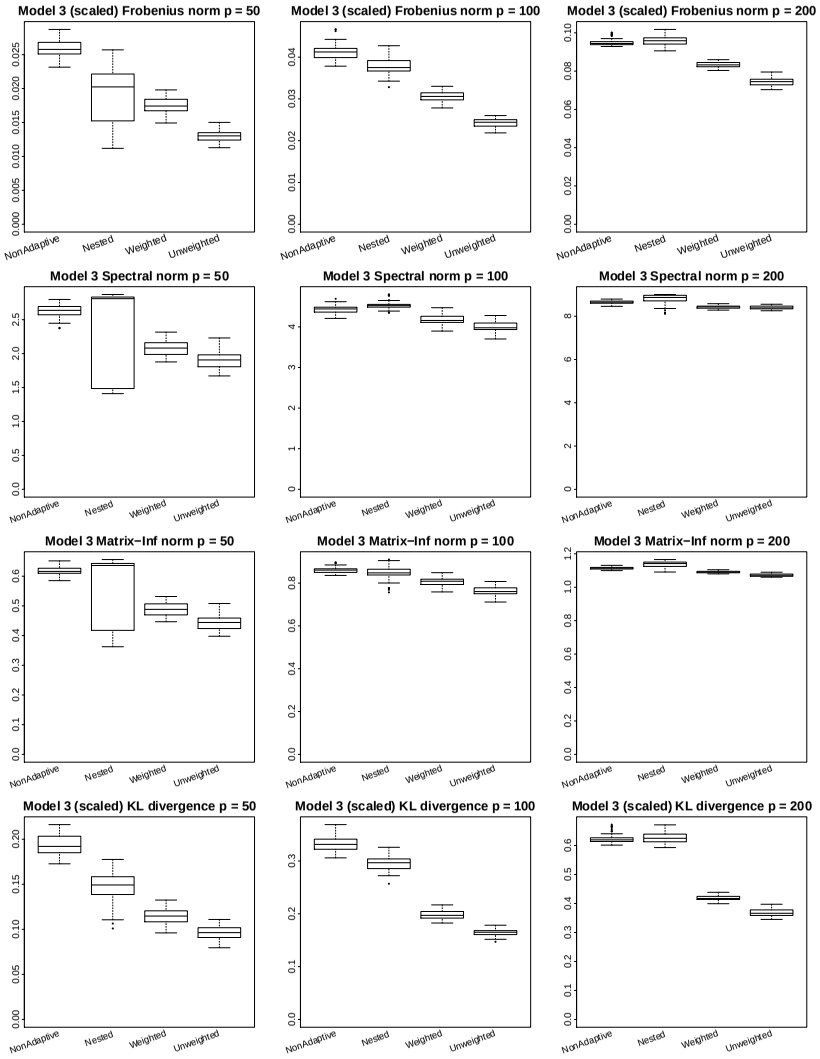

Figure 7: Estimation accuracy when data are generated from Model 3, which has large variable bandwidth.

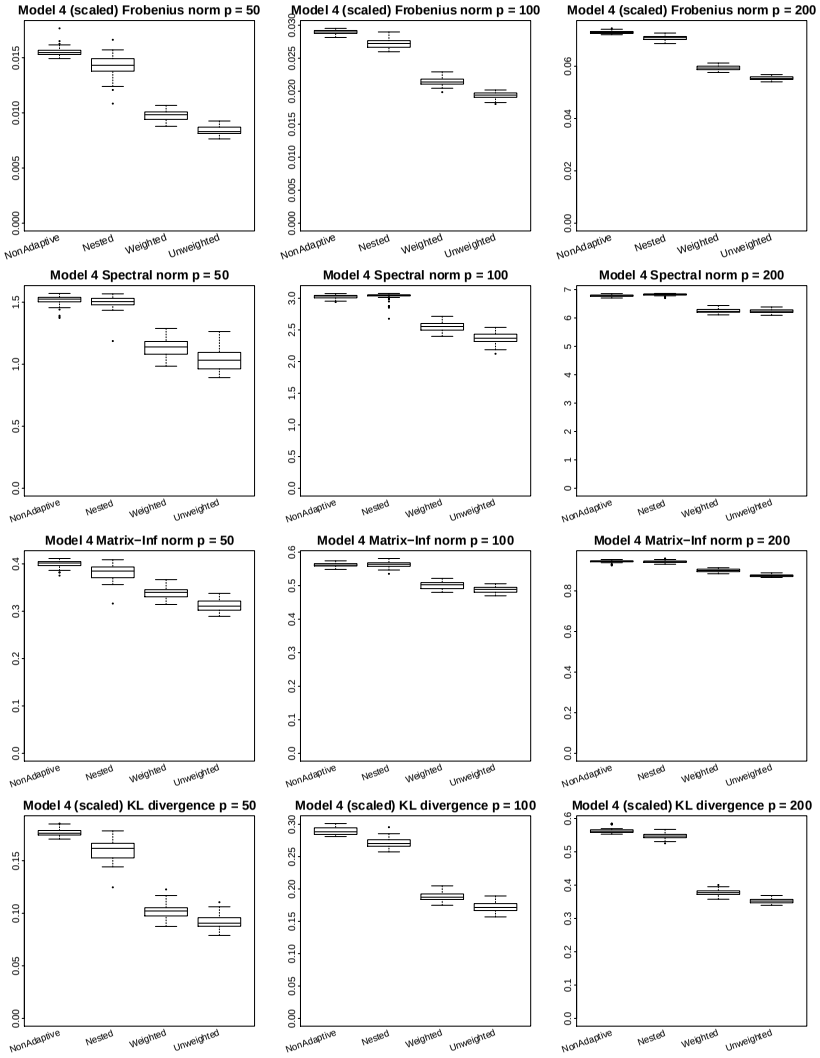

Figure 8: Estimation accuracy when data are generated from Model 4, which is block-diagonal.

6. Applications to Data Examples

In this section, we illustrate the practical merits of our proposed method by applying it to two data examples. We start with an application to genomic data where our method can help model the local correlations along the genome. In Section 6.2 we compare our method with other estimators within the context of a sound recording classification problem.

6.1 An Application to Genomic Data

We consider an application of our estimator to modeling correlation along the genome. Genetic mutations that occur close together on a chromosome are more likely to be co-inherited than mutations that are located far apart (or on separate chromosomes). This leads to local correlations between genetic variants in a population. Biologists refer to this local dependence as *linkage disequilibrium* (LD). The width of this dependence is known to vary along the genome due to the variable locations of recombination hotspots, which suggests that adaptively banded estimators may be quite suitable in these contexts.

We study HapMap phase 3 data from the International HapMap project (Consortium et al., 2010). The data consist of $n = 167$ humans from the YRI (Yoruba in Ibadan, Nigeria) population, and we focus on $p = 201$ consecutive tag SNPs on chromosome 22 (after filtering out infrequent sites with minor allele frequency $\leq 10\%$).

While tag SNP data, which take discrete values $\{0, 1, 2\}$, are non-Gaussian, we argue that our estimator is still sensible to use in this case. First, the parameterization $\Omega = L^T L$ does not depend on the Gaussian assumption. Moreover the estimator corresponds to minimizing a penalized Bregman divergence of the log-determinant function (Ravikumar et al., 2011). Furthermore, the least-squares term in (5) can be interpreted as minimizing the prediction error in the linear models (1) while the log terms act as log-barrier functions to impose positive diagonal entries (which ensures that the resulting $\hat{L}$ is a valid Cholesky factor).

To gauge the performance of our estimator on modeling LD, we randomly split the 167 samples into training and testing sets of sizes 84 and 83, respectively. Along a path of tuning parameters with decreasing values, estimators $\hat{L}$ are computed on the training data. To evaluate $\hat{L}$ on a vector $\tilde{x}$ from the test data set, we can compute the error in predicting $\hat{L}_{rr}\tilde{x}_r$ using $-\sum_{k=1}^{r-1}\hat{L}_{r,k}\tilde{x}_k$ via (1) for each r, giving the error

$$\mathrm{err}(\tilde{x}) = \frac{1}{p-1}\sum_{r=2}^{p}\left(\hat{L}_{rr}\tilde{x}_r + \sum_{k=1}^{r-1}\hat{L}_{rj}\tilde{x}_k\right)^2. \tag{25}$$

This quantity (with mean and the standard deviation over test samples) is reported in Figure 9 for our estimator under the two weighting schemes. Recall that the quadratically decaying weights (7) act essentially like the ℓ_1 penalty. For numerical comparison, we also include the result of the estimator with ℓ_1 penalty, which is the *CSCS (Convex Sparse Cholesky Selection)* method proposed in Khare et al. (2016). For both the non-adaptive banding and the nested lasso methods, we found that their implementations fail to work due to the collinearity of the columns of $\mathbf{X}$.

Figure 9 shows that our estimators are effective in improving modeling performance over a diagonal estimator (attained when λ is sufficiently large) and strongly outperform

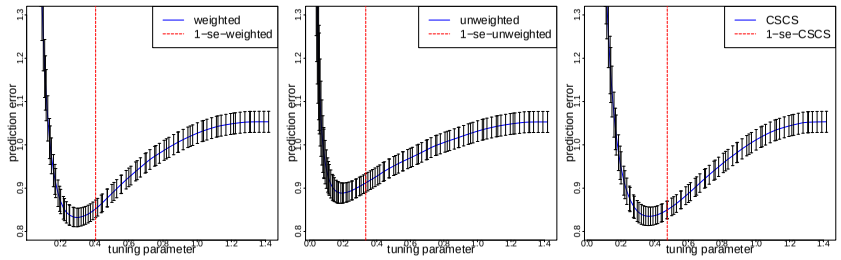

Figure 9: Prediction error (computed on an independent test set) of the weighted (left), unweighted (middle), and CSCS (right) estimators.

the plain MLE (as evidenced by the sharp increase in prediction error as $\lambda \to 0$). As expected, the weighted estimator performs very similarly to the CSCS estimator, which uses the ℓ_1 penalty. Both of these perform better than the unweighted one. However, the sparsity pattern obtained by the two penalties are different (as shown in Figure 10).

In Figure 10 we show the recovered signed support of the weighted, unweighted, and CSCS estimators and their corresponding precision matrices. Black, gray, and white stand for positive, negative, and zero entries, respectively. Tuning parameters are chosen using the one-standard-error rule (see, e.g., Hastie et al., 2009). The r-th row of the estimated matrix $\hat{L}$ reveals the number of neighboring SNPs necessary for reliably predicting the state of the r-th SNP. Interestingly, we see some evidence of small block-like structures in $\hat{L}$, consistent with the hotspot model of recombination as previously described. This regression-based perspective to modeling LD may be a useful complement to the more standard approach, which focuses on raw marginal correlations. Finally, the sparsity recovered by the CSCS estimator, which uses the ℓ_1 penalty, is less easily interpretable, since some entries far from the diagonal are non-zero, losing the notion of 'local'.

6.2 An Application to Phoneme Classification

In this section, we develop an application of our method to a classification problem described in Hastie et al. (2009). The data contain $n = 1717$ continuous speech recordings, which are categorized into two vowel sounds: 'aa' ($n_1 = 695$) and 'ao' ($n_2 = 1022$). Each observation (x_i, y_i) has a predictor $x_i \in \mathbb{R}^p$ representing the (log) intensity of the sound across $p = 256$ frequencies and a class label $y_i \in \{1, -1\}$. It may be reasonable to apply our method in this problem since the features are frequencies, which come with a natural ordering

In linear discriminant analysis (LDA), one models the features as multivariate Gaussian conditional on the class: $x_i|y_i = k \sim N_p(\mu^{(k)}, \Sigma)$ for $k \in \{1, -1\}$; in quadratic discriminant analysis (QDA), one allows each class to have its own covariance matrix: $x_i|y_i = k \sim N_p(\mu^{(k)}, \Sigma^{(k)})$. The LDA/QDA classification rules assign an observation $x \in \mathbb{R}^p$ to class k that maximizes $\hat{P}(y = k|x) \propto \hat{P}(x|y = k)\hat{P}(y = k)$, where the estimated probability

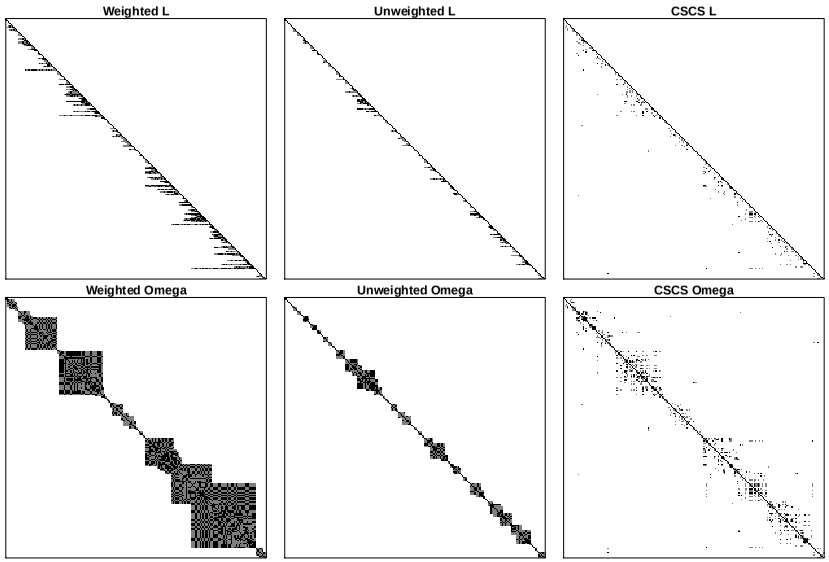

Figure 10: Estimates of linkage disequilibrium with tuning parameters selected by the one-standard-error rule and their corresponding precision matrix estimates.

	Unweighted	Weighted	Nested Lasso	Non-adaptive	CSCS
LDA	0.271	0.246	0.250	0.268	0.245
QDA	0.232	0.256	0.221	0.246	0.267

Table 1: Average test data classification error rate of discriminant analysis of phoneme data

$\hat{P}(x|y = k)$ is calculated using maximum likelihood estimates $\hat{\mu}^{(k)}$, $\hat{\Sigma}$, and $\hat{\Sigma}^{(k)}$. More precisely, in the ordered case, the resulting class k maximizes the LDA/QDA scores:

$$\begin{aligned}\delta^{(k)}_{\text{LDA}}(x) &= x^T\hat{\Omega}\hat{\mu}^{(k)} - \frac{1}{2}(\hat{\mu}^{(k)})^T\hat{\Omega}\hat{\mu}^{(k)} + \log\hat{\pi}^{(k)} \\ &= (\hat{L}x)^T\hat{L}\hat{\mu}^{(k)} - \frac{1}{2}\left\|\hat{L}\hat{\mu}^{(k)}\right\|_2^2 + \log\hat{\pi}^{(k)} \qquad (26)\\ \delta^{(k)}_{\text{QDA}}(x) &= x^T\hat{\Omega}^{(k)}\hat{\mu}^{(k)} - \frac{1}{2}(\hat{\mu}^{(k)})^T\hat{\Omega}^{(k)}\hat{\mu}^{(k)} + \log\hat{\pi}^{(k)} \\ &= (\hat{L}^{(k)}x)^T\hat{L}^{(k)}\hat{\mu}^{(k)} - \frac{1}{2}\left\|\hat{L}^{(k)}\hat{\mu}^{(k)}\right\|_2^2 + \log\hat{\pi}^{(k)}. \qquad (27)\end{aligned}$$

Note that it is the precision matrix, not the covariance matrix, that is used in the above scores. In the setting where $p > n$, the MLE of Ω or $\Omega^{(k)}$ does not exist. A regularized estimate of precision matrix that exploits the natural ordering information can be helpful in this setting.

To demonstrate the use of our estimator in the high-dimensional setting, we randomly split the data into two parts, with 10% of the data assigned to the training set and the remaining 90% of the data assigned to the test set. On the training set, we use 5-fold cross-validation to select the tuning parameter minimizing misclassification error on the validation data. The estimates $\hat{L}$ and $\hat{L}^{(k)}$ are then plugged into (26) and (27) along with $\hat{\mu}^{(k)} = \sum_{i\in\text{class }k} x_i/n^{(k)}$ and $\hat{\pi}^{(k)} = n^{(k)}/n_{\text{train}}$ to calculate the misclassification error in the test set. For comparison, we also include non-adaptive banding, the nested lasso, and CSCS. We compute the classification error (summarized in Table 1), averaged over 10 random train-test splits.

We first observe that, in general, the adaptive methods perform better than the non-adaptive one (which assumes a fixed bandwidth). It is again found that the performance of the weighted estimator is very similar to the one using ℓ_1 penalty (i.e., the CSCS method). And our results are comparable to the nested lasso both in LDA and QDA. Interestingly, we find that the weighted estimator does better in LDA while the unweighted estimator performs better in QDA. The reason, we suspect, is that QDA requires the estimation of more parameters than LDA and therefore favors more constrained methods like the unweighted estimator, which more strongly discourages non-zeros from being far from the diagonal than the weighted one.

An `R` (R Core Team, 2016) package, named `varband`, is available on `CRAN`, implementing our estimator. The estimation is very fast with core functions coded in `C++`, allowing us to solve large-scale problems in substantially less time than is possible with the `R`-based implementation of the nested lasso.

7. Conclusion

We have presented a new flexible method for learning local dependence in the setting where the elements of a random vector have a known ordering. The model amounts to sparse estimation of the inverse of the Cholesky factor of the covariance matrix with variable bandwidth. Our method is based on a convex formulation that allows it to simultaneously yield a flexible adaptively-banded sparsity pattern, enjoy efficient computational algorithms, and be studied theoretically. To our knowledge, no previous method has all these properties. We show how the matrix estimation problem can be decomposed into independent row estimation problems, each of which can be solved via an ADMM algorithm having efficient updates. We prove that our method recovers the signed support of the true Cholesky factor and attains estimation consistency rates in several matrix norms under assumptions as mild as those in linear regression problems. Simulation studies show that our method compares favorably to two pre-existing estimators in the ordered setting, both in terms of support recovery and in terms of estimation accuracy. Through a genetic data example, we illustrate how our method may be applied to model the local dependence of genetic variations in genes along a chromosome. Finally, we illustrate that our method has favorable performance in a sound recording classification problem.

Acknowledgments

We thank Kshitij Khare for a useful discussion in which he pointed us to the parametrization in terms of L. We thank Adam Rothman for providing `R` code for the non-adaptive banding and the nested lasso methods and Amy Williams for useful discussions about linkage disequilibrium. We also thank three referees and an action editor for helpful comments on an earlier manuscript. This work was supported by NSF DMS-1405746.

Appendix A. Decoupling Property

Let $S = \frac{1}{n}\mathbf{X}^T\mathbf{X} \in \mathbb{R}^{p\times p}$ be the sample covariance matrix. Then the estimator (5) is the solution to the following minimization problem:

$$\min_{\substack{L:L_{rr}>0\\ L_{rk}=0 \text{ for } r<k}} \left\{ -2\sum_{r=1}^{p}\log L_{rr} + \operatorname{tr}(SL^TL) + \lambda\sum_{r=2}^{p}\sum_{\ell=1}^{r-1}\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 L_{rm}^2} \right\}.$$

First note that under the lower-triangular constraint

$$\operatorname{tr}\left(SL^TL\right) = \frac{1}{n}\sum_{r=1}^{p}\operatorname{tr}\left(\mathbf{X}L_{r\cdot}^TL_{r\cdot}\mathbf{X}^T\right) = \frac{1}{n}\sum_{r=1}^{p}\left\|\mathbf{X}L_{r\cdot}^T\right\|_2^2 = \frac{1}{n}\sum_{r=1}^{p}\left\|\mathbf{X}_{1:r}L_{1:r,r}^T\right\|_2^2,$$

where $\mathbf{X}_{1:r}$ is a matrix of the first r columns of $\mathbf{X}$. Thus

$$\begin{aligned}
&-2\sum_{r=1}^{p}\log L_{rr} + \operatorname{tr}(SL^TL) + \lambda\sum_{r=2}^{p}\sum_{\ell=1}^{r-1}\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 L_{rm}^2}\\
=&-2\log L_{11} + \frac{1}{n}\left\|\mathbf{X}_1L_{11}\right\|_2^2 + \sum_{r=2}^{p}\left(-2\log L_{rr} + \frac{1}{n}\left\|\mathbf{X}_{1:r}L_{1:r,r}^T\right\|_2^2 + \lambda\sum_{\ell=1}^{r-1}\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 L_{rm}^2}\right).
\end{aligned}$$

Therefore the original problem can be decoupled into p separate problems. In particular, a solution $\hat{L}$ can be written in a row-wise form with

$$\hat{L}_{11} = \operatorname*{arg\,min}_{L_{11}>0}\left\{-2\log L_{11} + \frac{1}{n}\left\|\mathbf{X}_1L_{11}\right\|_2^2\right\} = \frac{1}{\sqrt{S_{11}}},$$

and for $r = 2,\ldots,p$,

$$\hat{L}_{1:r,r}^T = \operatorname*{arg\,min}_{\beta\in\mathbb{R}^r;\beta_r>0}\left\{-2\log\beta_r + \frac{1}{n}\left\|\mathbf{X}_{1:r}\beta\right\|_2^2 + \lambda\sum_{\ell=1}^{r-1}\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2\beta_m^2}\right\}.$$

Appendix B. A Closed-Form Solution to (9)

The objective function in (9) is a smooth function. Taking the derivative with respect to β and setting to zero gives the following system of equations:

$$-2\frac{1}{\beta_r}\mathbf{e}_r + \frac{2}{n}\mathbf{X}_{1:r}^T\mathbf{X}_{1:r}\beta + u^{(t-1)} + \rho\left(\beta - \gamma^{(t-1)}\right) = \mathbf{0}.$$

Letting $S^{(r)} = \frac{1}{n}\mathbf{X}_{1:r}^T\mathbf{X}_{1:r}$, then the equations above can be further decomposed into

$$\begin{aligned}
&-\frac{2}{\beta_r} + \left(2S_{rr}^{(r)} + \rho\right)\beta_r + 2S_{r,-r}^{(r)}\beta_{-r} + u_r^{(t-1)} - \rho\gamma_r^{(t-1)} = 0,\\
&\left(2S_{-r,-r}^{(r)} + \rho I\right)\beta_{-r} + 2S_{-r,r}^{(r)}\beta_r + u_{-r}^{(t-1)} - \rho\gamma_{-r}^{(t-1)} = \mathbf{0}.
\end{aligned}$$

Solving for β_{-r} in the second system of equations gives

$$\beta_{-r} = -\left(2S_{-r,-r}^{(r)} + \rho I\right)^{-1}\left(2S_{-r,r}^{(r)}\beta_r + u_{-r}^{(t-1)} - \rho\gamma_{-r}^{(t-1)}\right),$$

which is then plugged back in the first equation to give

$$2\frac{1}{\beta_r} + A\beta_r + B = 0,$$

where

$$\begin{aligned}
A &= 4S_{r,-r}^{(r)}\left(2S_{-r,-r}^{(r)} + \rho I\right)^{-1}S_{-r,r}^{(r)} - 2S_{r,r}^{(r)} - \rho,\\
B &= 2S_{r,-r}^{(r)}\left(2S_{-r,-r}^{(r)} + \rho I\right)^{-1}\left(u_{-r}^{(t-1)} - \rho\gamma_{-r}^{(t-1)}\right) - u_r^{(t-1)} + \rho\gamma_r^{(t-1)}.
\end{aligned}$$

Solving for β_r gives the closed-form update.

Appendix C. Dual Problem of (10)

Lemma 7 *A dual problem of* (10) *is*

$$\min_{a^{(\ell)}\in\mathbb{R}^r}\left\{\left\|y^{(t)} - \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}W^{(\ell)} * a^{(\ell)}\right\|_2^2 \quad \text{s.t.} \quad \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \quad \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0\right\}, \tag{28}$$

where $y^{(t)} = \beta^{(t)} + \frac{1}{\rho}u^{(t-1)}$. *Also, given a solution* $\hat{a}^{(1)},\ldots,\hat{a}^{(r-1)}$, *the solution to* (10) *can be written as*

$$\gamma^{(t)} = y^{(t)} - \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}W^{(\ell)} * \hat{a}^{(\ell)}. \tag{29}$$

Proof Note that

$$\begin{aligned}
\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2\gamma_m^2} &= \left\|\left(W^{(\ell)} * \gamma\right)_{g_{r,\ell}}\right\|_2\\
&= \max\left\{\left\langle W^{(\ell)} * a^{(\ell)}, \gamma\right\rangle, \quad \text{s.t.} \quad \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \quad \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0\right\}.
\end{aligned}$$

Thus, the minimization problem in (10) becomes

$$\begin{aligned}
&\min_{\gamma}\left\{\frac{1}{2}\left\|\gamma - y^{(t)}\right\|_2^2 + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}\left\|\left(W^{(\ell)} * \gamma\right)_{g_{r,\ell}}\right\|_2\right\}\\
=&\min_{\gamma}\left\{\max_{a^{(\ell)}}\left\{\frac{1}{2}\left\|\gamma - y^{(t)}\right\|_2^2 + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * a^{(\ell)}, \gamma\right\rangle, \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0\right\}\right\}\\
=&\max_{a^{(\ell)}}\left\{\min_{\gamma}\left\{\frac{1}{2}\left\|\gamma - y^{(t)}\right\|_2^2 + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * a^{(\ell)}, \gamma\right\rangle, \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0\right\}\right\},
\end{aligned}$$

where $y^{(t)} = \beta^{(t)} + \frac{1}{\rho}u^{(t-1)}$. We solve the inner minimization problem by setting the derivative to zero,

$$\gamma - y^{(t)} + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * a^{(\ell)} = 0,$$

which gives the primal-dual relation,

$$\gamma = -\frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * a^{(\ell)} + y^{(t)}.$$

Using this gives

$$\begin{aligned}
&\min_{\gamma}\left\{\frac{1}{2}\left\|\gamma - y^{(t)}\right\|_2^2 + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}\left\|\left(W^{(\ell)} * \gamma\right)_{g_{r,\ell}}\right\|_2\right\} \\
&= \max_{a^{(\ell)}}\left\{\frac{1}{2}\left\|-\frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * a^{(\ell)}\right\|_2^2 + \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * a^{(\ell)}, -\frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * a^{(\ell)} + y^{(t)}\right\rangle\right. \\
&\qquad \left.\text{s.t.} \quad \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \quad \left(a^{(\ell)}\right)_{g^c_{r,\ell}} = 0\right\} \\
&= \min_{a^{(\ell)}}\left\{\left\|y^{(t)} - \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * a^{(\ell)}\right\|_2^2 \quad \text{s.t.} \quad \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \quad \left(a^{(\ell)}\right)_{g^c_{r,\ell}} = 0\right\}.
\end{aligned}$$

■

Algorithm 3 BCD on the dual problem (28)

1: Let $y^{(t)} = \beta^{(t)} + \frac{1}{\rho}u^{(t-1)}$
2: Initialize $\hat{a}^{(\ell)} \leftarrow 0$ for all $\ell = 1, \cdots, r-1$
3: **for** $\ell = 1, \cdots, r-1$ **do**
4: $\quad \hat{z}^{(\ell)} \leftarrow y^{(t)} - \frac{\lambda}{\rho}\sum_{k=1}^{r-1} W^{(k)} * \hat{a}^{(k)}$ Find a root $\hat{\nu}_\ell$ that satisfies

$$h_\ell(\nu) := \sum_{m=1}^{\ell} \frac{w_{\ell m}^2}{\left(w_{\ell m}^2 + \nu\right)^2}\left(\hat{z}_m^{(\ell)}\right)^2 = \frac{\lambda^2}{\rho^2} \tag{30}$$

5: $\quad$ **for** $m = 1, \cdots, \ell$ **do**
6: $\quad\quad \hat{a}_m^{(\ell)} \leftarrow \frac{w_{\ell m}}{\frac{\lambda}{\rho}\left(w_{\ell m}^2 + [\hat{\nu}_\ell]_+\right)}\hat{z}_m^{(\ell)}$
7: **return** $\left\{\hat{a}^{(\ell)}\right\}$ as a solution to (28)
8: **return** $\gamma^{(t)} = y^{(t)} - \frac{\lambda}{\rho}\sum_{\ell=1}^{r-1} W^{(\ell)} * \hat{a}^{(\ell)}$ as a solution to (10)

Appendix D. Elliptical Projection

We adapt the same procedure as in Appendix B of Bien et al. (2016) to update one $a^{(\ell)}$ in Algorithm (3). By (10) we need to solve a problem of the form

$$\min_{a\in\mathbb{R}^\ell}\left\|\hat{z}^{(\ell)} - \tau D a\right\|_2^2 \quad \text{s.t.} \quad \|a\|_2 \le 1,$$

where $\tau = \frac{\lambda}{\rho}$ and $D = \operatorname{diag}(w_{\ell m})_{m\le\ell} \in \mathbb{R}^{\ell\times\ell}$. If $\left\|D^{-1}\hat{z}^{(\ell)}\right\|_2 \le \tau$, then clearly $\hat{a} = \frac{1}{\tau}D^{-1}\hat{z}^{(\ell)}$. Otherwise, we use the Lagrangian multiplier method to solve the constrained minimization problem above. Specifically, we find a stationary point of

$$\mathcal{L}(a,\nu) = \left\|\hat{z}^{(\ell)} - \tau D a\right\|_2^2 + \nu\tau^2\left(\|a\|_2^2 - 1\right).$$

Taking the derivative with respect to a and set it equal to zero, we have

$$\hat{a}_m = \frac{w_{\ell m}}{\tau(w_{\ell m}^2 + \hat{\nu})}\hat{z}_m^{(\ell)},$$

for each $m \le \ell$, and $\hat{\nu}$ is such that $\|\hat{a}\|_2 = 1$, which means it satisfies (30). By observing that $h_\ell(\nu)$ is a decreasing function of ν and $w_{\ell\ell} = \max_{m\le\ell} w_{\ell m}$, following Appendix B of Bien et al. (2016), we obtain lower and upper bounds for $\hat{\nu}$:

$$\left[\frac{1}{\tau}\left\|D\hat{z}^{(\ell)}\right\|_2 - w_{\ell\ell}^2\right]_+ \le \hat{\nu} \le \frac{1}{\tau}\left\|D\hat{z}^{(\ell)}\right\|_2,$$

which can be used as an initial interval for finding $\hat{\nu}$ using Newton's method. In practice, we usually find $\hat{\nu}$ from the equation $\frac{1}{h(\nu)} = \tau^{-2}$ for better numerical stability.

We end this section with a characterization of the solution to (10), which says that the solution can be written as $\gamma^{(t)} = y^{(t)} * \hat{t}$, where $\hat{t}$ is some data-dependent vector in $\mathbb{R}^r$.

Theorem 8 *A solution to* (10) *can be written as* $\gamma^{(t)} = y^{(t)} * \hat{g}$*, where the data-dependent vector* $\hat{g} \in \mathbb{R}^r$ *is given by*

$$\hat{g}_m = \prod_{\ell=m}^{r-1}\frac{[\hat{\nu}_\ell]_+}{w_{\ell m}^2 + [\hat{\nu}_\ell]_+}$$

and $\hat{g}_r = 1$*, where* $\hat{\nu}_\ell$ *satisfies* $\tau^2 = \sum_{m=1}^{\ell}\frac{w_{\ell m}^2}{\left(w_{\ell m}^2+\nu\right)^2}\left(\hat{z}_m^{(\ell)}\right)^2$.

Proof By Jenatton et al. (2011), we can get a solution to (10) in a single pass as described in Algorithm 3. If we start from $\hat{z}^{(1)} = y^{(t)}$, then for $\ell = 1, \cdots, r-1$ and each $m \le \ell$,

$$\hat{z}_m^{(\ell+1)} = \hat{z}_m^{(\ell)} - \tau w_{\ell m}\hat{a}_m^{(\ell)} = \frac{[\hat{\nu}_\ell]_+}{w_{\ell m}^2 + [\hat{\nu}_\ell]_+}\hat{z}_m^{(\ell)}.$$

By (29), $\gamma^{(t)} = \hat{z}^{(r-1)}$, and the result follows. ■

A key observation from this characterization is that a banded sparsity pattern is induced in solving (10), which in turn implies the same property of the output of Algorithm 1.

Corollary 9 *A solution* $\gamma^{(t)}$ *to* (10) *has banded sparsity, i.e.,* $\left(\gamma^{(t)}\right)_{1:\hat{J}} = 0$ *for* $\hat{J} = \max\{\ell : \hat{\nu}_\ell \le 0\}$.

Appendix E. Uniqueness of the Sparse Row Estimator

Lemma 10 *(Optimality condition) For any $\lambda > 0$ and a n-by-p sample matrix $\mathbf{X}$, $\hat{\beta}$ is a solution to the problem*

$$\min_{\beta \in \mathbb{R}^r} \left\{ -2\log \beta_r + \frac{1}{n} \|\mathbf{X}_{1:r}\beta\|_2^2 + \lambda \sum_{\ell=1}^{r-1} \sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 \beta_m^2} \right\}$$

if and only if there exist $\hat{a}^{(\ell)} \in \mathbb{R}^r$ for $\ell = 1, \ldots, r-1$ such that

$$-\frac{2}{\hat{\beta}_r}\mathbf{e}_r + \frac{2}{n}\mathbf{X}_{1:r}^T\mathbf{X}_{1:r}\hat{\beta} + \lambda \sum_{\ell=1}^{r-1} W^{(\ell)} * \hat{a}^{(\ell)} = 0 \tag{31}$$

with $\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}^c} = 0$, $\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}} = \frac{\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}}{\left\|\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}\right\|_2}$ for $\hat{\beta}_{g_{r,\ell}} \neq 0$ and $\left\|\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \leq 1$ for $\hat{\beta}_{g_{r,\ell}} = 0$.

Lemma 11 *Take $\hat{\beta}$ and $\hat{a}^{(\ell)}$ as in the previous lemma. Suppose that*

$$\left\|\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 < 1 \qquad \text{for} \quad \ell = 1, \ldots, J(\hat{\beta})$$

then for any other solution $\tilde{\beta}$ to (8), it is as sparse as $\hat{\beta}$ if not more. In other words,

$$K(\tilde{\beta}) \leq \hat{K}_r.$$

Lemma 12 *(Uniqueness) Under the conditions of the previous lemma, let $\hat{\mathcal{S}} = \left\{ i : \hat{\beta}_i \neq 0 \right\}$. If $\mathbf{X}_{\hat{\mathcal{S}}}$ has full column rank (i.e., $\operatorname{rank}\left(\mathbf{X}_{\hat{\mathcal{S}}}\right) = |\hat{\mathcal{S}}|$) then $\hat{\beta}$ is unique.*

Proof See Appendices J, K, and L. ■

Appendix F. Proof of Theorem 1

We start with introducing notation. **From now on we suppress the dependence on r in notation for simplicity**. We denote the group structure $g_\ell = \{1, \cdots, \ell\}$ for $\ell \leq r$ for each $r = 1, \ldots, p$. For any vector $\beta \in \mathbb{R}^r$, we let $\beta_{g_\ell} \in \mathbb{R}^\ell$ be the vector with elements $\{\beta_m : m \leq \ell\}$. We also introduce the weight vector $W^{(\ell)} \in \mathbb{R}^p$ with $\left(W^{(\ell)}\right)_m = w_{\ell m}$ where $w_{\ell m}$ can be defined as in (7) or $w_{\ell m} = 1$. Finally recalling from Section 4 the definition of $\mathcal{I}$, we denote $\mathcal{S} = \mathcal{I} \cup \{r\} = \{J+1, \ldots, r\}$ and $\mathcal{S}^c = \{1, 2, \ldots, J\}$.

The general idea of the proof depends on the primal-dual witness procedure in Wainwright (2009) and Ravikumar et al. (2011). Considering the original problem (8) for any $r = 2, \ldots, p$, we construct the primal-dual witness solution pairs $\left(\tilde{\beta}, \sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)$ as follows:

(a) Solve the restricted subproblem with the true bandwidth $K = r - 1 - J$:

$$\tilde{\beta} = \underset{\substack{\beta_r > 0 \\ \beta_{\mathcal{S}^c} = 0}}{\arg\min} \left\{ -2\log \beta_r + \frac{1}{n}\|\mathbf{X}_{1:r}\beta\|_2^2 + \lambda \sum_{\ell=1}^{r-1} \left\| \left(W^{(\ell)} * \beta \right)_{g_\ell} \right\|_2 \right\}.$$

The solution above can be written as

$$\tilde{\beta} = \begin{pmatrix} \mathbf{0}_J \\ \tilde{\gamma} \end{pmatrix},$$

where

$$\tilde{\gamma} = \underset{\gamma \in \mathbb{R}^{K+1}}{\arg\min} \left\{ -2\log \gamma_{K+1} + \frac{1}{n}\|\mathbf{X}_{\mathcal{S}}\gamma\|_2^2 + \lambda \sum_{\ell=1}^{K} \left\| \left(\tilde{W}^{(\ell)} * \gamma \right)_{g_\ell} \right\|_2 \right\},$$

with

$$\tilde{W}^{(\ell)} = \left(W^{(\ell+J)} \right)_{\mathcal{S}} \quad \Longleftrightarrow \quad \sum_{\ell=1}^{K} \left\| \left(\tilde{W}^{(\ell)} * \gamma \right)_{g_\ell} \right\|_2 = \sum_{\ell=J+1}^{r-1} \sqrt{\sum_{m=J+1}^{r-1} w_{\ell m}^2 \gamma_{m-J}^2}.$$

(b) By Lemma 10, there exist $\tilde{b}^{(\ell)} \in \mathbb{R}^{K+1}$ for $\ell = 1, \ldots, K$, such that $\left(\tilde{b}^{(\ell)}\right)_{g_\ell^c} = 0$ and

$$\left(\tilde{b}^{(\ell)}\right)_{g_{r\ell}} = \frac{\left(\tilde{W}^{(\ell)} * \tilde{\gamma}\right)_{g_\ell}}{\left\| \left(\tilde{W}^{(\ell)} * \tilde{\gamma}\right)_{g_\ell} \right\|_2},$$

satisfying

$$-\frac{2}{\tilde{\gamma}_{K+1}}\mathbf{e}_{K+1} + \frac{2}{n}\mathbf{X}_{\mathcal{S}}^T\mathbf{X}_{\mathcal{S}}\tilde{\gamma} + \lambda \sum_{\ell=1}^{K} \tilde{W}^{(\ell)} * \tilde{b}^{(\ell)} = 0.$$

(c) For $\ell = J+1, \ldots, r-1$, we let

$$\tilde{a}^{(\ell)} = \begin{pmatrix} \mathbf{0}_J \\ \tilde{b}^{(\ell-J)} \end{pmatrix}.$$

Then we have $\left(\tilde{a}^{(\ell)}\right)_{g_\ell^c} = 0$, $\left\|\left(\tilde{a}^{(\ell)}\right)_{g_\ell}\right\|_2 \leq 1$, $\left(\tilde{a}^{(\ell)}\right)_{g_\ell} = \frac{\left(W^{(\ell)} * \tilde{\beta}\right)_{g_\ell}}{\left\|\left(W^{(\ell)} * \tilde{\beta}\right)_{g_\ell}\right\|_2}$ for $\tilde{\beta}_{g_\ell} \neq 0$.

(d) For each $\ell = 1, ..., J$, we choose $\tilde{a}^{(\ell)} \in \mathbb{R}^r$ satisfying

$$\left(\tilde{a}^{(\ell)}\right)_{\ell'} = 0 \quad \text{for any } \ell' \neq \ell \quad \text{and} \quad \left(\tilde{a}^{(\ell)}\right)_\ell = -\frac{2}{\lambda w_{\ell\ell}}\left(S\tilde{\beta}\right)_\ell = -\frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_{\mathcal{S}}\tilde{\beta}_{\mathcal{S}}.$$

By construction and the fact that $w_{\ell\ell} = 1$,

$$\lambda\left(W^{(\ell)} * \tilde{a}^{(\ell)}\right)_\ell = \lambda w_{\ell\ell}\left(\tilde{a}^{(\ell)}\right)_\ell = -2\left(S\tilde{\beta}\right)_\ell.$$

By Lemma 10, $\{\tilde{a}^{(\ell)}\}$ satisfies the optimality condition (31):

$$-\frac{2}{\tilde{\beta}_r}\mathbf{e}_r + \frac{2}{n}\mathbf{X}_{1:r}^T\mathbf{X}_{1:r}\tilde{\beta} + \lambda\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)} = 0 \tag{32}$$

(e) Verify the strict dual feasibility condition for $\ell = 1, ..., J$

$$\left|\frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_{\mathcal{S}}\tilde{\beta}_{\mathcal{S}}\right| = \left|\left(\tilde{a}^{(\ell)}\right)_\ell\right| = \left\|\left(\tilde{a}^{(\ell)}\right)_{g_\ell}\right\|_2 < 1. \tag{33}$$

At a high level, steps (a) through (d) construct a pair $\left(\tilde{\beta}, \{\tilde{a}^{(\ell)}\}\right)$ that satisfies the optimality condition (31), but the $\{\tilde{a}^{(\ell)}\}$ is not necessarily guaranteed to be a member of $\partial\left(P(\tilde{\beta})\right)$. Step (e) does more than verifying the necessary conditions for it to belong to $\partial\left(P(\tilde{\beta})\right)$. The strict dual feasibility condition, once verified, ensures the uniqueness of the solution. Note that by construction in Step (b), $\{\tilde{a}^{(\ell)}\}$ satisfies dual feasibility conditions for $\ell = J+1, ..., r-1$ since $\left\{\tilde{b}^{(\ell)}\right\}$ does, so it remains to verify for $\ell = 1, ..., J$ (see Step (c)).

For each $\ell = 1, ..., J$, by the construction in Step (d), $\left(\tilde{a}^{(\ell)}\right)_{g_\ell^c} = 0$. Note that $\tilde{\beta}_{g_J} = 0$ implies $\tilde{\beta}_{g_\ell} = 0$. Thus, for $\tilde{a}^{(\ell)}$ to satisfy conditions in Lemma 10, it suffices to show (33).

If the primal-dual witness procedure succeeds, then by construction, the solution $\tilde{\beta}$, whose support is contained in the support of the true $L_{r\cdot}$, is a solution to (8). Moreover, by strict dual feasibility and Lemma 12, we know that $\tilde{\beta}$ is the unique solution $\hat{\beta}$ to the unconstrained problem (8). Therefore, the support of $\hat{\beta}$ is contained in the support of $L_{r\cdot}$.

In the following we adapt the same proof technique as Wainwright (2009) to show that the primal-dual witness succeeds with high probability, from which we first conclude that $K(\hat{\beta}) \leq K$.

F.1 Proof of Property 1 in Theorem 1

Proof We need to verify the strict dual feasibility (33). By (32),

$$-\frac{2}{\tilde{\beta}_r} + \frac{2}{n}\mathbf{X}_r^T\mathbf{X}_r\tilde{\beta}_r + \frac{2}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\tilde{\beta}_{\mathcal{I}} = 0, \tag{34}$$

$$\frac{2}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\tilde{\beta}_r + \frac{2}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\tilde{\beta}_{\mathcal{I}} + \lambda\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} = 0. \tag{35}$$

From (35),

$$\tilde{\beta}_{\mathcal{I}} = -\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left[\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\tilde{\beta}_r + \frac{\lambda n}{2}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right]. \tag{36}$$

Plugging (36) back into (34) and denoting $\mathbf{C}_{\mathcal{I}} = \mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}$ and $\mathbf{O}_{\mathcal{I}} = \mathbf{I} - \mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T$ as the orthogonal projection matrix onto the orthogonal

complement of the column space of $\mathbf{X}_{\mathcal{I}}$, we have

$$-\frac{2}{\tilde{\beta}_r} + \frac{2}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\tilde{\beta}_r - \lambda\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}} = 0,$$

which implies that

$$\tilde{\beta}_r = \frac{\frac{\lambda}{2}\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}} + \sqrt{\frac{\lambda^2}{4}\left(\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right)^2 + \frac{4}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r}}{\frac{2}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r} \tag{37}$$

and that

$$\begin{aligned}
\left(\tilde{a}^{(\ell)}\right)_\ell &= -\frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_{\mathcal{S}}\tilde{\beta}_{\mathcal{S}} = -\frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_r\tilde{\beta}_r - \frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_{\mathcal{I}}\tilde{\beta}_{\mathcal{I}} \\
&= -\frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_r\tilde{\beta}_r + \frac{2}{n\lambda}\mathbf{X}_\ell^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left[\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\tilde{\beta}_r + \frac{\lambda n}{2}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right] \\
&= -\frac{2}{n\lambda}\mathbf{X}_\ell^T\left[\mathbf{I} - \mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T\right]\mathbf{X}_r\tilde{\beta}_r + \mathbf{X}_\ell^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} \\
&= \mathbf{X}_\ell^T\left[\mathbf{C}_{\mathcal{I}} - \mathbf{O}_{\mathcal{I}}\left(\frac{2}{n\lambda}\mathbf{X}_r\tilde{\beta}_r\right)\right].
\end{aligned} \tag{38}$$

Conditioning on $\mathbf{X}_{\mathcal{I}}$, we can decompose $\mathbf{X}_r$ and $\mathbf{X}_\ell$ as

$$\begin{aligned}
\mathbf{X}_r^T &= \Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T + E_r^T, \\
\mathbf{X}_\ell^T &= \Sigma_{\ell\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T + E_\ell^T,
\end{aligned} \tag{39}$$

where $E_r \sim N\left(\mathbf{0}_n, \theta_r^{(r)}\mathbf{I}_{n\times n}\right)$ and $E_\ell \sim N\left(\mathbf{0}_n, \theta_r^{(\ell)}\mathbf{I}_{n\times n}\right)$, and $\theta_r^{(\ell)}$ and $\theta_r^{(r)}$ are defined in Section 4. Then

$$\mathbf{X}_\ell^T\mathbf{O}_{\mathcal{I}} = E_\ell^T\mathbf{O}_{\mathcal{I}} \quad \text{and} \quad \mathbf{O}_{\mathcal{I}}\mathbf{X}_r = \mathbf{O}_{\mathcal{I}}E_r,$$

and from (38)

$$\begin{aligned}
\left(\tilde{a}^{(\ell)}\right)_\ell &= E_\ell^T\left[\mathbf{C}_{\mathcal{I}} - \mathbf{O}_{\mathcal{I}}\left(\frac{2}{n\lambda}E_r\tilde{\beta}_r\right)\right] + \Sigma_{\ell\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} \\
&:= R^{(\ell)} + F^{(\ell)}.
\end{aligned} \tag{40}$$

We first bound $\max_\ell \left|F^{(\ell)}\right|$. Note that

$$\begin{aligned}
&\left\|\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right\|_\infty = \left\|\left(\sum_{\ell=J+1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right\|_\infty = \max_{m\in\mathcal{I}}\left|\sum_{\ell=m}^{r-1} w_{\ell m}\left(\tilde{a}^{(\ell)}\right)_m\right| \\
\leq &\max_{m\in\mathcal{I}}\sum_{\ell=m}^{r-1} w_{\ell m}\left|\left(\tilde{a}^{(\ell)}\right)_m\right| \leq \max_{m\in\mathcal{I}}\sum_{\ell=m}^{r-1}\frac{1}{(\ell-m+1)^2} \leq \sum_{k=1}^{\infty}\frac{1}{k^2} = \frac{\pi^2}{6},
\end{aligned} \tag{41}$$

where we used $\left\|\tilde{a}^{(\ell)}\right\|_\infty \le \left\|\tilde{a}^{(\ell)}\right\|_2 \le 1$. Therefore, by Assumption **A3**,

$$\max_{1\le\ell\le J}\left|\Sigma_{\ell\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right| \le 1-\alpha.$$

To give a bound on the random quantity $\left|R^{(\ell)}\right|$, we first state a general result that will be used multiple times later in the proof.

Lemma 13 *Consider the term $E_j^T\eta$ where $\eta\in\mathbb{R}^n$ is a random vector depending on $\mathbf{X}_\mathcal{I}$ and $\mathbf{X}_r$ and $E_j\sim N\left(\mathbf{0}_n,\theta_r^{(j)}\mathbf{I}_{n\times n}\right)$ for $j=1,\ldots,J,r$. If for some $\bar{Q}\ge 0$*

$$\mathrm{P}\left[\mathrm{Var}\left(E_j^T\eta\middle|\mathbf{X}_\mathcal{I},\mathbf{X}_r\right)\ge\bar{Q}\right]\le\bar{p}$$

then for any $a>0$,

$$\mathrm{P}\left[\left|E_j^T\eta\right|\ge a\right]\le 2\exp\left(-\frac{a^2}{2\bar{Q}}\right)+\bar{p}$$

Proof Define the event

$$\bar{\mathcal{B}}=\left\{\mathrm{Var}\left(E_j^T\eta\middle|\mathbf{X}_\mathcal{I}\right)\ge\bar{Q}\right\}.$$

Now for any a and conditioned on $\mathbf{X}_\mathcal{I}$ and $\mathbf{X}_r$,

$$\mathrm{P}\left[E_j^T\eta\ge a\right]\le\mathrm{P}\left[E_j^T\eta\ge a\middle|\bar{\mathcal{B}}^c\right]+\mathrm{P}\left[\bar{\mathcal{B}}\right]\le\mathrm{P}\left[E_j^T\eta\ge a\middle|\bar{\mathcal{B}}^c\right]+\bar{p}.$$

Conditioned on $\bar{\mathcal{B}}^c$, the variance of $E_j^T\eta$ is at most $\bar{Q}$. So by standard Gaussian tail bounds, we have

$$\mathrm{P}\left[E_j^T\eta\ge a\middle|\bar{\mathcal{B}}^c\right]=\mathrm{E}\left[\mathrm{P}\left(E_j^T\eta\ge a\middle|\mathbf{X}_\mathcal{I},\mathbf{X}_r\right)\middle|\bar{\mathcal{B}}^c\right]\le\mathrm{E}\left[2\exp\left(-\frac{a^2}{2\bar{Q}}\right)\middle|\bar{\mathcal{B}}^c\right]\le 2\exp\left(-\frac{a^2}{2\bar{Q}}\right).$$

■

Then note that $\mathrm{Var}\left(E_{i\ell}\right)=\theta_r^{(\ell)}\le\theta_r$ for $i=1,\ldots,n$. Now conditioned on both $\mathbf{X}_\mathcal{I}$ and $\mathbf{X}_r$, $R^{(\ell)}$ is zero-mean with variance at most

$$\begin{aligned}
&\mathrm{Var}\left(R^{(\ell)}\middle|\mathbf{X}_\mathcal{I}\right)\\
\le&\theta_r\left\|\mathbf{C}_\mathcal{I}-\mathbf{O}_\mathcal{I}\left(\frac{2}{n\lambda}E_r\tilde{\beta}_r\right)\right\|_2^2=\theta_r\left\{\mathbf{C}_\mathcal{I}^T\mathbf{C}_\mathcal{I}+\left\|\mathbf{O}_\mathcal{I}\left(\frac{2}{n\lambda}E_r\tilde{\beta}_r\right)\right\|_2^2\right\}\\
=&\theta_r\left\{\frac{1}{n}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_\mathcal{I}^T\left(\frac{1}{n}\mathbf{X}_\mathcal{I}^T\mathbf{X}_\mathcal{I}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_\mathcal{I}+\frac{4\tilde{\beta}_r^2\left\|\mathbf{O}_\mathcal{I}E_r\right\|_2^2}{n^2\lambda^2}\right\}\\
:=&\theta_r M_n,
\end{aligned}$$

where the first equality holds from Pythagorean identity. The next lemma bounds the random scaling M_n.

Lemma 14 *For $\varepsilon\in\left(0,\frac{1}{2}\right)$, denote*

$$\bar{M}_n(\varepsilon):=\frac{3\kappa^2\pi^2}{2}\frac{K}{n}+\frac{1}{\theta_r^{(r)}(n-K)(1-\varepsilon)}+\frac{16}{n\lambda^2},$$

then

$$\mathrm{P}\left[M_n\ge\bar{M}_n(\varepsilon)\middle|\mathbf{X}_\mathcal{I}\right]\le 7\exp\left(-n\min\left\{\frac{\alpha^2}{3\theta_r^{(r)}\kappa^2\pi^2K},\frac{\varepsilon^2}{4}\left(1-\frac{K}{n}\right)\right\}\right).$$

Proof See Appendix M. ■

Now by Lemma 13 and the union bound,

$$\mathrm{P}\left[\max_{1\le\ell\le J}\left|R^{(\ell)}\right|\ge\alpha\right]\le 2J\exp\left(-\frac{\alpha^2}{2\theta_r\bar{M}_n(\varepsilon)}\right)+7\exp\left(-c_3n\right),\tag{42}$$

for some constant c_3 independent of n and J. By the assumption that $\frac{K}{n}=o(1)$, we have that $\frac{K}{n}\le 1-\varepsilon$ for n large enough, thus

$$\bar{M}_n(\varepsilon)\le\frac{K}{n}\left(\frac{3\kappa^2\pi^2}{2}+\frac{1}{K\theta_r^{(r)}(1-\varepsilon)^2}+\frac{16}{K\lambda^2}\right)\le\frac{K}{n}\left(\frac{3\kappa^2\pi^2}{2}+\frac{4}{K\theta_r^{(r)}}+\frac{16}{K\lambda^2}\right).$$

For the exponential term in (42) to have faster decaying rate than the J term, we need

$$\frac{n}{K\log J}>\frac{\theta_r}{\alpha^2}\left(3\kappa^2\pi^2+\frac{8}{K\theta_r^{(r)}}+\frac{32}{K\lambda^2}\right).$$

■

F.2 Proof of Property 2 in Theorem 1

Next we study the ℓ_∞ error bound. The following theorem gives an ℓ_∞ error bound of $\tilde{\beta}$.

Proof Let $\delta = \tilde{\beta} - \beta^* = \tilde{\beta} - \left(L^T\right)_{1:r,r}$ and $\mathcal{W} = SL^T - (L)^{-1}$, then from (35) and the fact that L^{-1} is lower-triangular,

$$\begin{aligned}
\delta_{\mathcal{I}} =& -\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left[\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\tilde{\beta}_r + \left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)(L)_{\mathcal{I},r}^T\right] - \frac{n\lambda}{2}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} \\
=& -\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left[\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\left(\delta_r + \beta_r^*\right) + \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)(L)_{\mathcal{I},r}^T\right] \\
&-\frac{\lambda}{2}\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} \\
=& -\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\delta_r - \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(SL^T\right)_{\mathcal{I},r} \\
&-\frac{\lambda}{2}\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} \\
=& -\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_r\delta_r - \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r} - \frac{\lambda}{2}\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}.
\end{aligned} \tag{43}$$

From (34) and the fact that $\left(L^{-1}\right)_{rr} = \frac{1}{L_{rr}}$,

$$\begin{aligned}
&-\frac{1}{\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_r\delta_r + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\delta_{\mathcal{I}} + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_r\beta_r^* + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\beta_{\mathcal{I}}^* \\
=& -\frac{1}{\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_r\delta_r + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\delta_{\mathcal{I}} + \left(SL^T\right)_{rr} \\
=& \left(L^{-1}\right)_{rr} - \frac{1}{\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_r\delta_r + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\delta_{\mathcal{I}} + \mathcal{W}_{rr} \\
=& \frac{\delta_r}{L_{rr}\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_r\delta_r + \frac{1}{n}\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\delta_{\mathcal{I}} + \mathcal{W}_{rr} = 0.
\end{aligned} \tag{44}$$

Plugging (43) into (44), we have

$$\frac{\delta_r}{L_{rr}\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\delta_r = \mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{X}_r\mathbf{C}_{\mathcal{I}} - \mathcal{W}_{rr},$$

which implies

$$\delta_r = \left(\frac{1}{L_{rr}\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\right)^{-1}\left[\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{X}_r\mathbf{C}_{\mathcal{I}} - \mathcal{W}_{rr}\right].$$

Since $L_{rr} > 0$ and $\tilde{\beta}_r > 0$,

$$\begin{aligned}
|\delta_r| \le& \left|\left(\frac{1}{L_{rr}\tilde{\beta}_r} + \frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\right)^{-1}\right|\left(\left|\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}\right| + \left|\frac{\lambda}{2}\mathbf{X}_r\mathbf{C}_{\mathcal{I}}\right| + |\mathcal{W}_{rr}|\right) \\
\le& \left|\left(\frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\right)^{-1}\right|\left(\left|\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}\right| + \left|\frac{\lambda}{2}\mathbf{X}_r\mathbf{C}_{\mathcal{I}}\right| + |\mathcal{W}_{rr}|\right).
\end{aligned}$$

Now conditioned on $\mathbf{X}_{\mathcal{I}}$, by the decomposition (39), $\left(\frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\right)^{-1} = \left(\frac{1}{n}E_r^T\mathbf{O}_{\mathcal{I}}E_r\right)^{-1} = \frac{n}{\|\mathbf{O}_{\mathcal{I}}E_r\|_2^2}$. From Lemma 20, it follows that

$$\mathrm{P}\left[\left(\frac{1}{n}\mathbf{X}_r^T\mathbf{O}_{\mathcal{I}}\mathbf{X}_r\right)^{-1} \ge \frac{1}{\theta_r^{(r)}}\frac{n}{n-K}\frac{1}{1-\varepsilon}\right] \le \exp\left(-\frac{1}{4}(n-K)\varepsilon^2\right).$$

Also, by Lemma 19,

$$\mathrm{P}\left[\left|\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right| \ge 1\right] \le 2\exp\left(-\frac{n\alpha^2}{3\theta_r^{(r)}\kappa^2\pi^2K}\right) + 2\exp\left(-\frac{n}{2}\right).$$

To deal with the rest of terms in (44) that involve $\mathcal{W}$, we introduce the following concentration inequality to control its element-wise infinity norm.

Lemma 15 *Let $\mathcal{W} = SL^T - L^{-1}$. Under Assumptions **A4** and **A5**, there exist constants $C_1, C_2, C_3 > 0$ such that for any $0 < t \le 2\kappa$,*

$$\mathrm{P}\left[\|\mathcal{W}\|_\infty > t\right] \le 2p^2\exp\left(-\frac{C_3nt^2}{\kappa^2}\right) + 4p\exp\left(-\frac{C_1nt}{\kappa^2}\right) + 4p\exp\left(-C_2nt\right).$$

Proof See Appendix N. ■

In terms of the event

$$\mathcal{A} = \left\{\|\mathcal{W}\|_\infty \le \lambda\right\},$$

Lemma 15 states that

$$\mathrm{P}\left[\mathcal{A}^c\right] \le 2p^2\exp\left(-\frac{C_3n\lambda^2}{\kappa^2}\right) + 4p\exp\left(-\frac{C_1n\lambda}{\kappa^2}\right) + 4p\exp\left(-C_2n\lambda\right).$$

The next lemma shows that, on the event $\mathcal{A}$ and with the assumption that $\frac{\lambda^2}{n} = o(1)$, the term $\left|\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}\right|$ can be bounded by λ with high probability.

Lemma 16 *Using the general weigthing scheme* (7)*, we have*

$$\mathrm{P}\left[\left|\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}\right| \ge \lambda\middle|\mathcal{A}\right] \le 2\exp\left(-\frac{2n\alpha^2}{9\theta_r^{(r)}\kappa^2K\lambda^2}\right) + 2\exp\left(-\frac{n}{2}\right).$$

Proof Recall that by conditioning on $\mathbf{X}_{\mathcal{I}}$, the decomposition (39) gives

$$\mathbf{X}_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r} = \Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r} + E_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}.$$

On the event $\mathcal{A}$, by **A3** and (41),

$$\left|\Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\mathcal{W}_{\mathcal{I},r}\right| \le \left\|\Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\right\|_\infty\|\mathcal{W}_{\mathcal{I},r}\|_\infty \le \lambda.$$

Note that $\mathrm{Var}(E_{ir}) = \theta_r^{(r)}$ for $i = 1, \ldots, n$. Let $B^{(r)} := E_r^T \mathbf{X}_{\mathcal{I}} \left(\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathcal{W}_{\mathcal{I},r}$, then $B^{(r)}$ has mean zero and variance at most

$$\mathrm{Var}\left(B^{(r)} \middle| \mathbf{X}_{\mathcal{I}}\right) = \frac{\theta_r^{(r)}}{n} \mathcal{W}_{\mathcal{I},r}^T \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathcal{W}_{\mathcal{I},r} \leq \frac{9\theta_r^{(r)} \kappa^2 K \lambda^2}{n},$$

with probability greater than $1 - 2\exp\left(\frac{n}{2}\right)$. The result follows from Lemma 13. ■

Putting everything together and choosing the tuning parameter from (13), with a union bound argument and some algebra, we have shown that conditioned on $\mathbf{X}_{\mathcal{I}}$,

$$\begin{aligned}
&\mathrm{P}\left[|\delta_r| \geq \frac{1}{\theta_r^{(r)}} \frac{n}{n-K} \frac{1}{1-\varepsilon} \frac{5}{2}\lambda\right] \leq \mathrm{P}\left[|\delta_r| \geq \frac{5}{2\theta_r^{(r)}}\lambda\right] \leq \mathrm{P}\left[|\delta_r| \geq \frac{5}{2\theta_r^{(r)}}\lambda \middle| \mathcal{A}\right] + \mathrm{P}\left[\mathcal{A}^c\right] \\
&\leq \exp\left(-\frac{1}{4n}\left(1 - \frac{K}{n}\right)\varepsilon^2\right) + 2\exp\left(-\frac{n\alpha^2}{3\theta_r \kappa^2 \pi^2 K}\right) + 2\exp\left(-\frac{2n\alpha^2}{9\theta_r \kappa^2 K \lambda^2}\right) + 4\exp\left(-\frac{n}{2}\right) \\
&+ 2p^2 \exp\left(-\frac{C_3 n \lambda^2}{\kappa^2}\right) + 4p\exp\left(-\frac{C_1 n \lambda}{\kappa^2}\right) + 4p\exp\left(-C_2 n \lambda\right) \\
&\leq c_4 \exp\left(-c_5 n\right) + \frac{c_6}{p}, \qquad (45)
\end{aligned}$$

for some constants $c_4, c_5, c_6, x > 0$ that do not depend on n and p.

We now consider a bound for $\delta_{\mathcal{I}}$. Recall from (43) that

$$\delta_{\mathcal{I}} = F_1 + F_2$$

where

$$\begin{aligned}
F_1 &= -\left(\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathbf{X}_{\mathcal{I}}^T \mathbf{X}_r \delta_r, \\
F_2 &= -\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \quad \text{with} \quad \mathbf{D} = \left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}.
\end{aligned}$$

An ℓ_∞ bound of F_2 is given by

$$\|F_2\|_\infty \leq \left\| \left(\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} - \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \right) \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty + \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty. \qquad (46)$$

On the event $\mathcal{A}$, by (41),

$$\begin{aligned}
&\left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty \leq \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \right\|_\infty \left(\|\mathcal{W}_{\mathcal{I},r}\|_\infty + \frac{\lambda}{2} \|\mathbf{D}\|_\infty \right) \\
&\leq \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \right\|_\infty \left(1 + \frac{\pi^2}{12}\right) \lambda \leq 2\lambda \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty^2
\end{aligned}$$

To deal with the first term in (46), note that $X_{\mathcal{I}} = W_{\mathcal{I}} \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{1/2}$, where $W_{\mathcal{I}} \in \mathbb{R}^{n \times K}$ is a standard Gaussian random matrix, i.e., $(W_{\mathcal{I}})_{ij} \sim N(0,1)$. Thus we can write it as

$$\left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \left[\left(\frac{1}{n} W_{\mathcal{I}}^T W_{\mathcal{I}}\right)^{-1} - \mathbf{I}_K \right] \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty \leq \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty G,$$

where

$$G = \left\| \left[\left(\frac{1}{n} W_{\mathcal{I}}^T W_{\mathcal{I}}\right)^{-1} - \mathbf{I}_K \right] \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty.$$

By Lemma 5 in Wainwright (2009), we have, for some constant $c_7 > 0$.

$$\mathrm{P}\left[G \geq \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty \middle| \mathbf{X}_{\mathcal{I}}\right] \leq 4\exp\left(-c_7 \min\left\{K, \log J\right\}\right)$$

Note that conditioning on $\mathcal{A}$, $\left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \left(\mathcal{W}_{\mathcal{I},r} + \frac{\lambda}{2}\mathbf{D}\right) \right\|_\infty$ is upper bounded by $2\lambda \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty$. Thus,

$$\mathrm{P}\left[G \geq 2\lambda \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty^2 \middle| \mathcal{A}\right] \leq 4\exp\left(-c_7 \min\left\{K, \log J\right\}\right),$$

and

$$\begin{aligned}
&\mathrm{P}\left[\|F_2\|_\infty \geq 4\lambda \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty^2\right] \leq \mathrm{P}\left[\|F_2\|_\infty \geq 4\lambda \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2} \right\|_\infty^2 \middle| \mathcal{A}\right] + \mathrm{P}\left[\mathcal{A}^c\right] \\
&\leq 4\exp\left(-c_7 \min\left\{K, \log J\right\}\right) + \frac{c_6}{p}. \qquad (47)
\end{aligned}$$

Turning to F_1, conditioned on $\mathbf{X}_{\mathcal{I}}$, by decomposition (39), we have that

$$\|F_1\|_\infty \leq \left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \Sigma_{\mathcal{I}r} \right\|_\infty |\delta_r| + \left\| \left(\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathbf{X}_{\mathcal{I}}^T E_r \delta_r \right\|_\infty.$$

By (45) and **A3**,

$$\mathrm{P}\left[\left\| \left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1} \Sigma_{\mathcal{I}r} \right\|_\infty |\delta_r| \geq \frac{5}{2\theta_r^{(r)}}\lambda\right] \leq c_4 \exp\left(-c_5 n\right) + \frac{c_6}{p}.$$

Consider each coordinate $j \in \mathcal{I}$ of the random term whose variance is bounded by

$$\mathrm{Var}\left[\mathbf{e}_j^T \left(\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathbf{X}_{\mathcal{I}}^T E_r \delta_r \middle| \mathbf{X}_{\mathcal{I}}\right] \leq \theta_r \left\| \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \right\|_2 \frac{\delta_r^2}{n}.$$

By Lemma 18 and (45),

$$\mathrm{P}\left[\mathrm{Var}\left[\mathbf{e}_j^T \left(\mathbf{X}_{\mathcal{I}}^T \mathbf{X}_{\mathcal{I}}\right)^{-1} \mathbf{X}_{\mathcal{I}}^T E_r \delta_r \middle| \mathbf{X}_{\mathcal{I}}\right] \geq \frac{235}{4} \frac{\kappa^2}{\theta_r} \frac{\lambda^2}{n}\right] \leq 2\exp\left(-\frac{n}{2}\right) + c_4 \exp\left(-c_5 n\right) + \frac{c_6}{p}.$$

Thus by Lemma 13,

$$\mathrm{P}\left[\left\|\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\mathbf{X}_{\mathcal{I}}^T E_r\delta_r\right\|_\infty \geq \frac{5}{2\theta_r^{(r)}}\lambda\right] \leq 2\exp\left(-\frac{n}{18\theta_r\kappa^2}\right) + 2\exp\left(-\frac{n}{2}\right) + c_4\exp\left(-c_5 n\right) + \frac{c_6}{p},$$

and

$$\mathrm{P}\left[\|F_1\|_\infty \geq \frac{5}{\theta_r^{(r)}}\lambda\right] \leq 2\exp\left(-\frac{n}{18\theta_r\kappa^2}\right) + 2\exp\left(-\frac{n}{2}\right) + c_4\exp\left(-c_5 n\right) + \frac{c_6}{p}.$$

Combining with (45) and (47), we have

$$\mathrm{P}\left[\|\delta\|_\infty \geq 4\lambda\left\|\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1/2}\right\|_\infty^2 + \frac{5}{\theta_r^{(r)}}\lambda\right] \leq c_8\exp\left(-c_9 n\right) + 2\frac{c_6}{p} + 4\exp\left(-c_7\min\left\{K, \log J\right\}\right),$$

for some constants $c_8, c_9 > 0$ that do not depend on n and J. ■

F.3 Proof of Property 3 in Theorem 1

Finally we establish a $\beta_{\min}$ condition, which, combined with the ℓ_∞ rate, gives the other direction of the support recovery, i.e., $K(\hat{\beta}) \geq K$.

By the triangle inequality

$$\left|\tilde{\beta}_j\right| \geq \left|\beta_j\right| - \left|\tilde{\beta}_j - \beta_j\right|.$$

So if we have

$$\max_{j\geq J+1}\left\{\left|\beta_j\right| - \left|\tilde{\beta}_j - \beta_j\right|\right\} > 0,$$

then $K(\tilde{\beta}) \geq K$.

Appendix G. Proof of Theorem 3

Proof The overall proof techniques are the same as the proof of Theorem 1. The first part of the theorem holds if $\max_{2\leq r\leq p}\max_{1\leq\ell\leq J_r}|\tilde{a}^{(r\ell)}| < 1$. Now for each $r = 2, \ldots, p$ we proceed with the same primal-dual witness procedure and end up with the same decomposition (40).

Assumption **A3** ensures that $\max_{2\leq r\leq p}\max_{1\leq\ell\leq J_r}|F^{(r\ell)}| \leq 1-\alpha$. Following the same line of proof to deal with random term $R^{(r\ell)}$, we have that $R^{(r\ell)}$ is zero-mean Gaussian with conditional variance bounded above by the scaling

$$\theta_r\bar{M}_n^{(r)}(\varepsilon) = \frac{3\kappa^2\pi^2\theta_r}{2}\frac{K_r^*}{n} + \frac{\theta_r}{\theta_r^{(r)}}\frac{1}{(n-K_r^*)(1-\varepsilon)} + \frac{16\theta_r}{n\lambda^2}$$
$$\leq \frac{3\kappa^2\pi^2\theta_r}{2}\left(\frac{K}{n} + \frac{\kappa^2}{n\theta_r^{(r)}(1-\varepsilon)^2} + \frac{16}{n\lambda^2}\right),$$

for $\varepsilon \in \left(0, \frac{1}{2}\right)$ with high probability, where we use the fact that $K = o(n)$ implies that $\frac{K}{n} \leq \varepsilon$ for n large. And

$$\mathrm{P}\left[\left|R^{(r\ell)}\right| \geq \alpha\right] \leq 2\exp\left(-\frac{\alpha^2}{2\theta_r\bar{M}_n^{(r)}(\varepsilon)}\right) + 7\exp\left(-c_3 n\right).$$

Thus,

$$\mathrm{P}\left[\max_{2\leq r\leq p}\max_{1\leq\ell\leq J_r}\left|R^{(r\ell)}\right| \geq \alpha\right] \leq 2\sum_{r=2}^p J_r\exp\left(-\frac{\alpha^2}{2\theta_r\bar{M}_n^{(r)}(\varepsilon)}\right) + 7\sum_{r=2}^p J_r\exp\left(-c_3 n\right)$$
$$\leq p^2\exp\left(-\frac{\alpha^2}{3\kappa^2\pi^2\theta\frac{K}{n} + \frac{8\theta\kappa^2}{n} + \frac{32\theta}{n\lambda^2}}\right) + \frac{7}{2}p^2\exp\left(-c_3 n\right).$$

For the exponential term to decay faster than p^2, we need

$$\frac{n}{\log p} > \max\left\{\frac{2}{\alpha^2}\left(3\kappa^2\pi^2\theta K + 8\kappa^2\theta + \frac{32\theta}{\lambda^2}\right), \frac{2}{c_3}\right\}.$$

■

Appendix H. Proof of Theorem 4

Lemma 17 *Using the notation and conditions in Theorem 4, the following deviation bounds hold with high probability:*

$$\left\|\hat{L} - L\right\|_\infty \leq \zeta_\Gamma(K+1)\sqrt{\frac{\log p}{n}},$$
$$\left\|\hat{L} - L\right\|_1 \leq \zeta_\Gamma(K+1)\sqrt{\frac{\log p}{n}},$$
$$\left\|\hat{L} - L\right\|_2 \leq \zeta_\Gamma(K+1)\sqrt{\frac{\log p}{n}},$$
$$\left\|\hat{L} - L\right\|_F \leq \zeta_\Gamma\sqrt{\frac{(s+p)\log p}{n}}.$$

Proof By Theorem 3, with high probability, the support of $\hat{L}$ is contained in the true support and

$$\left\|\hat{L} - L\right\|_\infty \leq \zeta_\Gamma\sqrt{\frac{\log p}{n}}.$$

Note that

$$\left\|\hat{L} - L\right\|_\infty = \max_{2\leq r\leq p}\sum_{c=1}^r\left|\hat{L}_{rc} - L_{rc}\right| \leq \max_{2\leq r\leq p}(K_r+1)\left\|\hat{L} - L\right\|_\infty \leq (K+1)\left\|\hat{L} - L\right\|_\infty.$$

Denote $D = \max_{1\le c\le p-1} D_c$ where $D_c = |\{r = c, \ldots, p : L_{rc} \neq 0\}|$. Observing that $D \le K$, we have

$$\begin{aligned}\left|\left|\left|\hat{L} - L\right|\right|\right|_1 &= \max_{1\le c\le p-1} \sum_{r=1}^{c} \left|\hat{L}_{rc} - L_{rc}\right| \le \max_{1\le c\le p-1} (D_c + 1) \left\|\hat{L} - L\right\|_\infty \\ &\le (D+1)\left\|\hat{L} - L\right\|_\infty \le (K+1)\left\|\hat{L} - L\right\|_\infty .\end{aligned}$$

By Hölder's inequality

$$\left|\left|\left|\hat{L} - L\right|\right|\right|_2 \le \sqrt{\left|\left|\left|\hat{L} - L\right|\right|\right|_1 \left|\left|\left|\hat{L} - L\right|\right|\right|_\infty}.$$

Finally for Frobenius norm,

$$\left\|\hat{L} - L\right\|_F^2 = \sum_{r=2}^{p}\sum_{c=J_r+1}^{r} \left(\hat{L}_{rc} - L_{rc}\right)^2 \le \sum_{r=2}^{p}\sum_{c=J_r+1}^{r} \left\|\hat{L} - L\right\|_\infty^2 \le \zeta_\Gamma^2 \left(\sum_r K_r + p\right)\frac{\log p}{n}.$$

■

Proof [of Theorem 4] First note that

$$\begin{aligned}\hat{L}^T\hat{L} - L^TL &= \left(\hat{L} - L\right)^T\left(\hat{L} - L\right) + \hat{L}^TL + L^T\hat{L} - 2L^TL \\ &= \left(\hat{L} - L\right)^T\left(\hat{L} - L\right) + \left(\hat{L} - L\right)^TL + L^T\left(\hat{L} - L\right).\end{aligned}$$

Thus,

$$\begin{aligned}\left\|\hat{L}^T\hat{L} - L^TL\right\|_\infty &\le \left|\left|\left|\hat{L} - L\right|\right|\right|_\infty \left\|\hat{L} - L\right\|_\infty + 2|||L|||_\infty \left\|\hat{L} - L\right\|_\infty, \\ \left|\left|\left|\hat{L}^T\hat{L} - L^TL\right|\right|\right|_1 &= \left|\left|\left|\hat{L}^T\hat{L} - L^TL\right|\right|\right|_\infty \le 2|||L|||_\infty \left|\left|\left|\hat{L} - L\right|\right|\right|_\infty + \left\|\hat{L} - L\right\|_\infty^2.\end{aligned}$$

By Hölder's inequality

$$\left|\left|\left|\hat{L}^T\hat{L} - L^TL\right|\right|\right|_2 \le \sqrt{\left|\left|\left|\hat{L}^T\hat{L} - L^TL\right|\right|\right|_1 \left|\left|\left|\hat{L}^T\hat{L} - L^TL\right|\right|\right|_\infty}.$$

Finally, for Frobenius norm, observe that

$$\begin{aligned}\left\|L^T\left(\hat{L} - L\right)\right\|_F &= \left\|\mathrm{vec}\left(L^T\left(\hat{L} - L\right)\right)\right\|_2 = \left\|\left(I_p \otimes L^T\right)\mathrm{vec}\left(\hat{L} - L\right)\right\|_2 \\ &\le \left|\left|\left|I_p \otimes L^T\right|\right|\right|_2 \left\|\hat{L} - L\right\|_F = |||L|||_2 \left\|\hat{L} - L\right\|_F.\end{aligned}$$

Applying the same strategy to $\left\|\left(\hat{L} - L\right)\left(\hat{L} - L\right)\right\|_F$, we have

$$\left\|\hat{L}^T\hat{L} - L^TL\right\|_F \le \left(\left|\left|\left|\hat{L} - L\right|\right|\right|_2 + 2|||L|||_2\right)\left\|\hat{L} - L\right\|_F,$$

then the results follow from Corollary 17. ■

Appendix I. Proof of Theorem 6

Proof We adapt the proof technique of Rothman et al. (2008). Let

$$\begin{aligned}G(\Delta) = &-2\log\det(L+\Delta) + \mathrm{tr}\left(S(L+\Delta)^T(L+\Delta)\right) + \lambda\|(\Delta+L)\|_{2,1}^* \\ &+ 2\log\det L - \mathrm{tr}\left(SL^TL\right) - \lambda\|L\|_{2,1}^*,\end{aligned} \tag{48}$$

where L is the inverse of the Cholesky factor of the true covariance matrix, and the penalty is defined above as

$$\|L\|_{2,1}^* = \sum_{r=2}^{p}\sum_{\ell=1}^{r-1}\sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 L_{rm}^2}.$$

Since the estimator $\hat{L}$ is defined as

$$\hat{L} = \underset{L_{jk}=0:j<k}{\arg\min}\left\{-2\log\det L + \mathrm{tr}\left(SL^TL\right) + \lambda\|L\|_{2,1}^*\right\},$$

it follows that $G(\Delta)$ is minimized at $\hat{\Delta} = \hat{L} - L$. Consider the value of $G(\Delta)$ on the set defined as

$$\Theta_n(M) = \left\{\Delta :\ \Delta_{jk} = 0 \text{ for all } k > j,\ \ (\Delta+L)_{jj} > 0 \text{ for all } j\ , \|\Delta\|_F = Mr_n\right\},$$

where $M > 0$ and

$$r_n = \sqrt{\frac{(\sum_{r=2}^{p} K_r + p)\log p}{n}}.$$

The assumed scaling implies that $r_n \to 0$. We aim at showing that $\inf\{G(\Delta) :\ \Delta \in \Theta_n(M)\} > 0$. If it holds, then the convexity of $G(\Delta)$ and the fact that $G(\hat{\Delta}) \le G(\mathbf{0}) = 0$ implies

$$\|\hat{\Delta}\|_F = \|\hat{L} - L\|_F \le Mr_n.$$

We start with analyzing the logarithm terms in (48). First let $f(t) = \log\det(L + t\Delta)$. Using a Taylor expansion of $f(t)$ at $t = 0$ with $f'(t) = \mathrm{tr}[(L+t\Delta)^{-1}\Delta]$ and $f''(t) = -\mathrm{vec}\,\Delta^T(L+t\Delta)^{-1} \otimes (L+t\Delta)^{-1}\,\mathrm{vec}\,\Delta$, we have

$$\begin{aligned}&\log\det(L+\Delta) - \log\det(L) \\ =&\,\mathrm{tr}(L^{-1}\Delta) - (\mathrm{vec}\,\Delta)^T\left[\int_0^1 (1-\nu)(L+\nu\Delta)^{-1}\otimes(L+\nu\Delta)^{-1}d\nu\right](\mathrm{vec}\,\Delta).\end{aligned}$$

The trace term in (48) can be written as

$$\begin{aligned}\mathrm{tr}\left(S(L+\Delta)^T(L+\Delta)\right) - \mathrm{tr}\left(SL^TL\right) &= \mathrm{tr}\left(SL^T\Delta + S\Delta^TL + S\Delta^T\Delta\right) \\ &= 2\,\mathrm{tr}\left(SL^T\Delta\right) + \mathrm{tr}\left(S\Delta^T\Delta\right) \\ &\ge 2\,\mathrm{tr}\left(SL^T\Delta\right),\end{aligned}$$

where the last inequality comes from the fact that the sample covariance matrix S is positive semidefinite. Combining these with (48) gives

$$\begin{aligned} G(\Delta) \geq & 2(\operatorname{vec}\Delta)^T \left[\int_0^1 (1-\nu)(L+\nu\Delta)^{-1} \otimes (L+\nu\Delta)^{-1} d\nu\right] (\operatorname{vec}\Delta) \\ & + 2\operatorname{tr}[(SL^T - L^{-1})\Delta] + \lambda\left(\|L+\Delta\|_{2,1}^* - \|L\|_{2,1}^*\right) \\ \equiv & (a) + (b) + (c). \end{aligned} \tag{49}$$

The integral term (a) above has a positive lower bound. Recalling that $\sigma_{\min}(M) = \min_{\|x\|=1} x^T M x$ is a concave function of M (the minimum of linear functions of M is concave), we have

$$\begin{aligned} (a) &= 2\|\operatorname{vec}\Delta\|^2 \frac{\operatorname{vec}\Delta^T}{\|\operatorname{vec}\Delta\|}\left[\int_0^1 (1-\nu)(L+\nu\Delta)^{-1} \otimes (L+\nu\Delta)^{-1} d\nu\right] \frac{\operatorname{vec}\Delta}{\|\operatorname{vec}\Delta\|} \\ &\geq 2\|\Delta\|_F^2 \sigma_{\min}\left[\int_0^1 (1-\nu)(L+\nu\Delta)^{-1} \otimes (L+\nu\Delta)^{-1} d\nu\right] \\ &\geq 2\|\Delta\|_F^2 \left[\int_0^1 (1-\nu)\sigma_{\min}\left((L+\nu\Delta)^{-1} \otimes (L+\nu\Delta)^{-1}\right) d\nu\right] \\ &\geq 2\|\Delta\|_F^2 \int_0^1 (1-\nu)\sigma_{\min}^2(L+\nu\Delta)^{-1} d\nu \\ &\geq \|\Delta\|_F^2 \min_{0\leq\nu\leq 1} \sigma_{\min}^2(L+\nu\Delta)^{-1} \\ &\geq \|\Delta\|_F^2 \min\left\{\sigma_{\min}^2(L+\tilde{\Delta})^{-1} : \ \|\tilde{\Delta}\|_F \leq M r_n\right\}. \end{aligned} \tag{50}$$

The second inequality uses Jenson's inequality of the concave function $\sigma_{\min}(\cdot)$, and the third inequality uses the fact that $\sigma_{\min}(A \otimes A) = \sigma_{\min}(A)^2$ for any positive (semi)definite matrix A. Using triangle inequality on the matrix operator norm, we have

$$\sigma_{\min}^2(L+\tilde{\Delta})^{-1} = \sigma_{\max}^{-2}(L+\tilde{\Delta}) \geq \left(\|L\|_2 + \left\|\left\|\tilde{\Delta}\right\|\right\|_2\right)^{-2} \geq \frac{1}{2\|\|L\|\|_2^2} \geq \frac{\kappa^2}{2},$$

where the second inequality holds with high probability since $\left\|\left\|\tilde{\Delta}\right\|\right\|_2 \leq \|\tilde{\Delta}\|_F \leq M r_n \leq \|\|L\|\|_2$ as $r_n \to 0$ and the last inequality follows from Assumption **A4**. This gives the lower bound for the first term in (49):

$$(a) \geq \frac{1}{2}\kappa^2 \|\Delta\|_F^2 = \frac{1}{2}\kappa^2 M^2 r_n^2. \tag{51}$$

To deal with (b), we start by recalling some notation. We let $\mathcal{S} = \{(r,j) : L_{rj} \neq 0\}$ denote the support of L, and $s = \sum_{r=2}^p K_r$ be the number of non-zero off-diagonal elements. We also define

$$\|L\|_{2,1} = \sum_{r=2}^p \sum_{\ell=1}^{r-1} w_{\ell\ell}|L_{r\ell}| = \sum_{r=2}^p \sum_{\ell=1}^{r-1} |L_{r\ell}|,$$

where the last equality holds since $w_{\ell\ell} = 1$ by (7). Then, by the Cauchy-Schwarz inequality,

$$\begin{aligned} \left|\operatorname{tr}[(SL^T - L^{-1})\Delta]\right| &= \left|\sum_{r=1}^p \sum_{j=1}^r \left(SL^T - L^{-1}\right)_{rj} \Delta_{rj}\right| \\ &\leq \left|\sum_{r=1}^p \sum_{j\in\mathcal{I}_r} (SL^T - L^{-1})_{rj}\Delta_{rj}\right| + \left|\sum_{r=1}^p \sum_{j\notin\mathcal{I}_r} (SL^T - L^{-1})_{rj}\Delta_{rj}\right| \\ &\leq \sqrt{s+p}\left\|SL^T - L^{-1}\right\|_\infty \|\Delta_{\mathcal{S}}\|_F + \left\|SL^T - L^{-1}\right\|_\infty \|\Delta_{\mathcal{S}^c}\|_{2,1} \\ &\leq C_1\sqrt{s+p}\sqrt{\frac{\log p}{n}}\|\Delta_{\mathcal{S}}\|_F + C_1\sqrt{\frac{\log p}{n}}\|\Delta_{\mathcal{S}^c}\|_{2,1}, \end{aligned} \tag{52}$$

where the last inequality comes from Lemma 15 with probability tending to 1. To bound the penalty terms, we note that

$$\begin{aligned} &\|L+\Delta\|_{2,1}^* - \|L\|_{2,1}^* \\ =& \sum_{r=2}^p \sum_{\ell=1}^{r-1} \sqrt{\sum_{m=1}^{\ell} w_{\ell m}^2 (L_{rm}+\Delta_{rm})^2} - \|L_{\mathcal{S}}\|_{2,1}^* \\ =& \sum_{r=2}^p \sum_{\ell=1}^{r-1} \sqrt{\sum_{m:(r,m)\in\mathcal{S}} w_{\ell m}^2 (L_{rm}+\Delta_{rm})^2 + \sum_{m:(r,m)\notin\mathcal{S}} w_{\ell m}^2 (L_{rm}+\Delta_{rm})^2} - \|L_{\mathcal{S}}\|_{2,1}^* \\ \geq& \sum_{r=2}^p \sum_{\ell=1}^{r-1} \sqrt{\sum_{m:(r,m)\in\mathcal{S}} w_{\ell m}^2 (L_{rm}+\Delta_{rm})^2} + \sum_{r=2}^p \sum_{\ell:(r,\ell)\notin\mathcal{S}} |L_{r\ell}+\Delta_{r\ell}| - \|L_{\mathcal{S}}\|_{2,1}^* \\ =& \|L_{\mathcal{S}}+\Delta_{\mathcal{S}}\|_{2,1}^* + \|L_{\mathcal{S}^c}+\Delta_{\mathcal{S}^c}\|_{2,1} - \|L_{\mathcal{S}}\|_{2,1}^* \\ =& \|L_{\mathcal{S}}+\Delta_{\mathcal{S}}\|_{2,1}^* + \|\Delta_{\mathcal{S}^c}\|_{2,1} - \|L_{\mathcal{S}}\|_{2,1}^* \\ \geq& \|\Delta_{\mathcal{S}^c}\|_{2,1} - \|\Delta_{\mathcal{S}}\|_{2,1}^*, \end{aligned}$$

where the last inequality comes from triangle inequality. To give an upper bound on $\|L_{\mathcal{S}}\|_{2,1}^*$, we observe that $2\lambda b \leq a\lambda^2 + b^2/a$ holds for any $a > 0$, and obtain

$$\begin{aligned} 2\lambda\|\Delta_{\mathcal{S}}\|_{2,1}^* &= \sum_{r=2}^p 2\lambda \sum_{\ell=J_r+1}^{r-1} \sqrt{\sum_{m=J_r+1}^{\ell} w_{\ell m}^2 \Delta_{rm}^2} \\ &\leq \left(\sum_{r=2}^p K_r\right)\lambda^2 a + \sum_{r=2}^p \sum_{\ell=J_r+1}^{r-1} \sum_{m=J_r+1}^{\ell} w_{\ell m}^2 \Delta_{rm}^2/a \\ &= \left(\sum_{r=2}^p K_r\right)\lambda^2 a + \sum_{r=2}^p \sum_{m=J_r+1}^{r-1} \left(\sum_{\ell=m}^{r-1} w_{\ell m}^2\right)\Delta_{rm}^2/a. \end{aligned}$$

Now let

$$a = \frac{4}{\kappa^2}\max_r \max_{J_r+1\le m\le r-1}\sum_{\ell=m}^{r-1} w_{\ell m}^2$$
$$= \frac{4}{\kappa^2}\max_r \max_{J_r+1\le m\le r-1}\sum_{\ell=m}^{r-1}\frac{1}{(\ell-m+1)^4} \le \sum_{k=1}^{\infty}\frac{4}{k^4\kappa^2} \le \frac{C_2}{\kappa^2},$$

for some constant $C_2 > 0$, it follows that

$$\lambda\left\|\Delta_{\mathcal{S}}\right\|_{2,1}^* \le \frac{C_2}{\kappa^2}s\lambda^2 + \left\|\Delta_{\mathcal{S}}\right\|_F^2\frac{\kappa^2}{4} \le \frac{C_2}{\kappa^2}s\lambda^2 + \left\|\Delta\right\|_F^2\frac{\kappa^2}{4}.$$

Therefore,

$$\lambda\left(\left\|L+\Delta\right\|_{2,1}^* - \left\|L\right\|_{2,1}^*\right) \ge \lambda\left\|\Delta_{\mathcal{S}^c}\right\|_{2,1} - \frac{C_2}{\kappa^2}s\lambda^2 - \frac{\kappa^2}{4}\left\|\Delta\right\|_F^2. \tag{53}$$

Finally, combining (51), (52), and (53), we have

$$G(\Delta) \ge \frac{\kappa^2}{4}\left\|\Delta\right\|_F^2 - C_1\sqrt{\frac{(s+p)\log p}{n}}\left\|\Delta\right\|_F + \left(\lambda - C_1\sqrt{\frac{\log p}{n}}\right)\left\|\Delta_{\mathcal{S}^c}\right\|_{2,1} - \frac{C_2}{\kappa^2}s\lambda^2.$$

For any $\varepsilon < 1$, choose

$$\lambda = \frac{C_1}{\varepsilon}\sqrt{\frac{\log p}{n}}.$$

Since $\left\|\Delta\right\|_F = Mr_n$, we have

$$G(\Delta) \ge \frac{\kappa^2}{4}M^2r_n^2 - C_1Mr_n^2 + C_1\sqrt{\frac{\log p}{n}}\left(\frac{1}{\varepsilon}-1\right)\left\|\Delta_{\mathcal{S}^c}\right\|_{2,1} - \frac{C_2C_1^2}{\kappa^2\varepsilon^2}\frac{s\log p}{n}$$
$$\ge \left(\frac{\kappa^2}{4}M^2 - C_1M - \frac{C_2C_1^2}{\kappa^2\varepsilon^2}\right)r_n^2 > 0,$$

for M sufficiently large. ■

Appendix J. Proof of Lemma 10

Proof Denote

$$\mathcal{L}\left(\tau, z, \beta; \nu, \phi, a^{(\ell)}\right)$$
$$= -2\log\tau + \frac{1}{n}\left\|z\right\|_2^2 + \nu\left(\tau - \beta_r\right) + \frac{1}{n}\left\langle\phi, z - \mathbf{X}_{1:r}\beta\right\rangle + \lambda\sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * a^{(\ell)}, \beta\right\rangle.$$

Then the primal (8) can be written equivalently as

$$\min_{\tau,z,\beta}\left\{\max_{\nu,\phi,a^{(\ell)}}\left\{\mathcal{L}\left(\tau, z, \beta; \nu, \phi, a^{(\ell)}\right) : \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0\right\}\right\}.$$

The dual function can then be written as

$$g\left(\nu, \phi, a^{(\ell)}\right) = \inf_{\tau,z,\beta}\mathcal{L}\left(\tau, z, \beta; \nu, \phi, a^{(\ell)}\right)$$
$$= \inf_{\tau}\left\{-2\log\tau + \nu\tau\right\} + \inf_{z}\left\{\frac{1}{n}\left\|z\right\|_2^2 + \frac{1}{n}\left\langle\phi, z\right\rangle\right\}$$
$$+ \inf_{\beta}\left\{-\nu\beta_r - \frac{1}{n}\left\langle\mathbf{X}_{1:r}^T\phi, \beta\right\rangle + \lambda\sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * a^{(\ell)}, \beta\right\rangle\right\}$$
$$= 2\log\nu - 2\log 2 + 2 - \mathbb{1}_\infty\left\{\nu > 0\right\} - \frac{1}{4n}\left\|\phi\right\|_2^2$$
$$- \mathbb{1}_\infty\left\{-\nu\mathbf{e}_r - \frac{1}{n}\mathbf{X}_{1:r}^T\phi + \lambda\sum_{\ell=1}^{r-1}W^{(\ell)} * a^{(\ell)} = 0\right\},$$

where $\mathbf{e}_r \in \mathbb{R}^r$ is such that $(\mathbf{e}_r)_r = 1$ and $(\mathbf{e}_r)_j = 0$ for all $j \ne r$. Thus the dual problem (up to a constant) is

$$\max_{\nu,\phi,a^{(\ell)}} g\left(\nu, \phi, a^{(\ell)}\right)$$
$$= \min_{\nu,\phi,a^{(\ell)}}\left\{-2\log\nu + \frac{1}{4n}\left\|\phi\right\|_2^2 \quad \text{s.t.} \quad \nu > 0, \quad \left\|\left(a^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 \le 1, \left(a^{(\ell)}\right)_{g_{r,\ell}^c} = 0,\right.$$
$$\left.\nu\mathbf{e}_r + \frac{1}{n}\mathbf{X}_{1:r}^T\phi = \lambda\sum_{\ell=1}^{r-1}W^{(\ell)} * a^{(\ell)}\right\}.$$

The primal-dual relation is

$$\hat{\beta}_r = \hat{\tau} = \frac{2}{\hat{\nu}} \qquad \hat{\phi} = -2\hat{z} = -2\mathbf{X}_{1:r}\hat{\beta}.$$

This implies that at optimal points

$$-\frac{2}{\hat{\beta}_r}\mathbf{e}_r + 2S_{1:r,1:r}\hat{\beta} + \lambda\sum_{\ell=1}^{r-1}W^{(\ell)} * \hat{a}^{(\ell)} = 0,$$

with $\left\|(\hat{a}^{(\ell)})_{g_{r,\ell}}\right\|_2 \le 1, (\hat{a}^{(\ell)})_{g_{r,\ell}^c} = 0$.

If we denote the objective function as

$$f\left(\beta\right) = -2\log\beta_r + \left\langle S_{1:r,1:r}, \beta\beta^T\right\rangle + \lambda P(\beta),$$

then from the equality $f(\hat{\beta}) = \mathcal{L}\left(\hat{\tau}, \hat{z}, \hat{\beta}; \hat{\nu}, \hat{\phi}, \hat{a}^{(\ell)}\right)$ together with the primal-dual relation, we have

$$P(\hat{\beta}) = \sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * \hat{a}^{(\ell)}, \hat{\beta}\right\rangle = \sum_{\ell=1}^{r-1}\left\langle W^{(\ell)} * \hat{\beta}, \hat{a}^{(\ell)}\right\rangle.$$

Suppose there exists some ℓ with $\hat{\beta}_{g_{r,\ell}} \neq 0$ but $\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}} \neq \frac{\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}}{\left\|\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}\right\|_2}$, then $\left\langle W^{(\ell)} * \hat{\beta}, \hat{a}^{(\ell)} \right\rangle < \left\| \left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}} \right\|_2$ while for other ℓ' by Cauchy-Schwarz inequality we have $\left\langle W^{(\ell')} * \hat{\beta}, \hat{a}^{(\ell')} \right\rangle \leq \left\| \left(W^{(\ell')} * \hat{\beta}\right)_{g_{r,\ell'}} \right\|_2$. Therefore, summing over all $\ell = 1, \ldots, r-1$ would give

$$P(\hat{\beta}) = \sum_{\ell=1}^{r-1} \left\| \left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}} \right\|_2 > \sum_{r=2}^{p} \sum_{\ell=1}^{r-1} \left\langle W^{(\ell)} * \hat{\beta}, \hat{a}^{(\ell)} \right\rangle,$$

which leads to a contradiction. Thus $\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}} = \frac{\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}}{\left\|\left(W^{(\ell)} * \hat{\beta}\right)_{g_{r,\ell}}\right\|_2}$ for $\hat{\beta}_{g_{r,\ell}} \neq 0$ and $\left\|\hat{a}^{(\ell)}_{g_{r,\ell}}\right\|_2 \leq 1$ for $\hat{\beta}_{g_{r,\ell}} = 0$. ■

Appendix K. Proof of Lemma 11

Proof In this proof, we continue to use the notation in Appendix J. Observe that $\mathcal{L}\left(\tau, z, \beta; \nu, \phi, a^{(\ell)}\right)$ is jointly convex in τ, z and β, and it is strictly convex in τ and z. Thus, the minimizers $\hat{z}$ and $\hat{\tau}$ are unique.

To see this in a more general setting, without loss of generality, suppose $f(x, y)$ is convex in y and is strictly convex in x. Then for $x_1 \neq x_2$ and $\theta \in (0, 1)$ we have

$$f\left(\theta x_1 + (1-\theta) x_2, y\right) < \theta f\left(x_1, y\right) + (1-\theta) f\left(x_2, y\right)$$

Now suppose $(\hat{x}_1, \hat{y})$ and $(\hat{x}_2, \hat{y}_2)$ are both minima of f, then taking $\theta = 1/2$ we have $f\left(\frac{\hat{x}_1 + \hat{x}_2}{2}, \hat{y}\right) < f\left(\hat{x}_1, \hat{y}\right) = f\left(\hat{x}_2, \hat{y}\right)$, which leads to a contradiction.

By the primal-dual relation, we know that if $\hat{\beta}$ and $\tilde{\beta}$ are two solutions to (8), then $\hat{\beta}_r = \tilde{\beta}_r$ and $\mathbf{X}_{1:r}\hat{\beta} = \mathbf{X}_{1:r}\tilde{\beta}$. So from the equality $f(\hat{\beta}) = f(\tilde{\beta})$ we know that $P(\tilde{\beta}) = P(\hat{\beta})$. Also by

$$f\left(\hat{\beta}\right) = \mathcal{L}\left(\hat{\tau}, \hat{z}, \hat{\beta}; \hat{\nu}, \hat{\phi}, \hat{a}^{(\ell)}\right) \leq \mathcal{L}\left(\hat{\tau}, \hat{z}, \tilde{\beta}; \hat{\nu}, \hat{\phi}, \hat{a}^{(\ell)}\right) \leq \mathcal{L}\left(\tilde{\tau}, \tilde{z}, \tilde{\beta}; \tilde{\nu}, \tilde{\phi}, \tilde{a}^{(\ell)}\right) = f\left(\tilde{\beta}\right),$$

we have

$$\mathcal{L}\left(\hat{\tau}, \hat{z}, \hat{\beta}; \hat{\nu}, \hat{\phi}, \hat{a}^{(\ell)}\right) = \mathcal{L}\left(\hat{\tau}, \hat{z}, \tilde{\beta}; \hat{\nu}, \hat{\phi}, \hat{a}^{(\ell)}\right),$$

and thus

$$\sum_{\ell=1}^{r-1} \left\langle W^{(\ell)} * \hat{a}^{(\ell)}, \tilde{\beta} \right\rangle = \sum_{\ell=1}^{r-1} \left\langle W^{(\ell)} * \hat{a}^{(\ell)}, \hat{\beta} \right\rangle = P(\hat{\beta}) = P(\tilde{\beta}) = \sum_{\ell=1}^{r-1} \left\| \left(W^{(\ell)} * \tilde{\beta}\right)_{g_{r,\ell}} \right\|_2.$$

Now for any $\ell \leq r-1$ suppose $\left\|\left(\hat{a}^{(\ell)}\right)_{g_{r,\ell}}\right\|_2 < 1$, then for the equality above to hold, we must have $\tilde{\beta}_{g_{r,\ell}} = 0$. Therefore, by Lemma 10, $\hat{\beta}_{g_{r,\ell}} = 0 \implies \tilde{\beta}_{g_{r,\ell}} = 0$, so any other solutions to (8) cannot be less sparse than $\hat{\beta}$. ■

Appendix L. Proof of Lemma 12

Proof By Lemma 11, any other solution β to (8) must have $\beta_{g_{J(\hat{\beta})}} = 0$. Recall that $J(\hat{\beta}) = r - 1 - K(\hat{\beta})$. The original problem (8) can thus be written equivalently as

$$\min_{\gamma \in \mathbb{R}^{K(\hat{\beta})+1}} -2\log\gamma_{K(\hat{\beta})+1} + \frac{1}{n}\left\|\mathbf{X}_{\hat{\mathcal{S}}}\gamma\right\|_2^2 + \lambda \sum_{\ell=1}^{K(\hat{\beta})} \left\| \left(\hat{W}^{(\ell)} * \gamma\right)_{g_{r,\ell}} \right\|_2,$$

where $\hat{W}^{(\ell)} = \left(W^{(\ell+\hat{J})}\right)_{\hat{S}}$.

Note that the penalty term is a convex function of γ. The Hessian matrix of the first term is a diagonal matrix of dimension $|\hat{\mathcal{S}}| = K(\hat{\beta}) + 1$ with non-negative entries in the diagonal. The Hessian matrix of the second term is $2S_{\hat{\mathcal{S}}\hat{\mathcal{S}}}$. Then by Assumption **A1**, the uniqueness follows from strict convexity. ■

Appendix M. Proof of Lemma 14

Proof Recall that

$$M_n = \frac{1}{n}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}^T \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1} \left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} + \frac{4}{n^2\lambda^2}\tilde{\beta}_r^2 \left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2.$$

We cite Lemma 9 (specifically in the form (60)) in Wainwright (2009) here for completeness.

Lemma 18 (Wainwright 2009) *For $k \leq n$, let $\mathbf{X}_{\mathcal{I}} \in \mathbb{R}^{n\times k}$ have i.i.d. rows from a multivariate Gaussian distribution with mean $\mathbf{0}$ and covariance matrix Σ. If Σ has minimum eigenvalue $\kappa > 0$, then*

$$\mathrm{P}\left[\left\|\left(\frac{1}{n}X_{\mathcal{I}}^T X_{\mathcal{I}}\right)^{-1}\right\|_2 \geq \frac{9}{\kappa}\right] \leq 2\exp\left(-\frac{n}{2}\right).$$

By the lemma above, Assumption **A4**, and (41)

$$\begin{aligned}\frac{1}{n}\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}^T \left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1} \left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}} &\leq \frac{9\kappa^2}{n}\left\|\left(\sum_{\ell=1}^{r-1} W^{(\ell)} * \tilde{a}^{(\ell)}\right)_{\mathcal{I}}\right\|^2 \\ &\leq \frac{3\pi^2\kappa^2}{2}\frac{K}{n},\end{aligned}$$

with probability greater than $1 - 2\exp\left(-\frac{n}{2}\right)$.

Next we deal with the second term in M_n. Recall from (37) that

$$\begin{aligned}\frac{4}{n^2\lambda^2}\tilde{\beta}_r^2\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2 &= \frac{4}{n^2}\left(\frac{\frac{1}{2}\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}+\sqrt{\frac{1}{4}\left(\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right)^2+\frac{4}{\lambda^2 n}\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}}{\frac{2}{n}\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}\right)^2\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2\\ &\leq \frac{4}{n^2}\frac{\frac{1}{4}\left(\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right)^2+\frac{4}{\lambda^2 n}\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}{\frac{1}{n^2}\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^4}\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2\\ &= \frac{\left(\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right)^2}{\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}+\frac{16}{\lambda^2 n}.\end{aligned}$$

The next lemma gives us a handle on the numerator of the first term.

Lemma 19 *Using the general weight* (7)*, we have*

$$\mathrm{P}\left[\left|\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right|\geq 1\right]\leq 2\exp\left(-\frac{n\alpha^2}{3\theta\kappa^2\pi^2K}\right)+2\exp\left(-\frac{n}{2}\right).$$

Proof Conditioned on $\mathbf{X}_{\mathcal{I}}$, from the decomposition (39) and the definition of $\mathbf{C}_{\mathcal{I}}$

$$\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}=\Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}+E_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}.$$

By the irrepresentable assumption (**A3**) and (41),

$$\Sigma_{r\mathcal{I}}\left(\Sigma_{\mathcal{I}\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}\leq 1-\alpha.$$

Note that $\mathrm{Var}\left(E_{ir}\right)=\theta_r^{(r)}$ for $i=1,\ldots,n$. Let $B^{(r)}=E_r^T\mathbf{X}_{\mathcal{I}}\left(\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}$. By Lemma 18, $B^{(r)}$ has mean zero and variance at most

$$\mathrm{Var}\left(B^{(r)}\middle|\mathbf{X}_{\mathcal{I}}\right)=\frac{\theta_r^{(r)}}{n}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}^T\left(\frac{1}{n}\mathbf{X}_{\mathcal{I}}^T\mathbf{X}_{\mathcal{I}}\right)^{-1}\left(\sum_{\ell=1}^{r-1}W^{(\ell)}*\tilde{a}^{(\ell)}\right)_{\mathcal{I}}\leq\frac{3\theta_r^{(r)}\kappa^2\pi^2K}{2n},$$

with probability greater than $1-2\exp\left(\frac{n}{2}\right)$. By Lemma 13, we have that

$$\mathrm{P}\left[B^{(r)}\geq\alpha\right]\leq 2\exp\left(-\frac{n\alpha^2}{3\theta_r^{(r)}\kappa^2\pi^2K}\right)+2\exp\left(-\frac{n}{2}\right).$$

■

Since $\frac{\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}{\theta_r^{(r)}}\sim\chi^2\left(n-K\right)$. To bound it, we cite a concentration inequality from Wainwright (2009) (specifically (54b)) as the following lemma:

Lemma 20 (Tail Bounds for χ^2-variates, Wainwright 2009) *For a centralized χ^2-variate X with d degrees of freedom, for all $\varepsilon\in(0,1/2)$, we have*

$$\mathrm{P}\left[X\leq d(1-\varepsilon)\right]\leq\exp\left(-\frac{1}{4}d\varepsilon^2\right).$$

From Lemma 20 it follows that

$$\mathrm{P}\left[\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2\leq\theta_r^{(r)}\left(n-K\right)\left(1-\varepsilon\right)\right]\leq\exp\left(-\frac{1}{4}\left(n-K\right)\varepsilon^2\right),$$

which together with Lemma 19 implies that

$$\begin{aligned}&\mathrm{P}\left[\frac{\left(\mathbf{X}_r^T\mathbf{C}_{\mathcal{I}}\right)^2}{\left\|\mathbf{O}_{\mathcal{I}}E_r\right\|_2^2}\geq\frac{1}{\theta_r^{(r)}\left(n-K\right)\left(1-\varepsilon\right)}\right]\\ \leq&2\exp\left(-\frac{n\alpha^2}{3\theta_r^{(r)}\kappa^2\pi^2K}\right)+2\exp\left(-\frac{n}{2}\right)+\exp\left(-\frac{1}{4}\left(n-K\right)\varepsilon^2\right).\end{aligned}$$

The result follows from a union bound. ■

Appendix N. Proof of Lemma 15

Proof The proof strategy is based on the proof of Lemma 2 in Bien et al. (2016).

For the design matrix $\mathbf{X}_{n\times p}$ with independent rows, denote $X_i=\left(\mathbf{X}_{i\cdot}\right)^T\in\mathbb{R}^p$. Then X_i are i.i.d with mean 0 and true covariance matrix $\Sigma=\left(L^TL\right)^{-1}$ for $i=1,...,n$. And $\bar{X}=\frac{1}{n}\sum_{i=1}^n X_i$ has mean 0 and true covariance matrix $\frac{1}{n}\Sigma$.

Let $Y_i=LX_i\in\mathbb{R}^p$. Then Y_i are i.i.d with mean 0 and true covariance matrix $L\Sigma L^T=L\left(L^TL\right)^{-1}L^T=\mathbf{I}_p$. And $\bar{Y}=\frac{1}{n}\sum_{i=1}^n Y_i=\frac{1}{n}\sum_{i=1}^n LX_i=L\bar{X}$ has mean zero and covariance matrix $\frac{1}{n}\mathbf{I}_p$. Also the corresponding design matrix $\mathbf{Y}=\mathbf{X}L^T$ has independent rows.

$$\begin{aligned}SL^T&=\frac{1}{n}\sum_{i=1}^n\left(X_i-\bar{X}\right)\left(X_i-\bar{X}\right)^TL^T\\ &=\frac{1}{n}\sum_{i=1}^n\left(X_i-\bar{X}\right)\left(LX_i-L\bar{X}\right)^T=\frac{1}{n}\sum_{i=1}^n\left(X_i-\bar{X}\right)\left(Y_i-\bar{Y}\right)^T.\end{aligned}$$

So we have

$$\left(SL^T\right)_{ij}=n^{-1}\sum_{k=1}^p X_{ki}Y_{kj}-\bar{X}_i\bar{Y}_j.$$

Letting

$$\mathcal{W}=SL^T-L^{-1},$$

we have that

$$\left|\mathcal{W}_{ij}\right|\leq\left|n^{-1}\sum_{k=1}^p X_{ki}Y_{kj}-\left(L^{-1}\right)_{ij}\right|+\left|\bar{X}_i\bar{Y}_j\right|.$$

$$
\begin{aligned}
&\mathrm{P}\left[\max_{ij}|\mathcal{W}|_{ij} > t\right] \\
\leq &\mathrm{P}\left[\max_{ij}\left|n^{-1}\sum_{k=1}^{p} X_{ki}Y_{kj} - \left(L^{-1}\right)_{ij}\right| > \frac{t}{2}\right] + \mathrm{P}\left[\max_{ij}\left|\bar{X}_i\bar{Y}_j\right| > \frac{t}{2}\right] \\
\leq &\mathrm{P}\left[\left|n^{-1}\sum_{k=1}^{p} X_{ki}Y_{kj} - \left(L^{-1}\right)_{ij}\right| > \frac{t}{2} \text{ for some } i,j\right] \\
&+ \mathrm{P}\left[\max_{i}\left|\bar{X}_i\right| > \sqrt{\frac{t}{2}}\right] + \mathrm{P}\left[\max_{j}\left|\bar{Y}_j\right| > \sqrt{\frac{t}{2}}\right] \\
\leq &\sum_{ij}\mathrm{P}\left[\left|n^{-1}\sum_{k=1}^{p} X_{ki}Y_{kj} - \left(L^{-1}\right)_{ij}\right| > \frac{t}{2}\right] + \sum_{i}\mathrm{P}\left[\left|\bar{X}_i\right| > \sqrt{\frac{t}{2}}\right] + \sum_{j}\mathrm{P}\left[\left|\bar{Y}_j\right| > \sqrt{\frac{t}{2}}\right] \\
\leq &p^2\max_{ij}\mathrm{P}\left[\left|n^{-1}\sum_{k=1}^{p} X_{ki}Y_{kj} - \left(L^{-1}\right)_{ij}\right| > \frac{t}{2}\right] \\
&+ p\max_{i}\mathrm{P}\left[\left|\bar{X}_i\right| > \sqrt{\frac{t}{2}}\right] + p\max_{j}\mathrm{P}\left[\left|\bar{Y}_j\right| > \sqrt{\frac{t}{2}}\right] \\
:= &p^2\max_{ij} I_{ij} + p\max_{i} I_i^X + p\max_{j} I_j^Y .
\end{aligned}
$$

Consider I_i^X first. Since X_{ki} are independent sub-Gaussian with variance Σ_{ii} for $k = 1, .., n$, we have

$$
\begin{aligned}
\mathrm{E}\exp\left(t\frac{\bar{X}_i}{\sqrt{\Sigma_{ii}/n}}\right) &= \prod_{k=1}^{n}\mathrm{E}\exp\left(t\frac{X_{ki}}{\sqrt{n\Sigma_{ii}}}\right) \quad \text{by independence} \\
&\leq \prod_{k=1}^{n}\exp\left(\tilde{C}_1 t^2/n\right) = \exp(\tilde{C}_1 t^2) \quad \text{by the definition of sub-Gaussian,}
\end{aligned}
$$

so $\bar{X}_i$ is sub-Gaussian with variance Σ_{ii}/n.

By Lemma 5.5 in Vershynin (2010), we have

$$
\mathrm{P}\left[\left|\bar{X}_i\right|/\sqrt{\Sigma_{ii}^*} > t\right) \leq \exp\left(1 - t^2/K_1^2\right],
$$

where K_1 is a constant that does not depend on i.

Following the same argument we have

$$
\mathrm{E}\exp\left(t\bar{Y}_i/\sqrt{1/n}\right) = \prod_{k=1}^{n}\mathrm{E}\exp\left(tY_{ki}/\sqrt{n}\right) \leq \exp\left(\tilde{C}_2 t^2\right),
$$

thus

$$
\mathrm{P}\left[\left|\bar{Y}_i\right|/\sqrt{1/n} > t\right) \leq \exp\left(1 - t^2/K_2^2\right],
$$

where K_2 is a constant that does not depend on i. And we have

$$
\begin{aligned}
I_i^X + I_i^Y &= \mathrm{P}\left[\left|\bar{X}_i\right| > \sqrt{t/2}\right] + \mathrm{P}\left[\left|\bar{Y}_i\right| > \sqrt{t/2}\right] \\
&= \mathrm{P}\left[\frac{\left|\bar{X}_i\right|}{\sqrt{\Sigma_{ii}/n}} > \frac{\sqrt{t/2}}{\sqrt{\Sigma_{ii}/n}}\right] + \mathrm{P}\left[\left|\frac{\bar{Y}_i}{\sqrt{1/n}}\right| > \frac{\sqrt{t/2}}{\sqrt{1/n}}\right] \\
&\leq \exp\left(1 - \frac{nt}{2K_1^2\Sigma_{ii}^*}\right) + \exp\left(1 - \frac{nt}{2K_2^2}\right).
\end{aligned}
$$

Thus

$$
\max_i\left(I_i^X + I_i^Y\right) \leq 4\exp\left(-\frac{C_1 nt}{\max_i \Sigma_{ii}^*}\right) + 4\exp\left(-C_2 nt\right)
$$

for some constant C_1.

Now consider the term I_{ij}. We have shown that both $\mathbf{X}$ and $\mathbf{Y}$ have independent rows. So for any i, j, $Z_k^{(ij)} = X_{ki}Y_{kj}$ are independent for $k = 1, \ldots, n$. Let $X \sim N(\mathbf{0}, \Sigma)$ and $Y \sim N(0, \mathbf{I}_p)$, then

$$
\mathrm{E}\left(X_{ki}Y_{kj}\right) = \mathrm{Cov}\left(X, LX\right)_{ij} - 0 = \left[\mathrm{Cov}\left(X, X\right)L^T\right]_{ij} = \left(\Sigma L^T\right)_{ij} = \left(L^{-1}\right)_{ij}.
$$

If there exist ν_{ij} and c_{ij} such that

$$
\begin{aligned}
&\sum_{k=1}^{n}\mathrm{E}\left(X_{ki}^2Y_{kj}^2\right) \leq \nu_{ij} \\
&\sum_{k=1}^{n}\mathrm{E}\left\{\left(X_{ki}Y_{kj}\right)_+^q\right\} \leq \frac{q!}{2}\nu_{ij}c_{ij}^{q-2} \quad \text{for some} \quad q \geq 3 \in \mathbb{N},
\end{aligned}
$$

then by Theorem 2.10 (Corollary 2.11) in Boucheron et al. (2013), $\forall t > 0$, we have

$$
\mathrm{P}\left[\left|\sum_{k=1}^{n}\left(X_{ki}Y_{kj} - (L)_{ij}^{-1}\right)\right| > t\right] \leq 2\exp\left(-\frac{t^2}{2\left(\nu_{ij} + c_{ij}t\right)}\right).
$$

The rest of the proof focuses on characterizing ν_{ij} and c_{ij}. First, Lemma 5.5 in Vershynin (2010) shows that, for some constant K_3 that does not depend on j,

$$
\left(\mathrm{E}\left|X_{ij}/\sqrt{\Sigma_{jj}}\right|^q\right)^{1/q} \leq K_3\sqrt{q}
$$

holds for all $q \geq 1$. Thus,

$$
\mathrm{E}\left|X_{ij}\right|^q \leq K_3^q q^{q/2}\left(\Sigma_{jj}\right)^{q/2}.
$$

Following the same argument, there exists some constant K_4 that does not depend on j such that

$$
\mathrm{E}\left|Y_{ij}\right|^q \leq K_4^q q^{q/2}
$$

for all $q \geq 1$.

Therefore,

$$\sum_{k=1}^{n} \mathrm{E}\left(X_{ki}^2 Y_{kj}^2\right) \leq \sum_{k=1}^{n} \sqrt{\mathrm{E}X_{ki}^4 \mathrm{E}Y_{kj}^4} \leq n\sqrt{K_3^4 2^4 K_4^4 2^4 {\Sigma_{ii}}^2} = 16nK_3^2 K_4^2 \Sigma_{ii},$$

and

$$\sum_{k=1}^{n} \mathrm{E}\left\{(X_{ki}Y_{kj})_+^q\right\} \leq \sum_{k=1}^{n} \sqrt{\mathrm{E}X_{ki}^{2q} \mathrm{E}Y_{kj}^{2q}} \leq n\sqrt{K_3^{2q}(2q)^{2q} K_4^{2q} \left(\Sigma_{ii}\right)^2} = nK_3^q K_4^q (2q)^q \left(\Sigma_{ii}\right)^{q/2}.$$

So taking

$$\nu_{ij} = K_5 n \Sigma_{ii}^*,$$
$$c_{ij} = K_5 \sqrt{\Sigma_{ii}^*}$$

for some K_5 large enough and does not depend on i, j.

Now we have

$$I_{ij} \leq 2\exp\left(-\frac{n^2t^2}{4\left(2\nu_{ij} + c_{ij}tn\right)}\right) = 2\exp\left(-\frac{nt^2}{4\left(2K_5\Sigma_{ii}^* + K_5\sqrt{\Sigma_{ii}}t\right)}\right).$$

If $t \leq 2\max_i \sqrt{\Sigma_{ii}^*}$, then with $C_3 = (16K_5)^{-1}$ we have

$$I_{ij} \leq 2\exp\left(-\frac{C_2 nt^2}{\max_i \Sigma_{ii}^*}\right).$$

To sum up, for any $0 < t \leq 2\max_i \sqrt{\Sigma_{ii}^*}$,

$$\mathrm{P}\left[\max_{ij}|\mathcal{W}_{ij}| > t\right] \leq 2p^2\exp\left(-\frac{C_2 nt^2}{\max_i \Sigma_{ii}^*}\right) + 4p\exp\left(-\frac{C_1 nt}{\max_i \Sigma_{ii}^*}\right) + 4p\exp\left(-C_2 nt\right).$$

Abstract

A plethora of networks is being collected in a growing number of fields, including disease transmission, international relations, social interactions, and others. As data streams continue to grow, the complexity associated with these highly multidimensional connectivity data presents novel challenges. In this paper, we focus on the time-varying interconnections among a set of actors in multiple contexts, called layers. Current literature lacks flexible statistical models for dynamic multilayer networks, which can enhance quality in inference and prediction by efficiently borrowing information within each network, across time, and between layers. Motivated by this gap, we develop a Bayesian nonparametric model leveraging latent space representations. Our formulation characterizes the edge probabilities as a function of shared and layer-specific actors positions in a latent space, with these positions changing in time via Gaussian processes. This representation facilitates dimensionality reduction and incorporates different sources of information in the observed data. In addition, we obtain tractable procedures for posterior computation, inference, and prediction. We provide theoretical results on the flexibility of our model. Our methods are tested on simulations and infection studies monitoring dynamic face-to-face contacts among individuals in multiple days, where we perform better than current methods in inference and prediction.

Keywords: Dynamic multilayer network, edge prediction, face-to-face contact network, Gaussian process, latent space model

1. Introduction

Data on social interaction processes are rapidly becoming highly multidimensional, increasingly complex and inherently dynamic, providing a natural venue for machine learning as seen in applications such as disease transmission (Marathe and Ramakrishnan, 2013), international relations (Schein et al., 2016), social interactions (Guo et al., 2015), and others.

While modeling of a single network observation is still an active area of research, the increasing availability of multidimensional networks from World Wide Web architectures (Leetaru and Schrodt, 2013), telecommunication infrastructures (Blondel et al., 2015) and human sensing devices (Cattuto et al., 2010), have motivated more flexible statistical models. This endeavor is particularly relevant in the dynamic multilayer network field, providing information on the time-varying connectivity patterns among a set of actors in different contexts. Notable examples include dynamic relationships between individuals according to multiple forms of social interactions (Snijders et al., 2013), and time-varying connectivity structures among countries based on different types of international relations (Hoff, 2015).

In modeling these highly complex networks, it is of paramount interest to learn the wiring processes underlying the observed data and to infer differences in network structures across layers and times. Improved estimation of the data's generating mechanism can refine the understanding of social processes and enhance the quality in prediction of future networks. In order to successfully accomplish these goals, it is important to define statistical models which can incorporate the different sources of information in the observed data, without affecting flexibility. However, current literature lacks similar methods, to our knowledge.

Motivated by this gap, we develop a Bayesian nonparametric model for dynamic multilayer networks which efficiently incorporates dependence within each network, across time, and between the different layers, while preserving flexibility. Our formulation borrows network information by defining the edge probabilities as a function of pairwise similarities between actors in a latent space. To share information among layers without affecting flexibility in characterizing layer-specific structures, we force a subset of the latent coordinates of each actor to be common across layers, and let the remaining coordinates to vary between layers. Finally, we accommodate network dynamics by allowing these actors coordinates to change in time, and incorporate time information by modeling the dynamic actors coordinates via Gaussian processes (e.g., Rasmussen and Williams, 2006). Our model is tractable and has a theoretical justification, while providing simple procedures for inference and prediction. In addition, we find that our procedures outperform current methods in inference and out-of-sample prediction on both simulated and real data.

The paper proceeds as follows. Section 1.1 reviews recent contributions in the literature, and Section 1.2 provides a motivational example of dynamic multilayer networks. Section 2 describes our Bayesian latent space model, while Section 3 discusses its properties. Methods for posterior computation and prediction are provided in Section 4. Section 5 highlights the performance gains of our model compared to other possible competitors in a simulation study, whereas Section 6 illustrates on infection studies, monitoring face-to-face contacts, our success in inference and prediction, compared to possible competitors. Future directions of research and additional fields of application are discussed in Section 7.

1.1 Related Work

Current literature for multidimensional network data considers settings in which the multiple networks are either dynamic or multilayer. Statistical modeling of dynamic networks has focused on stochastic processes which are designed to borrow information between edges and across time (e.g., Hanneke et al., 2010; Snijders et al., 2010; Xing et al., 2010; Yang et al., 2011; Durante and Dunson, 2014; Crane, 2016), whereas inference for multilayer net-

works has motivated formulations which can suitably induce dependence between edges and across the different types of relationships—characterizing the multiple layers (e.g., Gollini and Murphy, 2016; Han et al., 2015; Heaney, 2014). These contributions have generalized exponential random graph models (Holland and Leinhardt, 1981; Frank and Strauss, 1986) and latent variables models (Nowicki and Snijders, 2001; Hoff et al., 2002; Airoldi et al., 2008) for a single network to allow inference in multidimensional frameworks, when the multiple networks arise either from dynamic or multilayer studies. These methods are valuable building blocks for more flexible models, but fall far short of the goal of providing efficient procedures in more complex settings when the networks are both dynamic and multilayer.

The routine collection of dynamic multilayer networks is a recent development and statistical modeling of such data is still in its infancy. For example, Lee and Monge (2011) considered a generalization of exponential random graph models for multilayer networks, but performed a separate analysis for each time point. Oselio et al. (2014) focused instead on a dynamic stochastic block model which borrows information across time and within each network, but forces the underlying block structures to be shared between layers. Dynamic multilayer networks are complex objects combining homogenous structures shared between actors, layers, and smoothly evolving across time, with layer-specific patterns and across-actor heterogeneity. Due to this, any procedure that fails to incorporate the different sources of information in the observed data (e.g., Lee and Monge, 2011) is expected to lose efficiency, whereas models focusing on shared patterns (e.g., Oselio et al., 2014) may lack flexibility.

More general formulations are the multilayer stochastic actor-oriented model (Snijders et al., 2013) and the multilinear tensor regression (Hoff, 2015). Snijders et al. (2013) allowed for dynamic inference on network properties within and between layers, but failed to incorporate across-actor heterogeneity. This may lead to a lack of flexibility in prediction. Hoff (2015) considered autoregressive models with the vector of parameters having a tensor factorization representation. This formulation allows for across-actor heterogeneity, but forces the model parameters to be constant across time. In addition, the parameterization of the interdependence between layers relies on homogeneity assumptions. Consistent with these methods, our representation incorporates the different types of dependencies in the observed data, but crucially preserves flexibility to avoid restrictive homogeneity assumptions.

1.2 Motivating Application

Our motivation is drawn from epidemiologic studies monitoring hourly face-to-face contacts among individuals in a rural area of Kenya, during three consecutive days. Data are available from the human sensing platform SocioPatterns (`http://www.sociopatterns.org`) and have been collected using wearable devices that exchange low-power radio packets when two individuals are located within a sufficiently close distance to generate a potential occasion of contagion. Leveraging this technology it is possible to measure for each hour in the three consecutive days which pairs of actors had a face-to-face proximity contact. These information are fundamental to monitor the spread of diseases and learn future patterns. Refer also to Cattuto et al. (2010) for a detailed description of the data collection technology, and Kiti et al. (2016) for a more in-depth discussion of our motivating application.

As illustrated in Figure 1, the observed data can be structured as a dynamic multilayer network characterized by a sequence of $V \times V$ symmetric adjacency matrices $Y_{t_i}^{(k)}$ collected

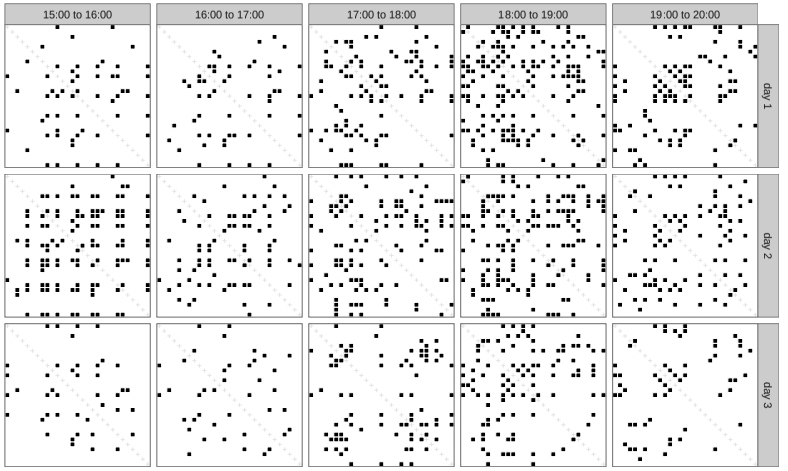

Figure 1: For five consecutive hours in the three days, adjacency matrices $Y_{t_i}^{(k)}$ representing the observed contact networks. Black refers to an edge, and white to a non-edge.

on a common time grid $t_1, \ldots, t_n$ in different days $k = 1, \ldots, K$. The matrices have entries $Y_{t_i[vu]}^{(k)} = Y_{t_i[uv]}^{(k)} = 1$ if actors v and u interact at time t_i in day k, and $Y_{t_i[vu]}^{(k)} = Y_{t_i[uv]}^{(k)} = 0$ otherwise, for every $v = 2, \ldots, V$ and $u = 1, \ldots, v-1$. Dynamic multilayer proximity data provide key information on infections spread (Cauchemez et al., 2011), facilitating the design of outbreak prevention policies (Vanhems et al., 2013). The importance of this endeavor has motivated a wide variety of descriptive studies summarizing the information provided by face-to-face proximity data in several environments, including hospitals (Vanhems et al., 2013), schools (Stehlé et al., 2011) and households (Kiti et al., 2016).

Although the above analyses provide key insights on the connectivity processes underlying the observed proximity data, explicitly accounting for variability in network structures via carefully tailored statistical models can lead to improved learning of the connectivity patterns and properties, while providing methodologies for formal inference in the network framework, including estimation techniques, uncertainty quantification and prediction. In Section 6, we apply our methodology to this motivating application, showing how a careful statistical model for dynamic multilayer network data can provide substantial performance gains in learning underlying social processes and predicting future contact patterns.

2. Dynamic Multilayer Latent Space Model

Let $Y_{t_i}^{(k)}$ denote the $V \times V$ adjacency matrix characterizing the undirected network observed at time $t_i \in \Re^+$ in layer k, for any $t_i = t_1, \ldots, t_n$ and $k = 1, \ldots, K$. Each matrix has binary elements $Y_{t_i[vu]}^{(k)} = Y_{t_i[uv]}^{(k)} \in \{0, 1\}$ measuring the absence or presence of an edge among actors

Type of information	**Illustrative example**
Network information	If individual v had a face-to-face contact with both actors u and w at time t_i in day k, this information may be relevant to learn the face-to-face contact behavior between u and w at time t_i in day k.
Layer information	If individuals v and u had a face-to-face contact at time t_i in day k, this information may be relevant to learn the contact behavior between v and u at the same time t_i in other days.
Time information	If individuals v and u had a face-to-face contact at time t_i in day k, this information may be relevant to learn the contact behavior between v and u at the next time t_{i+1} in the same day.

Table 1: Relevant sources of information characterizing a dynamic multilayer network.

v and u at time t_i in layer k, for every $v = 2, \ldots, V$ and $u = 1, \ldots, v-1$. When modeling the data $Y = \{Y_{t_i}^{(k)} : t_i = t_1, \ldots, t_n,\ k = 1, \ldots, K\}$, we assume that Y is a realization, on a finite time grid, of the stochastic process $\mathcal{Y} = \{\mathcal{Y}^{(k)}(t) : t \in \mathbb{T} \subset \Re^+,\ k = 1, \ldots, K\}$, and seek a provably flexible representation for the probabilistic generative mechanism associated with the stochastic process $\mathcal{Y}$. Note that, as each random adjacency matrix $\mathcal{Y}^{(k)}(t)$ is symmetric and the diagonal elements—denoting self-relations—are not of interest, it is sufficient to model its lower triangular elements $\{\mathcal{Y}_{vu}^{(k)}(t) : v = 2, \ldots, V,\ u = 1, \ldots, v-1\}$.

One major modeling objective is to carefully incorporate dependence among edges, between layers and across time, without affecting flexibility. Recalling the motivating application in Section 1.2 and Figure 1, it is reasonable to expect three main sources of information in the dynamic multilayer face-to-face contact data, summarized in Table 1. Incorporating such information can substantially improve the quality of inference and prediction, while facilitating dimensionality reduction. However, in reducing dimensionality and borrowing of information, it is important to avoid restrictive formulations that lead to inadequate characterizations of dynamic patterns, layer-specific structures, and across-actor heterogeneity.

We accomplish the aforementioned goals via a flexible dynamic latent bilinear model, combining shared and layer-specific actors coordinates which are allowed to change in time via Gaussian process priors. Section 2.1 describes our model formulation with a focus on sharing network and layer information, whereas Section 2.2 clarifies how time information is effectively incorporated via Gaussian processes.

2.1 Dynamic Bilinear Model with Shared and Layer-Specific Coordinates

In order to incorporate network and layer information, while preserving flexibility, we adapt latent bilinear models for a single network (Hoff, 2005) to our dynamic multilayer framework. In particular, we characterize the edges as conditionally independent Bernoulli random variables given their corresponding edge probabilities, and borrow information within each network by defining these probabilities as a function of the actors coordinates in a latent space. In order to incorporate dependence among the different layers, we force a subset of these coordinates to be common across layers, and allow the remaining coordinates to change

between layers. This last choice facilitates a flexible characterization of more irregular events and incorporates differences between layers in specific contact patterns.

Consistent with the aforementioned statistical model, and letting $\pi_{vu}^{(k)}(t) \in (0,1)$ denote the probability of an edge between actors v and u at time $t \in \mathbb{T}$ in layer k, we define

$$\mathcal{Y}_{vu}^{(k)}(t) \mid \pi_{vu}^{(k)}(t) \sim \text{Bern}\{\pi_{vu}^{(k)}(t)\}, \tag{1}$$

independently for every time $t \in \mathbb{T}$, layer $k = 1, \ldots, K$ and pair of actors $[vu]$, $v = 2, \ldots, V$, $u = 1, \ldots, v-1$. To incorporate our multilayer bilinear representation having shared and layer-specific latent coordinates, we express the log-odds of each edge probability as

$$\text{logit}\{\pi_{vu}^{(k)}(t)\} = \mu(t) + \sum_{r=1}^{R} \bar{x}_{vr}(t)\bar{x}_{ur}(t) + \sum_{h=1}^{H} x_{vh}^{(k)}(t)x_{uh}^{(k)}(t), \tag{2}$$

where $\bar{x}_{vr}(t) \in \Re$ is the rth coordinate of actor v at time t shared across the different layers, whereas $x_{vh}^{(k)}(t) \in \Re$ denotes the hth coordinate of actor v at time t specific to layer k, for every $t \in \mathbb{T}$, $k = 1, \ldots, K$, $v = 1, \ldots, V$, $r = 1, \ldots, R$ and $h = 1, \ldots, H$. Finally, $\mu(t) \in \Re$ represents a time-varying baseline parameter centering the log-odds processes to improve computational and mixing performance.

In equation (2) the probability of an edge between actors v and u at time $t \in \mathbb{T}$ in layer k, increases with $\sum_{r=1}^{R} \bar{x}_{vr}(t)\bar{x}_{ur}(t)$ and $\sum_{h=1}^{H} x_{vh}^{(k)}(t)x_{uh}^{(k)}(t)$. Note that $\sum_{r=1}^{R} \bar{x}_{vr}(t)\bar{x}_{ur}(t) \in \Re$ characterizes a similarity measure between actors v and u at time t common to all the layers, whereas $\sum_{h=1}^{H} x_{vh}^{(k)}(t)x_{uh}^{(k)}(t) \in \Re$ defines a layer-specific deviation from this shared similarity, which enhances flexibility in modeling network structures specific to layer k. These similarity measures are defined as the dot product of shared and layer-specific actors coordinates in a latent space, allowing actors with coordinates in the same direction to have an higher chance of contact than actors with coordinates in opposite directions.

The dot product characterization in equation (2) is in the same spirit as the factorization in Hoff (2005) for a single network, and allows dimensionality reduction from $n \times K \times V \times (V-1)/2$ time-varying log-odds to $n \times \{1 + V \times (R + H \times K)\}$ dynamic latent coordinates, where typically $R \ll V$ and $H \ll V$. Although it is possible to consider other concepts of similarity when relating the latent coordinates to the log-odds (e.g., Hoff et al., 2002), the dot product representation facilitates the definition of simple algorithms for posterior inference and has been shown to efficiently borrow information within the network, while accommodating topological structures of interest such as homophily, transitivity, and others.

2.1.1 Interpretation and Identifiability

Recall the motivating application described in Section 1.2, our representation has an intuitive interpretation. In fact, the latent coordinates of each actor may represent his propensity towards $R + H$ latent interests or tasks. According to the factorization in equation (2), actors having propensities for the different interests in the same directions are expected to be more similar than actors with interests in opposite directions. Therefore, these actors are more likely to interact according to equation (1). Part of these actors interests or tasks may be associated with a common routine or constrained by daytime schedules. Therefore, the actors propensities towards these interests are expected to remain constant across days

providing a subset of R shared coordinates. Finally, these propensities are allowed to change across time inducing dynamic variations in the contacts within each day.

Although inference for the latent coordinates is potentially of interest, the factorization in equation (2) is not unique. In fact, it is easy to show that there exist many different latent coordinates values leading to the same collection of edge probabilities under the factorization in equation (2). However, such an overcomplete representation does not lead to identifiability issues if inference focuses on identified functionals of the latent coordinates, and has beneficial effects in terms of posterior computation and borrowing of information (Bhattacharya and Dunson, 2011; Ghosh and Dunson, 2009). Our focus is not on estimating the latent coordinates, but on leveraging the factorization in equation (2) to enhance efficiency in learning of identified functionals of the edge probabilities and improve prediction of future networks. Therefore, we avoid identifiability constraints on the latent coordinates in equation (2) as they are not required to ensure identifiability of the edge probabilities.

2.2 Gaussian Process Priors for the Time-Varying Latent Coordinates

Equation (2) facilitates borrowing of information among edges and between layers. This is obtained by leveraging the shared dependence on a common set of latent coordinates. We additionally incorporate across-layer heterogeneity via a set of layer-specific latent positions. Moreover, these coordinates are allowed to vary across time in order to accommodate flexible dynamic variations in the multilayer network structure. While it is possible to estimate the edge probabilities separately for every time point, this approach may be suboptimal in ruling out relevant temporal dependence. As seen in Figure 1, it is reasonable to expect a degree of dependence between the contact networks observed at close times, with this dependence decreasing with the time lag. Therefore, a formulation sharing information across time may provide substantial benefits in terms of efficiency, uncertainty propagation, and prediction.

Motivated by dynamic modeling of a single network, Durante and Dunson (2014) addressed a related goal by considering Gaussian process priors for the actors latent coordinates, with an additional shrinkage effect to facilitate automatic adaptation of the latent space dimensions and avoid overfitting. In the spirit of their proposed methods, we define

$$\bar{x}_{vr}(\cdot) \sim \mathrm{GP}(0, \tau_r^{-1} c_{\bar{x}}), \qquad \text{with} \;\; c_{\bar{x}}(t_i, t_j) = \exp\{-\kappa_{\bar{x}}(t_i - t_j)^2\}, \kappa_{\bar{x}} > 0, \tag{3}$$

independently for $v = 1, \ldots, V$, $r = 1, \ldots, R$ and

$$x_{vh}^{(k)}(\cdot) \sim \mathrm{GP}(0, \tau_h^{(k)-1} c_x), \quad \text{with} \;\; c_x(t_i, t_j) = \exp\{-\kappa_x(t_i - t_j)^2\}, \kappa_x > 0, \tag{4}$$

independently for $v = 1, \ldots, V$, $h = 1, \ldots, H$ and $k = 1, \ldots, K$. In the prior specification given in equations (3)–(4), the quantities $c_{\bar{x}}(t_i, t_j)$ and $c_x(t_i, t_j)$ denote the squared exponential correlation functions of the Gaussian processes for the shared and layer-specific latent coordinates, respectively. The quantities $\tau_1^{-1}, \ldots, \tau_R^{-1}$ and $\tau_1^{(k)-1}, \ldots, \tau_H^{(k)-1}$, for each $k = 1, \ldots, K$, are instead positive shrinkage parameters controlling the concentration of the latent coordinates around the zero constant mean function. Focusing on the prior for the trajectories of the rth shared coordinates $\bar{x}_{vr}(\cdot)$, $v = 1, \ldots, V$, a value of τ_r^{-1} close to zero forces these trajectories to be concentrated around the zero constant mean function, reducing the effect of the rth shared dimension in defining the edge probabilities in equation (2).

In order to penalize highly parameterized representations and facilitate adaptive deletion of unnecessary dimensions, the above shrinkage effects are designed to be increasingly strong as the latent coordinates indices $r = 1, \ldots, R$ and $h = 1, \ldots, H$ increase. This goal is accomplished by considering the following multiplicative inverse gamma priors (Bhattacharya and Dunson, 2011) for the shrinkage parameters:

$$\frac{1}{\tau_r} = \prod_{m=1}^{r} \frac{1}{\delta_m}, \;\; r = 1, \ldots, R, \;\text{with}\; \delta_1 \sim \mathrm{Ga}(a_1, 1), \;\; \delta_{m \geq 2} \sim \mathrm{Ga}(a_2, 1), \tag{5}$$

$$\frac{1}{\tau_h^{(k)}} = \prod_{l=1}^{h} \frac{1}{\delta_l^{(k)}}, \;\; h = 1, \ldots, H, \;\; k = 1, \ldots, K, \;\text{with}\; \delta_1^{(k)} \sim \mathrm{Ga}(a_1, 1), \;\; \delta_{l \geq 2}^{(k)} \sim \mathrm{Ga}(a_2, 1). \tag{6}$$

According to Bhattacharya and Dunson (2011), the multiplicative inverse gamma prior in equations (5)–(6) induces prior distributions for the shrinkage parameters with a cumulative shrinkage effect. In particular, these priors are increasingly concentrated close to zero as the indices $r = 1, \ldots, R$ and $h = 1, \ldots, H$ increase, for appropriate $a_1 \in \Re^+$ and $a_2 \in \Re^+$, facilitating adaptive dimensionality reduction and reducing overfitting issues. Refer also to Durante (2017) for an additional discussion on the multiplicative inverse gamma prior and its shrinkage properties. To conclude the prior specification, we let $\mu(\cdot) \sim \mathrm{GP}(0, c_\mu)$, with $c_\mu(t_i, t_j) = \exp\{-\kappa_\mu(t_i - t_j)^2\}$, $\kappa_\mu > 0$.

The Gaussian process prior provides an accurate choice in our setting which incorporates time dependence, allowing the amount of information shared between networks to increase as the time lag decreases. Beside improving efficiency, the Gaussian process prior can deal with multilayer networks observed at potentially unequally spaced time grids, and is closely related to the multivariate Gaussian distribution, providing substantial benefits in terms of computational tractability and interpretability. In fact, following Rasmussen and Williams (2006), equations (3)–(4) imply the following prior for the shared and layer-specific latent coordinates at the finite time grid $t_1, \ldots, t_n$ on which data are observed:

$$\{\bar{x}_{vr}(t_1), \ldots, \bar{x}_{vr}(t_n)\}^\intercal \sim \mathrm{N}_n(0, \tau_r^{-1} \Sigma_{\bar{x}}), \tag{7}$$

independently for $v = 1, \ldots, V$, $r = 1, \ldots, R$ and

$$\{x_{vh}^{(k)}(t_1), \ldots, x_{vh}^{(k)}(t_n)\}^\intercal \sim \mathrm{N}_n(0, \tau_h^{(k)-1} \Sigma_x), \tag{8}$$

independently for $v = 1, \ldots, V$, $h = 1, \ldots, H$, and $k = 1, \ldots, K$. In equations (7)–(8), the $n \times n$ variance and covariance matrices $\Sigma_{\bar{x}}$ and Σ_x have elements $\Sigma_{\bar{x}[ij]} = \exp\{-\kappa_{\bar{x}}(t_i - t_j)^2\}$ and $\Sigma_{x[ij]} = \exp\{-\kappa_x(t_i - t_j)^2\}$, respectively. The same holds for the baseline process obtaining $\{\mu(t_1), \ldots, \mu(t_n)\}^\intercal \sim \mathrm{N}_n(0, \Sigma_\mu)$.

3. Model Properties

In order to ensure accurate learning and prediction, it is important to guarantee that our factorization in equation (2) along with the Gaussian process priors for its components are sufficiently flexible to approximate a broad variety of dynamic multilayer edge probability processes. These properties are stated in Propositions 1 and 2. See Appendix A for detailed proofs. In particular, Proposition 1 guarantees that equation (2) is sufficiently flexible to

characterize any collection $\pi(t) = \{\pi_{vu}^{(k)}(t) \in (0,1) : k = 1,\ldots,K,\ v = 2,\ldots,V,\ u = 1,\ldots,v-1\}$ for every time $t \in \mathbb{T}$.

Proposition 1 *Let $\pi(t) = \{\pi_{vu}^{(k)}(t) \in (0,1) : k = 1,\ldots,K,\ v = 2,\ldots,V,\ u = 1,\ldots,v-1\}$ denote the collection of edge probabilities between the actors in each layer at time $t \in \mathbb{T}$. Then every collection $\pi(t)$ can be represented as in equation (2) for some R and H.*

Although Proposition 1 guarantees that factorization in equation (2) is sufficiently general, it is important to ensure that the same flexibility is maintained when defining priors on the parameters in equation (2). Proposition 2 guarantees that our model and prior choices induce a prior on the dynamic multilayer edge probability process with full support.

Proposition 2 *If $\mathbb{T}$ is compact, then for every $\pi^0 = \{\pi_{vu}^{0(k)}(t) \in (0,1) : t \in \mathbb{T},\ k = 1,\ldots,K,\ v = 2,\ldots,V,\ u = 1,\ldots,v-1\}$ and $\epsilon > 0$,*

$$\text{pr}\left(\sup_{t\in\mathbb{T}}\left[\sum_{k=1}^{K}\sqrt{\sum_{v=2}^{V}\sum_{u=1}^{v-1}\{\pi_{vu}^{(k)}(t) - \pi_{vu}^{0(k)}(t)\}^2}\right] < \epsilon\right) > 0,$$

with $\pi_{vu}^{(k)}(t)$ factorized as in equation (2) with Gaussian process priors on the latent coordinates.

Full prior support is a key property in ensuring that our Bayesian formulation assigns a positive probability to a neighborhood of every possible true dynamic multilayer edge probability process, avoiding flexibility issues that may arise if zero mass is assigned to a subset of the parameters space where the truth may be.

In order to highlight the dependence structures induced by our model and priors, we additionally study the prior variances and covariances associated with the log-odds processes $z = \{z_{vu}^{(k)}(t) = \text{logit}\{\pi_{vu}^{(k)}(t)\} \in \Re : t \in \mathbb{T},\ k = 1,\ldots,K,\ v = 2,\ldots,V,\ u = 1,\ldots,v-1\}$. By conditioning on the shrinkage parameters, and leveraging equations (7) and (8), we obtain

$$\text{var}\{z_{vu}^{(k)}(t) \mid \tau, \tau^{(k)}\} = 1 + \sum_{r=1}^{R}\tau_r^{-2} + \sum_{h=1}^{H}\tau_h^{(k)-2}, \quad \text{cov}\{z_{vu}^{(k)}(t), z_{pq}^{(k)}(t) \mid \tau, \tau^{(k)}\} = 1,$$

for every layer $k = 1,\ldots,K$, time $t \in \mathbb{T}$ and pairs of actors $[vu]$, $v > u$ and $[pq]$, $p > q$ with $p \neq v$ or $q \neq u$. The covariance between different layers, at the same time $t \in \mathbb{T}$ is

$$\text{cov}\{z_{vu}^{(k)}(t), z_{vu}^{(g)}(t) \mid \tau, \tau^{(k)}, \tau^{(g)}\} = 1 + \sum_{r=1}^{R}\tau_r^{-2}, \quad \text{cov}\{z_{vu}^{(k)}(t), z_{pq}^{(g)}(t) \mid \tau, \tau^{(k)}, \tau^{(g)}\} = 1,$$

for every pair of layers k and g with $k \neq g$, time $t \in \mathbb{T}$ and pairs of actors $[vu]$, $v > u$ and $[pq]$, $p > q$ with $p \neq v$ or $q \neq u$. Finally, the covariances at different times are

$$\text{cov}\{z_{vu}^{(k)}(t_i), z_{vu}^{(k)}(t_j) \mid \tau, \tau^{(k)}\} = e^{-\kappa_\mu(t_i-t_j)^2} + \sum_{r=1}^{R}\tau_r^{-2}e^{-2\kappa_{\bar{x}}(t_i-t_j)^2} + \sum_{h=1}^{H}\tau_h^{(k)-2}e^{-2\kappa_x(t_i-t_j)^2},$$

$$\text{cov}\{z_{vu}^{(k)}(t_i), z_{vu}^{(g)}(t_j) \mid \tau, \tau^{(k)}, \tau^{(g)}\} = e^{-\kappa_\mu(t_i-t_j)^2} + \sum_{r=1}^{R}\tau_r^{-2}e^{-2\kappa_{\bar{x}}(t_i-t_j)^2},$$

$$\text{cov}\{z_{vu}^{(k)}(t_i), z_{pq}^{(k)}(t_j) \mid \tau, \tau^{(k)}\} = \text{cov}\{z_{vu}^{(k)}(t_i), z_{pq}^{(g)}(t_j) \mid \tau, \tau^{(k)}, \tau^{(g)}\} = e^{-\kappa_\mu(t_i-t_j)^2},$$

for every pair of layers k and g with $k \neq g$, times $t_i \in \mathbb{T}$, $t_j \in \mathbb{T}$ and pairs of actors $[vu]$, $v > u$ and $[pq]$, $p > q$ with $p \neq v$ or $q \neq u$.

It is easy to show that a priori the log-odds of the edge probabilities have mean zero, whereas, based on the above results, their variances increase with the sum of the shared and layer-specific shrinkage parameters. Allowing a subset of the coordinates to be common to all layers, has the effect of introducing dependence between the log-odds of edge probabilities in different layers. The Gaussian process priors provide an efficient choice to incorporate dependence between edge probabilities in different times. The strength of this dependence is regulated by the time lag and the positive smoothing parameters κ_μ, $\kappa_{\bar{x}}$ and κ_x. The lower these quantities, the stronger the dependence is between coordinates in different times.

4. Posterior Computation and Prediction

Equations (1)–(2) along with the Gaussian process priors for the latent coordinates can be seen as a nonlinear Bayesian logistic regression with the parameters entering in a bilinear form. Although performing posterior computation in this setting is apparently a cumbersome task, leveraging the Pólya-gamma data augmentation for Bayesian logistic regression (Polson et al., 2013) and adapting derivations in Durante and Dunson (2014), it is possible to obtain a simple and tractable Gibbs sampler having conjugate full conditionals. In fact, the Pólya-gamma data augmentation allows recasting the problem from a logistic regression to a multiple linear regression having transformed Gaussian response data, while derivations in Durante and Dunson (2014) provide results to linearize the factorization in equation (2).

Joining the above procedures and exploiting equations (7)–(8), the updating of the latent coordinates processes at every step simply relies on standard Bayesian linear regression. Algorithm 1 in Appendix B provides derivations and guidelines for step-by-step implementation of our Gibbs sampler. We summarize below the main steps of the MCMC routine.

Step [1]: For each time $t_i = t_1,\ldots,t_n$, layer $k = 1,\ldots,K$ and pair of actors $[vu]$, $v = 2,\ldots,V$, $u = 1,\ldots,v-1$, sample the corresponding Pólya-gamma augmented data.

Step [2]: Update the baseline process $\mu = \{\mu(t_1),\ldots,\mu(t_n)\}^\intercal$ from its full conditional multivariate Gaussian distribution. This is obtained by recasting the logistic regression for μ in terms of a multiple linear regression having transformed Gaussian response.

Step [3]: Update the shared coordinates. In performing this step we block-sample in turn the coordinates trajectories $\bar{x}_{(v)} = \{\bar{x}_{v1}(t_1),\ldots,\bar{x}_{v1}(t_n),\ldots,\bar{x}_{vR}(t_1),\ldots,\bar{x}_{vR}(t_n)\}^\intercal$ of each actor $v = 1,\ldots,V$ conditionally on the others $\{\bar{x}_{(u)} : u \neq v\}$. This choice allows us to linearize equation (2), with $\bar{x}_{(v)}$ acting as a coefficients vector and $\{\bar{x}_{(u)} : u \neq v\}$ representing appropriately selected regressors. Leveraging the Pólya-gamma data augmentation also this step relies on a multiple linear regression with transformed Gaussian response data, providing Gaussian full conditionals for each $\bar{x}_{(v)}$, $v = 1,\ldots,V$.

Step [4]: Update the layer-specific coordinates. For each layer $k = 1,\ldots,K$, this step relies on the same strategy considered for the shared coordinates, providing again Gaussian full conditionals for each $x_{(v)}^{(k)} = \{x_{v1}^{(k)}(t_1),\ldots,x_{v1}^{(k)}(t_n),\ldots,x_{vH}^{(k)}(t_1),\ldots,x_{vH}^{(k)}(t_n)\}^\intercal$, $v = 1,\ldots,V$ and $k = 1,\ldots,K$. Moreover the updating can be performed separately for each layer, allowing this step to be efficiently implemented in parallel.

Step [5] and [6]: The updating of the gamma parameters characterizing the priors in equations (5)–(6) follows conjugate analysis, proving gamma full conditionals.

Step [7]: Update the dynamic multilayer edge probabilities simply by applying equation (2) to the samples of the baseline process, the shared and the layer-specific coordinates.

In performing posterior computation we set R and H at conservative upper bounds, allowing the multiplicative inverse gamma priors for the shrinkage parameters to delete redundant latent space dimensions not required to characterize the data. Hence, posterior inference is not substantially affected by the choice of R and H, unless these bounds are fixed at excessively low values compared to the complexity of the data analyzed. We additionally assess the goodness of these bounds via in-sample and out-of-sample predictive performance.

4.1 Edge Prediction

Edge prediction is an important topic in dynamic modeling of multilayer networks. For example some networks may have unobserved edges due to inability to monitor certain types of relationships or actors at specific times. Likewise, some layers may be available in time earlier than others, facilitating prediction of those yet missing. The availability of efficient procedures that are able to reconstruct partially unobserved connectivity structures or forecast future networks can have important consequences in many applications, such as destabilization of terrorists networks or epidemic prevention (e.g., Tan et al., 2016).

Our statistical model for dynamic multilayer networks in equations (1)–(2) facilitates the definition of simple procedures for formal edge prediction relying on the expectation $\mathrm{E}\{\mathcal{Y}_{vu}^{(k)}(t_i) \mid Y_{\text{obs}}\}$ of the posterior predictive distribution for $\mathcal{Y}_{vu}^{(k)}(t_i)$, with Y_{obs} denoting the observed data. In fact, under equations (1)–(2), this functional is easily available as

$$\mathrm{E}\{\mathcal{Y}_{vu}^{(k)}(t_i) \mid Y_{\text{obs}}\} = \mathrm{E}_{\pi_{vu}^{(k)}(t_i)}[\mathrm{E}_{\mathcal{Y}_{vu}^{(k)}(t_i)}\{\mathcal{Y}_{vu}^{(k)}(t_i) \mid \pi_{vu}^{(k)}(t_i)\} \mid Y_{\text{obs}}] = \mathrm{E}\{\pi_{vu}^{(k)}(t_i) \mid Y_{\text{obs}}\}, \quad (9)$$

for every time $t_i \in \mathbb{T}$, layer $k = 1, \ldots, K$ and actors $v = 2, \ldots, V$, $u = 1, \ldots, v-1$, where $\mathrm{E}\{\pi_{vu}^{(k)}(t_i) \mid Y_{\text{obs}}\}$ simply coincides with the posterior mean of $\pi_{vu}^{(k)}(t_i)$. Hence prediction requires the posterior distribution of the edge probabilities. These quantities are available also for unobserved edges by adding the following data augmentation step in Algorithm 1:

Step [8]: Impute the missing edges given the current state of $\pi_{vu}^{(k)}(t_i)$ from a $\text{Bern}\{\pi_{vu}^{(k)}(t_i)\}$, for all the combinations of times $t_i \in \mathbb{T}$, layers $k = 1, \ldots, K$ and actors $v = 2, \ldots, V$, $u = 1, \ldots, v-1$ corresponding to unobserved edges.

5. Simulation Study

We consider a simulation study to evaluate the performance of our methodology in a simple scenario partially mimicking the size and structure of the face-to-face dynamic multilayer networks. Consistent with our aim we assess performance in the tasks outlined in Table 2.

To highlight the benefits of our methods (Joint Analysis), we compare the performance with two competitors. The first (Collapsed Analysis) assumes the layers arise from a common latent space model, forcing all the actors coordinates to be shared among layers. This formulation is a special case of our model holding out in (2) the layer-specific similarities.

Quantity	Focus of the performance assessment
Edge probabilities	Assess accuracy in learning the true edge probability process underlying the simulated network data. As already discussed, accurate modeling of the edge probabilities $\pi_{vu}^{(k)}(t_i)$ is fundamental for inference and prediction.
Unobserved edges	Assess out-of-sample predictive performance in forecasting future unobserved networks leveraging the expectation $\mathrm{E}\{\mathcal{Y}_{vu}^{(k)}(t_i) \mid Y_{\text{obs}}\}$ of the posterior predictive distribution for the unobserved edges.
Network density	Accuracy in modeling the expected overall chance of connectivity $\theta^{(k)}(t_i) = \mathrm{E}[\sum_{v=2}^{V}\sum_{u=1}^{v-1}\mathcal{Y}_{vu}^{(k)}(t_i)/\{V(V-1)/2\}] = \sum_{v=2}^{V}\sum_{u=1}^{v-1}\pi_{vu}^{(k)}(t_i)/\{V(V-1)/2\}$, for every time $t_i \in \mathbb{T}$ and layer $k = 1, \ldots, K$.
Actors degrees	Accuracy in learning the total number of different individuals $\mathrm{d}_v^{(k)}(t_i) = \mathrm{E}\{\sum_{u \neq v}\mathcal{Y}_{vu}^{(k)}(t_i)\} = \sum_{u \neq v}\pi_{vu}^{(k)}(t_i)$, each actor v is expected to interact with, for every $v = 1, \ldots, V$, time $t_i \in \mathbb{T}$ and layer $k = 1, \ldots, K$.

Table 2: Quantities of interest, which are considered in performance assessments. Although it is possible to provide inference on several properties, from an epidemiological perspective, the network density and actors degrees are of interest in characterizing the overall risk of contagion and the infectivity of each actor, respectively.

Hence, posterior analysis requires minor modifications of Algorithm 1. The second competitor (Separate Analysis) estimates the dynamic latent space model of Durante and Dunson (2014) separately for each layer. Although both methods are reasonable choices, modeling only shared structures lacks flexibility in capturing layer-specific patterns, whereas separate analyses lose efficiency in inference and prediction when the layers share common patterns. We describe the simulation setting in Section 5.1 and discuss results in Section 5.2.

5.1 Outline of the Simulation Settings

We consider $V = 30$ actors whose connections are monitored for $K = 2$ days on the same time grid $t_1, \ldots, t_{17}$, with $t_i \in \mathbb{T} = \{1, \ldots, 17\}$. In simulating the networks, we sample the edges from conditionally independent Bernoulli variables given their corresponding edge probabilities as in equation (1), with these probabilities defined to mimic possible scenarios in our application. To accomplish this goal, we consider, for each day, five representative edge probability matrices $\pi^{0(k)}(t_i)$ at times $t_i \in \{1, 5, 9, 13, 17\}$, displayed in Figure 2, and define the matrices at the remaining times as a convex combination of these representative matrices. Focusing, for example, on the times t_{14}, t_{15} and t_{16} between t_{13} and t_{17}, we let

$$\begin{aligned}
\pi^{0(k)}(t_{14}) &= 0.75\pi^{0(k)}(t_{13}) + 0.25\pi^{0(k)}(t_{17}),\\
\pi^{0(k)}(t_{15}) &= 0.50\pi^{0(k)}(t_{13}) + 0.50\pi^{0(k)}(t_{17}),\\
\pi^{0(k)}(t_{16}) &= 0.25\pi^{0(k)}(t_{13}) + 0.75\pi^{0(k)}(t_{17}).
\end{aligned}$$

The same construction holds for all the other time windows, except for times t_4 and t_6, where we induce a more rapid variation by letting $\pi^{0(k)}(t_4) = \pi^{0(k)}(t_6) = \pi^{0(k)}(t_5)$, instead

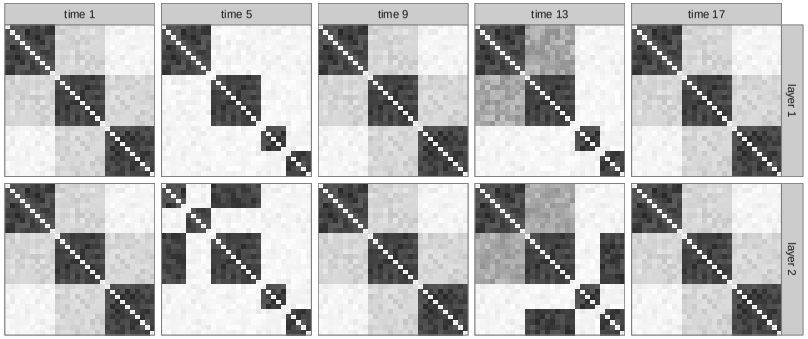

Figure 2: True representative edge probability matrices $\pi^{0(k)}(t_i)$. The color in each cell goes from white to black as the corresponding edge probability goes from 0 to 1.

of $\pi^{0(k)}(t_4) = 0.25\pi^{0(k)}(t_1) + 0.75\pi^{0(k)}(t_5)$, and $\pi^{0(k)}(t_6) = 0.75\pi^{0(k)}(t_5) + 0.25\pi^{0(k)}(t_9)$. We incorporate this setting to study the effects of the Gaussian process' constant smoothness assumption in scenarios having time-varying smoothness. In order to empirically evaluate Proposition 1, the edge probability matrices in Figure 2 are not generated from equation (2), but are instead constructed to characterize possible face-to-face contact scenarios.

Focusing on the first day, which corresponds to layer $k = 1$, the edge probability matrices at times t_1, t_9 and t_{17} characterize contacts during breakfast, lunch and dinner, respectively. These favor block-structures due to homophily by age and gender. In fact, it is reasonable to expect that young individuals, adult women and adult men, corresponding to actors in the first, second, and third block, may have a higher chance of contact with individuals in the same socio-demographic group. We additionally allow adult women to have a moderate chance of contact with young individuals and adult men during breakfast, lunch, and dinner times. The edge probability matrix at time t_5 characterizes instead block-structures due environmental restrictions during the morning, with young individuals attending school, adult women sharing the house, and two sub-groups of adult men working in two different places. Finally, the edge probability matrix at time t_{13} is similar to the one at time t_5 with exception of an increased chance of contact between young individuals and adult women who are expected to share the same environment in the afternoon after school.

The dynamic contact networks in the different days share similar patterns, as shown in Figure 1. We maintain this property by considering the same representative edge probability matrices in the second day, which corresponds to layer $k = 2$, with exception of t_5 and t_{13}. In the morning of the second day, we assume five young individuals contract a disease and remain at home. This increases their chance of contact with the adult women taking care of them, and reduces the probability of a contact with the other young individuals. The edge probability matrix in the afternoon of the second day characterizes a similar scenario, but focuses on five adult men. Including different edge probability matrices at times t_5 and t_{13}, allows us to assess performance in learning layer-to-layer differences in contact patterns.

	Squared Posterior Bias			Posterior Variance			Posterior Concentration		
		$n\downarrow$	$V\downarrow$		$n\downarrow$	$V\downarrow$		$n\downarrow$	$V\downarrow$
Joint	**0.009**	0.014	0.012	**0.011**	0.018	0.016	**0.020**	0.032	0.028
Collapsed	**0.016**	0.019	0.019	**0.007**	0.011	0.010	**0.023**	0.030	0.029
Separate	**0.016**	0.025	0.019	**0.018**	0.027	0.023	**0.034**	0.052	0.042

Table 3: For our methodology and the two competitors, measures of posterior concentration around the true dynamic multilayer edge probability process, at varying n and V. Bold numbers are the measures associated with our initial simulation scenario.

In order to assess predictive performance, we perform posterior analysis under our model and the competing methods, holding out from the observed data the networks from time t_{13} to t_{17} in the second day. This choice provides a scenario of interest in our application. For example a subset of actors may contract a disease at time t_{12} in the second day, motivating the design of prevention policies relying on the forecasted contact patterns at future times.

5.2 Results in the Simulation

We perform posterior computation under our model with $\kappa_\mu = \kappa_{\bar{x}} = \kappa_x = 0.05$ to favor smooth trajectories a priori and $a_1 = 2$, $a_2 = 2.5$ to facilitate adaptation of the latent spaces dimensions. Although our model can be easily modified to learn these hyperparameters from the data as in Murray and Adams (2010) and Bhattacharya and Dunson (2011), respectively, borrowing of information within the dynamic multilayer networks has the effect of reducing sensitivity to the choice of the hyperparameters. In fact, we found results robust to moderate changes in these quantities, and therefore prefer to elicit them to improve convergence and mixing. We consider 5000 Gibbs iterations with $R = H = 5$, and set a burn-in of 1000. Traceplots for the time-varying edge probabilities in the two layers show no evidence against convergence, and mixing is good in our experience with most of the effective sample sizes for the quantities of interest being around 1500 out of 4000 samples. Posterior computation for our competitors is performed with the same smoothing parameters and $a_1 = 2$, $a_2 = 2.5$, using $R + H = 10$ dimensional latent spaces, to improve comparison with our results.

5.2.1 Performance in Learning the True Edge Probability Process

Flexible modeling of $\pi^{(k)}(t)$ is fundamental for learning and prediction. Table 3 summarizes the concentration of the posterior distributions for the dynamic multilayer edge probabilities using the posterior mean of the squared difference between $\pi^{(k)}_{vu}(t_i) \mid Y_{\text{obs}}$ and $\pi^{0(k)}_{vu}(t_i)$. To provide empirical insights on posterior consistency we study this property also at varying n and V. In the first case we focus on the dynamic multilayer network studied at odd times $t_i \in \{1, 3, 5, \ldots, 17\}$, whereas in the second case we consider the reduced networks where four actors within each block are not analyzed. To highlight the contribution of the squared posterior bias and the posterior variance, we factorize the concentration measure as

$$\text{E}([\{\pi^{(k)}_{vu}(t_i) \mid Y_{\text{obs}}\} - \pi^{0(k)}_{vu}(t_i)]^2) = [\text{E}\{\pi^{(k)}_{vu}(t_i) \mid Y_{\text{obs}}\} - \pi^{0(k)}_{vu}(t_i)]^2 + \text{var}\{\pi^{(k)}_{vu}(t_i) \mid Y_{\text{obs}}\}.$$

To assess the overall performance, these measures are averaged across the edge probabilities

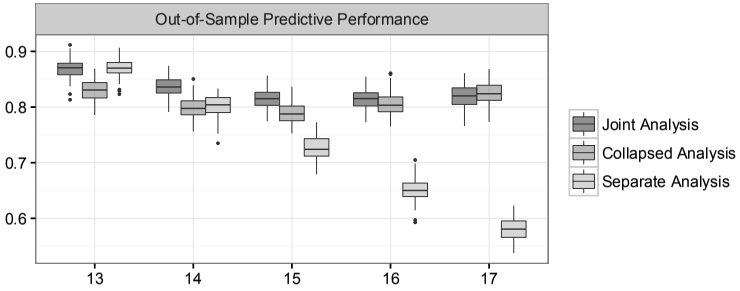

Figure 3: For times from t_{13} to t_{17} —held out in the second day from posterior computation —boxplots of the areas under the ROC curves (AUC) when predicting the unobserved edges with our method and the two competitors, from 100 simulations.

characterizing the dynamic multilayer network process.

According to Table 3, borrowing of information across layers has the effect of reducing both bias and posterior variance compared to the separate analyses, improving accuracy and efficiency in inference and prediction. Enhancing flexibility via layer-specific latent coordinates additionally facilitates bias reduction compared to collapsed analyses, but provides posterior distributions with slightly higher variance. This result is not surprising provided that the collapsed analyses assume the edge probability process to be common across layers, reducing the number of parameters. Moreover, although low variance is a desired feature when bias is small, this property may lead to poor inference and prediction when the posterior distribution is centered far from the truth. In our simulation—having few differences between the true edge probability processes in the two layers—the bias is low also for the collapsed analyses, but this bias is expected to grow when the layers have more differences.

The above results are maintained at varying n and V, while showing improved concentration for higher n or V. Although it would be interesting to prove posterior consistency, state-of-the-art literature provide results for the single binary outcome case (e.g., Ghosal and Roy, 2006), and it is not clear how to adapt this theory to our much complex network–valued data. However, results in Table 3 provide positive empirical support for this property.

5.2.2 Out-of-sample Predictive Performance

As discussed in Sections 2 and 4, developing models characterized by lower bias is important to improve inference and prediction. In fact, our method has an improved ability to predict unobserved edges compared to the competing models, as shown in Figure 3.[1] In predicting held-out edges we leverage the procedures discussed in Section 4.1. Since equation (1) is also valid for our competitors, results in Section 4.1 can be used for the collapsed and separate

1. In assessing predictive performance in Figure 3, we generate for each time from t_{13} to t_{17}—held out in the second day from posterior computation—100 networks from (1) with edge probabilities $\pi_{vu}^{0(2)}(t_i)$, and compute for each network the area under the ROC curve when predicting its edges with the expectation of the posterior predictive distribution associated with each method—according to Section 4.1.

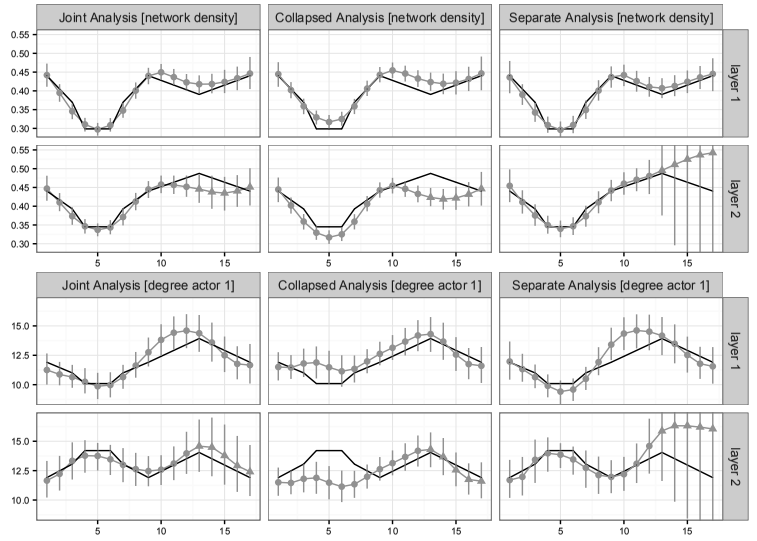

Figure 4: For the three methods, posterior mean (grey lines) and pointwise 0.95 credibility intervals (grey segments) for the dynamic expected network density (upper panels) and the dynamic expected degree of the first actor (lower panels) in the two layers. Black lines are the true trajectories, and triangles the held-out networks.

analyses after replacing $\mathrm{E}\{\pi_{vu}^{(k)}(t_i) \mid Y_{\mathrm{obs}}\}$ with $\mathrm{E}\{\pi_{vu}(t_i) \mid Y_{\mathrm{obs}}\}$ and $\mathrm{E}\{\pi_{vu}^{(k)}(t_i) \mid Y_{\mathrm{obs}}^{(k)}\}$, respectively.

According to Figure 3 the separate analysis obtains good predictive performance for the times subsequent to the last observed network, but this accuracy decays with increasing time lag. As the underlying edge probability process is smooth, it is reasonable to expect good predictive performance at time t_{13} exploiting information at time t_{12}, whereas the reduced accuracy for later times is likely due to inefficient exploitation of the information from the first layer. As expected, the collapsed analysis provides accurate predictions when there is a high degree of similarity between the edge probabilities in the two layers, such as at time t_{17}, but the accuracy decreases in correspondence of more evident differences. Differently from the above procedures, our model incorporates dependence between layers without assuming a single edge probability process common to all of them, providing predictions which are less sensitive to the underlying data generating mechanism. In fact, as shown in Figure 3, we obtain an improved prediction of unobserved edges compared to the competing methods.

5.2.3 Performance in Learning Network Properties of Interest

Accurate modeling of the dynamic multilayer edge probabilities has key benefits in improving inference on time-varying network structures in the different layers. Figure 4 summarizes

the posterior distribution of the dynamic expected network density, and the time-varying expected degree of a selected actor in the two layers.

As shown in Figure 4, our method outperforms the competing approaches also in providing inference for the selected network properties. The collapsed analysis forces the trajectories of these networks summary measures to be equal across layers, causing poor performance in capturing differences among layers in specific times. Modeling the dynamic edge probability processes underlying each layer separately improves flexibility, but the inefficient exploitation of the information shared between layers leads to poor performance in modeling network properties associated with unobserved edges. Our formulation in equations (1)–(2) incorporates dependence between layers and preserves flexibility via a set of layer-specific latent coordinates, which reduces in-sample and out-of-sample bias. Although our model has accurate performance, the constant smoothness assumption characterizing the Gaussian process priors leads to a slight over-smoothing around the more rapid variation in times t_4 and t_6. One possibility to avoid this behavior is to replace the Gaussian process priors with nested Gaussian processes (Zhu and Dunson, 2013) having time-varying smoothness.

6. Application to Dynamic Multilayer Face-to-Face Contact Data

We now turn to applying the methods proposed in Sections 2 and 4 to the face-to-face contact networks described in Section 1.2. Raw contact data are available for 75 individuals belonging to five different households in rural Kenya. Each household has different families living in the same compound and reporting to one head. Face-to-face contacts for the individuals in each household are collected hourly from 06:00 to 20:00 during three consecutive days, with these three days windows differing for most of the households. Hence, contact data are unavailable for almost all the pairs corresponding to actors in different households, making it impossible for any methodology to infer across-households connectivity structures. In order to avoid complications due to non-overlapping days, we focus on the face-to-face contact networks for the individuals in the most populated household comprising $V = 29$ actors. This choice is further supported by the fact that within households contacts play a fundamental role in the speed of contagion, motivating primary interests in household-based analyses; see e.g., House and Keeling (2009) and the references cited therein.

6.1 Results in the Application

The face-to-face proximity data can be structured as a dynamic multilayer network recording for each day $k \in \{1, 2, 3\}$ the time-varying face-to-face contacts among the $V = 29$ actors on the same hourly basis $t_1, \ldots, t_{14}$, where $t_i \in \{1, \ldots, 14\}$ is simply a discrete time index denoting the current hour. We apply our statistical model and the competing methods to the aforementioned data, where we hold out the contact network at the last time in the third day $Y^{(3)}_{t_{14}}$ to assess out-of-sample predictive performance.[2]

2. Posterior computation under the three models uses the same default hyperparameters as in the simulation study. Similarly to the simulation study, we consider 5000 Gibbs iterations and obtain no evidence against convergence after a burn-in of 1000. The effective sample sizes for the quantities of interest for inference are around 1200 out of 4000 samples. Although this provides a slightly reduced result compared to the simulation studies, the mixing is still good given the complexity of our dynamic multilayer network data.

		Area under the curve			Accuracy with cutoff 0.5		
Number of latent coordinates		8	10	12	8	10	12
Joint	In–sample	0.97	0.97	0.97	95%	95%	94%
	Out–of–sample	0.95	0.95	0.95	94%	94%	95%
Collapsed	In–sample	0.94	0.94	0.95	92%	92%	92%
	Out–of–sample	0.95	0.95	0.95	94%	94%	94%
Separate	In–sample	0.97	0.97	0.97	94%	94%	94%
	Out–of–sample	0.82	0.83	0.82	89%	89%	89%

Table 4: For our method and the two competitors, in-sample and out-of-sample predictive performance measured via the AUC, and the percentage of correctly predicted edges—using a cutoff probability of 0.5—at varying $R + H$, with $R = H$.

6.1.1 In-sample and Out-of-sample Predictive Performance

As one assessment of our proposed methodology, Table 4 compares our performance for in-sample and out-of-sample edge prediction with those provided by the competing procedures. Consistent with the strategy outlined in equation (9), the ROC curves for in-sample edge prediction are constructed using the observed data Y_{obs} and the posterior mean of their corresponding edge probabilities, estimated under the three different methods. The ROC curves for assessing out-of-sample predictive performance are defined in a similar way, but focusing on the held-out network at time t_{14} in day 3. To evaluate sensitivity to the choice of the upper bounds for the latent space dimensions, we study predictive performance also under other settings of R and H, including $R = H = 4$ and $R = H = 6$.

Edge prediction is clearly more accurate in-sample than out-of-sample. This is because Y_{obs} is part of the posterior computation, whereas the network at time t_{14} in day 3 is held out. According to Table 4, the separate analysis achieves comparable results to our model for in-sample edge prediction in accommodating layer-specific patterns, but provides poor predictions of future edges due to inability to incorporate information from the previous days. The collapsed analysis allows instead borrowing of information between the three days via shared coordinates, but does not incorporate differences in contact patters across these days. As a result, the collapsed analysis provides comparable performance to our model for out-of-sample edge prediction, but has a reduced in-sample predictive ability. Our dynamic multilayer representation efficiently incorporates both shared structures and layer-specific differences, facilitating good predictive performance both in-sample and out-of-sample. As discussed in Section 4, these results are not substantially affected by moderate variations in R and H, and therefore we perform posterior inference for $R = H = 5$, as in the simulation.

6.1.2 Learning Network Properties of Interest

The above results motivate additional posterior analyses of the dynamic multilayer stochastic process estimated under our model. Figure 5 summarizes the posterior distribution for the trajectory of the expected network density in the three days. The expected frequency

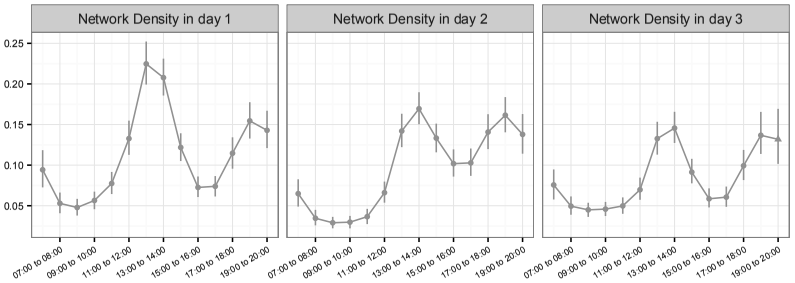

Figure 5: Posterior mean (grey lines) and pointwise 0.95 credibility intervals (grey segments) for the time-varying expected network density in the three days. The triangle for the last time in the third day denotes the held-out contact network.

of proximity contacts evolves on similar patterns during the three days, while showing some day-specific variations at certain hours. This result further confirms the importance of analyzing such data with statistical models that are able to borrow information across days, while maintaining flexibility in capturing day-specific patterns. Consistent with Kiti et al. (2016), the expected network density remains in general on low levels during the morning and afternoon when the actors are in different environments such as school and workplace, and peaks in correspondence of lunch and dinner times when the households members congregate. We learn a similar pattern when considering the dynamic expected frequencies of contact within and between groups of actors having similar traits, such as gender and age.[3] These trajectories provide key additional information compared to the expected network density, highlighting how infectious diseases can spread within and between groups of actors. The posterior mean of these trajectories is visualized in Figure 6.

According to Figure 6, all the trajectories inherit the pattern discussed for the expected network density, with clear peaks during lunch and dinner times. Although there are not evident differences in the dynamic expected frequencies of face-to-face contact within and between gender groups, we notice how contacts among males are typically less likely than contacts between females, whereas face-to-face interactions among actors of different genders become notable during lunch. Therefore, these hours might be at risk of spreading diseases from a gender group to the other. Consistent with the static analyses considered in Kiti et al. (2016), we observe more differences in the trajectories by age groups, with a substantially high chance of contact between young actors, whereas the dynamic expected frequency of interaction among adults remains on low levels. In fact, young individuals potentially have less restrictions from environment or work schedule than adults, and therefore have more chances of interaction, especially with actors of their same age. Hence, diseases may spread more easily among young individuals and reach adults during lunch times when the chance of contact between the two age groups is higher.

3. We can easily derive the posterior mean of these trajectories by averaging, for each time t_i and day k, all the estimated edge probabilities corresponding to pairs of actors having the same combination of traits, e.g., both males, both females, one male and one female.

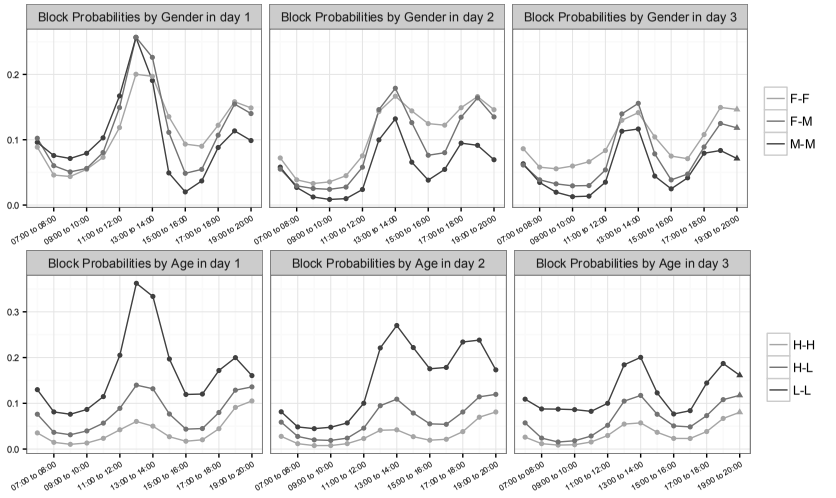

Figure 6: Upper panels: posterior mean of the dynamic expected frequencies of contact for actors having same gender—both males or both females—and different gender, in each day. Lower panels: same quantities with respect to high (≥ 15) and low (<15) age groups.

Figures 5 and 6 provide global measures for the dynamic risk of contagion in the network and for groups of actors. In order to develop more refined prevention policies it is of key interest to monitor the infectivity of each actor, and how this measure evolves with time and days. Consistent with this goal, Figure 7 provides a graphical analysis of selected contact networks, with the actors positions depending on the estimated edge probabilities averaged, for each day, over the two time windows having the more dense networks which may lead to a faster disease spread. As shown in Figure 7, the contact patterns in the same time window share a similar configuration across the three days, while displaying some day-to-day difference in the connectivity behavior of subsets of actors. For example, the community structure formed by actors 6, 17 and 28 during lunch times is less separated from the rest of the network in the first day, compared to the second and third day. This result provides additional support for our methodology which can simultaneously incorporate shared patterns and possible day-specific deviations from these common structures. Consistent with Figures 5 and 6, young individuals—represented by circles—are typically characterized by more frequent contacts, whereas the adult actors—corresponding to squares—have a more peripheral position in the network. As a result the degree of the young individuals is typically higher, making these actors particularly relevant in the economy of disease contagion and transmission. In this respect, actors 9 and 15 may represent dangerous hubs.

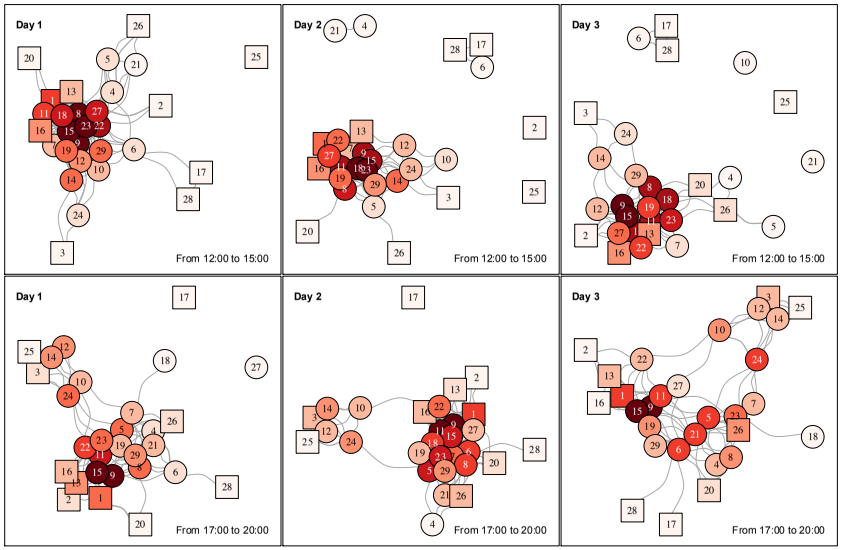

Figure 7: Weighted network visualization with weights obtained by averaging the posterior mean of the edge probabilities in the two time windows having the more dense networks, within each of the three days. Squares and circles represent the actors having high (≥ 15) and low (< 15) age, respectively. The color of each node goes from white to dark red as the estimated expected degree of the corresponding actor increases, relative to the others. Actors positions are obtained by applying the Fruchterman and Reingold (1991) force–directed placement algorithm, whereas the width of each edge is proportional to its averaged edge probability.

We can additionally notice some community structure within the network, particularly during dinner times. For example, actors 3, 10, 12, 14, 24 and 25 are tightly connected, but separated from the others, with exception of the young subjects 10 and 24 which may play a key role in the transmission of a disease from their community to the rest of the network. Other two communities can be more clearly observed during dinner times in day three. It is interesting to notice how these groups of actors comprise both young and adult individuals, and therefore may represent different families within the household under analysis.

7. Discussion

The increasing availability of multidimensional, complex, and dynamic information on social interaction processes motivates a growing demand for novel statistical models. In order to successfully enhance quality in inference and prediction, these models need to efficiently incorporate the complex set of dependencies in the observed data, without affecting flexibility. Motivated by this consideration and by epidemiological studies monitoring disease transmission via dynamic face-to-face interactions, we have developed a Bayesian nonparametric model for dynamic multilayer networks leveraging latent space representations. In order to preserve flexibility and borrow information across layers and time, we modeled the edge probabilities as a function of shared and layer-specific latent coordinates which evolve in time via Gaussian process priors. We provided theoretical support for our model, and developed simple procedures for posterior computation and formal prediction. Finally, we illustrated on both simulated data and on infection studies monitoring face-to-face contacts that our methods perform better than competitors in terms of inference and prediction.

Although we focus on face-to-face interaction networks collected at multiple times and days, our methods have a broad range of applications. Notable examples include dynamic cooperations among countries with respect to different types of international relations, time-varying interactions between researchers according to multiple forms of academic collaborations, and dynamic contacts between terrorists in relation to different types of dark interactions. In all these relevant applications, our flexible methodology can provide an appealing direction in accurately learning and predicting hidden wiring mechanisms and their implication in several environments and phenomena.

In addition, our methods motivate further directions of research. An important one is to facilitate scaling to larger dynamic multilayer network data. Currently, the computational complexity of our Gibbs sampler—as a function of the dimensions of the input data—is of order $O(VKn^3)$, and corresponds to the most intensive step updating the layer-specific latent coordinates trajectories for the V actors. Although the latent space representation reduces computational complexity from quadratic in the number of actors V to linear, the cubic complexity in the number of time points n associated with the Gaussian process prior, may still represent a computational barrier when data are monitored for wide time windows. A possible strategy to successfully address this issue is to consider more scalable processes such as the low-rank approximations to the Gaussian process (Banerjee et al., 2013) or state-space models. Another important generalization is accommodating the more informative contact counts instead of just a binary variable indicating presence or absence of face-to-face interactions. In accomplishing this goal one possibility is to adapt the methodology proposed in Canale and Dunson (2011) to our framework and assume the weighted edges are realizations from a rounded Gaussian whose mean is factorized as in equation (2). Finally, additional studies on the theoretical properties of these stochastic processes, such as those recently considered in Crane (2017), are of relevant interest.

Appendix A. Proofs of Propositions 1 and 2

Proof of Proposition 1. As the logistic mapping is one-to-one continuous, Proposition 1 is valid if and only if—for each time $t \in \mathbb{T}$—every possible collection of log-odds $z(t) = \{z_{vu}^{(k)}(t) \in \Re : k = 1, \ldots, K,\ v = 2, \ldots, V,\ u = 1, \ldots, v-1\}$ can be factorized as

$$z_{vu}^{(k)}(t) = \mu(t) + \bar{s}_{vu}(t) + s_{vu}^{(k)}(t) = \mu(t) + \bar{x}_v(t)^\intercal \bar{x}_u(t) + x_v^{(k)}(t)^\intercal x_u^{(k)}(t),$$

for all $k = 1, \ldots, K,\ v = 2, \ldots, V,\ u = 1, \ldots, v-1$, where $x_v^{(k)}(t) = \{x_{v1}^{(k)}(t), \ldots, x_{vH}^{(k)}(t)\}^\intercal$ and $\bar{x}_v(t) = \{\bar{x}_{v1}(t), \ldots, \bar{x}_{vR}(t)\}^\intercal$, for every $v = 1, \ldots, V$.

Assume without loss of generality $\mu(t) = 0$ for every $t \in \mathbb{T}$ and let $\bar{X}(t)$ and $X^{(k)}(t)$ for $k = 1, \ldots, K$, denote the $V \times R$ and $V \times H$ matrices containing the shared and layer-specific latent coordinates, respectively, at time $t \in \mathbb{T}$. Since we are not interested in the diagonal elements of the $V \times V$ edge probabilities and log-odds matrices, it is always possible to write

$$Z^{(k)}(t) = \bar{S}(t) + S^{(k)}(t), \quad k = 1, \ldots, K,$$

where $Z^{(k)}(t)$ is the $V \times V$ symmetric matrix having the log-odds of the edges at time t in layer k as off-diagonal elements, whereas $\bar{S}(t)$ and $S^{(k)}(t)$ are $V \times V$ positive semidefinite symmetric matrices having quantities $\bar{s}_{vu}(t),\ v = 2, \ldots, V,\ u = 1, \ldots, v-1$ and $s_{vu}^{(k)}(t)$, $v = 2, \ldots, V,\ u = 1, \ldots, v-1$ as off-diagonal elements. Since we are not interested in self-relations, there is no loss of generality in assuming $\bar{S}(t)$ and $S^{(k)}(t)$ are positive semidefinite, since for any configuration of shared and layer-specific similarities there exist infinitely many positive semidefinite matrices having these quantities as off-diagonal elements.

Since $\bar{S}(t)$ and $S^{(k)}(t)$ are positive semidefinite, they admit the eigendecompositions $\bar{S}(t) = \bar{U}(t)\bar{\Lambda}(t)\bar{U}(t)^\intercal$ and $S^{(k)}(t) = U^{(k)}(t)\Lambda^{(k)}(t)U^{(k)}(t)^\intercal$, where $\bar{U}(t)$ and $U^{(k)}(t)$ denote the $V \times R_t$ and $V \times H_t^{(k)}$ matrices of eigenvectors, whereas $\bar{\Lambda}(t)$ and $\Lambda^{(k)}(t)$ are the corresponding diagonal matrices with the positive eigenvalues. Therefore, letting $R \geq R_t$ for every $t \in \mathbb{T}$ and $H \geq H_t^{(k)}$, for every $k = 1, \ldots, K$ and $t \in \mathbb{T}$, Proposition 1 follows after defining $\bar{X}(t)$ and $X^{(k)}(t)$ as the block matrices $\bar{X}(t) = \{\bar{U}(t)\bar{\Lambda}(t)^{1/2}, 0_{V \times (R - R_t)}\}$ and $X^{(k)}(t) = \{U^{(k)}(t)\Lambda^{(k)}(t)^{1/2}, 0_{V \times (H - H_t^{(k)})}\}$ for every $k = 1, \ldots, K$. ■

Proof of Proposition 2. Leveraging proof of Corollary 2 in Durante and Dunson (2014), to prove Proposition 2 it suffices to show that

$$\text{pr}\left(\sup_{t \in \mathbb{T}} \left[\sum_{k=1}^{K} \sqrt{\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{z_{vu}^{(k)}(t) - z_{vu}^{0(k)}(t)\}^2}\right] < \epsilon\right) > 0,$$

where $z_{vu}^{(k)}(t)$ and $z_{vu}^{0(k)}(t)$ are the log-odds of $\pi_{vu}^{(k)}(t)$ and $\pi_{vu}^{0(k)}(t)$, respectively. Recalling the proof of Proposition 1, the above probability can be factorized as

$$\text{pr}\left(\sup_{t \in \mathbb{T}} \left[\sum_{k=1}^{K} \sqrt{\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{\mu(t) + \bar{s}_{vu}(t) + s_{vu}^{(k)}(t) - \mu^0(t) - \bar{s}_{vu}^0(t) - s_{vu}^{0(k)}(t)\}^2}\right] < \epsilon\right),$$

with $\bar{s}_{vu}(t) = \bar{x}_v(t)^\intercal \bar{x}_u(t)$, $s_{vu}^{(k)}(t) = x_v^{(k)}(t)^\intercal x_u^{(k)}(t)$, $\bar{s}_{vu}^0(t) = \bar{x}_v^0(t)^\intercal \bar{x}_u^0(t)$ and $s_{vu}^{0(k)}(t) = x_v^{0(k)}(t)^\intercal x_u^{0(k)}(t)$. Exploiting the triangle inequality and the independence of the Gaussian process priors for the different trajectories, a lower bound for the above probability is

$$\text{pr}\left(\sup_{t \in \mathbb{T}} \left[\sqrt{\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{\mu(t) - \mu^0(t) + \bar{s}_{vu}(t) - \bar{s}_{vu}^0(t)\}^2}\right] < \frac{\epsilon}{2K}\right) \times$$
$$\times \prod_{k=1}^{K} \text{pr}\left(\sup_{t \in \mathbb{T}} \left[\sqrt{\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{s_{vu}^{(k)}(t) - s_{vu}^{0(k)}(t)\}^2}\right] < \frac{\epsilon}{2K}\right).$$

Applying Theorem 2 in Durante and Dunson (2014) to each term in this factorization, it is easy to show that all the above probabilities are strictly positive, proving Proposition 2. ■

Appendix B. Pseudocode for Posterior Computation

Algorithm 1 provides guidelines for step-by-step implementation of our Gibbs sampler.

Algorithm 1 Gibbs sampler for the dynamic multilayer latent space model

[1] Generate the Pólya-gamma augmented data
for each $t_i = t_1, \ldots, t_n$, $k = 1, \ldots K$, $v = 2, \ldots, V$ and $u = 1, \ldots, v-1$ **do**
Sample the augmented data $\omega_{vu}^{(k)}(t_i)$ from the full conditional Pólya-gamma

$$\omega_{vu}^{(k)}(t_i) \mid - \sim \text{PG}\left\{1, \mu(t_i) + \bar{x}_v(t_i)^\intercal \bar{x}_u(t_i) + x_v^{(k)}(t_i)^\intercal x_u^{(k)}(t_i)\right\},$$

where $\text{PG}(a, b)$ is the Pólya-gamma random variable with parameters $a > 0$ and $b \in \Re$.
end for

---

[2] Update the baseline trajectory $\mu = \{\mu(t_1), \ldots, \mu(t_n)\}^\intercal$ from $\mu \mid - \sim \text{N}_n(\mu_\mu, \Psi_\mu)$ where $\Psi_\mu = \left[\text{diag}\left\{\sum_{k=1}^{K}\sum_{v=2}^{V}\sum_{u=1}^{v-1} \omega_{vu}^{(k)}(t_1), \ldots, \sum_{k=1}^{K}\sum_{v=2}^{V}\sum_{u=1}^{v-1} \omega_{vu}^{(k)}(t_n)\right\} + \Sigma_\mu^{-1}\right]^{-1}$ and $\mu_\mu = \Psi_\mu \eta_\mu$ with

$$\eta_\mu = \begin{bmatrix} \sum_{k=1}^{K}\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{Y_{t_1[vu]}^{(k)} - 1/2 - \omega_{vu}^{(k)}(t_1)[\bar{x}_v(t_1)^\intercal \bar{x}_u(t_1) + x_v^{(k)}(t_1)^\intercal x_u^{(k)}(t_1)]\} \\ \vdots \\ \sum_{k=1}^{K}\sum_{v=2}^{V}\sum_{u=1}^{v-1} \{Y_{t_n[vu]}^{(k)} - 1/2 - \omega_{vu}^{(k)}(t_n)[\bar{x}_v(t_n)^\intercal \bar{x}_u(t_n) + x_v^{(k)}(t_n)^\intercal x_u^{(k)}(t_n)]\} \end{bmatrix}.$$

---

[3] Sample the vectors of shared coordinates $\bar{x}_v(t_1), \ldots, \bar{x}_v(t_n)$ **for** $v = 1, \ldots, V$ **for** each actor $v = 1, \ldots, V$ **do**
Block-sample $\{\bar{x}_v(t_1), \ldots, \bar{x}_v(t_n)\}$ given the others $\{\bar{x}_u(t_i) : u \neq v, t_i = t_1, \ldots t_n\}$.

[a] Let $\bar{x}_{(v)} = \{\bar{x}_{v1}(t_1), \ldots, \bar{x}_{v1}(t_n), \ldots, \bar{x}_{vR}(t_1), \ldots, \bar{x}_{vR}(t_n)\}^\intercal$

[b] Define a Bayesian logistic regression with $\bar{x}_{(v)}$ acting as coefficient vector and having prior, according to equation (7), $\bar{x}_{(v)} \sim \text{N}_{n \times R}\left\{0, \text{diag}(\tau_1^{-1}, \ldots, \tau_R^{-1}) \otimes \Sigma_{\bar{x}}\right\}$

[c] For every $k = 1, \ldots, K$, the Bayesian logistic regression for the updating of $\bar{x}_{(v)}$ is

$$Y^{(k)}_{(v)} \sim \text{Bern}(\pi^{(k)}_{(v)}), \quad \text{logit}(\pi^{(k)}_{(v)}) = 1_{V-1} \otimes \mu + \bar{X}_{(-v)}\bar{x}_{(v)} + X^{(k)}_{(-v)}x^{(k)}_{(v)},$$

with

- $Y^{(k)}_{(v)}$ obtained by stacking vectors $\{Y^{(k)}_{t_1[vu]}, \ldots, Y^{(k)}_{t_n[vu]}\}^\intercal$ for all pairs having v as a one of the two actors
- $\pi^{(k)}_{(v)}$ the corresponding vector of edge probabilities
- $x^{(k)}_{(v)} = \{x^{(k)}_{v1}(t_1), \ldots, x^{(k)}_{v1}(t_n), \ldots, x^{(k)}_{vH}(t_1), \ldots, x^{(k)}_{vH}(t_n)\}^\intercal$
- $\bar{X}_{(-v)}$ and $X^{(k)}_{(-v)}$the matrices of regressors whose entries are suitably chosen from $\{\bar{x}_u(t_i) : u \neq v, t_i = t_1, \ldots t_n\}$ and $\{x^{(k)}_u(t_i) : u \neq v, t_i = t_1, \ldots t_n\}$

According to the above specification, and letting $\Omega^{(k)}_{(v)}$ denote the diagonal matrix with the corresponding Pólya-gamma augmented data, we obtain

$$\bar{x}_{(v)} \mid - \sim \text{N}_{n\times R}\left(\mu_{\bar{x}_{(v)}}, \Psi_{\bar{x}_{(v)}}\right),$$

with

$$\Psi_{\bar{x}_{(v)}} = \{\bar{X}^\intercal_{(-v)}(\Omega^{(1)}_{(v)} + \ldots + \Omega^{(K)}_{(v)})\bar{X}_{(-v)} + \text{diag}(\tau_1, \ldots, \tau_R) \otimes \Sigma^{-1}_{\bar{x}}\}^{-1},$$
$$\mu_{\bar{x}_{(v)}} = \Psi_{\bar{x}_{(v)}}(\bar{X}^\intercal_{(-v)}[\textstyle\sum_{k=1}^K\{Y^{(k)}_{(v)} - 1_{V-1} \otimes 1_n 0.5 - \Omega^{(k)}_{(v)}(1_{V-1} \otimes \mu + X^{(k)}_{(-v)}x^{(k)}_{(v)})\}]).$$

end for

---

[4] Sample the layer-specific coordinates $x^{(k)}_v(t_1), \ldots, x^{(k)}_v(t_n)$ for $v = 1, \ldots, V$ and $k = 1, \ldots, K$

for each layer $k = 1, \ldots, K$ **do**
  for each actor $v = 1, \ldots, V$ **do**
    Block-sample $\{x^{(k)}_v(t_1), \ldots, x^{(k)}_v(t_n)\}$ given $\{x^{(k)}_u(t_i) : u \neq v, t_i = t_1, \ldots t_n\}$. In particular, letting $x^{(k)}_{(v)} = \{x^{(k)}_{v1}(t_1), \ldots, x^{(k)}_{v1}(t_n), \ldots, x^{(k)}_{vH}(t_1), \ldots, x^{(k)}_{vH}(t_n)\}^\intercal$ and adapting derivations in step [3] to the sampling of the layer-specific coordinates, we obtain

$$x^{(k)}_{(v)} \mid - \sim \text{N}_{n\times H}\left(\mu_{x^{(k)}_{(v)}}, \Psi_{x^{(k)}_{(v)}}\right),$$

with

$$\Psi_{x^{(k)}_{(v)}} = \{X^{(k)\intercal}_{(-v)}\Omega^{(k)}_{(v)}X^{(k)}_{(-v)} + \text{diag}(\tau^{(k)}_1, \ldots, \tau^{(k)}_H) \otimes \Sigma^{-1}_x\}^{-1},$$
$$\mu_{x^{(k)}_{(v)}} = \Psi_{x^{(k)}_{(v)}}[X^{(k)\intercal}_{(-v)}\{Y^{(k)}_{(v)} - 1_{V-1} \otimes 1_n 0.5 - \Omega^{(k)}_{(v)}(1_{V-1} \otimes \mu + \bar{X}_{(-v)}\bar{x}_{(v)})\}].$$

  end for
end for

---

[5] Update the gamma quantities defining the shared shrinkage parameters $\tau_1^{-1}, \ldots, \tau_R^{-1}$

$$\delta_1 \mid - \sim \text{Ga}\left\{a_1 + \frac{V \times n \times R}{2}, 1 + \frac{1}{2}\sum_{m=1}^R \theta^{(-1)}_m \sum_{v=1}^V \bar{x}^\intercal_{vm}\Sigma^{-1}_{\bar{x}}\bar{x}_{vm}\right\},$$
$$\delta_{r\geq 2} \mid - \sim \text{Ga}\left\{a_2 + \frac{V \times n \times (R - r + 1)}{2}, 1 + \frac{1}{2}\sum_{m=r}^R \theta^{(-r)}_m \sum_{v=1}^V \bar{x}^\intercal_{vm}\Sigma^{-1}_{\bar{x}}\bar{x}_{vm}\right\},$$

where $\theta^{(-r)}_m = \prod_{f=1, f\neq r}^m \delta_f$ for $r = 1, \ldots, R$ and $\bar{x}_{vm} = \{\bar{x}_{vm}(t_1), \ldots, \bar{x}_{vm}(t_n)\}^\intercal$.

---

[6] Sample the variables defining the layer-specific parameters $\tau_1^{(k)-1}, \ldots, \tau_H^{(k)-1}$, $k = 1, \ldots, K$

for each layer $k = 1, \ldots, K$ **do**

$$\delta^{(k)}_1 \mid - \sim \text{Ga}\left\{a_1 + \frac{V \times n \times H}{2}, 1 + \frac{1}{2}\sum_{l=1}^H \theta^{(-1)}_l \sum_{v=1}^V x^{(k)\intercal}_{vl}\Sigma^{-1}_x x^{(k)}_{vl}\right\},$$
$$\delta^{(k)}_{h\geq 2} \mid - \sim \text{Ga}\left\{a_2 + \frac{V \times n \times (H - h + 1)}{2}, 1 + \frac{1}{2}\sum_{l=h}^H \theta^{(-h)}_l \sum_{v=1}^V x^{(k)\intercal}_{vl}\Sigma^{-1}_x x^{(k)}_{vl}\right\},$$

where $\theta^{(-h)}_l = \prod_{f=1, f\neq h}^l \delta^{(k)}_f$ for $h = 1, \ldots, H$ and $x^{(k)}_{vl} = \{x^{(k)}_{vl}(t_1), \ldots, x^{(k)}_{vl}(t_n)\}^\intercal$.
end for

---

[7] Obtain the posterior samples for the edge probabilities $\pi^{(k)}_{vu}(t_i)$ via

$$\pi^{(k)}_{vu}(t_i) = [1 + \exp\{-\mu(t_i) - \bar{x}_v(t_i)^\intercal\bar{x}_u(t_i) - x^{(k)}_v(t_i)^\intercal x^{(k)}_u(t_i)\}]^{-1},$$

for every $t_i = t_1, \ldots, t_n$, layer $k = 1, \ldots, K$ and actors $v = 2, \ldots, V$, $u = 1, \ldots, v - 1$.

---

[8] Impute the missing edges given the current state of $\pi^{(k)}_{vu}(t_i)$ from a Bern$\{\pi^{(k)}_{vu}(t_i)\}$, for all the combinations of times $t_i \in \mathbb{T}$, layers $k = 1, \ldots, K$ and actors $v = 2, \ldots, V$, $u = 1, \ldots, v - 1$ corresponding to unobserved edges.

Time-Accuracy Tradeoffs in Kernel Prediction: Controlling Prediction Quality

Editor: Michael Mahoney

Abstract

Kernel regression or classification (also referred to as *weighted* ϵ-NN methods in Machine Learning) are appealing for their simplicity and therefore ubiquitous in data analysis. However, practical implementations of kernel regression or classification consist of quantizing or sub-sampling data for improving time efficiency, often at the cost of prediction quality. While such tradeoffs are necessary in practice, their statistical implications are generally not well understood, hence practical implementations come with few performance guarantees. In particular, it is unclear whether it is possible to maintain the statistical accuracy of kernel prediction—crucial in some applications—while improving prediction time.

The present work provides guiding principles for combining kernel prediction with data-quantization so as to guarantee good tradeoffs between prediction time and accuracy, and in particular so as to approximately maintain the good accuracy of vanilla kernel prediction.

Furthermore, our tradeoff guarantees are worked out explicitly in terms of a tuning parameter which acts as a *knob* that favors either time or accuracy depending on practical needs. On one end of the knob, prediction time is of the same order as that of *single*-nearest-neighbor prediction (which is statistically inconsistent) while maintaining consistency; on the other end of the knob, the prediction risk is nearly minimax-optimal (in terms of the original data size) while still reducing time complexity. The analysis thus reveals the interaction between the data-quantization approach and the kernel prediction method, and most importantly gives explicit control of the tradeoff to the practitioner rather than fixing the tradeoff in advance or leaving it opaque.

The theoretical results are validated on data from a range of real-world application domains; in particular we demonstrate that the theoretical *knob* performs as expected.

1. Introduction

Kernel regression or classification approaches—which predict at a point x by weighting the contributions of nearby sample points using a *kernel* function—are some of the most studied approaches in nonparametric prediction and enjoy optimality guarantees in general theoretical settings. In Machine Learning, these methods often appear as *weighted* ϵ-Nearest-Neighbor prediction, and are ubiquitous due to their simplicity.

However, vanilla kernel prediction (regression or classification) methods are rarely implemented in practice since they can be expensive at prediction time: given a large training data $\{X_i, Y_i\}$ of size n, predicting Y at a new query x can take time $\Theta(n)$ since much of the data $\{X_i\}$ has to be visited to compute kernel weights.

Practical implementations therefore generally combine fast-similarity search procedures with some form of data-quantization or sub-sampling (where the original large training data $\{X_i, Y_i\}$ is replaced with a smaller quantization set $\{q, Y_q\}$[1], see Figure 1) for faster processing (see e.g. Lee and Gray, 2008; Atkeson et al., 1997). However, the effect of these approximations on prediction accuracy is not well understood theoretically, hence good tradeoffs rely mostly on proper engineering and domain experience. A main motivation of this work is to elucidate which features of practical approaches to time-accuracy tradeoffs should be most emphasized in practice, especially in applications where it is crucial to approximately maintain the accuracy of the original predictor (e.g. medical analytics, structural-health monitoring, robotic control, where inaccurate prediction is relatively costly, yet fast prediction is desired).

The present work provides simple guiding principles that guarantee good tradeoffs between prediction time and accuracy under benign theoretical conditions that are easily met in real-world applications.

We first remark that fast-similarity search procedures alone can only guarantee sub-optimal time-improvement, replacing the linear order $O(n)$ with a root of n; this is easy to show (see Proposition 1). Therefore, proper data-quantization or sub-sampling is crucial to achieving good tradeoffs between prediction time and accuracy. In particular we first show that it is possible to guarantee prediction time of order $O(\log n)$ for structured data (data on a manifold or sparse data) while maintaining a near minimax prediction accuracy *as a function of the original data size* n (rather than the suboptimal quantization size).

Interestingly our sufficient conditions on quantization for such tradeoffs are not far from what is already intuitive in practice: quantization centers (essentially a compression of the data) are usually picked so as to be *close to the data*, yet at the same time *far apart* so as to succinctly capture the data (illustrated in Figure 1). Formalizing this intuition, we consider quantization centers $Q = \{q\}$ that form (a) an r-cover of the data $\{X_i\}$ (i.e. r-close to data), and (b) an r-packing, i.e. are r far-apart. We show that, with proper choice of r, and after *variance correction*, the first property (a) maintains minimax prediction accuracy, while the second property (b) is crucial to fast prediction.

As alluded to earlier, the achievable tradeoffs are worked out in terms of the unknown *intrinsic* structure of the data, as captured by the now common notion of *doubling dimension*, known to be small for structured data. The tradeoffs improve with the doubling dimension of the data, independent of the *ambient* dimension D of Euclidean data in $\mathbb{R}^D$. In fact our analysis is over a generic metric space and its intrinsic structure and thus allow general representations of the data.

Finally, the most practical aspect of our tradeoff guarantees is that they explicitly capture the interaction between the quantization parameter r and the kernel bandwidth h. Note that, for a *fixed* h, it is clear that increasing r (more quantization) can only improve time while potentially decreasing accuracy; however the choice of h is not fixed in practice, and paired with the choice of r, the direction of the tradeoffs become unclear. Our analysis simplifies these choices, as we show that the ratio $\alpha = r/h$ acts as a practical *knob* that

1. Y_q is some label assigned to quantization point q, depending on the labels of those data points X_i's represented by q.

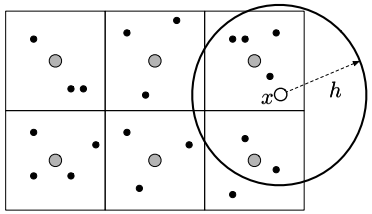

Figure 1: Quantization in kernel regression: given a bandwidth $h > 0$, the estimate $f_Q(x)$ is a weighted average of the Y contributions of quantization-centers $q \in Q$ (gray points) which fall in the ball $B(x, h)$. Each $q \in Q$ contributes the average Y value of the sample points close to it.

can be tuned ($\alpha \to 1$ or $\alpha \to 0$) to favor either prediction time or accuracy according to application needs. In other words, rather than fixing a tradeoff, our analysis shows how to *control* the tradeoff through the interaction of the parameters r and h; such simplified control is valuable to practitioners since appropriate tradeoffs differ across applications.

The resulting approach to kernel prediction, which we term *Kernel-Netting*, or *Netting* for short, can be instantiated with existing fast-search procedures and quantization methods properly adjusted to satisfy the two conditions (a) and (b). In particular, the two conditions are maintained by a simple *farthest-first-traversal* of the data, and are shown experimentally to yield the tradeoffs predicted by the analysis. In particular the prediction accuracy of the vanilla kernel predictor is nearly maintained as shown on datasets from real-world applications. Furthermore, actual tradeoffs are shown empirically to be easily controlled through the knob parameter α.

The rest of the paper is organized as follows. In Section 2 we discuss related work, followed by a discussion of our theoretical results in Section 3. A detailed instantiation of *Netting* is presented in Section 4. This is followed by experimental evaluations in Section 5. All the supporting proofs of our theoretical results are deferred to the appendix.

2. Related Work

We discuss various types of tradeoffs studied in the literature.

2.1 Tradeoffs in General

While practical tradeoffs have always been of interest in Machine Learning, they have been gaining much recent attention as the field matures into new application areas with large data

sizes and dimension. There are many important directions with respect to time-accuracy tradeoffs. We next overview a few of the recent results and directions.

One line of research is concerned with deriving faster implementations for popular procedures such as Support Vector Machines (e.g. Bordes et al., 2005; Rahimi and Recht, 2007; Le et al., 2013; Dai et al., 2014; Alaoui and Mahoney, 2015), parametric regression via sketching (e.g. Clarkson and Woodruff, 2013; Pilanci and Wainwright, 2014; Clarkson et al., 2013; Shender and Lafferty, 2013; Raskutti and Mahoney, 2014).

Another line of research is concerned with understanding the difficulty of learning in constrained settings, including under time constraints, for instance in a minimax sense or in terms of computation-theoretic hardness (see e.g. Agarwal et al., 2011; Cai et al., 2015; Chandrasekaran and Jordan, 2013; Berthet and Rigollet, 2013; Zhu and Lafferty, 2014).

Our focus in this paper is on kernel prediction approaches, and most closely related works are discussed next.

2.2 Tradeoffs in Kernel Prediction

Given a bandwidth parameter $h > 0$, a kernel estimate $f_n(x)$ is obtained as a weighted average of the Y values of (predominantly) those data points that lie in a ball $B(x, h)$. Note that data points outside of $B(x, h)$ might also contribute to the estimate but they are typically given negligible weights. These weights are computed using *kernel* functions that give larger weights to data points closest to x. Kernel weights might be used directly to average Y values (kernel regression, see Gyorfi et al., 2002), or they might be combined in more sophisticated ways to approximate f by a polynomial in the vicinity of x (local polynomial regression, see Gyorfi et al., 2002).

In the naive implementation, evaluation takes time $\Omega(n)$ since weights have to be computed for all points. However many useful approaches in the applied literature help speedup evaluation by combining fast proximity search procedures with methods for approximating kernel weights (see e.g. Carrier et al., 1988; Lee and Gray, 2008; Atkeson et al., 1997; Morariu et al., 2009). More specifically, let $X_{1:n} = \{X_i\}_1^n$, such faster approaches quickly identify the samples in $B(x, h) \cap X_{1:n}$, and quickly compute the kernel weights of these samples. The resulting speedup can be substantial, but *guarantees* on speedups are hard to obtain as this depends on the unknown size of $B(x, h) \cap X_{1:n}$ for future queries x. In particular, it is easy to show as in Proposition 1 below, that $|B(x, h) \cap X_{1:n}|$ is typically at least a root of n for settings of h optimizing statistical accuracy (e.g. ℓ_2 excess risk).

Proposition 1 *There exists a distribution P supported on a subset on $\mathbb{R}^D$ such that the following holds. Let $X_{1:n} \sim P^n$ denote a randomly drawn train set of size n, and $h = O\left(n^{-1/(2+D)}\right)$ (this is the order of a statistically optimal bandwidth in kernel regression where $\mathbb{E}[Y|x]$ is Lipschitz, see Gyorfi et al., 2002). Fix any x in the interior of the support of P. For n sufficiently large, we have with probability at least $1/2$ on $X_{1:n}$ that*

$$|B(x, h) \cap X_{1:n}| = \Omega\left(n^{2/(2+D)}\right).$$

The distribution P in the above proposition corresponds to actually reasonable distribution such as ones with (upper and lower) bounded density on a full-dimensional subset

of $\mathbb{R}^D$. The proposition (whose proof is given in the appendix) is easily extended to low-dimensional subsets $\mathcal{X}$ of $\mathbb{R}^D$, resulting in larger lower-bounds of the form $\Omega\left(n^{2/(2+d)}\right)$, $d = \dim(\mathcal{X})$ (lower-dimensional balls tend to have larger mass).

Approaches that further quantize the data $X_{1:n}$ (or sub-sample from it), e.g. Carrier et al. (1988) can attain better time complexity, however likely at the cost of decreased accuracy in estimates. The resulting tradeoffs on time and accuracy are generally not well understood, and largely depend on how the data is compressed. The present work derive general insights on how to quantize to guarantee good tradeoffs.

The present work extends on insights from an earlier conference work (Kpotufe, 2009) which provides initial results in the case of regression. However, that earlier work only manages a fixed (theoretical) tradeoff between time complexity and accuracy. Instead, as discussed above, the present work provides a *controllable tradeoff* and works out the continuum of achievable rates and time complexity as the knob α is tuned up or down. This requires a refined analysis of all supporting results. Furthermore, the main theoretical results are now shown to carry over to the classification regime as a corollary to the risk bounds for regression; the time complexity bounds are the same for regression and classification since kernel classification involves no extra-work over kernel regression. Finally, the refined analysis of the present work is further supported by extensive experimental evaluation.

3. Overview of Theoretical Results

We start this section with our main theoretical assumptions and useful definitions towards the discussion of results.

3.1 Preliminaries

We are interested in classification or regression where the learner has access to training data $(X_{1:n}, Y_{1:n}) = \{X_i, Y_i\}_1^n \sim P_{X,Y}^n$ where $P_{X,Y}$ is unknown. The goal is to return a regression estimate or classifier that maps future inputs X to outputs Y while achieving good tradeoffs on accuracy and estimation time for $Y = Y(X)$.

The input X belongs to a metric space $(\mathcal{X}, \rho)$. The learner has access to ρ while $\mathcal{X}$ is only observed through the data $X_{1:n}$. The output Y belongs to a space $\mathcal{Y}$, where $\mathcal{Y} = \{0, 1\}$ in the case of classification, or $\mathcal{Y} = \mathbb{R}^{d_Y}$ in the case of regression (we allow multivariate regression outputs).

Next we overview our working assumptions on the input and output spaces. Our main assumptions are rather mild and are specified under Assumptions 1, 2. Our theoretical results generally have no other assumption unless explicitly specified.

3.1.1 Input Space $\mathcal{X}$

We need to capture the complexity of the input data X through notions of data space complexity such as *metric dimension* of the underlying space $(\mathcal{X}, \rho)$.

For intuition, consider a natural two-dimensional object such as a square. A square can be covered by $4 = 2^2$ squares of half its side length. Similarly, a cube can be covered by $8 = 2^3$ cubes of half its side length. Notice that the exponents correspond to the natural

dimensions of the objects. This sort of intuition can be formalized in a number of ways involving how the space $\mathcal{X}$ might be covered by subsets such as *balls* under the metric ρ.

Definition 2 *Let $x \in \mathcal{X}$ and $r > 0$. The* ball $B(x, r)$ *is defined as* $\{x' \in \mathcal{X} : \rho(x', x) \leq r\}$.

Next we introduce proper definitions of what we mean by a *cover* of a space, along with related notions that appear throughout the discussion.

Definition 3 (Covers, packings, and nets) *Consider a metric space $(\mathcal{X}, \rho)$ and $r > 0$.*

- *$Q \subset \mathcal{X}$ is an r-cover of $\mathcal{X}$ if for all $x \in \mathcal{X}$, there exists $q \in Q$, s.t. $\rho(x, q) \leq r$. In other words, the balls $B(q, r)$* cover *$\mathcal{X}$, i.e. $\mathcal{X} \subset \cup_{q \in Q} B(q, r)$.*
- *$Q \subset \mathcal{X}$ is an r-packing if for all $q, q' \in Q$, $\rho(q, q') > r$.*
- *$Q \subset \mathcal{X}$ is an r-net of $X_{1:n}$ if it is an r-cover and an r-packing.*

Note that, on the algorithmic side, we will be interested in packings and covers of the input data $X_{1:n}$ (rather than of $\mathcal{X}$) as a means to attain good time-accuracy tradeoffs.

We can now introduce the following (common) notion of metric dimension.

Definition 4 *The* doubling dimension *of $(\mathcal{X}, \rho)$ is the smallest d such that any ball $B(x, r)$ can be covered by 2^d balls of radius $r/2$.*

The *doubling dimension* captures the inherent complexity of various settings of contemporary interest including sparse datasets and low-dimensional manifolds (Dasgupta and Freund, 2008) and is common in the Machine Learning literature (see for instance Krauthgamer and Lee, 2004; Clarkson, 2005; Beygelzimer et al., 2006; Dasgupta and Freund, 2008; Gottlieb et al., 2013; Reddi and Poczos, 2014).

We have the following assumptions on X:

Assumption 1 *The metric space $(\mathcal{X}, \rho)$ has bounded diameter $\max_{x,x' \in \mathcal{X}} \rho(x, x') = \Delta_{\mathcal{X}}$, and doubling dimension d.*

3.1.2 Output Space $\mathcal{Y}$

Both classification and regression can be treated under the same assumptions on conditional distributions $P_{Y|x}$. In particular we are interested in the behavior of the unknown *regression function* f:

Definition 5 *The* regression function *is defined for all $x \in \mathcal{X}$ as $f(x) = \mathbb{E}[Y|x]$. For classification, its range is $[0, 1]$ while for regression, its range is $\mathbb{R}^{d_Y}$. In a slight abuse of notation, we will let the norm $\|f(x) - f(x')\|$ denote the absolute value on $[0, 1]$ (classification) or the Euclidean norm on $\mathbb{R}^{d_Y}$ (regression).*

We have the following assumptions:

Assumption 2 *The regression function f is λ-Lipschitz for some unknown $\lambda > 0$:*

$$\forall x, x' \in \mathcal{X}, \quad \left\|f(x) - f(x')\right\| \leq \lambda \rho\left(x, x'\right).$$

Let $Y(x) \sim P_{Y|x}$, its variance, namely $\mathbb{E}_{Y|X=x} \|Y - f(x)\|^2$, is uniformly bounded by σ_Y^2 over $x \in \mathcal{X}$. Furthermore, f is bounded over $\mathcal{X}$, i.e. $\sup_{x,x' \in \mathcal{X}} \|f(x) - f(x')\| \leq \Delta_f$.

The Lipschitz condition is common and known to be mild: it captures the idea that whenever x and x' are close, so are $f(x)$ and $f(x')$, uniformly.

Note that the boundedness conditions hold automatically in the case of classification since then Y is itself bounded. In the case of regression, Y itself is allowed to be unbounded; the boundedness assumption on f is immediate from the continuity of f (implied by the Lipschitz condition) whenever $(\mathcal{X}, \rho)$ has bounded diameter (see Assumption 1).

3.1.3 Risk and Excess Risk of a Regression Estimate

Suppose $g : \mathcal{X} \to \mathcal{Y}$ is some estimate of f. We define its ℓ_2 *pointwise risk at* x to be $R(g,x) \doteq \mathbb{E}_{Y|X=x} \|Y - g(x)\|^2$ and its *integrated risk* to be $R(g) \doteq \mathbb{E}_X R(g,X)$. Standard manipulations show that

$$\begin{aligned} R(g,x) &= R(f,x) + \|f(x) - g(x)\|^2, \text{ and therefore} \\ R(g) &= R(f) + \mathbb{E}_X \|g(X) - f(X)\|^2. \end{aligned}$$

In this paper we are interested in the *integrated excess risk*

$$\|g - f\|^2 \doteq R(g) - R(f) = \mathbb{E}_X \|g(X) - f(X)\|^2. \tag{1}$$

Many factors contribute to the complexity of nonparametric regression, more precisely, to the excess risk $\|f_n - f\|^2$ of the regression estimate f_n. Important quantities identified in the literature are the *smoothness* of the regression function $f(x)$, the *Y-variance* $\mathbb{E}\left[\|Y - f(x)\|^2 | X = x\right] \leq \sigma_Y^2$, and the *dimension* of the input space $\mathcal{X}$.

Curse of dimension. Suppose $\mathcal{X} \subset \mathbb{R}^D$. Then, for *any* regression estimate f_n, there exists $P_{X,Y}$ where f is λ-Lipschitz, such that the error $\|f_n - f\|^2$ is of the order $\left(\lambda^D \sigma_Y^2 / n\right)^{2/(2+D)}$ (Stone, 1982). Clearly, the dimension D has a radical effect on the quality of estimates. With kernel regression estimates however, D in the above rate can be replaced by $d \ll D$, where d is the doubling dimension as we will soon see.

Such adaptivity in kernel regression was first shown in Bickel and Li (2006) for data on a manifold,[2] and more recently in Kpotufe and Garg (2013) for a different measure of intrinsic dimension related to *doubling measures* (Clarkson, 2005) and doubling dimension.

We will show how to maintain adaptive rates in terms of the unknown doubling dimension while reducing the data to speedup prediction. This will also be true in the case of classification as explained below.

3.1.4 Risk and Excess risk of a Classifier

The pointwise risk of a classifier $l : \mathcal{X} \mapsto \{0,1\}$ is defined as $R_{0,1}(l,x) = \mathbb{E}_{Y|X=x} \mathbb{1}[l(x) \neq Y]$, and the integrated risk, or *classification error*, is given as $R_{0,1}(l) = \mathbb{E}_X R(l,X)$.

A kernel classifier is a so-called *plug-in* classifier. These are classifiers of the form $l_g(x) = \mathbb{1}[g(x) \geq 1/2]$ where $g \in [0,1]$ is an estimate of the regression function $f(x) = \mathbb{E}[Y|x]$. It is well known that the *Bayes* classifier l_f attains the smallest pointwise risk at every $x \in \mathcal{X}$.

The excess risk of a plug-in classifier is directly upper-bounded by regression excess risk (Devroye et al., 1996):

$$R_{0,1}(l_g) - R_{0,1}(l_f) \leq 2\mathbb{E}\,|g(X) - f(X)| \leq 2\,\|f - g\|. \tag{2}$$

2. The paper concerns local polynomial regression but the results are easily extended to kernel regression.

We can therefore proceed with a single analysis for both classification and regression based solely on the assumptions on the regression function f. We note that the above discussion on *curse of dimension* also apply to classification, unless more regularity is assumed on f (see e.g. a discussion of such additional *noise* assumptions in Audibert and Tsybakov, 2007).

3.2 Results and Key Insights on Tradeoffs

We are now ready to discuss the two main goals of Netting, namely improved estimates and good evaluation time. Many instantiations of the approach are possible, combining a choice of kernel function, and choice of quantization Q with fast-proximity search. The results in this section remain generic, and only assume that Q forms an r-net of the data for some r properly tied to the kernel bandwidth. In Section 4 we discuss how to exactly obtain such quantizations, and discuss details of the prediction procedures.

In contrast with usual analyses of kernel regression, the added technicality in establishing these results is in dealing with non-i.i.d. data: the quantization points $q \in Q$ on which the estimates are defined, and their assigned Y_q values, are *interdependent*, and also depend on the data in nontrivial manners (since we only assume a generic Q that forms an r-net). These interdependencies are handled by properly decomposing the risk, and conditioning on the right sequence of events (see conditional variance and bias bounds of Appendix A).

3.2.1 Main Results

Our main results on tradeoffs are given in the next theorem. The theorem relies on the benign Assumptions 1 and 2 on $\mathcal{X}$ and $\mathcal{Y}$, and considers Netting with a generic quantization Q of the data. It is shown that good tradeoffs can be guaranteed whenever Q is an r-net of the data (see Definition 3). The tradeoffs are given in terms of a *knob* $\alpha = r/h$ which can be dialed up or down to favor either accuracy or time. The regression estimate, under a generic quantization Q is given as follows:

Definition 6 (Regression estimate) *Given a bandwidth $h > 0$, and $0 < \alpha < 3/4$, consider an αh-net Q of the sample $X_{1:n}$, where Q is independent of $Y_{1:n}$. Assign every point $X_i \in X_{1:n}$ to a single $q \in Q$ such that $\rho(X_i, q) \leq \alpha h$. For $q \in Q$, let n_q denote the number of points from $X_{1:n}$ assigned to it, and let $\bar{Y}_q$ denote the average Y value of points assigned to q.*

Let the kernel $K(u)$ be a non increasing function of $u \in [0,\infty)$; K is positive on $u \in [0,1)$, maximal at $u = 0$, and is 0 for $u \geq 1$. Define the regression estimate as

$$\begin{aligned} f_Q(x) &= \sum_{q \in Q} w_q(x) \bar{Y}_q, \text{ where} \\ w_q &= \frac{n_q (K(\rho(x,q)/h) + \epsilon)}{\sum_{q' \in Q} n_{q'} (K(\rho(x,q')/h) + \epsilon)}, \end{aligned} \tag{3}$$

for a positive correction $0 < \epsilon \leq K(3/4)/n^2$.

Most common kernels satisfy the above conditions, e.g., triangle kernel $K(u) = |1-u|_+$, box kernel $K(u) = \mathbb{1}[u \leq 1]$, Epanechnikov $K(u) = (1-u^2)_+$, etc.

The Kernel correction ϵ simply insures that we do not divide by 0; the (technical) upper-bound on ϵ ensures that the error term induced by ϵ is of smaller order than the desired rate. Our results hold for any ϵ as described above, and in our implementation we just set it very small to $1/n^2$.

Theorem 7 *Let f_Q be defined as in (5). The following holds under Assumptions 1 and 2.*

1. Regression: *for any $h > 0$, we have*

$$\mathop{\mathbb{E}}_{(X_{1:n},Y_{1:n})} \|f_Q - f\|^2 \leq \frac{C\left(\sigma_Y^2 + \Delta_f^2\right)}{n \cdot ((3/4-\alpha)h/(2\Delta_{\mathcal{X}}))^d} + (1+\alpha)^2\lambda^2 h^2 + \frac{\Delta_f^2}{n}$$

   where d is the doubling dimension of $\mathcal{X}$, $\Delta_{\mathcal{X}}$ is its diameter, and the constant C depends only on $K(\cdot)$.

2. Classification: *it follows by (2) that the excess risk of the corresponding Netting classifier $l_{f_Q} = \mathbb{1}[f_Q \geq 1/2]$ over the Bayes classifier $l_f = \mathbb{1}[f \geq 1/2]$ satisfies*

$$\mathbb{E}_{X_{1:n},Y_{1:n}} R_{0,1}(l_{f_Q}) - R_{0,1}(l_f) \leq 2\left(\frac{C\left(\sigma_Y^2 + \Delta_f^2\right)}{n \cdot ((3/4-\alpha)h/(2\Delta_{\mathcal{X}}))^d} + (1+\alpha)^2\lambda^2 h^2 + \frac{\Delta_f^2}{n}\right)^{1/2}.$$

3. Time complexity: *the estimate $f_Q(x)$, used in either regression or classification, can be obtained in worst-case time $C'\left(\log(\Delta_{\mathcal{X}}/\alpha h) + \alpha^{-d}\right)$, for some C' that depends on d, but independent of the choice of $x \in \mathcal{X}$, h and α.*

The choice of $0 < \alpha < 3/4$ in the above theorem can be relaxed to any $0 < \alpha < \alpha_0 < 1$, simply replacing $3/4$ everywhere it appears with α_0. The need to for an upper-bound less than 1 on α stems from the need for considering only those centers q that fall in the interior of $B(x,h)$ and hence contribute non-negligible weight to the estimate $f_Q(x)$.

The accuracy results (items 1 and 2) of the above theorem holds simultaneously for any h and is decomposed into variance and bias terms. Thus the bound can be optimized over choices of h as is done later in Corollary 8 (which further establishes that a good choice of h can be obtained through cross-validation).

The risk bounds mainly depend on α through the variance terms of the form $C/n \cdot ((3/4-\alpha)h)^d$ while the bias term is effectively $O(\lambda h)^2$. This bound is best as $\alpha \to 0$ and recovers known variance bounds (see e.g. Gyorfi et al., 2002; Tsybakov and Zaiats, 2009) for kernel regression and classification for $\alpha = 0$ (in which case there is no quantization, i.e. $Q = X_{1:n}$). We emphasize that the bound here is adaptive to the unknown intrinsic dimension d of the data space $\mathcal{X}$ (for $\mathcal{X} \subset \mathbb{R}^D$), which is now known to be a feature of kernel regression and other distance-based procedures (see e.g. Bickel and Li, 2006; Scott and Nowak, 2006; Lafferty and Wasserman, 2007; Kpotufe, 2011; Kpotufe and Dasgupta, 2012; Kpotufe and Garg, 2013; Gottlieb et al., 2013). In other words, the achieved tradeoffs are best for structured data as captured by its intrinsic dimension d.

The time complexity of Theorem 7 is expressed as worst-case over any choice of x and h. In particular, it depends exponentially on the unknown doubling dimension d of $\mathcal{X}$ (through

α and possibly through C'), which as previously discussed, can be much smaller than the ambient dimension D for structured high-dimensional data (e.g. $\mathcal{X}$ is $O(d)$-sparse, or is an $O(d)$-dimensional submanifold of $\mathbb{R}^D$). This sort of worst-case time dependence on intrinsic dimension cannot be avoided as one can construct doubling-metrics $\mathcal{X}$ where fast-similarity search requires time $\Omega\left(2^{O(d)}\log n\right)$ (see e.g. Krauthgamer and Lee, 2004), but fortunately does not seem typical of practical data (see experiments).

The time complexity of the theorem is best as $\alpha \to 3/4$ and depends on the number of points in the range $B(x,h) \cap Q$ (which can be shown to be at most $O(\alpha^{-d})$, independent of n) but does not depend on the number of points in $B(x,h) \cap X_{1:n}$ (the effective range for vanilla kernel-prediction which can be a root of n as shown in Proposition 1). For fixed $\alpha \approx 3/4$, the time complexity is of order $O(\log(\Delta_{\mathcal{X}}/h))$; thus if h is of the form $n^{-1/O(d)}$ (the theoretical order for risk-optimal h) the time complexity is $O(\log n)$.

We emphasize that a time complexity of $O(\log n)$ is the best attainable for fast-range search (see e.g. Krauthgamer and Lee, 2004; Beygelzimer et al., 2006) when the range $B(x,h)$ contains a *constant* number of points. In particular $O(\log n)$ is the time complexity for *single*-nearest-neighbor search (a range of 1 point). This is interesting in that the procedure remains statistically consistent (unlike 1-NN or any constant-NN approach), i.e., $f_Q \to_P f$ for fixed α provided $h \to 0$ and $nh^d \to \infty$.

As is often the case when providing guarantees which hold in the worst-case, the bounds of the above theorem are quite conservative in practice, but accurately identify the dependence of the Netting approach on the parameter α. This is further shown in the experimental evaluations of Section 5; in particular the dependence on the unknown d is often much milder than the worst-case time complexity above, as the achievable time-savings are significant for relatively small values of α ensuring good accuracy.

We discuss the main technical insights in our analysis in the next two subsections on accuracy and time complexity.

3.2.2 Maintaining Good Accuracy

While Q in Theorem 7 is an αh-net, the accuracy statements (items 1 and 2) in fact only require Q to be an αh-cover of $X_{1:n}$. As stated, the classification result (item 2) is a direct consequence of the regression result (item 1). We therefore only need to discuss the technical insights behind the regression accuracy bounds. Item 1 of Theorem 7 is obtained as Lemma 14 proved in the appendix. The main insights are as follows.

As is well known, the excess ℓ_2 risk of a regression estimate f_Q is a sum of its variance and its square bias. The bias of a kernel regression estimate $\hat{f}(x)$ at a point x is a function how far the data points contributing to the estimate are from x, and is order $O(h)$. So, suppose Q is an αh-cover of the data; every center q being close to the data $X_{1:n}$, the data points contributing to the estimate $f_Q(x)$ (the points assigned to the centers q contributing to the estimate) are $O(h)$ close to x, so the bias remains of order $O(h)$ (Lemma 13).

The variance of a quantization-based estimator such as f_Q is more problematic and requires **variance correction**, consisting here of weighting every center q by the number n_q of data points assigned to it. To see this, remember that the variance of a kernel estimate $\hat{f}(x)$ (in fact of distance-based estimates in general) depend on the number of points say n_x contributing to the estimate, and is of the form $1/n_x$. Without the variance correction (i.e.

if every q is weighted only by the kernel K) the information in n_x is lost; hence effectively only the net centers in $B(x,h) \cap Q$ contribute to the estimate; suppose there are $n_{Q,x} < n_x$ such centers, we will then get a worse variance bound of the form $1/n_{Q,x}$. By adjusting the kernel weights of every q with n_q, we properly account for all data contributing their estimates, and can show that the variance of f_Q is then of similar order as that of a vanilla kernel estimate (Lemma 12).

Analysis outline. The bias analysis is broken into the bias due to net centers q close to the query x, and the bias due to centers q far from x; for q's close to x the analysis is fairly standard by following the above insights; the new technicality is in handling the bias due to q's far from x, which is done by considering both situations where x is appropriately close to the data and far from the data.

For the variance analysis, notice that our basic variance correction can be viewed as replacing the original kernel K with one that accounts for both distances $\rho(x,q)$ and density at q. This makes the variance analysis relatively non-standard, along with the fact that we have little control over the data-dependent choice of Q. The variance analysis is divided over queries x that are *particularly* close to centers in Q (and therefore result in high weights w_q and low variance) and those queries x that are far from Q (and therefore result in unstable estimates). Integrating properly over the data space $\mathcal{X}$ and the choice of data $X_{1:n}, Y_{1:n}$ helps circumvent the dependence of Q on $X_{1:n}$, and also reveals that the estimator f_Q remains adaptive to the unknown intrinsic dimension d of $\mathcal{X}$ (by further breaking the integration over an appropriately refined $O(h)$-cover of $\mathcal{X}$ depending on α).

Risk dependence on α. The risk bound of Theorem 7 depends on α through the variance term of the form $1/n \cdot ((3/4-\alpha)h)^d$, assuming $\Delta_{\mathcal{X}} = 1$. Noting that the typical volume of a ball of radius r in a d-dimensional space is of the form r^d, if P_X is nearly uniform in a neighborhood of a query x (or has upper and lower bounded density) then the term $n \cdot ((3/4-\alpha)h)^d$ corresponds to the expected number of points in a ball $B(x,(3/4-\alpha)h)$. In contrast, the variance of a kernel estimate would depend on the number of points in the ball $B(x,h)$. The difference is easily explained: the estimate $f_Q(x)$ is based on the data through assigned centers $q \in Q$ falling in $B(x,h)$; however, the data assigned to these q's—this is the actual data driving the estimate and its variance—are only guaranteed to be in $B(x,(1-\alpha)h)$. Rather than using 1, i.e., considering q's as far as h from x, we consider only q's at most $3h/4$ from x to ensure they contribute non-negligible weights w_q to $f_Q(x)$ (in fact, we can use any $0 < \alpha_0 < 1$ rather than $3/4$), which results in a variance bound depending on the mass of $B(x,(3/4-\alpha)h)$. Thus the risk bound captures the worst-case dependence on α and cannot be further tightened without additional assumptions of the interaction between Q and P_X.

Choice of h. It follows from Theorem 7 above that the bandwidth h can be chosen by cross-validation to obtain a nearly minimax-optimal rate in terms of the unknown distributional parameters d and λ, where α is viewed as a constant. This is stated in the corollary below where $\hat{h}$ is assumed to be picked out of a range $H \doteq \{\Delta_{\mathcal{X}} \cdot 2^{-i}/(3/4-\alpha)\}_0^{\lceil \log n \rceil}$, using an independent validation sample of size n.

Corollary 8 *Assume the conditions of Theorem 7. Assume further that $\mathcal{Y}$ has bounded diameter, and w.l.o.g. contains the 0 vector. Let $\Delta_{\mathcal{Y}} = \max\left\{diam(\mathcal{Y}), \sigma_Y^2 + \Delta_f^2\right\}$. Suppose $n \geq \left(\frac{\lambda \Delta_{\mathcal{X}}}{\Delta_{\mathcal{Y}}(3/4-\alpha)}\right)^{1/(2+d)}$. There exist C depending on $\mathcal{X}$ and the kernel K such that the following holds. Define*

$$\Phi(n) = C\left(\frac{\lambda \Delta_{\mathcal{X}}}{3/4-\alpha}\right)^{2d/(2+d)}\left(\frac{\Delta_{\mathcal{Y}}^2}{n}\right)^{2/(2+d)}, \text{ and } C_1 = \frac{K(3/4)+\epsilon}{K(0)+\epsilon}, C_2 = 1/C_1.$$

A bandwidth $\hat{h}$ can be selected by cross-validation over $O(\log n)$ choices to guarantee

$$\mathbb{E}\left\|f_{Q_{\alpha\hat{h}}} - f\right\|^2 \leq \Phi(n) + 4\Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln n}{n}} + 2(C_2-C_1)^2\Delta_{\mathcal{Y}}^2 \cdot \mathbb{1}\left[n < \left(\frac{\Delta_{\mathcal{Y}}(3/4-\alpha)}{\lambda\Delta_{\mathcal{X}}}\right)^2\right]. \quad (4)$$

In the case of classification, by equation (2), the excess risk for $l_{f_{Q_{\alpha\hat{h}}}}$ is bounded by twice the square-root of the r.h.s. above.

Notice that, for n sufficiently large, the third term in (4) is 0, so the rate is given by $\Phi(n)$. This rate is minimax-optimal for α fixed, with respect to the intrinsic dimension d and Lipschitz parameter λ (see matching lower-bound in Kpotufe, 2011).

3.2.3 Maintaining a Fast Evaluation Time

The time complexity of Theorem 7 (item 3) only requires that the quantization Q be an αh-packing of the data $X_{1:n}$. Together with the requirement of Q being an αh-cover for good accuracy, we get the theorem's requirement of Q being an αh-net.

The time complexity relies on noticing that the time to estimate $f_Q(x)$ depends on the number of centers q in the range $B(x,h) \cap Q$ and how fast these points can be identified by a given fast-range search procedure. The weights n_q can be precomputed during preprocessing and therefore do not contribute to estimation time.

Intuitively, the farther points in $B(x,h) \cap Q$ are, the fewer such points there should be. In particular, if they are over h far apart, there could only be one point in $B(x,h) \cap Q$. This intuition carries over to αh-nets where all points in $B(x,h) \cap Q$ are over αh apart. This is stated in the following lemma which relies on simple arguments that are standard in analyses of fast proximity search procedures. Its proof is given in the appendix.

Lemma 9 *Suppose $\mathcal{X}$ has doubling dimension d. Let Q be a set of centers forming an αh-packing, $0 < \alpha < 1$. Then for any fixed $c \geq 1$, $\max_{x \in \mathcal{X}} |Q \cap B(x, c \cdot h)| \leq C\alpha^{-d}$, where C depends on d and c.*

Again, the above bound cannot be tightened, since following directly from the definition of doubling-dimension, it is easy to construct $\mathcal{X}$ such that there is a ball of radius 1 with largest α-packing of size roughly α^{-d} (e.g. $\mathcal{X}$ is a d-dimensional hypercube with l_∞ metric).

Now it is left to ensure that $Q \cap B(x,h)$ can be identified quickly. As previously discussed, we can employ a generic fast-range search procedure. We will expect the time complexity to be of the form $\tau(Q) + \alpha^{-d}$, where $\tau(Q)$ is the time to identify a near-neighbor q of a query x in Q (range-search typically then consists of traversing a precomputed neighborhood of q). In particular, the statement of Theorem 7 relies on results from Krauthgamer and Lee (2004) and is proven in Lemma 16 in the appendix.

4. Detailed Instantiation of Netting

We now discuss instantiations of the insights of Theorem 7. In Section 4.1 below, we discuss a few ways to exactly obtain an r-net of the data. This is followed by the regression and classification procedures in Section 4.2.

4.1 Obtaining an r-net

Algorithm 1 below details a standard way to building an r-net offline using a *farthest-first-traversal*. This is an $O(n^2)$ procedure, but is easily implemented to handle all $r > 0$ simultaneously in $O(n)$ space (notice that $Q_r \subset Q_{r'}$ in Algorithm 1 whenever $r > r'$).

Algorithm 1: r-net with farthest-first traversal

Input: points $\{x_i\}$ of size n, $r > 0$.
Initialize $Q_r \leftarrow \{x_1\}$.
Define $\rho(x_i, Q_r) \doteq \min_{x_j \in Q_r} \rho(x_i, x_j)$.
while $\max_{\{x_i\}} \rho(x_i, Q_r) > r$ **do**
  Add $x \doteq \text{argmax}_{\{x_i\}} \rho(x_i, Q_r)$ to Q_r.
end while
Return r-net Q_r.

For fixed r, an r-net can be obtained *online* in time $\sum_{i=1}^{n} t(i)$ where $t(\cdot)$ is the time-complexity of an online black-box nearest neighbor search procedure (e.g. Krauthgamer and Lee, 2004; Beygelzimer et al., 2006). Thus, if interested in a fixed r, the r-net could be obtained in time $O(n \times$ time for a nearest-neighbor search) which, as observed empirically for fast-search procedures, could behave as low as $O(n \log n)$ depending on the fast-search procedure and the data (see e.g. the nice discussions in Krauthgamer and Lee, 2004; Beygelzimer et al., 2006). This online approach is given in Algorithm 2.

Algorithm 2: r-net online

Input: points $\{x_i\}$ of size $n > 1$, $r > 0$.
Initialize $Q_r \leftarrow \{x_1\}$.
Define $\rho(x_i, Q_r) \doteq \min_{x_j \in Q_r} \rho(x_i, x_j)$.
for $i = 2$ to n **do**
  Add x_i to Q_r if $\rho(x_i, Q_r) > r$.
end for
Return r-net Q_r.

Proposition 10 (Correctness of Algorithms 1 and 2) *Q_r is an r-net over $\{x_i\}$.*

Proof By construction Q_r is an r-packing in both procedures. It is also an r-cover since the only points not added to (the current) Q_r are within distance r of Q_r. ■

4.2 Prediction Procedure

Algorithm 3 describes the prediction procedure f_Q in the case of regression. Instantiations for classification follow as direct plug-ins $l_{f_Q} \doteq \mathbb{1}[f_Q \geq 1/2]$ of the corresponding regression estimate f_Q as discussed in Section 3.1.4.

Algorithm 3: Netting: r-nets, $f_Q(x)$

Input: $h > 0$, query point x, αh-net Q of the data.
Assign every $x \in X_{1:n}$ to closest center $q \in Q$ (break ties arbitrarily).
Precomputed: $\bar{Y} \leftarrow$ average Y value over training data.
  $n_q \leftarrow$ number of training points assigned to $q \in Q$.
  $\bar{Y}_q \leftarrow$ Average Y value of training points assigned to $q \in Q$.
  Pick any $0 < \epsilon \leq K(3/4)/n^2$.

$$\textbf{Return} \quad f_Q(x) \leftarrow \frac{\sum_{q \in Q} n_q K(\rho(x,q)/h)\bar{Y}_q + \epsilon n \bar{Y}}{\sum_{q' \in Q} n_{q'} K(\rho(x,q')/h) + \epsilon n}.$$

The estimation of $f_{Q_r}(x)$ is already given in Theorem 7, and is given in an equivalent form (closer to implementation) in Algorithm 3. The form given in Algorithm 3 pulls out the kernel correction ϵ and makes it clear that we only need to identify those q's with nonnegative kernel values (using any black-box range-search procedure). In light of Theorem 7 we can expect this version of Netting to be competitive with kernel regression in terms of accuracy but considerably better in terms of time complexity. We will see that this holds empirically.

5. Experiments

In this section we discuss the practical benefits of Netting, and in particular verify experimentally that the knob α can be adjusted to favor estimation time or prediction accuracy on benchmark datasets from a diverse set of application domains.

5.1 Tradeoff Between Estimation Time and Prediction Accuracy

Datasets. We selected a number of prediction benchmarks from different application domains, including some large-scale prediction tasks. Datasets are summarized in Table 1.

The first prediction task is taken from robotic controls. The goal here is to learn the inverse dynamics for the movement of an anthropomorphic robotic arm. That is, we want to predict the torque required to move the robotic arm to a given state, where each state is a 21-dimensional vector of position, velocity and acceleration (Vijayakumar and Schaal, 2000).[3] Different torques are applied at seven joint positions, we predict the first torque value in our experiments as a regression task. This dataset contains 44,484 training examples.

The second prediction task comes from the medical image analysis domain. The dataset consists of 384 features extracted from 53,500 Computed Tomography (CT) scan images

3. The dataset was taken from Rasmussen and Williams (2006).

Dataset Name	Application Domain	n	D	Task
SARCOS[3]	Robotic Control	44k	21	regression
Location of CT slices (axial)[4]	Medical Image Analysis	54k	384	regression
MiniBooNE[4]	Particle Physics	130k	50	classification

Table 1: Summary of the datasets used for time-accuracy tradeoff experiments.

Datasets	SARCOS (42k)	CT Slices (51k)	MiniBooNE (128k)
$\alpha = 1/6$	0.99 - 2.03	0.93 - 1.29	0.99 - 1.17
$\alpha = 2/6$	**0.99 - 4.10**	0.92 - 2.04	0.99 - 1.65
$\alpha = 3/6$	**0.98 - 6.31**	**0.91 - 3.17**	**0.99 - 4.05**
$\alpha = 4/6$	**0.96 - 7.70**	**0.91 - 5.40**	**0.98 - 6.42**
$\alpha = 5/6$	0.89 - 9.26	0.85 - 11.94	**0.94 - 8.83**
$\alpha = 6/6$	0.77 - 10.14	0.43 - 15.33	0.88 - 10.22

Table 2: The two numbers in each cell are *error ratio*, **vs.** *time ratio* (w.r.t. base kernel method), for different datasets. The error ratio (loss in accuracy) is the error of the base kernel method over the error of the method (for a given α value). The time ratio (time improvement) is the estimation time of the base kernel method over the estimation time of the method (for a given α value). Shown are averages over multiple runs (as described in the experimental section). For the MiniBooNE dataset, the error is the 0-1 classification error, while for the other datasets we use RMSE. Some of the best tradeoffs are highlighted, appearing at different α values for different datasets. As predicted by the analysis, in many such cases, little accuracy is lost when following our conditions on quantization. Furthermore, as predicted by the analysis, the *knob* α can be seen to control the tradeoffs, i.e. relative accuracy goes down as $\alpha \to 1$, while time gain goes up.

from 74 distinct patients (Graf et al., 2011).[4] The goal is to predict the relative location of the CT slice on the axial axis of the human body. This is a regression task.

The third prediction task is from Particle Physics, where the goal is to classify elementary particles. Particles are either electron neutrinos (signal) or muon neutrinos (background) collected from the MiniBooNE (Booster Neutrino) experiment (Roe et al., 2005).[4] There are 50 features computed for each event (observation), with a total of 130,065 events.

Experimental setup. We consider increasing settings of the trade-off knob α from $\frac{1}{6}, \frac{2}{6}, \ldots, \frac{6}{6}$, while we monitor the prediction accuracy and evaluation time for different sample sizes of each dataset. The results (accuracy and prediction time w.r.t. the vanilla kernel method) for the largest sample sizes are reported in Table 2, while in Figure 2 we report results for increasing sample sizes.

A basic experiment is as follows. We select 2,000 random samples from each dataset for testing, and use (part of) the rest for training. Training sizes are logarithmically space

4. The dataset was taken from UCI Machine Learning repository (Lichman, 2013).

from 100 samples to the maximum training dataset size. For each training size, results are averaged over 5 draws of training and testing samples.

Implementation details. Both r-nets and kernel regression (baseline) can significantly benefit from using a fast nearest neighbor search mechanism. We use the default fast rangesearch functionality available in Matlab for nearest neighbor search in all our experiments. The choice of weighting kernel can also affect the prediction quality. We use the triangular kernel ($K(u) = (1 - |u|)_+$) for all our experiments; we get similar trends (with slightly worse accuracies) if we use the box kernel instead.

The bandwidth parameter for each procedure (corresponding to each choice of α, where $\alpha = 0$ is the vanilla kernel regression estimate) were selected using a 5-fold cross validation (over the training sample).

Bandwidth range. For a good range of bandwidth (for any procedure) we use a two step approach: we first approximate a good bandwidth choice h_1 by iterating over 10 sizes ranging from minimum training-data diameter to maximum training-data diameter (equally spaced). We then use h_1 to get a refined range to search, namely $[h_1/2, 2h_1]$, over which we do a full sweep of 100 equally spaced bandwidth values.

Demo code. A Matlab implementation of the r-nets algorithm along with a test demo is available at `http://www.cse.ucsd.edu/~naverma/code/rnets_prediction.zip`.

5.2 Discussion of Results

We report the root mean squared error (RMSE) for regression tasks, and the 0-1 loss for classification.

In Figure 2, the errors and estimation (wall-clock) times are reported for each dataset for increasing values of the sample size n. For baseline comparison we also include the performance of a simple "average" predictor, i.e. one that returns the global average Y value of the training samples.

In Table 2, the results are on the same experiments as in Figure 2, but we now focus on the largest sample size for each dataset. While Figure 2 shows the general trend of tradeoffs as n varies, Table 2 emphasizes the exact accuracy and time ratios relative to the vanilla kernel procedure as a function of the knob α.

The empirical results match the theoretical analysis. The knob α is seen to control the achievable tradeoffs, i.e., an α value close to 0 results in an accuracy on par with that of kernel regression, while as $\alpha \to 1$, the accuracy decreases while time improves, sometimes dramatically for some of the datasets. Some of the best tradeoffs are highlighted in bold in Table 2. Some of the best tradeoffs are obtained for SARCOS (regression) and the MiniBoone (classification) tasks, where we observe negligible decrease in accuracy for nearly 8 to 9 times speedups in prediction time. The largest decrease in accuracy is observed with the CT Slices dataset, although the achieved tradeoffs are still of significant practical value.

The general trend is maintained as the sample size n grows (see Figure 2), with better accuracy for low-values of α (as the statistical aspect gets easier with sample size), and more speedup (as also suggested by the time bounds in the earlier analysis).

Finally, we contrast these results with those obtained using a more common quantization approach such as a *kd-tree*. A kd-tree (see appendix) is a hierarchical partitioning of the

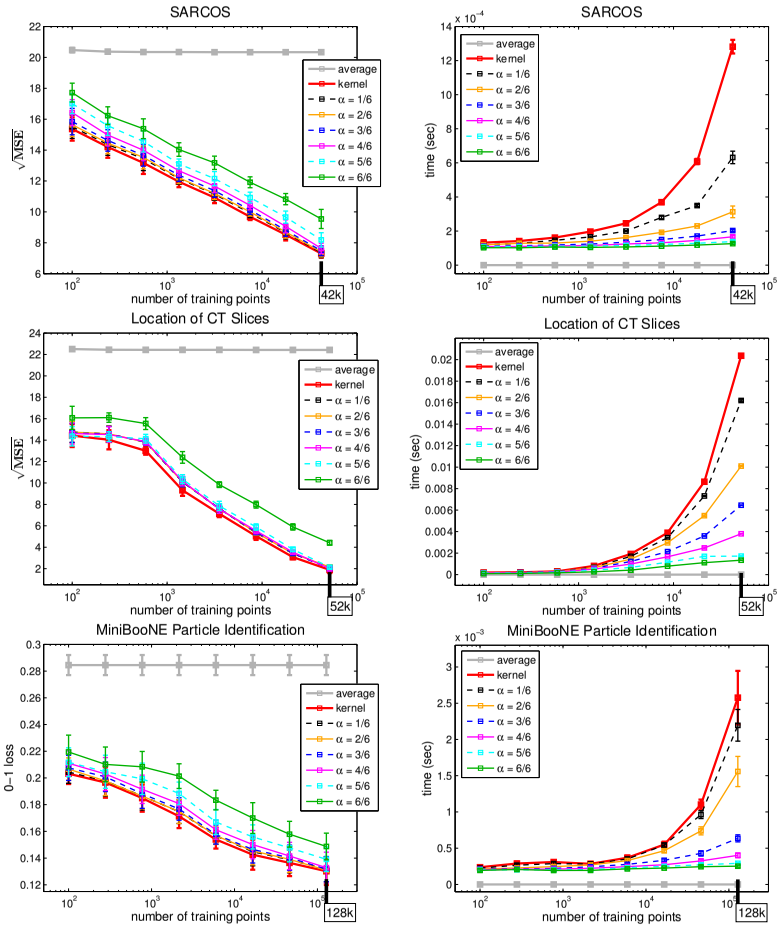

Figure 2: Average prediction error (left column) and the corresponding evaluation time (right column) of r-nets (Algorithm 3).

space that aims to quickly decrease the diameter of the data in each partition-cell. Each level of a kd-tree (from 0 to about $\log n$, with the last level being all of the data) yields a quantization Q of the data by simply assigning datapoints in each cell to their mean. For comparison, we pick a bandwidth h by cross-validation (as described above for the other methods), and estimate f by the quantized predictor f_Q of (5). In other words we simply replace our earlier quantization with r-nets with those defined by levels of the common kd-tree. Again we use the default Matlab fast-similarity search over Q.

The resulting error and time ratios (w.r.t. the base kernel method) are given in Table 3 below, where we only show the last few levels which the best prediction errors (note that the last level, not shown, is exactly the vanilla kernel method since there is no quantization).

Datasets	SARCOS (42k)	CT Slices (51k)	MiniBooNE (128k)
level 14	0.80 - 1.58	0.34 - 4.22	0.90 - 4.95
level 15	0.93 - 1.42	0.41 - 2.89	0.92 - 3.49
level 16	-	-	0.95 - 2.24

Table 3: kd-tree quantization results

We see that the best error-ratios (error of kernel over error of f_Q) attained are worse than those using the r-nets as prescribed by our analysis, and furthermore the time-speedups (time of kernel over time of f_Q) are also significantly worse. This is most apparent for the CT Slices dataset, which seems the hardest for maintaining the accuracy of the original kernel predictor (0.41-2.89 is the best tradeoff for kd-tree, vs, 0.91-5.40 for the r-net approach). We note however that, if time is favored, then a kd-tree can be preferable to the r-net approach since much better time can be attained at lower tree levels (further quantization) but with significant decrease in prediction accuracy (see Appendix C).

6. Final Remarks and Potential Future Directions

Our analysis reveals simple sufficient conditions on data-quantization to approximately maintain prediction accuracy while significantly improving prediction time. Furthermore, we identify a practical knob tying together quantization and prediction parameters, so as to simplify practical control of achievable tradeoffs. These new insights are validated experimentally on real-world datasets.

One possible future direction is to extend the insights herein to situations where the data is a mixture of structured subspaces of varying complexity so as to better capture the richness of real-world data. It could be that different quantization schemes should be employed for each such subspace once identified. Another potential direction is in characterizing what happens with a random subsampling scheme (as a way to quantize data) rather than with data-quantization; in particular it will be interesting to characterize situations where a random subsample (approximately) achieves the sufficient quantization conditions derived in the present work.

Acknowledgements

We would like to thank Kevin Liou for assisting in running the experiments.

Appendix A. Analysis for r-nets

We first analyze the risk for a fixed choice of h, then we give guarantees for a simple cross-validation procedure for choosing a good h.

Throughout this section we assume that Q is independent of $Y_{1:n}$, and is an αh-cover of $X_{1:n}$. Here we consider the Kernel Netting estimate f_Q defined as follows.

Let the kernel $K(u)$ be a non increasing function of $u \in [0,\infty)$; K is positive on $u \in [0,1)$, maximal at $u = 0$, and is 0 for $u \geq 1$. For $q \in Q$, let n_q denote the number of points from $X_{1:n}$ assigned to it, and let $\bar{Y}_q$ denote the average Y value of points assigned to q.

Define the regression estimate as

$$\begin{aligned} f_Q(x) &= \sum_{q\in Q} w_q(x)\bar{Y}_q, \text{ where} \\ w_q &= \frac{n_q(K(\rho(x,q)/h)+\epsilon)}{\sum_{q'\in Q} n_{q'}(K(\rho(x,q')/h)+\epsilon)}, \end{aligned}$$

where the positive constant $\epsilon \leq K(3/4)/n^2$ ensures the ratio is well defined.

All the results below are given under Assumptions 1 and 2.

A.1 Risk Bound for Fixed h

Throughout this section we assume $0 < h < \Delta_{\mathcal{X}}$, $0 < \alpha < 3/4$ and we let $Q = Q_{\alpha h}$. We'll bound the risk for f_Q for any fixed choice of h. The results in this section only require the fact that Q is a cover of the data and thus preserves local information.

For any estimator $f_n(x) \doteq f_n(x; X_{1:n}, Y_{1:n})$, define $\widetilde{f}_n(x) \doteq \mathbb{E}_{Y_{1:n}|X_{1:n}} f_n(x)$, i.e., the conditional expectation of the estimate for $X_{1:n}$ fixed. In particular we will be interested in $\widetilde{f}_Q(x) \doteq \mathbb{E}_{Y_{1:n}|X_{1:n}} f_Q(x)$. We have the following standard decomposition of the (conditional) excess risk into variance and bias terms:

$$\forall x \in \mathcal{X},\ \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \|f_n(x) - f(x)\|^2 = \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|f_n(x) - \widetilde{f}_n(x)\right\|^2 + \left\|\widetilde{f}_n(x) - f(x)\right\|^2. \quad (5)$$

For linear estimates (as those discussed in this work), the above decomposition yields the following simple proposition providing a rough bound on the risk for all $x \in \mathcal{X}$.

Proposition 11 *Fix $x \in \mathcal{X}$ and consider a linear estimate $f_n(x) = \sum_i w_i(x) Y_i$, where $\sum_i w_i(x) = 1$. We then have*

$$\forall x \in \mathcal{X},\ \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \|f_n(x) - f(x)\|^2 \leq \sigma_Y^2 + \Delta_f^2, \quad (6)$$

where σ_Y^2 and Δ_f^2 are respectively shown to bound the variance and bias terms in (5).

Proof It is easily verified that, for independent random vectors v_i with expectation $\mathbf{0}$, $\mathbb{E}\left\|\sum_i v_i\right\|^2 = \sum_i \mathbb{E}\|v_i\|^2$. We therefore have for the variance,

$$\mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|f_n(x) - \widetilde{f}_n(x)\right\|^2 \leq \sum_i w_i^2(x) \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|Y_i - \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} Y_i\right\|^2 \leq \sum_i w_i^2(x)\cdot\sigma_Y^2 \leq \sigma_Y^2.$$

For the bias term we have by a simple triangle inequality,

$$\left\|\widetilde{f}_n(x) - f(x)\right\|^2 = \left\|\sum_i w_i(x)\left(f(x_i) - f(x)\right)\right\|^2 \leq \left(\sum_i w_i(x)\Delta_f\right)^2 \leq \Delta_f^2.$$

■

The rough bound of Proposition 11 is used for particular $x \in \mathcal{X}$ that end up in potentially bad estimates. The following lemmas establish refined variance and bias bounds for those queries $x \in \mathcal{X}$ close to the data $X_{1:n}$.

We'll proceed by bounding each term of (5) separately in the following two lemmas, and then combining these bounds in Lemma 14. We let μ denote the marginal measure over $\mathcal{X}$ and μ_n denote the corresponding empirical measure.

Lemma 12 (Variance at x) *Let $h > 0$, and $0 < \alpha < 3/4$. Fix $X_{1:n}$, and let Q be an αh-cover of $X_{1:n}$. Let $x \in \mathcal{X}$ and let $\mathcal{E}_\alpha(x)$ denote the event that $X_{1:n} \cap (B(x,(3/4-\alpha)\cdot h)) \neq \emptyset$. We have*

$$\mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|f_Q(x) - \widetilde{f}_Q(x)\right\|^2 \leq \frac{2K(0)\cdot\sigma_Y^2}{K(3/4)\cdot n\cdot\mu_n\left(B(x,(3/4-\alpha)\cdot h)\right)}\cdot\mathbb{1}[\mathcal{E}_\alpha(x)] + \sigma_Y^2\cdot\mathbb{1}\left[\bar{\mathcal{E}}_\alpha(x)\right].$$

Proof Conditioned on $X_{1:n}$ and $Q \subset X_{1:n}$, the Y_i values are mutually independent and so are the $\bar{Y}_q$ values. Therefore, in what follows, we repeatedly use the fact that $\|\sum_i v_i\|^2 = \sum_i \mathbb{E}\|v_i\|^2$ for independent $\mathbf{0}$-mean vectors v_i. We have

$$\begin{aligned} \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|f_Q(x) - \widetilde{f}_Q(x)\right\|^2 &= \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|\sum_{q\in Q} w_q(x)\left(\bar{Y}_q - \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \bar{Y}_q\right)\right\|^2 \\ &= \sum_{q\in Q} w_q^2(x) \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|\bar{Y}_q - \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \bar{Y}_q\right\|^2 \\ &= \sum_{q\in Q} w_q^2(x) \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|\sum_{i:X_i\in X_{1:n}(q)} \frac{1}{n_q}\left(Y_i - \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} Y_i\right)\right\|^2 \\ &= \sum_{q\in Q} w_q^2(x) \sum_{i:X_i\in X_{1:n}(q)} \frac{1}{n_q^2} \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} \left\|Y_i - \mathop{\mathbb{E}}_{Y_{1:n}|X_{1:n}} Y_i\right\|^2 = \sum_{q\in Q} w_q^2(x)\frac{\sigma_Y^2}{n_q} \\ &\leq \left(\max_{q\in Q}\left\{w_q(x)\frac{\sigma_Y^2}{n_q}\right\}\right)\sum_{q\in Q} w_q = \max_{q\in Q}\left\{w_q(x)\frac{\sigma_Y^2}{n_q}\right\} \\ &= \max_{q\in Q} \frac{(K(x,q,h)+\epsilon)\sigma_Y^2}{\sum_{q'\in Q} n_{q'}(K(x,q',h)+\epsilon)} \\ &\leq \min\left\{\sigma_Y^2, \frac{2K(0)\sigma_Y^2}{\sum_{q\in Q} n_q K(x,q,h)}\right\}. \end{aligned} \quad (7)$$

Assume the event $\mathcal{E}_\alpha(x)$. To bound the fraction in (7), we lower-bound the denominator as:

$$\sum_{q\in Q} n_q K(x,q,h) \geq \sum_{q:\rho(x,q)\leq 3h/4} n_q K(3/4) \geq K\left(3/4\right)\cdot n\cdot \mu_n(B(x,(3/4-\alpha)\cdot h)).$$

The last inequality follows by remarking that, since Q is an αh-cover of $X_{1:n}$, the ball $B(x,(3/4-\alpha)\cdot h)$ can only contain points from $\cup_{q:\rho(x,q)\leq 3h/4} X_{1:n}(q)$. Plug this last inequality into (7) and conclude. ■

Lemma 13 (Bias at x) *Fix $X_{1:n}$, let $0<\alpha<3/4$, and $h>0$. Suppose Q is an αh-cover of $X_{1:n}$. Let $x\in\mathcal{X}$, and define $\mathcal{E}_\alpha(x)$ as the event that $X_{1:n}\cap(B(x,(3/4-\alpha)\cdot h))\neq\emptyset$. We have*

$$\left\|\widetilde{f}_Q(x)-f(x)\right\|^2 \leq \left((1+\alpha)^2\lambda^2h^2+\frac{\Delta_f^2}{n}\right)\cdot \mathbb{1}[\mathcal{E}_\alpha(x)]+\Delta_f^2\cdot\mathbb{1}\left[\bar{\mathcal{E}}_\alpha(x)\right].$$

Proof The bias term $\left\|\widetilde{f}_Q(x)-f(x)\right\|^2$ equals

$$\left\|\sum_{q\in Q}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}(f(X_i)-f(x))\right\|^2 \leq \sum_{q\in Q}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}\|f(X_i)-f(x)\|^2 \quad (8)$$

$$\leq \sum_{q\in Q}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}\lambda^2\rho\left(X_i,x\right)^2 \quad (9)$$

where in (8) we applied Jensen's inequality on the norm square. It immediately follows from (8) that $\left\|\widetilde{f}_Q(x)-f(x)\right\|^2$ is at most Δ_f^2, for any $x\in\mathcal{X}$.

Now assume the event $\mathcal{E}_\alpha(x)$. We bound the r.h.s of (8) by breaking the summation over the following two subsets of Q: those centers q close to x and those far from x. Starting with close centers, and using (9) we have

$$\sum_{q:\rho(x,q)<h}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}\lambda^2\rho\left(X_i,x\right)^2 \leq \sum_{q:\rho(x,q)<h}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}\lambda^2\left(\rho\left(x,q\right)+\rho\left(q,X_i\right)\right)^2$$

$$\leq \sum_{q:\rho(x,q)<h}\frac{w_q(x)}{n_q}\sum_{i:X_i\in X_{1:n}(q)}(1+\alpha)^2\lambda^2h^2.$$

Next, we have

$$\sum_{q:\rho(x,q)\geq h}\frac{w_q(x)}{n_q}\sum_{X_i\in X_{1:n}(q)}\|f(X_i)-f(x)\|^2 \leq \sum_{q:\rho(x,q)\geq h} w_q(x)\Delta_f^2$$

$$= \frac{\Delta_f^2\sum_{q:\rho(x,q)\geq h} n_q\epsilon}{\sum_{q:\rho(x,q)\geq h} n_q\epsilon+\sum_{q:\rho(x,q)<h} n_q\left(K(x,q,h)+\epsilon\right)}$$

$$= \Delta_f^2\left(1+\frac{\sum_{q:\rho(x,q)<h} n_q\left(K(x,q,h)+\epsilon\right)}{\sum_{q:\rho(x,q)\geq h} n_q\epsilon}\right)^{-1}$$

$$\leq \Delta_f^2\left(1+\frac{K(3/4)}{\sum_{q:\rho(x,q)\geq h} n_q\epsilon}\right)^{-1} \leq \Delta_f^2\left(1+\frac{K(3/4)}{n\epsilon}\right)^{-1} \leq \frac{\Delta_f^2}{1+n},$$

where the first inequality is due to the fact that, since $\mu_n(B(x,(3/4-\alpha)\cdot h))>0$, the set $B(x,3h/4)\cap Q$ cannot be empty (remember that Q is an αh-cover of $X_{1:n}$). This concludes the argument. ■

Lemma 14 (Integrated excess risk) *Given a bandwidth $h>0$, and $0<\alpha<3/4$, consider an αh-cover Q of the sample $X_{1:n}$. Assign every point $X_i\in X_{1:n}$ to a single $q\in Q$ such that $\rho\left(X_i,q\right)\leq\alpha h$. We have:*

$$\mathop{\mathbb{E}}_{(X_{1:n},Y_{1:n})}\|f_Q-f\|^2 \leq \frac{C\left(\sigma_Y^2+\Delta_f^2\right)}{n\cdot((3/4-\alpha)h/(2\Delta_{\mathcal{X}}))^d}+(1+\alpha)^2\lambda^2h^2+\frac{\Delta_f^2}{n}$$

where the constant C depends only on $K(\cdot)$.

Proof To ease notation, let $\tau\doteq(3/4-\alpha)$. Applying Fubini's theorem, the expected excess risk, $\mathbb{E}_{(X_{1:n},Y_{1:n})}\|f_Q-f\|^2$, can be written as

$$\mathop{\mathbb{E}}_{X}\mathop{\mathbb{E}}_{(X_{1:n},Y_{1:n})}\|f_Q(X)-f(X)\|^2\cdot\left(\mathbb{1}[\mu_n(B(X,\tau h))>0]+\mathbb{1}[\mu_n(B(X,\tau h))=0]\right).$$

By lemmas 12 and 13 and equation (5), for $X=x$ fixed, $\mathbb{E}_{(X_{1:n},Y_{1:n})}\|f_Q(x)-f(x)\|^2\cdot\mathbb{1}[\mu_n(B(x,\tau h))>0]$ is upper bounded by

$$C_1\mathop{\mathbb{E}}_{X_{1:n}}\left[\frac{\sigma_Y^2\mathbb{1}[\mu_n(B(x,\tau h))>0]}{n\mu_n(B(x,\tau h))}\right]+(1+\alpha)^2\lambda^2h^2+\frac{\Delta_f^2}{n}$$

$$\leq C_1\left(\frac{2\sigma_Y^2}{n\mu(B(x,\tau h))}\right)+(1+\alpha)^2\lambda^2h^2+\frac{\Delta_f^2}{n}, \quad (10)$$

where for the last inequality we used the fact that for a binomial $b(n,p)$, $\mathbb{E}\left[\frac{\mathbb{1}[b(n,p)>0]}{b(n,p)}\right]\leq\frac{2}{np}$ (see lemma 4.1 of Gyorfi et al. (2002)).

On the other hand, $\mathbb{E}_{(X_{1:n},Y_{1:n})} \|f_Q(x) - f(x)\|^2 \cdot \mathbb{1}[\mu_n(B(x,\tau h)) = 0]$ is upper bounded by

$$\left(\sigma_Y^2 + \Delta_f^2\right) \mathop{\mathbb{E}}_{X_{1:n}} \mathbb{1}[\mu_n(B(x,\tau h)) = 0] = \left(\sigma_Y^2 + \Delta_f^2\right)(1 - \mu(B(x,\tau h)))^n$$
$$\leq \left(\sigma_Y^2 + \Delta_f^2\right) e^{-n\mu(B(x,\tau h))} \leq \frac{\left(\sigma_Y^2 + \Delta_f^2\right)}{n\mu(B(x,\tau h))}. \quad (11)$$

Combining (10) and (11) we can then bound the expected excess risk as

$$\mathop{\mathbb{E}}_{(X_{1:n},Y_{1:n})} \|f_Q - f\|^2 \leq \frac{C_2\left(\sigma_Y^2 + \Delta_f^2\right)}{n} \mathop{\mathbb{E}}_{X}\left[\frac{1}{\mu(B(X,\tau h))}\right] + (1+\alpha)^2\lambda^2 h^2 + \frac{\Delta_f^2}{n}. \quad (12)$$

The expectation on the r.h.s. can now be bounded using a standard covering argument (see e.g. Gyorfi et al. (2002)). Let $\{z_i\}_1^N$ be a $\tau h/2$-cover of $\mathcal{X}$. Notice that for any z_i, $x \in B(z_i, \tau h/2)$ implies $B(x,\tau h) \supset B(z_i, \tau h/2)$. We therefore have

$$\begin{aligned}\mathop{\mathbb{E}}_{X}\left[\frac{1}{\mu(B(X,\tau h))}\right] &\leq \sum_{i=1}^N \mathop{\mathbb{E}}_{X}\left[\frac{\mathbb{1}[X \in B(z_i,\tau h/2)]}{\mu(B(X,\tau h))}\right] \leq \sum_{i=1}^N \mathop{\mathbb{E}}_{X}\left[\frac{\mathbb{1}[X \in B(z_i,\tau h/2)]}{\mu(B(z_i,\tau h/2))}\right] \\ &= N \leq C_3\left(\frac{2\Delta_{\mathcal{X}}}{\tau h}\right)^d, \text{ where } C_3 \text{ depends just on } \mathcal{X}.\end{aligned}$$

We conclude by combining the above with (12) to obtain

$$\mathop{\mathbb{E}}_{(X_{1:n},Y_{1:n})} \|f_Q - f\|^2 \leq \frac{C\left(\sigma_Y^2 + \Delta_f^2\right)}{n(\tau h/2\Delta_{\mathcal{X}})^d} + (1+\alpha)^2\lambda^2 h^2 + \frac{\Delta_f^2}{n}.$$

■

A.2 Choosing a Good h by Empirical Risk Minimization

In this section, we analyze the following simple procedure for choosing a good h:

> Define $H \doteq \{\Delta_{\mathcal{X}} \cdot 2^{-i}/(3/4-\alpha)\}_0^{\lceil \log n \rceil}$. For every $h \in H$, pick the αh-net $Q_{\alpha h}$ over the sample $(X_{1:n}, Y_{1:n})$, and let $f_{Q_{\alpha h}}$ be as previously defined (equation 5). Draw a new sample $(X'_{1:n}, Y'_{1:n})$ of size n. For every $h \in H$, test $f_{Q_{\alpha h}}$ on $(X'_{1:n}, Y'_{1:n})$; let the empirical risk be minimized at $\hat{h}$, i.e. $\hat{h} \doteq \operatorname{argmin}_{h\in H} \frac{1}{n}\sum_{i=1}^n \|f_{Q_{\alpha h}}(X'_i) - Y'_i\|^2$.
> Return $f_{Q_{\alpha\hat{h}}}$ as the final regression estimate.

Proof [Corollary 8] The sample size n is lower-bounded so that there exists a universal constant C_0 such that

$$\tilde{h} \doteq C_0\left(\frac{\Delta_{\mathcal{X}}}{3/4-\alpha}\right)^{d/(2+d)}\left(\frac{\Delta_{\mathcal{Y}}^2}{\lambda^2 n}\right)^{1/(2+d)}$$

is a dyadic number greater than $\Delta_{\mathcal{X}}/n$.

First, let's consider the situation where $h \in H$, i.e. $\tilde{h} \leq \Delta_{\mathcal{X}}/(3/4-\alpha)$. Note that, whenever $n \geq \left(\frac{\Delta_{\mathcal{Y}}(3/4-\alpha)}{\lambda\Delta_{\mathcal{X}}}\right)^2$, we can choose a universal C_0 above so that $\tilde{h} \in H$.

We have by Lemma 14 that for some C, regression with $\tilde{h}$ satisfies

$$\mathop{\mathbb{E}}_{X_{1:n},Y_{1:n}} \left\|f_{Q_{\alpha\tilde{h}}} - f\right\|^2 \leq C'\left(\frac{\lambda\Delta_{\mathcal{X}}}{3/4-\alpha}\right)^{2d/(2+d)}\left(\frac{\Delta_{\mathcal{Y}}^2}{n}\right)^{2/(2+d)}. \quad (13)$$

Applying McDiarmid's to the empirical risk followed by a union bound over H, we have that, with probability at least $1 - 1/\sqrt{n}$ over the choice of $(X'_{1:n}, Y'_{1:n})$, for all $h \in H$

$$\left|\mathop{\mathbb{E}}_{X,Y}\|f_{Q_{\alpha h}}(X) - Y\|^2 - \frac{1}{n}\sum_{i=0}^n \left\|f_{Q_{\alpha h}}(X'_i) - Y'_i\right\|^2\right| \leq \Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln(|H|\sqrt{n})}{n}}.$$

It follows that $\mathbb{E}_{X,Y}\left\|f_{Q_{\alpha\hat{h}}}(X) - Y\right\|^2 \leq \inf_{h\in H}\mathbb{E}_{X,Y}\|f_{Q_{\alpha h}}(X) - Y\|^2 + 2\Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln(|H|\sqrt{n})}{n}}$, which by equation (1) implies

$$\begin{aligned}\left\|f_{Q_{\alpha\hat{h}}} - f\right\|^2 &\leq \inf_{h\in H}\|f_{Q_{\alpha h}} - f\|^2 + 2\Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln(|H|\sqrt{n})}{n}} \quad (14)\\ &\leq \left\|f_{Q_{\alpha\tilde{h}}} - f\right\|^2 + 2\Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln(|H|\sqrt{n})}{n}}\end{aligned}$$

Take the expectation (given the randomness in the two samples) over this last inequality and apply (13) to obtain the first two terms of the bound on $\mathbb{E}\left\|f_{Q_{\alpha\hat{h}}} - f\right\|^2$.

Now consider the case where $\tilde{h} \notin H$, i.e. $\tilde{h} > \Delta_{\mathcal{X}}/(3/4-\alpha)$. Consider any $h \geq \Delta_{\mathcal{X}}/(3/4-\alpha)$. For any such h, and any query $x \in \mathcal{X}$, $0 \leq \rho(x,q) \leq \Delta_{\mathcal{X}} \leq 3h/4$ for all $q \in Q \subset \mathcal{X}$. It follows that for any $q \in Q$, $C_1/n \leq w_q \leq C_2/n$ where C_1, C_2 are as defined in the corollary's statement. In particular, the estimates (at any x) using $\tilde{h}$ or using $l_0 = \Delta_{\mathcal{X}}/(3/4-\alpha)$ differ by at most $(C_2 - C_1)\left\|\bar{Y}\right\| \leq (C_2 - C_1)\Delta_{\mathcal{Y}}$, where $\bar{Y} = \sum_i Y_i/n$. It follows that the difference in errors (fixing $X_{1:n}, Y_{1:n}$) is at most

$$\left\|f_{Q_{\alpha l_0}} - f\right\|^2 \leq \left(\left\|f_{Q_{\alpha\tilde{h}}} - f\right\| + \left\|f_{Q_{\alpha l_0}} - f_{Q_{\alpha\tilde{h}}}\right\|\right)^2 \leq 2\left\|f_{Q_{\alpha\tilde{h}}} - f\right\|^2 + 2(C_2 - C_1)^2\Delta_{\mathcal{Y}}^2.$$

Therefore, whenever $n < \left(\frac{\Delta_{\mathcal{Y}}(3/4-\alpha)}{\lambda\Delta_{\mathcal{X}}}\right)^2$, let $\tilde{h} > \Delta_{\mathcal{X}}/(3/4-\alpha)$, and obtain by (14) that

$$\left\|f_{Q_{\alpha\hat{h}}} - f\right\|^2 \leq 2\left\|f_{Q_{\alpha\tilde{h}}} - f\right\|^2 + 2(C_2 - C_1)^2\Delta_{\mathcal{Y}}^2 + 2\Delta_{\mathcal{Y}}^2\sqrt{\frac{\ln(|H|\sqrt{n})}{n}},$$

with probability at least $1 - 1/\sqrt{n}$. Again take the expectation w.r.t. the two samples and apply (13) to obtain the full corollary's statement. ■

Appendix B. Time Complexity Bounds

B.1 Time Bound of Proposition 1

The proof of Proposition 1 follows easily from considering the mass of balls in a high-dimensional space. The proof is given below.

Proof [Proposition 1] Let for instance P be uniform on a closed ball $\mathcal{X}$ of $\mathbb{R}^D$. Then any ball of radius h centered on the interior of $\mathcal{X}$ has mass $\Omega(h^D)$. Thus for $h = \Omega\left(n^{-1/(2+D)}\right)$, $\mathbb{E}\,|B(x,h) \cap X_{1:n}| = n \cdot P(B(x,h)) = \Omega\left(n^{2/(2+D)}\right)$. Now, let P_n denote the empirical distribution on $X_{1:n}$; it is well known that by Bernstein's bounds (Bousquet et al., 2004), we have with probability at least $1/2$ that

$$P(B(x,h)) \leq P_n(B(x,h)) + \sqrt{C \cdot P_n(B(x,h))/n} + C/n,$$

for some universal constant C. This implies that if $P_n(B(x,h)) < C/n$, then $P(B(x,h)) < 3C/n$. For n sufficiently large, $P(B(x,h)) = \Omega\left(n^{-D/(2+D)}\right) \geq 3C/n$, so we must have $P_n(B(x,h)) \geq C/n$. It then follows by the above Bernstein's inequality that $P(B(x,h)) \leq 3P_n(B(x,h))$, which yields the proposition's statement. ■

B.2 Evaluation Times for Netting

Proof [Proof of Lemma 9] It is well known that an r-packing Q of a ball $B(x,r')$, $r' > r$, has size at most that of an $r/2$-cover of $B(x,r')$ (Clarkson, 2005). This size is bounded by $C(r'/r)^d$, which is seen by applying the definition of doubling dimension recursively. ■

Lemma 15 (Paraphrased from Krauthgamer and Lee (2004)) *Let $\{x_i\}$ be a finite set of points from a metric space $(\mathcal{X}, \rho)$ with doubling dimension d.*

Define the aspect-ratio *of $\{x_i\}$ as $\tau \doteq \max_{i,j} \rho(x_i, x_j) \,/\, \min_{i,j} \rho(x_i, x_j)$. For any query $x \in \mathcal{X}$ and $r > 0$, the range $B(x,r) \cap \{x_i\}$ can be obtained in time at most*

$$C\left(|B(x, c \cdot r) \cap \{x_i\}| + \log \tau\right),$$

for some C depending on d, and a universal constant $c \geq 1$.

Lemma 16 *Assume the conditions of Theorem 7. For any $x \in \mathcal{X}$, the estimate $f_Q(x)$ can be computed in time $C\left(\log(\Delta_{\mathcal{X}}/\alpha h) + \alpha^{-d}\right)$, where C depends on d.*

Proof This is a direct corollary to Lemmas 9 and 15, by noticing that the aspect ratio of Q is at most $\Delta_{\mathcal{X}}/\alpha h$. ■

Appendix C. kd-tree Construction Details

Algorithm 4: kd-tree

Input: dataset $X_{1:n}$.
if $|X_{1:n}| \leq 1$ **then**
  Return leaf.
end if
Let j be the largest-variance coordinate of the data $x \in X_{1:n}$.
Define $t \doteq \text{median}\left\{x^j : x \in X_{1:n}\right\}$.
$X_{\text{left}} \doteq \{x \in X_{1:n} \mid x^j \leq t\}$.
$X_{\text{right}} \doteq \{x \in X_{1:n} \mid x^j > t\}$.
$\text{Tree}_{\text{left}} = k\text{d-tree}(X^{\text{left}}_{1:n})$.
$\text{Tree}_{\text{right}} = k\text{d-tree}(X^{\text{right}}_{1:n})$.
Return $(\text{Tree}_{\text{left}}, \text{Tree}_{\text{right}})$.

C.1 kd-tree Results

The following table lists the error and time ratios (w.r.t. to kernel prediction) achieved at every level of the tree (omitting the last level with no quantization).

Datasets	SARCOS (42k)	CT Slices (51k)	MiniBooNE (128k)
level 0	0.34 - 271.67	0.08 - 2,351.77	0.46 - 412.06
level 1	0.37 - 11.08	0.09 - 260.33	0.46 - 515.86
level 2	0.38 - 10.52	0.09 - 301.92	0.48 - 11.71
level 3	0.39 - 10.77	0.10 - 254.53	0.51 - 12.63
level 4	0.40 - 10.46	0.10 - 209.23	0.54 - 11.96
level 5	0.41 - 10.73	0.11 - 174.25	0.60 - 12.06
level 6	0.43 - 10.22	0.12 - 126.92	0.62 - 11.15
level 7	0.45 - 9.44	0.13 - 90.44	0.64 - 10.51
level 8	0.48 - 8.30	0.15 - 67.72	0.64 - 9.38
level 9	0.52 - 7.77	0.16 - 43.64	0.69 - 8.42
level 10	0.56 - 6.05	0.18 - 27.14	0.71 - 7.21
level 11	0.60 - 4.86	0.20 - 16.25	0.78 - 9.70

Editor: Xiaotong Shen

Abstract

For spiked population model, we investigate the large dimension N and large sample size M asymptotic behavior of the Support Vector Machine (SVM) classification method in the limit of $N, M \to \infty$ at fixed $\alpha = M/N$. We focus on the generalization performance by analytically evaluating the angle between the normal direction vectors of SVM separating hyperplane and corresponding Bayes optimal separating hyperplane. This is an analogous result to the one shown in Paul (2007) and Nadler (2008) for the angle between the sample eigenvector and the population eigenvector in random matrix theorem. We provide not just bound, but sharp prediction of the asymptotic behavior of SVM that can be determined by a set of nonlinear equations. Based on the analytical results, we propose a new method of selecting tuning parameter which significantly reduces the computational cost. A surprising finding is that SVM achieves its best performance at small value of the tuning parameter under spiked population model. These results are confirmed to be correct by comparing with those of numerical simulations on finite-size systems. We also apply our formulas to an actual dataset of breast cancer and find agreement between analytical derivations and numerical computations based on cross validation.

Keywords: Asymptotic behavior, Spiked population model, Support Vector Machine

1. Introduction

The Support Vector Machine (SVM) is a state-of-the-art powerful classification method proposed by Vapnik (Vapnik, 1995). It has been widely used in bioinformatics and many other disciplines and has achieved a lot of success. Like other classification methods, SVM may suffer from a loss of generalization ability in high dimensional situations as shown by Figure 1 which displays the application of SVM to a high dimensional two class toy example with class labels $+1$ and -1. The data have dimension $N = 100$, with $M_+ = 45$ data vectors from Class $+1$ represented as circles, and $M_- = 45$ data vectors from Class -1 represented as plus. The two distributions are nearly standard normal except that the mean in the first dimension is shifted to $+\mu$ and $-\mu$ for Class $+1$ and Class -1 respectively. Here $\mu = 1$. Figure 1 shows the projections of the data onto the two-dimensional subspace determined by the first dimension (dashed line) and the normal vector (solid line) of the SVM separating hyperplane. The angle between these two directions can be used to determine the generalization ability of the classifier. A classifier who has good generalization properties should have small angle. For the particular example shown in Figure 1, the angle is 56.6°. Therefore, projection of a new data vector onto the SVM direction cannot be expected to provide effective discrimination. As mentioned by Marron et al. (2007), the reason is that the estimated SVM classifier is driven only by very particular aspects of the realization of the training data at hand. New data will have their own quite different quirks, which will bear no relation to these.

Hall et al. (2005) studied the High Dimensional Low Sample Size (HDLSS) asymptotics of SVM and shown that for fixed sample size $M = M_+ + M_-$, as $N \to \infty$ the angle depends on the signal size μ which is defined as half of the distance between the means of two distributions for this example. Assume that μ increases with N as N^γ, then if $\gamma > 1/2$, SVM is strongly consistent, i.e., the angle approaches to 0°; if $\gamma < 1/2$, SVM is strongly inconsistent, i.e., the angle approaches to 90°; if $\gamma = 1/2$, the angle is between 0° and 90°. Therefore the signal size μ has to be large enough in order to gain some prediction power.

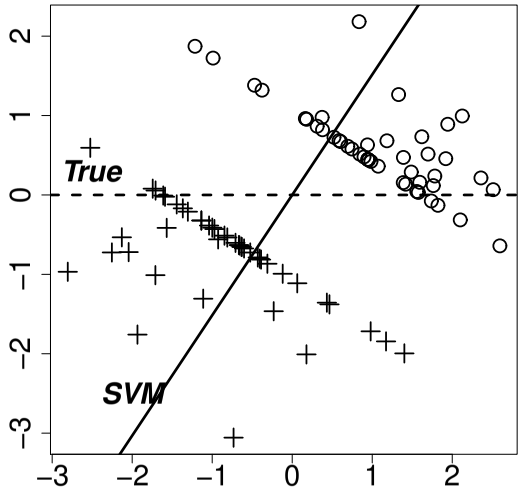

Figure 1: Toy examples, illustrating the performance of SVM on high dimensional data with $N = 100$ and sample size $M = M_+ + M_- = 90$. The circles denote the data from Class $+1$ and and the plus denote the data from Class -1. The dashed line represents the first dimension which is the true difference in the Gaussian means. The solid line represents the normal vector of SVM separating hyperplane. The angle between the solid and dashed lines is 56.6°.

Analogous conclusion has been drawn in the context of unsupervised learning for Principal Component Analysis (PCA). The study of sample covariance matrices is fundamental in multivariate analysis. It is well known that the sample covariance matrix is a consistent estimator of the population covariance matrix for fixed dimension N and sample size $M \to \infty$.

The PCA consistency in HDLSS context (fixed M and $N \to \infty$) was studied in Jung and Marron (2009); Jung et al. (2012) and it was shown that the asymptotic behavior of the Principal Component (PC) directions of sample covariance matrix depend on the size of the corresponding eigenvalues. Assume that the eigenvalue of the sample covariance matrix λ increases with N in the order of power γ, i.e. $\lambda \sim N^{\gamma}$. Then, if $\gamma>1/2$, the corresponding estimated PC direction is strongly consistent, i.e. the angle between the estimated direction and its population counterpart is $0°$; if $\gamma<1/2$, the corresponding estimated PC direction is strongly inconsistent, i.e. the angle is $90°$; if $\gamma = 1/2$, the angle is random and follows a certain distribution.

On the other hand, with the development of modern high-throughput technologies, it is not uncommon to have data where M is comparable in size to N, or substantially larger. There has been considerable effort to establish asymptotic results for sample eigenvalues and eigenvectors under the assumption that N and M grow at the same rate, that is, $M/N \to \alpha>0$ (see review Bai (1999)). The limiting distribution of eigenvalues of the sample covariance matrix was derived in Marcenko and Pastur (1967). Johnstone (2001) studied the distribution of the largest eigenvalue in PCA. Baik and Silverstein (2006) investigated the convergence of the sample eigenvalues and eigenvectors under the spiked population. The degree of discrepancy in terms of the angle between the directions of sample and population eigenvectors was further derived in Paul (2007); Nadler (2008) for both $0<\alpha<1$ and $\alpha>1$ situations. A phenomenon of retarded learning was observed that the angle goes through a critical phase transition from angle equal to $90°$ for $\lambda<\sqrt{\alpha}$ to angle less than $90°$ for $\lambda>\sqrt{\alpha}$. Therefore, one can only detect signals whose corresponding eigenvalues are larger than the critical value $\sqrt{\alpha}$ in PCA. More general results have been obtained by Hoyle and Rattray (2004) and Hoyle and Rattray (2007); Hoyle (2010) for general population covariance matrix.

In the present work, we study the analogous asymptotic results in the joint limit $N, M \to \infty$ with $M/N = \alpha$ in the supervised learning context for the SVM classification method. We focus on the generalization performance of SVM by deriving analytical results for the angle between the estimated direction and the true direction and investigating how this angle depends on μ, α and other model parameters. We consider a spiked population model and assume that the data from each class are generated from a purely noise model spiked with a few significant eigenvalues. We derive the analytical results using the replica method developed in statistical mechanics and also compare with numerical simulations on finite size systems. To the best of our knowledge, the present paper is the first that provides not just bounds, but sharp predictions of the asymptotic behavior of the SVM estimators in the limit $N, M \to \infty$ at fixed $M/N = \alpha$.

An immediate application of our analytical findings is for tuning parameter selection. SVM is required to solve problem of determining the tuning parameter τ that characterizes the strength of the penalty term. Cross validation (CV) is a practically useful strategy for handling this task; its basic concept is to evaluate the prediction error by examining the data under control. Smaller values of the CV error are expected to be better to express the generative model of the data. The minimum, if it exists, of the CV error when changing τ is thus considered to obtain an optimal value of τ. However, conducting CV through grid search for finding the minimizer of the CV error is rather computationally expensive especially for high dimensional data. Here we propose a new method of selecting optimal value of τ base on analytical evaluation for the angle between the estimated SVM direction and true direction which considerably reduces the computational cost. Under the spiked population assumption, smaller angle indicates smaller test error. A surprising finding is that SVM achieves its best performance at small value of the tuning parameter. All analytical results are confirmed by numerical experiments on finite-size systems and our formula is clarified to work well for moderate-size systems.

The rest of this paper is organized as follows: In Section 2, we state SVM in the context of spike population model. The analytical results for large N, M asymptotics are presented. In Section 3, we show the result of numerical experiments to support our analytical results. An application of the proposed tuning parameter selection method to the breast cancer data is also presented in this section. The last section is devoted to the conclusion.

2. Method

In the classification problem, we are given a training dataset consisting of M observations $(\mathbf{x}_i, y_i)$, for $i = 1, \cdots, M$. Here $\mathbf{x}_i \in R^N$ represents an input vector and $y_i \in \{+1, -1\}$ denotes the corresponding output class label. Each $(\mathbf{x}_i, y_i)$ is an independent random vector distributed according to a joint distribution function $p(\mathbf{x}, y)$. We assume that y has probability p_+ to be $+1$ and probability p_- to be -1 with $p_+ + p_- = 1$. Conditional on $y = +1, -1$, $\mathbf{x}$ follows multivariate distributions $p(\mathbf{x}|y = +1)$, $p(\mathbf{x}|y = -1)$ with mean $\boldsymbol{\mu}_+, \boldsymbol{\mu}_-$ and covariance matrices $\boldsymbol{\Sigma}_+, \boldsymbol{\Sigma}_-$, respectively. Without loss of generality, assume $\boldsymbol{\mu}_+ = -\boldsymbol{\mu}_- = \boldsymbol{\mu}$. Similar to linear discriminant analysis, we make an additional simplifying homoscedasticity assumption $\boldsymbol{\Sigma}_+ = \boldsymbol{\Sigma}_- = \boldsymbol{\Sigma}$. Here $\boldsymbol{\mu} \in R^N$ and $\boldsymbol{\Sigma}$ denotes the $N \times N$ matrix. Based on this setting, the data from two classes are generated from two multivariate distributions with the same covariance but different means. The signal size can be characterized by $\mu = \|\boldsymbol{\mu}\| = \sqrt{\sum_{j=1}^{N} \mu_j^2}$.

We consider a spiked covariance model here. For high dimensional data, typically only few components are biologically important. The remaining structures can be considered as i.i.d. background noise. Therefore, in high-dimensional settings, a collection of data can be modeled by a low-rank signal plus noise structure (Ma, 2013; Liu et al., 2008). We use a factor analysis model to explain correlations between a set of N variables by means of a smaller set of K causal factors. Specifically, we assume the following:

Assumption 1 *Each observation vector* $\mathbf{x}$ *from Class* $+1$ *can be viewed as an independent instantiation of the following generative model*

$$\mathbf{x} = \boldsymbol{\mu} + \sum_{m=1}^{K} \sigma \sqrt{\lambda_m} \mathbf{v}_m z_m + \boldsymbol{\epsilon}. \tag{1}$$

Here $\boldsymbol{\mu}$ *is the mean vector,* $\lambda_m>0$, $\mathbf{v}_m \in R^N$ *are orthonormal vectors, i.e.* $\mathbf{v}_m^T \mathbf{v}_m = 1$ *and* $\mathbf{v}_m^T \mathbf{v}_{m'} = 0$ *for* $m \neq m'$, $\hat{\boldsymbol{\mu}} = \boldsymbol{\mu}/\mu = \mathbf{v}_1$. *The random variables* $z_1, \cdots, z_K \overset{i.i.d}{\sim} N(0,1)$. *The vector* $\boldsymbol{\epsilon} = \{\epsilon_1, \cdots, \epsilon_N\}$ *whose elements* $\epsilon_j s$ *are i.i.d random variables with* $E(\epsilon_j) = 0$, $E(\epsilon_j^2) = \sigma^2$ *and* $E(\epsilon_j^3)<\infty$. *The* $\epsilon_j s$ *are independent of* $z_m s$. *The* $\mathbf{x}$ *from Class* -1 *can be modeled in a similar way with* $\boldsymbol{\mu}$ *replaced by* $-\boldsymbol{\mu}$.

In model (1), λ_m represents the strength of the m-th biological component, and σ^2 represents the level of background noise. The real biology is typically low-dimensional, i.e. $K \ll N$. Considering signal as one of the biological components, without loss of generality, we assume that $\boldsymbol{\mu}$ is in the same direction as $\mathbf{v}_1$, i.e. $\hat{\boldsymbol{\mu}} = \mathbf{v}_1$. Note that the eigenvalue λ_m is not necessarily decreasing in m and λ_1 is not necessarily the largest eigenvalue. From (1), the covariance matrix is

$$\boldsymbol{\Sigma} = \sigma^2 \mathbf{I}_N + \sum_{m=1}^{K} \sigma^2 \lambda_m \mathbf{v}_m \mathbf{v}_m^T, \tag{2}$$

where $\mathbf{I}_N$ is N-dimensional identity matrix. Although the ϵ_js are i.i.d, we didn't impose any parametric form for the distribution of ϵ_j which allows for very flexible covariance structures for $\mathbf{x}$, and thus the results are quite general. The requirement for the finite third order moment is to ensure Berry-Esseen central limit theorem applies. The Assumption 1 is also called spiked population model and has been used in many situations, see Baik and Silverstein (2006); Marcenko and Pastur (1967); Johnstone (2001) for examples. Such a population covariance is a finite rank perturbation of multiple of the identity matrix. In other words, all but finitely many eigenvalues of the population covariance matrix are the same. Examples of spiked data include speech recognition (Trevor Hastie, 1995), mathematical finance (LALOUX et al., 2000), wireless communications (Telatar, 1999), and physics of mixture (Sear and Cuesta, 2003).

The task of linear classification is to construct a hyperplane $\mathbf{x}^T\mathbf{w} = 0$ ($\mathbf{w} \in R^N$) so that the new data vector $\mathbf{x}$ is assigned to Class $+1$ when $\mathbf{x}^T\mathbf{w}>0$ and Class -1 otherwise. If the training data are linearly separable, SVM seeks to find this hyperplane such that the minimal distance between the hyperplane and the data point from each class is maximized. The hard-margin SVM solution can be formulated in terms of the following optimization problem

$$\begin{aligned} &\min_{\mathbf{w}} \left[\mathbf{w}^T\mathbf{w}\right] \\ \text{s.t.} \quad &\frac{y_i \mathbf{x}_i^T \mathbf{w}}{\sqrt{N}} \geq 1, \ i = 1, \cdots, M. \end{aligned} \tag{3}$$

To extend SVM to cases in which the data are not linearly separable, we introduce the slack variables ξ_i for $i = 1, \cdots, M$. The soft-margin SVM solution can be formulated in terms of the following optimization problem

$$\begin{aligned} &\min_{\mathbf{w}} \left[\mathbf{w}^T\mathbf{w} + \tau \sum_{i=1}^{M} \xi_i\right] \\ \text{s.t.} \quad &\frac{y_i \mathbf{x}_i^T \mathbf{w}}{\sqrt{N}} + \xi_i \geq 1, \ \xi_i \geq 0, \ i = 1, \cdots, M, \end{aligned} \tag{4}$$

where the tuning parameter τ determines the trade-off between increasing the margin-size and ensuring that the $\mathbf{x}_i$ lie on the correct side of the margin. For sufficiently large values of τ, the soft-margin SVM will behave identically to the hard-margin SVM. We will show below that, as $\tau \to \infty$, the asymptotic result of soft-margin SVM is the same as the asymptotic result of hard-margin SVM.

For the setting described in Assumption 1, the normal direction vector of the separating hyperplane based on Bayes optimal rule is in the same direction as $\boldsymbol{\mu}$. Therefore, the performance of any classification method can be evaluated by the angle between the normal direction vector of its separating hyperplane and $\boldsymbol{\mu}$. Propositions 1 and 2 provide the sharp prediction of the high-dimensional limiting angles for hard-margin SVM and soft-margin SVM respectively.

Proposition 1 *Under Assumption 1, in the limit $N, M \to \infty$, with fixed $\alpha = M/N$, denote θ the angle between $\boldsymbol{\mu}$ and $\mathbf{w}$ solved from the hard-margin SVM algorithm (3), then $\cos\theta$ converges to ρ that is determined by the following two nonlinear equations*

$$\frac{1-\rho^2}{1+\lambda_1\rho^2} = \alpha \int_{-\infty}^{z_c} Dz(z_c - z)^2, \tag{5}$$

$$\frac{\rho}{\sqrt{1+\lambda_1\rho^2}} = \alpha \int_{-\infty}^{z_c} Dz(z_c - z)\left(\frac{\mu}{\sigma} + \frac{\lambda_1\rho}{\sqrt{1+\lambda_1\rho^2}} z\right). \tag{6}$$

where z_c is an unknown parameter needs to be estimated, μ, σ, λ_1 are defined in (2), and the standard notation $Dz = \frac{dz}{\sqrt{2\pi}} \exp\left(-\frac{z^2}{2}\right)$.

All the proofs are given in the supplementary materials. From equations (5) and (6), we can solve two unknown parameters ρ and z_c given α, μ, σ, and λ_1. It is interesting to note that the results do not depend on $\lambda_2, \cdots, \lambda_K$ which means that only the variance along the signal direction has influence on SVM performance. This observation is also confirmed by extensive simulations in Section 3.1. All the biological components in orthogonal directions have no impact. The nonlinear equations (5) and (6) have no closed form solution. We have to use some numerical algorithms to solve them. As expected, it can be easily checked from the numerical studies in Section 3 that $\cos(\theta)$ increases with α as well as the signal to noise ratio μ/σ, but decreases with λ_1.

Proposition 2 *Under Assumption 1, in the limit $N, M \to \infty$, with fixed $\alpha = M/N$, denote θ the angle between $\boldsymbol{\mu}$ and $\mathbf{w}$ solved from the soft-margin SVM algorithm (4), then $\cos\theta$ converges to ρ that is determined by the following three nonlinear equations*

$$\frac{1-\rho^2}{1+\lambda_1\rho^2} - \alpha q^2 \hat{\tau}^2 \int_{-\infty}^{z_c - q\hat{\tau}} Dz - \alpha \int_{z_c - q\hat{\tau}}^{z_c} Dz(z_c - z)^2 = 0, \tag{7}$$

$$2q - 1 - \alpha q\hat{\tau} \int_{-\infty}^{z_c - q\hat{\tau}} Dzz - \alpha \int_{z_c - q\hat{\tau}}^{z_c} Dz(z_c - z)z = 0, \tag{8}$$

$$\frac{\rho F}{\sqrt{1+\lambda_1\rho^2}} - \frac{\alpha q\hat{\tau}\mu}{\sigma} \int_{-\infty}^{z_c - q\hat{\tau}} Dz - \frac{\alpha\mu}{\sigma} \int_{z_c - q\hat{\tau}}^{z_c} Dz(z_c - z) = 0, \tag{9}$$

where

$$F = 1 - \alpha\lambda_1 q\hat{\tau} \int_{-\infty}^{z_c - q\hat{\tau}} Dzz - \alpha\lambda_1 \int_{z_c - q\hat{\tau}}^{z_c} Dz(z_c - z)z,$$

and

$$z_c = \frac{1/\sqrt{q_0} - \mu\rho}{\sigma\sqrt{1+\lambda_1\rho}}, \qquad \hat{\tau} = \frac{\sigma\tau}{\sqrt{q_0}\sqrt{1+\lambda_1\rho}}.$$

Therefore, given $\alpha, \lambda_1, \mu, \sigma$, and τ, equations (7), (8), (9) can be used to solve three unknown parameters ρ, q_0, and q. The nonlinear equations (7), (8), and (9) have no closed form solution. We have to use some numerical algorithms to solve them. Under Assumption 1, if we further assume that $\boldsymbol{\epsilon}$ in (1) follows a normal distribution, then the SVM test error is $\varepsilon = \Phi\left(-\frac{\rho}{\sqrt{1+\lambda_1\rho^2}}\frac{\mu}{\sigma}\right)$, where $\Phi(\cdot)$ is the cumulative distribution function of $N(0,1)$.

It is interesting to note that, as $\tau \to \infty$, the two equations (7) and (9) are equivalent to (5) and (6) respectively. Therefore, for large τ, the behavior of soft-margin SVM is the same as hard-margin SVM. Our simulation studies in Section 3.2 will also confirm this.

For a given dataset, α, λ_1, μ, and σ can be estimated, therefore Proposition 2 allows us to select optimal tuning parameter τ by studying the dependence of ρ on τ for fixed $\alpha, \lambda_1, \mu, \sigma$.

We now discuss how to estimate λ_1, μ, and σ from the data. To estimate the background noise level σ^2, we use a robust variance estimate based on the full matrix of data values (Liu et al., 2008); that is, for the full set of $M \times N$ entries of the original $M \times N$ data matrix $\mathbf{X}$, we calculate the robust estimate of scale, the median absolute deviation from the median (MAD), to estimate σ as

$$\hat{\sigma} \quad = \quad \frac{\mathrm{MAD}_{\mathbf{X}}}{\mathrm{MAD}_{N(0,1)}}. \tag{10}$$

Here $\mathrm{MAD}_{\mathbf{X}} = \mathrm{median}(|x_{ij} - \mathrm{median}(\mathbf{X})|)$ and $\mathrm{MAD}_{N(0,1)} = \mathrm{median}(|r_i - \mathrm{median}(\mathbf{r})|)$, where $\mathbf{r}$ is a MN-dimensional vector whose elements are i.i.d. samples from $N(0,1)$ distribution.

To estimate λ_1, we use the results from Baik and Silverstein (2006) which shows that in the limit of $M, N \to \infty$, with fixed $\alpha = M/N$, the sample eigenvalue $\tilde{\lambda}_1$ satisfies

$$\tilde{\lambda}_1 \quad \xrightarrow{a.s.} \quad \begin{cases} (\lambda_1+1)\left(1+\frac{1}{\alpha\lambda_1}\right)-1, & \text{for} \quad \lambda_1 > \sqrt{1/\alpha}, \\ (1+\sqrt{1/\alpha})^2 - 1, & \text{for} \quad \lambda_1 \le \sqrt{1/\alpha}. \end{cases} \tag{11}$$

Therefore, for any finite α, $\tilde{\lambda}_1$ is not a consistent estimator of λ_1. We use equation (11) to estimate λ_1 as

$$\hat{\lambda}_1 \quad = \quad \begin{cases} \frac{1}{2}\left(\tilde{\lambda}_1 - \frac{1}{\alpha} + \sqrt{\left(\tilde{\lambda}_1 - \frac{1}{\alpha}\right)^2 - \frac{4}{\alpha}}\right), & \text{for} \quad \tilde{\lambda}_1 > 1/\alpha + 2\sqrt{1/\alpha}, \\ \sqrt{1/\alpha}, & \text{for} \quad \tilde{\lambda}_1 \le 1/\alpha + 2\sqrt{1/\alpha}. \end{cases} \tag{12}$$

To estimate μ, let M_+, M_1 denote the sample sizes of Class $+1$ and Class -1 respectively. Define $\boldsymbol{\mu}_c = \bar{\mathbf{x}}_+ - \bar{\mathbf{x}}_-$, where $\bar{\mathbf{x}}_+$ and $\bar{\mathbf{x}}_-$ represent the sample means for Class $+1$ and Class -1 respectively. The following Proposition describes the relationship between $\boldsymbol{\mu}_c$ and μ.

Proposition 3 *Under Assumption 1, in the limit $N, M \to \infty$, with fixed $\alpha = M/N$, $r_+ = M_+/M$, and $r_- = M_-/M$, then $\|\boldsymbol{\mu}_c\|^2$ converges to*

$$4\mu^2 + \frac{\sigma^2}{\alpha r_+ r_-}. \tag{13}$$

Therefore, we estimate μ as

$$\hat{\mu} = \frac{1}{2}\sqrt{\|\hat{\boldsymbol{\mu}}_c\|^2 - \frac{\hat{\sigma}^2}{\alpha r_+ r_-}},$$

where $\hat{\sigma}$ is given from (10) and $\hat{\boldsymbol{\mu}}_c = \frac{1}{M_+}\sum_{i=1}^{M_+}\mathbf{x}_i - \frac{1}{M_-}\sum_{i=1}^{M_-}\mathbf{x}_i$ is the sample estimation of $\boldsymbol{\mu}_c$.

3. Numerical Results

3.1 Hard-margin SVM

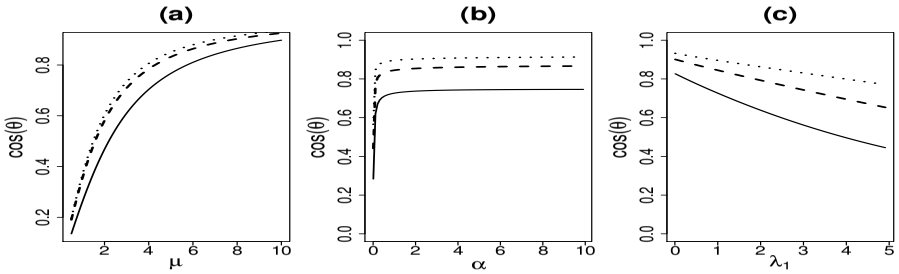

Figure 2: (a) Dependence of $\cos(\theta)$ on μ for fixed $\sigma = 1$, $\lambda_1 = 1$ and $\alpha = 0.1$ (solid), 0.5 (dashed), 1.5 (dotted); (b) Dependence of $\cos(\theta)$ on α for fixed $\lambda_1 = 1$ and $\mu = 3$ (solid), 5 (dashed), 7 (dotted); (c) Dependence of $\cos(\theta)$ on λ_1 for fixed $\alpha = 1$ and $\mu = 3$ (solid), 5 (dashed), 7 (dotted).

Figure 2 shows the dependence of $\cos(\theta)$ on the parameters μ, α, and λ_1 based on numerical solutions of equations (5) and (6). Here θ represents the angle between the directions of SVM separating hyperplane and Bayes optimal separating hyperplane. For spiked population model (1), the normal vector of Bayes optimal separating hyperplane lies in the direction of $\boldsymbol{\mu}$. Discrimination methods whose normal vector $\mathbf{w}/\|\mathbf{w}\|$ lies close to this direction should have good "generalization" properties, i.e., new data will be discriminated as well as possible. Figure 2(a) shows that, for fixed α and λ_1, the classification performance is improved as we increase the signal size μ. Figure 2(b) shows that, for fixed μ and λ_1, $\cos(\theta)$ increases with α, indicating that the classification performance is improved by adding more samples to the training data. For α<1/2, the increasing is faster; for α>2, the increasing becomes slower and saturated. This indicates that, for HDLSS situations, increasing training data can improve the prediction power dramatically; while for situations

when sample size is twice as big as the dimension, adding more samples can not gain too much power. Figure 2(c) shows that, for fixed μ and α, $\cos(\theta)$ decreases with λ_1 as expected.

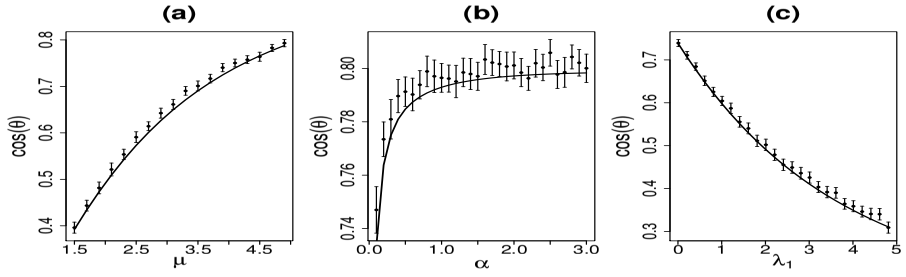

Figure 3: Comparison of analytical calculations with simulation experiments. The solid curves represent the theoretical results, the dots and bars represent the mean and standard error of the estimated $\cos\theta$ by applying SVM algorithm (3) to 100 simulated data sets for each parameter setting. In simulations, the dimension $N = 100$, the background noise $\sigma = 1$. The other parameters are: (a) $\alpha = 1, \lambda_1 = 2$; (b) $\mu = 5, \lambda_1 = 2$; (c) $\alpha = 1, \mu = 2$.

To examine the validity of our analysis and to determine the finite-size effect, Figure 3 provides the comparison with numerical simulations on finite size systems. Similar to Figure 2, we consider the dependence of $\cos(\theta)$ on three parameters μ, α and λ_1 in the plots in Figure 3 (a), (b), and (c) respectively. Here the dimension of the simulated data $N = 100$ and the data are generated according to Assumption 1 with ϵ_j follows i.i.d standard normal distribution. We repeat simulation 100 times for each parameter setting. The mean and standard errors over 100 replications are presented. From Figure 3, we can see that our analytical curves show fairly good agreement with the simulation experiment. Thus our analytical formulas (5) and (6) provide reliable estimates even for moderate system sizes. The benefit of these formulas is their computational ease. We also find that the simulation results for SVM estimators are independent of the choices of orthogonal components $\lambda_{m\geq 2}$ which further confirms that the analytical results described by Proposition 1 are correct.

3.2 Soft-margin SVM

Figure 4 shows the dependence of $\cos(\theta)$ on the parameters μ, α, and λ_1 based on the solution of nonlinear equations (7), (8), and (9) for fixed $\tau = 1$ and $\sigma = 1$. Similar to Figure 2, the $\cos\theta$ increases with μ and α but decreases with λ_1.

To study the the influence of the tuning parameter τ on the performance of the soft-margin SVM classification method (4). Figure 5 shows the dependence of $\cos(\theta)$ as function

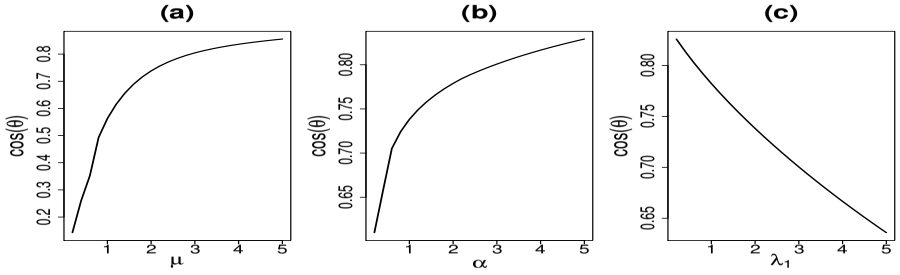

Figure 4: Dependence of $\cos(\theta)$ on μ, α, and λ_1 for $\tau = 1$ and $\sigma = 1$. (a) Dependence of $\cos(\theta)$ on μ for fixed $\lambda_1 = 2$ and $\alpha = 1$; (b) Dependence of $\cos(\theta)$ on α for fixed $\lambda_1 = 2$ and $\mu = 2$; (c) Dependence of $\cos(\theta)$ on λ_1 for fixed $\alpha = 1$ and $\mu = 2$.

of $\log\tau$ for fixed α, μ, λ_1, and σ. Both the analytical solution based on Proposition 2 and numerical experiment based on simulated finite dimensional data are provided and they excellently agree with each other. In simulation, we randomly generate a training set and a test set for the given parameter setting, the test error can be obtained by applying the classifier built from the training set to the test set. The results from the summary over 100 replications are given in Figure 5. From the upper panel, it is interesting to note that $\cos\theta$ reaches a maximum value as one decreases the tuning parameter τ to a threshold value. After that value, further decreasing τ cannot change $\cos\theta$. On the other hand, if we increase τ, $\cos\theta$ will approach the value determined by the hard-margin SVM method as shown by the dashed line in the upper panel of Figure 5. These observations are further confirmed by the dependence of test error ε on $\log\tau$ as shown in the lower panel. The test error reaches a minimum value if we decrease τ to the same threshold value as for $\cos\theta$. From equations (7), (8), and (9), it can be derived that the limiting value of $\cos\theta$ as $\tau \to 0$ is

$$\rho_c = \cos\theta_c = \sqrt{\frac{\alpha\left(\frac{\mu}{\sigma}\right)^2}{1+\alpha\left(\frac{\mu}{\sigma}\right)^2}} \tag{14}$$

which is independent of λ_1. This finding of λ_1 independence is also confirmed by numerical simulations with data on finite size systems. Therefore, if $\boldsymbol{\epsilon}$ in (1) follows a normal distribution, then the best test error we can achieve using the soft-margin SVM classification method (4) is $\Phi\left(-\frac{\rho_c}{\sqrt{1+\lambda_1\rho_c^2}}\frac{\mu}{\sigma}\right)$.

Koo et al. (2008) studied the asymptotic behavior of the coefficients of the linear SVM in the limit of $M \to \infty$ with N fixed. They established a Bahadur type representation of the coefficients and derived their asymptotic normality and statistical variability. Denote $\mathbf{w}^\star$ the minimizer of the population version of the SVM loss function. It was shown in Koo et al. (2008) that the SVM solution $\hat{\mathbf{w}}$ converges to $\mathbf{w}^\star$ which is in the same direction as $\boldsymbol{\mu}$

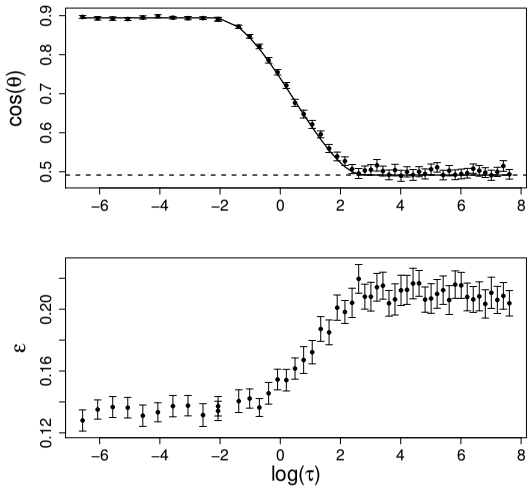

Figure 5: Upper panel: compare theoretical result with simulation experiment for the dependence of $\cos(\theta)$ on tuning parameter $\log(\tau)$ for fixed $\alpha = 1$, $\mu = 2$, $\sigma = 2$, and $\lambda_1 = 2$. The solid line is the theoretical curve, the dots and bars represent the mean and standard error based on 100 simulated data sets at each parameter setting. In simulation, the dimension $N = 100$. The dashed line represents the value based on the hard-margin SVM solution from equations (5) and (6). Lower panel: dependence of the test error ε on $\log(\tau)$ based on simulations.

under the spiked population setting (1). Therefore $\rho \to 1$ as $M \to \infty$ with N fixed. This can be confirmed in (14) by letting $\alpha \to \infty$ on the right hand side. On the other hand, if we let $N \to \infty$ with M fixed, from (14) we get $\rho_c \to 0$ if $\mu/\sqrt{N} \to 0$ and $\rho_c \to 1$ if $\mu/\sqrt{N} \to \infty$. This confirms the results of Hall et al. (2005) for HDLSS setting. Therefore, our asymptotic results are more general with both traditional and HDLSS asymptotics as special cases.

The analytical results in Figure 5 are based on the true values for α, λ_1, μ and σ which ultimately need to be estimated from the given data. In Figure 6 we provide the comparison between the results using the true values and the results using the estimated values for μ, α, λ_1 and σ. For each simulated data, we first estimate μ, α, λ_1 and σ and then use them to derive theoretical results. Figure 6 indicates that the influence of moderate estimation errors in the parameters is small.

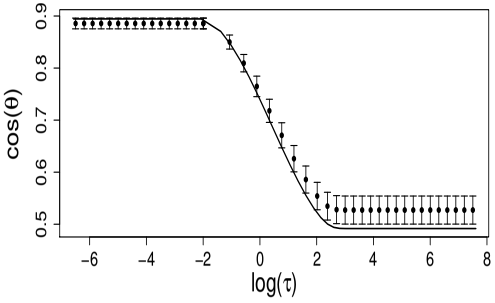

Figure 6: Comparison between the results using the true values and the results using the estimated values for parameters. Here the true parameter values are $\alpha = 1$, $\mu = 2$, $\sigma = 1$, and $\lambda_1 = 2$. The solid curve represents the results derived using the true values. The dots and bars represent the means and standard errors of the $\cos\theta$ values derived using the estimated parameters for 100 simulated data sets.

Although Figure 5 suggests that, for spiked population model, the best performance of SVM is achieved at the smallest value τ, in practice, using too tiny τ could cause difficulties in numerically solving the optimization problem. In order to provide a practical recommendation for the tuning parameter, we need to estimate the threshold value τ_c at which the limiting value $\cos\theta_c$ is almost achieved, i.e. the elbow point in Figure 5. More precisely, τ_c is defined as $\tau_c = \max\{\tau : \rho(\tau) = \rho_c\}$. In practice, we can compute τ_c by numerically finding the largest τ that can give $\cos\theta = \rho_c$ and use it as a guideline for choosing τ. Figure 7 displays the change of $\log\tau_c$ as functions of the parameters μ, α, λ_1. It is shown that $\log\tau_c$ decreases with all three parameters.

3.3 Check the model assumptions

The key assumptions for deriving the results in Propositions 1 and 2 are homoscedasticity (equal covariance) and spiked covariance condition (1). In this section, we use simulation to

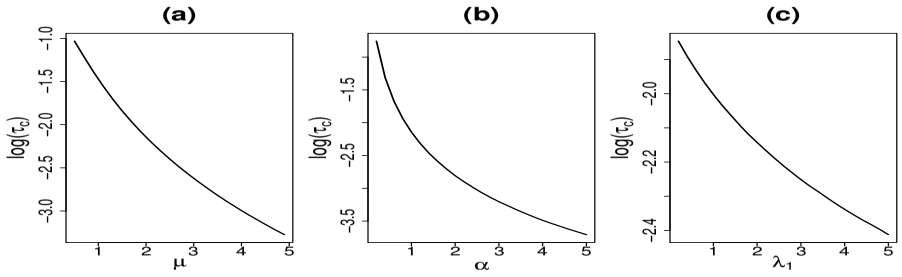

Figure 7: (a) Dependence of $\log(\tau_c)$ on μ for fixed $\lambda_1 = 2$ and $\alpha = 1$; (b) Dependence of $\log(\tau_c)$ on α for fixed $\lambda_1 = 2$ and $\mu = 2$; (c) Dependence of $\log(\tau_c)$ on λ_1 for fixed $\alpha = 1$ and $\mu = 2$.

study the validity of our method in situations where these assumptions are not true. Figure 8 is for situation where the two covariance matrices from the positive and negative classes are different. In simulation, we first generate M samples from $N(0, \sigma^2\mathbf{I}_p)$ distribution. Then $M/2$ of them are shifted by μ in x_1 direction to form the positive class and the remaining $M/2$ are shifted by $-\mu$ in x_1 direction to form the negative class. Both classes are further divided into two subclasses with sample size $M/4$ for each. In the positive class, the two subclasses are separated by shifting in x_2 direction by μ and $-\mu$ respectively. Similarly, the two subclasses in the negative class are separated by shifting in x_3 direction by μ and $-\mu$ respectively. The data generated in this way satisfies the spiked assumption but the two classes have different covariances. Figure 8 shows that the theoretical estimation and direct computation agree fairly well with each other. We have tried several different settings for μ, α and σ and got similar results. Therefore, our method is fairly robust to homoscedasticity as long as the spiked condition (1) holds for the covariance matrices of both classes.

Figures 9, 10, and 11 are for situations where the spiked assumption is violated. In simulation, we first generate M samples from $N(0, \mathbf{\Sigma})$ distribution. Then $M/2$ of them are shifted by μ in x_1 direction to form the positive class and the remaining $M/2$ are shifted by $-\mu$ in x_1 direction to form the negative class. The covariance matrix $\mathbf{\Sigma}$ is diagonal with the ith eigenvalue equal to $i\sigma^2$ for $i \leq K$ and σ^2 for $i > K$. The spiked condition requires $K \ll p$. If we increase K, the spiked condition can be violated. Figures 9, 10, and 11 show the results for $K = 0.1N$, $K = 0.3N$, and $K = 0.5N$ respectively. For situations where the number of uncommon eigenvalues K is less than 10% of the total number of variables N, our method can provide quite accurate estimation for $\cos\theta$ and also bigger $\cos\theta$ corresponds to smaller test error as illustrated in Figure 9. For situations where K is 30% of N, our method can still provide reasonable estimation for $\cos\theta$, but $\cos\theta$ cannot be used as a criterion for choosing τ because bigger $\cos\theta$ does not always correspond to

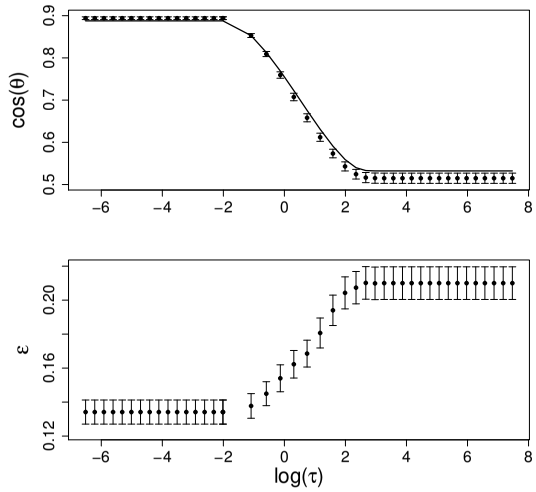

Figure 8: Comparison of theoretical prediction with direct computation for simulated data using parameters $\alpha = 1, \mu = 2, \sigma = 2$, and $\lambda_1 = 2$. In simulation, the covariances are different between the positive class and the negative class.

smaller test error as illustrated in Figure 10. For situations where K is 50% of N, our method cannot provide estimation for $\cos\theta$. Moreover, $\cos\theta$ and ε behavior in an opposite way, i.e. smaller $\cos\theta$ corresponds to smaller test error as illustrated in Figure 11.

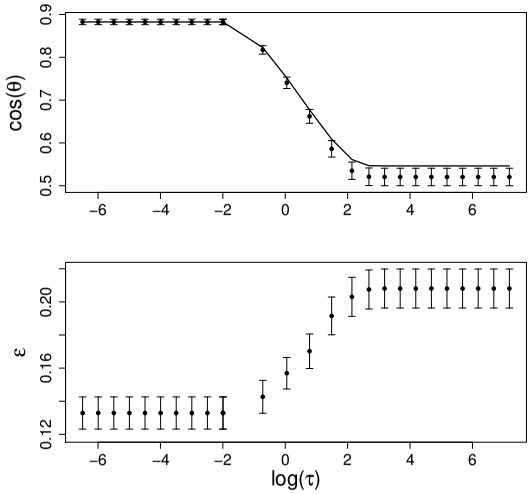

Figure 9: Comparison of theoretical prediction with direct computation for simulated data using parameters $\alpha = 1, \mu = 2, \sigma = 2$, and $\lambda_1 = 2$. In simulation, the number of the uncommon eigenvalues K is equal to 10% of the total number of variables N.

In summary, our simulations indicate that the proposed method depends on the spiked assumption but is not sensitive to the homoscedasticity violation. The spiked assumption is based on factor analysis which is one of the most useful tools for modeling common dependence among all the variables. In genetics, factor analysis modeling appeared to be useful tools to investigate the dependence structure in high-dimensional microarray data. It can fit the data with covariance matrix governed by linkage disequilibrium patterns (Rochat et al., 2007). For data set which cannot be modeled using spiked population, our results indicate that further exploring the data structure is useful for understanding the classification performance.

3.4 Real Data

We apply our methods to a breast cancer dataset from The Cancer Genome Atlas Research Network (Network, 2008) which include two subtypes: LumA and LumB. As in Liu et al. (2008), we filter the genes using the ratio of the sample standard deviation and sample mean of each gene. After gene filtering, the dataset contained 235 patients with 56 genes. Among the 235 samples, there are 154 LumA samples and 81 LumB samples.

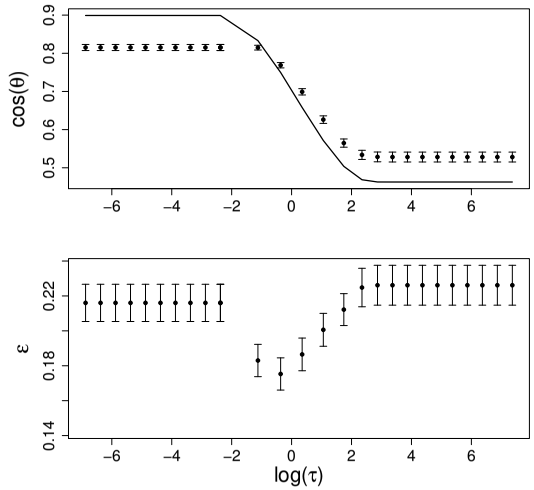

Figure 10: Comparison of theoretical prediction with direct computation for simulated data using parameters $\alpha = 1, \mu = 2, \sigma = 2$, and $\lambda_1 = 2$. In simulation, the number of the uncommon eigenvalues K is equal to 30% of the total number of variables N.

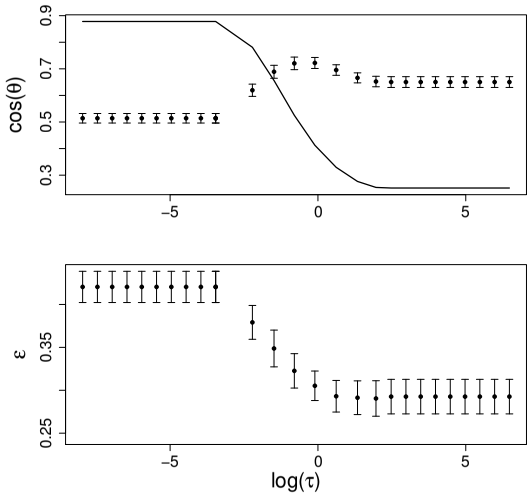

Figure 11: Comparison of theoretical prediction with direct computation for simulated data using parameters $\alpha = 1, \mu = 2, \sigma = 2$, and $\lambda_1 = 2$. In simulation, the number of the uncommon eigenvalues K is equal to 50% of the total number of variables N.

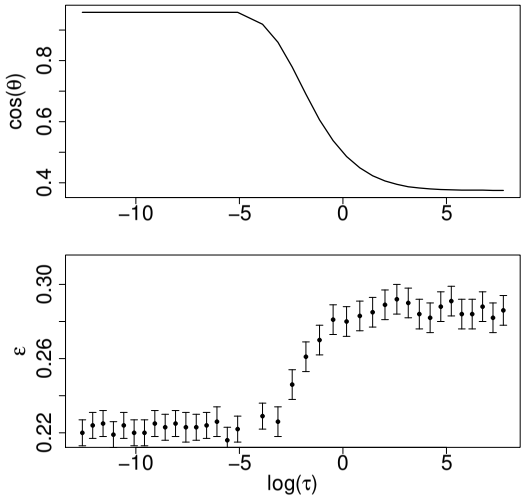

Figure 12: Upper panel: theoretical prediction of the dependence of $\cos(\theta)$ on tuning parameter $\log(\tau)$ based on the solutions from equations (7), (8) and (9) using parameters estimated from the breast cancer data. Lower panel: dependence of cross-validation error ε on tuning parameter $\log(\tau)$. The dots and bars represent the mean and standard error of the cross validation error based on 100 random splittings of the breast cancer data.

We consider LumA as Class +1 and LumB as Class -1. Assume the data are generated based on model (1), using the method discussed in Section 2, we obtain the following parameter estimations: $\hat{\mu} = 3.80$, $\hat{\sigma} = 2.32$, $\hat{\lambda}_1 = 4.06$, $\alpha = 4.20$, $N = 56$, $M = 235$, $M_+ = 154$, $M_- = 81$. The upper panel of Figure 12 shows the analytical curve for the dependence of $\cos\theta$ on τ. It shows that if we choose τ less than 6.19×10^{-3}, we can get the smallest angle. The lower panel of Figure 12 shows the dependence of the cross validation errors as a function of τ. The cross validation errors are computed by randomly splitting the data into two parts, 90% for training and 10% for test. The mean and standard error over 100 random splitting are reported in the lower panel of Figure 12. It shows that the cross validation error can achieve minimum value if τ is less than around 5×10^{-3}. The two results are consistent with each other and similar to the previous simulation results as shown in Figure 5. This indicates that model (1) is a reasonable assumption for this data set.

4. Conclusion

In this study, we examine the asymptotic behavior of SVM in the limit of $N, M \to \infty$ with fixed $\alpha = M/N$. We investigate the estimators of both the hard-margin SVM and the soft-margin SVM methods. Our focus is on the angle between the direction of the estimated separating hyperplane and the Bayes optimal separating hyperplane. Under spiked population model assumption, we analytically evaluate the relation between this angle and the SVM tuning parameter. On the basis of this finding, a new method of selecting tuning parameter is developed for analyzing high dimensional data which significantly reduces the computational cost. The analytical calculations are compared with numerical simulations on finite-size systems and the agreement between the numerical data and the analytical result is fairly good, and thus, our formulas are validated. Although the asymptotic results that we have obtained apply only to the spiked population model, they have shed a new light on the asymptotic behavior of SVM and can also improve the practical use of SVM in various aspects. For situations where the spiked model cannot be applied, one possible solution is to use the generalized spiked population model proposed in Bai and Yao (2012) to re-derive our results. This is one of our future research topics.

It is shown in Figure 1 that a lot of data points are piling up on the two boundaries. This is a phenomenon called data piling which has been studied in Marron et al. (2007) in more details. The reason is that the hinge loss function used in SVM is not continuous differentiable. The consequence of data piling is that the generalization performance is adversely affected. To overcome this problem, Marron et al. (2007) proposed a new classification method call Distance Weighted Discrimination (DWD) which does not have data piling problem. Simulation studies have shown that DWD typically yields better classification performance than SVM in high dimensions, but deeper theoretical evidence is strongly desired. It will be interesting to study the asymptotic property of DWD and compare it with SVM from a analytical point of view. This is another direction that we will pursue in future. The same technique can also be used in other popular classifier that currently heavily relies on cross validation. Examples include the hybrid of DWD and SVM proposed in Qiao and Zhang (2015) and the Large-Margin Unified Machines proposed in Liu et al. (2011).

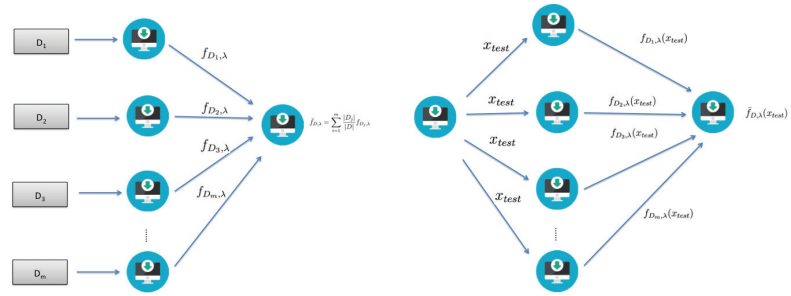
Abstract



This paper provides error analysis for distributed semi-supervised learning with kernel ridge regression (DSKRR) based on a divide-and-conquer strategy. DSKRR applies kernel ridge regression (KRR) to data subsets that are distributively stored on multiple servers to produce individual output functions, and then takes a weighted average of the individual output functions as a final estimator. Using a novel error decomposition which divides the generalization error of DSKRR into the approximation error, sample error and distributed error, we find that the sample error and distributed error reflect the power and limitation of DSKRR, compared with KRR processing the whole data. Thus a small distributed error provides a large range of the number of data subsets to guarantee a small generalization error. Our results show that unlabeled data play important roles in reducing the distributed error and enlarging the number of data subsets in DSKRR. Our analysis also applies to the case when the regression function is out of the reproducing kernel Hilbert space. Numerical experiments including toy simulations and a music-prediction task are employed to demonstrate our theoretical statements and show the power of unlabeled data in distributed learning.

Keywords: learning theory, distributed learning, kernel ridge regression, semi-supervised learning, unlabeled data, error decomposition

1. Introduction

Data from practical applications in medicine, finance, business and other fields are often stored distributively across multiple servers (called local processors) and may not be shared for reasons of preserving privacy. This requires privacy-preserving machine learning algorithms to discover population-wide patterns of the data without revealing any individual's sensitive information. Distributed learning (Balcan et al., 2012; Yan et al., 2013; Li et al., 2015; Xie et al., 2016) provides a promising way to tackle privacy-preserving learning problems.

Let m be the number of local processors and $D_j = \{(x_{i,j}, y_{i,j})\}_{i=1}^{|D_j|}$ be the data subset stored in the j-th local processor with $1 \le j \le m$ and $D = \bigcup_{j=1}^m D_j$ be the disjoint union of $\{D_j\}_{j=1}^m$, where $|D_j|$ denotes the cardinality of D_j. Distributed learning firstly gets an estimator $f_{D_j,\lambda}$ on each local processor based on D_j and some (regularization) parameter λ, and then launches the individual estimators to a central processor to get a final estimator $\overline{f}_{D,\lambda}$. To get an estimation for a new query point x_{test}, due to the purpose of privacy-preserving, x_{test} is firstly transmitted to each local processor to get an estimation $f_{D_j,\lambda}(x_{test})$, then all $f_{D_j,\lambda}(x_{test})$ with $1 \le j \le m$ are communicated to the central processor to synthesize the final estimation $\overline{f}_{D,\lambda}(x_{test})$. Flows of training and testing for distributed learning are exhibited in Figure 1. Distributed learning can thus be a privacy-preserving strategy in the sense that except for a real number $f_{D_j,\lambda}(x_{test})$, the individual's data information in each local processor is unknown to each other. The aim of statistics and learning theory is to verify that $\overline{f}_{D,\lambda}(x_{test})$ is a good approximation of the unknown but definite output of x_{text}.

(a) Flow of training (b) Flow of testing

Figure 1: Training and testing of distributed learning for privacy-preserving

In this paper, we focus on the distributed kernel ridge regression (DKRR). Let $(\mathcal{H}_K, \|\cdot\|_K)$ be the reproduced kernel Hilbert space (RKHS) induced by a Mercer kernel K on a metric (input) space $\mathcal{X}$. In a standard setting (Mann et al., 2009; Zhang et al., 2013; Lin et al., 2016), DKRR is defined with a regularization parameter $\lambda > 0$ by

$$\overline{f}_{D,\lambda} = \sum_{j=1}^m \frac{|D_j|}{|D|} f_{D_j,\lambda}, \tag{1}$$

where

$$f_{D_j,\lambda} = \arg\min_{f \in \mathcal{H}_K} \left\{ \frac{1}{|D_j|} \sum_{(x,y)\in D_j} (f(x)-y)^2 + \lambda \|f\|_K^2 \right\}, \qquad j = 1, \ldots, m. \tag{2}$$

The optimal learning rate for DKRR was presented in (Zhang et al., 2015) under some eigenfunction assumptions which were removed in (Lin et al., 2016) by using a novel integral operator approach. In these existing results on rigorous analysis for DKRR, there are still two critical problems which greatly hinder applications of DKRR in practice. One is that the optimal learning rate is built upon a strict condition bounding the number of local processors, making DKRR infeasible for large m. The other is that the target function called regression function f_ρ is assumed to be in $\mathcal{H}_K$ to achieve the optimal learning rate, which is difficult to verify in practice.

The aim of the present paper is to consider distributed semi-supervised learning with kernel ridge regression (DSKRR) and demonstrate that using additional unlabeled data in a semi-supervised setting can overcome the aforementioned hurdles of DKRR. Let $D_j \cup \tilde{D}_j(x)$ be the subset of the data for semi-supervised learning which is stored on the j-th local processor, where $\tilde{D}_j(x) = \{x_1^j, \ldots, x_{|\tilde{D}_j|}^j\}$. Based on $D_j \cup \tilde{D}_j(x), j = 1, \ldots, m$, we construct a training set associated with $D_j \cup \tilde{D}_j(x)$ as

$$D_j^* = \{(x_i^*, y_i^*)\}_{i=1}^{|D_j^*|}$$

with

$$x_i^* = \begin{cases} x_i, & \text{if } (x_i, y_i) \in D_j, \\ \tilde{x}_i, & \text{if } \tilde{x}_i \in \tilde{D}_j(x), \end{cases} \qquad \text{and} \qquad y_i^* = \begin{cases} \frac{|D_j^*|}{|D_j|} y_i, & \text{if } (x_i, y_i) \in D_j, \\ 0, & \text{otherwise}, \end{cases} \tag{3}$$

and denote $D^* = \bigcup_{j=1}^m D_j^*$. Define DSKRR by

$$\overline{f}_{D^*,\lambda} = \sum_{j=1}^m \frac{|D_j^*|}{|D^*|} f_{D_j^*,\lambda}. \tag{4}$$

We revise the standard integral operator framework (Smale and Zhou, 2007; Caponnetto and De Vito, 2007; Lin et al., 2016) to analyze the learning performance of algorithm (4). The main tool is a novel error decomposition that decomposes the generalization error of algorithm (4) into the approximation error, sample error and a new term called distributed error. The approximation error, which reflects the difference between a data-free limit of KRR and f_ρ, is standard. The sample error reflects the advantage of weighted averaging in (4) in the sense of scaling the generalization error of individual $f_{D_j^*,\lambda}$, $j = 1, 2, \ldots, m$, with an additional factor $\frac{|D_j^*|}{|D^*|}$. The distributed error describes the difference between the distributed algorithm (4) and KRR processing the whole data in one single processor via presenting a restriction to the number of local processors. We find that additional unlabeled data play crucial roles in deducing a small distributed error and thus relaxing heavily the restriction on m to achieve the optimal learning rate for DKRR. We also prove that DSKRR leads to satisfactory estimates for the sample error when $f_\rho \notin \mathcal{H}_K$, which is beyond the standard setting with $f_\rho \in \mathcal{H}_K$ in (Zhang et al., 2015; Lin et al., 2016). Experimental studies are carried out to verify our theoretical analysis.

2. Theoretical Assessments

The generalization ability of DSKRR will be analyzed in a standard learning theory framework, in which the sample in D is assumed to be independently drawn from ρ, a Borel

probability measure on $\mathcal{Z} := \mathcal{X} \times \mathcal{Y}$ with $\mathcal{Y} = \mathbb{R}$ and $\tilde{D}(x) = \cup_{j=1}^m \tilde{D}_j(x)$ from ρ_X, the marginal distribution of ρ. Our purpose is to estimate how the estimator $\overline{f}_{D^*,\lambda}$ based on D^* approximates the regression function $f_\rho(x) := \int_{\mathcal{Y}} y d\rho(y|x)$ with $\rho(\cdot|x)$ being the conditional distribution of ρ induced at $x \in \mathcal{X}$. Throughout this paper, we assume $|y| \le M$ almost surely for some constant $M > 0$ and $\mathcal{X}$ is compact, which implies $\|f_\rho\|_\infty \le M$ almost surely and $\kappa := \sqrt{\sup_{x \in \mathcal{X}} K(x,x)} < \infty$.

As convergence may be as slow as one wants without imposing any restriction on the distribution ρ (Györfy et al., 2002), we introduce the following regularity assumption on f_ρ. Let L_K be the integral operator on $\mathcal{H}_K$ (or $L^2_{\rho_X}$ with norm $\|\cdot\|_\rho\|$) defined by

$$L_K f = \int_{\mathcal{X}} K_x f(x) d\rho_X,$$

where K_x is the function $K(\cdot, x)$ in $\mathcal{H}_K$. The regularity condition in this paper is

$$f_\rho = L_K^r h_\rho, \quad \text{for some } r > 0 \text{ and } h_\rho \in L^2_{\rho_X}, \tag{5}$$

where L_K^r denotes the r-th power of $L_K : L^2_{\rho_X} \to L^2_{\rho_X}$, a compact and positive operator. This regularity condition is standard in learning theory and has been used in a large literature (Bauer et al., 2007; Caponnetto and De Vito, 2007; Smale and Zhou, 2007; Caponnetto and Yao, 2010; Shi et al., 2011; Guo et al., 2016; Hu et al., 2015; Lin and Zhou, 2016).

To derive fast learning rates, we should also present some restrictions on the capacity of $\mathcal{H}_K$. In this paper, we use the effective dimension $\mathcal{N}(\lambda)$ to measure the complexity of $\mathcal{H}_K$ with respect to ρ_X, which is defined to be the trace of the operator $(L_K + \lambda I)^{-1} L_K$, that is

$$\mathcal{N}(\lambda) = \mathrm{Tr}((\lambda I + L_K)^{-1} L_K), \qquad \lambda > 0.$$

We are in a position to present our main results, to be proved in Section 5. We first consider the traditional case of $f_\rho \in \mathcal{H}_K$ by imposing condition (5) with $r \ge 1/2$.

Theorem 1 *Assume $|y| \le M$ almost surely and that (5) holds with $1/2 \le r \le 1$. We have*

$$\begin{aligned} &\max\left\{E\left[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2\right], \lambda E\left[\|\overline{f}_{D^*,\lambda} - f_\rho\|_K^2\right]\right\} \\ \le\ & C\left[\lambda^{2r} + \sum_{j=1}^m \frac{|D_j^*|}{|D^*|}\left(\frac{\mathcal{A}^2_{D_j^*,\lambda}}{\lambda} + 1\right)^2 \left(\lambda^{2r-1}\mathcal{A}^2_{D_j^*,\lambda} + \frac{|D_j^*|}{|D^*|}\mathcal{A}^2_{D_j,\lambda}\right)\right], \end{aligned} \tag{6}$$

where C is a constant independent of m, $|D_j|$, $|D_j^*|$, or λ and

$$\mathcal{A}_{D,\lambda} = \frac{1}{|D|\sqrt{\lambda}} + \frac{\sqrt{\mathcal{N}(\lambda)}}{\sqrt{|D|}}. \tag{7}$$

To obtain explicit learning rates, we quantify the increment of $\mathcal{N}(\lambda)$ with a parameter $0 < s \le 1$ and a constant $C_0 > 0$ as

$$\mathcal{N}(\lambda) \le C_0 \lambda^{-s}, \qquad \forall \lambda > 0. \tag{8}$$

Condition (8) with $s = 1$ is always satisfied by taking $C_0 = \mathrm{Tr}(L_K) \le \kappa^2$. When $0 < s < 1$, condition (8) is more general than the eigenvalue decaying assumption in the literature (Caponnetto and De Vito, 2007; Steinwart et al., 2009). Based on Theorem 1 and condition (8), we derive the following optimal learning rate of algorithm (4).

Corollary 2 *Assume $|y| \le M$ almost surely, (8) with $0 < s \le 1$ and (5) with $1/2 \le r \le 1$. If $\lambda = |D|^{-\frac{1}{2r+s}}$, $|D_1| = |D_2| = \cdots = |D_m|$, $|D_1^*| = |D_2^*| = \cdots = |D_m^*|$, and*

$$m \le \min\left\{|D|^{\frac{2r+2s-1}{2r+s}}, |D^*||D|^{\frac{-s-1}{2r+s}}\right\}, \tag{9}$$

then

$$E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2] = \mathcal{O}\left(|D|^{-\frac{2r}{2r+s}}\right).$$

When $|D^*| = |D|$, the training set D^* defined by (3) for DSKRR is the same as D for DKRR. In such a situation (without using any unlabeled data), the output function $\overline{f}_{D^*,\lambda}$ produced by DSKRR algorithm (4) coincides with $\overline{f}_{D,\lambda}$ generated by DKRR algorithm (1), and the optimal learning rates stated in Corollary 2 are the same as those in (Lin et al., 2016; Guo et al., 2016) achieved under the restriction $m \le |D|^{\frac{2r-1}{2r+s}}$ given by (9). In particular, for the special case of $r = 1/2$ (that is, $f_\rho \in \mathcal{H}_K$), the number of local processors $m = \mathcal{O}(1)$ does not increase as the sample size $|D|$ becomes large, which is very restrictive and limits the use of distributed learning.

Corollary 2 tells us that additional unlabeled data can be used to relax the above restriction on m. For the special case with $r = 1/2$ and $s \ge 1/2$, when $|D^*| = |D|^{1+\frac{1}{1+s}}$ with additional unlabel data of size $|D|^{1+\frac{1}{1+s}} - |D|$, Corollary 2 asserts that the output function $\overline{f}_{D^*,\lambda}$ produced by DSKRR algorithm (4) achieves the optimal learning rates under the restriction $m \le |D|^{\frac{1}{1+s}}$. This allows the number of local processors to increase as the sample size $|D|$ does. Thus our analysis demonstrates the usage of additional unlabeled data in distributed learning, which is the first purpose of this paper.

The second purpose of this paper is to extend the range of r in (5) from $r \ge 1/2$ for the standard setting with $f_\rho \in \mathcal{H}_K$ to $0 < r < 1/2$ for considering the situation $f_\rho \notin \mathcal{H}_K$.

Theorem 3 *Assume $|y| \le M$ almost surely and that (5) holds with $0 < r < 1/2$. Let $0 < \lambda \le 1$. We have*

$$E\left[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2\right] \le \overline{C}\left[\lambda^{2r} + \sum_{j=1}^m \frac{|D_j^*|}{|D^*|}\left(\frac{\mathcal{A}^2_{D_j^*,\lambda}}{\lambda} + 1\right)^2\left(\lambda^{2r-1}\mathcal{A}^2_{D_j^*,\lambda} + \frac{|D_j^*|}{|D^*|}\mathcal{A}^2_{D_j,\lambda}\right)\right], \tag{10}$$

where $\overline{C}$ is a constant independent of m, $|D_j|$, $|D_j^*|$ or λ.

Theorem 3 yields the following optimal learning rate for algorithm (4) when $f_\rho \notin \mathcal{H}_K$, which has not been given in the literature of distributed learning (Zhang et al., 2015; Lin et al., 2016; Guo et al., 2016).

Corollary 4 *Assume $|y| \le M$ almost surely, (8) with $0 < s \le 1$ and (5) with $0 < r < 1/2$. If $r + s \ge 1/2$, $|D_1| = |D_2| = \cdots = |D_m|$, $|D_1^*| = |D_2^*| = \cdots = |D_m^*|$, $\lambda = |D|^{-\frac{1}{2r+s}}$, $|D^*| \ge |D|^{\frac{s+1}{2r+s}}$ and m satisfies (9), then*

$$E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2] = \mathcal{O}\left(|D|^{-\frac{2r}{2r+s}}\right).$$

3. Related Work and Discussion

As a state-of-the-art strategy to reduce the computational burden for some specified algorithms, distributed and parallel computation has triggered enormous research activities in the statistical and machine learning communities (Gillick et al., 2006). Distributed learning with ridge regression (Zhang et al., 2013), gradient descent algorithms (Shamir and Srebro, 2014), online learning (Zinkevich et al., 2010) and spectral algorithms (Guo et al., 2016) were proposed and their learning performances have been observed in many practical applications to be as good as that of a big processor which could handle the whole data, provided the number of servers m is not very large. Some theoretical bounds for m were presented in (Zhang et al., 2015; Lin et al., 2016; Guo et al., 2016; Blanchard and Mücke, 2016), asserting that the range of m depends on the regularity of f_ρ, which is difficult to verify in practice. This key problem makes users select only a small m or take m as a parameter in the learning process.

Compared with these results, there are two novelties of our results in this paper, though adding unlabeled data in the learning process causes additional computations. On one hand, if one takes m as a parameter in the learning process, the data should be re-divided again and again and thus it requires a large amount of communications. Our result avoids these re-division and communications in the sense that for a large range of m, if enough unlabeled data are given, optimal learning rates can be achieved. On the other hand, for some applications, data of small size (e.g. data in hospitals) are stored distributively across a great number of processors and cannot be shared each other for preserving privacy. The existing results (Zhang et al., 2015; Lin et al., 2016; Guo et al., 2016; Blanchard and Mücke, 2016) cannot tackle these problems in the sense that m is out of the range for the quantity to guarantee the optimal learning rate. The result in this paper presents a possibility to conquer this problem, provided there are additional unlabeled data.

We then compare our results with those in two closely related papers (Zhang et al., 2015; Lin et al., 2016). The seminal work (Zhang et al., 2015) considered the learning performance of algorithm (1) when $r = \frac{1}{2}$, i.e., $(f_\rho \in \mathcal{H}_K)$. Using a matrix decomposition approach, (Zhang et al., 2015) derived an optimal learning rate of order $\mathcal{O}(|D|^{-1/(s+1)})$ under the assumption that for some constants $k > 2$ and $A < \infty$, the normalized eigenfunctions $\{\phi_\ell\}_\ell$ of L_K in $L^2_{\rho_X}$ satisfy

$$\|\varphi_\ell\|^{2k}_{L^{2k}_{\rho_X}} = E\left[|\phi_\ell(x)|^{2k}\right] \le A^{2k}, \qquad \forall \ell \in \mathbb{N}. \tag{11}$$

Condition (11) was removed in (Lin et al., 2016), by using a novel integral operator approach based on a second order decomposition of difference of operator inverses. However, the analysis in (Lin et al., 2016) works only for $r > 1/2$. In our Corollary 2, we show that the optimal learning rate for DSKRR can be achieved for all $\frac{1}{2} \le r \le 1$ without assuming condition (11), provided additional unlabeled data are used. At the first glance, our approach in algorithm (4) incurs additional computation due to the unlabeled data. However, it is important for privacy-preserving learning when the data are stored in m (fixed) servers with $m > N^{\frac{2r-1}{2r+s}}$ and cannot be shared. Our result in Corollary 4 is new since optimal learning rates for DKRR when $f_\rho \notin \mathcal{H}_K$ have not been provided in the existing literate of distributed learning (Zhang et al., 2015; Lin et al., 2016; Guo et al., 2016).

Unlabeled data exist widely due to the expensive cost of label evaluation. Originally, unlabeled data are considered to be non-informative and often given up. However, with deeper understanding of semi-supervised learning, researchers recognize that unlabeled data can be useful in some special applications (Zhu and Goldberg, 2009) such as manifold learning (Belkin et al., 2006). In learning theory, it was found in (Caponnetto and Yao, 2010) that using unlabeled data can overcome the limitation that the optimal learning rate for KRR is only achievable for $f_\rho \in \mathcal{H}_K$. It was shown there that optimal learning rates for spectral algorithms might be achieved even when $f_\rho \notin \mathcal{H}_K$, provided enough unlabeled data were added in the training process. Similar results have been deduced for kernel-based conjugate gradient descent in (Blanchard and Krämer, 2010; Blanchard and Mücke, 2016). Results in the present paper show that unlabeled data also benefit distributed learning algorithms by allowing more local processors while achieving optimal learning rates. Furthermore, using some ideas from (Caponnetto and Yao, 2010), we succeed in conquering the bottleneck that optimal learning rates for distributed learning algorithms are achievable only when $f_\rho \in \mathcal{H}_K$. The numerical experiments to be reported in the last section motivated the last two authors (Lin and Zhou, 2016) to study the use of unlabeled data in distributed kernel-based gradient descent algorithms. Our results in the present paper also motivated a recent work (Guo et al., 2017) on error analysis for distributed manifold regularization algorithms.

4. Error Decomposition

The main tool in our analysis is a novel error decomposition for DSKRR. For this purpose, we introduce data-free limit and semi-supervised learning version of $f_{D_j,\lambda}$ as

$$f_\lambda = \arg\min_{f\in\mathcal{H}_K} \left\{ \int_{\mathcal{X}} (f(x) - f_\rho(x))^2 d\rho_X + \lambda \|f\|_K^2 \right\}$$

and

$$f^\diamond_{D_j,\lambda} = E^*[f_{D_j,\lambda}] := E[f_{D_j,\lambda}|D_j(x)].$$

The following proposition gives the error decomposition, whose proof is given at the end of this section.

Proposition 5 *Let $\overline{f}_{D,\lambda}$ be defined by (1). We have*

$$\frac{1}{2}E[\|\overline{f}_{D,\lambda} - f_\rho\|_\rho^2] \le \|f_\lambda - f_\rho\|_\rho^2 + \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|} E\left[\left\|f^\diamond_{D_j,\lambda} - f_\lambda\right\|_\rho^2\right], \tag{12}$$

and if $f_\rho \in \mathcal{H}_K$,

$$\frac{1}{2}E[\|\overline{f}_{D,\lambda} - f_\rho\|_K^2] \le \|f_\lambda - f_\rho\|_K^2 + \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_K^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|} E\left[\left\|f^\diamond_{D_j,\lambda} - f_\lambda\right\|_K^2\right]. \tag{13}$$

The three terms on the right-hand side of (12) (or (13)) are the approximation error, sample error and distributed error. The approximation error, independent of the sample,

describes the approximation capability of f_λ. The sample error connects the synthesized estimator (1) with the estimator (2). Compared with the sample error of the estimator (2), $E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right]$, there is an additional $\frac{|D_j|}{|D|}$ in our error decomposition, which reflects the power of the weighted averaging in (1) and shows the reason why the distributed algorithm (1) possesses similar learning performances as KRR processing the whole data D. Since $E^*[y_i] = f_\rho(x_i)$, it is easy to check that $f^\diamond_{D_j,\lambda}$ is the estimator derived from KRR with the noise-free data $\{(x_i, f_\rho(x_i))\}_{(x_i,y_i)\in D_j}$. This implies

$$f^\diamond_{D_j,\lambda} = \arg\min_{f\in\mathcal{H}_K} \left\{ \frac{1}{|D_j|} \sum_{(x,y)\in D_j} (f(x) - f_\rho(x))^2 + \lambda \|f\|_K^2 \right\}. \tag{14}$$

The distributed error presented in Proposition 5 measures the limitation of the distributed learning algorithm (1). Compared with the sample error $E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right]$ of estimator (2), the distributed error $E\left[\left\|f^\diamond_{D_j,\lambda} - f_\lambda\right\|_\rho^2\right]$ focuses on the noise-free data and therefore is smaller than $E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right]$. This makes algorithm (1) possess similar learning rates as that of KRR with the whole data D. However, since there are only $|D_j|$ samples, it is impossible to get upper bounds asymptomatically as $|D|^{-2r/(2r+s)}$ for $E\left[\left\|f^\diamond_{D_j,\lambda} - f_\lambda\right\|_\rho^2\right]$ when m is large. Thus, a restriction on m to guarantee the optimal learning rate is necessary.

To deduce a wide range of m, we need a tight bound for the distributed error. Noting that $f^\diamond_{D_j,\lambda}$ is independent of the sample outputs, it motivates us to employ the unlabeled part $\tilde{D}_j(x), j = 1, \ldots, m$ of the data set D_j^* in designing the algorithm (4). In the following, we combine the traditional integral operator approach (Smale and Zhou, 2004, 2005, 2007) with a recently developed second order decomposition of operator inverses (Lin et al., 2016; Guo et al., 2016) to derive a tight estimate for the distributed error of algorithm (4). Denote the sampling operator $S_D : \mathcal{H}_K \to \mathbb{R}^{|D|}$ (or $L^2_{\rho_X} \to \mathbb{R}^{|D|}$) by

$$S_D f := \{f(x_i)\}_{(x_i,y_i)\in D}.$$

Its adjoint $S_D^T : \mathbb{R}^{|D|} \to \mathcal{H}_K$ (or $\mathbb{R}^{|D|} \to L^2_{\rho_X}$) is given by

$$S_D^T \mathbf{c} := \frac{1}{|D|} \sum_{(x_i,y_i)\in D} c_i K_{x_i}, \qquad \mathbf{c} \in \mathbb{R}^{|D|}.$$

Let $L_{K,D}$ be the data-dependent approximation of L_K defined by

$$L_{K,D} f = S_D^T S_D f = \frac{1}{|D|} \sum_{(x,y)\in D} f(x) K_x.$$

Then it is easy to check (Smale and Zhou, 2007; Caponnetto and De Vito, 2007) that

$$f_{D,\lambda} = (L_{K,D} + \lambda I)^{-1} S_D^T y_D, \qquad f_\lambda = (L_K + \lambda I)^{-1} L_K f_\rho \tag{15}$$

and

$$f^\diamond_{D,\lambda} = (L_{K,D} + \lambda I)^{-1} L_{K,D} f_\rho, \tag{16}$$

where I is the identity operator and $y_D := (y_1, \ldots, y_{|D|})^T$. The following proposition presents error estimates for the sample and distributed errors.

Proposition 6 *Let $f_{D_j,\lambda}$, f_λ and $f^\diamond_{D_j,\lambda}$ be defined by (15) and (16). We have*

$$\max\{\|f_{D_j,\lambda}-f_\lambda\|_\rho, \sqrt{\lambda}\|f_{D_j,\lambda}-f_\lambda\|_K\} \le \mathcal{Q}^2_{D_j,\lambda}(\mathcal{P}_{D_j,\lambda}+\mathcal{S}_{D_j,\lambda}\|f_\lambda\|_K), \tag{17}$$

and

$$\max\{\|f^\diamond_{D_j,\lambda}-f_\lambda\|_\rho, \sqrt{\lambda}\|f^\diamond_{D_j,\lambda}-f_\lambda\|_K\} \le \mathcal{Q}^2_{D_j,\lambda}\mathcal{R}_{D_j,\lambda,f_\lambda-f_\rho}, \tag{18}$$

where

$$\mathcal{P}_{D,\lambda} := \left\|(L_K+\lambda I)^{-1/2}(L_Kf_\rho - S_D^Ty_D)\right\|_K,$$
$$\mathcal{Q}_{D,\lambda} := \|(L_K+\lambda I)^{1/2}(L_{K,D}+\lambda I)^{-1/2}\|,$$
$$\mathcal{S}_{D,\lambda} := \left\|(L_K+\lambda I)^{-1/2}(L_K-L_{K,D})\right\|,$$

and with a bounded measurable function g on $\mathcal{X}$,

$$\mathcal{R}_{D,\lambda,g} := \left\|(L_K+\lambda I)^{-1/2}\left(\int_{\mathcal{X}} g(x)K_xd\rho_X - \frac{1}{|D|}\sum_{(x,y)\in D} g(x)K_x\right)\right\|_K.$$

Proof Since

$$\begin{aligned} & f_{D_j,\lambda}-f_\lambda = (L_{K,D_j}+\lambda I)^{-1}S^T_{D_j}y_{D_j} - (L_K+\lambda I)^{-1}L_Kf_\rho \\ = \;& (L_{K,D_j}+\lambda I)^{-1}(S^T_{D_j}y_{D_j}-L_Kf_\rho) + [(L_{K,D_j}+\lambda I)^{-1}-(L_K+\lambda I)^{-1}]L_Kf_\rho, \end{aligned}$$

and

$$\|f\|_\rho = \|L_K^{1/2}f\|_K = \|L_K^{1/2}(L_K+\lambda I)^{-1/2}(L_K+\lambda I)^{1/2}f\|_K \le \|(L_K+\lambda I)^{1/2}f\|_K$$

for any $f\in L^2_{\rho_X}$, it follows from $A^{-1}-B^{-1}=A^{-1}(B-A)B^{-1}$ for positive operators A,B that

$$\begin{aligned} & \max\left\{\|f_{D_j,\lambda}-f_\lambda\|_\rho, \sqrt{\lambda}\|f_{D_j,\lambda}-f_\lambda\|_K\right\} \\ \le \;& \|(L_K+\lambda I)^{1/2}(L_{K,D_j}+\lambda I)^{-1}(S^T_{D_j}y_{D_j}-L_Kf_\rho)\|_K \\ + \;& \|(L_K+\lambda I)^{1/2}[L_{K,D_j}+\lambda I)^{-1}-(L_K+\lambda I)^{-1}]L_Kf_\rho\|_K \\ \le \;& \mathcal{Q}_{D_j,\lambda}\|(L_{K,D_j}+\lambda I)^{-1/2}(S^T_{D_j}y_{D_j}-L_Kf_\rho)\|_K \\ + \;& \|(L_K+\lambda I)^{1/2}(L_{K,D_j}+\lambda I)^{-1}(L_K-L_{K,D_j})(L_K+\lambda I)^{-1}L_Kf_\rho\|_K \\ \le \;& \mathcal{Q}^2_{D_j,\lambda}\|(L_K+\lambda I)^{-1/2}(S^T_{D_j}y_{D_j}-L_Kf_\rho)\|_K \\ + \;& \mathcal{Q}^2_{D_j,\lambda}\|(L_K+\lambda I)^{-1/2}(L_K-L_{K,D_j})\|\|(L_K+\lambda I)^{-1}L_Kf_\rho\|_K \\ \le \;& \mathcal{Q}^2_{D_j,\lambda}(\mathcal{P}_{D_j,\lambda}+\mathcal{S}_{D_j,\lambda}\|f_\lambda\|_K). \end{aligned}$$

This completes the proof of (17). Now we turn to prove (18). Due to (15) and (16), we have

$$\begin{aligned} & f^\diamond_{D_j,\lambda}-f_\lambda = (L_{K,D_j}+\lambda I)^{-1}L_{K,D_j}f_\rho - (L_K+\lambda I)^{-1}L_Kf_\rho \\ = \;& (L_{K,D_j}+\lambda I)^{-1}(L_{K,D_j}-L_K)f_\rho + [L_{K,D_j}+\lambda I)^{-1}-(L_K+\lambda I)^{-1}]L_Kf_\rho \\ = \;& (L_{K,D_j}+\lambda I)^{-1}(L_{K,D_j}-L_K)f_\rho + (L_{K,D_j}+\lambda I)^{-1}[L_K-L_{K,D_j}](L_K+\lambda I)^{-1}L_Kf_\rho \\ = \;& -(L_{K,D_j}+\lambda I)^{-1}[L_K-L_{K,D_j}](f_\rho-f_\lambda). \end{aligned}$$

Then

$$\begin{aligned} & \max\{\|f^\diamond_{D_j,\lambda}-f_\lambda\|_\rho, \sqrt{\lambda}\|f^\diamond_{D_j,\lambda}-f_\lambda\|_K\} \\ \le \;& \|(L_K+\lambda I)^{1/2}(L_{K,D_j}+\lambda I)^{-1}[L_K-L_{K,D_j}](f_\lambda-f_\rho)\|_K \\ \le \;& \mathcal{Q}_{D_j,\lambda}\|(L_{K,D_j}+\lambda I)^{-1/2}(L_{K,D_j}-L_K)(f_\lambda-f_\rho)\|_K \le \mathcal{Q}^2_{D_j,\lambda}\mathcal{R}_{D_j,\lambda,f_\lambda-f_\rho}. \end{aligned}$$

This completes the proof of Proposition 6. ■

If $f_\rho\in\mathcal{H}_K$, we have

$$\mathcal{R}_{D_j,\lambda,f_\lambda-f_\rho} = \|(L_K+\lambda I)^{-1/2}(L_{K,D_j}-L_K)(f_\lambda-f_\rho)\|_K \le \mathcal{S}_{D_j,\lambda}\|f_\lambda-f_\rho\|_K.$$

This implies that the distributed error can be bounded by $\mathcal{Q}^2_{D_j,\lambda}\mathcal{S}_{D_j,\lambda}\|f_\lambda-f_\rho\|_K$. Comparing with the sample error estimate (17) for an individual local processor, there is an additional term $\|f_\lambda-f_\rho\|_K$ in the distributed error estimate, since $\mathcal{P}_{D_j,\lambda}$, and $\mathcal{S}_{D_j,\lambda}$ are asymptotically equal due to Lemma 9 in Section 5. This together with Lemma 8 below shows that the distributed error estimate is essentially smaller than the sample error estimate for local processors under (5) with $r>1/2$, and presents the reason why DSKRR performs similarly as KRR on the whole data set D, provided m is not so large.

Recall the definitions of $\mathcal{Q}_{D_j,\lambda}$, $\mathcal{R}_{D_j,\lambda,f_\lambda-f_\rho}$ and $\mathcal{S}_{D_j,\lambda}$. These three quantities are independent of the outputs. Thus, the distributed error estimate decreases when additional unlabeled data are given. This explains why unlabeled data can enlarge the range of m to guarantee the optimal learning rates for DSKRR. On the other hand, it follows from the definition of $\mathcal{P}_{D,\lambda}$ that the sample error estimate depends heavily on the labels corresponding to unlabeled data. But (3) implies that for each fixed $1\le j\le m$,

$$S^T_{D^*_j}y_{D^*_j} = \frac{1}{|D^*_j|}\sum_{(x,y)\in D^*_j} y^*K_x = \frac{1}{|D^*_j|}\frac{|D^*_j|}{|D_j|}\sum_{(x,y)\in D_j} yK_x = S^T_{D_j}y_{D_j}.$$

Then $\mathcal{P}_{D^*_j,\lambda}=\mathcal{P}_{D_j,\lambda}$ for each $1\le j\le m$, which implies that the sample error estimate does not increase when the unlabeled data are added and shows the necessity of re-weighting of y in our definition in (3).

Thus, the unlabeled data in algorithm (4) can reduce the distributed error estimate without increasing the sample error estimate. The following proposition which can be deduced directly from Propositions 5 and 6, shows the detailed error decomposition for algorithm (4).

Proposition 7 *Let $\overline{f}_{D^*,\lambda}$ be defined by algorithm (4). If condition (5) holds with $0<r\le 1$, then for $1/2\le r\le 1$,*

$$\begin{aligned} & \frac{1}{2}\max\left\{E[\|\overline{f}_{D^*,\lambda}-f_\rho\|^2_\rho], \lambda E[\|\overline{f}_{D^*,\lambda}-f_\rho\|^2_K]\right\} \\ \le \;& \max\{\|f_\lambda-f_\rho\|^2_\rho, \lambda\|f_\lambda-f_\rho\|^2_K\} + \sum_{j=1}^m \frac{|D^*_j|^2}{|D^*|^2}E\left[\mathcal{Q}^4_{D^*_j,\lambda}(\mathcal{P}_{D_j,\lambda}+\mathcal{S}_{D^*_j,\lambda}\|f_\lambda\|_K)^2\right] \\ & + \sum_{j=1}^m \frac{|D^*_j|}{|D^*|}E\left[\mathcal{Q}^4_{D^*_j,\lambda}\mathcal{S}^2_{D^*_j,\lambda}\|f_\lambda-f_\rho\|^2_K\right] \end{aligned} \tag{19}$$

while for $0 < r < 1/2$,

$$E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2] \leq \|f_\lambda - f_\rho\|_\rho^2 + \sum_{j=1}^m \frac{|D_j^*|^2}{|D^*|^2} E\left[\mathcal{Q}_{D_j^*,\lambda}^4 (\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)^2\right] + \sum_{j=1}^m \frac{|D_j^*|}{|D^*|} E\left[\mathcal{Q}_{D_j^*,\lambda}^4 \mathcal{R}_{D_j^*,\lambda,f_\lambda - f_\rho}^2\right]. \quad (20)$$

We end this section by proving Proposition 5.

Proof of Proposition 5 For the sake of brevity, we only prove (12), since (13) can be derived by using the same method. Due to the triangle inequality and the elementary inequality $(a+b)^2 \leq 2a^2 + 2b^2$ for $a, b > 0$, we have

$$E[\|\overline{f}_{D,\lambda} - f_\rho\|_\rho^2] \leq 2\|f_\lambda - f_\rho\|_\rho^2 + 2E[\|\overline{f}_{D,\lambda} - f_\lambda\|_\rho^2]. \quad (21)$$

It follows from $\sum_{j=1}^m \frac{|D_j|}{|D|} = 1$ that

$$\|\overline{f}_{D,\lambda} - f_\lambda\|_\rho^2 = \left\|\sum_{j=1}^m \frac{|D_j|}{|D|}(f_{D_j,\lambda} - f_\lambda)\right\|_\rho^2$$

$$= \sum_{j=1}^m \frac{|D_j|^2}{|D|^2}\|f_{D_j,\lambda} - f_\lambda\|_\rho^2 + \sum_{j=1}^m \frac{|D_j|}{|D|}\left\langle f_{D_j,\lambda} - f_\lambda, \sum_{k\neq j}\frac{|D_k|}{|D|}(f_{D_k,\lambda} - f_\lambda)\right\rangle_\rho.$$

Taking expectations gives

$$E\left[\|\overline{f}_{D,\lambda} - f_\lambda\|_\rho^2\right] = \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|}\left\langle E[f_{D_j,\lambda}] - f_\lambda, E[\overline{f}_{D,\lambda}] - f_\lambda - \frac{|D_j|}{|D|}\left(E[f_{D_j,\lambda}] - f_\lambda\right)\right\rangle_\rho.$$

But

$$\sum_{j=1}^m \frac{|D_j|}{|D|}\left\langle E_{D_j}[f_{D_j,\lambda}] - f_\lambda, E[\overline{f}_{D,\lambda}] - f_\lambda\right\rangle_\rho = \left\langle E[\overline{f}_{D,\lambda}] - f_\lambda, E[\overline{f}_{D,\lambda}] - f_\lambda\right\rangle_\rho = \left\|E[\overline{f}_{D,\lambda}] - f_\lambda\right\|_\rho^2.$$

We see that $E\left[\|\overline{f}_{D,\lambda} - f_\lambda\|_\rho^2\right]$ equals

$$\sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] - \sum_{j=1}^m \frac{|D_j|^2}{|D|^2}\left\|E[f_{D_j,\lambda}] - f_\lambda\right\|_\rho^2 + \left\|E[\overline{f}_{D,\lambda}] - f_\lambda\right\|_\rho^2.$$

Furthermore, by the Schwarz inequality and $\sum_{j=1}^m \frac{|D_j|}{|D|} = 1$, we have

$$\|E[\overline{f}_{D,\lambda}] - f_\lambda\|_\rho^2 = \left\|\sum_{j=1}^m \frac{|D_j|}{|D|}\left(E[f_{D_j,\lambda}] - f_\lambda\right)\right\|_\rho^2 \leq \sum_{j=1}^m \frac{|D_j|}{|D|}\left\|E[f_{D_j,\lambda}] - f_\lambda\right\|_\rho^2.$$

Then

$$E\left[\|\overline{f}_{D,\lambda}] - f_\lambda\|_\rho^2\right] \leq \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|}\left\|E[f_{D_j,\lambda}] - f_\lambda\right\|_\rho^2.$$

Inserting the above inequalities into (21), we find

$$\frac{1}{2}E[\|\overline{f}_{D,\lambda} - f_\rho\|_\rho^2] \leq \|f_\lambda - f_\rho\|_\rho^2 + \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|}\left\|E[f_{D_j,\lambda}] - f_\lambda\right\|_\rho^2.$$

According to Jensen's inequality, we obtain

$$\left\|E[f_{D_j,\lambda}] - f_\lambda\right\|_\rho^2 \leq E\left[\left\|f_{D_j,\lambda}^\diamond - f_\lambda\right\|_\rho^2\right],$$

which implies

$$\frac{1}{2}E[\|\overline{f}_{D,\lambda} - f_\rho\|_\rho^2] \leq \|f_\lambda - f_\rho\|_\rho^2 + \sum_{j=1}^m \frac{|D_j|^2}{|D|^2} E\left[\|f_{D_j,\lambda} - f_\lambda\|_\rho^2\right] + \sum_{j=1}^m \frac{|D_j|}{|D|} E\left[\left\|f_{D_j,\lambda}^\diamond - f_\lambda\right\|_\rho^2\right].$$

This completes the proof of Proposition 5. ■

5. Proofs

According to Proposition 7, to prove Theorems 1 and 3, we only need to bound $\|f_\lambda - f_\rho\|_\rho$, $\|f_\lambda - f_\rho\|_K$, $\mathcal{Q}_{D_j^*,\lambda}$, $\mathcal{P}_{D_j,\lambda}$, $\mathcal{R}_{D_j^*,\lambda,g}$ and $\mathcal{S}_{D_j^*,\lambda}$. The following two lemmas present bounds for these quantities. The first one can be found in (Smale and Zhou, 2007), which estimates the approximation error of algorithm (4).

Lemma 8 *Assume (5) with* $0 < r \leq 1$. *There holds*

$$\|f_\lambda - f_\rho\|_\rho \leq \lambda^r \|h_\rho\|_\rho. \quad (22)$$

Furthermore, if $1/2 \leq r \leq 1$, *then we have*

$$\|f_\lambda - f_\rho\|_K \leq \lambda^{r-1/2}\|h_\rho\|_\rho. \quad (23)$$

The second lemma presents bounds for $\mathcal{Q}_{D_j^*,\lambda}$, $\mathcal{P}_{D_j,\lambda}$, $\mathcal{R}_{D_j^*,\lambda,g}$ and $\mathcal{S}_{D_j^*,\lambda}$. In particular, (24) was proved in (Guo et al., 2016), (25) and (27) were given in (Lin et al., 2016) and (26) can be found in (Caponnetto and De Vito, 2007). Recall the quantity $\mathcal{A}_{D,\lambda}$ defined by (7).

Lemma 9 *Let* D *be a sample drawn independently according to* ρ *and* $0 < \delta < 1$. *If* $|y| \leq M$ *almost surely, then each of the following estimates holds with confidence at least* $1 - \delta$,

$$\mathcal{Q}_{D,\lambda}^2 \leq 2\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}\log\frac{2}{\delta}}{\sqrt{\lambda}}\right)^2 + 2, \quad (24)$$

$$\mathcal{S}_{D,\lambda} \leq 2(\kappa^2+\kappa)\mathcal{A}_{D,\lambda}\log(2/\delta), \quad (25)$$

$$\mathcal{P}_{D,\lambda} \leq 2M(\kappa+1)\mathcal{A}_{D,\lambda}\log(2/\delta), \quad (26)$$

$$\mathcal{R}_{D,\lambda,g} \leq 2\|g\|_\infty(\kappa+1)\mathcal{A}_{D,\lambda}\log(2/\delta). \quad (27)$$

We can now use Proposition 7 and the above lemmas to prove our main results.

Proof of Theorem 1 As $r \geq 1/2$, Lemma 8 implies that

$$\max\left\{\|f_\lambda - f_\rho\|_\rho, \sqrt{\lambda}\|f_\lambda - f_\rho\|_K\right\} \leq \lambda^r \|h_\rho\|_\rho. \tag{28}$$

For an arbitrary fixed $j \in \{1, \ldots, m\}$, it follows from Lemma 9 that there exist three subsets $\mathcal{Z}_{1,\delta}^{|D_j^*|}$, $\mathcal{Z}_{2,\delta}^{|D_j^*|}$ and $\mathcal{Z}_{3,\delta}^{|D_j^*|}$ of $\mathcal{Z}^{|D_j^*|}$ with measures at least $1-\delta/3$ such that for $D_j^* \in \mathcal{Z}_{1,\delta}^{|D_j^*|} \cap \mathcal{Z}_{2,\delta}^{|D_j^*|} \cap \mathcal{Z}_{3,\delta}^{|D_j^*|}$ there holds

$$\begin{aligned}
\mathcal{Q}^2_{D_j^*,\lambda} &\leq 2\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}\log\frac{6}{\delta}}{\sqrt{\lambda}}\right)^2 + 2,\\
\mathcal{S}_{D_j^*,\lambda} &\leq 2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}\log\frac{6}{\delta},\\
\mathcal{P}_{D_j,\lambda} &\leq 2M(\kappa+1)\mathcal{A}_{D_j,\lambda}\log\frac{6}{\delta}.
\end{aligned}$$

This together with

$$\|f_\lambda\|_K = \|(L_K+\lambda I)^{-1}L_K f_\rho\|_K \leq \|f_\rho\|_K \leq \|L_K^{r-1/2}\|\|L_K^{1/2}h_\rho\|_K \leq \kappa^{2r-1}\|h_\rho\|_\rho$$

yields that with confidence at least $1-\delta$, there holds

$$\begin{aligned}
&\mathcal{Q}^2_{D_j^*,\lambda}(\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)\\
\leq\ & 16(\kappa+1)\log^3\frac{6}{\delta}\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]\left[M\mathcal{A}_{D_j,\lambda} + \kappa^{2r}\|h_\rho\|_\rho\mathcal{A}_{D_j^*,\lambda}\right].
\end{aligned}$$

Using the probability to expectation formula

$$E[\xi] = \int_0^\infty \text{Prob}\left[\xi > t\right] dt \tag{29}$$

for nonnegative random variables to $\xi_1 = \mathcal{Q}^4_{D_j^*,\lambda}(\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)^2$ and

$$\text{Prob}\left[\xi_1 > u\right] = \text{Prob}\left[\xi_1^{\frac{1}{2}} > u^{\frac{1}{2}}\right] \leq 6\exp\left\{-[16\mathcal{B}(D_j^*,\lambda)]^{-\frac{1}{3}}u^{\frac{1}{6}}\right\}$$

for $u \geq 256\log^6 6\mathcal{B}(D_j^*,\lambda)^2$, we have

$$\begin{aligned}
&E\left[\mathcal{Q}^4_{D_j^*,\lambda}(\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)^2\right] \leq 256\log^6 6\mathcal{B}(D_j^*,\lambda)^2\\
+\ & 6\int_0^\infty \exp\left\{-[16\mathcal{B}(D_j^*,\lambda)]^{-\frac{1}{3}}u^{\frac{1}{6}}\right\}du = 256(6+\log^6 6)\mathcal{B}^2(D_j^*,\lambda)\int_0^\infty u^{6-1}\exp\{-u\}\,du,
\end{aligned}$$

where

$$\mathcal{B}(D_j^*,\lambda) := (\kappa+1)\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]\left(M\mathcal{A}_{D_j,\lambda} + \kappa^{2r}\|h_\rho\|_\rho\mathcal{A}_{D_j^*,\lambda}\right). \tag{30}$$

Due to the expression $\int_0^\infty u^{d-1}\exp\{-u\}\,du = \Gamma(d)$ for Gamma functions with $d > 0$, we have

$$E\left[\mathcal{Q}^4_{D_j^*,\lambda}(\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)^2\right] \leq 256(6+\log^6 6)5!\mathcal{B}^2(D_j^*,\lambda). \tag{31}$$

According to Lemma 9, there exist two subsets $\mathcal{Z}_{1',\delta}^{|D_j^*|}$ and $\mathcal{Z}_{2',\delta}^{|D_j^*|}$ of $\mathcal{Z}^{|D_j^*|}$ with measures at least $1-\delta/2$ such that for $D_j^* \in \mathcal{Z}_{1',\delta}^{|D_j^*|} \cap \mathcal{Z}_{2',\delta}^{|D_j^*|}$ there holds

$$\begin{aligned}
&\mathcal{Q}^2_{D_j^*,\lambda}\mathcal{S}_{D_j^*,\lambda}\|f_\lambda - f_\rho\|_K\\
\leq\ & 4(\kappa^2+\kappa)\log\frac{4}{\delta}\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}\right)^2+1\right]\mathcal{A}_{D_j^*,\lambda}\|f_\lambda - f_\rho\|_K.
\end{aligned} \tag{32}$$

Since $r \geq 1/2$, plugging (23) into (32), with confidence at least $1-\delta$, there holds

$$\begin{aligned}
&\mathcal{Q}^2_{D_j^*,\lambda}\mathcal{S}_{D_j^*,\lambda}\|f_\lambda - f_\rho\|_K\\
\leq\ & 4\kappa(\kappa+1)\lambda^{r-1/2}\|h_\rho\|_\rho\log\frac{4}{\delta}\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}\right)^2+1\right]\mathcal{A}_{D_j^*,\lambda}.
\end{aligned}$$

The same method as that in deriving (31) yields

$$\begin{aligned}
&E\left[\mathcal{Q}^4_{D_j^*,\lambda}\mathcal{S}^2_{D_j^*,\lambda}\|f_\lambda - f_\rho\|_K^2\right]\\
\leq\ & 256\kappa^2(\kappa+1)^2(4+\log^6 4)5!\|h_\rho\|_\rho^2\lambda^{2r-1}\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\mathcal{A}^2_{D_j^*,\lambda}.
\end{aligned} \tag{33}$$

Inserting (28), (31), (30) and (33) into (19), we obtain

$$\begin{aligned}
&\max\left\{E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2], \lambda E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_K^2]\right\} \leq 2\lambda^{2r}\|h_\rho\|_\rho^2\\
&+512\kappa^2(\kappa+1)^2(4+\log^6 4)5!\|h_\rho\|_\rho^2\lambda^{2r-1}\sum_{j=1}^m\frac{|D_j^*|}{|D^*|}\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\mathcal{A}^2_{D_j^*,\lambda}\\
&+512(6+\log^6 6)5!(\kappa+1)^2\sum_{j=1}^m\frac{|D_j^*|^2}{|D^*|^2}\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\\
&\times\left[M\mathcal{A}_{D_j,\lambda} + \kappa^{2r}\|h_\rho\|_\rho\mathcal{A}_{D_j^*,\lambda}\right]^2.
\end{aligned}$$

Then (6) follows from $\mathcal{A}_{D_j^*,\lambda} \leq \mathcal{A}_{D_j,\lambda}$ and the above estimate with

$$C := 2\|h_\rho\|_\rho^2 + 512(6+\log^6 6)5!(\kappa+1)^2[(\kappa+1)^2+1]^2\max\left\{\kappa^2\|h_\rho\|_\rho^2, (M+\|h_\rho\|_\rho\kappa^r)^2\right\}.$$

This completes the proof of Theorem 1. ∎

Proof of Corollary 2 Let $\lambda = |D|^{-\frac{1}{(2r+s)}}$. Since $r+s \geq r \geq 1/2$, we obtain from (7), (8) and $|D_1| = \cdots = |D_m|$ that

$$\mathcal{A}_{D_j,\lambda} \leq m|D|^{-\frac{2r+s-1/2}{2r+s}} + \sqrt{C_0 m}|D|^{-\frac{r}{2r+s}} \qquad \forall j = 1, \ldots, m. \tag{34}$$

Since $|D_1^*| = \cdots = |D_m^*|$, we have

$$\mathcal{A}_{D_j^*,\lambda} \leq m|D^*|^{-1}|D|^{\frac{1}{4r+2s}} + \sqrt{C_0 m}|D^*|^{-1/2}|D|^{\frac{s}{4r+2s}}, \qquad \forall\ j = 1, \ldots, m. \tag{35}$$

This implies

$$\lambda^{-1/2}\mathcal{A}_{D_j^*,\lambda} \leq m|D^*|^{-1}|D|^{\frac{2}{4r+2s}} + \sqrt{C_0 m}|D^*|^{-1/2}|D|^{\frac{s+1}{4r+2s}}.$$

Due to (9), we have

$$\lambda^{-1/2}\mathcal{A}_{D_j^*,\lambda} \leq \sqrt{C_0} + 1. \tag{36}$$

Plugging (34), (35), (36) and (9) into (6) and noticing $\frac{|D_j^*|}{|D^*|} = \frac{1}{m}$ and $m \leq |D|^{\frac{2r+2s-1}{2r+s}}$, we obtain

$$E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2] \leq C|D|^{-2r/(2r+s)} + 8C(\sqrt{C_0}+2)^6|D|^{-2r/(2r+s)}.$$

This completes the proof of Corollary 2. ■

Proof of Theorem 3 The proof is almost the same as that of Theorem 1. The only difference is that when $0 < r < 1/2$, we have

$$\|f_\lambda\|_K = \|(L_K+\lambda I)^{-1}L_K f_\rho\|_K \leq \|(L_K+\lambda I)^{-1}L_K^{1/2+r}\|\|L_K^{1/2}h_\rho\|_K \leq \lambda^{r-1/2}\|h_\rho\|_\rho \tag{37}$$

and

$$\|f_\lambda - f_\rho\|_\infty \leq \|f_\lambda\|_\infty + \|f_\rho\|_\infty \leq \kappa\|f_\lambda\|_K + M \leq M + \kappa\lambda^{r-1/2}\|h_\rho\|_\rho. \tag{38}$$

Since $0 < r < 1/2$, we also see from Lemma 8 that

$$\|f_\lambda - f_\rho\|_\rho \leq \lambda^r\|h_\rho\|_\rho. \tag{39}$$

It follows from (37), (27) and the same method as that for deriving (31) that

$$\begin{aligned} E\left[\mathcal{Q}_{D_j^*,\lambda}^4(\mathcal{P}_{D_j,\lambda} + \mathcal{S}_{D_j^*,\lambda}\|f_\lambda\|_K)^2\right] &\leq 512(6+\log^6 6)5!(\kappa+1)^2\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2 \\ &\times \left[M\mathcal{A}_{D_j,\lambda} + \kappa\lambda^{r-1/2}\|h_\rho\|_\rho\mathcal{A}_{D_j^*,\lambda}\right]^2. \end{aligned} \tag{40}$$

Combining (38) and (27) with the same method as that for deriving (33) yields

$$\begin{aligned} &E\left[\mathcal{Q}_{D_j^*,\lambda}^4\mathcal{R}_{D_j^*,\lambda,f_\lambda-f_\rho}^2\right] \\ \leq\ & 512(\kappa+1)^2(4+\log^6 4)5!(M+\kappa\lambda^{r-1/2}\|h_\rho\|_\rho)^2\left[\left(\frac{2(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\mathcal{A}_{D_j^*,\lambda}^2. \end{aligned} \tag{41}$$

Inserting (39), (40) and (41) into (20), we have

$$\begin{aligned} &E\left[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2\right] \leq 2\lambda^{2r}\|h_\rho\|_\rho^2 + 1024(\kappa+1)^2(4+\log^6 4)5!(M+\kappa\lambda^{r-1/2}\|h_\rho\|_\rho)^2 \\ &\times\sum_{j=1}^m\frac{|D_j^*|}{|D^*|}\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2\mathcal{A}_{D_j^*,\lambda}^2 \\ &+1024(6+\log^6 6)5!(\kappa+1)^2\sum_{j=1}^m\frac{|D_j^*|^2}{|D^*|^2}\left[\left(\frac{(\kappa^2+\kappa)\mathcal{A}_{D_j^*,\lambda}}{\sqrt{\lambda}}\right)^2+1\right]^2 \\ &\times\left[M\mathcal{A}_{D_j,\lambda} + \kappa\lambda^{r-1/2}\|h_\rho\|_\rho\mathcal{A}_{D_j^*,\lambda}\right]^2. \end{aligned}$$

Together with the restrictions $0 < \lambda \leq 1$ and $2r < 1$, this yields (10) with

$$\overline{C} := 2\|h_\rho\|_\rho^2 + 1024(6+\log^6 6)5!(\|h_\rho\|_\rho + M)^2(\kappa+1)^4[(\kappa^2+\kappa)^2+1]^2.$$

This completes the proof of Theorem 3. ■

Proof of Corollary 4 Due to $r+s \geq 1/2$ and (9), we get (34), (35) and (36). Inserting (34), (35), (36) and (9) into (10), we obtain from $|D^*| \geq |D|^{\frac{1+s}{2r+s}}$ that

$$\begin{aligned} &E[\|\overline{f}_{D^*,\lambda} - f_\rho\|_\rho^2] \leq \overline{C}|D|^{-2r/(2r+s)} \\ +\ & \overline{C}((\sqrt{C_0}+1)^2+1)^2\sum_{j=1}^m\frac{|D_j^*|}{|D|}\left[\frac{1}{m}\mathcal{A}_{D_j,\lambda}^2 + \lambda^{2r-1}\mathcal{A}_{D_j^*,\lambda}^2\right] \\ \leq\ & [\overline{C} + 2\overline{C}((\sqrt{C_0}+1)^2+1)^2((1+\sqrt{C_0})^2))]|D|^{-\frac{2r}{2r+s}}, \end{aligned}$$

where we have used $|D^*| \geq |D|^{\frac{2r+s+1}{2r+s}}$ in the last inequality. This completes the proof of Corollary 4. ■

6. Experimental Verifications

In this section, we report experimental studies to justify the statements in Section 2. We employ two criteria for the comparison. The first criterion is the *global error* (GE) which is the mean square error of a testing set with $N = |D|$ examples used in the training flow. GE provides a baseline to assess the performance of DSKRR. The second criterion is the *average error* (AE) which is the mean square error of algorithm (4). Regularization parameters in all experiments are selected by the 5-fold cross-validation.

6.1 Toy simulations

In this part, we carry out three simulations to verify our theoretical statements. The first two simulations are devoted to verifying Corollaries 2 and 4, respectively. The last simulation focuses on the relation between the generalization performance of algorithm (4) and the size of unlabeled data to show the power of unlabeled data in distributed learning.

Simulation 1: We generate $N = 5000$ examples for training. The inputs $\{x_i\}_{i=1}^N$ are independently drawn according to the uniform distribution on the (hyper-)cube $[0,1]^d$

with $d = 1$ or $d = 3$. The corresponding outputs are generated from the regression models $y_i = g_j(x_i)+\varepsilon_i, i = 1, \ldots, N, j = 1, 2$, where ε_i is the independent Gaussian noise $\mathcal{N}(0, 1/5)$,

$$g_1(x) := \begin{cases} x, & 0 < x \le 0.5, \\ 1 - x, & 0.5 < x \le 1, \end{cases} \tag{42}$$

and

$$g_2(x) := h_2(\|x\|_2) := \begin{cases} (1 - \|x\|_2)^6(35\|x\|_2^2 + 18\|x\|_2 + 3), & 0 < \|x\|_2 \le 1, x \in \mathbb{R}^3, \\ 0, & \|x\|_2 > 1. \end{cases} \tag{43}$$

We also generate 500 test examples $\{(x_i', y_i')\}_{i=1}^{500}$ with $\{x_i'\}$ drawn independently according to the uniform distribution and $y_i' = g_j(x_i'), j = 1, 2$. The number m of local processors varies from 2 to 60. The $SN \in \{0, 2000, 4000, 6000, 8000, 10000\}$ unlabeled examples $\{\tilde{x}_i\}_{i=1}^{SN}$ are independently drawn according to the uniform distribution on the (hyper-)cube $[0, 1]^d$. It can be found in (Wu, 1995; Schaback and Wendland, 2006) that $g_1 \in W_1^1$ and $g_2 \in W_3^4$, where W_d^α denotes the α-order Sobolev space on $[0, 1]^d$. Furthermore, it is easy to see that $g_1 \notin W_1^2$ and $g_2 \notin W_3^5$. If we define $K_1(x, x') = 1 + \min(x, x')$ and $K_2(x, x') = h_3(\|x - x'\|_2)$ with

$$g_3(x) := h_3(\|x\|_2) := \begin{cases} (1 - \|x\|_2)^4(4\|x\|_2 + 1), & 0 < \|x\|_2 \le 1, x \in \mathbb{R}^3, \\ 0, & \|x\|_2 > 1, \end{cases} \tag{44}$$

then we know (Wu, 1995; Schaback and Wendland, 2006) that K_1 and K_2 are reproducing kernels for W_1^1 and W_3^2, respectively. Obviously, $g_1 \in \mathcal{H}_{K_1}$ and $g_2 \in \mathcal{H}_{K_2}$. The $N + SN$ sample points are evenly distributively stored in m local processors and algorithm (4) is applied to the training set. The testing results of GEs and AEs are recorded and shown in Figure 2.

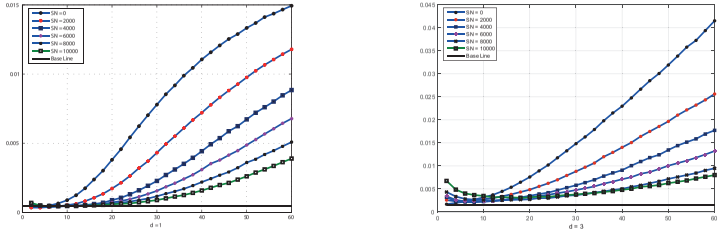

Figure 2: Performances of algorithm (4) with different scale of $|D^*|$ when $f_\rho \in \mathcal{H}_K$

In Figure 2, AE curves are recorded by different SN. When m is not too large, as shown in Figure 2, AEs are always comparable to GEs. Furthermore, there exists an upper bound of the number of local processors, m_{SN} (e.g., $m_{100,00} \approx 30$), lager than which AE curves increase dramatically. This result confirms Corollary 2 which indicates that DSKRR can achieve the optimal learning rate as long as m is not too large. Moreover, when we add more

unlabeled data into the training set, i.e., increasing SN, the upper bound m_{SN} increases and AEs decrease (e.g., the AE curve for $SN = 100, 00$ is almost below all the other curves). This shows the power of adding unlabeled data into training data, as condition (9) shows.

Simulation 2: We generate a training set from the regression model $y_i = g_3(x_i)+\varepsilon_i, i = 1, \ldots, N$ with $N = 5000$, where the inputs $\{x_i\}_{i=1}^N$ are independently drawn according to the uniform distribution on $[0, 1]^3$. We also generate 500 test examples $\{(x_i', y_i')\}_{i=1}^{500}$ with x_i' drawn independently according to the uniform distribution and $y_i' = g_3(x_i')$. The number of servers m varies from 2 to 90 and the number of unlabeled examples is $SN \in \{0, 2000, 4000, 6000, 8000, 10000\}$. We utilize $K_3(x, x') = h_2(\|x - x'\|_2)$ as the kernel. It can be found in (Wu, 1995; Schaback and Wendland, 2006) that K_3 is a reproducing kernel for W_3^4. Obviously, $g_3 \notin \mathcal{H}_{K_3}$. GEs and AEs are recorded and shown in Figure 3.

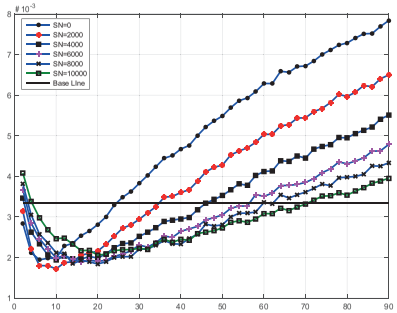

Figure 3: Performances of algorithm (4) with different scale of $|D^*|$ when $f_\rho \notin \mathcal{H}_K$

This simulation shows similar results as Simulation 1. The only difference is that the regression function $g_3 \notin \mathcal{H}_{K_3}$. This demonstrates the statement of Corollary 4, saying that even when the regression function is not in the RHKS, the optimal learning rate of algorithm (4) can be achieved. Based on Simulations 1 and 2, we find that adding unlabeled data into the training set can essentially improve the learning performance of algorithm (1).

Simulation 3: The experimental setting of this simulation is the same as that in Simulation 1. We generate $N = 500$ observations as a training set and 50 observations as a testing set. Here, we fix the size of local processors to be $m = 10$ and vary the number of unlabeled data SN from 50 to 10000. The aim is to describe the relation between the generalization ability of algorithm (4) and the size of unlabeled data. The simulation results are reported in Figure 4.

In Figure 4, we construct two straight lines (black and blue lines) as base lines for comparisons. The black straight line is the GE, while the blue line is the AE value with $SN = 0$. We change the size of unlabeled data and apply algorithm (4) on the training set. It is shown in Figure 4 that the AE's curve decreases dramatically and can achieve the GE value when we add about $10N$ unlabeled data. However, when we add more unlabeled data

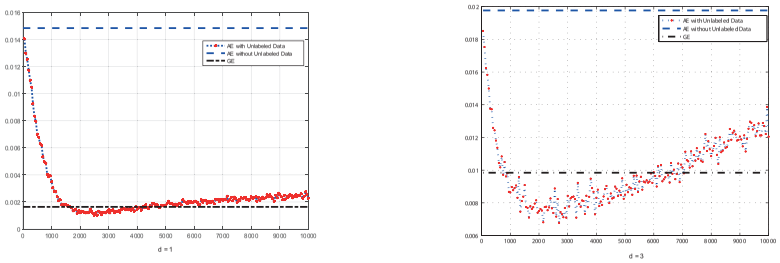

Figure 4: Relation between generalization error and the size of unlabeled data

into the training data, the AE curve begins to increase slowly. This phenomenon indicates two important observations. On one hand, adding unlabeled data into the training set can essentially improve the learning performance of DSKRR. On the other hand, if the size of unlabeled data is too large, the optimal learning rate has reasonable probabilities to be broken out. From our simulations, we suggest that $SN \leq 10N$. Here, we need to mention that for stabilizing the AE's curve, the simulation is repeated 10 times. The drawn curve is the average values of AE.

All these simulations verify our theoretical statements in Section 2 and show the power of unlabeled data in distributed semi-supervised learning.

6.2 Real data experiment

In this part, we focus on the Million Song data (Bertin-Mahieux et al., 2011) that describes a learning task of predicting the year in which a song is released based on audio features associated with the song. The dataset consists of $463,715$ training examples and $51,630$ test examples. Each example is a song released between 1922 and 2011, and the song is represented as a vector of timbre information computed about the song. Each sample point consists of a pair $(x_i, y_i) \in [0,1]^d \times [1922, 2011]$ with $d = 90$.

For the Million Song data, we normalize the feature vectors x so that the timbre signals have mean 0 and standard deviation 1. We also give a feature weight vector $W = (w_1, \ldots, w_d)^\top$ for setting $x_{ij} := w_j x_{ij}$. Here we choose $w_j = 1$ if $j \leq 12$ and $w_j = 0.2$ if $12 < j \leq 90$. Finally, we use the Gaussian kernel $K(x, x') = \exp\left\{-\frac{\|x-x'\|_2^2}{2\beta^2}\right\}$ in our experiments with bandwidth parameter $\beta = 6$ and regularization parameter $\lambda = N^{-1}/2$.

For each feature $X_j = (x_{1j}, \ldots, x_{Nj})^\top$, we denote $x_j^{min} = \min\{x_{1j}, \ldots, x_{Nj}\}$ and $x_j^{max} = \max\{x_{1j}, \ldots, x_{Nj}\}$. Then we generate the unlabeled data $\tilde{x}_{ij}, j = 1, \ldots, SN$, independently from the uniform distribution $U[x_j^{min}, x_j^{max}]$. It should be noted that the distributions for the labeled data and unlabeled data are different, making the learning task a so-called mismatch problem. Algorithm (4) is applied to the training examples with six partitions $m \in \{300, 500, 700, 900, 1100, 1300\}$. Finally, we plot AE curves of DSKRR with 3 different sizes of unlabeled samples in Figure 5. As exhibited in Figure 5, DSKRR

has better performance when SN increases if $m \geq 300$. This phenomenon confirms the observation that adding unlabeled data into training examples can improve the order of m, as condition (9) shows.

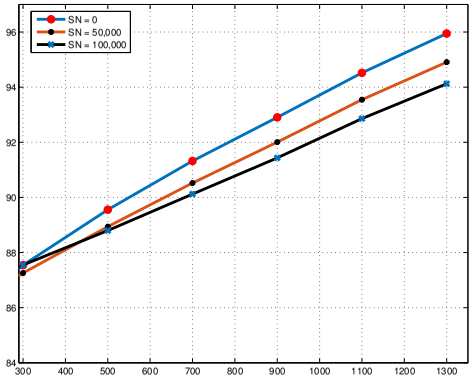

Figure 5: Performance of DSKRR with unlabeled data on Million Song data

Acknowledgments

The work described in this paper is supported partially by the Research Grants Council of Hong Kong [Project No. CityU 11304114] and the National Natural Science Foundation of China (Grant Numbers 61502342, 11401462, 11461161006, 11471292). This paper was written when the last author visited Shanghai Jiaotong University (SJTU). The hospitality and sponsorships from SJTU and Ministry of Education are greatly appreciated. The authors would like to thank the referees for constructive suggestions and Dr. Yucheng Zhang for discussing with the numerical simulations.

Abstract

Markov chain Monte Carlo methods are often deemed too computationally intensive to be of any practical use for big data applications, and in particular for inference on datasets containing a large number n of individual data points, also known as tall datasets. In scenarios where data are assumed independent, various approaches to scale up the Metropolis-Hastings algorithm in a Bayesian inference context have been recently proposed in machine learning and computational statistics. These approaches can be grouped into two categories: divide-and-conquer approaches and, subsampling-based algorithms. The aims of this article are as follows. First, we present a comprehensive review of the existing literature, commenting on the underlying assumptions and theoretical guarantees of each method. Second, by leveraging our understanding of these limitations, we propose an original subsampling-based approach relying on a control variate method which samples under regularity conditions from a distribution provably close to the posterior distribution of interest, yet can require less than $\mathcal{O}(n)$ data point likelihood evaluations at each iteration for certain statistical models in favourable scenarios. Finally, we emphasize that we have only been able so far to propose subsampling-based methods which display good performance in scenarios where the Bernstein-von Mises approximation of the target posterior distribution is excellent. It remains an open challenge to develop such methods in scenarios where the Bernstein-von Mises approximation is poor.

1. Introduction

Performing inference on tall datasets, that is datasets containing a large number n of individual data points, is a major aspect of the big data challenge. Statistical models, and Bayesian methods in particular, commonly demand Markov chain Monte Carlo (MCMC) algorithms to make inference, yet running MCMC on such tall datasets is often far too computationally intensive to be of any practical use. Indeed, MCMC algorithms such as the Metropolis-Hastings (MH) algorithm require at each iteration to sweep over the

whole dataset. Frequentist or variational Bayes approaches are thus usually preferred to a fully Bayesian analysis in the tall data context on computational grounds. However, they might be difficult to put in practice or justify in scenarios where the likelihood function is complex; e.g. non-differentiable (Chernozhukov and Hong, 2003). Moreover, some applications require precise quantification of uncertainties and a full Bayesian approach might be preferable in those instances. This is the case for example for applications from experimental sciences, such as cosmology (Trotta, 2006) or genomics (Wright, 2014), were such big data problems abound. Consequently, much efforts have been devoted over recent years to develop scalable MCMC algorithms. These approaches can be broadly classified into two groups: divide-and-conquer approaches and subsampling-based algorithms. Divide-and-conquer approaches divide the initial dataset into batches, run MCMC on each batch separately, and then combine these results to obtain an approximation of the posterior: Subsampling approaches aim at reducing the number of individual data point likelihood evaluations necessary at each iteration of the MH algorithm.

After briefly reviewing the limitations of MCMC for tall data, introducing our notation and two running examples in Section 2, we first review the divide-and-conquer literature in Section 3. The rest of the paper is devoted to subsampling approaches. In Section 4, we discuss pseudo-marginal MH algorithms. These approaches are exact in the sense that they target the correct posterior distribution. In Section 5, we review other exact approaches, before relaxing exactness in Section 6. Throughout, we focus on the assumptions and guarantees of each method. We also illustrate key methods on two running examples. Finally, in Section 7, we improve over our so-called confidence sampler in (Bardenet et al., 2014), which samples from a controlled approximation of the target. We demonstrate these improvements yield significant reductions in computational complexity at each iteration in Section 8. In particular, our improved confidence sampler can break the $\mathcal{O}(n)$ barrier of number of individual data point likelihood evaluations per iteration in favourable cases. Its main limitation is the requirement for cheap-to-evaluate proxies for the log-likelihood, with a known error. We provide examples of such proxies relying on Taylor expansions.

All examples can be rerun or modified using the companion IPython notebook[1] to the paper.

2. Bayesian inference, MCMC, and tall data

In this section, we describe the inference problem of interest and the associated MH algorithm. We also detail the two running examples on which we benchmark key methods in Section 4, 5 and 6.

2.1 Bayesian inference

Consider a dataset

$$\mathcal{X} = \{x_1, ..., x_n\} \subset \mathbb{X} \subset \mathbb{R}^d, \tag{1}$$

and a parameter space Θ. We assume the data are conditionally independent with associated likelihood $\prod_{i=1}^n p(x_i|\theta)$ given a parameter value θ and we denote $\ell(\theta)$ the associated average log-likelihood

$$\ell(\theta) = \frac{1}{n}\sum_{i=1}^n \log p(x_i|\theta) = \frac{1}{n}\sum_{i=1}^n \ell_i(\theta). \tag{2}$$

We follow a Bayesian approach where one assigns a prior $p(\theta)$ to the unknown parameter, so that inference relies on the posterior distribution

$$\pi(\theta) = p(\theta|x) \propto \gamma(\theta) \triangleq p(\theta)e^{n\ell(\theta)}, \tag{3}$$

where γ denotes an unnormalized version of π. In most applications, π is intractable and we will focus here on Markov chain Monte Carlo methods (MCMC; Robert and Casella, 2004) and, in particular, on the Metropolis-Hastings (MH) algorithm to approximate it.

1. https://github.com/rbardenet/2017-JMLR-MCMCForTallData

2.2 The Metropolis-Hastings algorithm

A standard approach to sample approximately from $\pi(\theta)$ is to use MCMC algorithms. To illustrate the limitation of MCMC in the tall data context, we focus here on the MH algorithm (Robert and Casella, 2004, Chapter 7.3). The MH algorithm simulates a Markov chain $(\theta_k)_{k\geq 0}$ of invariant distribution π. Then, under weak assumptions, see e.g. (Douc et al., 2014, Theorem 7.32), the following central limit theorem holds for suitable test functions h

$$\sqrt{N_{\text{iter}}}\left[\frac{1}{N_{\text{iter}}}\sum_{k=0}^{N_{\text{iter}}} h(\theta_k) - \int h(\theta)\,\pi(\theta)d\theta\right] \to \mathcal{N}(0, \sigma^2_{\text{lim}}(h)), \tag{4}$$

where convergence is in distribution.

MH$\big(\gamma(\cdot),\, q(\cdot|\cdot),\, \theta_0,\, N_{\text{iter}}\big)$

Figure 1: Pseudocode of the MH algorithm targeting the distribution π. Note that π is only involved in ratios, so that one only needs to know an unnormalized version γ of π.

The pseudocode of MH targeting a generic distribution π is given in Figure 1. In the case of Bayesian inference with independent data (3), Step 5 is equivalent to setting

$$\log\alpha(\theta,\theta') \;=\; \log\left[\frac{p(\theta')}{p(\theta)}\frac{q(\theta|\theta')}{q(\theta'|\theta)}\right] + n\left[\ell(\theta') - \ell(\theta)\right]. \tag{5}$$

When the dataset is tall ($n \gg 1$), evaluating the log likelihood ratio in (5) is too costly an operation and rules out the applicability of such a method. As we shall see, two possible options are to either divide the dataset into tractable batches, or approximate the acceptance ratio in (5) using only part of the dataset.

2.3 Running examples

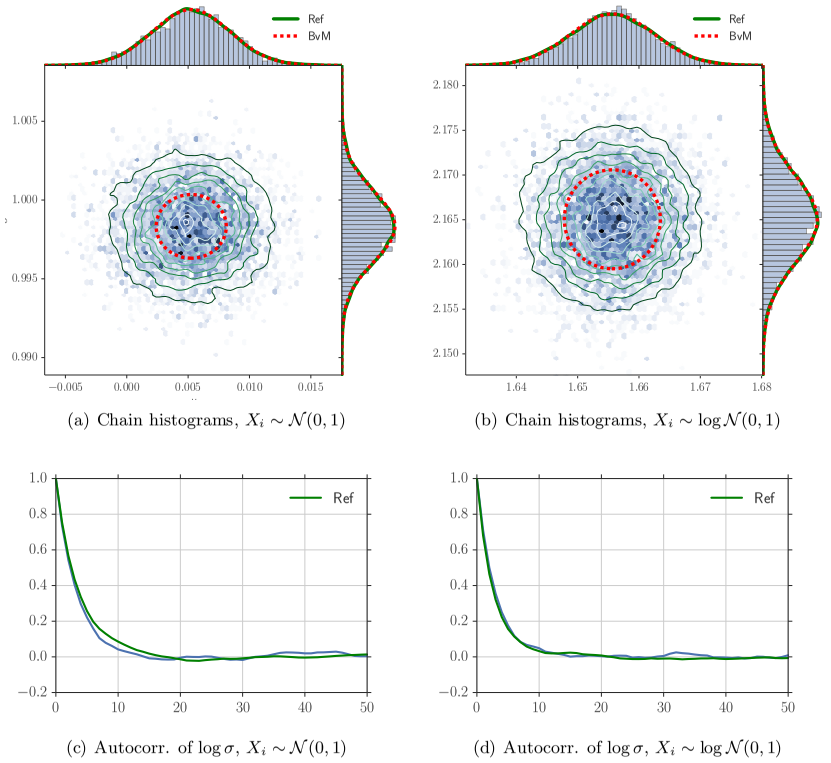
We will evaluate some of the described approaches on two illustrative simple running examples. We fit a one-dimensional normal distribution $p(\cdot|\mu,\sigma) = \mathcal{N}(\cdot|\mu,\sigma^2)$ to 10^5 i.i.d. points drawn according to $X_i \sim \mathcal{N}(0,1)$ and lognormal observations $X_i \sim \log\mathcal{N}(0,1)$, respectively. The latter example illustrates a misspecification of the model. We assign a flat prior $p(\mu, \log\sigma) \propto 1$. For all algorithms, we start the chain at the maximum a posteriori (MAP) estimate. The MH proposal is an isotropic Gaussian random walk, whose stepsize is first set proportional to $1/\sqrt{n}$ and then adapted during the first 1 000 iterations so as to reach 50% acceptance. When applicable, we also display the number of likelihood evaluations per iteration, and compare it to the n evaluations required at each iteration by the MH algorithm.

In Figure 2, we illustrate the results of 10 000 iterations of vanilla MH on each of the two datasets. MH does well, as the posterior coincides with that of a longer reference run of 50 000 iterations in each case, and the autocorrelations show a fast exponential decrease. The Bernstein-von Mises approximation (van der Vaart, 2000, Chapter 10.2), a Gaussian centered at the true value, with covariance minus the scaled inverse Fisher information, is a very good approximation to the posterior in both cases. We are thus in simple cases of heavy concentration of the posterior, where subsampling should help a lot if it is to be of any help in tackling tall data problems.

3. Divide-and-conquer approaches

A natural way to tackle tall data problems is to divide the data into batches, run MH on each batch separately, and then combine the results.

3.1 Representing the posterior as a combination of batch posteriors



Assume data $\mathcal{X}$ are divided in B batches $\mathbf{x}_1, \ldots, \mathbf{x}_B$. Relying on the equality

$$p(\theta|\mathcal{X}) \propto \prod_{i=1}^{B} p(\theta)^{1/B} p(\mathbf{x}_i|\theta), \tag{6}$$

Huang and Gelman (2005) propose to combine the batch posterior approximations using Gaussian approximations or importance sampling. Scott et al. (2013) propose to average samples across batches, noting this is exact under Gaussian assumptions. Neiswanger et al. (2014) propose to run an MCMC chain on each batch $\mathbf{x}_i$ targeting an artificial batch posterior

$$\pi_i(\theta) \propto p(\theta)^{1/B} p(\mathbf{x}_i|\theta),$$

fit a smooth approximation to each batch posterior, and multiply them. These methods are however theoretically justified only when batch posteriors are Gaussian, or when the size *of*

(a) Chain histograms, $X_i \sim \mathcal{N}(0,1)$

(b) Chain histograms, $X_i \sim \log\mathcal{N}(0,1)$

(c) Autocorr. of $\log\sigma$, $X_i \sim \mathcal{N}(0,1)$

(d) Autocorr. of $\log\sigma$, $X_i \sim \log\mathcal{N}(0,1)$

Figure 2: Results of 10 000 iterations of vanilla MH fitting a Gaussian model to one-dimensional Gaussian and lognormal synthetic data, on the left and right panel, respectively. Figures 2(a) and 2(b) show the chain histograms, joint and marginals; the x-axis corresponds to the mean of the fitted Gaussian, the y-axis to the standard deviation. We have superimposed a kernel density estimator of a long MH chain for reference in green and the Bernstein-von Mises Gaussian approximation in red. Figures 2(c) and 2(d) show the marginal autocorrelation of $\log\sigma$ in blue. The green curves are baselines that correspond to the long MH reference run depicted in green in the top panel; although the green autocorrelation functions are of limited interest when comparing them to vanilla MH, we use them as reference in all similar later figures.

each batch goes to infinity, to guarantee that the used smooth approximation of each batch posterior is accurate.

There are few results available on how the properties of combined estimators scale with the number of batches B. Neiswanger et al. (2014) fit a kernel density estimator to the samples of each batchwise chain, and multiply the resulting kernel density estimators. A sample from this mixture approximation to π is then obtained through an additional MCMC step. Under simplifying assumptions (all MCMC chains are assumed being independent draws from their targets, for example), a bound on the MSE of the final estimator is obtained. However, this bound explodes as the kernel bandwidth goes to zero, and more importantly, it is exponential in the number of batches B. In a tall data context, the number of batches is expected to grow with n to ensure that the size of each batch is less than $\mathcal{O}(n)$. Thus, the proposed bound is currently not informative for tall data.

As pointed out by Wang and Dunson (2013), if the supports of the π_i are almost disjoint, then the product of their approximations will be a poor approximation to π. To improve the overlap between the approximations of the π_i's, Wang and Dunson (2013) propose to replace the posterior in (6) by the product of the Weierstrass transforms of each batch posterior. When the approximation of π_i is an empirical measure, its Weierstrass transform corresponds to a kernel density estimator. The product of the Weierstrass transforms can be interpreted as the marginal distribution of an extended distribution on Θ^{B+1}, where the first B copies of θ are associated to the B batches, and the remaining copy is conditionally Gaussian around a weighted mean of the first B copies. Unfortunately, sampling from the posterior of this artificial model is difficult when one only has access to approximate samples of each π_i.

Although it is not strictly speaking a Monte Carlo method, we note that Xu et al. (2014) and Gelman et al. (2014) propose an expectation-propagation-like algorithm that similarly tackles the issue of disjoint approximate batch posterior supports. Each batch of data points is represented by its individual likelihood times a *cavity* distribution. The cavity distribution is itself the product of the prior and a number of terms that represent the contributions of other batches to the likelihood. The algorithm iterates between 1) simulating from each batchwise likelihood times a batch-specific cavity distribution, and 2) fitting each batch-specific cavity component. Again, while these approaches are computationally feasible and appear to perform well experimentally, it is difficult to assert the characteristics of the proposed approximation of the posterior and there is no convergence guarantee available for this iterative algorithm.

3.2 Replacing the posterior by a geometric combination of batch posteriors

Another avenue of research consists in avoiding multiplying the batch posteriors by replacing the target by a different combination of the latter.

By introducing a suitable metric on the space of probability measures such as the Wasserstein metric, it is for example possible to define the barycenter or the median of a set of probability measures. Minsker et al. (2014) propose to output the median of the batch posteriors, while Srivastava et al. (2015) use the Wasserstein barycenter, which can be computed efficiently in practice using the techniques developed by Cuturi and Doucet (2014). While this idea has some appeal, the statistical meaning of these median or mean measures

is unclear, and the robustness of the median estimate advocated in (Minsker et al., 2014) may also be a drawback, as in some circumstances valuable information contained in some batches may be lost.

To conclude, divide-and-conquer techniques appear as a natural approach to handle tall data. However, the crux is how to efficiently combine the batch posterior approximations. The main issues are that the batch posterior approximations potentially have disjoint supports, that the multiplicative structure of the posterior (3) leads to poor scaling with the number of batches, that theoretical guarantees are often asymptotic in the batch size, and that cheap-to-sample combinations of batch posteriors are difficult to interpret.

4. Exact subsampling approaches: Pseudo-marginal MH

Pseudo-marginal MH (Lin et al., 2000; Beaumont, 2003; Andrieu and Roberts, 2009) is a variant of MH, which relies on unbiased estimators of an unnormalized version of the target. Pseudo-marginal MH is useful to help understand several potential approaches to scale up MCMC. We start by describing pseudo-marginal MH in Section 4.1. Then, we present two pseudo-marginal approaches to tall data in Section 4.2 and Section 4.3.

4.1 Pseudo-marginal Metropolis-Hastings

Assume that instead of being able to evaluate $\gamma(\theta)$, we have access to an unbiased, almost-surely *non-negative* estimator $\hat{\gamma}(\theta)$ of the unnormalized target $\gamma(\theta)$. Pseudo-marginal MH substitutes a realization of $\hat{\gamma}(\theta')$ to $\gamma(\theta')$ in Step 5. Similarly, it replaces $\gamma(\theta)$ in Step 5 by the realization of $\hat{\gamma}(\theta)$ that was computed when the parameter value θ was accepted. Pseudo-marginal MH is of considerable practical importance, with applications such as particle marginal MH (Andrieu et al., 2010) and MCMC versions of the approximate Bayesian computation paradigm (Marin et al., 2012). It is thus worth investigating its use in the context of tall data problems.

The possibility to use an unbiased estimator of γ comes at a price: first, the asymptotic variance σ^2_{lim} in (4) of an MCMC estimator based on a pseudo-marginal chain will always be larger than that of an estimator based on the underlying "marginal" MH (Andrieu and Vihola, 2015). Second, the qualitative properties of the underlying MH may not be preserved, meaning that the rate of convergence to the invariant distribution may go from geometric to subgeometric, for instance; see Andrieu and Roberts (2009) and Andrieu and Vihola (2015) for a detailed discussion. In practice, if the variance of $\hat{\gamma}(\vartheta)$ is large for some value $\vartheta \in \Theta$, then an MH move to ϑ might be accepted while $\hat{\gamma}(\vartheta)$ largely overestimates $\gamma(\vartheta)$. In that case, it is difficult for the chain to leave ϑ, and pseudo-marginal MH chains thus tend to get stuck if the variance of the involved estimators is not controlled. When some tunable parameter allows to control this variance, Doucet et al. (2015) show that, in order to minimize the variance of MCMC estimates for a fixed computational complexity, the variance of the log-likelihood estimator should be kept around 1.0 when the ideal MH having access to the exact likelihood generates quasi-i.i.d samples from π; or set to around 3.0 when it exhibits very large integrated autocorrelation times. In practice, the integrated autocorrelation times of averages under the ideal MH are unknown as this algorithm cannot be implemented. In this common scenario, Doucet et al. (2015) recommend keeping the variance around 1.5 as this is a value which ensures a small penalty in performance even in

scenarios where 1.0 or 3.0 are actually optimal. They also show that the penalty incurred for having a variance too small (i.e. inferior to 0.2) or too large (i.e. superior to 10) is very large. When mentioning pseudo-marginal MH algorithms, we will thus comment on the variance of the logarithm of the involved estimators $\hat{\gamma}(\theta)$, or, if not available, of their relative variance.

4.2 Unbiased estimation of the likelihood using unbiased estimates of the log-likelihood

As described in Section 4.1, pseudo-marginal MH requires an almost-surely nonnegative unbiased estimator $\hat{\gamma}(\theta)$ of the unnormalized posterior at θ, for any θ in Θ. It is easy to check that, by sampling $x_1^*, \ldots, x_t^*$ from the dataset $\mathcal{X}$ with or without replacement, we obtain the following unbiased estimator of the log-likelihood $n\ell(\theta)$

$$n\hat{\ell}(\theta) = \frac{n}{t}\sum_{i=1}^{t} \log p(x_i^*|\theta). \tag{7}$$

We denote by $\hat{\ell}(\theta)$ the subsampling estimate of the average log-likelihood and denote by $\sigma_t(\theta)^2$ its variance. Obviously, exponentiating (7) does not provide an unbiased estimate of the likelihood $e^{n\ell(\theta)}$. However, an interesting question is whether one can design a procedure which outputs an unbiased, almost-surely nonnegative estimate of $e^{n\ell(\theta)}$ using unbiased estimates of $n\ell(\theta)$ such as $n\hat{\ell}(\theta)$. Without making any further assumption about $n\hat{\ell}(\theta)$, it was recently shown by Jacob and Thiery (2015) that it is not possible. However, this can be done if one further assumes, for instance, that there exists $a(\theta)$ such that $\ell_i(\theta) > a(\theta)$ for all i, see (Jacob and Thiery, 2015, Section 3.1) who rely on a technique by Rhee and Glynn (2015) generalizing (Bhanot and Kennedy, 1985). Unfortunately, as we shall see, the resulting estimator $\hat{\gamma}(\theta)$ typically has a very large relative variance, resulting in very poor performance of the associated pseudo-marginal chain.

We apply (Rhee and Glynn, 2015, Theorem 1) to build an unbiased non-negative estimator of $\gamma(\theta)/p(\theta)$, which is equivalent to defining $\hat{\gamma}(\theta)$. For $j \geq 1$, let

$$D_j^* = \frac{n}{t}\sum_{i=1}^{t} \log p(x_{i,j}^*|\theta) - na(\theta), \tag{8}$$

be an unbiased estimator of $n\left(\ell(\theta) - a(\theta)\right)$, where the $x_{i,j}^*$'s are drawn with replacement from $\mathcal{X}$ for each i, and are further independent across j. In (Jacob and Thiery, 2015, Section 3.1), N is an integer-valued random variable whose tails do not decrease too fast, in the sense that $\mathbb{P}(N \geq k) \geq C(1+\epsilon)^{-k}$. To ease computations, we take N to be geometric with parameter $\epsilon/(1+\epsilon)$. This corresponds to the lightest tails allowed by (Jacob and Thiery, 2015, Section 3.1), since $\mathbb{P}(N \geq k) = (1+\epsilon)^{-k}$. Finally, let

$$Y \triangleq e^{na(\theta)}\left[1 + \sum_{k=1}^{N} \frac{1}{\mathbb{P}(N \geq k)}\frac{1}{k!}\prod_{j=1}^{k} D_j^*\right]. \tag{9}$$

By (Rhee and Glynn, 2015, Theorem 1), Y is a non-negative unbiased estimator of the likelihood $e^{n\ell(\theta)}$. As mentioned in Section 4.1, it is crucial, if we want to plug $\hat{\gamma}(\theta) = Y \times p(\theta)$ in a pseudo-marginal algorithm, to control the variance of its logarithm. The variance of $\log Y$ is difficult to compute, so we use here the relative variance of Y as a proxy.

Proposition 1 *Let $\theta \in \Theta$ and Y be the almost surely non-negative estimator of $e^{n\ell(\theta)}$ defined in* (9)*. Then its relative variance satisfies*

$$\frac{\mathrm{Var}Y}{e^{2n\ell(\theta)}} \geq \frac{e^{-2n(\ell(\theta)-a(\theta))+2n\sqrt{(1+\epsilon)[\sigma_t(\theta)^2+(\ell(\theta)-a(\theta))^2]}}}{n\sqrt{(1+\epsilon)[\sigma_t(\theta)^2+(\ell(\theta)-a(\theta))^2]}} + \mathcal{O}(1). \tag{10}$$

The proof of Proposition 1 can be found in Appendix A. It follows from (10) that in order for the relative variance of Y not to increase exponentially with n, it is necessary that $n\sigma_t(\theta)$ is of order 1. But $\sigma_t(\theta)$ is of order $t^{-1/2}$, so that the batchsize t would have to be of order n^2, which is impractical. It is also necessary that $\sqrt{1+\epsilon}$ is of order $1+n^{-1}$ to control the term in $(\ell(\theta)-a(\theta))$. This means that ϵ should be taken of order n^{-1}, but then the mean $(1+\epsilon)\epsilon^{-1}$ of the geometric variable N will be of order n. This entails that the number of terms in the randomly truncated series (9) should be of order n, which defeats the purpose of using this estimator.

Hence for the reasons outlined in Section 4.1, we expect the pseudo-marginal MH relying on Y to be highly inefficient. Indeed, we have not been able to obtain reasonably mixing chains even on our Gaussian running example. We have experimented with various choices of ϵ, and with various values of t, but none yielded satisfactory results. We conclude that this approach is not a viable solution to MH for tall data.

We note that Strathmann et al. (2015) have recently proposed a different way to exploit the methodology of Rhee and Glynn (2015) in the context of tall data. However, their methodology does not provide unbiased estimates of the posterior expectations of interest. It only provides unbiased estimates of some biased MCMC estimates of these expectations, these biased MCMC estimates corresponding to running an MCMC kernel on the whole dataset for a finite number of iterations. Strathmann et al. (2015) suggest that it might be possible to combine their algorithm with the recent scheme of Glynn and Rhee (2014) to obtain unbiased estimates of the posterior expectations. It is unclear whether this could be achieved under realistic assumptions on the MCMC kernel.

4.3 Building $\hat{\gamma}(\theta)$ with auxiliary variables

In (MacLaurin and Adams, 2014), the authors propose an alternative MCMC to sample from π which, similarly to the method described previously, only requires evaluating the likelihood of a subset of the data at each iteration. Assume a bound $\ell_i(\theta) \geq b_i(\theta)$ is available for each i and θ. For simplicity, we further assume that $b_i(\theta) = b(\theta, x_i)$ only depends on i through x_i. This is the case in the experiments of (MacLaurin and Adams, 2014), as well as ours. Note also that in Section 4.2, we used a bound that was uniform in the data index i; we could have used similarly a non-uniform bound, but this would have made the derivation of Proposition 1 unnecessarily heavy.

As noted in (MacLaurin and Adams, 2014), we can then define the following extended target $\tilde{\pi}$ distribution on $\Theta \times \{0,1\}^n$

$$\begin{aligned}\tilde{\pi}(\theta, z) &\propto p(\theta) \prod_{i=1}^{n} \left[\exp\left(\ell_i(\theta)\right) - \exp\left(b_i(\theta)\right)\right]^{z_i} \exp\left(b_i(\theta)\right)^{1-z_i} \\ &= p(\theta) \prod_{i=1}^{n} \exp\left(b_i(\theta)\right) \prod_{i=1}^{n} \left[\exp\left(\ell_i(\theta) - b_i(\theta)\right) - 1\right]^{z_i}. \end{aligned} \tag{11}$$

This distribution satisfies two important features: it admits $\pi(\theta)$ as a marginal distribution, and its pointwise evaluation only requires to evaluate $\ell_i(\theta)$ for those i's for which $z_i = 1$. Note that evaluating $\tilde{\pi}(\theta, z)$ however requires to evaluate $\prod_{i=1}^{n} \exp(b_i(\theta))$, and the bounds $b_i(\theta)$ thus must be chosen so that this computation is cheap. This is the case for the lower bound of the logistic regression log-likelihood model discussed in (MacLaurin and Adams, 2014), which is a quadratic form in $t_i \theta^T x_i$, where t_i is the ± 1 label of datum x_i. The idea of replacing the evaluation of the target by a Bernoulli draw and the evaluation of a lower bound has been exploited previously in the physics literature; see e.g. (Mak, 2005).

Any MCMC sampler could be used to sample from $\tilde{\pi}$. MacLaurin and Adams (2014) propose an MH-within-Gibbs sampler that leverages the known conditional $\tilde{\pi}(z|\theta)$. The expected cost of one conditional MH iteration on θ at equilibrium, that is the average number of indices i such that $z_i = 1$, is $\mathcal{O}(n)$, and the constant is related to the expected relative tightness of the bound, see (MacLaurin and Adams, 2014, Section 3.1). The number of likelihood evaluations for an update of z conditional on θ is explicitly controlled in (MacLaurin and Adams, 2014) by either specifying a maximum number of attempted flips, or implicitly specifying the fraction of flips to 1.

The authors of MacLaurin and Adams (2014) remarked that their methodology is related to pseudo-marginal techniques but did not elaborate. We show here how it is indeed possible to exploit the extended target distribution $\tilde{\pi}$ in (11) to obtain an unbiased estimate of an unnormalized version of π. More precisely, we have

$$p(x_i|\theta) = \sum_{z_i \in \{0,1\}} p\left(x_i, z_i|\theta\right)$$

where $p\left(z_i|\theta, x_i\right) = \{1 - \exp(b_i(\theta) - \ell_i(\theta))\}^{z_i} \exp(b_i(\theta) - \ell_i(\theta))^{1-z_i}$. Hence, the marginal distribution of z_i under this extended model is given by

$$\begin{aligned} p(z_i = 1|\theta) &= \int p(z_i = 1, x_i|\theta) dx_i \\ &= \int \left[\exp(\ell_i(\theta)) - \exp(b_i(\theta))\right] dx_i \\ &= 1 - I_\theta, \end{aligned} \tag{12}$$

where $I_\theta \triangleq \int \exp(b(\theta, x)) dx$. Using Bayes' theorem, we obtain accordingly

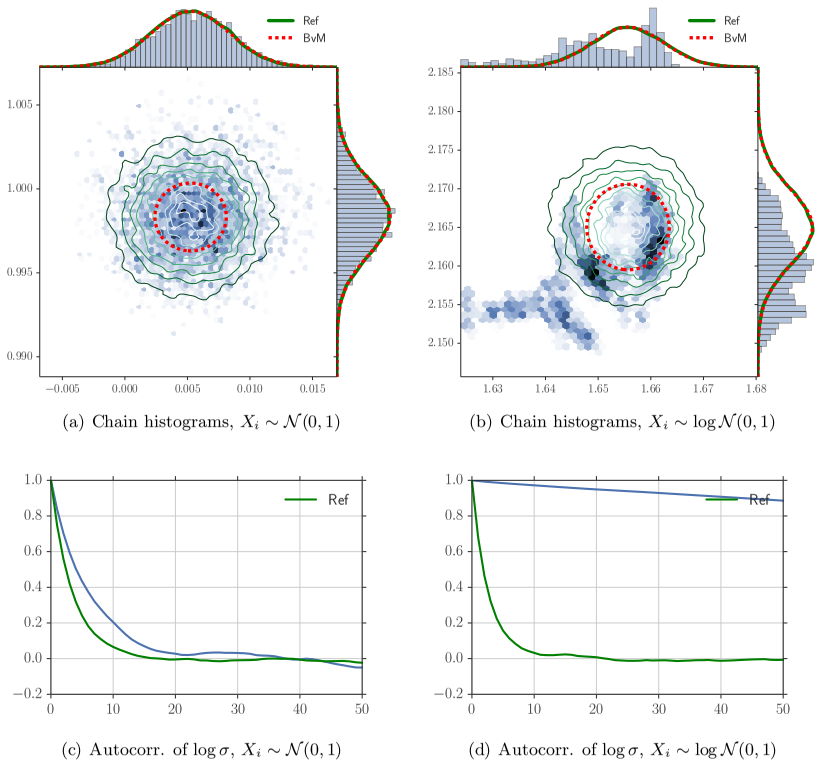
$$p(x_i|\theta, z_i = 1) = \frac{\exp(\ell_i(\theta)) - \exp(b_i(\theta))}{1 - I_\theta},\ p(x_i|\theta, z_i = 0) = \frac{\exp(b_i(\theta))}{I_\theta}.$$

An obvious unbiased estimator of the unnormalized posterior is thus given by

$$\hat{\gamma}(\theta) = p(\theta) \prod_{i=1}^{n} p(x_i|\theta, z_i) \tag{13}$$

where each z_i is drawn independently given θ from (12). Note that in the case of logistic regression, if $b_i(\theta)$ is chosen to be the quadratic lower bound given in (MacLaurin and Adams, 2014), its integral I_θ is a Gaussian integral and can thus be computed. Finally, similarly to the Firefly algorithm of MacLaurin and Adams (2014), the number of evaluations of the likelihood per iteration is nI_θ, loosely speaking.

Although the pseudo-marginal variant of Firefly we propose has the disadvantage of requiring the integrals I_θ to be tractable, it comes with two advantages. First, the sampling of z does not require to evaluate the likelihood at all. If computing all bounds does not become a bottleneck, this avoids the need to explicitly state a resampling fraction at the risk of augmenting the variance of the likelihood estimator. Second, the properties of this variant are easier to understand, as it is a 'standard' pseudo-marginal MH and hence the results from Section 4.1 apply. In particular, although it has the correct target distribution, the asymptotic variance of ergodic averages is inflated compared to the ideal algorithm.



As explained in Section 4.1, we consider the variance of the log likelihood estimator.

Proposition 2 *Let $\theta \in \Theta$. With the notations introduced in Section 4.3,*

$$\mathrm{Var}_z \left[\sum_{i=1}^{n} \log p(x_i|\theta, z_i)\right] = I_\theta(1 - I_\theta) \sum_{i=1}^{n} \log^2 \left[\frac{I_\theta}{1 - I_\theta} \left(e^{\ell_i(\theta) - b_i(\theta)} - 1\right)\right] \tag{14}$$

The proof of Proposition 2 can be found in Appendix B. Proposition 2 can be interpreted as follows: the variance is related to how tight the bound is. In general, obtaining a variance of order 1 will only be possible if *most* bounds $b_i(\theta)$ are very tight, and the bigger n, the tighter the bounds have to be. These conditions will typically not be met when a fixed fraction of "outlier" x_i's correspond to untight bounds.

We give the results of the original Firefly MH on our running Gaussian and log normal examples in Figure 3. We bound each $\ell_i(\theta)$ using a 2nd order Taylor expansion at the MLE and the Taylor-Lagrange inequality, see Section 7.2.1 for further details. This bound is very tight in both cases, so that we are in the favourable case where only a few components of z are 1 at each iteration, and the number of likelihood evaluations per full joint iteration is thus roughly the fraction of points for which z_i has been resampled. We chose the fraction of resampled points to be 10% here, and initialized z to have 10% of ones. Trying smaller fractions led to very slowly mixing chains even for the Gaussian example. Estimating the number of likelihood evaluations per full joint iteration as the sum of the number of resampled z_i's and the number of "bright" points, we obtained in both the Gaussian and lognormal case an almost constant number of likelihood evaluations close to 10%, so that only a few points are bright. This can be explained by the tightness of the Taylor bound, which leads Firefly MH to almost exclusively replace the evaluation of the likelihood by that of the Taylor bound. Finally, unlike the other algorithms we applied, we observed that a bad choice of the initial value of z can easily take θ out of the posterior mode. To be fair, we thus discarded the first 1 000 iterations as a burn-in before plotting.

(a) Chain histograms, $X_i \sim \mathcal{N}(0,1)$

(b) Chain histograms, $X_i \sim \log\mathcal{N}(0,1)$

(c) Autocorr. of $\log\sigma$, $X_i \sim \mathcal{N}(0,1)$

(d) Autocorr. of $\log\sigma$, $X_i \sim \log\mathcal{N}(0,1)$

Figure 3: Results of 10 000 iterations of Firefly MH (MacLaurin and Adams, 2014) on our Gaussian and lognormal running examples. See Section 4.3 and the caption of Figure 2 for details.

As expected, the algorithm behaves erratically in the lognormal case, as failure to attempt a flip of each z_i draws the μ-component of the chain towards the few large values of $(x_i - \mu)^2$ which are bright. Since the bright points are rarely updated, the chain mixes very slowly.

5. Other exact approaches

Other exact approaches have been proposed, which do not rely on pseudo-marginal MH.

5.1 Forgetting about acceptance probability: stochastic approximation approaches

Welling and Teh (2011) proposed an algorithm based on stochastic gradient Langevin dynamics (SGLD). This is an iterative algorithm which at iteration $k+1$ uses the following update rule

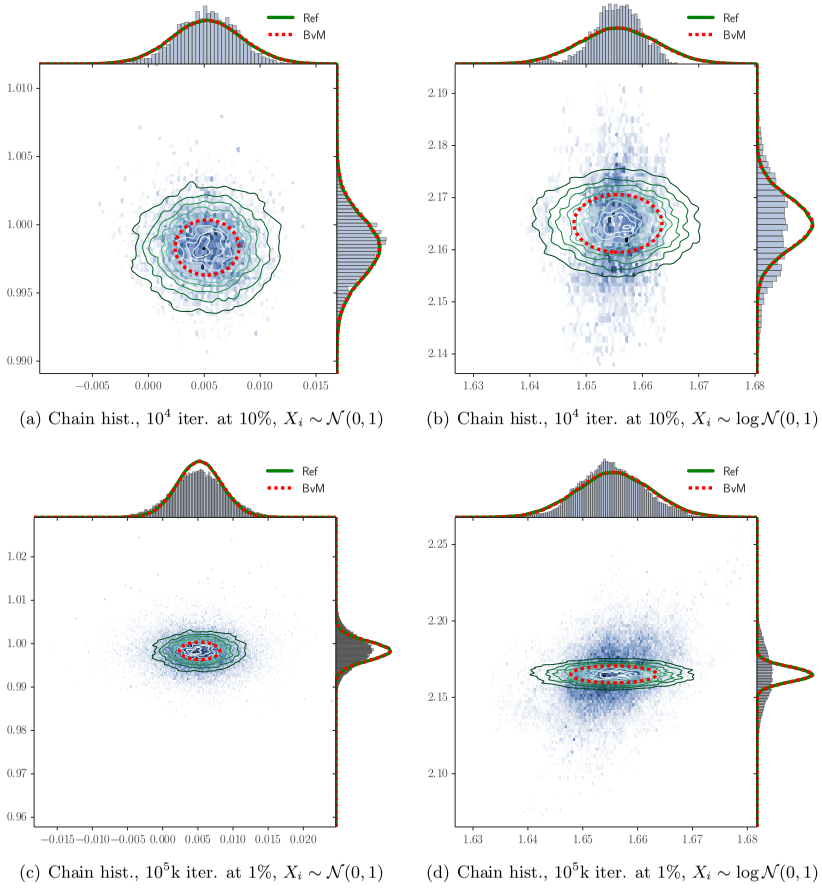
$$\theta_{k+1} = \theta_k + \frac{\epsilon_{k+1}}{2}\left[\nabla \log p(\theta) + \frac{n}{t}\sum_{i=1}^{t} \nabla \log p(x^*_{i,k}|\theta)\right] + \sqrt{\epsilon_{k+1}}\eta_{k+1}, \tag{15}$$

(ϵ_k) is a sequence of time steps, (η_k) are independent $\mathcal{N}(0, I_d)$ vectors and

$$\frac{n}{t}\sum_{i=1}^{t} \nabla \log p(x^*_{i,k}|\theta)$$

is an unbiased estimate of the score computed at each iteration using a random subsample $\left\{x^*_{i,k}\right\}$ of the observations. This approach is reminiscent of the Metropolis-adjusted Langevin algorithm (MALA; Robert and Casella 2004, Section 7.8.5), where the proposal given by

$$\theta' = \theta + \frac{\epsilon}{2}\left[\nabla \log p(\theta) + \sum_{i=1}^{n} \nabla \log p(x_i|\theta)\right] + \sqrt{\epsilon}\eta,$$



is used in an MH acceptance step, where $\epsilon \sim \mathcal{N}(0, I_d)$. The point of Welling and Teh (2011) is that if one suppresses the MH acceptance step, computes an unbiased estimate of the score but introduces a sequence of stepsizes (ϵ_k) that decreases to zero at the right rate, then

$$\left(\sum_{k=0}^{N_{\text{iter}}} \epsilon_k\right)^{-1} \sum_{k=0}^{N_{\text{iter}}} \epsilon_k \delta_{\theta_k}$$

is an approximation to π. The algorithm has been analyzed recently in (Teh et al., 2016), where it has been established that it provides indeed a consistent estimate of the target. Additionally, a central limit theorem holds with convergence rate $N_{\text{iter}}^{-1/3}$, which is slower than the traditional Monte Carlo rate $N_{\text{iter}}^{-1/2}$. It is yet unclear how SGLD compares to other subsampling schemes in theory: it may require a smaller fraction of the dataset per iteration, but more iterations are needed to reach the same accuracy.

In practice, we show the results of SGLD on our two running examples in Figure 5.1. The stepsize ϵ_k is chosen proportional to $k^{-1/3}$, following the recommendations of Teh et al. (2016). We show the results of two choices for the subsample size t: 10% and 1% of the data, with respectively 10 000 and 100 000 iterations, so that both runs amount to the same 10% fraction of the budget of the vanilla MH in Figure 2. Both runs are still far from convergence on the lognormal example: subsampling draws the chain away from the support of the posterior, and one has to wait for smaller stepsizes to avoid overconfident moves. But then, the variance of the final estimate gets bigger. Constant stepsizes lead to comparable results (not shown).

Finally, we note that subsampling for Hamiltonian Monte Carlo (HMC; Duane et al., 1987) has also been recently considered. Chen et al. (2014) propose a modification of

(a) Chain hist., 10^4 iter. at 10%, $X_i \sim \mathcal{N}(0,1)$

(b) Chain hist., 10^4 iter. at 10%, $X_i \sim \log\mathcal{N}(0,1)$

(c) Chain hist., 10^5k iter. at 1%, $X_i \sim \mathcal{N}(0,1)$

(d) Chain hist., 10^5k iter. at 1%, $X_i \sim \log\mathcal{N}(0,1)$

Figure 4: Results of SGLD (Welling and Teh, 2011) on our Gaussian and lognormal running examples. See Section 5.1 and the caption of Figure 2 for details.

HMC that is inspired by the SGLD with decreasing stepsize of Welling and Teh (2011), while Betancourt (2015) explores why naive approaches suffer from unacceptable biases. The algorithm of Chen et al. (2014) is however a heuristic, which further relies on the subsampling noise being Gaussian. As demonstrated in (Bardenet et al., 2014) and in Section 6.2, relying on a Gaussian noise assumption can yield arbitrarily poor performance when this assumption is violated.

5.2 Delayed acceptance

Banterle et al. (2015) remarked that if we decompose the acceptance ratio in a product of positive functions

$$\alpha(\theta,\theta') = \prod_{i=1}^{B} \rho_i(\theta,\theta')$$

then the MH-like algorithm that accepts the move from θ to θ' with probability

$$\prod_{i=1}^{B} \min\left[\rho_i(\theta,\theta'),1\right]$$

still admits π as invariant distribution. In practice, in the case of tall data, we can divide the dataset into B batches and use for example

$$\rho_i\left(\theta,\theta'\right) = \frac{p(\theta')^{1/B} p(\mathbf{x}_i|\theta') q(\theta|\theta')}{p(\theta)^{1/B} p(\mathbf{x}_i|\theta) q(\theta'|\theta)}.$$

This allows us to reject candidate θ' without having to compute the full likelihoods and the calculations of $\rho_i(\theta,\theta')$ can be done in parallel. However, as remarked by Banterle et al. (2015), the resulting Markov chain has a larger asymptotic variance σ^2_{lim} in (4) than the original MH, and it does not necessarily inherit the ergodicity of the original MH. Furthermore, by construction, every accepted point has to be evaluated on the whole dataset, and the average proportion of data points used is thus lower bounded by the acceptance rate of the algorithm, which in practice is often around 25%. Overall, it is an easy-to-implement feature that does not add any bias, but its benefits are inherently limited, and speed of convergence might be affected.

5.3 Piecewise deterministic Markov chain Monte Carlo methods

The Bouncy Particle Sampler (BPS) is an MCMC algorithm where the target distribution of interest is explored using a continuous-time piecewise-deterministic process. In other words, the state of the Markov process moves along straight lines around the space and, when facing a high energy barrier, it is not rejected but its path is modified by bouncing against this barrier. The BPS was originally proposed in the physics literature by Peters and de With (2012). Several generalizations of this method have then been proposed by Bouchard-Côté et al. (2015). In the context of tall data, in particular, Bouchard-Côté et al. (2015) show that one can use subsampling and preserve the correct target distribution. This has also been noticed by Bierkens et al. (2016), who propose an algorithm related to BPS

but using an alternative bouncing mechanism. However, these approaches also suffer from severe limitations.

First, for subsampling to preserve the invariant distribution, the statistical model under consideration needs to satisfy strong regularity conditions, which have only been established for logistic regression; see (Bouchard-Côté et al., 2015) and (Bierkens et al., 2016). These conditions can be relaxed, but at the price of introducing a bias that is difficult to control (Pakman et al., 2016). Second, it is shown in (Bouchard-Côté et al., 2015, Section 4.6) that, although these subsampling BPS algorithms might have a cost of $\mathcal{O}(1)$ per iteration instead of $\mathcal{O}(n)$ for standard MH, the asymptotic variance of the corresponding averages is empirically of order $\mathcal{O}(n)$ instead of $\mathcal{O}(1)$ for a correctly scaled random walk MH. Hence the gains brought by these approaches over a correctly scaled random walk MH are debatable.

6. Approximate subsampling approaches

In this Section, we consider again subsampling approaches where, at each MH iteration, a subset of data points is used to approximate the acceptance ratio (5). As mentioned in Section 4.2, it is very simple to obtain an unbiased estimator of the log-likelihood $n\ell(\theta)$ based on random samples $x_1^*, \ldots, x_t^*$ from the dataset $\mathcal{X}$; see (7). Similarly, one can also easily obtain an unbiased estimator of the average log likelihood ratio $[\ell(\theta') - \ell(\theta)]$

$$\Lambda_t^*(\theta, \theta') \triangleq \frac{1}{t} \sum_{i=1}^{t} \log \frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}. \tag{16}$$

Note that unlike the exact approaches of Sections 4 and 5, the methods reviewed in Section 6 do not attempt to sample exactly from π, but just from an approximation to π.

6.1 Naive subsampling

The first approach one could try is to only use a random fixed proportion of data points to estimate π at any newly drawn θ. We highlight that this leads to a nontrivial mixture target that is hard to interpret, where all subsampled posteriors appear, suitably rescaled. Assume that at each new θ drawn in an MH run, we draw n independent Bernoulli variables and let

$$\hat{\ell}(\theta) = \frac{1}{n} \sum_{i=1}^{n} \frac{z_i}{\lambda} \ell_i(\theta) \tag{17}$$

be an unbiased estimator of the average log likelihood $\ell(\theta)$, where $z_i \sim B(1, \lambda)$ i.i.d. Now one could think of plugging estimates $\hat{\gamma}(\theta) = p(\theta) e^{n\hat{\ell}(\theta)}$ in Steps 2 and 3 of MH in Figure 1. However, as $\hat{\gamma}(\theta)$ is not an unbiased estimator of $\gamma(\theta)$, this algorithm samples from a target distribution which is proportional to $p(\theta)\mathbb{E}e^{n\hat{\ell}(\theta)} \neq \gamma(\theta)$, where the expectation is w.r.t the distributions of the Bernoulli random variables $\{z_i\}$. Now

$$\begin{aligned} \mathbb{E}e^{n\hat{\ell}(\theta)} &= \prod_{i=1}^{n} \left[\lambda e^{\ell_i(\theta)/\lambda} + (1-\lambda)\right] \\ &= \sum_{r=0}^{n} \sum_{\#I_r = r} \lambda^r (1-\lambda)^{n-r} p(x_{I_r}|\theta)^{1/\lambda}, \end{aligned}$$

where I_r denotes a set of r distinct indices in $\{1, \ldots, n\}$, $x_{I_r} = \{x_i; i \in I_r\}$, and with the convention $p(x_\emptyset|\theta) = 1$. Each subsampled likelihood contributes to the target, exponentiated to the power $1/\lambda$, resulting in a nontrivial mixture of rescaled data likelihood terms. To further simplify, assume $p(x_{I_r}|\theta) \approx p_r(\theta)$ for each set of indices I_r, that is, the variance of the likelihood under subsampling is small, then

$$\mathbb{E}e^{n\hat{\ell}(\theta)} \approx \sum_{r=0}^{n} C_n^r \lambda^r (1-\lambda)^{n-r} p_r(\theta)^{1/\lambda} = \mathbb{E}_{R\sim B(n,\lambda)} p_R^{1/\lambda}(\theta), \tag{18}$$

where $B(n, \lambda)$ denotes the binomial distribution with parameters n and λ. Noticing that $p_r(\theta)$ is roughly exponentially decreasing in r, the values or r that are larger than the mode of the binomial probability mass function are unlikely to contribute a lot to (18). The largest subsample size contributing to (18) is thus roughly $n\lambda$, and the power $1/\lambda$ makes this term of the same scale as $p(x_1, \ldots, x_n|\theta)$. Broadly speaking, subsampling has a "broadening" effect due to the contribution of the likelihoods of small subsamples.

Alternately, if one starts with the biased estimator of the average log likelihood

$$\tilde{\ell}(\theta) = \frac{1}{n} \sum_{i=0}^{n} z_i \ell_i(\theta), \tag{19}$$

instead of (17) one ends up with

$$\begin{aligned} \mathbb{E}e^{n\tilde{\ell}(\theta)} &= \prod_{i=1}^{n} \left[\lambda e^{\ell_i(\theta)} + (1-\lambda)\right] \\ &= \sum_{r=0}^{n} \sum_{\#I_r = r} \lambda^r (1-\lambda)^{n-r} p(x_{I_r}|\theta) \\ &\approx \mathbb{E}_{R\sim B(n,\lambda)} p_R(\theta). \end{aligned} \tag{20}$$

Again, all subsampled likelihoods contribute, but without being further exponentiated. Still, the result is a much broadened target, as values of r that are larger than $n\lambda$ are unlikely to contribute a lot. In this case, the broadening effect of subsampling is not only due to the contribution of small subsamples, but also to the absence of bias correction in (19).

We have thus seen that naive subsampling is nontrivial tempering, so that the target is not preserved. Additionally, as mentioned in Section 4.1, the variance of the log likelihood estimator needs to be kept around a constant, 1 or 3 depending on hypotheses, in order for pseudo-marginal MH to be efficient. This means that λ should be such that

$$\frac{(1-\lambda)}{\lambda} \sum_{i=1}^{n} \ell_i(\theta)^2$$

is of order 1 in the case of (17). This entails that λ should be close to 1, so that there is no substantial gain in terms of number of likelihood evaluations. In the case of (19),

$$\lambda(1-\lambda) \sum_{i=1}^{n} \ell_i(\theta)^2$$

can be of order 1 if $\lambda \sim n^{-1}$. But then the leading terms in the mixture target (20) will be the subsampled likelihoods corresponding to small subsamples, so that the target will be very different from the actual target π.

Overall, naive subsampling is a very poor approach. However, it allows us to identify the main issues a good subsampling approach should tackle: guaranteeing its target, not loosing too much convergence speed compared to the MH algorithm based on the true likelihood, and cutting the likelihood evaluation budget. As shown in (Bardenet et al., 2014), the first point is an algorithmic design issue, while the last two points are related to controlling the variance of the log likelihood ratios.

6.2 Relying on the CLT

Several authors have appealed to the central limit theorem to justify their assumption that the average subsampled log likelihoods and log likelihood ratios in (7) and (16) are Gaussianly distributed.

If the distribution of the log likelihood ratio estimate minus the true log-likelihood ratio was normal with known variance σ^2 and mean $-\sigma^2/2$, Ceperley and Dewing (1999) have proposed an MH with a corrected acceptance ratio that is exact, i.e., that still targets π. However, this distribution is never exactly normal and the variance of the noise is unknown. In Nicholls et al. (2012), it is proposed to estimate the noise variance and the author propose a heuristic argument to explain why this inexact chain might give reasonable approximate results, but the Gaussian assumption remains crucial there. As shown in (Bardenet et al., 2014) and in Figures 5 and 6 of this paper, this assumption can be easily violated when subsampling tall data if the log likelihood ratios $\ell_i(\theta') - \ell_i(\theta)$ are heavy-tailed. Missing log likelihoods in the tails will lead to erroneous decisions, and uncontrolled results.

6.2.1 A pseudo-marginal approach with variance reduction under Gaussian assumption

Quiroz et al. (2014) propose a methodology to use MH for tall data which also relies on the assumption that the log-likelihood estimator is Gaussian with mean $\ell(\theta)$, for every θ. By introducing a bias correction providing an approximately unbiased estimate of the likelihood, this corresponds to a pseudo-marginal MH algorithm whose target distribution is proportional to $p(\theta)\mathbb{E}e^{n\hat{\ell}(\theta)-\hat{b}(\theta)}$, where $\hat{b}(\theta)$ is an estimate of the bias $b(\theta)$ satisfying $\mathbb{E}e^{n\hat{\ell}(\theta)} = e^{n\ell(\theta)+b(\theta)}$. They rightly notice that, ideally, if one wants to keep the variance of average subsampled log likelihoods small, one should not subsample data points with or without replacement, but one should rather perform importance sampling with the weight of data point i being proportional to $|\ell_i(\theta)|$. While this variance reduction approach obviously defeats the purpose of subsampling, Quiroz et al. (2014) propose to use as weights an approximation of the log-likelihood, based e.g. on a Gaussian process or splines trained on a small subset of computed likelihoods $\ell_i(\theta)$. Finally, a heuristic to adaptively choose the size of the total subsample so as to keep the variance of the log likelihood controlled is proposed. The method is demonstrated to work on a bivariate probit model using only 10% of the full dataset. However, as a general purpose method, it suffers from two limitations. First, it is based on Gaussian assumptions, which can be unreasonable as noted above and it is unclear whether it will be robust to these CLT approximations not being valid. Second,

the proposed importance sampling step requires to learn a good proxy for $x \mapsto p(x|\theta)$ for each θ drawn during the MCMC run. The fitted proxies should thus be cheap to train and evaluate, but at the same time accurate if any variance reduction is to be obtained.

6.2.2 Adaptive subsampling with T-tests

Still assuming the noise of the log likelihood is Gaussian, given a drawn $\theta \in \Theta$, one can try to adaptively choose the size of the subsample $\{x_1^*, \dots, x_t^*\}$ to be used in the unbiased estimators (7) or (16), so as to take the correct acceptance decision with high probability. Upon noting that the MH acceptance decision is equivalent to deciding whether $\log \alpha(\theta, \theta') > u$, or equivalently

$$\frac{1}{n}\sum_{i=1}^{n} \log \frac{p(x_i|\theta')}{p(x_i|\theta)} > \frac{1}{n}\log u - \frac{1}{n}\log\left[\frac{p(\theta')q(\theta|\theta')}{p(\theta)q(\theta'|\theta)}\right] \tag{21}$$

with $u \sim \mathcal{U}_{[0,1]}$ drawn beforehand, statistical tests can be used to assert whether (21) holds with a given level of "confidence". As far as we are aware, Bulgak and Sanders (1988) were the first to consider such a procedure. They used it in a simulated annealing algorithm maximizing a function defined as an expectation w.r.t a probability distribution, and approximated using Monte Carlo. Simulated annealing is a simple non-homogeneous variant of the MH algorithm where the the target distribution is annealed over the iterations. The same application received more attention later (Alkhamis et al., 1999; Wang and Zhang, 2006). Applied to the standard MH, the method has been considered by Singh et al. (2012), and more recently by Korattikara et al. (2014) specifically for tall data. Korattikara et al. (2014) propose an MH-like algorithm called *Austerity MH* that incorporates a sequential T-test to check (21) for each pair (θ, θ'), thus relying on *several* CLTs. They demonstrate dramatic reductions in the average number of subsamples used per MCMC iteration on particular applications. However, as noted in (Korattikara et al., 2014; Bardenet et al., 2014), the results can be arbitrarily far from the original MH when the CLT approximations are not valid.

We show the results of 10 000 iterations of Austerity MH on our two running examples in Figure 5. The parameters are $\epsilon = 0.05$, corresponding to the p-value threshold in the aforementioned T-test, and an initial subsample size of 100 at each iteration. In the Gaussian case, the posterior is rightly centered, but is slightly too wide. This is a tempering effect due to too small subsamples, while the CLT-based Student approximation seems reasonable, as shown in Figure 6. In the lognormal case, the departure of the chain from the actual posterior is more remarkable, and relatedly the CLT approximations of Austerity MH are inaccurate for the chosen initial subsample size of 100, as we demonstrate in Figure 6. This explains the strong mismatch of the chain and the posterior in Figure 5(b). The standard deviation of the fitted Gaussian is largely underestimated, due to small subsamples which do not include enough of the tails of the log likelihood ratios, which coincide with the tails of $\mathcal{X}$. Finally, the reductions in the number of samples needed per iteration are quite interesting: half of the iterations require less than 4% of the dataset for the lognormal case, but this is at the price of a large error in the posterior approximation. Augmenting the initial size of the subsample will likely make the CLT approximations tighter, but there is no generic answer as to which size to choose: any fixed choice will fail on an example where the log likelihood ratios have heavy enough tails. In both the Gaussian and the

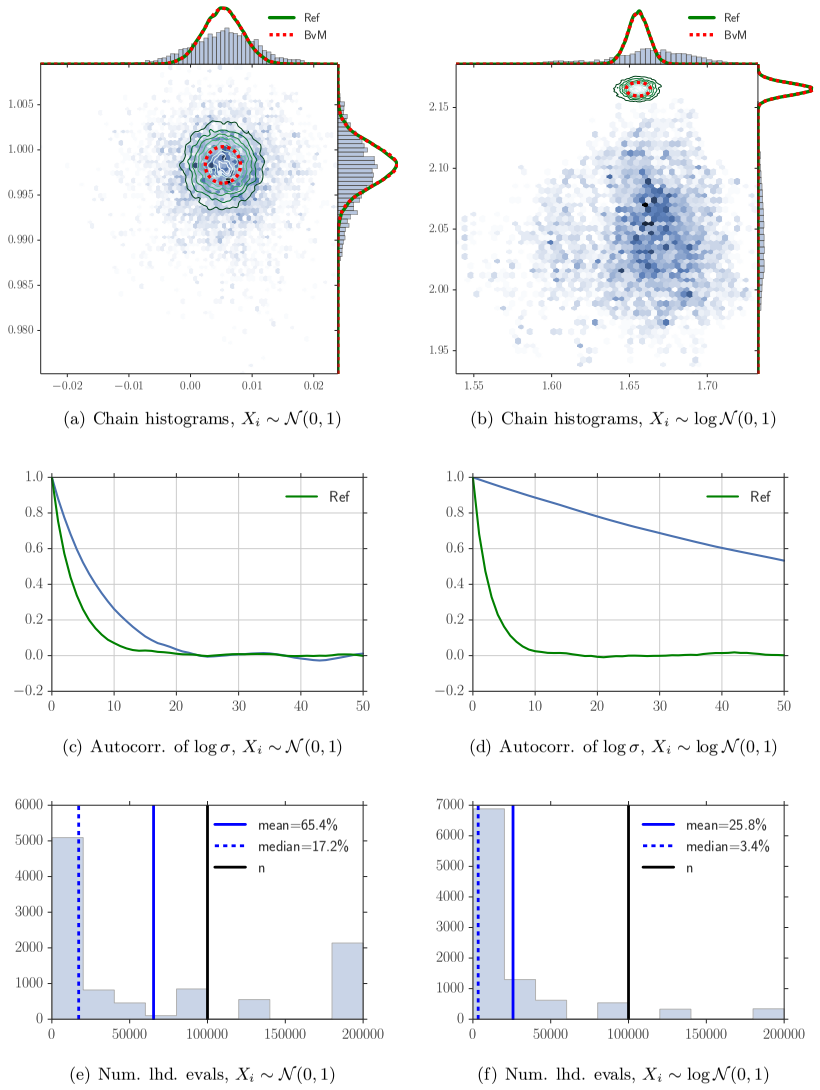
lognormal example, it is actually safer to go with the Bernstein-von Mises approximation, which costs little more than a run of stochastic gradient descent, and only requires one CLT approximation, for a sample of size $n \gg 1$. This illustrates the danger of using CLT-based approximations for small sample sizes, which is related to asymptotic arguments on small batches in Section 3.

Overall, CLT-based approaches to MH with tall data lead to heuristics with interesting reductions in the number of samples used, but they have little theoretical backing so far and they are not robust to the involved CLT approximations being inaccurate. We note also that the CLT is assumed to provide a good approximation for the log likelihood or log likelihood ratio for *any* $\theta, \theta' \in \Theta$, which amounts to more than one Gaussian assumption. The approaches in this section should thus be applied with care. As a minimal sanity-check, we recommend using tests of Gaussianity across $\Theta \times \Theta$ to make sure the CLT assumptions are realistic. Note that even then, there is no guarantee the above algorithms have π for target, if any.

6.3 Exchanging acceptance noise for subsampling noise

This section is an original contribution, which illustrates a way to obtain subsampling algorithms with guarantees under weaker assumptions than Gaussianity. This approach is impractical, but it is of methodological and illustrative interest. First it illustrates a potentially useful technique to *take advantage of* subsampling noise. Second, it is our first illustration of the seemingly inevitable $\mathcal{O}(n)$ average number of subsamples required per MCMC iteration as soon as we do not use any CLT-based approximation and require theoretical guarantees.

Let $\theta, \theta' \in \Theta$, and let $x_1^*, \ldots, x_t^*$ be drawn independently with replacement from $\mathcal{X}$. Let $\Lambda_t^*(\theta, \theta')$ be the average subsampled log likelihood ratio defined in (16). Now, we remark that MH has some inherent noise in its acceptance decision (21), encapsulated by the uniform variable $u \sim \mathcal{U}[0, 1]$. Why, then, not rely on the subsampling noise to guarantee exploration, and accept a move if and only if



$$\Lambda_t^*(\theta, \theta') + \frac{1}{n} \log \left[\frac{p(\theta')q(\theta|\theta')}{p(\theta)q(\theta'|\theta)} \right] > 0 \tag{22}$$

instead of (21)? This idea has been first used by Branke et al. (2008) to develop heuristics for simulated annealing in the presence of noise. We formalize this argument here in the context of subsampling. For the sake of simplicity, assume for a moment we have a flat prior and a symmetric proposal, so that (22) becomes

$$\Lambda_t^*(\theta, \theta') > 0.$$

We do not assume that the $\Lambda_t^*(\theta, \theta')$'s are Gaussianly distributed, but we make the parametric assumption that the second and third absolute moments σ^2 and ρ of $-\log p(x_i^*|\theta') + \log p(x_i^*|\theta)$ are known and independent of θ, θ'. Applying the Berry-Esseen inequality (van der Vaart and Wellner, 1996) to the variables $-\log p(x_i^*|\theta') + \log p(x_i^*|\theta)$ yields

$$\left| \mathbb{P}(-\Lambda_t^*(\theta, \theta') \leq u) - \Phi\left(\frac{u + \Lambda_n(\theta, \theta')}{\sigma/\sqrt{t}} \right) \right| \leq \frac{K(\sigma, \rho)}{\sqrt{t}} \tag{23}$$

for any $u \in \mathbb{R}$, where Φ is the cdf of a $\mathcal{N}(0,1)$ variable, and

$$\Lambda_n(\theta,\theta') \triangleq \frac{1}{n}\sum_{i=1}^{n} \log \frac{p(x_i|\theta')}{p(x_i|\theta)}$$

is the average log likelihood ratio. When $u = 0$, (23) yields

$$\left|\mathbb{P}(\Lambda_t^*(\theta,\theta') \geq 0) - \Phi\left(\frac{\Lambda_n(\theta,\theta')}{\sigma/\sqrt{t}}\right)\right| \leq \frac{K(\sigma,\rho)}{\sqrt{t}}. \tag{24}$$

Now let $C, \lambda > 0$ be such that for any $x \in \mathbb{R}$,

$$\left|\Phi(x) - \frac{1}{1+e^{-\lambda x}}\right| \leq C.$$

Bowling et al. (2009) for instance, empirically found $C = 0.0095$ and $\lambda = 1.702$. Combining this bound with (24), we obtain

$$\left|\mathbb{P}(\Lambda_t^*(\theta,\theta') \geq 0) - \frac{1}{1+e^{-\frac{\lambda\Lambda_n(\theta,\theta')}{\sigma/\sqrt{t}}}}\right| \leq C + \frac{K(\sigma,\rho)}{\sqrt{t}}.$$

Hence, the acceptance probability of an algorithm that would accept the move from θ to θ' by checking whether $\Lambda^*(\theta,\theta') > 0$ is close to the acceptance probability of an MCMC algorithm with a Baker acceptance criterion (Robert and Casella, 2004, Section 7.8.1) that targets π^β with temperature $\beta = \frac{\lambda\sqrt{t}}{n\sigma}$. Arguments such as (Bardenet et al., 2014, Lemma 3.1, Proposition 3.2) could then help concluding that the distance between the kernels of both Markov chains is controlled, which would yield positive ergodicity results, in the line of (Bardenet et al., 2014, Proposition 3.2). This reasoning shows again a close relation between

subsampling and tempering, as in Section 6.1, with a clear link between the variance of the subsampled log likelihood ratios and the temperature.

Now, from a practical point of view, in simple applications such as logistic regression, σ is of the order of $\|\theta - \theta'\|$, which in turn should be of order $\mathcal{O}_p(n^{-1/2})$ if the MCMC proposal is a Gaussian random walk with covariance similar to that of π, see Bardenet et al. (2014). This means that t has to be of order n for the temperature β to be of order 1, and this approach is thus bound to use $\mathcal{O}(n)$ subsamples per iteration! In conclusion, robustness to non-Gaussianity leads to requiring a fixed proportion of the whole dataset on average, even in the favourable case when one controls the first three moments of the subsampling noise and one swaps subsampling noise for the inherent MCMC acceptance noise.

6.4 Confidence samplers

In (Bardenet et al., 2014), we proposed a controlled approximation of the acceptance decision (21). Indeed, let us fix θ, θ' and momentarily assume that $x \mapsto \log[p(x|\theta')/p(x|\theta)]$ was Lipschitz with known constant. Then, having observed the log likelihood ratio at some points $\{x_i^*, i = 1, \ldots, t\} \subset \mathcal{X}$, one could build a lower and an upper bound for the complete log likelihood ratio

$$\frac{1}{n}\sum_{i=1}^{n} \log\left[\frac{p(x_i|\theta')}{p(x_i|\theta)}\right],$$

simply by associating each x_i with the nearest point among $\{x_1^*, \ldots, x_t^*\}$. These bounds could be refined by augmenting the set of observed log likelihoods ratios, until eventually one knows for sure whether (21) holds.

Now, concentration inequalities allow softer bounds and require less than this Lipschitz assumption. If one knows a bound for the range

$$C_{\theta,\theta'} \triangleq \max_{i=1}^{n} \left|\log\left[\frac{p(x_i|\theta')}{p(x_i|\theta)}\right]\right|, \tag{25}$$

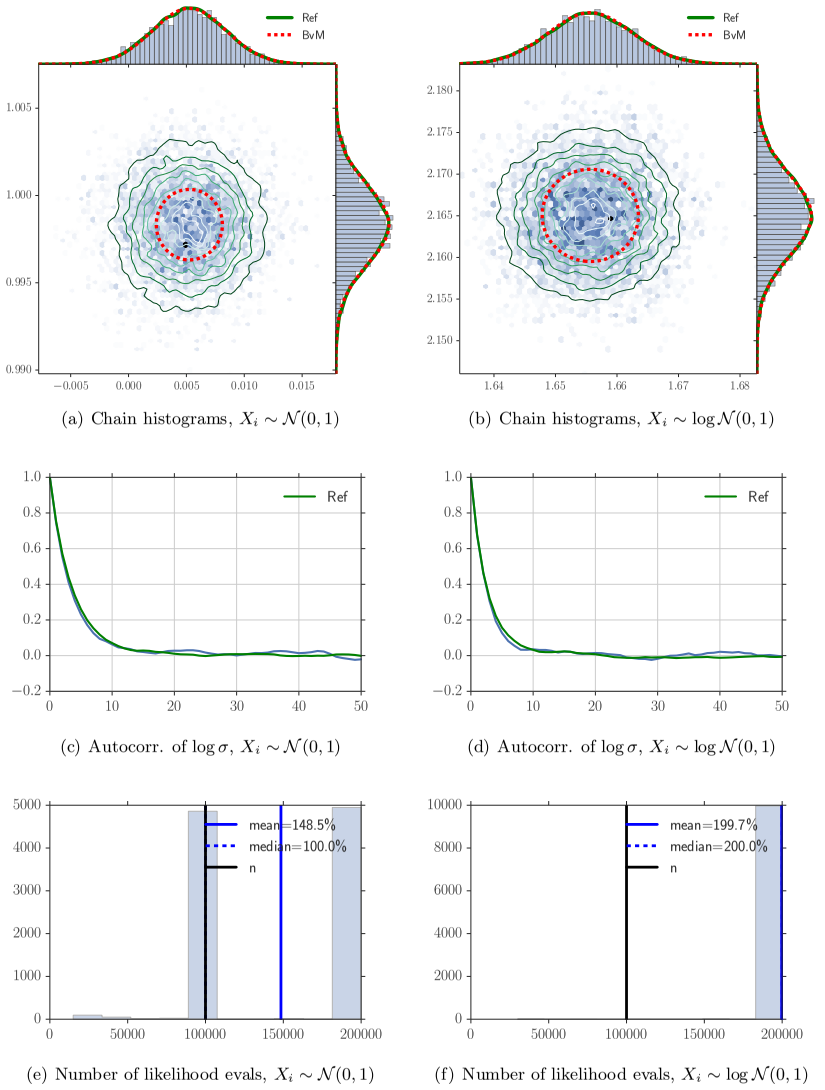
then concentration inequalities such as Hoeffding's or Bernstein's, yield confidence bounds $c_t(\delta)$ such that

$$\mathbb{P}\left(\left|\frac{1}{t}\sum_{i=1}^{t} \log\left[\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}\right] - \frac{1}{n}\sum_{i=1}^{n} \log\left[\frac{p(x_i|\theta')}{p(x_i|\theta)}\right]\right| > c_t(\delta)\right) \geq 1 - \delta, \tag{26}$$

where the probability is taken over $x_1^*, \ldots, x_t^*$ drawn uniformly from $\mathcal{X}$, with or without replacement. Borrowing from the bandit literature, we explain in (Bardenet et al., 2014) how to leverage such confidence bounds to automatically select a subsample size T such that the right MH acceptance decision is taken with a user-specified probability $1 - \delta$. Note that for our algorithm to bring any improvement over the ideal MH, the range (25) must be cheap to compute, i.e. cheaper than $\mathcal{O}(n)$. This is the case for logistic regression, for example, but it is the major limitation of the approach in Bardenet et al. (2014). We showed in (Bardenet et al., 2014, Proposition 3.2) that if the ideal MH sampler is uniformly ergodic then the resulting algorithm inherits the uniform ergodicity of the ideal MH sampler, with a convergence speed that is within $\mathcal{O}(\delta)$ of that of the ideal MH. Importantly, we showed that our sampler then admits a limiting distribution, which is also within $\mathcal{O}(\delta)$ of π. Uniform

ergodicity is a very strong assumption and it would be worth extending these results to the geometrically ergodic scenario. There has recently been work in this direction (Alquier et al., 2016; Pillai and Smith, 2014; Rudolf and Schweizer, 2015).

On the negative side, we demonstrated in (Bardenet et al., 2014) that vanilla confidence samplers still require $\mathcal{O}(n)$ samples at each iteration at equilibrium, where the proportionality constant is the variance of the log likelihood ratio under subsampling. This statement relies on the leading term in $c_t(\delta)$ being of order $t^{-1/2}$. In practice, the results of the vanilla confidence sampler on our running examples are shown in Figure 7. We set $\delta = 0.1$ and we place ourselves in the favourable scenario where the algorithm has access to the actual range of each log likelihood ratio. The number of likelihood evaluations is estimated as follows: we take by default *twice* the detected value T for the subsample size in general, but only *once* when the previous iteration required computing all n likelihoods at the current state of the chain. Still, even in these favourable conditions, the algorithm basically requires essentially the whole dataset at each iteration.



Concentration inequalities are "worst-case" guarantees, and the theoretical results come at the price of a smaller reduction in the number of samples required. When the target is locally Gaussian, e.g. when Bernstein-von Mises yields a good approximation, there is potentially a lot to be gained, as empirically demonstrated by Korattikara et al. (2014), for example. In the current paper, we propose in Section 7 a modified confidence sampler that can leverage concentration of the target to yield dramatic empirical gains while not sacrificing any theoretical guarantee of the confidence sampler. The basic tool is a cheap proxy for the log likelihood ratio that acts as a control variate in the concentration inequality (26). Using a 2nd order Taylor expansion centered at the maximum of the likelihood – obtained with a stochastic gradient descent for example – allows to replace many likelihood evaluations by the evaluation of this Taylor expansion. Figure 8 shows the results of this new confidence sampler with proxy on our running Gaussian and lognormal examples. Our algorithm outperforms all preceding methods, using almost no sample in the Gaussian case where it *automatically* detects that a quadratic form is enough to represent the log likelihood ratio. Finally, we demonstrate in Sections 7.2.3 and 8 that this new algorithm can require less than $\mathcal{O}(n)$ likelihood evaluations per iteration. Combined with the statements in Bardenet et al. (2014) that each iteration is almost as efficient as the ideal MH, which is further supported by the match of the autocorrelation functions in Figures 8(c) and 8(d), this opens up big data horizons. We give full details on the confidence algorithm with proxy in Section 7.

7. An improved confidence sampler

In this section, we build upon the confidence sampler in (Bardenet et al., 2014) by introducing likelihood proxies, which act as control variates for the individual likelihoods.

7.1 Introducing proxies in the confidence sampler

We start by recalling the pseudocode of the confidence sampler in (Bardenet et al., 2014) in Figure 9, using sampling with replacement and a generic empirical concentration bound $c_t(\delta)$. In practice, one can think of the empirical Bernstein bound of Audibert et al. (2009)

(a) Chain histograms, $X_i \sim \mathcal{N}(0,1)$

(b) Chain histograms, $X_i \sim \log\mathcal{N}(0,1)$

(f) Number of likelihood evals, $X_i \sim \log\mathcal{N}(0,1)$

Figure 8: Results of 10 000 iterations of the confidence sampler of Section 7 with a single 2nd order Taylor proxy at θ_{MAP}.

$$c_t(\delta) = \hat{\sigma}_{t,\theta,\theta'}\sqrt{\frac{2\log(3/\delta)}{t}} + \frac{6C_{\theta,\theta'}\log(3/\delta)}{t}, \tag{27}$$

where $\hat{\sigma}_{t,\theta,\theta'}$ is the sample standard deviation of the log likelihood ratio

$$\left\{\log\left[\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}\right], i = 1,\dots,t\right\},$$

and $C_{\theta,\theta'}$ is their range, defined in (25). We emphasize that other choices of sampling procedure and concentration inequalities are valid, as long as they guarantee a concentration like (26). We refer the reader to (Bardenet et al., 2014) for a proof of the correctness of the confidence sampler and implementation details.

The bottleneck for the performance of the confidence sampler was identified in (Bardenet et al., 2014) as the expectation w.r.t. $\pi(\theta)q(\theta'|\theta)$ of the variance of the log likelihood ratio $\log p(x|\theta')/p(x|\theta)$ w.r.t. to the empirical distribution of the observations. We now propose a control variate technique inspired from the Firefly MH of MacLaurin and Adams (2014) to lower this variance down when an accurate and cheap proxy of the log likelihood is known.

We require a proxy for the log likelihood ratio that may decrease the variance of the log likelihood ratio or its range. More precisely, let $\wp_i(\theta,\theta')$ be such that for any $\theta,\theta' \in \Theta$,

1. $\wp_i(\theta,\theta') \approx \ell_i(\theta') - \ell_i(\theta)$
2. $\sum_{i=1}^n \wp_i(\theta,\theta')$ can be computed cheaply.
3. $|\ell_i(\theta') - \ell_i(\theta) - \wp_i(\theta,\theta')|$ can be bounded uniformly in $1 \le i \le n$, and the bound is cheap to compute.

We now simply remark that the acceptance decision (21) in MH is equivalent to checking whether

$$\frac{1}{n}\sum_{i=1}^n\left[\log\frac{p(x_i|\theta')}{p(x_i|\theta)} - \wp_i(\theta,\theta')\right] > \frac{1}{n}\log u - \frac{1}{n}\log\left[\frac{p(\theta')q(\theta|\theta')}{p(\theta)q(\theta'|\theta)}\right] - \frac{1}{n}\sum_{i=1}^n\wp_i(\theta,\theta'). \tag{28}$$

Building the confidence sampler on (28) leads to the same pseudocode as in Figure 9, except that Step 14 is replaced by

$$\Lambda^* \leftarrow \frac{1}{b}\left(t\Lambda^* + \sum_{i=t+1}^b\left[\log\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)} - \wp_i(\theta,\theta')\right]\right),$$

the condition in Step 19 is replaced by

$$\left|\Lambda^* + \frac{1}{n}\sum_{i=1}^n\wp_i(\theta,\theta') - \psi(u,\theta,\theta')\right| \ge c,$$

and the condition in Step 21 becomes

$$\Lambda^* > \psi(u,\theta,\theta') - \frac{1}{n}\sum_{i=1}^n\wp_i(\theta,\theta').$$

Figure 9: Pseudocode of the confidence MH from (Bardenet et al., 2014). Note that although we present the algorithm with uniform subsampling *without replacement*, batches can be drawn with or without replacement at Step 12, as long as a valid concentration inequality is used at Step 16. Our contribution is a modification of Steps 14, 19 and 21 to introduce proxies for the log likelihood ratios, see Section 7.

For completeness, we restate here in Proposition 3 that the vanilla confidence sampler inherits the uniform ergodicity of the underlying MH sampler, that its target is within $\mathcal{O}(\delta)$ of π, and that the difference in speed of convergence is also controlled by δ. Let P be the underlying MH kernel, and $\tilde{P}$ the kernel of the confidence sampler described in this section.

Proposition 3 *Let P be uniformly geometrically ergodic, i.e., there exists an integer m, a probability measure ν on $(\Theta, \mathcal{B}(\Theta))$ and $0 \leq \rho < 1$ such that for all $\theta \in \Theta$, $P^m(\theta,\cdot) \geq (1-\rho)\,\nu(\cdot)$. Hence there exists $A < \infty$ such that*

$$\forall\theta \in \Theta, \forall k > 0,\ \|P^k(\theta,\cdot) - \pi\|_{TV} \leq A\rho^{\lfloor k/m \rfloor}. \tag{29}$$

Then there exists $B < \infty$ and a probability distribution $\tilde{\pi}$ on $(\Theta, \mathcal{B}(\Theta))$ such that for all $\theta \in \Theta$ and $k > 0$,

$$\|\tilde{P}^k(\theta,\cdot) - \tilde{\pi}\|_{TV} \leq B[1-(1-\delta)^m(1-\rho)]^{\lfloor k/m \rfloor}. \tag{30}$$

Furthermore, $\tilde{\pi}$ satisfies

$$\|\pi - \tilde{\pi}\|_{TV} \leq \frac{Am\delta}{1-\rho}. \tag{31}$$

Even in the presence of proxies, the proofs of (Bardenet et al., 2014, Lemma 3.1, Proposition 3.2) apply with straightforward modifications, so that we can extend Proposition 3 to the proxy case. The major advantage of this new algorithm is that the sample standard deviation $\hat{\sigma}_{t,\theta,\theta'}$ and range $C_{\theta,\theta'}$ in the concentration inequality (27) are replaced by those of

$$\left\{\log\left[\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}\right] - \wp_i(\theta,\theta'), i = 1,\ldots,t\right\}.$$

If $\wp_i(\theta,\theta')$ is a good proxy for the log likelihood ratio, one can thus expect significantly more accurate confidence bounds, leading in turn to reduction in the number of samples used.

7.2 An example proxy: Taylor expansions

In general, the choice of proxy $\wp$ will be problem-dependent, and the availability of a good proxy at all is a *strong* assumption, although not as strong as our previous requirement in Bardenet et al. (2014) that the range (25) can be computed cheaply, which basically corresponds to $\wp_i(\theta,\theta')$ being identically zero for all i. Indeed, we show in this section that all models that possess up to third derivatives can typically be tackled using Taylor expansions as proxies. In Section 8, we detail the case of logistic regression and gamma linear regression.

7.2.1 Taylor expansions

We expand ℓ_i around some reference value $\theta_\star$ to obtain an estimate

$$\hat{\ell}_i(\theta) = \ell_i(\theta_\star) + g_{i,\star}^T(\theta - \theta_\star) + \frac{1}{2}(\theta-\theta_\star)^T H_{i,\star}(\theta-\theta_\star),$$

where $g_{i,\star}$ and $H_{i,\star}$ are respectively the gradient and the Hessian of ℓ_i at $\theta_\star$. The choice of $\theta_\star$ is deferred to Section 7.2.2. Let us now define $\wp_i(\theta,\theta') = \hat{\ell}_i(\theta') - \hat{\ell}_i(\theta)$. The average $\frac{1}{n}\sum_{i=1}^n \wp_i(\theta,\theta')$ can be computed in $\mathcal{O}(1)$ time if one has precomputed

$$\hat{\mu} = \frac{1}{n}\sum_{i=1}^n g_{i,\star}$$

and

$$\hat{S} = \frac{1}{n}\sum_{i=1}^{n} H_{i,\star}.$$

Indeed, the following holds

$$\frac{1}{n}\sum_{i=1}^{n} \wp_i(\theta,\theta') = \hat{\mu}^T(\theta'-\theta) + \frac{1}{2}(\theta'-\theta)^T\hat{S}(\theta+\theta'-2\theta_\star).$$

Finally, assuming

$$\left.\frac{\partial \ell_i}{\partial\theta^{(j)}\partial\theta^{(k)}\partial\theta^{(l)}}\right|_{\theta_\star}$$

can be bounded uniformly in i,j,k,l, the absolute difference $\ell_i(\theta') - \ell_i(\theta) - \wp_i(\theta,\theta')$ can be bounded using the Taylor-Lagrange inequality. To conclude, all conditions of Section 7.1 are satisfied by the proxy $\wp_i$.

7.2.2 Drop proxies along the way

When the mass of the posterior is concentrated around the maximum likelihood estimator θ_{MLE}, a single proxy – say a Taylor proxy centered at $\theta_\star = \theta_{\text{MLE}}$ – can represent the target quite accurately. This is the proxy we used in the running examples of Section 6, see Figure 8. When the posterior does not concentrate, or the proposal is not local enough, such a proxy will be inaccurate, potentially resulting in insufficient subsampling gains. There are various tricks that can be applied. One can either precompute proxies across Θ if one has an idea where the modes of π are, and then use the closest proxy to the current state of the chain at each iteration. Alternately, if one agrees to look at the whole dataset every α iterations, we can *drop proxies along the way*, i.e. set $\theta_\star$ to the current state of the chain every α MH iterations. The whole dataset needs to be browsed at each change of the reference point $\theta_\star$, since there is typically some preprocessing to do in order to compute later bounds. In the case of 2nd order Taylor expansions, for example, one has to compute the full gradient, Hessian, and any other quantity needed to bound the third derivatives. What the user should aim at is to sacrifice a proportion α of the budget of the ideal MH to make the remaining iterations cheaper. The proof of Proposition 3 easily generalizes to the case of proxies dropped every constant number of iterations. We demonstrate the empirical performance of such an approach in Sections 8.1.3 and 8.2.2.

7.2.3 A heuristic on the subsampling gain

In (Bardenet et al., 2014), we presented a heuristic that showed the original confidence sampler required $\mathcal{O}(n)$ likelihood evaluations per iteration. At the time, it seemed every attempt at marrying subsampling and MH was fundamentally $\mathcal{O}(n)$. We first repeat here the heuristic from (Bardenet et al., 2014), before arguing that the contributions of this paper can lower this budget to $o(n)$, even $\mathcal{O}(1)$ up to polylogarithmic factors in very favourable conditions.

Assuming a symmetric proposal and a flat prior, the stopping rule of the **while** loop in the original confidence sampler in Figure 9 is met whenever

$$\frac{1}{t}\sum_{i=1}^{t}\log\left[\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}\right] - \frac{1}{n}\log u$$

is of the same order as the confidence bound $c_t(\delta)$, that is, when $c_t(\delta)$ is of order $1/n$. We consider the Bernstein bound in (27) and we assume the range $C_{t,\theta,\theta'}$ grows with n strictly slower than $\sqrt{n}$. The latter assumption is realistic: $C_{t,\theta,\theta'}$ is often dominated by some power of $\max\|x_i\|_\infty$, and if $x_1,\dots,x_n$ are drawn i.i.d. from a subgaussian distribution, then $\mathbb{E}\max_{i=1}^n x_i = \mathcal{O}(\sqrt{\log n})$ (Cesa-Bianchi and Lugosi, 2006, Lemma A.13). The leading term of the Bernstein bound is proportional to $\hat{\sigma}_{t,\theta,\theta'}/\sqrt{t}$. In simple models such as logistic regression, $\hat{\sigma}_{t,\theta,\theta'}$ is proportional to $\|\theta-\theta'\|$.

Assuming n is large enough that standard asymptotics apply and the target is approximately Gaussian, the results of Roberts and Rosenthal (2001) lead to choose the covariance matrix of the proposal such that $\|\theta-\theta'\|$ is of order $n^{-1/2}$. Summing up, we exit the **while** loop when

$$\frac{1}{n} \sim \frac{1}{\sqrt{t}\sqrt{n}},$$

which leads to $t \sim n$.

Now consider the confidence sampler with second-order Taylor proxies introduced in Section 7.2.1. $\hat{\sigma}_{t,\theta,\theta'}$ and $C_{t,\theta,\theta'}$ now correspond to the standard deviation and range of

$$\left\{\log\left[\frac{p(x_i^*|\theta')}{p(x_i^*|\theta)}\right] - \wp_i^*(\theta,\theta')\right]; 1\le i\le t\right\}.$$

Now let us assume the third-order derivatives at the reference point $\theta_\star$ can be bounded, say by some constant times $\max_i\|X_i\|_\infty^3$ as will be the case for the exponential family models of Section 8. Then $\hat{\sigma}_{t,\theta,\theta'}$ and $C_{t,\theta,\theta'}$ are dominated by

$$\max_i \|X_i\|_\infty^3\left(\|\theta-\theta_\star\|^3 + \|\theta'-\theta_\star\|^3\right). \tag{32}$$

But $\|\theta-\theta_\star\|$ is of order $n^{-1/2}$ if standard asymptotics (van der Vaart, 2000) yield good approximations and $\theta_\star$ is set to the maximum of the posterior. Alternatively, if one has implemented the strategy of dropping proxies regularly, then $\|\theta-\theta_\star\|$ should be of order $n^{-1/2}$ since we assume the covariance matrix of the proposal distribution is of order $1/n$. Again assuming that $\max_i\|X_i\|_\infty^3$ grows, say, like $\rho(n) = o(n^{1/3})$, we now exit the while loop when

$$\frac{1}{n} \sim \frac{\rho(n)^3}{\sqrt{t}n^{3/2}} = \frac{o(1)}{\sqrt{t}\sqrt{n}}.$$

Thus, when the target is approximately Gaussian and the chain is in the mode, the cost in likelihood evaluations per iteration of the confidence sampler with proxy is likely to be $o(n)$. The actual order of convergence depends on the rate of growth of the bounds on the third derivatives. For example, in the case of independent Gaussian data and still assuming (32), we have $t = \mathcal{O}(1)$ up to polylogarithmic factors.

8. Experiments

As a proof of concept, all experiments in this section avoid loading the dataset or proxy-related quantities into memory by building, maintaining and querying from a disk-based database using *SQLite*[2].

8.1 Logistic regression

8.1.1 A Taylor proxy for logistic regression

In logistic regression, the likelihood is defined by $\ell_i(\theta) = \phi(t_i x_i^T \theta)$, where

$$\phi(z) = -\log(1 + e^{-z})$$

and the label t_i is in $\{-1, +1\}$. We can use the Taylor expansion proxy of Section 7.2.1, using

$$g_{i,\star} = \phi'(t_i x_i^T \theta_\star) t_i x_i$$

and

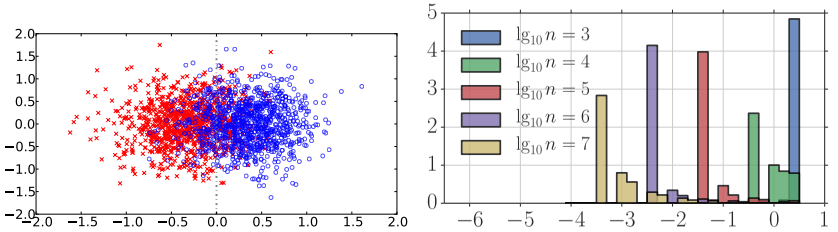
$$H_{i,\star} = \phi''(t_i x_i^T \theta_\star) x_i x_i^T$$

Furthermore,

$$\frac{\partial}{\partial\theta^{(j)}\partial\theta^{(k)}\partial\theta^{(l)}}\ell_i(\theta) = t_i\phi'''(t_i x_i^T\theta)x_i^{(j)}x_i^{(k)}x_i^{(l)}$$

and

$$\left|\phi'''(z)\right| = \frac{1}{4}\left|\frac{\tanh(z/2)}{\cosh^2(z/2)}\right| \leq \frac{1}{4},$$



so that

$$\begin{aligned}&|\ell_i(\theta') - \ell_i(\theta) - \wp_i(\theta, \theta')| \\ &\qquad \leq \frac{1}{24}\max_{i=1}^{n}\|x_i\|^3\left\{\|\theta - \theta_\star\|^3 + \|\theta' - \theta_\star\|^3\right\}.\end{aligned}$$

8.1.2 A toy example that requires $\mathcal{O}(1)$ likelihood evaluations

In this section, we consider the simple two-dimensional logistic regression dataset in (Bardenet et al., 2014, Section 4.2.2), where the features within each class are drawn from a Gaussian. The dataset is depicted in Figure 10(a). We consider subsets of the dataset with increasing size $\log_{10} n \in \{3, 4, 5, 6, 7\}$, run a confidence MH chain for each n, started at the MAP, with $\delta = 0.1$ and a single proxy around the MAP. We report the numbers of likelihood evaluations L at each iteration in Figure 10(b). The fraction of likelihood evaluations compared to MH roughly decreases by a factor 10 when the size of the dataset is multiplied by 10: the number of likelihood evaluations is constant for n large enough. In other words, 1 000 random data points at each iteration are enough to get within $\mathcal{O}(\delta)$ of the actual posterior, the rest of the dataset appears to be superfluous. There is a *saturation* phenomenon. By relaxing the goal of sampling from π into sampling from a controlled approximation, we can break the $\mathcal{O}(n)$ barrier and in this particular example reach a cost per iteration of $\mathcal{O}(1)$.

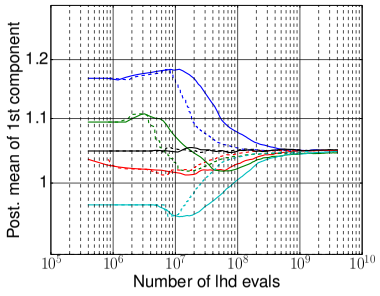
(b) log Fraction $\log_{10}(L/n)$ of number of likelihood evals

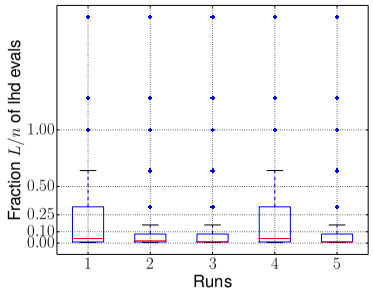
Figure 10: Results of 10 000 iterations of confidence MH with a single Taylor proxy, applied to a synthetic logistic regression dataset vs. n

8.1.3 The *covtype* dataset



We consider the dataset *covtype.binary*[3] described in Collobert et al. (2002). The dataset consists of 581,012 points, of which we pick $n = 400,000$ as a training set, following the maximum training size in Collobert et al. (2002). The original dimension of the problem is 54, with the first 10 attributes being quantitative. To illustrate our point without requiring a more complex sampler than MH, we only consider the 10 quantitative attributes. We use the preprocessing and Cauchy prior recommended by Gelman et al. (2008).

We run 5 independent chains for 10 000 iterations, dropping proxies every 10 iterations as explained in Section 7.2.2. We obtain a Gelman-Rubin statistic of 1.01 (Robert and Casella, 2004, Section 12.3.4), which suggests the between-chain variance is low enough that we can stop sampling.



We estimate the number of likelihood evaluations L_k at MH iteration k as follows. First, note that –dropping proxies or not– on a regular iteration where the proxy is not necessarily recomputed, L_k can take values up to $2n$, unlike MH, which can store the evaluation of the likelihood at the current state of the chain from one iteration to the next, and thus only requires n likelihood evaluations per iteration. Second, at an iteration where the proxy is recomputed, the whole data has to be read anyway, so that we choose here to perform a normal MH iteration. This requires the maximum $2n$ likelihood evaluations, Assuming the cost of the likelihood evaluation is the bottleneck, we neglect here the additional cost of computing the proxy itself, and only report $L_k = 2n$ when the proxy is recomputed. Third, whenever we compute the full likelihood at a state of the chain, we store it until the chain leaves that state, similarly to any implementation of MH. Thus, at an iteration that follows a full read of the data, i.e. $L_{k-1} = 2n$, we only count the likelihood evaluations of the proposed state.

We summarize the results in Figure 11. All runs use on average 27 to 42% of n likelihood evaluations per iteration. Since we compute the proxy every $\alpha = 10$ iterations, there is a necessary $2 \times 10 = 20\%$ of n that is due to recomputing the proxy. We manually assessed

3. available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html`

(a) Posterior mean vs. iteration number

(b) Fraction of likelihood evaluations

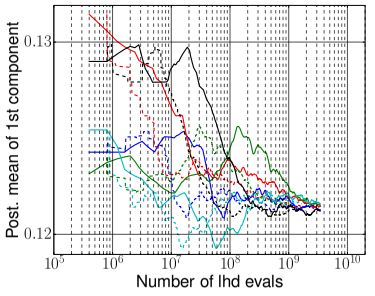
Figure 11: Results of 5 runs of a confidence sampler with Taylor proxies dropped every 10 iterations, applied to logistic regression on *covtype*. In Figure 11(a), a solid line corresponds to the online posterior mean of the 1st component of the chain vs. the budget of MH, while a dashed line of the same color corresponds to the budget of the confidence sampler.

the value of α, and recomputing the proxy less often increases the average number of likelihood evaluations (not shown). Thanks to these forced 20%, the rest of the iterations are considerably cheaper than n, since 50% of the iterations require less than 5% of the dataset, as shown in Figure 11(b). Relatedly, although subsampling implies a forced $2n$ likelihood evaluations to start and thus shows an initial delay in Figure 11(a), it quickly catches up and converges faster. The gains are two- or threefold, which is of limited overall practical interest, but we know from Section 7.2.3 and Figure 10(b) that increasing n will also improve the gain.

8.2 Gamma linear regression

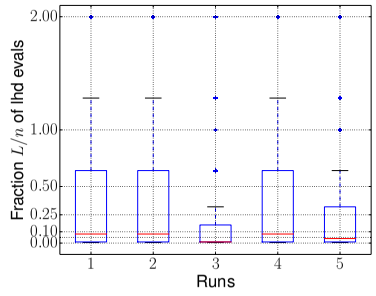
8.2.1 A Taylor proxy for gamma regression

In gamma regression, the nonnegative response y is assumed to be gamma-distributed



$$y \sim \Gamma\left(\kappa, \frac{e^{x^T\theta}}{\kappa}\right)$$

where $\Gamma(\kappa, s)$ is the gamma distribution with shape parameter κ and scale parameters s. Assuming κ is known, the log likelihood is thus given by



$$\log p(y|x,\theta) \propto -\kappa y e^{-\theta^T x} - \kappa\theta^T x$$

up to an additive constant, so that

$$\nabla \log p(y|x,\theta) = \kappa\left(y e^{-x^T\theta} - 1\right) x,$$

(a) Posterior mean vs. iteration number

(b) Fraction of likelihood evaluations

Figure 12: Results of 5 runs of a confidence sampler with Taylor proxies dropped every 10 iterations, applied to gamma linear regression on *covtype*. In Figure 12(a), a solid line corresponds to the online posterior mean of the 1st component of the chain vs. the budget of MH, while a dashed line of the same color corresponds to the budget of the confidence sampler.

$$\mathrm{Hess}(\log p(y|x,\theta)) = -\kappa y e^{-x^T\theta} x x^T$$

and

$$\frac{\partial}{\partial\theta^{(j)}\partial\theta^{(k)}\partial\theta^{(l)}} \log p(y|x,\theta) = \kappa y e^{-x^T\theta} x^{(j)} x^{(k)} x^{(l)}.$$

Furthermore, we can bound

$$\left|\frac{\partial}{\partial\theta^{(j)}\partial\theta^{(k)}\partial\theta^{(l)}} \log p(y|x,\theta)\right| \leq \kappa \max_{i=1}^{n} |y| \exp\left(-\min_{i=1}^{n} x_i^T\theta\right) \max_{1\leq i\leq n} \|x_i\|_\infty^3.$$

The Taylor proxies of Section 7.2.1 can thus be applied.

8.2.2 The *covtype* dataset

As an application, we consider the *covtype* dataset again and regress the nonnegative feature "horizontal distance to nearest wildfire ignition" onto the other quantitative features. We run 5 independent chains for 10 000 iterations, dropping proxies every 10 iterations as explained in Section 7.2.2. We obtain a Gelman-Rubin statistic of 1.001, which again suggests we can stop sampling. We estimate the evaluation budget as in Section 8.1.3. We summarize the results in Figure 12.

All runs use on average 33 to 54% of n likelihood evaluations per iteration, from which $2\times 10 = 20\%$ are due to recomputing the proxy every 10 iterations. Recomputing the proxy less often increases the average number of likelihood evaluations (not shown). Thanks to these forced 20% the rest of the iterations are considerably cheaper than n, since, as in Section 8.1.3, 50% of the iterations require less than 10% of the dataset. Relatedly, and

similarly to the logistic regression task in Section 8.1.3 subsampling converges two or three times faster in this example. Again, this is a proof of concept that subsampling works, and we know from Section 7.2.3 and Figure 10(b) that increasing n will also improve the gain.

9. Discussion

We have reviewed recent advances in applying MCMC to tall datasets. Divide-and-conquer approaches have yet to solve the recombination problem, i.e. how to obtain a *meaningful* distribution in a *stable* manner from the output of individual chains on a growing number of smaller datasets. Subsampling approaches face different issues, namely that of approaching the right target at a known speed, and of keeping the overall budget in terms of likelihood evaluations per iteration low.

We have proposed an alternative original subsampling approach and have shown that, under strong ergodicity assumptions on the original MH sampler, our algorithm samples from a controlled approximation of the posterior distribution of interest. While these strong assumptions are rarely satisfied in practice, our experiments suggest that our results extend to more general scenarios. Recent bounds by Rudolf and Schweizer (2015) support this, extending the results of Mitrophanov (2005) on perturbations of uniformly ergodic Markov chains to geometrically ergodic chains, and explicitly including our algorithm.

In terms of scaling, our methodology is able to lower the natural cost of $\mathcal{O}(n)$ subsamples per iteration to as low as $\mathcal{O}(1)$ in favourable scenarios, while providing MCMC estimates whose asymptotic variance is of order $\mathcal{O}(1)$. However, we have yet only observed these dramatic gains in contexts where the Bernstein-von Mises approximation is already excellent. So although our algorithm improves on other proposed subsampling approaches, the benefits of such an approach appear limited. Indeed, computing the Bernstein-von Mises approximation for regular models can be typically achieved in only a couple of passes over the data, using for example stochastic gradient to compute the maximum likelihood estimator, and the observed information matrix at this point to estimate the Hessian.

Since the first preprint of the current paper, our Taylor-based control variates have become a popular idea for tall data (Quiroz et al., 2014; Bierkens et al., 2016; Giles et al., 2016). Similarly to our methodology, the algorithms in these references allow to lower the cost per iteration to $\mathcal{O}(1)$ in favourable scenarios and provide MCMC estimates whose asymptotic variance is of order $\mathcal{O}(1)$. However, they similarly only appear to work well when the Bernstein-von Mises approximation is excellent, their performance degrading quickly otherwise (Galbraith, 2016). A similar problem arises with other techniques which implicitly use some form of control variates, such as (MacLaurin and Adams, 2014).

Hence, further work should focus on demonstrating the applicability of subsampling approaches to cases where it is either difficult to compute Bernstein-von Mises even if it is a good approximation (Chernozhukov and Hong, 2003), or – more importantly – cases where n is not large enough that Bernstein-von Mises yields a good approximation and cases where the posterior does not concentrate.

Define

$$S_n = e^{na(\theta)} \left[1 + \sum_{k=1}^{n} \frac{1}{k!} \prod_{j=1}^{k} D_j^* \right]. \tag{33}$$

By construction and the monotone convergence theorem, $\mathbb{E}S_n \to \mathbb{E}S = e^{n\ell(\theta)}$, where

$$S = e^{na(\theta)} \left[1 + \sum_{k=1}^{\infty} \frac{1}{k!} \prod_{j=1}^{k} D_j^* \right].$$

From (Rhee and Glynn, 2015, Theorem 1), the second moment of Y is

$$\mathbb{E}Y^2 = \sum_{k=0}^{\infty} \frac{1}{\mathbb{P}(N \geq k)} \left[\mathbb{E}(S - S_{k-1})^2 - \mathbb{E}(S - S_k)^2 \right],$$

with the convention $S_{-1} = 0$ and $S_0 = e^{na(\theta)}$. We note that

$$(S - S_k)^2 = e^{2na(\theta)} \sum_{p=k+1}^{\infty} \sum_{q=k+1}^{\infty} \frac{1}{p!q!} \prod_{u=1}^{p} D_u^* \prod_{v=1}^{q} D_v^*.$$

Hence

$$\begin{aligned}
e^{-2na(\theta)} &\left[\mathbb{E}(S - S_{k-1})^2 - \mathbb{E}(S - S_k)^2 \right] \\
&= \frac{1}{k!k!} \mathbb{E} \prod_{u=1}^{k} D_u^* \prod_{v=1}^{k} D_v^* + 2 \sum_{j=k+1}^{\infty} \frac{1}{k!j!} \mathbb{E} \prod_{u=1}^{j} D_u^* \prod_{v=1}^{k} D_v^* \\
&= \frac{1}{k!k!} \left[n^2 \sigma_t(\theta)^2 + n^2 (\ell(\theta) - a(\theta))^2 \right]^k \\
&\quad + 2 \sum_{j=k+1}^{\infty} \frac{1}{k!j!} \left[n(\ell(\theta) - a(\theta)) \right]^{j-k} \left[n^2 \sigma_t(\theta)^2 + n^2 (\ell(\theta) - a(\theta))^2 \right]^k \\
&\geq \frac{\left[n^2 \sigma_t(\theta)^2 + n^2 (\ell(\theta) - a(\theta))^2 \right]^k}{k!k!}.
\end{aligned}$$

Now, since $k!k! \leq 4^{-k}(2k+1)!$, letting

$$A_n \triangleq (1+\epsilon)[n^2\sigma_t(\theta)^2 + n^2(\ell(\theta)-a(\theta))^2],$$

and by definition of N, it comes

$$\begin{aligned}
\frac{\mathrm{Var}Y}{e^{2n\ell(\theta)}} &\geq e^{-2n(\ell(\theta)-a(\theta))}\sum_{k=0}^{\infty}\frac{[2\sqrt{A_n}]^{2k}}{(2k+1)!} - 1 \\
&= \frac{e^{-2n(\ell(\theta)-a(\theta))}}{2\sqrt{A_n}}\sinh(2\sqrt{A_n}) - 1 \\
&= \frac{e^{-2n(\ell(\theta)-a(\theta))}}{4\sqrt{A_n}}\left[e^{2\sqrt{A_n}} - e^{-2\sqrt{A_n}}\right] - 1 \\
&= \frac{e^{-2n(\ell(\theta)-a(\theta))+2n\sqrt{(1+\epsilon)[\sigma_t(\theta)^2+(\ell(\theta)-a(\theta))^2]}}}{n\sqrt{(1+\epsilon)[\sigma_t(\theta)^2+(\ell(\theta)-a(\theta))^2]}} + \mathcal{O}(1).
\end{aligned}$$

Appendix B: Proof of Proposition 2

We write

$$\begin{aligned}
\mathrm{Var}_z\left[\sum_{i=1}^{n}\log p(x_i|\theta,z_i)\right] &= \sum_{i=1}^{n}\left[\mathbb{E}\log^2 p(x_i|\theta,z_i) - (\mathbb{E}\log p(x_i|\theta,z_i))^2\right] \\
&= \sum_{i=1}^{n}\left[(1-I_\theta)\log^2\left(\frac{e^{\ell_i(\theta)}-e^{b_i(\theta)}}{1-I_\theta}\right) + I_\theta\log^2\left(\frac{e^{b_i(\theta)}}{I_\theta}\right)\right] \\
&\quad - \left[(1-I_\theta)\log\left(\frac{e^{\ell_i(\theta)}-e^{b_i(\theta)}}{1-I_\theta}\right) + I_\theta\log\left(\frac{e^{b_i(\theta)}}{I_\theta}\right)\right]^2 \\
&= I_\theta(1-I_\theta)\sum_{i=1}^{n}\left[\log\left(\frac{e^{\ell_i(\theta)}-e^{b_i(\theta)}}{1-I_\theta}\right) - \log\left(\frac{e^{b_i(\theta)}}{I_\theta}\right)\right]^2 \\
&= I_\theta(1-I_\theta)\sum_{i=1}^{n}\log^2\left[\frac{I_\theta}{1-I_\theta}\left(e^{\ell_i(\theta)-b_i(\theta)}-1\right)\right].
\end{aligned}$$

Abstract

There is a large literature explaining why AdaBoost is a successful classifier. The literature on AdaBoost focuses on classifier margins and boosting's interpretation as the optimization of an exponential likelihood function. These existing explanations, however, have been pointed out to be incomplete. A random forest is another popular ensemble method for which there is substantially less explanation in the literature. We introduce a novel perspective on AdaBoost and random forests that proposes that the two algorithms work for similar reasons. While both classifiers achieve similar predictive accuracy, random forests cannot be conceived as a direct optimization procedure. Rather, random forests is a self-averaging, interpolating algorithm which creates what we denote as a "spiked-smooth" classifier, and we view AdaBoost in the same light. We conjecture that both AdaBoost and random forests succeed because of this mechanism. We provide a number of examples to support this explanation. In the process, we question the conventional wisdom that suggests that boosting algorithms for classification require regularization or early stopping and should be limited to low complexity classes of learners, such as decision stumps. We conclude that boosting should be used like random forests: with large decision trees, without regularization or early stopping.

Keywords: AdaBoost, random forests, tree-ensembles, overfitting, classification

1. Introduction

In the "boosting" approach to machine learning, a powerful ensemble of classifiers is formed by successively refitting a weak classifier to different weighted realizations of a data set. This intuitive procedure has seen a tremendous amount of success. In fact, shortly, after its introduction, in a 1996 NIPS conference, Leo Brieman crowned AdaBoost (Freund and Schapire, 1996) (the first boosting algorithm) the "best off-the-shelf classifier in the world (Friedman et al., 2000)." AdaBoost's early success was immediately followed by efforts to explain and recast it in more conventional statistical terms. The statistical view of boosting holds that AdaBoost is a stage-wise optimization of an exponential loss function (Friedman et al., 2000). This realization was especially fruitful leading to new "boosting machines" (Friedman, 2001; Ridgeway, 2006) that could perform probability estimation and regression as well as adapt to different loss functions. The statistical view, however, is not the only explanation for the success of AdaBoost. The computer science literature has found generalization error guarantees using VC bounds from PAC learning theory and margins (Guestrin, 2006). While some research has cast doubt on the ability of any one of these to fully account for the performance of AdaBoost they are generally understood to be satisfactory (Schapire, 2013).

This paper parts with traditional perspectives on AdaBoost by concentrating our analysis on the implications of the algorithm's ability to perfectly fit the training data in a wide variety of situations. Indeed, common lore in statistical learning suggests that perfectly fitting the training data must inevitably lead to "overfitting." This aversion is built into the DNA of a statistician who has been trained to believe, axiomatically, that data can always be decomposed into signal and noise. Traditionally, the "signal" is always modeled smoothly. The resulting residuals represent the "noise" or the random component in the data. The statistician's art is to walk the balance between the signal and the noise, extracting as much signal as possible without extending the fit to the noise. In this light, it is counterintuitive that any classifier can ever be successful if every training example is "interpolated" by the algorithm and thus fit without error.

The computer scientist, on the other hand, does not automatically decompose problems into signal and noise. In many classical problems, like image detection, there is no noise in the classical sense. Instead there are only complex signals. There are still residuals, but they do not represent irreducible random errors. If the task is to classify images into those with cats and without, the problem is hard not because it is noisy. There are no cats wearing dog disguises. Consequently, the computer scientist has no dogmatic aversion to interpolating training data. This was the breakthrough.

It is now well-known that interpolating classifiers can work, and work well. The AdaBoost classifier created a huge splash by being better than its established competitors (for instance, CART, neural networks, logistic regression) (Breiman, 1998) and substantively better than the technique of creating an ensemble using the bootstrap (Breiman, 1996). The statistics community was especially confounded by two properties of AdaBoost: 1) interpolation (perfect prediction in sample) was achieved after relatively few iterations, 2) generalization error continues to drop even after interpolation is achieved and maintained.

The main point of this paper is to demonstrate that AdaBoost and similar algorithms work not in spite, but because of interpolation. To bolster this claim, we will draw a constant analogy with random forests (Breiman, 2001), another interpolating classifier. The random forests algorithm, which is also an ensemble-of-trees method, is generally regarded to be among the very best commonly used classifiers (Manuel Fernández-Delgado and Amorim, 2014). Unlike AdaBoost, for which there are multiple accepted explanations, random forest's performance is much more mysterious since traditional statistical frameworks do not necessarily apply. The statistical view of boosting, for example, cannot apply to random forests since the algorithm creates decision trees at random and then averages the results—there is no stage-wise optimization. In this paper, we will put forth the argument that both algorithms are effective for the same reason. We consider AdaBoost and random forests as canonical examples of "interpolating classifiers," which we define to be a classifier's al-

gorithmic property of fitting the training data completely without error. Each of these interpolating classifiers also exhibits a self-averaging property. We attempt to show that these two properties together make for a classifier with low generalization error. While it is easy to see that random forests has both of these mechanisms by design, it is less clear that this is true for AdaBoost.

It is worth noting that Breiman noticed the connection between random forests and AdaBoost as well, although his notion of a random forest was more general, including other types of large ensembles of randomly grown trees (Breiman, 2001). In his 2001 *Random Forests* paper, he conjectured that the weights of AdaBoost might behave like an ergodic dynamic system, converging to an invariant distribution. When run for a long time, the additional rounds of AdaBoost were equivalent to drawing trees randomly grown according to this distribution, much like a random forest. Recent work has followed up on this idea, proving that the weights assigned by AdaBoost do indeed converge to a invariant distribution [1] (Belanich and Ortiz, 2012). In this work, the authors also show that functions of these weights, such as the generalization error and margins, also converge. This work certainly complements ours, but we focus on the similarity between AdaBoost and random forests through the lens of the type of decision surfaces both classifiers produce, and ability of both algorithms to achieve zero error on the training set.

One of our key contributions will be to present a decomposition of AdaBoost as the weighted sum of interpolating classifiers. Another contribution will be to demonstrate the mechanism by which interpolation combined with averaging creates an effective classifier. It turns out that interpolation provides a kind of robustness to noise: if a classifier fits the data extremely locally, a "noise" point in one region will not affect the fit of the classifier at a nearby location. When coupled with averaging, the result is that the fit stabilizes at regions of the data where there is signal, while the influence of noise points on the fit becomes even more localized. It will be easy to see this point holds true for random forests. For AdaBoost, it is less clear, however, and a decomposition of AdaBoost and simulation results in Section 4 will demonstrate this crucial point. We will observe that the error of AdaBoost at test points near noise points will continue to decrease as AdaBoost is run for more iterations, demonstrating the localizing effect of averaging interpolating classifiers.

We will begin in Section 2 by critiquing some of the existing explanations of AdaBoost. In particular, we will discuss at length some of the shortcomings of the statistical optimization view of AdaBoost. In Section 3, we will discuss the merits of classification procedures that interpolate the training data, that is, that fit the training data set with no error. The main conclusion from this section is that interpolation, done correctly, can provide robustness to a fit in the presence of noise. This discussion will be augmented with simulations discussing the performance of random forests, AdaBoost, and other algorithms in a noisy environment. We will then derive our central observation in Section 4, namely that AdaBoost can be decomposed as a sum of classifiers, each of which fits the training data perfectly. The implication from this observation is that for the best performance, we should run AdaBoost for many iterations with deep trees. The deep trees will allow the component classifiers to interpolate the data, while a large number of iterations will lend to a bagging

1. More specifically, they consider the so called "Optimal AdaBoost" algorithm, which is assume to pick the base classifier with lowest weighted error at each round. They show that the per round average of any measurable function of the training weights converges under mild conditions.

effect. We will then demonstrate this intuition in a real data example in Section 5. Finally, we conclude with a brief discussion in Section 6.

2. Competing Explanations for the Effectiveness of Boosting

In this section we will present an overview of some of the most popular explanations for the success of boosting, with analysis of both the strengths and weaknesses of each approach. Our emphasis will focus on the margins view of boosting and the statistical view of boosting, each of which has a large literature and has led to the development of variants of boosting algorithms. For a more extensive review of the boosting literature, one is well-advised to consult Schapire and Freund (2012).

Before we begin, we will briefly review the AdaBoost algorithm not only to refresh the reader's mind, but also to establish the exact learning algorithm this paper will consider, as there are many variants of AdaBoost. To this end, the reader is invited to review Algorithm 1. In our setting, we are given N training points $(\mathbf{x}_i, y_i)$ where $\mathbf{x}_i \in \mathcal{X}$ and $y_i \in \{-1, +1\}$. On round m, where $m = 1, \ldots, M$, we fit a weak classifier $G_m(\mathbf{x})$ to a version of the data set reweighted by some weighting vector $\mathbf{w}_m$. We then calculate the weighted misclassification rate of our chosen learner, and update the weighting measure used in the next round, $\mathbf{w}_{m+1}$. The final classifier is output as the sign of a weighted linear combination of classifiers produced from each stage of the algorithm. In practice, one sometimes limits the number of rounds of boosting as a form of regularization. We will discuss this point more in the next section, and challenge its usefulness in later parts of the paper.

Algorithm 1: AdaBoost Hastie et al. (2009)

1. Initialize the observation weights $w_i = \dfrac{1}{N},\ i = 1, 2, \ldots, N.$
2. For $m = 1$ to M:
   (a) Fit a classifier $G_m(\mathbf{x})$ to the training data using weights w_i.
   (b) Compute $\text{err}_m = \dfrac{\sum_{i=1}^{N} w_i I\left(y_i \neq G_t\left(\mathbf{x}_i\right)\right)}{\sum_{i=1}^{N} w_i}$.
   (c) Compute $a_m = \log\left(\dfrac{1 - \text{err}_t}{\text{err}_t}\right)$.
   (d) Set $w_i \leftarrow w_i \cdot \exp\left(a_t \cdot I\left(y_i \neq G_t\left(\mathbf{x}_i\right)\right)\right)$
   (e) Set $f_i(\mathbf{x}) = \sum_{m=1}^{M} a_m G_m\left(\mathbf{x}\right)$
3. Output $f(\mathbf{x}) = \text{sign}\left(f_M(\mathbf{x})\right)$

2.1 Margin View of Boosting

Some of the earliest attempts to understand AdaBoost's performance predicted that its generalization error would increase with the number of iterations: as AdaBoost is run for

more rounds, it is able to fit the data increasingly well which should lead to overfitting. However, in practice we observe that running boosting for many rounds does not overfit in most cases. One of the first attempts to resolve this paradox was explored by Schapire et al. (1998), who focused on the *margins* of AdaBoost. The margins can be thought of as a measure of how confident a classifier is about how it labels each point, and one would hypothetically desire to produce a classifier with margins as large as possible. Schapire et al. (1998) proved that AdaBoost's generalization error decreases as the size of the margins increase. Indeed, in practice one observes that as AdaBoost is run for many iterations, test error decreases while the size of the empirical margins increase. In fact, recent research has demonstrated that AdaBoost can be reformulated exactly as mirror descent applied to the problem of maximizing the smallest margin in the training set under suitable separability conditions (Freund et al., 2013).

One could take these observations to suggest that a more effective algorithm might be designed to explicitly optimize margins. However, one can find evidence against this hypothesis in Breiman's *arc-gv* algorithm (Breiman, 1999). Breiman designed the *arc-gv* algorithm to maximize the minimum margin in a data set, and he found that this algorithm actually had worse generalization error than AdaBoost. Moreover, he developed generalization error bounds based on the minimum margin of a classifier which were tighter than those established by Shapire, casting doubt on the existing margin explanation. Other algorithms designed to maximize margins, such as *LP-Boost* have also been found to perform worse than AdaBoost in practice (Wang et al., 2011). Critics of these supposed counterexamples to the margin view of boosting note that AdaBoost's success likely depends on the entire distribution of margins on the data, not just the smallest margin. More recent work has improved upon the Breiman's generalization bound by taking into account other aspects of the margin that more closely reflect its distribution, adding new life to the margin explanation of AdaBoost (Gao and Zhou, 2013). While the margin explanation of AdaBoost is certainly intuitive, its role in producing low generalization error is still an area of active research.

2.2 Statistical Optimization View of Boosting

Friedman et al. (2000) take great strides to clear up the mystery of boosting to provide statisticians with a statistical view of the subject. The heart of their article is the recasting of boosting as a statistically familiar program for finding an additive model by means of a forward stage-wise approximate optimization of an exponential criterion. In short, this view places boosting firmly in classical statistical territory by clearly defining it as a procedure to search through the space of convex combinations of *weak* learners or *base* classifiers. This explanation has been widely assimilated and has reappeared in the statistical literature as well as in a plethora of computer science articles. Subsequent to the seminal publication of Friedman et al. (2000) there has been a flurry of activity dedicated to theoretical analysis of the algorithm. This was made possible by the identification of boosting as optimization, which therefore admits of a mathematically tractable representation. Research on the optimization properties of AdaBoost and the exponential loss function is still an active area of research, see Mukherjee et al. (2013), for example.

Although the statistical optimization perspective of AdaBoost is surely interesting and informative, there remain problems. First, we observe that the fact that AdaBoost minimizes an exponential loss may not alone account for its performance as a classifier. Wyner (2003) introduces a variant of AdaBoost called Beta-Boost which is very similar to AdaBoost except that by design the exponential loss function is constant throughout the iterations. Despite this, Beta-Boost was able to demonstrate similar performance to AdaBoost on simulated data sets. Furthermore, among many similar examples in the literature, Mease and Wyner (2008) present a simulation example in which the the exponential loss is monotonically increasing with the number of iterations of AdaBoost on a test set, while the generalization error decreases. In this example, the value of the exponential loss is uninformative about how well the classifier generalizes. Freund et al. (2013) also provide evidence to this end. They conduct an experiment that compares AdaBoost to two AdaBoost variants that minimize the exponential loss function at differing rates: one performs the minimization very quickly through gradient descent, while the other performs the minimization quite slowly. They find that AdaBoost performed significantly better than these two competitors, suggesting that AdaBoost's strong performance cannot be tied exclusively to its action on the exponential loss function.

We also contend that some of the mathematical theory connected with the statistical optimization view of boosting has a disconnect with the types of boosting algorithms that work in practice. The optimization theory of boosting insists that overfitting can be avoided by requiring the set of weak learners, to be just that: *weak*. Bühlmann and Yu (2003) argues that one can avoid overfitting by employing regularization with weak base learners. However, empirical evidence points to quite the opposite: boosting deep trees for many iterations tends to produce a better classifier than boosted stumps with regularization (Mease and Wyner, 2008). The use of early-stopping as a form of regularization has also been called into question (Mease and Wyner, 2008). The thrust of our paper will be to demonstrate why we *should* actually expect boosting with deep trees run for many iterations to have better generalization error. Recent work also suggests that boosting low complexity classifiers may not be able to achieve good accuracy in difficult classification tasks such as speech recognition or image recognition (Cortes et al., 2014). This paper proposes an algorithm called "DeepBoost" which encourages boosting high complexity base classifiers—such as very deep decision trees—but in a "capacity-conscious" way. One last problem with theory associated with the statistical view of boosting is that by its very nature it suggests that we should be able to extract conditional class probability estimates from the boosted fit, as the procedure is apparently maximizing a likelihood function. Mease and Wyner (2008), however, point out a number of examples where the implied conditional class estimates from the boosting fit diverge to zero and one. While boosting appears to do an excellent job as a classifier, it apparently fails to estimate probability quantiles correctly.

We can now summarize the main empirical contradictions with existing theoretical explanations of boosting, which motivates the view we present in this paper:

1. Boosting works well, perhaps best in terms of performance if not efficiency, with "strong learners" like C4.5 and CART (Niculescu-Mizil and Caruana, 2005).

2. The value of exponential loss does not always bear a clear relationship to generalization error (Mease and Wyner, 2008).

3. The optimization theory offers no explanation as to why the training error can be zero, yet the test error continues to descend (Freund and Shapire, 2000)

This paper will squarely depart from the statistical optimization view by asserting that AdaBoost may be best thought of as a (self) smoothed, interpolating classifier. We will see that unlike the statistical optimization view, this perspective suggests that for best performance once should run many iterations of AdaBoost with deep trees. This will allow us to draw a number of analogies between AdaBoost and random forests. A key component to this argument will consist of explaining the success of interpolating classifiers in noisy environments. We will pursue this line of thought in the following section.

3. Interpolating Classifiers

Algorithm 2: Random Forests Hastie et al. (2009)

1. For $b = 1$ to B:
   (a) Draw a bootstrap sample $\mathbf{X}^*$ of size N from the training data
   (b) Grow a decision tree T_b to the data $\mathbf{X}^*$ by doing the following recursively until the minimum node size n_{min} is reached:
      i. Select m of the p variables
      ii. Pick the best variable/split-point from the m variables and partition
2. Output the ensemble $\{T_b\}_b^B$

Let $\hat{C}_b(\mathbf{x}^*)$ be predicted class of tree T_b. Then $\hat{C}_{rf}^B(\mathbf{x}^*) = \text{majority vote}\{\hat{C}_b(\mathbf{x}^*)\}_1^B$.

It is a widely held belief by statisticians that if a classifier interpolates all the data, that is, it fits all the training data without error, then it cannot be consistent and should have a poor generalization error rate. In this section, we demonstrate that there are interpolating classifiers that defy this intuition: in particular, AdaBoost and random forests will serve as leading examples of such classifiers. We argue that these classifiers achieve good out of sample performance by maintaining a careful balance between the complexity required to perfectly match the training data and a general semi-smoothness property. We begin with a quick review of the random forests classifier, which will be in constant analogy with AdaBoost.

3.1 Random Forests

Random forests has gained tremendous popularity due to robust performance across a wide range of data sets. The algorithm is often capable of achieving best-in-class performance with respect to low generalization error and is not highly sensitive to choice of tuning parameters, making it the off-the-shelf tool of choice for many applications.

Algorithm 2 reviews the procedure for constructing a random forests model. Note that in many popular implementations, such as `R` implementation `randomForest` Liaw and Wiener (2002) built from Breiman's CART software, n_{min} is set to one for classification. This implies that each decision tree is designed to be grown to maximal depth and therefore

necessarily interpolates the data in its bootstrap sample (assuming as least one continuous predictor). This results in each tree being a low bias but high variance estimator. Variance is then reduced by averaging across trees, resulting in a "smoothing" of the estimated response surface. The random predictor selection within each tree further reduces variance by lowering the correlation across the trees. The final random forest classifier still fits the entire training data set perfectly, at least with very high probability. To see this is true, consider any given training point. As the number of trees increases, with probability close to one, that point will be present in the majority of the bootstrap samples used to fit the trees in the forest. Thus the point will get the correct training set label when the votes are tabulated to determine the final class label.

We wish to emphasize that despite its success, random forests is not directly optimizing any loss function across the entire ensemble; each tree is grown independently of the other trees. While each tree may optimize a criteria such as the Gini index, the full ensemble is not constructed in any optimization-driven fashion such as is the case for AdaBoost. While there has been recent theoretical work describing the predictive surface of random forests (Wager and Walther, 2015), the analysis required unnatural assumptions that are hard to justify in practice (such as the growth rate of minimum leaf size). Rather, we postulate that the success of the algorithm is due to its interpolating nature plus the self-averaging mechanism. We next consider the implications of interpolating classifiers more broadly.

3.2 Local Robustness of Interpolating Classifiers

Let us begin with a definition of interpolation:

Definition: Let X_i be vector observations of predictor variables a let Y_i be the observed class label. A classifier $f(X)$ is said to be an *interpolating* classifier if for every training set example, the classifier assigns the correct class label; that is for every i, $f(X_i) = Y_i$.

The term "interpolation" is likely jarring for some readers. In many contexts, one often thinks about interpolating a set of points with classically smooth functions, such as polynomial splines. However, strictly speaking, there are many other ways that one might interpolate a set of points—through the fit of an AdaBoost classifier, for instance! Since the notion of fitting a set of points without error is central to this paper, and since the common definition of interpolation does not preclude the kinds of fits we consider, we felt it appropriate to proceed with the term.

Many statisticians are not comfortable with classifiers that interpolate the training data: common wisdom suggests that any classifier which fits the training data perfectly must have poor generalization error. Indeed, one of the first interpolating classifiers that might come to one's mind, the one-nearest neighbor, can be shown to be inconsistent and have poor generalization error in environments with noise. Specifically, Cover and Hart (1967) have shown that the asymptotic generalization error for the one-nearest neighbor classifier is at least as large as the Bayes error rate. However, the claim that all interpolating classifiers overfit is problematic, especially in light of the demonstrated success of classifiers that perfectly fit the training data, such as random forests.

One of our key insights reverses the common intuition about classifiers: interpolation can prevent overfitting. An interpolated classifier, if sufficiently local, minimizes the influence of noise points in other parts of the data. In order to make this point conceptually clear, it is helpful to put ourselves in familiar territory with a regression example.

Suppose we are trying to predict a continuous response y based on real-valued x observations. Let us assume that the true underlying model is $y = x + \epsilon$, where ϵ is a mixture of a point mass at zero and some heavy-tailed distribution. In other words, we'll assume that most points in a given training set reflect the true linear relationship between y and x, but a few observations will be noise points. This is analogous to the types of probability models we typically consider in classification settings, such as those found in later sections of the paper. Figure 1 shows hypothetical training data: note that the only "noise" point is found at $x = 0.4$. We then consider fitting three models to this data: two interpolating functions, given by the blue and black lines, and an ordinary regression fit given by the red line. The first thing to notice is that the two interpolating fits differ only from the true target mean model $y = x$ only at the noise point $x = 0.4$. In contrast, the fit of the regression line deviates from the underlying target over the entire range of x. The one noise point corrupted the entire fit of the regression line, while the interpolating lines were able to minimize the influence of the noise point by adapting to it only very locally. Moreover, one should note that between the two interpolating fits, the blue line interpolates more locally than the black line, and thus its overall fit is even less influenced by the noise point. This simplified example is of course meant to be didactic, but we will show throughout the rest of this paper that in practice AdaBoost and random forest do indeed produce fits similar to the blue line.

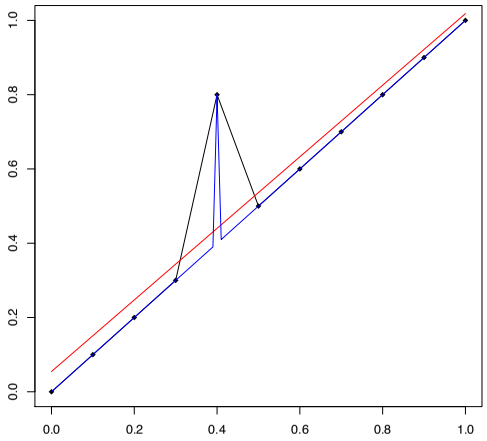

Figure 1: Three estimated regression functions with two interpolating fits (black and blue) and an ordinary least squares fit (red).

While it is conceptually clear that it is desirable to produce fits like the blue interpolating line in the previous example, one may wonder how such fits can be achieved in practice. In the classification setting, we will argue throughout this paper that this type of fit can be realized through the process of averaging interpolating classifiers. We will refer to the decision surface produced by this process as being *spiked-smooth*. The decision surface is *spiked* in the sense that it is allowed to adapt in very small regions to noise points, and it is *smooth* in the sense that it has been produced through averaging. A technical definition of a spiked-smooth decision surface would lead us too far astray. It may be helpful instead to consider the types of classifiers that do not produce a spiked-smooth decision surface, such as a logistic regression. Logistic regression separates the input space into two regions with a hyperplane, making a constant prediction on each region. This surface is not spiked-smooth because it does not allow for local variations: in large regions (namely, half-spaces), the classifier's predictions are constrained to be the same sign. Figure 2 provides a graphical illustration of this intuition.

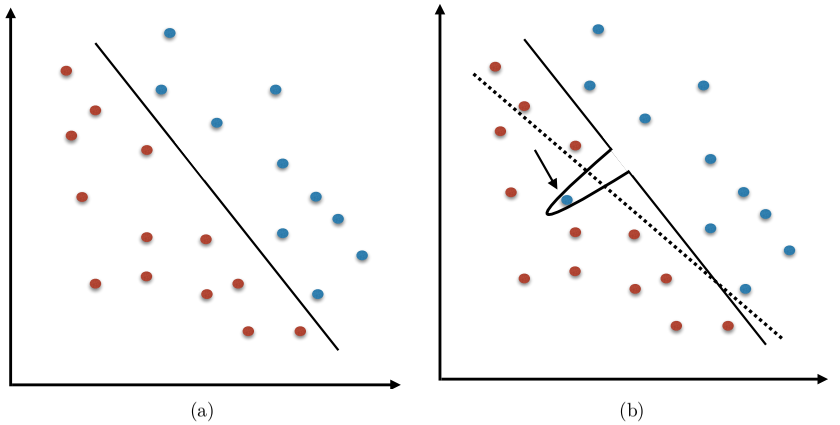

Figure 2: An illustration of the robustness to noise of interpolating classifiers. In 2a a classifier (such as a logistic regression) is fit to a set of training data, and the decision boundary produced by this classifier is shown as a solid line. In 2b, the same type of classifier is fit to the training data, except a noise point is added to the data (the blue point marked by the arrow). The one noise point shifts the entire decision boundary, which is shown as the dotted line. On the other hand, the decision boundary produced by a classifier which interpolates very locally is shown as a solid line. It is clear that this classifier is able to adapt locally to the noise point, and the overall fit does not get corrupted.

Intuitively, we expect ensembles of interpolating classifiers to generalize well because they are flexible enough to fit a complex signal, and "local" enough to prevent the undue influence of noise points. It is clear that random forests are averaged collections of interpolating classifiers, and we will show in section 4 that AdaBoost may be thought of in

the same way. Classically smooth classifiers—such as logistic regression or pruned CART trees—are forced to produce fits that are locally constant. It is harder for such classifiers to "recover" from making a mistake at a noise point since the surface of the fit will affect the fit at nearby points. Interpolating classifiers are flexible enough to make mistakes in "small regions." When averaged over many such classifiers, the influence of the noise point can be easily smoothed out. Later examples in the paper will visualize this process, and will demonstrate that the later iterations of AdaBoost have a smoothing effect which shrinks down the influence of noise points on the overall fit of the classifier.

With this discussion in mind, let us consider another conceptual example, this time in the classification setting. Suppose we have have two predictors x_1 and x_2 distributed independently and uniformly on $[0,1]^2$ and $y \in \{-1,+1\}$. Further suppose that the true conditional class probability function is

$$\mathbb{P}(\mathbf{x}) = \mathbb{P}(y=1|\mathbf{x}) = p = .75$$

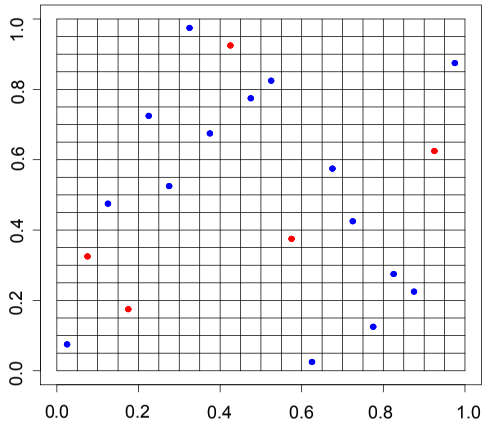
for all $\mathbf{x}$. This is a pure noise model with no signal, but in general one could view this as a subspace of a more complex model in which the $\mathbb{P}(\mathbf{x})$ function is approximately constant. Since the Bayes decision rule is to classify every point as a "+1", we would desire an algorithm that will match the Bayes rule as close as possible. Again, we stress that this closeness should be judged with respect to the population or a hold-out sample. On this training data, any interpolating classifier will necessarily differ from the Bayes rule for $1-p = 25\%$ of the points on average.

Figure 3 shows a possible sample of training data from this model of size $n = 20$. The blue points represent the "+1"'s and the red points represent the "-1"'s. There are $5/20 = 25\%$ red points. The training data was sampled according to a Latin Hypercube design using the midpoints of the squares so that the points would be evenly spaced, but that is not essential.

Figure 4 shows four hypothetical classifiers that could result from fitting boosted decision tree models to the training data in Figure 3. When decision trees are used as base learners for data with continuous predictors, it is a common convention to restrict the split points of the trees to be the midpoints of the predictors in the training data. Consequently, the classifier in each small square shown in Figure 3 will necessarily be constant throughout; this is the finest resolution of the classifier resulting from boosting decision tress assuming no sub-sampling. Thus, Figure 4a represents the interpolating classifier closest to the Bayes rule. (In these plots, pink squares represent "-1"'s and light blue squares represent "+1"'s.) Note that the interpolation is in fact quite local; the estimated function varies rapidly in the small neighborhoods of the pink squares. For such a classification rule the percentage of points in a hold-out sample that would differ from the Bayes rule (in expectation over training sets) would be $(1-p)n/n^d$ where $p = \mathbb{P}(y=1|\mathbf{x})$ and d is the dimensionality of the predictor space (for our example, $d=2$). We will present evidence later that in noisy environments boosting sufficiently large trees does actually tend to find such rules as that in Figure 4a. Interestingly, since

$$\lim_{n\to\infty}(1-p)n/n^d = 0$$

such rules are in fact consistent. This illuminates the point that interpolation does not rule out consistency. By allowing the decision boundary to be "mostly" smooth, with spikes of



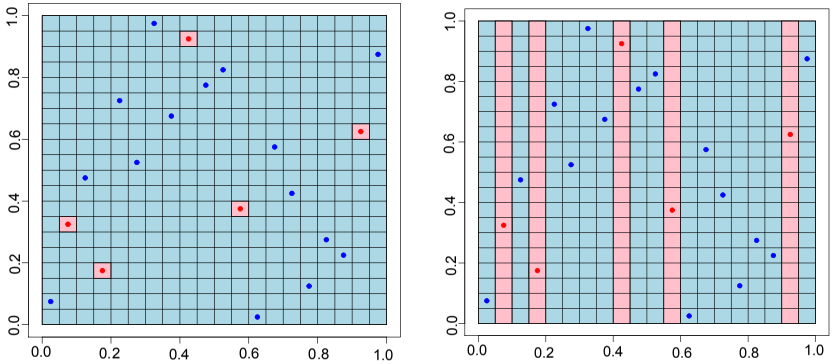


Figure 3: Training Data

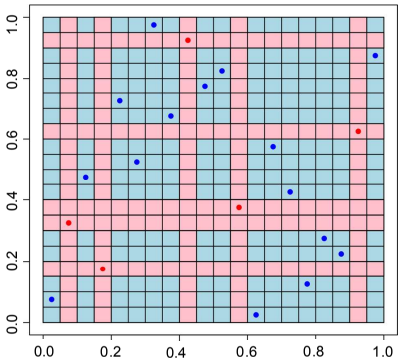
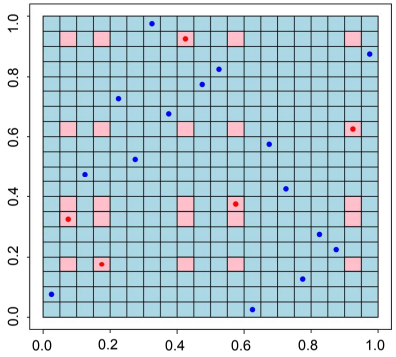
vanishing measure, it is possible to obtain consistency in the limit as $n \to \infty$, even while classifying every training point correctly. This stands in direct contrast to the conclusion of others such as Bickel et al. (2006) who have observed that the "empirical optimization problem necessarily led to rules which would classify every training set observation correctly and hence not approach the Bayes rule whatever be n."



While a classifier such as that in Figure 4a would preform well and is even consistent, many possible interpolators exist, such as the others displayed in Figure 4. Figure 4b shows the (hypothetical) result of allowing the boosting algorithm to use trees involving only x_1 and not x_2. It is interesting to note that this classifier has severely overfit, even though it is a simpler model, depending on only one of the two predictors. The classifier in Figure 4c has an even worse error rate, while the classifier in Figure 4d differs from the Bayes rule with rate $((1-p)n)^2/n^2$. This final example illustrates the type of structure and error rate that occurs when stumps are used as the weak learner. In fact, Mease and Wyner (2008) show that the additive nature of stumps results in boosted classifiers that differ from the Bayes rule at a rate of at least $(1-p)^d(1-1/d)^d$ and hence is not consistent. The reason for this is that using linear combinations of stumps does not provide enough flexibility to interpolate locally around points for which the observed class differs from the Bayes rule. In contrast, boosting larger trees, such as those grown in random forests interpolating with spikes of increasingly smaller size. Some simulations demonstrating the superior performance of larger trees over stumps are given in Mease and Wyner (2008) and here in Section 4.3.

The different classification rules represented by the four plots all interpolate the training data; however, their performances on the population vary considerably due to different degrees of local interpolations of noise. In the sequel, we will show how random forests and boosted ensembles of large trees results in classifiers that are robust to noise. The classifiers behave in noisy regions as in Figure 4a. AdaBoost and random forests average



(a) Hypothetical Classifier 1

(b) Hypothetical Classifier 2

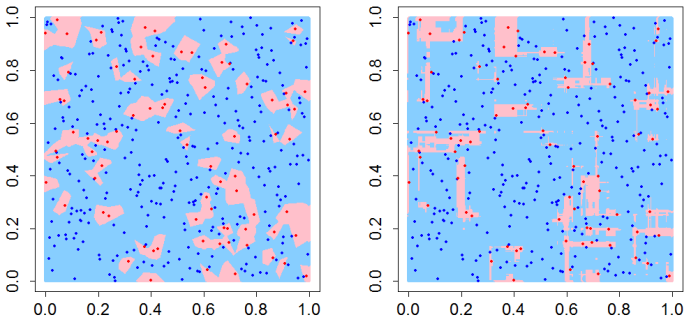
(c) Hypothetical Classifier 3

(d) Hypothetical Classifier 4

Figure 4: Four different hypothetical classifiers on a pure noise response surface where $\mathbb{P}(y = 1|\mathbf{x}) = 0.75$.

many individually overfit classifiers, similar to the one in Figure 4b. The final result is a robust classifier, that is spiked-smooth; it fits the noise but only extremely locally.

3.3 A Two-Dimensional Example with Pure Noise



We will begin with an easy to visualize example that demonstrates how fine interpolation can provide robustness in a noisy setting. In particular, we compare the performance of AdaBoost, random forests and one-nearest neighbors, which are all interpolating classifiers. We will see see graphically that AdaBoost and random forests interpolate more locally around error points in the training data than the one-NN classifier. Consequently, AdaBoost and random forests are less affected by noise points as one-NN and have lower generalization error. We will show that the self-averaging property of AdaBoost and random forests is crucial. This property will be discussed in subsequent sections.

The implementation of AdaBoost is carried out according to the algorithm described earlier. The base learners used are trees fit by the `rpart` package (Therneau and Atkinson, 1997) in `R`. The trees are grown to a maximum depth of 8, meaning they may have at most $2^8 = 256$ terminal nodes. This will be the implementation of AdaBoost we will consider throughout the remainder of this paper.

We will consider again the "pure noise" model as described in the previous section, where the probability that y is equal to $+1$ for every $\mathbf{x}$ is some constant value $p > .5$. For the training data we will take $n = 400$ points uniformly sampled on $[0, 1]^2$ according to a Latin Hypercube using the midpoints as before. For the corresponding y values in training data we will randomly choose 80 points to be -1's so that $\mathbb{P}(y = 1|\mathbf{x}) = .8$.

Figure 5 displays the results for the following: (a) one-NN, (b) AdaBoost , and (c) random forests. Regions classified as $+1$ are colored light blue and regions classified as -1 are colored pink. The training data is displayed with blue points for $y = +1$ and red points for $y = -1$. Since the Bayes' rule would be to classify every point as $+1$, we judge the performance of the classifiers by the fraction of the unit square that matches the Bayes' rule. The nearest neighbor rule in this example classifies 79% of the region as $+1$ (we expect $p = 80\%$ on average for the one-NN) while AdaBoost performs substantially better classifying 87% of the square as $+1$ after 100 iterations (which is long after the training error equals zero). This is evidence of boosting's robustness to noise discussed in the previous section. The random forests (with 500 trees) does even better, classifying 94% of the figure as $+1$. Visually, it is obvious that the random forests and AdaBoost classifier is more spiked-smooth than one-nearest neighbors, which allows it to be less sensitive to noise points. AdaBoost and random forests do in fact overfit the noise—but only the noise. They do not allow the overfit to metastasize to modestly larger neighborhoods around the errors. It is interesting to note that there seems to be a large degree of overlap between the regions classified as -1 by both the random forests and AdaBoost; one-NN does not seem to visually follow a similar pattern.

As we will see in the Section 3.6, by increasing the sample size, number of dimensions and iterations the performance is even better. The agreement with the Bayes rule for AdaBoost and random forests converge to practically 100% despite the fact that both algorithms still interpolate the training data without error.

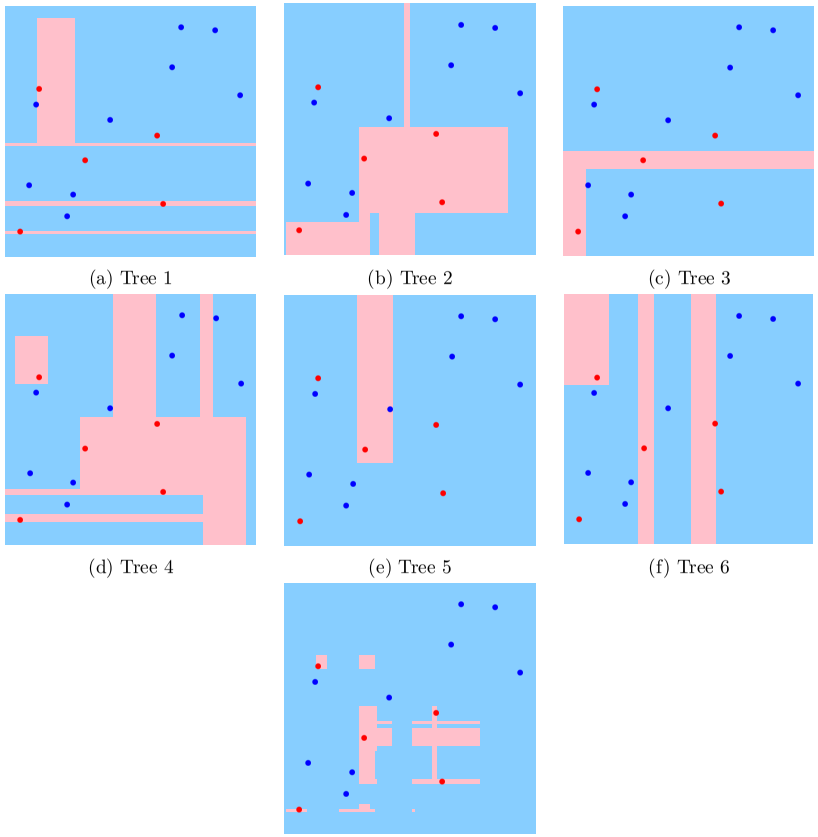
(a) one-NN (b) AdaBoost

(c) Random Forests

Figure 5: Performance of one-NN, AdaBoost, and random forests on a pure noise response surface with $\mathbb{P}(y = 1|\mathbf{x}) = .8$ and $n = 400$ training points.

3.4 A Visualization of Spiked-Smoothing

We have argued that local interpolation such as in Figure 4c is desirable, and we have demonstrated that AdaBoost and random forest classifiers can achieve such a fit in the previous simulation. Now, we turn to the crucial point of how these classifiers achieve such a fit. To this end, we will graphically display the process of spiked-smoothing in the case of the random forest classifier from the previous simulation. Each of the first six plots in Figure 6 shows the classification rule fit by different decision trees in the random forest. We have restricted each plot to a subset of the unit square to aide in visual ease. The bottom plot, Figure 6g shows the classifier created from a majority vote of each of the six random forest decision trees. As in the previous sections, the light blue regions indicate where a classifier returns $y = +1$, and the pink regions indicate where a classifier returns $y = -1$.



As before, we remark that the Bayes rule in this case would be to classify every point as $y = +1$, and so agreement with the Bayes rule in the plots below can be visualized as the proportion of the figure that is light blue. The first thing to notice is that each decision tree fails to reproduce the Bayes rule. Indeed, since each tree interpolates its bootstrap sample, each figure is bound to contain regions of pink, since most bootstrap samples will contain at least a few noise points. However, one will also notice that these regions of pink tend to be localized into thin strips (this is especially apparent in trees one, three, five, and six). In other words, noise points tend not to ruin the fit of the decision tree at nearby points.. The magic of spiked-smoothing is revealed in the classifier 6g created by a majority vote of the six decision trees. By itself, each decision tree is a poor classifier (evinced by relatively large regions of pink). However, when voted these regions of pink get shrunk down into smaller regions, indicating better agreement with the Bayes rule. One can easily imagine that if these "thin strips" were actually much wider, as in the case of fitting stumps, averaging would not be able to reduce the influence of these noise points enough. The end effect of averaging is to create a decision surface which is affected only very minimally by the noise points in the training set. A simulation in Section 4 will demonstrate that the additional iterations of AdaBoost serve to "shrink" the fit around noise points, much as the regions of pink in this example became more localized after averaging.

3.5 A Two-Dimensional Example with Signal

In light of the example in the previous section, one might note that certain non-interpolating algorithms, such as a pruned CART tree, would recover the Bayes error rate exactly. In this section, we consider an example where a much more complex classifier is required to recover the signal, yet the self-averaging property is still needed to prevent over-fitting to noise.

We consider $n = 1000$ training points sampled uniformly on $[0, 1]^2$ with the Latin Hypercube design. In this simulation, there is signal present. Inside of a circle of radius 0.4 centered in the square, the probability that $y = +1$ is set to 0.1, while the probability that $y = +1$ outside the circle is set to 0.9.

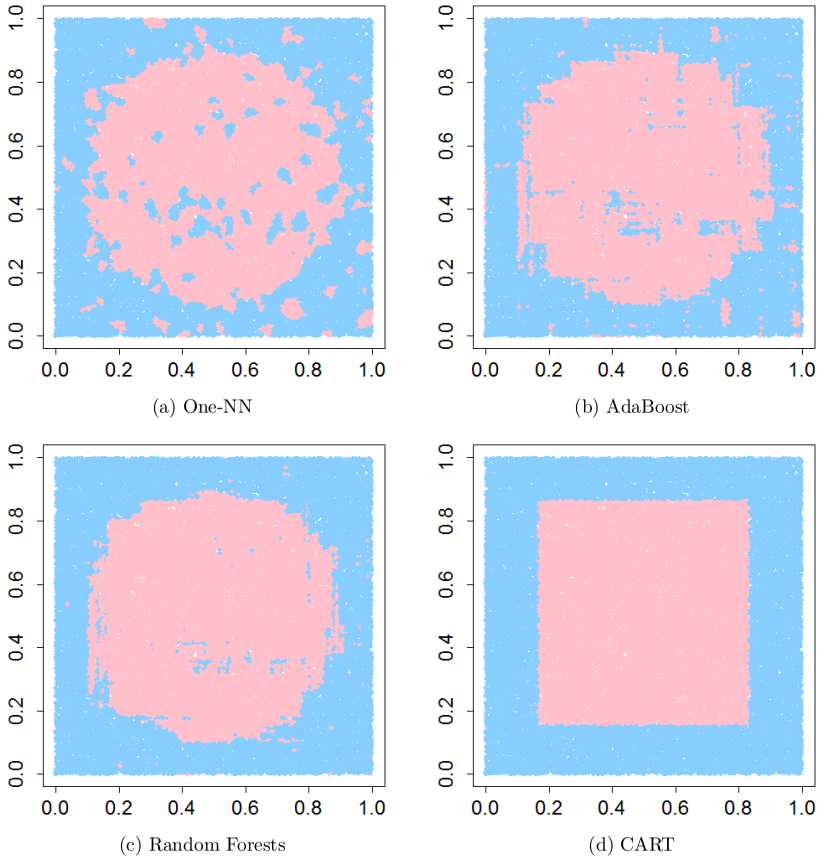
This simulation setting is similar to the previous one, except that the probability that $y = +1$ varies at different points over the unit square. One can see in Figure 7 that the Bayes rule in this setting is just to label every point inside the circle $y = +1$ and every point outside the circle $y = -1$, which gives a Bayes error rate of 0.1. We can then compare

(a) Tree 1 (b) Tree 2 (c) Tree 3

(d) Tree 4 (e) Tree 5 (f) Tree 6

(g) Majority Tree Vote

Figure 6: First six trees from a random forest, along with the classifier created by a majority vote over the trees.



the performance of AdaBoost, random forests, and CART as in the previous section by examining how much of the circle gets classified as $y = +1$ and how much of the outer region is classified as $y = -1$. We run AdaBoost for 500 iterations, fit a random forests model with 500 trees, and build a CART tree that is pruned using cross-validation. Note that we prune the CART tree in order to show how a "classical" statistical model of limited complexity performs on the classification task.

We find that AdaBoost and random forests have an overall error rate of around 0.13, one-nearest neighbor has an overall error rate of 0.20, and CART has an error rate of 0.18. CART fails to perform well in this example because it is not allowed enough complexity to capture the circular pattern. To do so via only the splits parallel to the axes allowed by the algorithm would require a very deep tree (as allowed in random forests and AdaBoost), which pruning does not afford. Rather, a shallow tree can only recover a simple rectangular pattern due to its shallow depth. One-NN, on the other hand, again suffers from its inability to keep the interpolation localized. Outside of the circle, one can observe small "islands" of pink surrounding noise points: by failing to localize the fit, test points near these noise points get classified incorrectly. Again, one finds that random forests and AdaBoost have superior performance because they tend to finely interpolate the training data, and the process of spiked-smoothing shrinks down the influence of noise points.

3.6 A Twenty-Dimensional Example

We now repeat the simulation in Section 3.3 with a larger sample size and in 20 dimensions instead of 2. Specifically, the training data now has $n = 5000$ observations sampled according to the midpoints of a Latin Hypercube design uniformly on $[0, 1]^{20}$. We again randomly select 20% or 1000 of these points to be -1's with the remaining 4000 to be $+1$'s.

Since in 20 dimensions it is difficult to display the resulting classification rules graphically we instead examine the rules on a hold out sample of 10,000 points sampled uniformly and independently on $[0, 1]^{20}$. Figure 8 plots the proportion of points in the hold out sample classified by AdaBoost as $+1$ as a function of the number of iterations. This proportion peaks at .1433 at nine iterations but then gradually decreases to .0175 by 100 iterations and is equal to .0008 by 1,000 iterations. The fact that by 1,000 iterations only 8 of the 10,000 points in the hold out sample are classified as $+1$ means there is very little overfitting. The large number of iterations has the effect of smoothing out the classifier resulting in a rule that agrees with the Bayes rule for 99.92% of the points. Recall that AdaBoost fits the training data perfectly, and thus differs from the Bayes rule on 20% of this sample. We see clearly here that AdaBoost overfits with respect to the training data but not with respect to the population. Again, this is a result of extremely local interpolation of the points in the training data for which the observed class differs from the Bayes rule. A random forests model fit to the training data agrees with the Bayes rule at every point except for one, and hence has exceptional generalization error.

(a) One-NN (b) AdaBoost

(c) Random Forests (d) CART

Figure 7: Performance of AdaBoost, random forests, and CART on a response surface where $\mathbb{P}(y = 1|\mathbf{x}) = 0.10$ inside the circle and $\mathbb{P}(y = 1|\mathbf{x})) = 0.90$ outside of the circle. There are $n = 1000$ training points and the Bayes error is 0.10.

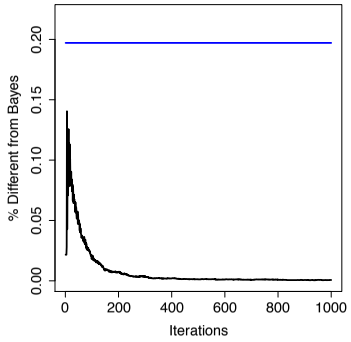


Figure 8: This plot shows the proportion of points in a test set for which the predictions made by AdaBoost and the Bayes rule differ, as a function of the number of boosting rounds (black). The blue line shows this proportion for the one nearest neighbor classifier. Note that the agreement of AdaBoost and the Bayes rule increases with the number of boosting rounds.

4. Self-Averaging Property of Boosting

4.1 Boosting is Self-Smoothing

In the previous sections, we have demonstrated simple examples where random forests and AdaBoost yield the strongest performance with respect to the Bayes rule. We have argued that these algorithms are successful classifiers due to the fact that they fit initially complex models by interpolating the training data but also exhibit smoothing properties via self-averaging that stabilizes the fit in regions with signal, while continuing to keep localized the effect of noise points on the overall fit. While this smoothing mechanism is obvious for random forests via the averaging over decision trees, it is less obvious for AdaBoost. In this section we explain why the additional iterations in boosting way beyond the point at which perfect classification of the training data (i.e interpolation) has occurred actually has the effect of smoothing out the effects of noise rather than leading to more and more overfitting. To the best of our knowledge, this is a novel perspective on the algorithm. To explain our key idea, we will recall the pure noise example from before with $p = .8$, $d = 20$ and $n = 5000$.

Recall that the classifier produced by AdaBoost corresponds to $\mathrm{I}[f_M(x) > 0]$ where

$$f_M(x) = \sum_{m=1}^{M} \alpha_m G_m(x)$$

as defined earlier. Taking $M = 1000$ which was successful in our example let us rewrite this as

$$f_{1000}(x) = \sum_{m=1}^{1000} \alpha_m G_m(x) = \sum_{j=1}^{10} \sum_{k=1}^{100} \alpha_{100(j-1)+k} G_{100(j-1)+k}(x) = \sum_{j=1}^{10} \sum_{k=1}^{100} h_k^j(x)$$

where

$$h_k^j(x) \equiv \alpha_{100(j-1)+k} G_{100(j-1)+k}(x).$$

Now define

$$h_K^j(x) \equiv \sum_{k=1}^{K} h_k^j(x)$$

and note that for every $j \in \{1, ..., 10\}$ and every $K \in \{1, ...100\}$ that $\mathrm{I}[h_K^j(x) > 0]$ is itself a classifier made by linear combinations of classification trees. The ten plots in Figure 9 display the performance on the hold-out sample for these ten classifiers corresponding to the ten different values for j as a function of K. Interestingly, each of these 10 classifiers by itself displays the characteristic of boosting: the agreement with the Bayes rule increases as more terms are added (for instance, as K is increased).

A second interesting fact about these 10 individual classifiers in the decomposition is that each one achieves perfect separation of the training data and thus each one is an interpolating classifier. This result can be expected in general, provided the total number of iterations for each classifier in the decomposition is sufficiently large. This is clear for the first classifier, since it is simply AdaBoost itself and will necessarily achieve zero training error under some standard conditions as discussed in Jiang (2002). The second classifier in the decomposition is simply AdaBoost weight carried over from the first classifier. Since re-weighting the training data does not prevent AdaBoost from obtaining zero training error, the second classifier also interpolates eventually, as does the third, and so on.

Decomposing boosting in this way offers an explanation of why the additional iterations lead to robustness and better performance in noisy environments rather than severe overfitting. In this example, AdaBoost for 100 iterations is an interpolating classifier. It makes some errors, mostly near the points in the training data for which the label differs from the Bayes rule, although these are localized. Boosting for 1000 iterations is thus a point-wise weighted average of 10 interpolating classifiers. The random errors near the points in the training data for which the label differ from the Bayes' rule cancel out in the ensemble average and become even more localized. Of course, the final classifier is still an interpolating classifier as it is an average of 10 interpolating classifiers. In this way, boosting is self-smoothing, self-averaging or self-bagging process that reduces overfitting as the number of iterations increase. The additional iterations provide averaging and smoothing—not overfitting. Empirically this is very similar to random forests and provides evidence that both algorithms, which perform well in our examples, actually do so using the same mechanism.

We further illustrate this phenomenon of increasing localization of the interpolating resulting from this averaging through the following simulation. We take the same training data as before but this time we form the hold out sample by taking a point a (Euclidean) distance of .1 from each of the 1000 points labeled as -1 in the training data in a random direction. Due to the forced (and unnatural) close proximity of the points in the hold out

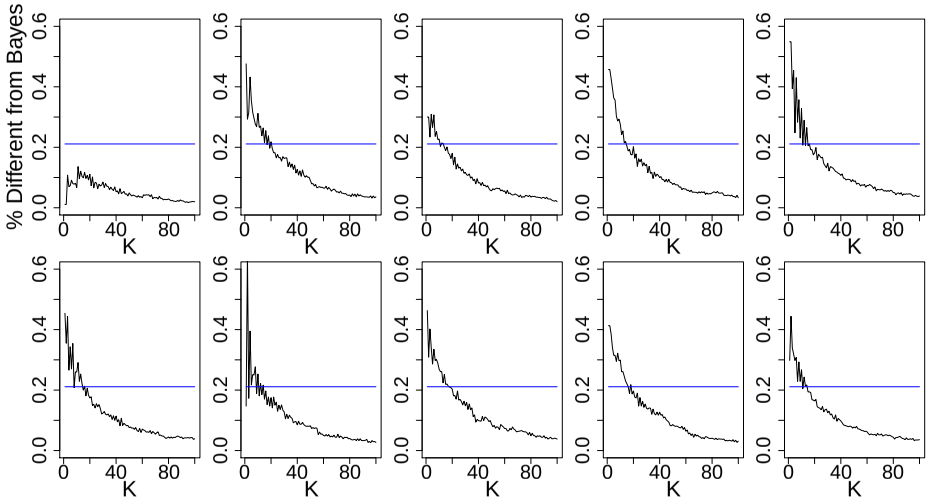

Figure 9: A decomposition of boosting

to training set deviations from the Bayes' rule (points with -1 labels), the error rate is much higher than it would be for a random sample. However, the interpolation continues to become more localized as the iterations proceed (see Figure 10) so even points that are quite close to the label errors (the -1 points) eventually become classified correctly as $+1$. Comparison to Figure 8 shows that this localization continues at a steady rate even after the error on the random hold-out sample is practically zero. In contrast, the nearest neighbor interpolator this simulation yielded 100% disagreement with the Bayes' rule.

4.2 A Five-Dimensional Example

We will now consider a second simulation to further illustrate how this self-averaging property of AdaBoost helps prevent overfitting and improves performance. In this simulation we add signal while retaining significant random noise. Let $n = 400$, $d = 5$ and sample $\mathbf{x}_i$ distributed *iid* uniform on $[0, 1]^5$. The true model from for the simulation is

$$\mathbb{P}(y = 1|\mathbf{x}) = .2 + .6\ \mathrm{I}\left[\sum_{j=1}^{2} x_j > 1\right].$$

The Bayes' error is 0.20 and the optimal Bayes' decision boundary is the diagonal of the unit square in x_1 and x_2. Even with this small sample size, AdaBoost interpolates the training data after 10 iterations. So we boost for 100 iterations which decomposes into ten

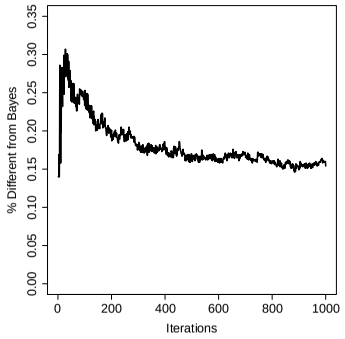

Figure 10: This plot shows the proportion of points in a test set for which the predictions made by AdaBoost and the Bayes rule differ, as a function of the number of boosting rounds (black). The test set has been chosen to contain excess points near the error points in the training set.

sets of ten (which is analogous to the 10 sets of 100 from the 20 dimensional example in the previous section).

The ten plots in the first two rows in Figure 11 show the performance of the ten classifiers corresponding to this decomposition with respect to a hold out sample of 1000 points. Each point in the figure represents a point classified differently from the Bayes rule. While each of the ten classifiers in the decomposition classifies a number of these 1000 points incorrectly especially along the Bayes boundary, exactly which points are classified incorrectly varies considerably from one classifier to the next. The final classifier (displayed in the last plot), which corresponds to AdaBoost after 100 iterations, makes fewer mistakes than each of the ten individual classifiers. Since AdaBoost is a point-wise weighted average of the 10 classifiers, the averaging over the highly variable error locations made by each classifier reduces substantially the number of errors made by the ensemble. The percentage of points classified differently from the Bayes' rule by the final classifier is 118/1000=0.118 while after the first ten there were still 162/1000=0.162 classified differently from the Bayes rule. Averaged over 200 repetitions of this simulation these numbers are .19 after the first ten iterations and .15 after 100 iterations confirming that the performance does improve by running beyond the point at which interpolation initially occurs as (a result of this self-smoothing).

In this example, we also have evidence that AdaBoost takes some measure to decorrelate the errors made by its base classifiers, as hypothesized in Amit et al. (2000) and suggested in Figure 11. To this end, we computed the correlation between $\mathbb{I}[h^1_{10}(X) = Y], \ldots, \mathbb{I}[h^{10}_{10}(X) = Y]$ over a large test set. The correlations ranged from 0.4 to 0.56, with an average value of 0.488. As a comparison, we also considered a similar calculation for the decomposition produced from a random forest with 500 trees, and from bagging 1000 depth 8 trees. As with AdaBoost, we can also decompose these classifiers into a sum of interpolating classifiers: 25

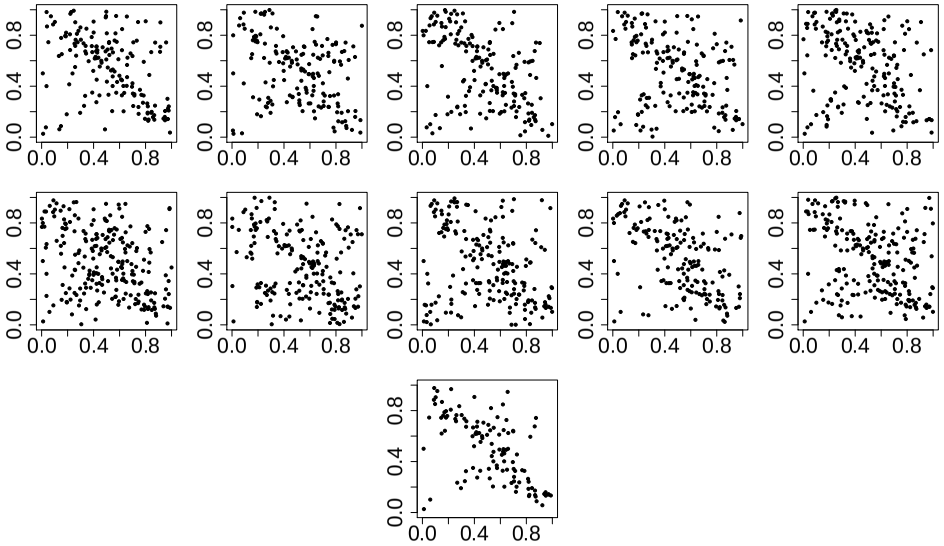

Figure 11: Errors made by each classifier in a decomposition of boosting (first two rows) and errors made by the final classifier (bottom)

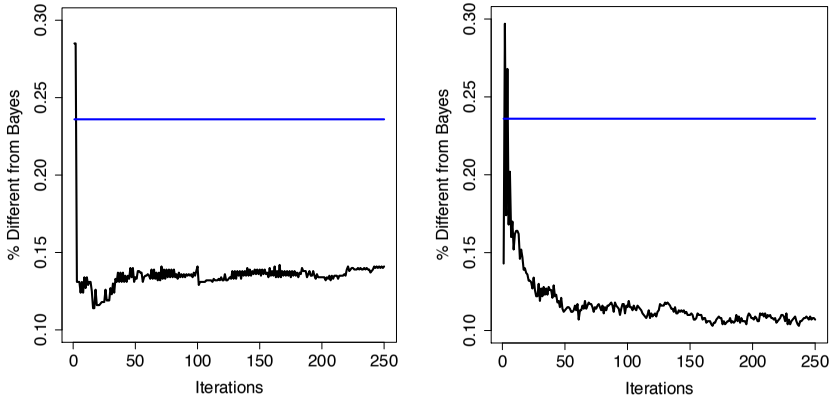
sub-ensembles of 20 trees in the case of the random forest, and 10 sub-ensembles of trees in the case of bagged trees. The interpolating classifiers produced by the random forest had error correlations ranging from 0.75 to 0.87, with an average of 0.81, while the correlations for the bagged trees ranged from 0.9 to 0.94, with an average value of 0.92. In other words, the sub-ensembles produced by random forests and AdaBoost are less correlated than the bagged trees, with AdaBoost being markedly less so. When voting across constituents in its decomposition, it is clear that such a decorrelating effect would help to increase the effectiveness of the voting mechanism to cancel out error points. While we observed this phenomenon in a few data sets, we cannot state under what conditions it happens more generally. However, it is know that boosting generally outperforms bagging, and that bagged trees will be much more correlated.



4.3 Comparison to Boosted Stumps

Throughout this paper we have considered AdaBoost with large trees of up to 2^8 terminal nodes. We have shown that AdaBoost with such large trees is a classifier which interpolates the data in such a way that it performs well out of sample for problems in which the Bayes' error rate is substantially larger than zero. In this section we will consider the performance of AdaBoost with stumps as the base learner. The statistical theory predicts that AdaBoost with stumps will overfit less than AdaBoost with larger trees, as expressed, for instance, in Jiang (2002). It is also thought that stumps should be preferable when the Bayes' decision rule is additive in the original predictors. For instance the seminal book by Hastie et al. (2009, chapter 10) advocates using trees of a depth one greater than the dominant level of interaction, which is generally quite low.

AdaBoost with stumps does not self-smooth nearly as well as with larger trees, likely because the the classifiers in the decomposition are more highly correlated, and the "rough" fits from stumps fail to interpolate the training data locally enough; the fit is not spiked-smooth around the training set error points. Consequently, AdaBoost with stumps as base learners is outperformed by AdaBoost with large trees as base learners, when the Bayes error rate is high. This is the case even when the Bayes rule is additive. This result is matched by random forests which works best with large trees. Its randomly chosen predictors at each splitting opportunity lowers the correlation among the trees and the resulting fit is more spiked-smooth.

To illustrate this with an example, we return to the five dimensional simulation from Section 4.2 which has an additive Bayes decision rule. Figure 12 displays the percentage of points that are classified differently from the Bayes rule in the hold out sample of 1000, as a function of the number of iterations. It can be seen that the stumps (left panel) do not perform as well as the 2^8 node trees (right panel). After 250 iterations, AdaBoost with stumps yields 141/1000 points in the hold out sample classified differently from the Bayes rule, compared to 116/1000 for this same data set using instead AdaBoost with 2^8 node trees. In fact, the stumps seems to suffer from overfitting when run beyond only 25 iterations, while the 2^8 trees do not have a problem with overfitting as the number of iterations are increased.

These numerical values are based only on a single run of this simulation, but the qualitative finding is reproducible over repeated runs. The result serves to illustrate that the

Figure 12: Comparison of AdaBoost with stumps (a) and 2^8 node trees (b) for the five dimensional simulation. The blue line corresponds to One-NN.

good out-of-sample performance of AdaBoost using large trees resulting from the local interpolation of noise points is not shared by AdaBoost using stumps. The idea that stumps will perform better in noisy environments because they overfit less is not supported by this simulation. While the stumps do overfit less on the training data, as evidenced by the fact that they did not give zero training error, they actually overfit worse than the larger trees out of sample. Again, we attribute this to boosting with stumps lacking the self-smoothing property and not being flexible enough to interpolate the noise locally.

5. Real Data Example

In previous sections, we explored the mechanism of spiked smoothing in simulation experiments where it was easy for us to identify noise points. Recall that with a fully specified probability model, noise points are simply sample points whose sign differs from the Bayes' rule. While simulated examples are certainly good for illustration, one may wonder whether these settings are overly simplistic. Data in the real world is typically generated by more complicated—and unknown—probability models with heteroskedastic noise components. Since boosted trees have been empirically successful in such settings, it pays to move our discussion to the context of a data set arising in the real world.

5.1 Phoneme Data

In this section, we will discuss spiked smoothing in the context of a data set arising in a speech recognition task designed to discriminate "nasal" vowels from "oral" vowels in spoken

language [2]. For a collection of 5404 examples of spoken vowels, this data set contains the amplitudes of the first 5 harmonic frequencies as collected by a cochlea spectra (hearing aid), along with a label of either nasal or oral (n=5404, p=5). The goal is then to use these harmonic frequencies to correctly identify the type of vowel. While there are many potential data sets we could have considered, this one is convenient to analyze since it consists of a relatively small number of real valued covariates. This makes it easier to talk about "neighborhoods" of points later in our discussion.

We begin by dividing the phoneme data set up into a training set consisting of 70% of the samples, and a testing set consisting of 30% of the examples. Depth eight decision trees boosted for 1000 rounds and a random forest classifier both achieve comparable test error rates of 9.0% and 9.4%, respectively [3]. Figure 13 demonstrates that boosting deep trees is preferable to shallow trees in this data set. Each frame in the figure shows the testing error in black and the training error in red as a function of the number of boosting iterations for different depth trees. One can readily observe that test error steadily decreases with the depth of tree used in AdaBoost. It is interesting to note that boosting trees of all depths are slow to overfit the data, even with boosted stumps after 1000 iterations. It is also worth noting that boosted depth 8 trees quickly interpolate the training data, as indicated by the sharply decreasing red line. This raises the often asked question: what is AdaBoost doing after it achieves a perfect fit on the training set?

Any discussion of spiked smoothing on real data is complicated by the reality that it is impossible to identify noise points without knowing the underlying probability model. As a substitute for noise points, we flipped the signs of 100 randomly chosen points in our training data set (about 2% of the data) and analyzed the fits of boosted trees and a random forest classifier around these points. After refitting the models to the perturbed data, we find the the testing errors are 10.2% and 10.0% for boosted depth eight trees and a random forest, respectively. Figure 14 illustrates that even after thousands of rounds of boosting, test error continues to decrease. The punchline is that both algorithms are able to achieve fits with comparable test set error even after flipping the sign of a large number of points in the training set.

As a comparison with another interpolating classifier, we also repeated the same experiment with a one nearest-neighbors classifier. We found the one nearest neighbor achieved a test error rate of 10.5% when fit on the original training set, and a test error rate of 12.6% when fit on the noisy training set. The increase in error rate when noise is added to the training set is larger than that of AdaBoost or a random forest, which coincides with the results form the simulated example in section 3.3. Furthermore, two sample t-tests reveal that the increase in error rate for one nearest-neighbors is significant at the 0.01 level in both cases (p-values less than $1e^{-16}$ in both cases).

We will argue that additional rounds of boosting are helping to "smooth out" and "localize" the influence of the 100 noise points that we introduced into our training set. In section 3.3, we illustrated the action of spiked smoothing in diagrams which showed AdaBoost's fit on a two dimensional plane. In this slightly higher dimensional example,

2. The original data can be found at the following address: https://www.elen.ucl.ac.be/neural-nets/Research/Projects/ELENA/databases/REAL/phoneme/phoneme.txt.
3. The error rates reported are the result from repeating the fitting procedure on 100 random train/test set splits and considering the average error on the test set.

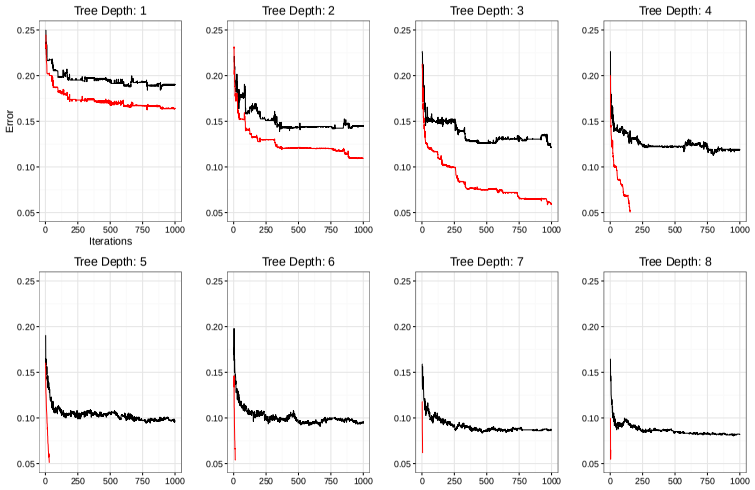

Figure 13: Plots of testing and training error as a function of number of boosting iterations for trees of different depths. The black lines show the test error rates while the red lines show training error rates. Notice that depth seven and eight boosted trees quickly fit the training data, as depicted by the rapidly decreasing red lines.

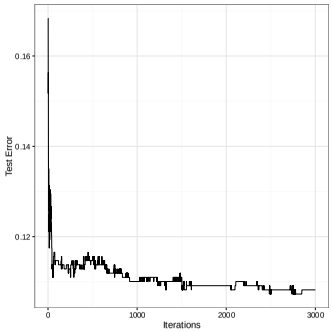

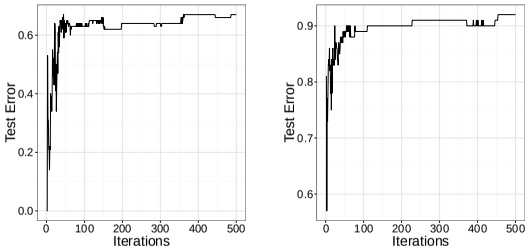

Figure 14: Plot of testing error for depth 8 boosted trees fit to a training set which has flipped labels for 100 randomly selected examples.

we instead consider small neighborhoods around each of the noise points and track the fraction of points in these neighborhoods that agree with the sign of the "correct label",

that is, before flipping the sign. [4]. Panels (a) and (b) of Figure 15 plot this fraction as a function of the number of boosting iterations for two representative "noise points." In both panels, it is clear that as the number of iterations increases, the fraction of points in each neighborhood that agrees with the original sign of the training point increases. Recall that in this case AdaBoost still fits its training data perfectly: the in-sample AdaBoost fit agrees with the sign of the flipped training point in both figures. Despite this, the algorithm still fits a majority of points in a neighborhood of each of these noise points in the correct way. The classifier is producing a spiked smooth fit, that is, it fits the data in such a way to localize the influence of noise points. One can interpret the increasing homogeneity in each neighborhood as the result of averaging. The first few iterations of deeply boosted trees produce a fit that interpolates the training data, but this fit is quite complicated in the sense that it assigns large numbers of points in the neighborhood to both '+1' and '-1'. As the number of iterations increases, this fraction increases so that the fit becomes more smooth in the classical sense.

(a) (b)

Figure 15: The fraction of points in a neighborhood that agree with the sign of the original training point before its sign was flipped. Figures (a) and (b) plot this proportion for two different, representative noise points.

5.2 Additional Data Sets

We repeated a version of the analysis conducted in Section 5.1 for five additional data sets from the UCI repository: Haberman, Wisconsin breast cancer, voting, Pima, and German credit. In our analysis we did the following: we added 5% label noise to the training data, missing values were imputed with the mean prior to model fitting, and all experiments were conducted on 50 random training-testing splits of each data set. Table 1 reports the mean increase in testing error after adding 5% label noise over the 50 random training-testing splits. For example, on the original haberman data set, AdaBoost achieved an average error rate of 34.225%, and on the noisy version of the data set achieved an average error rate of 34.354%. The mean difference of 0.13% is reported in the table. It is also apparent in each setting that AdaBoost and random forest are relatively immune to the addition of label noise. The stars in the Table 1 report the significance level when comparing the increase in error rate for AdaBoost and a random forest with that of one-nearest neighbors using a two-sample t-test. With the exception of the German credit data, the increase in error rate for one nearest neighbors was larger than that of one nearest neighbors with statistical significance.

4. We choose each neighborhood to be a rectangle centered at the point of interest, with side lengths chosen in such as way that the neighborhood contains only a small number of training points. We then chose 100 points uniformly at random in this rectangle and computed the AdaBoost classifier at each point: these points are obviously not included in the original data set.

Data set	AdaBoost	Random Forest	1-NN
Haberman	0.13^{**}	0.52^{*}	**1.55**
breast_cancer	0.20^{***}	0.39^{***}	**2.29**
voting	1.63^{**}	0.30^{***}	**2.71**
Pima	0.56^{***}	0.45^{***}	**1.75**
German	0.29	0.68	**0.68**

Table 1: The increase in average testing error after changing the sign of 5% of the training data. The stars in the table report the significance level when comparing the increase in error rate for AdaBoost and a random forest with that of one-nearest neighbors using a two-sample t-test. One star denotes significance at the 10% level, two stars denotes significance at the 5% level, and three stars denotes significance at the 1% level.

6. Concluding Remarks

AdaBoost is an undeniably successful algorithm and random forests is at least as good, if not better. But AdaBoost is as puzzling as it is successful; it broke the basic rules of statistics by iteratively fitting even noisy data sets until every training set data point was fit without error. Even more puzzling, to statisticians at least, it will continue to iterate an already perfectly fit algorithm which lowers generalization error. The statistical view of boosting understands AdaBoost to be a stage wise optimization of an exponential loss, which suggest (demands!) regularization of tree size and control on the number of iterations. In contrast, a random forest is not an optimization; it appears to work best with large trees and as many iterations as possible. It is widely believed that AdaBoost is effective because it is an optimization, while random forests works—well because it works. Breiman conjectured that "it is my belief that in its later stages AdaBoost is emulating a random forest" (Breiman, 2001). This paper sheds some light on this conjecture by providing a novel intuition supported by examples to show how AdaBoost and random forest are successful for the same reason.

A random forests model is a weighted ensemble of interpolating classifiers by construction. Although it is much less evident, we have shown that AdaBoost is also a weighted ensemble of interpolating classifiers. Viewed in this way, AdaBoost is actually a "random" forest of forests. The trees in random forests and the forests in the AdaBoost each interpolate the data without error. As the number of iterations increase the averaging of decision surface because smooths but nevertheless still interpolates. This is accomplished by whittling down the decision boundary around error points. We hope to have cast doubt on the commonly held belief that the later iterations of AdaBoost only serve to overfit the data.

Instead, we argue that these later iterations lead to an "averaging effect", which causes AdaBoost to behave like a random forest.

A central part of our discussion also focused on the merits of interpolation of the training data, when coupled with averaging. Again, we hope to dispel the commonly held belief that interpolation always leads to overfitting. We have argued instead that fitting the training data in extremely local neighborhoods actually serves to prevent overfitting in the presence of averaging. The local fits serve to prevent noise points from having undue influence over the fit in other areas. Random forests and AdaBoost both achieve this desirable level of local interpolation by fitting deep trees. It is our hope that our emphasis on the "self-averaging" and interpolating aspects of AdaBoost will lead to a broader discussion of this classifier's success that extends beyond the more traditional emphasis on margins and exponential loss minimization.

Abstract

We present a general framework for graph clustering and bi-clustering where we are given a general observation (called a label) between each pair of nodes. This framework allows a rich encoding of various types of pairwise interactions between nodes. We propose a new tractable and robust approach to this problem based on convex optimization and maximum likelihood estimators. We analyze our algorithms under a general statistical model extending the planted partition and stochastic block models. Both sufficient and necessary conditions are provided for successful recovery of the underlying clusters. Our theoretical results subsume many existing graph clustering results for a wide range of settings, including planted partition, weighted clustering, submatrix localization and partially observed graphs. Furthermore, our results are applicable to novel settings including time-varying graphs, providing new insights to solutions of these problems. We provide empirical results on both synthetic and real data that corroborate with our theoretical findings.

Keywords: graph clustering, convex optimization, low-rank matrix, information divergence, time-varying graphs, pairwise observation, dynamic graphs

1. Introduction

In the standard formulation of graph clustering, we are given an unweighted graph and seek a partitioning of the nodes into disjoint groups such that members of the same group are more densely connected than those in different groups. Here, the presence of an edge represents certain affinity or similarity between the nodes, and the absence of an edge represents the lack thereof.

In many applications, from chemical interactions to social networks, the interactions between nodes are much richer than a simple "edge" or "non-edge". Such extra information can be used to improve the clustering quality. We may represent each type of pairwise interaction by a *label*. One simple setting of this type is weighted graphs, where instead of a 0-1 graph, we have edge weights representing the strength of the pairwise interaction. In this case the observed label between each pair is a real number. In a more general setting, the label need not be a number. For example, on social networks like Facebook, the label between two persons may be "they are friends", "they went to different schools", "they liked 21 common pages", or the concatenation of them. In such cases different labels carry different information about the underlying community structure. A standard approach that converts these pairwise interactions into a simple edge/non-edge and then applies standard clustering algorithms, often does not work well here, as much of the information may be lost. Even in the simple case of a standard weighted/unweighted graph, it may not be immediately clear how information in the graph should be used in clustering. For example, should the absence of an edge be interpreted as a *neutral* observation carrying no information, or as a *negative* observation indicating dissimilarity between the two nodes?

We emphasize that our notion of labels (types of pairwise observations) is very general. A label can take real, discrete, categorical or even mixed values—we will see several such examples in Section 4. A label can even take the form of a time series, i.e., a record of time varying interactions such as "A and B messaged each other on June 1st, 4th, 15th and 21st", or "they used to be friends, but they stop talking to each other since 2012". The labeled graph model is therefore an immediate tool for analyzing time-varying graphs.

In this paper, we present a new and principled approach for graph clustering that is directly based on general pairwise labels. We assume that between each pair of nodes i and j, one observes a label L_{ij} that takes values in a label set $\mathcal{L}$. The set $\mathcal{L}$ may be continuous, discrete or mixed, and need not have any algebraic or geometric structure. The standard graph model corresponds to a binary label set $\mathcal{L} = \{\text{edge}, \text{non-edge}\}$, and a weighted graph corresponds to $\mathcal{L} = \mathbb{R}$. Given the matrix of observed labels $L = (L_{ij}) \in \mathcal{L}^{n\times n}$ between n nodes, the goal is to partition these nodes into disjoint clusters. Our algorithmic approach is based on finding a partition that optimizes a weighted objective that is appropriately constructed from the observed labels. This formulation leads to a combinatorial optimization problem, and our algorithms use its convex relaxation.

To systematically evaluate clustering performance, we consider a generalization of the stochastic block model and the planted partition model (Holland et al., 1983; Condon and Karp, 2001). Our model assumes that the observed labels are generated based on an underlying set of ground truth clusters, where node pairs from the same cluster generate labels using a distribution μ over $\mathcal{L}$, and pairs from different clusters use a different distribution ν. The standard planted partition model corresponds to the case where μ and ν are Bernoulli distributions with $\mu(\text{edge}) = p$ and $\nu(\text{edge}) = q, p \neq q$. We provide theoretical guarantees for our algorithm under this generalized model.

By specializing to concrete examples of the distributions μ and ν, our results cover a wide range of clustering settings—with theoretical guarantees matching or stronger than existing work—including the standard stochastic block model, partially observed graphs, weighted graphs and submatrix localization. Our framework in fact allows us to handle new classes of problems that are not a priori obvious to be a special case of our model, including the clustering of time-varying graphs.

Our framework easily generalizes to the bi-clustering setting, where pairwise labels are observed between two disjoint sets of nodes, potentially from different domains, and the task is to jointly cluster these two sets of nodes given the bipartite label observations. All our algorithmic and statistical results extend to this bi-clustering setting with only minor changes.

Remark 1 *Preliminary versions of some of the results here have appeared in part in Chen et al. (2014b) and Lim et al. (2014). The theory was previously stated with respect to only discrete label sets, but are now extended to general label sets, including continuous and mixed-valued labels, which appear frequently in applications (see, for example, Section 4). We also include a more detailed and systematic discussion on the bi-clustering setting and various special cases. Implementation details of efficient first-order solvers are now included. We also report a much more extensive set of empirical results on both synthetic and real data, including comparison with other methods.*

1.1 Related Work

The planted partition model/stochastic block model (Condon and Karp, 2001; Holland et al., 1983) are standard models for studying graph clustering. Variants of the models cover partially observed graphs (Oymak and Hassibi, 2011; Chen et al., 2014a), weighted graphs and the submatrix localization and bi-clustering problems (Balakrishnan et al., 2011; Kolar et al., 2011). All these models are special cases of ours. Various algorithms have been proposed and analyzed under these models, such as spectral clustering (McSherry, 2001; Chaudhuri et al., 2012; Rohe et al., 2011), convex optimization approaches (Mathieu and Schudy, 2010; Ames and Vavasis, 2011) and tensor decomposition methods (Anandkumar et al., 2014). Ours is based on convex optimization, generalizing the convexified maximum likelihood approach in Chen et al. (2014c).

Time-varying graphs arise in a broad range of applications, and the problem of clustering such graphs has been studied in various context (see Fortunato, 2010; Sun et al., 2007; Chakrabarti et al., 2006; Kawadia and Sreenivasan, 2012; Nguyen et al., 2011, and the references therein). The stochastic block model has also been extended in a number of ways to accommodate time-varying graphs. For example, Han et al. (2015) consider multiple, independent graphs, where edge distributions can differ in each graph and each cluster membership pair. In the work of Xu and Hero (2014); Matias and Miele (2016), the cluster membership of an individual node is allowed to change with time. Another extension is in allowing mixed cluster membership in time-varying networks, as done by Fu et al. (2009). These extensions allow additional flexibilities, but the existing solutions lack the kind of theoretical performance guarantees afforded by our approach. Also note that dealing with time-varying graph is only *one* of the applications of our general theory on clustering based on pairwise labels.

Most related to our setting is the *labelled stochastic block model* proposed by Heimlicher et al. (2012) and Lelarge et al. (2013). A main difference in their model is that they assume each pairwise observation is from a two-step process: first an edge/non-edge is observed; if it is an edge then a label is associated with it. In our model all observations are in the form of labels—in particular, an edge or no-edge is also a label—which covers their setting as a special case. Our model is therefore more general and natural, and as a result our theory covers a broad class of subproblems including time-varying graphs. Moreover, their analysis is mainly restricted to the two-cluster setting with edge probabilities on the order of $\Theta(1/n)$, while we allow for an arbitrary number of clusters and a wide range of edge/label distributions. In addition, we consider the setting where the distributions of the labels are not precisely known. Algorithmically, they use belief propagation (Heimlicher et al., 2012) and spectral methods (Lelarge et al., 2013).

Appearing after the conference versions of this paper, the work by Jog and Loh (2015) studies a form of labelled stochastic block model and thus is also related to ours. Restricting to the homogeneous case with equal-size clusters, they derive recovery conditions in terms of the Renyi divergence. Their results are based on the maximum likelihood decoder, which is not computationally feasible. Another recent work by Chen et al. (2015) also studies the statistical limits of information recovery from pairwise observations. Their model is however quite different from ours, and the results are again based on the intractable maximum likelihood decoder.

2. Problem Setup and Algorithms

We assume n nodes are partitioned into r disjoint clusters of size at least K. The clusters are unknown and considered as the ground truth. For each pair of nodes (i, j), a label $L_{ij} \in \mathcal{L}$ is observed, where $\mathcal{L}$ is the set of all possible values of the label. These labels are generated independently across node pairs according to some distributions μ and ν on $\mathcal{L}$.[1] In particular, if nodes i and j are in the same cluster, the observed label L_{ij} follows the distribution μ, otherwise L_{ij} follows ν. The goal is to recover the ground truth clusters given the pairwise labels, which is represented as a matrix $L = (L_{ij}) \in \mathcal{L}^{n\times n}$. We encode the true clusters as an $n \times n$ *cluster matrix* Y^*, where $Y^*_{ij} = 1$ if nodes i and j belong to the same cluster and $Y^*_{ij} = 0$ otherwise, with the convention that $Y^*_{ii} = 1$ for all i. The problem is therefore to find Y^* given L.

We take an optimization approach to this problem. To motivate our algorithm, first consider the case of clustering a weighted graph, where $\mathcal{L} = \mathbb{R}$ and all labels are real numbers. Suppose that positive weights indicate affinity between node pairs while negative weights indicate dissimilarity. A natural approach is to partition the nodes in a way that maximizes the total weight inside the clusters (this is equivalent to *correlation clustering* by Bansal et al. 2004). Mathematically, this formulation is to find a clustering, represented by a cluster matrix $Y \in \{0, 1\}^{n\times n}$, such that the sum $\sum_{i,j} L_{ij}Y_{ij}$ is maximized. In the setting of general labels, we pick a *weight function* $w : \mathcal{L} \to \mathbb{R}$, which assigns a number $W_{ij} = w(L_{ij})$ to the label L_{ij} observed at each pair (i, j). We then solve the following max-weight problem:

$$\begin{aligned} \max_{Y} \quad & \langle W, Y\rangle \\ \text{s.t.} \quad & Y \text{ is an } n \times n \text{ cluster matrix,} \end{aligned} \tag{1}$$

where $\langle W, Y\rangle := \sum_{i,j} W_{ij}Y_{ij}$ is the trace inner product. Note that once the weight function is specified, this formulation effectively converts the problem of clustering from labels into a weighted clustering problem.

The optimization program (1) is non-convex due to the combinatorial constraint. Our algorithm is based on a convex relaxation of (1), using the fact that any cluster matrix is a symmetric positive semidefinite, block-diagonal 0-1 matrix. Relaxing the constraint in (1) leads to the following convex optimization problem:

$$\begin{aligned} \max_{Y} \quad & \langle W, Y\rangle \\ \text{s.t.} \quad & Y \in \mathcal{S}^n_+, \\ & 0 \le Y_{ij} \le 1, \forall (i, j), \end{aligned} \tag{2}$$

where $\mathcal{S}^n_+$ denotes the set of $n \times n$ symmetric positive semidefinite matrices. We say that the program (2) recovers the true clusters if it has a unique optimal solution equal to the true cluster matrix Y^*.

1. More precisely, we assume that there is a σ-algebra $\mathcal{F}$ such that $(\mathcal{L}, \mathcal{F})$ is a measurable space, endowed with probability measures μ and ν.

One has the freedom of choosing the weight function w. Here, the likelihood ratio between label distributions μ and ν will play an important role. We assume that the measures μ and ν are absolutely continuous with each other, as well as with some base measure λ on $\mathcal{L}$. With a slight abuse of notation, the likelihoods of a label $l \in \mathcal{L}$ with respect to μ and ν are given by

$$\mu(l) = \frac{\mathrm{d}\mu}{\mathrm{d}\lambda}(l) \quad \text{and} \quad \nu(l) = \frac{\mathrm{d}\nu}{\mathrm{d}\lambda}(l),$$

where $\frac{\mathrm{d}\mu}{\mathrm{d}\lambda}$ and $\frac{\mathrm{d}\nu}{\mathrm{d}\lambda}$ are the respective Radon-Nikodym derivatives. In the sequel, unless specified otherwise, we will always assume that λ is the counting measure if $\mathcal{L}$ is a discrete label set, in which case we simply have $\mu(l) = \Pr(L_{ij} = l)$. For a continuous set $\mathcal{L}$, we use the Lebesgue base measure and hence $\mu(l)$ is the usual density function of μ. Later we will encounter more general, mixed-valued label sets $\mathcal{L}$.

Intuitively, a weight function w should assign $w(L_{ij}) > 0$ to a label L_{ij} with $\mu(L_{ij}) > \nu(L_{ij})$, so the program (2) is encouraged to place nodes i and j in the same cluster, the more likely possibility; similarly we should have $w(L_{ij}) < 0$ if $\mu(L_{ij}) < \nu(L_{ij})$. In other words, a good weight function should reflect the information in μ and ν. Our theoretical results in Section 3 characterize the performance of the program (2) for *any* given weight function w. Building on this general result, we further derive robust and optimal choices of w. Since μ and ν are often unknown, Section 3 also includes results when w is chosen based on distributions that are different from the true distributions.

For cluster recovery to be possible, the observed labels must contain sufficient information to distinguish different clusters. If $\mu = \nu$, the observed labels for intra- and inter-cluster pairs will have the same distribution, in which case the data L is distributed independently of the underlying clusters and recovery is impossible. In general, the problem becomes harder if μ and ν are more similar to each other. We quantify this relation precisely in Section 3.

2.1 Alternative Formulations and the Bi-clustering Problem

Program (2) uses the fact that Y^* is symmetric positive semidefinite. The following program, which is based on a more relaxed constraint using the nuclear norm $\|\cdot\|_*$,[2] also works and has essentially the same theoretical guarantees:

$$\begin{aligned} \max_{Y} \quad & \langle W, Y \rangle, \\ \text{s.t.} \quad & \|Y\|_* \le \|Y^*\|_* \\ & 0 \le Y_{ij} \le 1, \forall (i,j). \end{aligned} \tag{3}$$

Intuitively, this relaxed problem uses the fact that a cluster matrix always satisfies $\|Y^*\|_* = n$, which is much smaller than a general $n \times n$ binary matrix.

The formulation (3) has the advantage that it applies directly to a bi-clustering setting. In this setting, there are two disjoint sets of nodes $\mathcal{N}_1$ and $\mathcal{N}_2$, where $|\mathcal{N}_1| = n_1$ and $|\mathcal{N}_2| = n_2$. Each of the sets $\mathcal{N}_1$ and $\mathcal{N}_2$ are partitioned into r clusters $\{C_k, k \in [r]\}$ and $\{C'_k, k \in [r]\}$, respectively, where the clusters C_k and C'_k are associated with each other and called a bi-cluster. Similarly to the clustering case, the true cluster matrix $Y^* \in \{0,1\}^{n_1 \times n_2}$ is defined as $Y^*_{ij} = 1$ if and only if $(i,j) \in C_k \times C'_k$ for some $k \in [r]$. Labels are generated from the distribution μ for each pair (i,j) with $Y^*_{ij} = 1$, and from ν otherwise. Here Y^* is not necessarily a square or positive semidefinite matrix. The program (3) still applies, with the understanding that the matrices W and Y have size $n_1 \times n_2$ instead of $n \times n$.

While we always have $\|Y^*\|_* = n$ in the clustering case, this is not the case in general for bi-clustering. The value of $\|Y^*\|$ used in the constraint of (3) is usually unknown in practice, in which case we can instead solve an equivalent formulation in terms of a Lagrange multiplier:

$$\begin{aligned} \max_{Y} \quad & \langle W, Y \rangle - \eta \|Y\|_* \\ \text{s.t.} \quad & 0 \le Y_{ij} \le 1, \forall (i,j). \end{aligned} \tag{4}$$

The formulations (2)–(4) are semidefinite programs that can be solved in polynomial time by various methods. In Section 5 we describe efficient first order solvers and discuss other implementation details. Note that by convex duality, if the constrained formulation (3) succeeds in recovering the true cluster matrix Y^*, then there exists a multiplier η for which the Lagrangian formulation (4) also succeeds.[3] Therefore, all our theoretical results for the formulations (2) and (3) in Section 3 also hold for the formulation (4) with a suitable η.

3. Theoretical Results

In this section, we provide theoretical analysis for the performance of the convex formulations (2) and (3) under the statistical model described in Section 2. We give sufficient and necessary conditions for cluster recovery, and discuss choices of the weight function. All our results apply to both clustering and bi-clustering settings. In the bi-clustering case, we let $n = \max\{n_1, n_2\}$, and recall that (C_k, C'_k) is the k-th bi-cluster for $k \in [r]$. The minimum cluster size is $K = \min_{k \in [r]} \min\left\{|C_k|, |C'_k|\right\}$. These notations are consistent with the clustering setting, for which n is the total number of nodes and K the minimum cluster size.

Our main result is a general theorem that gives sufficient conditions for the programs (2) and (3) to recover the true cluster matrix Y^*. These conditions are stated in terms of the minimum cluster size K, the label distributions μ and ν, as well as any given weight function $w(\cdot)$ through the quantities

$$\mathbb{E}_\mu w := \int_{\mathcal{L}} w(l)\,\mathrm{d}\mu \quad \text{and} \quad \mathrm{Var}_\mu w := \int_{\mathcal{L}} [w(l) - \mathbb{E}_\mu w]^2\,\mathrm{d}\mu;$$

$\mathbb{E}_\nu w$ and $\mathrm{Var}_\nu w$ are defined similarly. We assume in the sequel that all the relevant integrals and expectations are well-defined. With these notations, we now state our general theorem.

Theorem 2 (Main) *Suppose b is any number that satisfies $|w(l)| \le b$ almost everywhere (a.e.) over $\mathcal{L}$ with respect to μ and ν. There exists a universal constant $c > 0$ such that if*

$$-\mathbb{E}_\nu w \ge c \frac{b \log n + \sqrt{K \log n}\sqrt{\mathrm{Var}_\nu w}}{K}, \tag{5}$$

$$\mathbb{E}_\mu w \ge c \frac{b \log n + \sqrt{n \log n}\sqrt{\max(\mathrm{Var}_\mu w, \mathrm{Var}_\nu w)}}{K}, \tag{6}$$

2. The nuclear norm of a matrix is defined as the sum of its singular values. A cluster matrix is positive semidefinite, so its nuclear norm is equal to its trace and also called the trace norm.

3. Both (3) and (4) are strictly feasible, so strong duality holds by Slater's condition.

then Y^* is the unique solution to the programs (2) *and* (3) *with probability at least* $1 - n^{-10}$.[4]

We prove this claim in Section 7. Theorem 2 is in fact a special case of the more general Theorem 9 (Section 3.5), which does not require the boundedness assumption $w(l) \le b$.

Theorem 2 is valid for any given weight function w. Below we discuss how to choose w optimally, and then address the case where w deviates from the optimal choice.

3.1 Optimal Weights

A candidate for a good weight function w can be derived from the maximum likelihood estimator (MLE) of Y^*. Given the observed label matrix L, the log-likelihood of the true cluster matrix taking the value Y is

$$\begin{aligned}\log p\big(L \,|\, Y^* = Y\big) &= \sum_{i,j} \log \left[\mu(L_{ij})^{Y_{ij}} \nu(L_{ij})^{1-Y_{ij}}\right] \\ &= \sum_{i,j} Y_{ij} \underbrace{\log \frac{\mu(L_{ij})}{\nu(L_{ij})}}_{W_{ij}} + \underbrace{\sum_{i,j} \log \nu(L_{ij})}_{c} \\ &= \langle W, Y\rangle + c.\end{aligned}$$

The MLE, which maximizes the above expression over Y, therefore corresponds to using the log likelihood ratio as the weight function:

$$w(l) \leftarrow w^{\text{MLE}}(l) := \log \frac{\mu(l)}{\nu(l)}.$$

Specializing Theorem 2 to the weight function w^{MLE}, we obtain the following theorem that characterizes the performance of using the MLE weights in the convex relaxations. Here $D(\cdot \,\|\, \cdot)$ denotes the KL divergence between two distributions.

Theorem 3 (MLE) *Suppose that $w = w^{MLE}$ is used as the weight function, and b and ζ are any numbers that satisfy with $D(\nu\|\mu) \le \zeta D(\mu\|\nu)$ and $\left|\log \frac{\mu(l)}{\nu(l)}\right| \le b, \forall l \in \mathcal{L}$. There exists a universal constant $c > 0$ such that if*

$$D(\nu\|\mu) \ge c(b+2)\frac{\log n}{K}, \tag{7}$$

$$D(\mu\|\nu) \ge c(\zeta+1)(b+2)\left(\frac{n \log n}{K^2}\right), \tag{8}$$

then with probability at least $1 - n^{-10}$, Y^* is the unique solution to the programs (2) *and* (3)*. Moreover, it always holds that $D(\nu\|\mu) \le (2b+3)D(\mu\|\nu)$, so we can take $\zeta = 2b + 3$.*

We prove this claim in Appendix A. The two conditions (7) and (8) are not symmetric due to the fact that there are more cross-cluster pairs than in-cluster pairs in general. The quantity ζ accounts for the asymmetry between $D(\nu\|\mu)$ and $D(\mu\|\nu)$.

4. In all subsequent results, we use an arbitrary choice of exponent in the failure probability n^{-10}. It is easily seen from Theorem 9 that the constant c scales linearly with the exponent.

Theorem 3 has the intuitive interpretation that the in/cross-cluster label distributions μ and ν should be sufficiently different, measured by their KL divergence, for the underlying clusters to be recovered. Using a classical result in information theory (Topsoe, 2000), we may replace the KL divergences with a quantity called the triangle discrimination that is often easier to work with. This is summarized in the following corollary.

Corollary 4 (MLE 2) *Suppose w^{MLE} is used, and b, ζ are defined as in Theorem 3. There exists a universal constant c such that Y^* is the unique solution to the programs* (2) *and (3) with probability at least $1 - n^{-10}$ if*

$$\int_{\mathcal{L}} \frac{(\mu(l) - \nu(l))^2}{\mu(l) + \nu(l)} \, \mathrm{d}\lambda \ge c(\zeta+1)(b+2)\left(\frac{n \log n}{K^2}\right). \tag{9}$$

One may take $\zeta = 2b + 3$.

We prove this claim in Appendix A. Note that the left hand side of (9) is the *triangle discrimination* between μ and ν, which lower bounds of the KL-divergence (cf. Lemma 23.) It can be seen that the constant c if Corollary 4 may be trivially chosen such that it only differs from the c in Theorem 3 by a factor of 2. In general, we do not assume any special relationship between universal constants.

The MLE weight function w^{MLE} turns out to be near-optimal, at least in the two-cluster case, in the sense that no other weight function (in fact, no other algorithm) has significantly better statistical performance. This is shown by establishing a necessary condition for *any* algorithm to recover the true clustering Y^*. Here, an algorithm is a measurable function $\hat{Y}$ that maps the data L to a clustering represented by a cluster matrix.

Theorem 5 (Converse) *The following holds for some universal constants $c, c' > 0$. Suppose $K = \frac{n}{2}$, and the quantity b defined in Theorem 3 satisfies $b \le c'$. If*

$$\int_{\mathcal{L}} \frac{(\mu(l) - \nu(l))^2}{\mu(l) + \nu(l)} \, \mathrm{d}\lambda \le \frac{c \log n}{n}, \tag{10}$$

then $\inf_{\hat{Y}} \sup_{Y^*} \mathbb{P}\big(\hat{Y}(L) \ne Y^*\big) \ge \frac{1}{2}$, where the supremum is over all possible cluster matrices.

We prove this claim in Appendix B.

Under the assumption of Theorem 5, the conditions (9) and (10) match up to a constant factor, showing that program (3) with the MLE weights w^{MLE} is statistically order-wise optimal.

3.2 Monotonicity

We sometimes do not know the exact label distributions μ and ν in computing the MLE weights w^{MLE}. Instead, we may construct the weights using the log likelihood ratios of some "incorrect" distributions $\bar{\mu}$ and $\bar{\nu}$. Our algorithms have a nice *monotonicity* property: as long as the divergence between the true μ and ν is larger than that between $\bar{\mu}$ and $\bar{\nu}$ (hence an "easier" problem), then the algorithm still has the same (if not better) probability of success, even though the wrong weights are used.

More precisely, we say that the pair (μ, ν) is *more divergent* than $(\bar{\mu}, \bar{\nu})$ if, for each $l \in \mathcal{L}$, we have

$$\text{either} \quad \frac{\mu(l)}{\nu(l)} \ge \frac{\mu(l)}{\bar{\nu}(l)} \ge \frac{\bar{\mu}(l)}{\bar{\nu}(l)} \ge 1 \quad \text{or} \quad \frac{\nu(l)}{\mu(l)} \ge \frac{\nu(l)}{\bar{\mu}(l)} \ge \frac{\bar{\nu}(l)}{\bar{\mu}(l)} \ge 1.$$

Theorem 6 (Monotonicity) *Suppose that we use the weight function* $w(l) = \log \frac{\bar{\mu}(l)}{\bar{\nu}(l)}, \forall l \in \mathcal{L}$, *while the actual label distributions are* μ *and* ν. *If the conditions in Theorem 3 or Corollary 4 hold with* μ, ν *replaced by* $\bar{\mu}, \bar{\nu}$, *and* (μ, ν) *is more divergent than* $(\bar{\mu}, \bar{\nu})$, *then with probability at least* $1 - n^{-10}$, Y^* *is the unique solution to programs* (2) *and* (3).

We prove this claim in Appendix C.

Theorem 6 suggests that one may choose the weight function by using the log likelihood ratios of a *conservative* estimate (i.e., a less divergent one) of the true label distribution pair.

3.3 Using Inaccurate Weights

We now consider a more general way of choosing the weight function w, which need not be conservative, but is only required to be not too far from the true log-likelihood ratios w^{MLE}. Let

$$\varepsilon(l) := w(l) - w^{\text{MLE}}(l) = w(l) - \log \frac{\mu(l)}{\nu(l)}$$

be the weighting error for each label $l \in \mathcal{L}$. Then the quantities $\Delta_\mu := \int_{\mathcal{L}} \varepsilon(l)\, \mathrm{d}\mu$ and $\Delta_\nu := \int_{\mathcal{L}} \varepsilon(l)\, \mathrm{d}\nu$ represent the average errors with respect to μ and ν. Note that Δ_μ and Δ_ν can be positive or negative. The theorem below characterizes the performance of using such an inaccurate weight function w.

Theorem 7 (Inaccurate Weights) *Let* b *and* ζ *be defined as in Theorem 3. Suppose that the weight function* w *satisfies*

$$|w(l)| \le \alpha \left| \log \frac{\mu(l)}{\nu(l)} \right|, \ \forall l \in \mathcal{L}, \quad |\Delta_\mu| \le \gamma D(\mu\|\nu), \quad \textit{and} \quad |\Delta_\nu| \le \gamma D(\nu\|\mu)$$

for some numbers $\alpha > 0$ *and* $\gamma < 1$. *Then* Y^* *is unique solution to the programs* (2) *and* (3) *with probability at least* $1 - n^{-10}$ *provided that*

$$D(\nu\|\mu) \ge c \frac{\alpha^2}{(1-\gamma)^2}(b+2)\frac{\log n}{K} \quad \textit{and} \quad D(\mu\|\nu) \ge c \frac{\alpha^2}{(1-\gamma)^2}(\zeta+1)(b+2)\left(\frac{n \log n}{K^2}\right).$$

We prove this claim in Appendix D.

Therefore, as long as the errors Δ_μ and Δ_ν in w are not too large, the condition for recovery is order-wise similar to that of the MLE weight given in Theorem 3. The numbers α and γ measure the level of inaccuracy in the weight function w with respect to the ideal choice w^{MLE}. The last two conditions in Theorem 7 thus quantify the relation between the inaccuracy in w and the statistical price to pay for using such a weight.

3.4 Linear Weights

We next consider a weight function that is an alternative to the MLE weights, and may be preferable in certain scenarios. It is based on a linear approximation to the MLE weight function, hence referred to as the *linear weights*:

$$w^{\text{LIN}}(l) := \frac{\mu(l) - \nu(l)}{\mu(l) + \nu(l)}.$$

It is straightforward to show that

$$\mathbb{E}_\mu w^{\text{LIN}} = -\mathbb{E}_\nu w^{\text{LIN}} = \frac{\text{Var}_\mu w^{\text{LIN}} + \text{Var}_\nu w^{\text{LIN}}}{2} = \frac{1}{2}\int_{\mathcal{L}} \frac{(\mu(l) - \nu(l))^2}{\mu(l) + \nu(l)}\, \mathrm{d}\lambda.$$

Using this observation, we immediately obtain the following corollary for w^{LIN} from Theorem 2.

Corollary 8 (Linear) *Suppose the weight function* w^{LIN} *is used. There exists a universal constant* c *such that* Y^* *is the unique solution to the program* (3) *with probability at least* $1 - n^{-10}$ *if*

$$\int_{l \in \mathcal{L}} \frac{(\mu(l) - \nu(l))^2}{\mu(l) + \nu(l)}\, \mathrm{d}\lambda \ge c \frac{n \log n}{K^2}. \tag{11}$$

Note the the left hand side of (11) coincides with the triangle discrimination term that has appeared in Corollary 4 as a lower bound of the KL-divergence. Comparing Corollary 8 above to the converse results in Theorem 5, we see that, at least for the case of two equal-size clusters, the linear weight function w^{LIN} provides order-wise optimal recovery guarantees.

The linear weights $w^{\text{LIN}}(l)$ are always between -1 and 1 and thus well bounded. Empirically, it is observed that w^{LIN} performs slightly worse than the MLE weight function w^{MLE} in general. However, in certain cases w^{LIN} can actually outperform w^{MLE}. In particular, comparing Corollaries 4 and 8 suggests that this most likely happens when the quantity ζ is large, i.e., $D(\nu\|\mu) \gg D(\mu\|\nu)$. We demonstrate this phenomenon in our empirical results in Section 6.2, where ζ is large in the case of dense graphs.

3.5 Unbounded Weights

The general result in Theorem 2 is valid for any weight function that is uniformly bounded, i.e., $|w(l)| \le b$ a.e. on $\mathcal{L}$. (The theorem becomes vacuous if $b \to \infty$.) We now give a more general result, which allows some of the weights to have arbitrarily large magnitudes. Unbounded weights arise when some of the pairwise observations are highly certain, or given as hard constraints. For example, the label between nodes i and j may have the form l_{same} = "these nodes are known to be in the same cluster", in which case assigning an unbounded weight $w(l_{\text{same}}) \to \infty$ in the program (1) forces the nodes i and j to be clustered together. Similarly, for two nodes that are known to be in different clusters, a large negative weight would be desirable.

We identify the set of labels associated with unbounded weights as

$$\mathcal{L}_\infty := \{l \in \mathcal{L} : |w(l)| > b_\infty\},$$

where b_∞ should be thought of as a very large positive number. For all $l \notin \mathcal{L}_\infty$, we assume that $|w(l)| \le b$ for some $b < b_\infty$. We further assume that the weight function w is $\mathcal{L}_\infty$-*consistent* in the sense that

$$\mu(l) = 0, \ \ \forall l \in \mathcal{L}_\infty : w(l) < 0 \qquad \text{and} \qquad \nu(l) = 0, \ \ \forall l \in \mathcal{L}_\infty : w(l) > 0.$$

This condition ensures that whenever a node pair is assigned with unbounded weight, the sign of the weight is consistent with the true cluster relation between the pair, that is, with probability one,

$$W_{ij}(2Y^*_{ij} - 1) > 0, \quad \forall (i,j) : L_{ij} \in \mathcal{L}_\infty. \tag{12}$$

Denote by $s_\mu := \int_{\mathcal{L}_\infty} \mathrm{d}\mu$ the total probability of the labels in $\mathcal{L}_\infty$ under the distribution μ, and

$$\tilde{w}_b(l) := \begin{cases} 0 & \text{if } l \in \mathcal{L}_\infty, \\ w(l) & \text{otherwise,} \end{cases}$$

the weight function restricted to labels with bounded weights. Finally, in the bi-clustering setting, we need an additional parameter ξ that measures bi-cluster skewness:

$$\xi := \max_{k\in[r]} \left\{ \sqrt{\frac{|C_k|}{|C'_k|}}, \sqrt{\frac{|C'_k|}{|C_k|}} \right\}.$$

In the standard clustering case we simply have $\xi = 1$.

Under the above setting, we have the following result valid for unbounded weights with arbitrarily large b_∞.

Theorem 9 *Suppose that the weight function w is $\mathcal{L}_\infty$-consistent, and $\beta > 0$ is any fixed number. There exists a universal constant $c > 0$ such that the following is true. If*

$$\mathbb{E}_\mu \tilde{w}_b \geq 0, \tag{13}$$

$$-\mathbb{E}_\nu \tilde{w}_b > c\,\frac{b\beta\log n + \sqrt{K\beta\log n}\sqrt{\mathrm{Var}_\nu \tilde{w}_b}}{K}, \tag{14}$$

and at least one of the following two inequalities holds:

$$\mathbb{E}_\mu \tilde{w}_b > c\,\frac{b\beta\log n + \sqrt{n\beta\log n}\sqrt{\max(\mathrm{Var}_\mu \tilde{w}_b, \mathrm{Var}_\nu \tilde{w}_b)}}{K}, \tag{15}$$

$$s_\mu + \frac{\mathbb{E}_\mu \tilde{w}_b}{b_\infty} > c\,\max\left\{ \max\left\{1, \frac{b\xi}{b_\infty}\right\}\frac{\beta\log n}{K}, \frac{n\max(\mathrm{Var}_\mu \tilde{w}_b, \mathrm{Var}_\nu \tilde{w}_b)}{Kb_\infty^2} \right\}, \tag{16}$$

then with probability at least $1 - n^{-\beta}$ the solution to the programs (2) *and* (3) *is unique and equals Y^*.*

We prove this claim in Section 7.

Theorem 9 is particularly useful when we take $b_\infty \to \infty$ while keeping b, n and K finite. In this case the condition (16) simplifies to

$$s_\mu > c\frac{\beta\log n}{K}, \tag{17}$$

a lower bound on the probability of observing a label from $\mathcal{L}_\infty$ between two nodes in the same cluster. The conditions (17) together with (14) are sufficient for successful recovery of Y^*. Significantly, these conditions only depend *logarithmically* on n, which is in contrast to the dependence on $\sqrt{n}$ in Theorem 2. This improvement demonstrates the benefit of assigning unbounded weights to labels in $\mathcal{L}_\infty$ (i.e., label with high certainty).

Also note that Theorem 2 is a special case of Theorem 9, as we show in Section 7.

4. Consequences and Applications

We now apply the general results in the last section to different concrete cases. In sections 4.1 and 4.2, we consider two clustering settings with sub-Gaussian weights or non-uniform edge probabilities, both of which generalize the standard stochastic block model. In these settings two immediate corollaries of our main theorems recover, and in fact improve upon, existing results. In sections 4.3 and 4.4, we turn to the more complicated setting of clustering time-varying graphs and derive several new results.

Throughout this section we use c, c_0 etc. to denote universal positive constants.

4.1 Clustering a Sub-Gaussian Matrix with Partial Observations

Analogous to the planted partition and stochastic block models for unweighted graphs, the *submatrix localization* problem concerns clustering a weighted graph whose adjacency matrix has sub-Gaussian entries. This problem is often used as an idealized model for the bi-clustering of drugs and proteins, species and gene sequences, customers and products, and other forms of object-feature pairs (see Kolar et al., 2011, and references therein).

Here we consider a generalization of this problem, where some of the entries are unobserved. This setting arises when the relations between some node pairs are costly to determine, so it is unknown whether or not they are connected by an edge, nor is the weight of the edge (Shamir and Tishby, 2011). For simplicity, we state our results assuming that the adjacency matrix and its submatrices are symmetric, and that the entries of the matrix are Gaussian. Our theoretical results apply to the general sub-Gaussian case without change.

Specifically, we observe a matrix $L \in (\mathbb{R}\cup\{?\})^{n\times n}$, where $L_{ij} =?$ with probability $1-s$, and otherwise L_{ij} follows the Gaussian distribution $\mathcal{N}(u_{ij}, 1)$.[5] Here $L_{ij} =?$ denotes that the relation between the i-th and j-th nodes is unobserved. The means $\{u_{ij}\}$ of the Gaussians satisfy the following: within L there are r submatrices of size at least $K\times K$ with disjoint row and column support; we have $u_{ij} = \bar{u}$ if the pair (i,j) is inside one of the submatrices, and $u_{ij} = \underline{u}$ if outside, where $\bar{u} > \underline{u} \geq 0$. The goal is to locate these submatrices with elevated means given the large matrix L. We may think of this problem as finding clusters in a weighted graph with the partially observed adjacency matrix L.

This problem is a special case of our general framework with a mixed-valued label set $\mathcal{L} = \mathbb{R}\cup\{?\}$. The base measure λ is chosen to be such that it equals the Lebesgue measure on $\mathbb{R}$ and 1 on $\{?\}$. Then the density functions of μ and ν are

$$\mu(l) = \begin{cases} 1-s, & \text{if } l =?, \\ s\cdot\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(l-\bar{u})^2}{2}\right), & \text{if } l\in\mathbb{R}, \end{cases} \quad \text{and} \quad \nu(l) = \begin{cases} 1-s, & \text{if } l =?, \\ s\cdot\frac{1}{\sqrt{2\pi}}\exp\left(-\frac{(l-\underline{u})^2}{2}\right), & \text{if } l\in\mathbb{R}. \end{cases}$$

The MLE weight function therefore has the form

$$w^{\mathrm{MLE}}(l) \propto \begin{cases} 0, & \text{if } l =?, \\ l - (\bar{u}+\underline{u})/2, & \text{if } l\in\mathbb{R}. \end{cases}$$

5. Equivalently, L_{ij} is generated according to $\mathcal{N}(u_{ij}, 1)$, and then is replaced by ? with probability $1-s$.

This submatrix localization problem is most interesting when $\bar{u} - \underline{u} \leq c_0\sqrt{\log n}$ for some universal constant $c_0 > 0$,[6] which we assume to hold in the sequel. Observe that $D(\mu\|\nu) = D(\nu\|\mu) = \frac{1}{4}s(\bar{u} - \underline{u})^2$. In Appendix E we apply the general result in Theorem 2 to derive the following recovery guarantee.

Corollary 10 (Gaussian Graphs) *Under the above setting, if*

$$s\,(\bar{u} - \underline{u})^2 \geq c\frac{n\log^3 n}{K^2}, \tag{18}$$

then with probability at least $1 - 2n^{-10}$, Y^* *is the unique solution to the programs* (2) *and* (3) *with the weight function* $w = w^{MLE}$.

In the full observation case $s = 1$, Corollary 10 recovers the results in Ames (2014); Balakrishnan et al. (2011); Kolar et al. (2011) up to log factors. Our results are more general as we allow for partial observation, which is not considered in previous work. Corollary 10 allows the observation probability to be as small as $s = \Omega(\frac{n}{K^2})$, or the signal strength to be $\bar{u} - \underline{u} = \Omega(\frac{\sqrt{n}}{K})$ (ignoring log factors). In general we see a quadratic tradeoff between these two quantities: with four times more observations, the signal strength can be 50% smaller.

4.2 Planted Partition with Non-Uniform Edge Probabilities

Recall that in the standard planted partition model, the observed unweighted graph is generated by independently connecting each node pair with probability p if they are in the same cluster, or with probability q if they are in different clusters, where $p, q \in [0, 1]$ are two fixed numbers. Here we consider a more general setting, where the in/cross-cluster edge probabilities can be different across node pairs. This setting has a range of applications as discussed at the end of this sub-section.

Concretely, suppose that each node pair (i, j) is associated with two numbers P_{ij} and Q_{ij}. Independently for each (i, j), the values of P_{ij} and Q_{ij} are generated randomly according to some distribution ψ on $[0, 1] \times [0, 1]$, which is assumed to have a density function with respect to some reference measure λ_0. Conditioned on P_{ij} and Q_{ij}, the nodes i and j are connected by an edge with probability P_{ij} if they are in the same cluster, or with probability Q_{ij} if they are in different clusters. For each (i, j), one knows the values of P_{ij} and Q_{ij}, but not which of them is the probability that generates the edge. Assuming that there are r ground-truth clusters of size at least K, the goal is to find these clusters given the graph adjacency matrix $A \in \{0, 1\}^{n\times n}$ and the edge probabilities (P_{ij}) and $(Q_{ij}) \in [0, 1]^{n\times n}$.

This model can be cast as a special case of our labeled framework, in which each pairwise label is a triplet of the form $L_{ij} = (A_{ij}, P_{ij}, Q_{ij}) \in \mathcal{L} = \{0, 1\} \times [0, 1] \times [0, 1]$. Note that the labels take a combination of discrete and real values. If we choose the base measure λ to be the product of the counting measure on $\{0, 1\}$ and λ_0, then the density functions of μ and ν are given as follows: for each $l = (a, p, q) \in \{0, 1\} \times [0, 1] \times [0, 1]$,

$$\mu(l) = \begin{cases} p\psi(p, q), & \text{if } a = 1, \\ (1 - p)\psi(p, q), & \text{if } a = 0, \end{cases} \quad \text{and} \quad \nu(l) = \begin{cases} q\psi(p, q), & \text{if } a = 1, \\ (1 - q)\psi(p, q), & \text{if } a = 0. \end{cases}$$

6. Otherwise, if $\bar{u} - \underline{u} > c_0\sqrt{\log n}$ for some sufficiently large constant $c_0 > 0$, then with high probability the smallest entry inside the submatrices will dominate the largest entry outside, so simple element-wise thresholding finds the submatrices (Balakrishnan et al., 2011; Kolar et al., 2011).

The MLE weight function therefore has the form

$$w^{\text{MLE}}(l) = w^{\text{MLE}}\big((a, p, q)\big) = a\log\frac{p}{q} + (1 - a)\log\frac{1 - p}{1 - q}. \tag{19}$$

Applying Corollary 4 for MLE weights, we immediately obtain the following recovery guarantee:

Corollary 11 (Non-uniform Edge Probabilities, I) *Under the above setting, suppose that there exist* ζ *and* b *such that* $D(\nu\|\mu) \leq \zeta D(\mu\|\nu)$ *and* $|\log\frac{\mu(l)}{\nu(l)}| \leq b$ *almost everywhere. If*

$$\mathbb{E}_{(P,Q)\sim\psi}\left[\frac{(P - Q)^2}{(P + Q)(2 - P - Q)}\right] \geq c\,(\zeta + 1)(b + 2)\frac{n\log n}{K^2}.$$

then with probability at least $1 - n^{-10}$, Y^* *is the unique solution to the programs* (2) *and* (3) *with the MLE weight function in* (19). *One may take* $\zeta = 2b + 3$.

Here the notation $(P, Q) \sim \psi$ means that (P, Q) is a pair of numbers sampled from the distribution ψ.

We can simplify the above condition considerably by considering a conservative weight function (cf. Section 3.2): on the RHS of (19) we replace p and q with $\bar{p} = \frac{3}{4}p + \frac{1}{4}q$ and $\bar{q} = \frac{1}{4}p + \frac{3}{4}q$, respectively, which leads to the weight function

$$\bar{w}^{\text{MLE}}(l) = \bar{w}^{\text{MLE}}\big((a, p, q)\big) = a\log\frac{3p + q}{p + 3q} + (1 - a)\log\frac{4 - 3p - q}{4 - p - 3q}. \tag{20}$$

These weights are clearly bounded by a constant. Applying Theorem 6 for monotonicity together with Corollary 4 for MLE weights, we obtain the following recovery guarantee:

Corollary 12 (Non-uniform Edge Probabilities, II) *Under the above setting, suppose that* $P \geq Q$ *almost surely with respect to* ψ. *If*

$$\mathbb{E}_{(P,Q)\sim\psi}\left[\frac{(P - Q)^2}{P(1 - Q)}\right] \geq c\,\frac{n\log n}{K^2},$$

then with probability at least $1 - n^{-10}$, Y^* *is the unique solution to the programs* (2) *and* (3) *with the conservative MLE weight function* $\bar{w}^{MLE}$ *in* (20).

As a passing observation, we note the $\log n$ factor in the above two corollaries can be removed by a slightly more careful analysis; see Remark 20.

Below we discuss two applications of Corollary 12, which leads to generalization and improvement over existing results.

4.2.1 CLUSTERING PARTIALLY OBSERVED UNWEIGHTED GRAPHS

In Section 4.1 we discussed clustering Gaussian weighted graphs with partial observations. Here we consider such a similar setting for unweighted graphs under the planted partition model.[7]

7. The planted partition model satisfies the sub-Gaussian assumption, so the results in Section 4.1 in fact apply to this setting. Here we take into account the variance information to derive tighter bounds.

Specifically, suppose that the edge probabilities $(P_{ij}, Q_{ij}) \sim \psi$ is distributed as $(P_{ij}, Q_{ij}) = (p, q)$ with some probability s, and $P_{ij} = Q_{ij} = \frac{1}{2}$ with probability $1 - s$, where $p > q$ are two fixed numbers. This setting extends the standard planted partition model to partial observation: with probability $1 - s$, the connection A_{ij} between a pair (i, j) is known to be purely random and uninformative about the cluster membership of i and j—having such a purely random observation is equivalent to saying that one does not observe whether or not i and j are connected by an edge.[8] This setting is sometimes called the planted partition model with partial or *censored* edge observation. Note that the conservative MLE weight function (20) assigns zero weight to unobserved/uninformative pairs, as should be expected.

By calculating the left hand side of the condition in Corollary 12, we immediately obtain the following guarantee.

Corollary 13 *Under the above planted partition model with partial observation, if*

$$\frac{s(p-q)^2}{p(1-q)} \geq c\,\frac{n \log n}{K^2},$$

then with probability at least $1 - n^{-10}$*,* Y^* *is the unique solution to the programs* (2) *and* (3) *with the conservative MLE weight function* $\bar{w}^{MLE}$ *in* (20)*.*

In the full observation setting $s = 1$, the above result matches the best existing bounds for standard planted partition (e.g., in Chen et al., 2014c; Anandkumar et al., 2014), up to a $\log n$ factor that can be removed (see the remark after Corollary 12). In the partial observation setting $s < 1$, the work by Vinayak et al. (2014); Chen et al. (2014a) gives a similar bound under the additional assumption $p > 0.5 > q$, which is not required by Corollary 13. For general p and q, the best existing bounds can be found in Oymak and Hassibi (2011); Chen et al. (2014c), where unobserved entries in the adjacency matrix A are replaced with 0 and recovery is guaranteed under the condition $\frac{s(p-q)^2}{p(1-sq)} \gtrsim \frac{n \log n}{K^2}$.[9] Our result is tighter when p and q are close to 1. Finally, we note that our result is non-asymptotic and valid under any scaling of the parameters n, K, r, p, q, s.

4.2.2 PLANTED PARTITION WITH NON-UNIFORM UNCERTAINTY

We next consider an application of Corollary 12 to a further generalization of the partial observation setting above. In the above setting, if an entry A_{ij} of the adjacency matrix is unobserved or purely random, the cluster relation between the nodes i and j is completely uncertain (based on only A_{ij}). Here we assume that each A_{ij} is associated with a different, continuous level of uncertainty. For some node pairs, the observation A_{ij} of the existence of an edge (or respectively, the absence of an edge) may be generated by accurate measurements, and therefore a strong indicator that the nodes i and j should be assigned to the same (or respectively, different) clusters.

For example, in *crowd-clustering* a number of users are asked whether or not they think a pair of nodes (e.g., movies or images) are similar, and the final graph is constructed by aggregating the users' answers by say majority voting (Gomes et al., 2011; Yi et al., 2012). The uncertainty levels are naturally non-uniform across pairs: a pair receiving a large number of unanimous votes

8. This model can be rephrased in the following equivalent form: given a partially observed adjacency matrix $A \in \{0, 1, ?\}^{n \times n}$, one replaces each unobserved entry ? in A with an independent Bernoulli random variable.
9. We use $\gtrsim$ when the inequality is up to a constant factor.

is associated with high confidence, whereas those with a few votes or divergent votes have low confidence, and a pair receiving no votes is completely uncertain.

In such a setting, each pairwise observation A_{ij} should be treated differently according to its level of uncertainty. Often, one has prior knowledge on the uncertainty levels, for example when the graph is built from a known process as in the crowd-clustering example. Intuitively, using such knowledge improves clustering performance. It is, however, less clear how this knowledge can be used and how much improvement it can provide. Below we use Corollary 12 to obtain a quantitative answer.

For simplicity, we focus on a special case of the setting in Corollary 12: we assume that the distribution ψ of edge probabilities is symmetric, in the sense that we always have $Q_{ij} \equiv 1 - P_{ij}$, where $Q_{ij} \in [0, \frac{1}{2}]$.[10] In this case, the quantity Q_{ij} can be interpreted as the probability of an erroneous observation—namely, a no-edge between two nodes in the same cluster (a false negative), or an edge between two nodes in different clusters (a false positive). Therefore, Q_{ij} measures the level of uncertainty in the observation A_{ij} at (i, j). In particular, $Q_{ij} = 0$ means that A_{ij} is a noiseless observation of the cluster relation between i and j, whereas $Q_{ij} = \frac{1}{2}$ corresponds to a completely uncertain observation with no information.

For each observation $A_{ij} \in \{0, 1\}$ with an uncertainty level $Q_{ij} \in [0, \frac{1}{2}]$, the conservative MLE weight function (20) assigns the weight

$$W_{ij} = (2A_{ij} - 1) \log \frac{3 - 2Q_{ij}}{1 + 2Q_{ij}}.$$

Note that the magnitude $|W_{ij}|$ of the weight is small for a high uncertainty level Q_{ij}; in particular, one has $W_{ij} = 0$ for a completely uncertain observation with $Q_{ij} = \frac{1}{2}$.

Using these weight, Corollary 12 guarantees that the programs (2) and (3) recover the clusters with high probability provided that

$$\mathbb{E}\left[\left(\frac{1}{2} - Q\right)^2\right] \gtrsim \frac{n \log n}{K^2},$$

where the expectation is with respect to $(P, Q) \sim \psi$. We can compare this result with the presumably sub-optimal unweighted approach, which ignores the non-uniformity of the uncertainty level and uses uniform weights $W_{ij} = 2A_{ij} - 1 \in \{-1, 1\}$. By Theorem 2 this unweighted approach succeeds if

$$\left(\frac{1}{2} - \mathbb{E}Q\right)^2 \gtrsim \frac{n \log n}{K^2}.$$

The difference between the left hand sides of the last two conditions is $\mathbb{E}[Q^2] - (\mathbb{E}Q)^2 = \mathrm{Var}[Q]$, the variance of the uncertainty level.[11] This is therefore evidence that the weighted approach is indeed better than the unweighted one, and the gain is large precisely when the uncertainty level is very non-uniform with a high variance. We refer the readers to Chen et al. (2014b) for empirical verification of this gain as well as further discussion and applications.

Of course our results are not limited to the symmetric setting $Q_{ij} \equiv 1 - P_{ij}$. Corollary 12 is applicable under a general distribution ψ of P_{ij} and Q_{ij}, in which case a larger value of $|P_{ij} - Q_{ij}|$ corresponds to a lower level of uncertainty. We omit discussion of this general setting due to space limit.

10. That is, the density function $\psi(p, q)$ is supported on the line segment $\{(p, q) \in \mathbb{R}^2 : q = 1 - p, 0 \leq q \leq \frac{1}{2}\}$.
11. Asymptotically the difference between the right hand sides can be made arbitrarily small, regardless of the contants. Furthermore, empirically the constants involved are very similar, depending on how the weights are bounded.

4.3 Clustering Time-varying Multiple-snapshot Graphs

Standard graph clustering concerns the partition of a single, static graph. We now consider a setting where the graph is time-varying. Specifically, for each time interval $t = 1, 2, \ldots, T$, one observes a snapshot of the (label) graph $L^{(t)} \in \mathcal{L}^{n\times n}$. In this subsection, we assume that each snapshot is generated by the distributions μ and ν independently of other snapshots. In the next subsection we consider the more general setting of Markov snapshots.

We can map this problem into our labeled framework, by considering the whole time sequence of $\bar{L}_{ij} := (L_{ij}^{(1)}, \ldots, L_{ij}^{(T)})$ as a single label observed at the pair (i, j). In this case the label set is the set of all possible sequences, i.e., $\bar{\mathcal{L}} = \mathcal{L}^T$, and the label distributions are (with a slight abuse of notation) given by the products $\mu(\bar{L}_{ij}) = \prod_{t=1}^{T} \mu(L_{ij}^{(t)})$ and $\nu(\bar{L}_{ij}) = \prod_{t=1}^{T} \nu(L_{ij}^{(t)})$. The MLE weight (normalized by T) is therefore the average log-likelihood ratio:

$$w^{\text{MLE}}(\bar{L}_{ij}) = \frac{1}{T} \log \frac{\mu(\bar{L}_{ij})}{\nu(\bar{L}_{ij})} = \frac{1}{T} \sum_{t=1}^{T} \log \frac{\mu(L_{ij}^{(t)})}{\nu(L_{ij}^{(t)})}.$$

Since the weight $w^{\text{MLE}}(\bar{L}_{ij})$ is the average of T independent random variables, its variance scales as $\frac{1}{T}$. Applying Theorem 2 and following almost identical arguments as in the proof of Theorem 3, we obtain the following guarantee for clustering a time-varying graph with independent snapshots.

Corollary 14 (Independent Snapshots) *Suppose that* $|\log \frac{\mu(l)}{\nu(l)}| \le b, \forall l \in \mathcal{L}$ *and* $D(\nu\|\mu) \le \zeta D(\mu\|\nu)$. *If*

$$D(\nu\|\mu) \ge c(b+2)\frac{\log n}{K} \qquad \text{and} \tag{21}$$

$$D(\mu\|\nu) \ge c(b+2)\max\Big\{\frac{\log n}{K}, (\zeta+1)\frac{n\log n}{TK^2}\Big\}, \tag{22}$$

then with probability at least $1 - n^{-10}$, Y^* *is the unique solution to the programs* (2) *and* (3) *with the MLE weights given above.*

Note that setting $T = 1$ above recovers the result in Theorem 3 for clustering a single label graph.

The second term on the right hand side of (22) usually dominates. In this case, Corollary 14 says that the clustering problem becomes easier if T is larger (i.e., more snapshots of the graph are observed), and the relation between T and cluster recovery is quantified precisely. As a concrete example, suppose that each snapshot is generated by the standard planted partition model with edge probabilities p and q, where $q = p/2$. By Corollary 14 we need $p \gtrsim \frac{n\log n}{TK^2}$ to guarantee cluster recovery. Therefore, if four times more snapshots are available, then one can recover clusters whose sizes K are 50% smaller. Similarly, we see a tradeoff between the number of snapshots T and the graph sparsity p.

4.4 Markov Sequence of Snapshots

We now consider a more general and useful setting for time-varying graphs, where the graph snapshots are not assumed to be independent but instead form a Markov chain.

For simplicity we assume that the Markov chain is time-invariant and has a finite state space and a unique stationary distribution that is also the initial distribution. Therefore, the observations

$L_{ij}^{(t)}, t = 1, 2, \ldots$ at each pair (i, j) are generated by first drawing a label $L_{ij}^{(1)}$ from the stationary distribution μ_0 (or ν_0, according to the cluster membership of i and j) over the finite set $\mathcal{L}$ at $t = 1$, then applying a one-step transition to obtain the label at each subsequent t. In particular, given the previously observed label l, let the intra-cluster and inter-cluster conditional distributions of the next observation be $\mu(\cdot|l)$ and $\nu(\cdot|l)$. We assume that the Markov chains $\{L_{ij}^{(1)}, L_{ij}^{(2)}, \ldots\}$ with respect to both μ and ν are geometrically ergodic, in the sense that for each integer $\tau \ge 1$ and pair $L_{ij}^{(1)}, L_{ij}^{(\tau+1)}$,

$$\Big|\Pr_\mu\big(L_{ij}^{(\tau+1)}|L_{ij}^{(1)}\big) - \mu_0\big(L_{ij}^{(\tau+1)}\big)\Big| \le \kappa\phi^\tau \quad \text{and} \quad \Big|\Pr_\nu\big(L_{ij}^{(\tau+1)}|L_{ij}^{(1)}\big) - \nu_0\big(L_{ij}^{(\tau+1)}\big)\Big| \le \kappa\phi^\tau \tag{23}$$

for some constants $\kappa \ge 1$ and $0 < \phi < 1$ that only depend on μ and ν. Let $D_l(\mu\|\nu)$ denote the KL-divergence between $\mu(\cdot|l)$ and $\nu(\cdot|l)$; $D_l(\nu\|\mu)$ is similarly defined. Let

$$\mathbb{E}_{\mu_0} D_l(\mu\|\nu) := \textstyle\sum_{l\in\mathcal{L}} \mu_0(l) D_l(\mu\|\nu)$$

and similarly for $\mathbb{E}_{\nu_0} D_l(\nu\|\mu)$. As in the previous subsection, we use the average log-likelihood ratio $w^{\text{MLE}}(\bar{L}_{ij}) = \frac{1}{T}\log\frac{\mu(\bar{L}_{ij})}{\nu(\bar{L}_{ij})}$ as the weight, where $\mu(\bar{L}_{ij})$ is the joint distribution of the sequence $\bar{L}_{ij} = \big(L_{ij}^{(1)}, \ldots, L_{ij}^{(T)}\big)$ under the above Markov chain; similarly for $\nu(\bar{L}_{ij})$. Finally, define the quantity

$$\Phi := \frac{\kappa}{(1-\phi)\min_{l\in\mathcal{L}}\{\mu_0(l), \nu_0(l)\}}.$$

With these notations, we have the following corollary of Theorem 2.

Corollary 15 (Markov Snapshots) *Under the above setting, suppose that for each label pair* $(l, l') \in \mathcal{L}\times\mathcal{L}$, *we have* $\Big|\log\frac{\mu_0(l)}{\nu_0(l)}\Big| \le b$, $\Big|\log\frac{\mu(l'|l)}{\nu(l'|l)}\Big| \le b$, $D(\nu_0\|\mu_0) \le \zeta D(\mu_0\|\nu_0)$ *and* $\mathbb{E}_{\nu_0} D_l(\nu\|\mu) \le \zeta\mathbb{E}_{\mu_0} D_l(\mu\|\nu)$ *for some numbers* b *and* ζ. *If*

$$\frac{1}{T}D(\nu_0\|\mu_0) + \Big(1-\frac{1}{T}\Big)\mathbb{E}_{\nu_0} D_l(\nu\|\mu) \ge c(b+2)\frac{\log n}{K}, \tag{24}$$

$$\frac{1}{T}D(\mu_0\|\nu_0) + \Big(1-\frac{1}{T}\Big)\mathbb{E}_{\mu_0} D_l(\mu\|\nu) \ge c(b+2)\max\Big\{\frac{\log n}{K}, (\zeta+1)\Phi\frac{n\log n}{TK^2}\Big\}, \tag{25}$$

then with probability at least $1 - n^{-10}$, Y^* *is the unique solution to the programs* (2) *and* (3) *with MLE weight function* w^{MLE}.

See Appendices F for the proof of this claim, and G for additional discussion of the assumptions.

As an illuminating example, consider the case where $\mu_0 \approx \nu_0$, i.e., the marginal distributions for individual snapshots are very close or even identical in and across clusters. This means that the information about cluster membership is not contained in the labels themselves in individual snapshots, but instead in the *change* of labels between snapshots. This point is made evident in the left hand sides of (24) and (25), as first terms therein are approximately zero. In this case, *it is necessary to use the temporal information* in order to perform clustering. Such information would be lost if one disregards the ordering of the snapshots (for example, by averaging the snapshots) and then applies a single-snapshot clustering algorithm. This example therefore highlights a crucial difference between clustering time-varying graphs and static graphs.

5. Implementation

The convex programs (2) and (4) used in our clustering approach are semidefinite programs and can be solved efficiently by the Alternating Direction Method of Multipliers (ADMM) (Boyd et al., 2011). We provide the pseudocode for a complete implementation of the programs (2) and (4) in Algorithms 1 and 2 below.

Algorithm 1 ADMM solver for Program (2)

Input: Weight matrix $W \in \mathbb{R}^{n\times n}$ symmetric, convergence threshold $\epsilon > 0$
Output: Y

1. $\rho \leftarrow 1, k \leftarrow 0$
2. $Y^k \leftarrow 0, Q^k \leftarrow 0, (Y^k, Q^k \in \mathbb{R}^{n\times n})$
3. $X^{k+1} \leftarrow U \max\{\Lambda, 0\}U^\top$, where $U\Lambda U^\top$ is an eigen-decomposition of $(Y^k - Q^k + \frac{1}{\rho}W)$.
4. $Y^{k+1} \leftarrow \min\left\{\max\left\{X^{k+1} + Q^k, 0\right\}, 1\right\}$
5. $Q^{k+1} \leftarrow Q^k + X^{k+1} - Y^{k+1}$
6. If $\|X^{k+1} - Y^{k+1}\|_F \le \epsilon \max\{\|X^{k+1}\|_F, \|Y^{k+1}\|_F\}$ and $\|Y^{k+1} - Y^k\|_F \le \epsilon\|Q^{k+1}\|_F$ then stop and output $Y = Y^{k+1}$.
7. (Optional) Update ρ and Q^{k+1}
8. $k \leftarrow k + 1$, go to step 3.

The inputs and outputs of Algorithms 1 and 2 are the same terms used in the programs (2) and (4), respectively. We find that in practice, using the tuning parameter $\eta = \sqrt{2n}$ for the program (4) works well. The criterion for convergence is specified by the threshold $\epsilon > 0$, and using $\epsilon = 10^{-4}$ provides a good tradeoff between the convergence time and the quality of the solution. All our experiment results in Section 6 are based on these choices of η and ϵ.

In both Algorithms 1 and 2, an optional Step 7 for updating ρ can be used to potentially improve the speed of convergence. Boyd et al. (2011) suggest one such updating rule, which takes an additional parameter τ and aims to balance the primal and dual residuals. In particular, if $\|X^{k+1} - Y^{k+1}\|_F > \tau\rho\|Y^{k+1} - Y^k\|_F$, then set $\rho \leftarrow 2\rho$ and $Q^{k+1} \leftarrow Q^{k+1}/2$. On the other hand, if $\tau\|X^{k+1} - Y^{k+1}\|_F < \rho\|Y^{k+1} - Y^k\|_F$, then set $\rho \leftarrow \rho/2$ and $Q^{k+1} \leftarrow 2Q^{k+1}$. Typically $\tau = 10$ is a stable choice, which we use in all our experiments. For further details of this updating rule we refer the reader to Boyd et al. (2011).

In practice, due to finite precision and numerical errors, the output matrix Y will not in general have entries that are exactly 0 or 1, even if the true cluster matrix Y^* is in fact the unique optimal solution. If this is the case, a simple rounding of Y will give the correct solution, from which the clusters can then be obtained by sorting the rows. If Y can not be rounded into a cluster matrix, we use a simple k-means algorithm to the rows of Y to extract a desired number of clusters.

Algorithm 2 ADMM solver for Program (4)

Input: Weight matrix $W \in \mathbb{R}^{n_1\times n_2}$, tuning parameter $\eta > 0$, convergence threshold $\epsilon > 0$
Output: Y

1. $\rho \leftarrow 1, k \leftarrow 0$
2. $Y^k \leftarrow 0, Q^k \leftarrow 0, (Y^k, Q^k \in \mathbb{R}^{n_1\times n_2})$
3. $X^{k+1} \leftarrow U \max\{\Sigma - \frac{\eta}{\rho}, 0\}V^\top$, where $U\Sigma V^\top$ is an SVD of $(Y^k - Q^k)$.
4. $Y^{k+1} \leftarrow \min\left\{\max\left\{X^{k+1} + Q^k + \frac{1}{\rho}W, 0\right\}, 1\right\}$
5. $Q^{k+1} \leftarrow Q^k + X^{k+1} - Y^{k+1}$
6. If $\|X^{k+1} - Y^{k+1}\|_F \le \epsilon \max\{\|X^{k+1}\|_F, \|Y^{k+1}\|_F\}$ and $\|Y^{k+1} - Y^k\|_F \le \epsilon\|Q^{k+1}\|_F$ then stop and output $Y = Y^{k+1}$.
7. (Optional) Update ρ and Q^{k+1}
8. $k \leftarrow k + 1$, go to step 3.

6. Empirical results

In this section we report empirical results by applying Algorithm 1 to a variety of both synthetic and real data sets.[12] In our experiments, unless specified otherwise, we report the "full recovery rate" based on 100 repeated trials, i.e., the fraction of trials where the output of Algorithm 1 (after rounding to the nearest 0 and 1) equals Y^* exactly. Error bars show 95% confidence intervals.

6.1 Clustering with General Labels

We first evaluate graph clustering performance on a generic graph model with 5 labels. We use $n = 200$ with 4 equal-size clusters. In each experiment, two distributions μ and ν are randomly chosen from a uniform prior over all distributions as the in-cluster and the cross-cluster label distributions. Then, 100 random graphs are generated using this (μ, ν) pair, and each clustering outcome is checked against the corresponding ground truth. This is repeated 500 times to get a large variety of pairs. In other words, 500 random (μ, ν) pairs are generated, each tested on 100 random graphs. According to Theorem 3, the KL-divergence between μ and ν is the key deciding factor for the successful recovery of the underlying true clusters. The results are shown in Figure 1. In the left panel of Figure 1, we use the sum $D(\mu\|\nu) + D(\nu\|\mu)$ as the predictor (the horizontal axis is cut off at 2 since beyond this range all recovery rates are essentially 1). In the right panel, we use $\min\{D(\mu\|\nu), D(\nu\|\mu)\}$ as the predictor. The results indeed support the theoretical prediction as given by conditions (7) and (8) of Theorem 3.

12. Although we only report results from Algorithm 1 and for standard clustering, we note that similar results are obtained with Algorithm 2 and in the bi-clustering case as well.

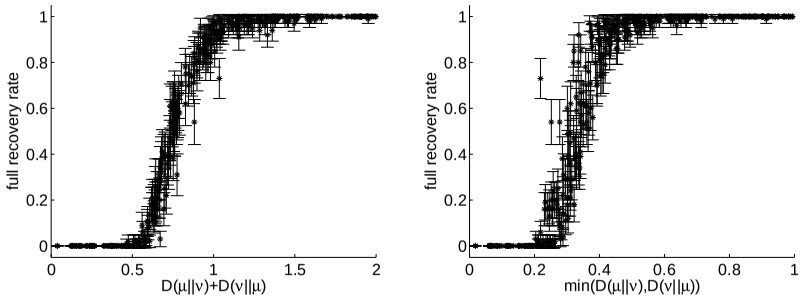

Figure 1: Clustering performance under different label distributions

6.2 Clustering Sparse/Dense Graphs with Partial Observations

In the next experiment, we test the planted partition model with partial observations. The model is as described in Section 4.2. Each pair is observed with probability s. For each observed in-cluster pairs, an edge is generated with probability p while for each observed cross-cluster pairs, an edge is generated with probability q. We consider both sparse graphs (p and q close to 0) and dense graphs (p and q close to 1). For the sparse case, we fix $q = 0.02$ and vary p, whereas for the dense case, we fix $p = 0.98$ and vary q.

Figures 2 and 3 show the results for graphs with $n = 200$, and Figures 4 and 5 show the results for $n = 1000$, with 4 equal-size clusters in both cases. For $n = 200$, we set the observation probability to $s = 0.8$; for $n = 1000$, we use $s = 0.5$ since the problem is significantly easier.

For comparison, we include results for the MLE weights (w^{MLE}), the linear weights (w^{LIN}), and the uniform weights. An imputation scheme labeled "MLE (no partial)", where all unobserved entries are treated as "no edge", is also included.

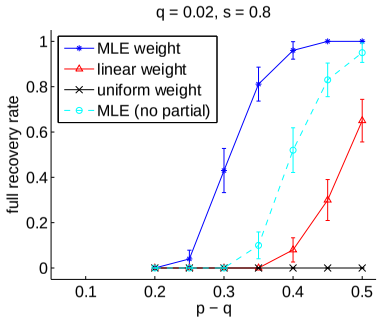

Figure 2: Clustering sparse graph ($n = 200$)

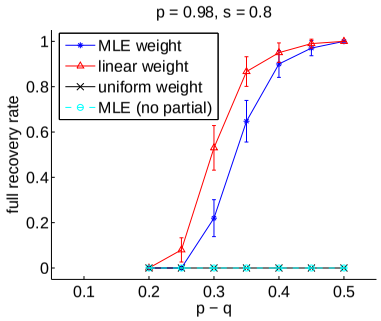

Figure 3: Clustering dense graph ($n = 200$)

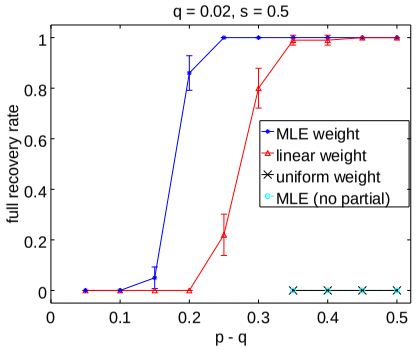

Figure 4: Clustering sparse graph ($n = 1000$)

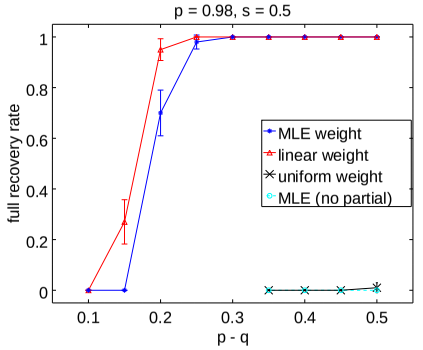

Figure 5: Clustering dense graph ($n = 1000$)

Corollary 11 predicts more success as the ratio $\frac{s(p-q)^2}{p(1-q)}$ gets larger. All else being the same, label distributions with small ζ (corresponding to sparse graphs in the planted partition setting, where $\frac{D(\nu\|\mu)}{D(\mu\|\nu)}$ is small) are easier to solve. Note that these predictions are with respect to the MLE weights. Both predictions are consistent with the empirical results given in Figures 2–5. The results also indicate that the MLE weights outperform the other weights in the sparse settings. On the other hand, in the dense case, we observe that the linear weights outperform the MLE weights by a small margin. This empirical observation is consistent with the prediction given in Section 3.4.

To give an idea of the computation time involved, Figures 6 and 7 plot the average CPU time needed to solve program (2) with Algorithm 1 on a typical quad-core desktop machine in Matlab. A commonly observed trend is that the number of iterations needed to converge is usually small when the problem is either too "hard" ($p - q$ small) or too "easy" ($p - q$ large). Note that we did not attempt to optimize the algorithm in terms of speed. Improvement in the computational aspect is certainly an interesting direction to explore.

We next examine the effect of varying cluster size K on the performance, with the total number of nodes held fixed. Figures 8 and 9 show clustering results with various values of K for $n = 400$. We choose a particular value of (p, q, s) that shows an interesting region. As expected, the success rates improve when K grows. The results remain qualitatively similar for other values of p, q and s.

6.2.1 COMPARISON WITH SPECTRAL METHODS

Lelarge et al. (2013) proposed a labeled stochastic block model, which is a special case of our model (cf. Section 1.1). In particular, their setup is restricted to only the two-cluster case, with balanced cluster sizes (i.i.d. uniform cluster membership). They proposed a spectral method specially tailored for this case. In this section, we compare our approach with theirs on the exact same setup that they use. In this setup, each pairwise observation can be an edge/non-edge. Each edge can take one of two possible labels. This is equivalent to a 3-label case in our setup. Figure 10 shows the results in terms of the "overlap" (as used by Lelarge et al. (2013)), which is a measure of how closely the resulting clusters match the ground truth. In Fig. 10, "convex" refers to results

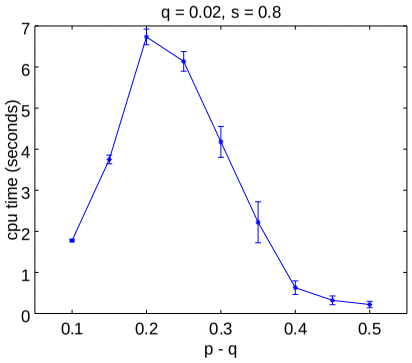

Figure 6: CPU time (sparse graph, $n = 200$)

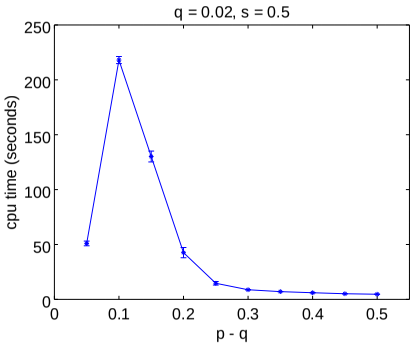

Figure 7: CPU time (sparse graph, $n = 1000$)

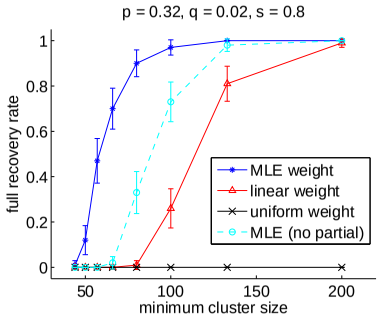

Figure 8: Clustering sparse graph ($n = 400$)

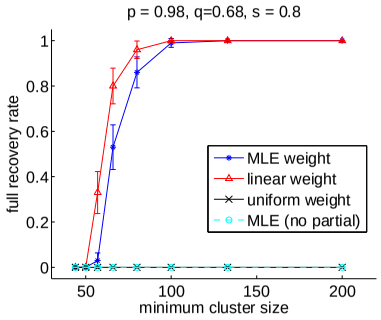

Figure 9: Clustering dense graph ($n = 400$)

based on Algorithm 1, where the final clustering is obtained by running K-means on the normalized rows of the output matrix. "Spectral" refers to results based on the proposed spectral method by Lelarge et al. (2013). We can observe that both approaches produce comparable results. Although computationally more costly,[13] our approach can handle a much wider range of problem setups, and as shown in Section 6.5.1, can significantly outperform the spectral method in many cases.

13. We note that computationally the cost is typically dominated by the SVD operations, especially for large n. For spectral clustering, only 1 SVD needs to be performed, whereas the ADMM solver performs 1 SVD per iteration. The number of iterations may range from just a few to several hundreds, depending on the problem.

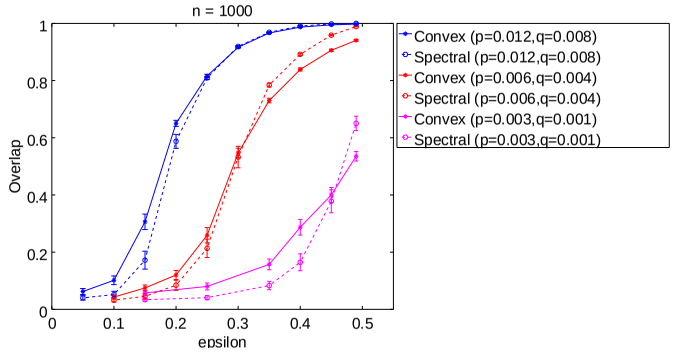

Figure 10: Comparison with spectral method. p and q are within-cluster and between-cluster edge probabilities, respectively. ϵ denotes the difference in within/between-cluster label distributions, where 0 is the smallest and 0.5 is the largest.

6.3 Gaussian Graphs and Inaccurate Weights

In this experiment, we evaluate real-valued labels drawn from Gaussian distributions. We also evaluate the effect of using weights that deviate from the MLE weights. Figure 11 shows clustering results on graphs with $n = 200$ and 8 equal-size clusters. The cross-cluster label distribution has mean 0 and variance 1. The in-cluster label distribution has the same variance but with elevated mean of $\mu = 2$ (blue) and $\mu = 1.5$ (red). Obviously, the case of $\mu = 2$ is an easier problem. In each case, we run Algorithm 1 using MLE weights that correspond to an in-cluster distribution with mean $\mu + \Delta$ instead of μ. Figure 11 shows that clustering performance drops when the deviation gets sufficiently large. Observe that negative Δ (conservative weights) performs better—consistent with Theorem 6. Figure 12 shows results based on the same settings, except that random noise is added to the (true) MLE weight, where the noise is uniformly distributed within the range $[-\Delta, \Delta]$. We observe a gradual drop of performance with respect to Δ, as predicted by Theorem 7.

6.4 Clustering with Highly Certain Observations

We empirically test the prediction of Theorem 9 regarding highly certain observations. For partially observed graphs with uncertain observations, the sufficient condition for recovery given by Corollary 13 requires that the fraction of observed entries, s, grows linearly with n (ignoring logarithmic term) if the other parameters p, q and K are held fixed. On the other hand, if all observed entries are highly certain, Theorem 9 predicts that s needs to grow only logarithmically with respect to n.

We run two experiments, each with $n = 600, 1200, 1800, 2400$. In all cases, the cluster size K is fixed at 150, and the labels are either "edge", "no edge" or "unobserved". In the first experiment we consider uncertain observations, where each observed entry is equal to the corresponding entry of Y^* with probability 0.7, and otherwise it is flipped. In the second experiment with highly certain

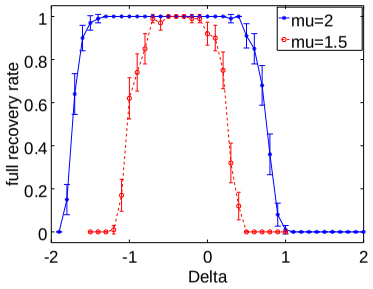

Figure 11: Systematic weight deviation

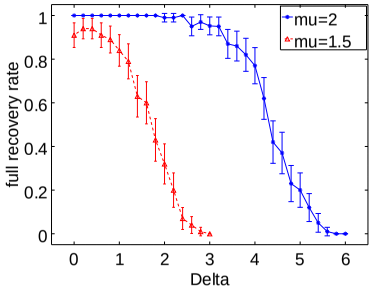

Figure 12: Random weight deviation

observations, all observed entries are equal to Y^* with probability 1. In both experiments, we search for the smallest fraction of observed entries needed to achieve a 90% full-recovery rate.

The results are shown in Figure 13. The plots indeed suggest a linear dependency on n for the uncertain observations, but a sub-linear dependency on n for the highly certain case.

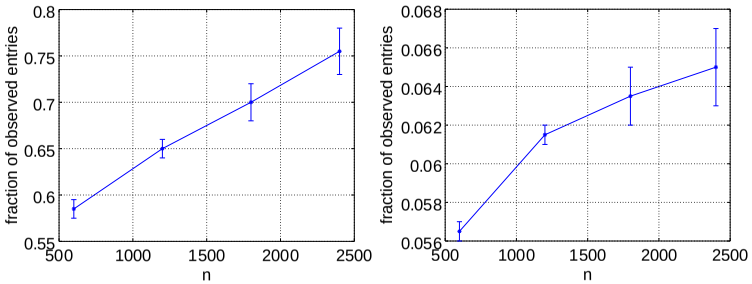

Figure 13: Fraction of observed entries needed for 90% full-recovery rate. Left panel: uncertain observations. Right panel: highly-certain observations.

6.5 Clustering Time-varying Graphs

We next investigate clustering performance on time-varying graphs. Figure 14 shows results based on multiple independent snapshots of partially observed graphs. Each graph is generated according to the planted partition model with partial observation (20% observed) as described in Section 4.2.1, with uniform error rate $q = 1 - p$ for all node pairs. We tested a wide range of error rates ($q \in [0.006, 0.325]$), and the horizontal axis tracks the corresponding KL divergence between μ and ν. We used $n = 200$ with 8 equal-size clusters. As predicted by Corollary 14, the clustering performance improves as the number of snapshots T grows.

Figure 15 shows results for Markov label sequences. Here, we test a simple model with two labels "interaction" and "no-interaction" (equivalent to "edge" and "no-edge"). For within-cluster pairs, the probability of interaction is greater (i.e., equal to $0.5 + \epsilon$) in the next time-step if there is no interaction in the current time-step, and vice versa. For inter-cluster pairs, the occurrence of interaction/no-interaction is completely random (i.e., $\epsilon = 0$) and therefore independent across snapshots. In this setting, both the marginal and stationary distributions for μ and ν are identical in every time step, and therefore at least two consecutive time steps are needed for informative clustering (cf. Section 4.4). The figure shows results for 200 nodes partitioned into 8 equal-size clusters, with the horizontal axis tracking the average KL-divergence between the conditional distributions (by varying ϵ). As predicted by Corollary 15, the performance improves as the number of snapshots T increases.

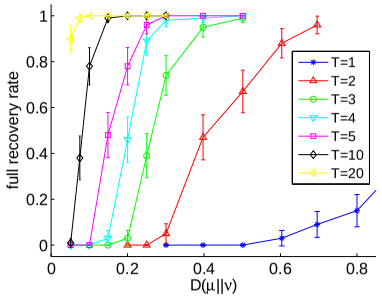

Figure 14: Independent snapshots

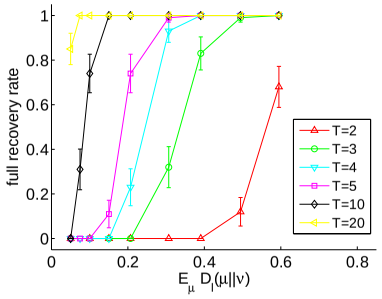

Figure 15: Markov snapshots

6.5.1 COMPARISON WITH EVOLUTIONARY SPECTRAL CLUSTERING

In this section, we compare our approach with an existing approach in clustering time-varying graphs based on evolutionary spectral clustering, as proposed by Chi et al. (2009). In particular, to handle time-varying graphs, one can assign a weight to each time step and compute a weighted average of the normalized graph Laplacian in each time step, then perform standard spectral clustering using this averaged graph Laplacian. We use the same settings as in Figure 14, except that we use the fully-observed case, to make sure that the comparison is fair.[14] For our approach, the final cluster assignments are obtained via running K-means on the normalized rows of the output matrix of the convex program. For spectral clustering, the final cluster assignments are based on K-means on the normalized rows of the top-K left singular vectors of the averaged graph Laplacian. For reference, we also include the results based on simply running K-means on the normalized rows of the averaged graph Laplacian. Figure 16 shows the results for $T = 1$, $T = 2$ and $T = 3$ in terms

14. Our method has extra advantage in the partially observed case, since it is generally unclear what weight to use for spectral clustering in this case. We tested a few imputation scheme for spectral clustering but the results are qualitatively the same.

of full clusters recovery rate. Figure 17 shows the pairwise error rate, which is the fraction of all node pairs that have been wrongly classified as either belonging to the same or different clusters.

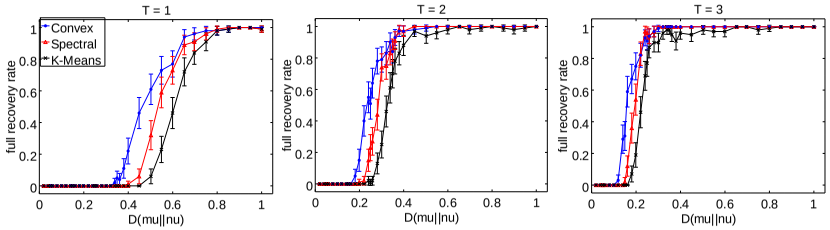

Figure 16: Comparison with evolutionary spectral clustering (full recovery rate)

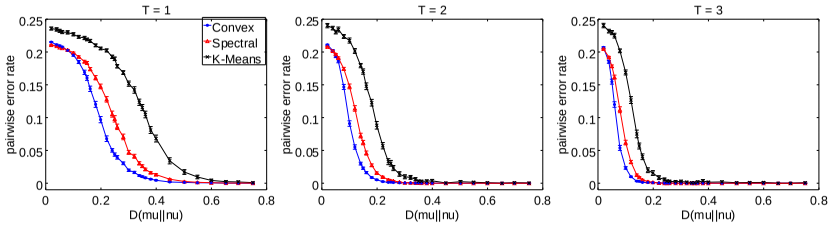

Figure 17: Comparison with evolutionary spectral clustering (pairwise error rate)

As expected, the overall performance improves as more snapshots are included. Among the three approaches, ours performs the best in terms of clustering error rates, but at the expense of higher computational cost relative to the other two.

6.6 Real-world Data Set

We consider three real-world data sets for which reliable ground truth is available. All three sets involve interactions among different social groups, with different clustering structures and different temporal granularity.

The *Reality Mining* data set (Eagle and Pentland, 2006) contains individuals from two main groups, the MIT Media Lab and the Sloan Business School, which we use as the ground-truth clusters. The data set records when two individuals interact, i.e., become proximal of each other or make a phone call, over a 9-month period. We choose a window of 14 weeks (the Fall semester) during which most individuals have non-empty interaction data. This sub-dataset consists of $n = 85$ individuals with 25 of them from Sloan and 60 from the Media Lab. We represent the data as a time-varying graph with 14 snapshots (one per week), each with two observations $\mathcal{L}_t = \{$"interact", "no-interact"$\}$: "interact" if a pair of individuals interact within the week, and "no-interact" otherwise. Note that with T snapshorts, the full label set $\mathcal{L} = \mathcal{L}_1 \times \ldots \times \mathcal{L}_T$ consists of all possible binary sequences of length T.

We compare three models on this data set: the Markov snapshot model in Section 4.4, the independent snapshot model in Section 4.3, and a single snapshot approach (i.e., our approach with $T = 1$) applied to a static graph generated by taking the union of all snapshots (i.e., two individuals are connected if they interact during any of the 14 weeks). In each trial, the in/cross-cluster label distributions are estimated from a fraction of randomly selected pairwise interaction data. In particular, each parameter (i.e., the interaction probability and the transition kernel) is estimated using the corresponding empirical frequency in the selected data, regularized by adding 1 to each count. We use the MLE weights in all instances. To ensure that a valid clustering is always obtained, we run K-means on the normalized rows of the output matrix of Algorithm 1.

Figure 18 shows the results with respect to varying number of snapshots (left panel) and varying number of training pairs used for parameter estimation (right panel). For comparison, we also added result based on evolutionary spectral clustering (Chi et al., 2009). The vertical axis shows the fraction of pairs whose cluster relationships are correctly identified. The accuracy generally improves when more snapshots are used. However, the improvement with respect to T is lower than expected, most likely due to the fact that the snapshots are not independent. The union model is expected to improve with T for *sparse* graphs—due to increase in the KL-divergence between the in/cross-cluster distributions. Overall, the Markov model managed to achieve higher accuracy than both the union and independent model, though the best accuracy is achieved by the evolutionary spectral clustering approach. Further inspection of the data suggests that the snapshots are non-stationary in the sense that the earlier snapshots have rather different label distributions than the later snapshots.

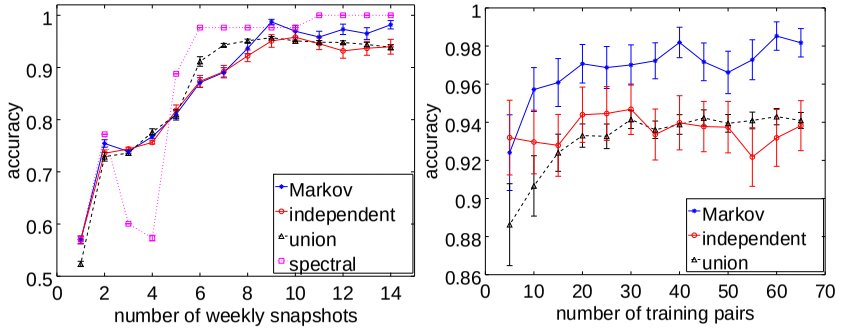

Figure 18: Reality Mining data set. Left: Varying number of snapshots (50 training pairs). Right: Varying number of training pairs (14 snapshots).

The next two data sets, *Workplace* and *Primary-school*, are from Genois et al. (2015) and Stehl et al. (2011), respectively. The Workplace data involves human contacts among 92 employees in an office building, where the ground truth clusters correspond to 5 different departments. We split this data set (over 10 days) into 10 daily snapshots, each with a binary $\{$"interact", "no-interact"$\}$ observation set. The Primary-school data involves contacts among 232 children in a primary school

(teachers are omitted), where the ground truth clusters correspond to 10 different classes. We split this data set (over 2 days) into 18 hourly snapshots, with the same binary observation per snapshot.

Figures 19 and 20 show the empirical results using the Markov snapshot, independent snapshot and single snapshot models described above, as well as evolutionary spectral clustering. All 3 models achieve comparable clustering accuracy in the Workplace data set, while the union model performs significantly worse in the Primary-school data set. The evolutionary spectral clustering approach performs worse overall—with large variations across varying number of snapshots. We believe that this is due to its sensitivity to the distribution of the top eigenvectors of the graph Laplacian.

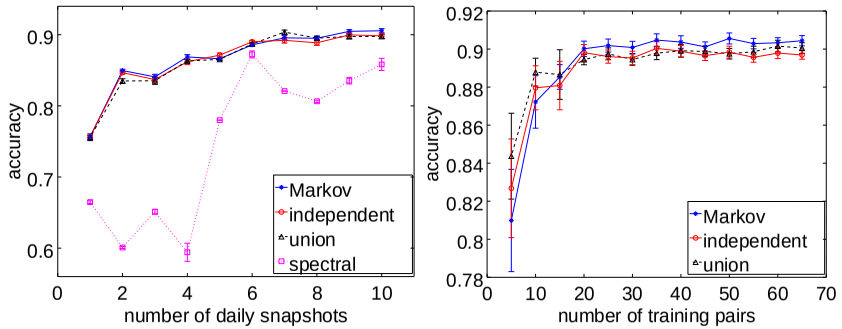

Figure 19: Workplace data set. Left: Varying number of snapshots (40 training pairs). Right: Varying number of training pairs (10 snapshots).

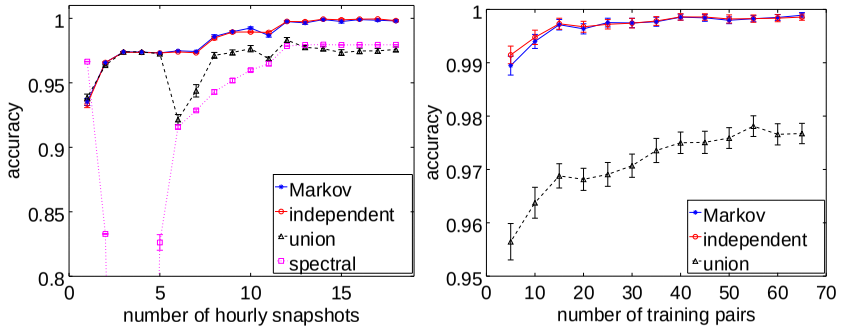

Figure 20: Primary-school data set. Left: Varying number of snapshots (50 training pairs). Right: Varying number of training pairs (18 snapshots).

7. Proof of Theorems 2 and 9

In this section, we prove the general results in the two main theorems. Observe that Theorem 2 is a special case of Theorem 9 with $\beta = 10$: if the weight function w is bounded, then there exists some b_∞ such that the set $\mathcal{L}_\infty$ is empty, in which case we have $\tilde{w}_b \equiv w$ and the conditions (14) and (15) in Theorem 9 reduce to (5) and (6) in Theorem 2. Therefore, it suffices to prove Theorem 9.

7.1 Notations

We need some additional notation to account for the bi-clustering setting. Recall that $|\mathcal{N}_1| = n_1$ and $\mathcal{N}_2 = n_2$, and set $n = \max\{n_1, n_2\}$. For a node $i \in \mathcal{N}_1$, let $\mathcal{C}_i$ be the cluster that contains node i and $K_i = |\mathcal{C}_i|$. Similarly, $\mathcal{C}'_j$ is the cluster that contains a node j in $\mathcal{N}_2$, and $K'_j = |\mathcal{C}'_j|$. Each cluster $\mathcal{C}_i$ in $\mathcal{N}_1$ is associated with exactly one cluster $\mathcal{C}'_j$ in $\mathcal{N}_2$, which is denoted by $\mathcal{C}_i \sim \mathcal{C}'_j$. These notations are consistent with those for clusteirng, with the understanding that $\mathcal{N}_1 = \mathcal{N}_2$, $n_1 = n_2 = n$, $\mathcal{C}_i = \mathcal{C}'_i$ and $K_i = K'_i$.

Let $\Omega = \{(i,j) : L_{ij} \in \mathcal{L}_\infty\}$ and $R = \{(i,j) : Y^*_{ij} = 1\}$. Let $\mathcal{P}_\Omega$ be the projection operator on matrices such that

$$(\mathcal{P}_\Omega Z)_{ij} = \begin{cases} Z_{ij} & \text{if } (i,j) \in \Omega, \\ 0 & \text{otherwise.} \end{cases}$$

The projections $\mathcal{P}_R$, $\mathcal{P}_{\Omega \cap R}$ etc are defined similarly.

Let $U\Sigma V^\top$ be the rank-r SVD of Y^*, where r is the number of groud-truth clusters and the rank of Y^*. Note that

$$(UU^\top)_{ij} = \begin{cases} \frac{1}{K_i} & \text{if } \mathcal{C}_i = \mathcal{C}_j, \\ 0 & \text{otherwise,} \end{cases} \tag{26}$$

$$(VV^\top)_{ij} = \begin{cases} \frac{1}{K'_i} & \text{if } \mathcal{C}'_i = \mathcal{C}'_j, \\ 0 & \text{otherwise,} \end{cases} \tag{27}$$

and

$$(UV^\top)_{ij} = \begin{cases} \frac{1}{\sqrt{K_i K'_j}} & \text{if } \mathcal{C}_i \sim \mathcal{C}'_j, \\ 0 & \text{otherwise.} \end{cases} \tag{28}$$

Define the projection operator

$$\mathcal{P}_T Z := UU^\top Z + ZVV^\top - UU^\top ZVV^\top \tag{29}$$

and its complementary projection

$$\mathcal{P}_{T^\perp} Z := Z - \mathcal{P}_T Z.$$

Denote by $\|\cdot\|$ the spectral norm (largest singular value) of a matrix. For any matrix X with $\|X\| \le \eta_0$, the matrix $UV^\top + \eta_0^{-1}\mathcal{P}_{T^\perp}X$ is a subgradient of the nuclear norm $\|\cdot\|_*$ at Y^* (Recht et al., 2010). It follows that for any feasible solution Y to the program (3), we have

$$0 \ge \|Y\|_* - \|Y^*\|_* \ge \langle UV^\top + \eta_0^{-1}\mathcal{P}_{T^\perp}X, Y - Y^* \rangle,$$

which implies

$$\langle X, Y^* - Y \rangle \ge \langle \mathcal{P}_T X - \eta_0 UV^\top, Y^* - Y \rangle. \tag{30}$$

7.2 Preliminary Lemmas

The proof of Theorem 9 builds on the following four lemmas. The first lemma gives a closed form expression for the projected matrix $\mathcal{P}_T Z$.

Lemma 16 *For any matrix Z and each index (i,j), we have*

$$(\mathcal{P}_T Z)_{ij} = \frac{1}{K_i}\sum_{k\in\mathcal{C}_i} Z_{kj} + \frac{1}{K'_j}\sum_{l\in\mathcal{C}'_j} Z_{il} - \frac{1}{K_i K'_j}\sum_{k\in\mathcal{C}_i}\sum_{l\in\mathcal{C}'_j} Z_{kl}. \tag{31}$$

Proof The lemma is immediate by the definition (29) of the projection $\mathcal{P}_T$ and the expressions (26) and (27) for the matrices $UU^\top$ and $VV^\top$. ■

Recall that W is the weight matrix used in program (3). The second lemma controls the spectral norm and the element magnitudes of the matrix $\mathcal{P}_\Omega UV^\top$.

Lemma 17 *Define*

$$\eta_1 := c_1 \frac{\beta\log n + \sqrt{K s_\mu(1-s_\mu)\beta\log n}}{K}.$$

With probability at least $1-n^{-\beta}$ the followings hold:

$$\|\mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top]\| \le \eta_1 \tag{32}$$

and for all i,j

$$|(\mathcal{P}_T(\mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top]))_{ij}| \le \begin{cases} \frac{\eta_1}{\sqrt{K_i K'_j}} & \text{if } \mathcal{C}_i \sim \mathcal{C}'_j \\ 0 & \text{otherwise} \end{cases} \tag{33}$$

Proof For the first inequality (32), consider $\mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top]$ as the sum of independent, zero-mean random matrices:

$$\mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top] = \sum_{(i,j),\mathcal{C}_i\sim\mathcal{C}'_j} X_{i,j},$$

where, noting the expression (28), we define

$$X_{i,j} := \mathcal{P}_\Omega\left(\frac{1}{\sqrt{K_i K'_j}}(e_i e_j^\top)\right) - \mathbb{E}\mathcal{P}_\Omega\left(\frac{1}{\sqrt{K_i K'_j}}(e_i e_j^\top)\right)$$

with e_i denoting the i-th standard basis vector. Note that

$$\|X_{i,j}\| \le \frac{1}{K}, \quad \forall i,j,$$

and

$$\left\|\sum_{(i,j),\mathcal{C}_i\sim\mathcal{C}'_j} \mathbb{E}X_{i,j}X_{i,j}^\top\right\| = \left\|\sum_{(i,j),\mathcal{C}_i\sim\mathcal{C}'_j} \frac{s_\mu(1-s_\mu)}{K_i K'_j}(e_i e_i^\top)\right\| \le \frac{s_\mu(1-s_\mu)}{K}.$$

Similarly we have $\left\|\sum_{(i,j),\mathcal{C}_i\sim\mathcal{C}'_j} \mathbb{E}X_{i,j}^\top X_{i,j}\right\| \le \frac{s_\mu(1-s_\mu)}{K}$. By applying the matrix Bernstein inequality (Tropp, 2012), we obtain the desired inequality (32).

Turning to the inequality (33), let $Z := \mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top]$. Note that each entry of Z is an independent zero-mean random variable. From the expression (31), let $\hat{z}$ be the first term of its RHS, which is an average of K_i independent zero-mean random variables with $|Z_{kj}| \le \frac{1}{\sqrt{K_i K'_j}}$ and

$$\mathrm{Var}(Z_{kj}) = \frac{s_\mu(1-s_\mu)}{K_i K'_j}.$$

By the standard Bernstein's inequality, we obtain that $|\hat{z}| \le \frac{\eta_1}{\sqrt{K_i K'_j}}$ with probability at least $1-n^{-\beta-2}$. The same reasoning can be used to arrive at the same bound for the second and the third RHS term of expression (31). Applying a union bound over all (i,j) we obtain the desired inequality (33). ■

The next lemma is an analogue of Lemma 17 and controls the matrix $\mathcal{P}_{\Omega^c\cap R}W$.

Lemma 18 *Define*

$$\eta_2 := c_2\left(b\beta\log n + \sqrt{n\mathrm{Var}_\mu(\tilde{w}_b)\beta\log n}\right),$$
$$\eta_3 := c_3\left(b\xi\beta\log n + \sqrt{n\mathrm{Var}_\mu(\tilde{w}_b)\beta\log n}\right).$$

With probability at least $1-n^{-\beta}$ the followings hold:

$$\|\mathcal{P}_{\Omega^c\cap R}W - \mathbb{E}[\mathcal{P}_{\Omega^c\cap R}W]\| \le \eta_2 \tag{34}$$

and for all i,j

$$|(\mathcal{P}_T(\mathcal{P}_{\Omega^c\cap R}W - \mathbb{E}[\mathcal{P}_{\Omega^c\cap R}W]))_{ij}| \le \begin{cases} \min\left\{\frac{\eta_2}{K}, \frac{\eta_3}{\sqrt{K_i K'_j}}\right\} & \text{if } \mathcal{C}_i\sim\mathcal{C}'_j, \\ 0 & \text{otherwise.} \end{cases} \tag{35}$$

Proof This claim follows the same arguments as in the proof of Lemma 17. ■

The last lemma is again analogous to Lemma 17 and controls the matrix $\mathcal{P}_{\Omega^c\cap R^c}W$.

Lemma 19 *Define*

$$\eta_4 := c_4\left(b\beta\log n + \sqrt{n\mathrm{Var}_\nu(\tilde{w}_b)\beta\log n}\right),$$
$$\eta_5 := c_5\frac{b\beta\log n + \sqrt{K\mathrm{Var}_\nu(\tilde{w}_b)\beta\log n}}{K}.$$

With probability at least $1-n^{-\beta}$ the followings hold:

$$\|\mathcal{P}_{\Omega^c\cap R^c}W - \mathbb{E}[\mathcal{P}_{\Omega^c\cap R^c}W]\| \le \eta_4 \tag{36}$$

and for all i,j

$$|(\mathcal{P}_T(\mathcal{P}_{\Omega^c\cap R^c}W - \mathbb{E}[\mathcal{P}_{\Omega^c\cap R^c}W]))_{ij}| \le \begin{cases} 0 & \text{if } \mathcal{C}_i\sim\mathcal{C}'_j, \\ \eta_5 & \text{otherwise,} \end{cases} \tag{37}$$

Proof This claim follows the same arguments as in the proof of Lemma 17. ■

Remark 20 *The $\sqrt{\log n}$ factors in the expressions of η_2, η_3 and η_4 can be removed via a more careful analysis, for example by using the results in Bandeira and van Handel (2016). We do not delve into the details here.*

7.3 Proof of Theorem 9

We are now ready to complete the proof of Theorem 9. We will show that with probability at least $1 - n^{-\beta}$ the following inequality holds for all $Y \neq Y^*$ feasible to the program (3):

$$\langle W, Y^* - Y \rangle > 0,$$

which implies that Y^* is the unique solution of program (3). Note that the feasible set of the program (2) is a subset of the feasible set of the program (3) (but always contains Y^*). This means that whenever Y^* is the unique solution of the program (3), it is also the unique solution of the program (2).

To proceed, we decompose $\langle W, Y^* - Y \rangle$ as follows:

$$\begin{aligned}\langle W, Y^* - Y \rangle =& \langle \mathcal{P}_{\Omega \cap R} W, Y^* - Y \rangle + \langle \mathcal{P}_{\Omega \cap R^c} W, Y^* - Y \rangle + \langle \mathcal{P}_{\Omega^c \cap R} W, Y^* - Y \rangle \\ &+ \langle \mathcal{P}_{\Omega^c \cap R^c} W, Y^* - Y \rangle.\end{aligned} \tag{38}$$

We analyze separately the four terms on the RHS above.

For the first RHS term, note that by the assumption (12), all entries of the matrix $\mathcal{P}_{\Omega \cap R} W$ are positive with probability one. We therefore have

$$\begin{aligned}&\langle \mathcal{P}_{\Omega \cap R} W, Y^* - Y \rangle \\ &\geq b_\infty K \langle \mathcal{P}_\Omega UV^\top, Y^* - Y \rangle \\ &= b_\infty K \left(\langle \mathbb{E}[\mathcal{P}_\Omega UV^\top], Y^* - Y \rangle + \langle \mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top], Y^* - Y \rangle \right) \\ &= b_\infty K \left(\langle s_\mu UV^\top, Y^* - Y \rangle + \langle \mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top], Y^* - Y \rangle \right) \\ &\overset{(a)}{\geq} b_\infty K \left(\langle s_\mu UV^\top, Y^* - Y \rangle + \langle \mathcal{P}_T(\mathcal{P}_\Omega UV^\top - \mathbb{E}[\mathcal{P}_\Omega UV^\top]) - \eta_1 UV^\top, Y^* - Y \rangle \right) \\ &\overset{(b)}{\geq} b_\infty K \left(\langle s_\mu UV^\top, Y^* - Y \rangle + \langle -2\eta_1 UV^\top, Y^* - Y \rangle \right) \\ &= b_\infty K (s_\mu - 2\eta_1) \langle UV^\top, Y^* - Y \rangle,\end{aligned}$$

where we apply the bounds (30) and (32) in the step (a), and the bound (33) in the step (b). Again by assumption (12) we have $\langle \mathcal{P}_{\Omega \cap R} W, Y^* - Y \rangle \geq 0$. We conclude that

$$\langle \mathcal{P}_{\Omega \cap R} W, Y^* - Y \rangle \geq \max\{0, b_\infty K (s_\mu - 2\eta_1)\} \cdot \langle UV^\top, Y^* - Y \rangle. \tag{39}$$

For the second RHS term in (38), it follows immediately from the assumption (12) that

$$\langle \mathcal{P}_{\Omega \cap R^c} W, Y^* - Y \rangle \geq 0. \tag{40}$$

Turning to the third RHS term in (38), we have

$$\begin{aligned}&\langle \mathcal{P}_{\Omega^c \cap R} W, Y^* - Y \rangle \\ =& \langle \mathbb{E}[\mathcal{P}_{\Omega^c \cap R} W], Y^* - Y \rangle + \langle \mathcal{P}_{\Omega^c \cap R} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R} W], Y^* - Y \rangle \\ =& \langle (\mathbb{E}_\mu \tilde{w}_b) Y^*, Y^* - Y \rangle + \langle \mathcal{P}_{\Omega^c \cap R} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R} W], Y^* - Y \rangle \\ \overset{(a)}{\geq}& \langle (\mathbb{E}_\mu \tilde{w}_b) Y^*, Y^* - Y \rangle + \langle \mathcal{P}_T(\mathcal{P}_{\Omega^c \cap R} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R} W]) - \eta_2 UV^\top, Y^* - Y \rangle \\ \overset{(b)}{\geq}& \max\left\{ \left(\mathbb{E}_\mu \tilde{w}_b - \frac{2\eta_2}{K} \right) \langle Y^*, Y^* - Y \rangle, (K \mathbb{E}_\mu \tilde{w}_b - 2\eta_3) \langle UV^\top, Y^* - Y \rangle \right\},\end{aligned} \tag{41}$$

where we use the bounds (30) and (34) in the step (a), and the bound (35) in the step (b); also in (b) we use the inequality $\langle (\mathbb{E}_\mu \tilde{w}_b) Y^*, Y^* - Y \rangle \geq \langle (K \mathbb{E}_\mu \tilde{w}_b) UV^\top, Y^* - Y \rangle$, which follows from the assumption (13).

Finally, letting J denote the all one matrix, we can bound the last RHS term in (38) as

$$\begin{aligned}&\langle \mathcal{P}_{\Omega^c \cap R^c} W, Y^* - Y \rangle \\ &= \langle \mathbb{E}[\mathcal{P}_{\Omega^c \cap R^c} W], Y^* - Y \rangle + \langle \mathcal{P}_{\Omega^c \cap R^c} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R^c} W], Y^* - Y \rangle \\ &= (-\mathbb{E}_\nu \tilde{w}_b) \langle J - Y^*, Y \rangle + \langle \mathcal{P}_{\Omega^c \cap R^c} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R^c} W], Y^* - Y \rangle \\ &\overset{(a)}{\geq} (-\mathbb{E}_\nu \tilde{w}_b) \langle J - Y^*, Y \rangle + \langle \mathcal{P}_T(\mathcal{P}_{\Omega^c \cap R^c} W - \mathbb{E}[\mathcal{P}_{\Omega^c \cap R^c} W]) - \eta_4 UV^\top, Y^* - Y \rangle \\ &\overset{(b)}{\geq} (-\mathbb{E}_\nu \tilde{w}_b - \eta_5) \langle J - Y^*, Y \rangle - \langle \eta_4 UV^\top, Y^* - Y \rangle,\end{aligned} \tag{42}$$

where we use the bounds (30) and (36) in the step (a), and the bound (37) in the step (b).

Applying the above inequalities (39), (40), (41) and (42) to the equation (38), we obtain that

$$\begin{aligned}\langle W, Y^* - Y \rangle \geq& \max\left\{ \left(\mathbb{E}_\mu \tilde{w}_b - \frac{2\eta_2 + \eta_4}{K} \right) \langle Y^*, Y^* - Y \rangle, \right. \\ &\left. (b_\infty K (s_\mu - 2\eta_1) + K \mathbb{E}_\mu \tilde{w}_b - 2\eta_3 - \eta_4) \langle UV^\top, Y^* - Y \rangle \right\} \\ &+ (-\mathbb{E}_\nu \tilde{w}_b - \eta_5) \langle J - Y^*, Y \rangle \\ =& \max\left\{ \left(\mathbb{E}_\mu \tilde{w}_b - \frac{2\eta_2 + \eta_4}{K} \right) \langle Y^*, Y^* - Y \rangle, \right. \\ &\left. b_\infty K \left(s_\mu + \frac{\mathbb{E}_\mu \tilde{w}_b}{b_\infty} - \left(2\eta_1 + \frac{2\eta_3 + \eta_4}{b_\infty K} \right) \right) \langle UV^\top, Y^* - Y \rangle \right\} \\ &+ (-\mathbb{E}_\nu \tilde{w}_b - \eta_5) \langle J - Y^*, Y \rangle.\end{aligned} \tag{43}$$

We see that the condition (14) in the theorem statement ensures that $-\mathbb{E}_\nu \tilde{w}_b - \eta_5 > 0$. On the other hand, the condition (15) ensures that

$$\mathbb{E}_\mu \tilde{w}_b - \frac{2\eta_2 + \eta_4}{K} > 0,$$

whereas the condition (16) ensures that

$$s_\mu + \frac{\mathbb{E}_\mu \tilde{w}_b}{b_\infty} - \left(2\eta_1 + \frac{2\eta_3 + \eta_4}{b_\infty K} \right) > 0.$$

Either of last two inequalities is sufficient to guarantee that the right hand side of the equation (43) is strictly positive. This completes the proof of Theorem 9.

8. Conclusion

In this paper we presented a general framework for graph clustering by assuming that all pairwise observations are in the form of labels. The algorithm involves solving a tractable convex optimization problem with an appropriately weighted objection function based on the observed labels.

A key contribution of our theoretical results is in showing that the MLE weights are order-wise optimal under a generalized version of the stochastic block model, thus providing a principled way of assigning weights to the observed graph. Our main results also identify the relevant parameters that are crucial to the successful recovery of the underlying clusters. These include the minimum cluster size, the distance between the label distributions, as well as properties of the observations such as the number of snapshots in a time-varying graph.

This framework recovers as special cases a broad range of existing results in graph clustering, and in fact provides substantial improvement for many of them. Important features such as partial observability and non-uniform uncertainties can be readily analyzed using our results, which provide new insights in many applications. Moreover, our framework is powerful enough to yield new results on novel settings such as the clustering of time-varying graphs.

An interesting future direction is to extend the proposed approach to problems with more complex structures such as overlapping clusters. Another important direction is to develop scalable solution applicable to very large data sets, both in terms of storage and computational complexity.

Appendix A. Proofs of Theorem 3 and Corollary 4

In this section, we prove Theorem 3 and Corollary 4 for using MLE weights.

A.1 Proof of Theorem 3

Throughout this subsection, w always means the MLE weight function w^{MLE}. The proof is based on several lemmas. The first lemma, proved in Section A.1.1 to follow, bounds the log-likelihood ratios.

Lemma 21 *Suppose that* $\left|\log \frac{\mu(l)}{\nu(l)}\right| \le b, \forall l \in \mathcal{L}$. *Then, for any* $l \in \mathcal{L}$,

$$\left|\log \frac{\mu(l)}{\nu(l)}\right| \le (b+2)\left|\frac{\mu(l)-\nu(l)}{\mu(l)+\nu(l)}\right|.$$

The second lemma, proved in Section A.1.2 to follow, controls the variance terms.

Lemma 22 *Suppose that* $|\log \frac{\mu(l)}{\nu(l)}| \le b, \forall l \in \mathcal{L}$ *and* $D(\nu\|\mu) \le \zeta D(\mu\|\nu)$, *then*

$$\mathrm{Var}_\nu w \le 3(b+2)D(\nu\|\mu) \tag{44}$$

and

$$\max(\mathrm{Var}_\mu w, \mathrm{Var}_\nu w) \le (\zeta+1)(b+2)D(\mu\|\nu). \tag{45}$$

The last lemma is a classical result in information theory. The lemma bounds the KL divergence $D(\mu\|\nu)$ and $D(\nu\|\mu)$ in terms of the triangle discrimination between μ and ν.

Lemma 23 (Topsoe 2000) *The following holds for any distributions* μ *and* ν, *assuming that* μ *and* ν *are absolutely continuous with each other and with respect to a base measure* λ:

$$\min\{D(\mu\|\nu), D(\nu\|\mu)\} \ge \frac{1}{2}\int_{\mathcal{L}} \frac{(\mu(l)-\nu(l))^2}{\mu(l)+\nu(l)}\,\mathrm{d}\lambda.$$

We are now ready to prove Theorem 3. To this end, we verify that the conditions (5) and (6) in Theorem 2 are satisfied under the assumption of Theorem 3. Note that

$$-\mathbb{E}_\nu w = -\int_{\mathcal{L}} \log\frac{\mu(l)}{\nu(l)}\,\mathrm{d}\nu = D(\nu\|\mu).$$

Combining the assumption (7) in Theorem 3 with the previous bound (44), the first condition (5) in Theorem 2 is satisfied as follows:

$$\begin{aligned}\frac{b\log n}{K} + \frac{\sqrt{K\log n}\sqrt{\mathrm{Var}_\nu w}}{K} &\le \frac{(b+2)\log n}{K} + \sqrt{\frac{\log n}{K}}\sqrt{3(b+2)D(\nu\|\mu)} \\ &\le cD(\nu\|\mu) + c'\sqrt{D(\nu\|\mu)}\sqrt{D(\nu\|\mu)} \\ &\le c''D(\nu\|\mu) = -c''\mathbb{E}_\nu w.\end{aligned}$$

Turning to the condition (6), we note that $\mathbb{E}_\mu w = D(\mu\|\nu)$. Combining the assumption (8) in Theorem 3 with the previous bound (45) in a similar manner establishes the condition (6).

Finally, the last sentence in the statement of Theorem 3 is a special case of the following more general result, which is useful later in the proof of Theorem 5.

Lemma 24 *Suppose that* $\left|\log \frac{\mu(l)}{\nu(l)}\right| \le b, \forall l \in \mathcal{L}$. *Then we have*

$$D(\nu\|\mu) + D(\mu\|\nu) \le (b+2)\int_{\mathcal{L}} \frac{(\nu(l)-\mu(l))^2}{\nu(l)+\mu(l)}\,\mathrm{d}\lambda$$

and

$$\frac{1}{2b+3} \le \frac{D(\nu\|\mu)}{D(\mu\|\nu)} \le 2b+3.$$

Proof We have

$$\begin{aligned}\frac{D(\nu\|\mu)}{D(\mu\|\nu)}+1 &= \frac{D(\nu\|\mu)+D(\mu\|\nu)}{D(\mu\|\nu)}\\ &= \frac{\int_{\mathcal{L}}(\nu(l)-\mu(l))\log\frac{\nu(l)}{\mu(l)}\,\mathrm{d}\lambda}{D(\mu\|\nu)}\\ &\overset{(a)}{\leq} \frac{(b+2)\int_{\mathcal{L}}\frac{(\nu(l)-\mu(l))^2}{\nu(l)+\mu(l)}\,\mathrm{d}\lambda}{D(\mu\|\nu)},\end{aligned}$$

where we use Lemma 21 in the inequality (a). This proves the first equation in the lemma. Bounding the right side of (a) using Lemma 23, we prove the upper bound in the second equation of the lemma. The lower bound in the second equation follows from switching the roles of μ and ν. ■

A.1.1 PROOF OF LEMMA 21

Consider the function $g(p)=\log\frac{1-p}{p}$ for $p\in[\frac{1}{e^b+1},0.5]$. By the convexity of $g(p)$ in this range we can linearly upper-bound it and show that $\log\frac{1-p}{p}\leq b\left(\frac{e^b+1}{e^b-1}\right)(1-2p)$. Taking $p=\frac{\nu}{\mu+\nu}$, we then have

$$\left|\log\frac{\mu}{\nu}\right| = \left|\log\frac{1-p}{p}\right| \leq b\left(\frac{e^b+1}{e^b-1}\right)|1-2p| = b\left(\frac{e^b+1}{e^b-1}\right)\left|\frac{\mu-\nu}{\mu+\nu}\right| \leq (b+2)\left|\frac{\mu-\nu}{\mu+\nu}\right|.$$

A.1.2 PROOF OF LEMMA 22

We need a version of the Padé approximation for logarithms:

$$\log\frac{1}{x}\geq\frac{(1-x)(5+x)}{2+4x},\quad\forall x>0,$$

which follows from that fact that the function $g(x)=\log\frac{1}{x}-\frac{(1-x)(5+x)}{2+4x}$ has a unique minimum $g(1)=0$. Using this inequality, we obtain that

$$\begin{aligned}3\int_{\mathcal{L}}\log\frac{\nu(l)}{\mu(l)}\,\mathrm{d}\nu-\int_{\mathcal{L}}\left|\frac{\mu(l)-\nu(l)}{\mu(l)+\nu(l)}\right|\left|\log\frac{\mu(l)}{\nu(l)}\right|\,\mathrm{d}\nu &= 2\int_{\mathcal{L}}\frac{2\mu(l)+\nu(l)}{\mu(l)+\nu(l)}\log\frac{\nu(l)}{\mu(l)}\,\mathrm{d}\nu\\ &\geq 2\int_{\mathcal{L}}\frac{2\mu(l)+\nu(l)}{\mu(l)+\nu(l)}\frac{(1-\frac{\mu(l)}{\nu(l)})(5+\frac{\mu(l)}{\nu(l)})}{2+4\frac{\mu(l)}{\nu(l)}}\,\mathrm{d}\nu\\ &= \int_{\mathcal{L}}\frac{(\nu(l)-\mu(l))(5\nu(l)+\mu(l))}{\mu(l)+\nu(l)}\,\mathrm{d}\lambda\\ &= -4+8\int_{\mathcal{L}}\frac{\mu(l)^2}{\mu(l)+\nu(l)}\,\mathrm{d}\lambda\\ &\overset{(a)}{\geq} 0,\end{aligned}$$

where the last inequality (a) follows from the fact that $\int_{\mathcal{L}}\frac{\mu(l)^2}{\mu(l)+\nu(l)}\,\mathrm{d}\lambda\geq\frac{1}{2}$. The first inequality (44) in the lemma then follows from

$$\begin{aligned}\mathrm{Var}_\nu w &\leq \mathbb{E}_\nu w^2\\ &= \int_{\mathcal{L}}\left(\log\frac{\mu(l)}{\nu(l)}\right)^2\,\mathrm{d}\nu\\ &\overset{(a)}{\leq} (b+2)\int_{\mathcal{L}}\left|\frac{\mu(l)-\nu(l)}{\mu(l)+\nu(l)}\right|\left|\log\frac{\mu(l)}{\nu(l)}\right|\,\mathrm{d}\nu\\ &\overset{(b)}{\leq} 3(b+2)\int_{\mathcal{L}}\log\frac{\nu(l)}{\mu(l)}\,\mathrm{d}\nu\\ &= 3(b+2)D(\nu\|\mu),\end{aligned}$$

where the step (a) follows from Lemma 21 and the step (b) follows from the inequality above.

For the second inequality (45), again by using Lemma 21 we obtain that

$$\begin{aligned}\max(\mathrm{Var}_\mu w,\mathrm{Var}_\nu w) &\leq \mathbb{E}_\mu w^2+\mathbb{E}_\nu w^2\\ &= \int_{\mathcal{L}}(\mu(l)+\nu(l))\left(\log\frac{\mu(l)}{\nu(l)}\right)^2\,\mathrm{d}\lambda\\ &\leq (b+2)\int_{\mathcal{L}}(\mu(l)+\nu(l))\left|\frac{\mu(l)-\nu(l)}{\mu(l)+\nu(l)}\right|\left|\log\frac{\mu(l)}{\nu(l)}\right|\,\mathrm{d}\lambda\\ &= (b+2)\big(D(\mu\|\nu)+D(\nu\|\mu)\big)\\ &\leq (\zeta+1)(b+2)D(\mu\|\nu).\end{aligned}$$

A.2 Proof of Corollary 4

The corollary follows immediately from Theorem 3, by lower bounding the left hand sides of the equations (7) and (8) using Lemma 23.

Appendix B. Proof of Theorem 5

In this section, we prove the converse result in Theorem 5. We use a standard technique of converting a statistical estimation problem to multiple hypothesis testing—in particular, we shall apply Theorem 2.5 of Tsybakov (2009). We will consider the standard clustering case where Y^* is symmetric. Set $M=n$ and let $\theta_0\in\{0,1\}^{n\times n}$ be a fixed cluster matrix corresponding to two equal sized clusters. For $k=1,\ldots,\frac{M}{2}$, let θ_k be the cluster matrix of a new clustering by swapping the 1st member of cluster 1 with the k-th member of cluster 2. Likewise, for $k=\frac{M}{2}+1,\ldots,M$, θ_k is obtained by swapping the 2nd member of cluster 1 with the k-th member of cluster 2. Let $L^0,L^1,\ldots,L^M$ be the random label matrices generated by the corresponding clustering.

Since the label of each pair (i,j) is generated independently, we have:

$$\begin{aligned} D(L^j \| L^0) &= \sum_{i<j} D(L^k_{ij} \| L^0_{ij}) \\ &\overset{(a)}{=} (n-2) D(\mu\|\nu) + (n-2) D(\nu\|\mu) \\ &\overset{(b)}{\leq} (n-2)(b+2) \int_{\mathcal{L}} \frac{(\nu(l)-\mu(l))^2}{\nu(l)+\mu(l)} \,\mathrm{d}\lambda \\ &\overset{(c)}{\leq} (c'+2) c \log n; \end{aligned}$$

here in step (a) we use the fact that due to the membership swap, exactly $n-2$ intra-cluster pairs in θ_0 become inter-cluster pairs in θ_j and vise-versa, step (b) follows from the first equation in Lemma 24, and step (c) holds due to the assumption (10) of the theorem and that b is bounded by a universal constant.

The result then follows from taking c sufficiently small and applying Theorem 2.5 of Tsybakov (2009).

Appendix C. Proof of Theorem 6

In this section we prove the monotonicity property in Theorem 6. Let $E = \{l \in \mathcal{L} : \bar{\mu}(l) \geq \bar{\nu}(l)\}$ and $E^c = \mathcal{L} \setminus E$. Since (μ,ν) is strictly more divergent than $(\bar{\mu},\bar{\nu})$, we have that for all $l \in E$, $\mu(l) \geq \bar{\mu}(l) \geq \bar{\nu}(l) \geq \nu(l)$ and for all $l \in E^c$, $\nu(l) \geq \bar{\nu}(l) > \bar{\mu}(l) \geq \mu(l)$.

Suppose that the label matrix L is generated using the following two-stage procedure:

1. First, generate a matrix $\bar{L}$ from $(\bar{\mu},\bar{\nu})$. Set $L \leftarrow \bar{L}$.

2. Second:

   - For each (i,j) where $Y^*_{ij} = 0$, if $L_{ij} \in E$, then with probability $1 - \frac{\nu(L_{ij})}{\bar{\nu}(L_{ij})}$, set $L_{ij} \leftarrow l$ where l is drawn from the set E^c with distribution $\frac{\nu(l)-\bar{\nu}(l)}{\int_{l' \in E^c} \nu(l')-\bar{\nu}(l') \,\mathrm{d}\lambda(l')}$. Let Ω_- be the set of all such entries, i.e. where L_{ij} has switched from E to E^c.
   - For each (i,j) where $Y^*_{ij} = 1$, if $L_{ij} \in E^c$, then with probability $1 - \frac{\mu(L_{ij})}{\bar{\mu}(L_{ij})}$, set $L_{ij} \leftarrow l$ where l is drawn from the set E with distribution $\frac{\mu(l)-\bar{\mu}(l)}{\int_{l' \in E} \mu(l')-\bar{\mu}(l') \,\mathrm{d}\lambda(l')}$. Let Ω_+ be the set of all such entries, i.e. where L_{ij} has switched from E^c to E.

It is straightforward to verify that the resulting distribution of L is identical to that generated by the pair (μ,ν).

Consider the program (3) with $\bar{L}$ as input, and let $\bar{W}$ be the corresponding MLE weights. Since the pair $(\bar{\mu},\bar{\nu})$ satisfies the condition of Theorem 3, we have that with probability at least $1-n^{-10}$, the matrix Y^* is the unique optimal solution and hence satisfies $\langle \bar{W}, Y^* \rangle > \langle \bar{W}, Y \rangle$ for any feasible solution $Y \neq Y^*$. Now, consider the program (3) with L as the input, using the corresponding MLE

weights W based on $(\bar{\mu},\bar{\nu})$. We have that for any feasible $Y \neq Y^*$,

$$\begin{aligned} \langle W, Y^* \rangle - \langle \bar{W}, Y^* \rangle &= \sum_{(i,j)\in\Omega_+} (W_{ij} - \bar{W}_{ij}) Y^*_{ij} \\ &\geq \sum_{(i,j)\in\Omega_+} (W_{ij} - \bar{W}_{ij}) Y_{ij} \\ &\geq \sum_{(i,j)\in\Omega_-} (W_{ij} - \bar{W}_{ij}) Y_{ij} + \sum_{(i,j)\in\Omega_+} (W_{ij} - \bar{W}_{ij}) Y_{ij} \\ &= \langle W, Y \rangle - \langle \bar{W}, Y \rangle, \end{aligned}$$

which implies that

$$\langle W, Y^* \rangle - \langle W, Y \rangle \geq \langle \bar{W}, Y^* \rangle - \langle \bar{W}, Y \rangle > 0.$$

Therefor, Y^* is still the unique optimal solution.

Appendix D. Proof of Theorem 7

In this section, we prove Theorem 7 for using inaccurate weights. Our strategy is to apply Theorem 2. To avoid confusion we use b' and c' to denote the constants b and c in Theorem 2.

To show that the condition (5) in Theorem 2 is satisfied, we upper bound its right hand side as follows:

$$\begin{aligned} c' \frac{b' \log n + \sqrt{K \log n} \sqrt{\mathrm{Var}_\nu w}}{K} &\overset{(a)}{\leq} \frac{c' b' (1-\gamma)^2}{c\alpha^2 (b+2)} D(\nu\|\mu) + \sqrt{3c'^2 \alpha^2 (b+2) D(\nu\|\mu) \frac{\log n}{K}} \\ &\leq \frac{c'(1-\gamma)^2}{c\alpha} D(\nu\|\mu) + \sqrt{\frac{3c'^2(1-\gamma)^2}{c} D(\nu\|\mu)^2} \\ &\overset{(b)}{\leq} (1-\gamma) D(\nu\|\mu) \\ &\overset{(c)}{\leq} D(\nu\|\mu) - \Delta_\nu \\ &= -\mathbb{E}_\nu w, \end{aligned}$$

where in step (a) we use $\mathrm{Var}_\nu w \leq \alpha^2 \mathrm{Var}_\nu w^{\mathrm{MLE}}$ due to the condition $|w| \leq \alpha |\log \frac{\mu}{\nu}|$ and apply the bound (44), step (b) holds by choosing an appropriately large c, and in step (c) we use the assumption $|\Delta_\nu| \leq \gamma D(\nu\|\mu)$ in the statement Theorem 7.

We can use similar arguments, using the bound (45) instead of (44), to prove that the condition (6) in Theorem 2 is satisfied. Theorem 7 then follows from applying Theorem 2.

Appendix E. Proof of Corollary 10

In this section, we prove Corollary 10 for clustering Gaussian graphs. Ideally we would like apply Theorem 3 as we are using the MLE weight. A minor technical difficulty is that the boundedness condition $|w^{\mathrm{MLE}}(L_{ij})| \leq b$ is not satisfied as the Gaussian entries of L are unbounded. To overcome this we use a standard truncation argument.

Without loss of generality assume that $\underline{u} = 0$. Define a truncated version $\tilde{w}$ for the weight function w^{MLE} by

$$\tilde{w}(l) = \begin{cases} 0, & \text{if } |l| > c'\sqrt{\log n} \text{ or } l = ?, \\ l - (\bar{u} + \underline{u})/2, & \text{if } |l| < c'\sqrt{\log n}, \end{cases}$$

where $c' > 4c_0$ is a universal constant to be chosen later. With the goal of applying Theorem 2 to this weight function, we verify that the conditions of the theorem are satisfied. By the assumption $\bar{u} \le \underline{u} + c_0\sqrt{\log n} = c_0\sqrt{\log n}$, the weight function $\tilde{w}$ satisfies $\tilde{w}(l) \le b = (c' + c_0)\sqrt{\log n}, \forall l \in \mathcal{L}$, so the boundedness condition holds. We next verify the condition (6). Letting $\phi(x) = (2\pi)^{-1/2}e^{-x^2/2}$ be the density function of the standard normal, we note that

$$\begin{aligned} \mathbb{E}_\mu \tilde{w} = \int_{l:|l|<c'\sqrt{\log n}} w^{\text{MLE}}(l)\,\mathrm{d}\mu &= \int_{\mathcal{L}} w^{\text{MLE}}(l)\,\mathrm{d}\mu - \int_{l:|l|>c'\sqrt{\log n} \text{ or } l=?} w^{\text{MLE}}(l)\,\mathrm{d}\mu \\ &= \frac{s\bar{u}}{2} - s\int_{|l|>c'\sqrt{\log n}} (l - \bar{u}/2)\phi(l-\bar{u})\,\mathrm{d}l \\ &\ge \frac{s\bar{u}}{2} - s\int_{|l|>c'\sqrt{\log n}} (|l| + \bar{u}/2)\phi(l-\bar{u})\,\mathrm{d}l \\ &\ge \frac{s\bar{u}}{2} - 4s\underbrace{\int_{c'\sqrt{\log n}/2}^{+\infty} l\phi(l)\,\mathrm{d}l}_{T}, \end{aligned}$$

where the last inequality follows from the fact that $\bar{u} \le c_0\sqrt{\log n} < \frac{c'\sqrt{\log n}}{4}$. We control the term T as

$$T = (2\pi)^{-\frac{1}{2}} \int_{c'\sqrt{\log n}/2}^{+\infty} xe^{-x^2/2}\,\mathrm{d}x \overset{(a)}{\le} (2\pi)^{-\frac{1}{2}} \int_{c'\sqrt{\log n}/2}^{+\infty} e^{-(x-1/2)^2/2}\,\mathrm{d}x \overset{(b)}{\le} \frac{1}{n^2} \overset{(c)}{\le} \frac{\bar{u}}{16},$$

where the step (a) follows from $x \le e^{x-1/2}$, (b) follows from the standard Gaussian tail bound $1 - \Phi(t) \le e^{-t^2/2}$ and the fact that c' is sufficiently large, and (c) follows from the assumption (18) of Corollary 10. It follows that $\mathbb{E}_\mu \tilde{w} \ge \frac{s\bar{u}}{4}$. On the other hand, since $\tilde{w}$ is a truncated version of w^{MLE}, we have

$$\max\{\text{Var}_\mu \tilde{w}, \text{Var}_\nu \tilde{w}\} \le \max\{\text{Var}_\mu w^{\text{MLE}}, \text{Var}_\nu w^{\text{MLE}}\} \le s(\bar{u}^2 + 1) \le 2c_0^2 s \log n.$$

Combining the above bounds, it is easy to check that the condition (6) of Theorem 2 is satisfied under the assumption (18) of Corollary 10. Similar lines of arguments establish the condition (5) of Theorem 2. This theorem therefore guarantees that the program (2) with the weight function $w = \tilde{w}$ recovers the true cluster matrix Y^* with probability at least $1 - n^{-10}$.

Now, by choosing the constant c' to be sufficiently large and using the Gaussian tail bound and the union bound, we are guaranteed that with probability at least $1 - n^{-10}$, $\tilde{w}(L_{ij}) = w^{\text{MLE}}(L_{ij})$ for all (i, j). In the intersection of the above two events (which occurs with probability at least $1 - 2n^{-10}$), the program (2) with the weight function $\tilde{w}$ is identical to that with the weight function w^{MLE}, both of which recover the true Y^*. The same holds for the program (3).

Appendix F. Proof of Corollary 15

In this section we prove Corollary 15 for clustering with Markov snapshots. The MLE weight in this case is given by

$$\begin{aligned} w^{\text{MLE}}(\bar{L}_{ij}) =& \frac{1}{T}\log\frac{\mu_0(L_{ij}^{(1)})\mu(L_{ij}^{(2)}|L_{ij}^{(1)})\ldots\mu(L_{ij}^{(T)}|L_{ij}^{(T-1)})}{\nu_0(L_{ij}^{(1)})\nu(L_{ij}^{(2)}|L_{ij}^{(1)})\ldots\nu(L_{ij}^{(T)}|L_{ij}^{(T-1)})} \\ =& \frac{1}{T}\log\frac{\mu_0(L_{ij}^{(1)})}{\nu_0(L_{ij}^{(1)})} + \frac{1}{T}\sum_{t=2}^{T}\log\frac{\mu(L_{ij}^{(t)}|L_{ij}^{(t-1)})}{\nu(L_{ij}^{(t)}|L_{ij}^{(t-1)})}. \end{aligned}$$

In the sequel, we will focus on an in-cluster pair (i, j) with label distribution μ and drop the subscript ij in L_{ij}. The same analysis holds for the cross-cluster pair (i, j).

It is convenient to consider an auxiliary Markov chain $X_1, \ldots X_T$ where each state is characterized by a label pair $X_t = (L^{(t-1)}, L^{(t)})$ for $t > 1$, and $X_1 = L^{(1)}$. We define the function f on the domain of X_t such that

$$f(L) = \log\frac{\mu_0(L)}{\nu_0(L)} \quad \text{and} \quad f(L, L') = \log\frac{\mu(L'|L)}{\nu(L'|L)}.$$

We therefore have

$$w^{\text{MLE}}(\bar{L}) = \frac{1}{T}\sum_{t=1}^{T} f(X_t).$$

It is straightforward to show that

$$\mathbb{E}_\mu(f(X_1)) = D(\mu_0\|\nu_0) \quad \text{and} \quad \mathbb{E}_\mu(f(X_t)) = \mathbb{E}_{\mu_0} D_l(\mu\|\nu) \ \text{ for } t > 1,$$

whence

$$\mathbb{E}_\mu(w^{\text{MLE}}) = \frac{1}{T}D(\mu_0\|\nu_0) + \Big(1 - \frac{1}{T}\Big)\mathbb{E}_{\mu_0} D_l(\mu\|\nu). \tag{46}$$

The rest of the proof concerns bounding $\text{Var}_\mu(w^{\text{MLE}})$. Following the proof of Lemma 22, the variance of $f(X_t)$ can be bounded by

$$\text{Var}_\mu(f(X_1)) \le 3(b+2)D(\mu_0\|\nu_0) \quad \text{and} \quad \text{Var}_\mu(f(X_t)) \le 3(b+2)\mathbb{E}_{\mu_0} D_l(\mu\|\nu) \quad (t > 1).$$

We now bound the covariance $\text{Cov}_\mu(f(X_t), f(X_{t+\tau+1}))$ for $t \ge 2$ and $\tau \ge 0$:

$$\begin{aligned} &\text{Cov}_\mu(f(X_t), f(X_{t+\tau+1})) \\ =& \mathbb{E}_\mu\left[\log\frac{\mu(L^{(t)}|L^{(t-1)})}{\nu(L^{(t)}|L^{(t-1)})}\log\frac{\mu(L^{(t+\tau+1)}|L^{(t+\tau)})}{\nu(L^{(t+\tau+1)}|L^{(t+\tau)})}\right] - \mathbb{E}_{\mu_0} D_l(\mu\|\nu)^2 \\ =& \sum_{L^{(t-1)}} \mu_0(L^{(t-1)}) \sum_{L^{(t)}} \mu(L^{(t)}|L^{(t-1)}) \log\frac{\mu(L^{(t)}|L^{(t-1)})}{\nu(L^{(t)}|L^{(t-1)})} \sum_{L^{(t+\tau)}} \Pr_\mu(L^{(t+\tau)}|L^{(t)}) D_{L^{(t+\tau)}}(\mu\|\nu) \\ &- \mathbb{E}_{\mu_0} D_l(\mu\|\nu)^2 \\ \overset{(a)}{\le}& \sum_{L^{(t-1)}} \mu_0(L^{(t-1)}) \sum_{L^{(t)}} \mu(L^{(t)}|L^{(t-1)}) \left|\log\frac{\mu(L^{(t)}|L^{(t-1)})}{\nu(L^{(t)}|L^{(t-1)})}\right| \sum_{L^{(t+\tau)}} \kappa\phi^\tau D_{L^{(t+\tau)}}(\mu\|\nu) \\ \le& \frac{\kappa\phi^\tau}{\min_l \mu_0(l)} b\mathbb{E}_{\mu_0} D_l(\mu\|\nu), \end{aligned}$$

where in the step (a) we use the geometric ergodicity assumption of μ, i.e.,

$$|\Pr_\mu(L^{(t+\tau)}|L^{(t)}) - \mu_0(L^{(t+\tau)})| \le \kappa\phi^\tau.$$

The same bound also applies to the case $t = 1$. Note that the covariance bound is independent of t and only dependent on τ.

We proceed to bound $\mathrm{Var}_\mu(w^{\mathrm{MLE}})$ as follows:

$$\begin{aligned}
\mathrm{Var}_\mu(w^{\mathrm{MLE}}) &= \frac{1}{T^2}\sum_{t=1}^{T}\mathrm{Var}_\mu(f(X_t)) + \frac{2}{T^2}\sum_{t=1}^{T-1}\sum_{t'=t+1}^{T}\mathrm{Cov}_\mu(f(X_t), f(X_{t'})) \\
&\le \frac{1}{T^2}\sum_{t=1}^{T}\mathrm{Var}_\mu(f(X_t)) + \frac{2}{T}\sum_{\tau=0}^{T-2}\frac{T-1-\tau}{T}\frac{\kappa\phi^\tau}{\min_l \mu_0(l)} b\mathbb{E}_{\mu_0} D_l(\mu\|\nu) \\
&\le \frac{3(b+2)}{T}\left(\frac{1}{T}D(\mu_0\|\nu_0) + \frac{T-1}{T}\mathbb{E}_{\mu_0} D_l(\mu\|\nu)\right) + \frac{2\kappa}{(1-\phi)\min_l \mu_0(l)} b\frac{\mathbb{E}_{\mu_0} D_l(\mu\|\nu)}{T} \\
&\le c\frac{(b+2)\Phi}{T}\left(\frac{1}{T}D(\mu_0\|\nu_0) + \frac{T-1}{T}\mathbb{E}_{\mu_0} D_l(\mu\|\nu)\right). \qquad (47)
\end{aligned}$$

With the above bounds (46) and (47), we complete the proof of Corollary 15 by applying Theorem 2.

Appendix G. Example of Markov Chain with Explicit Bound on Φ

The snapshots in the Markov model are not independent. Therefore, given T snapshots we do not expect a T-fold increase in the information as in the independent snapshot model. In the conditions given in Corollary 15, this penalty is characterized by the parameter Φ defined in Section 4.4. To provide a sense of what values it may take, we now derive an explicit bound for a simple class of 2-state sequences (i.e., $|\mathcal{L}| = 2$).

As in Section F, we first focus on an in-cluster pair (i, j) with label distribution μ, and drop the subscript ij in L_{ij}. Suppose the transition matrix for the distribution μ is

$$\begin{bmatrix} 1-p_0 & p_0 \\ p_1 & 1-p_1 \end{bmatrix},$$

where $0 < p_0, p_1 < 1$. If we identify the label set $\mathcal{L}$ with $\{\text{edge}, \text{non-edge}\}$, then p_0 can be thought of as the probability that an edge "flips" into a non-edge, and p_1 as the probability that a non-edge flips into an edge. Let $\rho := 1 - p_0 - p_1$. By eigen-decomposition we can show that the transition matrix after t transitions is

$$\begin{bmatrix} \frac{p_1}{p_0+p_1}\left(1 + \frac{p_0}{p_1}\rho^t\right) & \frac{p_0}{p_0+p_1}(1-\rho^t) \\ \frac{p_1}{p_0+p_1}\left(1-\rho^t\right) & \frac{p_0}{p_0+p_1}(1 + \frac{p_1}{p_0}\rho^t) \end{bmatrix},$$

and the stationary distribution on the two states, written as a vector, is given by

$$\mu_0 = \begin{bmatrix} \dfrac{p_1}{p_0+p_1} & \dfrac{p_0}{p_0+p_1} \end{bmatrix}.$$

This Markov chain of the observed sequence of an in-cluster pair satisfies the inequality

$$|\Pr_\mu(L^{(1+t)}|L^{(1)}) - \mu_0(L^{(1+t)})| \le |\rho|^t$$

for all integer $t \ge 1$.

Now suppose that the cross-cluster distribution ν is of a similar form as μ, i.e., has the transition matrix

$$\begin{bmatrix} 1-p_0' & p_0' \\ p_1' & 1-p_1' \end{bmatrix},$$

for some p_0' and p_1'. By similar arguments, ν has the stationary distribution $\nu_0 = [p_1'/(p_0' + p_1'), p_0'/(p_0' + p_1')]$, and satisfies $|\Pr_\nu(L^{(1+t)}|L^{(1)}) - \nu_0(L^{(1+t)})| \le |\rho'|^t$, where $\rho' := 1 - p_0' - p_1'$. Therefore, the geometric ergodicity condition in (23) of Section 4.4 holds with parameters $\kappa = 1$ and $\phi = \max\{|\rho|, |\rho'|\}$. The parameter Φ, having the value

$$\Phi = \frac{1}{\left(1 - \max\{|\rho|, |\rho'|\}\right)\min\left\{\frac{p_0}{p_0+p_1}, \frac{p_1}{p_0+p_1}, \frac{p_0'}{p_0'+p_1'}, \frac{p_1'}{p_0'+p_1'}\right\}}$$

is a constant independent of the parameters n, K, T etc.

The value of Φ determines how much new information is contained in a new snapshot. For example, suppose that $p_1 = p_0 \in (0, \frac{1}{2}]$ and $p_1' = p_0' \in (0, \frac{1}{2}]$, in which case the stationary distributions $\mu_0 = \nu_0 = [\frac{1}{2}\ \frac{1}{2}]$ are fixed, and hence

$$\Phi = \frac{1}{\min\{p_0, p_0'\}}.$$

The value of Φ is large when the flipping probabilities p_0, and p_0' are close to zero. In this case the next snapshot is almost always the same as the current snapshot, hence providing little extra information. On the other hand, if these probabilities are closer to $\frac{1}{2}$, say $p_0 = p_1 = \frac{1}{2}$ and $p_0' = p_1' = \frac{1}{4}$, then $\Phi = 4$ is small. In this case the snapshots have more independence and thus the next snapshot provides fresh information.

Also note that in the above case, the marginal distributions of in- and cross- cluster pairs are the same: $\mu_0 = \nu_0 = [\frac{1}{2}\ \frac{1}{2}]$. In this case, information about the clustering only comes from the "flipping" pattern in the snapshots. For example, if $p_0 = p_1 = \frac{1}{2}$ and $p_0' = p_1' = \frac{1}{4}$, then in a long sequence of snapshots, the fractions of "edge" and "non-edge" labels in a in-cluster pair and a cross-cluster pair are both close to 50%, but we will see more flippings on pairs in the same cluster.

Abstract

In a series of recent works, we have generalised the consistency results in the stochastic block model literature to the case of uniform and non-uniform hypergraphs. The present paper continues the same line of study, where we focus on partitioning weighted uniform hypergraphs—a problem often encountered in computer vision. This work is motivated by two issues that arise when a hypergraph partitioning approach is used to tackle computer vision problems:
(i) The uniform hypergraphs constructed for higher-order learning contain all edges, but most have negligible weights. Thus, the adjacency tensor is nearly sparse, and yet, not binary.
(ii) A more serious concern is that standard partitioning algorithms need to compute all edge weights, which is computationally expensive for hypergraphs. This is usually resolved in practice by merging the clustering algorithm with a tensor sampling strategy—an approach that is yet to be analysed rigorously.

We build on our earlier work on partitioning dense unweighted uniform hypergraphs (Ghoshdastidar and Dukkipati, ICML, 2015), and address the aforementioned issues by proposing provable and efficient partitioning algorithms. Our analysis justifies the empirical success of practical sampling techniques. We also complement our theoretical findings by elaborate empirical comparison of various hypergraph partitioning schemes.

Keywords: Hypergraph partitioning, planted model, spectral method, tensors, sampling, subspace clustering

1. Introduction

Over several decades, the study of networks or graphs has played a key role in analysing relational data or pairwise interactions among entities. While networks often arise naturally in social or biological contexts, there are several machine learning algorithms that construct graphs to capture the similarity among data instances. A classic example of this approach is the spectral clustering algorithm of Shi and Malik (2000) that performs image segmentation by partitioning a graph constructed on the image pixels, where the weighted edges capture the visual similarity of the pixels. In general, graph partitioning and related problems are quite popular in unsupervised learning (Ng et al., 2002; Cour et al., 2007), dimensionality reduction (Zhao and Liu, 2007), semi-supervised learning (Belkin et al., 2004) as well as transductive inference (Wang et al., 2008). In spite of the versatility of the graph based approaches, these methods are often incapable of handling complex networks that involve multi-way interactions. For instance, consider a market transaction database, where each transaction or purchase corresponds to a multi-way connection among commodities involved in the transaction (Guha et al., 1999). Such networks do not conform with a traditional graph structure, and need to be modelled as hypergraphs. Similar multi-way interactions have been considered in the case of molecular interaction networks (Michoel and Nachtergaele, 2012), VLSI circuits (Karypis and Kumar, 2000), tagged social networks (Ghoshal et al., 2009), categorical databases (Gibson et al., 2000), computer vision (Agarwal et al., 2005) among others. In this work, we consider the network clustering problem for hypergraphs, where all the edges are of same cardinality. Uniform hypergraph partitioning finds use in computer vision applications such as subspace clustering (Agarwal et al., 2005; Rota Bulo and Pelillo, 2013), geometric grouping (Govindu, 2005; Chen and Lerman, 2009) or higher-order matching (Duchenne et al., 2011).

Uniform hypergraphs have been in the limelight of theoretical research for more than a century with the problem of hypergraph colorability surfacing in early 20^{th} century (Bernstein, 1908) to recent works establishing sharp phase transitions in random hypergraphs (see references in Bapst and Coja-Oghlan, 2015). However, there has been much less interest in studying practical machine learning problems that deal with uniform hypergraphs. For instance, restricting our discussion to the network partitioning, one can immediately notice a sharp contrast in the theoretical understanding of the problem in the context of graph and hypergraphs. Spectral graph partitioning algorithms have been analysed from different perspectives since the works of McSherry (2001) and Ng et al. (2002). The seminal work of Rohe et al. (2011), which studied standard spectral clustering under the stochastic block model, drew the attention of both statisticians and computer scientists, and has led to significant advancements in understanding of when the partitions can be detected, and which algorithms achieve optimal error rates (see Abbe and Sandon, 2016, for the current state of the art). In contrast, a similar line of study in the context of hypergraphs is quite recent (Ghoshdastidar and Dukkipati, 2014, 2015b, 2017; Florescu and Perkins, 2016).

Florescu and Perkins (2016) recently solved the problem of optimally detecting two equal-sized partitions in a planted unweighted hypergraph governed by a single parameter. On the other hand, the primary focus of our works has been to analyse the consistency of hypergraph partitioning approaches used in practice under a more general planted model. In Ghoshdastidar and Dukkipati (2014), we presented a generic planted model for dense uniform hypergraphs, and analysed the tensor decomposition based clustering algorithm of Govindu (2005) under this model. Subsequently, in Ghoshdastidar and Dukkipati (2015b), we found that a wide class of so-called "higher order" clustering algorithms can be unified by a common framework of tensor trace maximisation, which is quite similar in spirit to the associativity maximisation problem posed in the case of graph partitioning (Shi and Malik, 2000). We further proposed to solve a relaxation of the problem using a simple, spectral scheme that was consistent, and achieved better error rates compared to our previously studied approach. An extension of the whole setting to the case of sparse non-uniform hypergraphs came next on our agenda (Ghoshdastidar and Dukkipati, 2017), and we proved consistency of a spectral approach for non-uniform hypergraph partitioning.

Like graphs, sparsity turns out to be an important characteristics of real-world hypergraphs. While this fact complicates analysis of the algorithms (see Ghoshdastidar and Dukkipati, 2017; Florescu and Perkins, 2016), it definitely provides significant computational relief. For instance, it is easy to realise that for any network clustering scheme, the computational complexity is at least linear in the number of edges. Hence, for a m-uniform hypergraph on n vertices, any standard approach should have a $O(n^m)$ runtime unless the hypergraph is sparse. This is precisely the problem that one encounters in vision applications, where the network is not given a priori, but one constructs a weighted hypergraph using m-way similarities among data instances. Thus, one needs to spend $O(n^m)$ runtime to construct the entire adjacency tensor only to realise at the end that only few edges have significant weights, and will aid the partitioning scheme. This scenario motivates the study in our present work, where we allow the planted hypergraph to have weighted edges, and still be sparse (in the sense that most weights are close to zero). But, at the same time, the non-zero entries are not known a priori, and hence, efficient schemes are required to perform the partitioning by observing only a small subset of the $O(n^m)$ edge weights.

1.1 Contributions in this Paper

We build on our earlier work. To be precise, we study the approach presented in Ghoshdastidar and Dukkipati (2015b), which solves a relaxation of the tensor trace maximisation (TTM) problem that lies at the heart of a variety of higher order learning methods. On the other hand, the model under consideration is that of sparse planted uniform hypergraph similar to the one studied in Ghoshdastidar and Dukkipati (2017). However, unlike previous works, we do not restrict the edge weights to be binary, but arbitrary random variables lying in the interval $[0, 1]$. So, the sparsity parameter in our model reduces the mean edge weights, leading to a large amount of edges with negligibly small weights, and hence, creating computational challenges of identifying significant edges. The planted model is formally described in Section 2, while our spectral approach is briefly recapped in Section 3. It might come as a surprise to many that this work does not make use the wide range of tensor decomposition techniques that have now become standard tools in machine learning. In Section 2, we discuss in detail how our model violates the common structural assumptions used in the tensor literature.

Our first contribution is presented in Section 4, where we analyse the basic TTM approach under the above mentioned planted model for weighted m-uniform hypergraphs. We note that in Ghoshdastidar and Dukkipati (2015b), we had studied the problem only in the dense unweighted case, whereas similarity hypergraphs encountered in subspace clustering etc. are weighted and typically have large number of insignificant edges (sparse). Furthermore, we recall that spectral partitioning methods, for graphs or hypergraphs, typically require a final step of distance based clustering. While k-means is the practical choice at this stage, theoretical studies even in the block model literature often use alternative schemes that are easy to analyse. Adhering to our goal of studying practical methods, our analysis utilises guarantees of k-means algorithm (Ostrovsky et al., 2012) instead of resorting to standard assumptions (Lei and Rinaldo, 2015) or other schemes (Gao et al., 2015). In this general setting, Theorem 2 presents the error rate of the TTM approach under mild restrictions on sparsity. Furthermore, recent results of Florescu and Perkins (2016) for the

special case of bi-partitioning suggests that our analysis is nearly optimal. We also show that the performance of this method is similar to the normalised hypergraph cut approach studied in Ghoshdastidar and Dukkipati (2017), and is superior than tensor decomposition based partitioning of Ghoshdastidar and Dukkipati (2014).

The second and key contribution in this paper is the analysis of a sampled variant of the TTM approach given in Section 5. As noted above, any basic partitioning scheme would have a $\Omega(n^m)$ runtime merely due to the construction of the entire adjacency tensor. We consider a scenario where only N edges are randomly sampled (with replacement) according to some pre-specified distribution. Theorem 9 provides a lower bound on the sample size N so that the sampled variant achieves desired error rate. The proof of this result borrows ideas from matrix sampling techniques (Drineas et al., 2006), but mainly relies on a trick of rephrasing the problem such that matrix Bernstein inequality can be applied. The analysis provides quite striking conclusions. For instance, under a simplified setting, if hypergraph is dense and consists of a constant number of partitions, then it is sufficient to observe only $\Omega(n(\ln n)^2)$ uniformly sampled edges. For sparse hypergraphs, uniform sampling cannot improve upon the $\Omega(n^m)$ runtime, but a certain choice of sampling distribution works with only $N = \Omega(n(\ln n)^2)$. To the best of our knowledge, this is the first work that analyses graph / hypergraph partitioning with sampling, and such sampling rates have not been previously observed in any related tensor problem. Typically, most methods need to observe about $\Omega(n^{m/2})$ entries of the tensor in order to estimate its decomposition (see, for instance, Bhojanapalli and Sanghavi, 2015; Jain and Oh, 2014), whereas we find that much less observations are required for the purpose of clustering. Our analysis also justifies the popularity of the iterative sampling schemes (Chen and Lerman, 2009; Jain and Govindu, 2013) in the higher order clustering literature.

Our final contribution is purely algorithmic. We present an iteratively sampled variant of the TTM algorithm, and conduct an extensive numerical comparison of various methods in the context of both hypergraph partitioning and subspace clustering. Section 6 presents a wide variety of empirical studies that (i) validate our theoretical findings regarding relative merits of TTM over previously studied algorithms, (ii) compare spectral methods to other hypergraph partitioning algorithms, including popular hMETIS tool (Karypis and Kumar, 2000), and (iii) weigh the merits of hypergraph partitioning in subspace clustering applications, including benchmark problems. Such empirical studies, though often seen in the subspace clustering works, was long overdue in the higher order learning literature. We also hope that the implementations will help standardising subsequent studies in this direction.[1]

We also note here that to achieve clarity of presentation, the sections only contain the outline of proofs of the main results. The proofs of the intermediate lemmas and corollaries are given in the appendix that follows after the concluding section (Section 7).

1.2 Notations

We conclude this section by stating the standard terminology and notations that we follow in the rest of the paper. We denote tensors in bold faces ($\mathbf{A}, \mathbf{B}$ etc.), matrices in capitals (A, Z etc.), while vectors and scalars will be understood from the context. We use Trace($\cdot$)

1. Codes are available at: `http://sml.csa.iisc.ernet.in/SML/code/Feb16TensorTraceMax.zip` and also on the personal webpage of first author.

to write the sum of diagonal entries of a matrix or tensor, and $\|\cdot\|_2$ for Euclidean norm for vector and the spectral norm for matrix. For a matrix, say A, $A_{i\cdot}$ (or $A_{\cdot i}$) represents its i^{th} row (column), $\|A\|_F$ denotes its Frobenius norm, and $\lambda_i(A)$ is the i^{th} largest eigenvalue or singular value of A (depending on context). We also use the standard $O(\cdot)$, $o(\cdot)$ and $\Omega(\cdot)$ notations, where, unless specified otherwise, the corresponding quantities are viewed as function of n. In addition, $\mathbb{1}\{\cdot\}$ is the indicator function, and $\ln(\cdot)$ is natural logarithm.

Moreover, the results in this paper consider two sources of randomness—the random model for hypergraph, and random sampling of edges (or tensor entries). We make this distinction in the notation for expectation, variance and probability by specifying the underlying measure. For instance, $\mathsf{E}_H[\cdot]$ is expectation with respect to distribution of the planted model, and $\mathsf{E}_{S|H}[\cdot]$ is the expectation over sampling distribution conditioned on a given random hypergraph. Similar subscripts have been used for probability, $\mathsf{P}(\cdot)$, and variance, $\mathsf{Var}(\cdot)$. Note that for a matrix A, $\mathsf{E}_H[A]$ refers to its entry-wise expectation.

2. Formal Description of the Problems

We consider the following random model. Let $\mathcal{V} = \{1, 2, \dots n\}$ be a set of n nodes, and $\psi : \{1, 2, \dots, n\} \to \{1, 2, \dots, k\}$ be a (hidden) partition of the nodes into k classes. For a node i, we denote its class by ψ_i. For a fixed integer $m \geq 2$, let $\alpha_n \in [0, 1]$, and $\mathbf{B} \in [0, 1]^{k \times k \times \dots \times k}$ be a symmetric k-dimensional tensor of order m. Let $\mathcal{E}$ be the collection of all subsets of $\mathcal{V}$ of size m. A random weighted m-uniform hypergraph $(\mathcal{V}, \mathcal{E}, w)$ is generated through the random function $w : \mathcal{E} \to [0, 1]$ such that

$$\mathsf{E}[w(\{i_1, i_2, \dots, i_m\})] = \alpha_n \mathbf{B}_{\psi_{i_1} \psi_{i_2} \dots \psi_{i_m}} \tag{1}$$

for all $e = \{i_1, i_2, \dots, i_m\} \in \mathcal{E}$, and the collection of random variables $(w(e))_{e \in \mathcal{E}}$ are mutually independent. For convenience, we henceforth write w_e instead of $w(e)$. The above model extends the planted partition model for graphs (McSherry, 2001), and is a weighted variant of the planted uniform hypergraph model studied in our earlier works. In particular, if $\alpha_n = 1$ and w_e are independent Bernoulli random variables satisfying (1), then one retrieves the model of Ghoshdastidar and Dukkipati (2014). We present our results for weighted hypergraphs due to their extensive use in computer vision (e.g., Agarwal et al., 2005). Note that the edge distributions are governed by $\mathbf{B}$ and ψ, and hence, depend only on the class membership. In addition, α_n accounts for sparsity of the hypergraph. Under this setting, the objective of a hypergraph partitioning algorithm is to estimate ψ from a given random instance of the m-uniform hypergraph $(\mathcal{V}, \mathcal{E}, w)$. Throughout this paper, we are interested in bounding the error incurred by a partitioning algorithm, defined as a multi-class 0-1 loss

$$\mathsf{Err}(\psi, \psi') = \min_{\sigma} \sum_{i=1}^{n} \mathbb{1}\{\psi_i \neq \sigma(\psi'_i)\}\,, \tag{2}$$

where ψ and ψ' denote the true and the estimated partitions, respectively, and σ is any permutation on $\{1, 2, \dots, k\}$. Note that we also allow number of classes k to grow with n.

The first part of the paper builds on the tensor trace maximisation method of Ghoshdastidar and Dukkipati (2015b), and we prove statistical consistency of TTM under the above sparse planted partition model. To be precise, we show that under certain conditions

on α_n and $\mathbf{B}$, this method achieves $\mathsf{Err}(\psi, \psi') = o(n)$. In the block model terminology (Mossel et al., 2013), this statement implies that the algorithm is weakly consistent. Furthermore, if the hypergraph is dense ($\alpha_n = 1$), then we show that TTM can exactly recover the partitions, *i.e.*, $\mathsf{Err}(\psi, \psi') = o(1)$, and hence, exhibits strong consistency properties. From the recent work of Florescu and Perkins (2016), which studies the special case of bi-partitioning, one can see that our restrictions on α_n are nearly optimal (upto a difference of $(\ln n)^2$) in the case of bi-partitioning as one cannot detect partitions for sparser hypergraphs.

Next we study partitioning algorithms that compute weights of only N out of $\binom{n}{m}$ edges. For the theoretical analysis, we assume that there is a known probability mass function $(p_e)_{e \in \mathcal{E}}$, and N edges are sampled with replacement from this distribution. We are interested in finding the minimum N that guarantees weak consistency of the sampled TTM approach. We focus on two sampling distributions: (i) uniform sampling, and (ii) weighted sampling where $p_e \propto w_e$. Surprisingly, we see that if $\alpha_n = 1$ (dense case), only $N = \Omega(nk^{2m-1}(\ln n)^2)$ edges are sufficient for either sampling strategies. This leads to a drastic improvement in runtime, particularly if $k = O(1)$, and even in general, since typically k grows much slower than n. However, if α_n decays rapidly with n, then more samples are needed for the case of uniform sampling, whereas the alternative strategy still works for $N = \Omega(nk^{2m-1}(\ln n)^2)$. A comparison with tensor literature is not very meaningful, but known methods of the latter field typically need to observe $\Omega(n^{m/2})$ tensor entries (Bhojanapalli and Sanghavi, 2015). In practice, however, computing the weighted sampling distribution requires a single pass over the adjacency tensor, which still takes $O(n^m)$ time. But, we argue that practical iterative schemes essentially approximate this distribution without observing the entire tensor.

2.1 A Look at Alternative (or Possible) Approaches

This may be a good time to reflect on the history of both hypergraphs and tensors with the focus of understanding the theoretical or practical tools that either fields provide for the planted uniform hypergraph problem. Before proceeding further, it will be helpful to take a look at the adjacency tensor of the random (planted) hypergraph.

Let $\mathbf{A} \in [0, 1]^{n \times n \times \dots \times n}$ be the symmetric adjacency tensor of order m. Let $Z \in \{0, 1\}^{n \times k}$ be the assignment matrix of the latent partition ψ, *i.e.*, $Z_{ij} = \mathbb{1}\{\psi_i = j\}$. Then we have

$$\mathbf{A}_{i_1 i_2 \dots i_m} = \begin{cases} \sum_{j_1, \dots, j_m = 1}^{k} \alpha_n \mathbf{B}_{j_1 j_2 \dots j_m} Z_{i_1 j_1} \dots Z_{i_m j_m} + \mathbf{E}_{i_1 i_2 \dots i_m} & \text{for distinct } i_1, \dots, i_m \\ 0 & \text{otherwise,} \end{cases} \tag{3}$$

where $\mathbf{E}$ is a symmetric random tensor with zero mean entries. For ease of understanding, one may ignore the $O(n^{m-1})$ entries of $\mathbf{A}$ with repeated indices to write

$$\mathbf{A} \approx \alpha_n (\mathbf{B} \times_1 Z \times_2 Z \times_3 \dots \times_m Z) + \text{noise term}, \tag{4}$$

where $\times_l$ denotes the mode-l product between a tensor and a matrix (De Lathauwer et al., 2000).[2] The basic problem is to detect Z from a given $\mathbf{A}$.

2. Consider a matrix $B \in \mathbb{R}^{p \times n_l}$ and a m^{th}-order tensor $\mathbf{A} \in \mathbb{R}^{n_1 \times n_2 \times \dots \times n_m}$. The mode-$l$ product of $\mathbf{A}$ and B is a m^{th}-order tensor, represented as $\mathbf{A} \times_l B \in \mathbb{R}^{n_1 \times \dots n_{l-1} \times p \times n_{l+1} \times \dots \times n_m}$, whose elements are
$$(\mathbf{A} \times_l B)_{i_1 \dots i_{l-1} j i_{l+1} \dots i_m} = \textstyle\sum_{i_l} \mathbf{A}_{i_1 \dots i_{l-1} i_l i_{l+1} \dots i_m} B_{j i_l}.$$

The above form is quite similar to the representation of a tensor in terms of its higher order singular value decomposition or HOSVD (De Lathauwer et al., 2000). In fact, it shows that the random adjacency tensor has a multilinear rank approximately $k \ll n$, and clearly suggests that the partitioning problem should be viewed as a tensor decomposition problem. This hint was quickly picked up by Govindu (2005), who proposed a spectral approach for higher order clustering based on HOSVD. Long after this work, tensor methods have gained significant popularity in machine learning in recent years. However, only few works (Bhaskara et al., 2014; Anandkumar et al., 2015) consider decomposition of tensor into asymmetric rank-one terms, while most of the machine learning literature (Anandkumar et al., 2014; Ma et al., 2016) consider decomposition into symmetric rank-one terms. To be more precise, (3) suggests that

$$\mathbf{A} \approx \sum_{j_1,..,j_m=1}^{k} \alpha_n \mathbf{B}_{j_1 j_2 \ldots j_m} Z_{.j_1} \otimes Z_{.j_2} \otimes \ldots \otimes Z_{.j_m} + \text{noise},$$

where $\otimes$ is the tensor outer product. Clearly the k^m rank-one terms are asymmetric. It is well known that such a tensor can be represented by a symmetric outer product decomposition only in an algebraically closed field (Comon et al., 2008), *i.e.*, one can write as sum of symmetric rank-one terms, but the vectors in the decomposition are not guaranteed to be real, and hence, will be of little use. We note that though the works of Bhaskara et al. (2014) and Anandkumar et al. (2015) are applicable, their incoherence assumption is clearly violated in the present context where the same vectors appear in all m modes, and with multiplicity greater than one.

Under simpler settings such as the one described later in Section 4.1, one can express $\mathbf{A}$ as a sum of $(k+1)$ symmetric terms of the form

$$\mathbf{A} \approx \sum_{j=1}^{k} \alpha_n p Z_{.j}^{\otimes m} + \alpha_n q v^{\otimes m} + \text{noise}, \tag{5}$$

where $v = \sum_j Z_{.j}$ and p, q are parameters defining $\mathbf{B}$. Such tensors, which have a finite symmetric CP-rank (Candecomp/Parafac), have been extensively studied in machine learning. For a single rank-one term, optimal detection rates are known under Gaussian noise (Richard and Montanari, 2014). Though there is no distributional assumption on the noise term in our case, (1) does imply that the variance of the noise is smaller than the signal, *i.e.*, specialised to this setting, our model lies in the detection region. Unfortunately, single rank-one term occurs for $k = 1$, which does not correspond to any meaningful hypergraph problem, and hence, such results are of little use in our case. It may seem that the case of $k \geq 2$ can still be tackled using tensor power iteration based approaches (Anandkumar et al., 2014, 2015), but the necessary incoherence criterion is violated even here since v has a significant overlap with each $Z_{.j}$. To summarise, it suffices to say that existing guarantees in the tensor literature are not directly applicable for solving (5), but it does not rule out the possibility that a careful analysis of power iterations (Anandkumar et al., 2014) or alternative approaches (Ma et al., 2016) may lead to alternative partitioning techniques. That being said, one should note that (5) is merely a special case of (3), where HOSVD still appears to be the natural answer.

Interestingly, uniform hypergraphs predate the tensor literature, and one may refer to Berge (1984) for early development. Even hypergraph partitioning came into practice (Schweikert and Kernighan, 1979) before tensor decompositions gained popularity. However, initial approaches to hypergraph partitioning in VLSI (Karypis and Kumar, 2000) and database (Gibson et al., 2000) communities relied on clever combination of heuristics with no known performance guarantees. Subsequent works in computer vision (Agarwal et al., 2005) and machine learning (Zhou et al., 2007) proposed spectral solutions for the problem. Such approaches are more amenable for a theoretical analysis. While the analysis in Ghoshdastidar and Dukkipati (2017) and Florescu and Perkins (2016) are somewhat based on the hypergraph cut approach of Zhou et al. (2007), the algorithm studied in this paper is closely related to work of Agarwal et al. (2005). The key idea of such spectral schemes is to reduce the hypergraph into a graph and then apply spectral clustering. Quite surprisingly, we show in this paper that both schemes perform better than HOSVD based partitioning both theoretically (Remark 5) and numerically (Section 6.1). This is counter-intuitive since one would expect significant information loss during the reduction to a graph. A careful look at the algorithm presented in the next section would reveal that this is not the case. While most information in modes $3, \ldots, m$ are lost, one can still estimate Z from the first two modes, which suffices for the purpose of detecting planted partitions. This observation is reinforced by the recent study of Florescu and Perkins (2016), where the authors show that a reduction based spectral approach can optimally detect two partitions all the way down to the limit of identifiability of the partitions.

We conclude this section with a brief mention of the wide variety of other higher order learning methods, which include tensor based clustering algorithms (Shashua et al., 2006; Chen and Lerman, 2009; Arias-Castro et al., 2011; Ochs and Brox, 2012), other unsupervised tensorial learning schemes (Duchenne et al., 2011; Nguyen et al., 2015), as well as related optimisation approaches (Leordeanu and Sminchisescu, 2012; Rota Bulo and Pelillo, 2013; Jain and Govindu, 2013), and can easily be represented as instances of the uniform hypergraph partitioning problem. In Ghoshdastidar and Dukkipati (2015b), we showed that most of the above methods can be unified by a general *tensor trace maximisation* (TTM) problem. A spectral solution to this problem is analysed in the present paper, and thus, we believe that some of our conclusions can also be extended to these alternative approaches. We also numerically compare with some of these methods in Section 6.

3. Tensor Trace Maximisation (TTM)

In this section, we briefly recap the work in Ghoshdastidar and Dukkipati (2015b) and then present the basic approach that will be later analysed and modified in the remainder of the paper. Let $(\mathcal{V}, \mathcal{E}, w)$ be a given weighted uniform hypergraph, where $\mathcal{E}$ is the collection of all sets of m vertices, and $w : \mathcal{E} \to [0, 1]$ associates a weight with every edge. We consider the problem of partitioning $\mathcal{V}$ into k disjoint sets, $\mathcal{V}_1, ..., \mathcal{V}_k$, such that the total weight of edges within each cluster is high, and the partition is 'balanced'. In the case of graphs, *i.e.*, for $m = 2$, the popular heuristic for achieving these two conditions is the normalised cut minimisation problem, or equivalently normalised associativity maximisation problem (Shi and Malik, 2000; von Luxburg, 2007). We extend this approach to uniform hypergraphs.

3.1 TTM Approach and Algorithm

We consider the problem of finding the partition of the vertices that maximises the normalised associativity. This is subsequently formulated in terms of a tensor trace maximisation objective. We define few terms. The degree of any node $v \in \mathcal{V}$ is the total weight of edges on which v is incident, *i.e.*, $\deg(v) = \sum_{e\in\mathcal{E}:v\in e} w_e$. For any collection of nodes $\mathcal{V}_1 \subseteq \mathcal{V}$, we define its volume as $\mathrm{vol}(\mathcal{V}_1) = \sum_{v\in\mathcal{V}_1} \deg(v)$ and its associativity as $\mathrm{assoc}(\mathcal{V}_1) = \sum_{e\in\mathcal{E}:e\subset\mathcal{V}_1} w_e$, which is the total weight of edges contained within $\mathcal{V}_1$. The normalised associativity of a partition $\mathcal{V}_1, ..., \mathcal{V}_k$ is given as

$$\text{N-Assoc}(\mathcal{V}_1, \ldots, \mathcal{V}_k) = \sum_{i=1}^{k} \frac{\mathrm{assoc}(\mathcal{V}_i)}{\mathrm{vol}(\mathcal{V}_i)} \,. \tag{6}$$

Observe that the above definitions coincide with the corresponding terms in graph literature (Shi and Malik, 2000). We now follow the popular goal of finding clusters that maximises the normalised associativity (6). In the case of graphs, it is well known that the problem can be reformulated in terms of the adjacency matrix of the graphs, which results in a matrix trace maximisation problem (von Luxburg, 2007). Furthermore, a spectral relaxation allows one to find an approximate solution for the problem by computing the k dominant eigenvectors of the normalised adjacency matrix.[3] A similar approach is possible in the case of uniform hypergraphs. Let $\mathbf{A}$ be the adjacency tensor (of order m), *i.e.*,

$$\mathbf{A}_{i_1 i_2 \ldots i_m} = \begin{cases} w_{\{i_1,i_2,\ldots,i_m\}} & \text{if } i_1, i_2, \ldots, i_m \text{ are distinct,} \\ 0 & \text{otherwise.} \end{cases} \tag{7}$$

Define $\beta_1, ..., \beta_m \in [0, 1]$ with $\sum_{l=1}^{m} \beta_l = 1$, and $Y^{(1)}, \ldots, Y^{(m)} \in \mathbb{R}^{n\times k}$ with $Y_{ij}^{(l)} = \left(\frac{\mathbb{1}\{i\in\mathcal{V}_j\}}{\mathrm{vol}(\mathcal{V}_j)}\right)^{\beta_l}$. Then, one can rewrite (6) (see appendix for details) as

$$\text{N-Assoc}(\mathcal{V}_1, \ldots, \mathcal{V}_k) = \frac{1}{m!}\mathrm{Trace}\left(\mathbf{A} \times_1 Y^{(1)^T} \times_2 Y^{(2)^T} \times_3 \ldots \times_m Y^{(m)^T}\right) \,, \tag{8}$$

where $\times_l$ denotes the mode-l product. Thus, for some chosen parameters $\beta_1, \ldots, \beta_m$, one can pose the associativity maximisation problem as a tensor trace maximisation (TTM).

In Ghoshdastidar and Dukkipati (2015b), we showed that the above optimisation has connections with the tensor eigenvalue problem (Lim, 2005) and the tensor diagonalisation problem (Comon, 2001). More interestingly, it also lies at the heart of several higher-order learning algorithms. For instance, $\beta_1 = \ldots = \beta_m = \frac{1}{m}$ results in the method of Shashua et al. (2006), while the same strategy when used with $k = 1$ has been used to successively extract clusters (Rota Bulo and Pelillo, 2013; Leordeanu and Sminchisescu, 2012). A similar idea lies in some tensor matching algorithms (Duchenne et al., 2011; Nguyen et al., 2015). Another strategy is to set $\beta_1 = \beta_2 = \frac{1}{2}$ and $\beta_3 = \ldots = \beta_m = 0$. This squeezes the tensor into a matrix, which allows one to use subsequently graph partitioning tools. Our algorithm described below takes this route, and similar ideas have been previously used (Agarwal et al., 2005; Arias-Castro et al., 2011). This reduction also corresponds to the clique expansion of a hypergraph, where every m-way edge is replaced by $\binom{m}{2}$ pairwise edges.

3. Dominant eigenvectors are the orthonormal eigenvectors corresponding to the largest k eigenvalues.

We list our basic spectral approach in Algorithm TTM, and we later study the consistency of TTM and its sampled variants. Note that a spectral relaxation of the problem is a two-fold procedure, where first we construct a matrix from the affinity tensor $\mathbf{A}$, and then relax the problem into a matrix spectral decomposition type objective. This principle is reminiscent of the classical technique for studying spectral properties of hypergraphs (Bolla, 1993), and is closely related to approach of the clustering graph approximations of hypergraphs (Agarwal et al., 2006).

Algorithm TTM : Spectral relaxation of tensor trace maximisation problem

Input: Affinity tensor $\mathbf{A}$ of the m-uniform hypergraph $(\mathcal{V}, \mathcal{E}, w)$, where $|\mathcal{V}| = n$.

1: Read $\mathbf{A}$, and compute the $n \times n$ matrix A as $A_{ij} = \sum_{i_3,\ldots,i_m=1}^{n} \mathbf{A}_{iji_3\ldots i_m}$.

2: Let $D \in \mathbb{R}^{n\times n}$ be diagonal with $D_{ii} = \sum_{j=1}^{n} A_{ij}$, and $L = D^{-1/2}AD^{-1/2}$.

3: Compute k dominant eigenvectors of L, denoted by $X \in \mathbb{R}^{n\times k}$.

4: Normalise rows of X to have unit norm, and denote this matrix as $\overline{X}$.

5: Run k-means on the rows of $\overline{X}$.

Output: Partition of $\mathcal{V}$ that correspond to the clusters obtained from k-means.

A careful look at computational complexity of the algorithm will be helpful for our discussions in Section 5. To this end, we note that our analysis assumes the use k-means approach of Ostrovsky et al. (2012), which has a complexity of $O(k^2n + k^4)$ since the data is embedded in a k-dimensional space. Furthermore, Steps 2 to 4 involve only matrix operations with the eigenvector computation being the most expensive operation. One may compute the k dominant eigenvectors using power iterations, which can be done provably in $O(kn^2 \ln(kn))$ runtime (Boutsidis et al., 2015). However, the computational bottleneck of the algorithm is Step 1, which has complexity of $m^2|\mathcal{E}| = O(m^2n^m)$. This is not surprising since any network partitioning method should have have complexity at least linear in the number of edges. But it gets quite challenging in computer vision problems, where one often requires to consider higher order relations, for instance $m = 4$ used in Duchenne et al. (2011), $m = 5$ in Chen and Lerman (2009) and even $m = 8$ in Govindu (2005). The aim of Section 5 is to reduce this complexity to m^2N by sampling only $N \ll n^m$ edges.

4. Consistency of Algorithm TTM under Planted Partition Model

The first task in our agenda is to analyse the basic TTM approach. This section extends the results in Ghoshdastidar and Dukkipati (2015b) to the the planted partition model for sparse weighted hypergraphs described in Section 2. Recall that our aim is to derive an upper bound on $\mathsf{Err}(\psi, \psi')$, where ψ and ψ' denote the true and the estimated clusters. Moreover, for the purpose of analysis we assume that the k-means step is performed using Lloyd's approach with the seeding described in (Ostrovsky et al., 2012). The reason for this consideration is the known theoretical guarantee for this method.

We briefly recall the planted model for weighted m-uniform hypergraphs described in Section 2. An underlying function ψ groups the n nodes into k clusters, and ψ_i denotes the true cluster of node i. For any edge $e = \{i_1, i_2, \ldots, i_m\}$, its weight w_e is a random variable taking values in $[0,1]$ with mean given by (1), where the parameters $\alpha_n \in [0,1]$ and symmetric m-way tensor $\mathbf{B} \in [0,1]^{k \times k \times \ldots \times k}$, respectively, govern the mean edge weight and the relative weights of edges formed among nodes from different classes.[4] For instance, in Section 4.1, we consider an example where given $p, q \in [0,1]$, the tensor $\mathbf{B}$ is constructed such that $\mathsf{E}[w_e] = \alpha_n(p+q)$ if all nodes in the edge belong to the same cluster, and $\mathsf{E}[w_e] = \alpha_n q$ if the participating nodes are from different clusters. Thus, in this case, the mean weight of edges residing within in each cluster is larger than inter-cluster edge weights. In addition to above, we also assume that all edge weights $(w_e)_{e \in \mathcal{E}}$ are mutually independent.

Consider a random m-uniform hypergraph $(\mathcal{V}, \mathcal{E}, w)$ generated according to the above model. As a consequence of (1), the expected affinity tensor of the hypergraph

$$\mathsf{E}_H[\mathbf{A}_{i_1 i_2 \ldots i_m}] = \begin{cases} \alpha_n \mathbf{B}_{\psi_{i_1} \psi_{i_2} \ldots \psi_{i_m}} & \text{if } i_1, i_2, \ldots, i_m \text{ are distinct, and} \\ 0 & \text{otherwise,} \end{cases} \tag{9}$$

has a block structure, ignoring entries with repeated indices. Obviously, the k^m blocks are aligned with the underlying clusters, which gives rise to the representation mentioned in (3). Algorithm TTM first squeezes the adjacency tensor $\mathbf{A}$ to a $n \times n$ matrix A. To analyse the algorithm in the expected case, let $\mathcal{A} = \mathsf{E}_H[A]$ and $\mathcal{D} = \mathsf{E}_H[D]$, where A and D are the matrices computed in Algorithm TTM. Observe that if the algorithm had access to the expected affinity tensor (9), then $\mathcal{A}$ corresponds to the matrix computed in the first step of the algorithm, and $\mathcal{D}_{ii} = \sum_{j=1}^{n} \mathcal{A}_{ij}$. From the definition of the model, it can be seen that $\mathcal{A}_{ii} = 0$ for all i, and for $i \neq j$,

$$\mathcal{A}_{ij} = (m-2)! \sum_{\substack{i_3 < i_4 < \ldots < i_m, \\ i,j \notin \{i_3, \ldots, i_m\}}} \alpha_n \mathbf{B}_{\psi_i \psi_j \psi_{i_3} \ldots \psi_{i_m}} , \tag{10}$$

where the factor $(m-2)!$ takes into account all permutations of $\{i_3, \ldots, i_m\}$. The key observation here is that $\mathcal{A}_{ij} = \mathcal{A}_{i'j'}$ whenever $\psi_i = \psi_{i'}$ and $\psi_j = \psi_{j'}$, which holds since, under the present model, nodes in the same cluster are statistically identical. Thus, one can define a matrix $G \in \mathbb{R}^{k \times k}$ such that $\mathcal{A}_{ij} = G_{\psi_i \psi_j}$ for all $i \neq j$. This implies that, ignoring the diagonal entries, $\mathcal{A}$ is essentially of rank k.

Let $Z \in \{0,1\}^{n \times k}$ be the assignment matrix corresponding to partition ψ, *i.e.*, $Z_{ij} = \mathbb{1}\{i \in \psi(j)\}$, and let the sizes of the k clusters be $n_1 \geq n_2 \geq \ldots \geq n_k$. We define

$$\delta = \lambda_k(G) \min_{1 \leq i \leq n} \frac{n_{\psi_i}}{\mathcal{D}_{ii}} - \max_{1 \leq i,j \leq n} \left| \frac{G_{\psi_i \psi_i}}{\mathcal{D}_{ii}} - \frac{G_{\psi_j \psi_j}}{\mathcal{D}_{jj}} \right| , \tag{11}$$

where $\lambda_k(G)$ is the smallest eigenvalue of G. The following lemma, proved in the appendix, shows that if $\delta > 0$, then Algorithm TTM correctly identifies the underlying clusters in the expected case.

4. Note that α_n plays the role of a sparsity parameter commonly introduced to define sparse stochastic block models (Lei and Rinaldo, 2015), and a smaller α_n increases the complexity of the problem. However, unlike the unweighted case, all edges are present in our setting but most of the weights are very small.

Lemma 1 *Let $\mathcal{L} = \mathcal{D}^{-1/2} \mathcal{A} \mathcal{D}^{-1/2}$. If δ in (11) satisfies $\delta > 0$, then there exists an orthonormal matrix $U \in \mathbb{R}^{k \times k}$ such that the k leading orthonormal eigenvectors of $\mathcal{L}$ correspond to the columns of the matrix $\mathcal{X} = Z(Z^T Z)^{-1/2} U$.*

It is easy to see that $\mathcal{X}$ has k distinct rows, each corresponding to a true cluster. Hence, clustering the rows of $\mathcal{X}$ (or its row normalised form) using k-means gives an accurate clustering of the nodes. In the random case, however, the dominant eigenvectors of L computed in TTM need not always reflect the true assignment matrix Z. The following result shows that under certain conditions on the model parameters, the eigenvectors are still close to $\mathcal{X}$, and hence, the number of mis-clustered nodes (2) grows slowly.

Theorem 2 *Let $(\mathcal{V}, \mathcal{E}, w)$ be a random m-uniform hypergraph on $|\mathcal{V}| = n$ vertices generated from the model described above. Define $d = \min_{1 \leq i \leq n} \mathsf{E}_H[\deg(i)]$ and, without loss of generality, assume that the cluster sizes are $n_1 \geq n_2 \geq \ldots \geq n_k$. Let δ be as defined in (11). There exists an absolute constant $C > 0$, such that, if $\delta > 0$ and*

$$\delta^2 d > \frac{C k n_1 (\ln n)^2}{n_k} \tag{12}$$

for all large n, then with probability $(1 - o(1))$, the partitioning error for TTM is

$$\mathsf{Err}(\psi, \psi') = O\left(\frac{k n_1 \ln n}{\delta^2 d} \right). \tag{13}$$

The bound in (13) along with the condition in (12) immediately suggests that TTM is weakly consistent, *i.e.*, $\mathsf{Err}(\psi, \psi') = o(n)$ or the fractional of mis-clustered vertices vanishes as $n \to \infty$. However, in certain (dense) cases, even $\mathsf{Err}(\psi, \psi') \to 0$ as we will discuss later. Note that d grows with n though this dependence is not made explicit in the notation. We also allow k to vary with n. The condition on $\delta^2 d$ in (12) ensures that the hypergraph is sufficiently dense so that the following three conditions hold, respectively: (i) the matrix A computed in Algorithm TTM concentrates near its expectation, (ii) the k dominant eigenvectors of L contain information about the partition, and (iii) the k-means step provides a near optimal solution. While restricting d from below in (12) essentially limits the sparsity of the hypergraph, the quantity δ on the other hand quantifies the complexity of the model.

The threshold for identifying two partitions, derived in Florescu and Perkins (2016), shows that the condition in (12) differs from the threshold for identifiability only by logarithmic factors. These extra $\ln n$ factors arise since (i) we consider weighted hypergraphs, and (ii) we do not substitute k-means by alternative strategies. Note that even works on stochastic block model (Lei and Rinaldo, 2015; Gao et al., 2015) do not consider these two factors, and hence, even in the case of graphs, it is not known till date whether the logarithmic terms can be avoided when these practical aspects are included in the analysis. We point out that the present analysis incorporates the guarantees for k-means derived in Ostrovsky et al. (2012), which was also used in our earlier work (see Lemma 4.8 of Ghoshdastidar and Dukkipati, 2017).

4.1 A Special Case

To gain insights into the implications of Theorem 2, we consider the following special case of the planted partition model. The partition ψ is defined such that the k clusters are of equal

size. Moreover, the tensor $\mathbf{B}$ in (1) is given by $\mathbf{B}_{j_1 j_2 \ldots j_m} = (p+q)$ if $j_1 = j_2 = \ldots = j_m$, and q otherwise, where $p, q \in [0,1]$ with $q \leq (1-p)$. Thus, in this model, edges residing within each cluster have a high weight (in the expected sense) as compared to other edges.[5] This model corresponds to the decomposition of $\mathbf{A}$ mentioned in (5). We state the following consistency result for dense hypergraphs.

Corollary 3 *Let $\alpha_n = 1$ and $k = O\left(\frac{n^{1/4}}{\ln n}\right)$. Then with probability $(1 - o(1))$,*

$$\mathsf{Err}(\psi, \psi') = O\left(\frac{n^{(3-m)/2}}{(\ln n)^{2m-3}}\right) . \tag{14}$$

According to the notions of consistency defined in Mossel et al. (2013), it can be seen that for $m = 2$, Algorithm TTM is weakly consistent, *i.e.*, $\mathsf{Err}(\psi, \psi') = o(n)$. We note here that, in this sense, the algorithm is not worse than spectral clustering that is also known to be weakly consistent (Rohe et al., 2011). However, for $m \geq 3$, $\mathsf{Err}(\psi, \psi') = o(1)$ for Algorithm TTM, which implies that it is strongly consistent in this case. In other words, the algorithm can exactly recover the partitions for large n. This conclusion is intuitively acceptable since in this case, uniform hypergraphs for large m have a large number of edges that provides 'more' information about the partition, providing a smaller error rate.

In the sparse regime, the question one is interested in is the minimum level of sparsity under which weak consistency of an algorithm can be proved. The following result answers this question. For the case of graphs ($m = 2$), Lei and Rinaldo (2015) showed that weak consistency is achieved by spectral clustering for $\alpha_n \geq \frac{C \ln n}{n}$, which matches our result upto a factor of $(\ln n)^2$. In fact, our proof also allows the difference to be reduced to a factor of $\omega(\ln n)$, but this difference has negligible effect in practice.

Corollary 4 *Let $k = O(\ln n)$. There exists an absolute constant $C > 0$, such that, if*

$$\alpha_n \geq \frac{C(\ln n)^{2m+1}}{n^{m-1}} , \tag{15}$$

then $\mathsf{Err}(\psi, \psi') = O\left(\frac{n}{(\ln n)^2}\right) = o(n)$ with probability $(1 - o(1))$.

While the stochastic block model has been extensively studied for graphs, the existing hypergraph literature provides consistency results for only two other approaches:

- a uniform hypergraph partitioning method that uses a higher order singular value decomposition (HOSVD) of the adjacency tensor (Govindu, 2005; Ghoshdastidar and Dukkipati, 2014), and
- a non-uniform hypergraph partitioning approach that solves a spectral relaxation of the normalised hypergraph cut (NH-Cut) problem (Zhou et al., 2007; Ghoshdastidar and Dukkipati, 2017). Florescu and Perkins (2016) also use a similar method.

5. The model considered here may be viewed as the four parameter stochastic block model (Rohe et al., 2011) defined by the parameters (n, k, p_n, q_n), where n nodes are divided into k partitions of equal size. Edges within a cluster occur with probability $(p_n + q_n)$, while inter-cluster edges occur with probability q_n. Here, we set $p_n = \alpha_n p$ and $q_n = \alpha_n q$ for some constants $p, q \in [0,1]$ with $q \leq (1-p)$.

We comment on the theoretical performance of TTM in comparison with these two approaches. In particular, we focus on the settings of Corollaries 3 and 4. The following remark is quite surprising since both TTM and NH-Cut reduce the hypergraphs to graphs, and hence, apparently incur some loss. Yet both outperform HOSVD, which appears to be the most natural solution according to the representation in (3). This fact is also validated numerically in Section 6.1.

Remark 5 *Under the setting of Corollary 3, the error bound for the NH-Cut algorithm is*

$$\mathrm{Err}_{\text{NH-Cut}}(\psi, \psi') = O\left(\frac{n^{(3-m)/2}}{(\ln n)^{2m-3}}\right)$$

with probability $(1 - o(1))$, while the corresponding bound for HOSVD algorithm is

$$\mathrm{Err}_{\text{HOSVD}}(\psi, \psi') = O\left(\frac{n^{(4-m)/2}}{(\ln n)^{2m-1}}\right) .$$

Thus the performance of NH-Cut is similar to TTM, and both methods have a smaller error bound than HOSVD.

Similarly, in the case of Corollary 4, the lower bound on sparsity for NH-Cut is same as in (15) *up to a constant scaling. However, HOSVD achieves weak consistency only for*

$$\alpha_n \geq \frac{C'(\ln n)^{m+1.5}}{n^{(m-1)/2}}$$

for some $C' > 0$. This is larger than the allowable sparsity for TTM or NH-Cut.

4.2 Proof of Theorem 2

Here, we give an outline of the proof of Theorem 2 using a series of technical lemmas. The proofs of these results are given in the appendix. The proof has a modular structure which consists of (i) deriving certain conditions on the model parameters such that Algorithm TTM incurs no error in the expected case, (ii) subsequent use of matrix concentration inequalities and spectral perturbation bounds to claim that (almost surely) the dominant eigenvectors in the random case do not deviate much from the expected case, and (iii) finally, the proof of correctness of the k-means step.

Recall that the first step of the proof is taken care of by Lemma 1. For convenience, define $\mathcal{D}_{\min} = \min_{1 \leq i \leq n} \mathcal{D}_{ii}$. One can see that $\mathcal{D}_{\min} = (m-1)!d$. Hence, for the subsequent analysis as well as for all the proofs, it is more convenient to expand (12) as

$$\mathcal{D}_{\min} > \max\left\{C_1 \ln n, \frac{C_2 \ln n}{\delta^2}, \frac{C_3 k n_1 \ln n}{n_k \epsilon^2 \delta^2}\right\} , \tag{16}$$

where the constants $C_1, C_2, C_3 > 0$ take into account the additional factor of $(m-1)!$. Note that the last term dominates, and corresponds to (12) when $\epsilon = (\ln n)^{-1/2}$. The subsequent results show that the eigenvector matrix X computed from a random realisation of the hypergraph is close to $\mathcal{X}$ almost surely, and hence, one can expect a good clustering in the random case.

Lemma 6 proves a concentration bound for the normalised affinity matrix L computed in Algorithm TTM. The proof, given in the appendix, relies on an useful characterisation of the matrix A. To describe this representation, we define for each edge $e \in \mathcal{E}$, a matrix $R_e \in \{0,1\}^{n\times n}$ as $(R_e)_{ij} = 1$ if $i,j \in e, i \neq j$, and zero otherwise. Quite similar to the representation of (10), one can note that

$$A = (m-2)! \sum_{e\in\mathcal{E}} w_e R_e \ . \tag{17}$$

This characterisation is quite useful since the independence of $(w_e)_{e\in\mathcal{E}}$ ensures that A is represented as a sum of independent random matrices, and hence, one can use matrix concentration inequalities (Tropp, 2012) to derive a tail bound for $\|A - \mathcal{A}\|_2$.

Lemma 6 *If there exists n_0 such that $\mathcal{D}_{\min} > 9(m-1)!\ln n$ for all $n \geq n_0$, then with probability $\big(1 - O(n^{-2})\big)$,*

$$\|L - \mathcal{L}\|_2 \leq 12\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}} \ . \tag{18}$$

The above result directly leads to a bound on the perturbation of the eigenvectors as shown in Lemma 4.7 of Ghoshdastidar and Dukkipati (2017). The result adapted to our setting is stated below.

Lemma 7 *Assume there is an n_0 such that $\mathcal{D}_{\min} > 9(m-1)!\ln n$ and $\delta > 24\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}}$ for all $n \geq n_0$. Then the following statements hold with probability $\big(1 - O(n^{-2})\big)$.*

1. *The matrix X does not have any row with zero norm, and hence, its row normalised form, denoted by $\overline{X}$, is well-defined.*
2. *There is an orthonormal matrix $Q \in \mathbb{R}^{k\times k}$ such that*

$$\big\|\overline{X} - ZQ\big\|_F \leq \frac{24}{\delta}\sqrt{\frac{(m-1)!2kn_1\ln n}{\mathcal{D}_{\min}}} \ . \tag{19}$$

Finally, we analyse the k-means step of the algorithm, where the rows of $\overline{X}$ are assigned to k centres. Define $S \in \mathbb{R}^{n\times k}$ such that $S_{i\cdot}$ denotes the centre to which $\overline{X}_{i\cdot}$ is assigned. Also define the collection of nodes $\mathcal{V}_{err} \subset \mathcal{V}$ such that

$$\mathcal{V}_{err} = \left\{ i \in \mathcal{V} : \|S_{i\cdot} - Z_{i\cdot}Q\|_2 \geq \frac{1}{\sqrt{2}} \right\} \ . \tag{20}$$

The following result, adapted from Ghoshdastidar and Dukkipati (2017), shows that on one hand $\mathcal{V}_{err}$ contains all the mis-labelled nodes, whereas, on the other, it proves that under the conditions of Theorem 2, the k-means algorithm of Ostrovsky et al. (2012) finds a near optimal solution for which $|\mathcal{V}_{err}|$ can be bounded from above.

Lemma 8 *Under the conditions stated in* (16)*, for small enough ϵ,*

$$\mathsf{Err}(\psi,\psi') \leq |\mathcal{V}_{err}| \leq 8(1+\epsilon^2)^2\|\overline{X} - ZQ\|_F^2 \tag{21}$$

with probability $\big(1 - O(n^{-2} + \sqrt{\epsilon})\big)$.

Theorem 2 follows by setting $\epsilon = (\ln n)^{-1/2}$, and using the bound on $\|\overline{X} - ZQ\|_F$ in (19).

5. Sampling Techniques for Algorithm TTM

We now present the second, and key, contribution in this work. Recall from the discussions in Section 3 that the overall computational complexity of TTM is $O(m^2n^m + kn^2\ln(kn) + k^2n + k^4)$, where the first term clearly dominates for $m \geq 3$. A practical solution to this problem is to simply compute the weights of few edges, or equivalently, sample few entries of the adjacency tensor $\mathbf{A}$. This strategy has often been used in computer vision, but to the best of our knowledge, there is no known theoretical study of the approach. The only relevant theoretical works (Bhojanapalli and Sanghavi, 2015; Jain and Oh, 2014) are in a different context, where the authors study factorisation of partially observed tensors. While the latter work assumes an uniform sampling, the former presents distributions that are more adapted to the tensor. We later compare these results with our findings.

In contrast, practical higher order learning methods exhibit considerable variety in sampling techniques. Govindu (2005) used a sampling that uniformly selects fibers of the tensor, which is similar in spirit to the well known column sampling technique for matrices. Ideas along the same lines, and also a Nyström approximation, for the HOSVD based approach were suggested in Ghoshdastidar and Dukkipati (2015a). A more efficient technique of iterating between sampling and clustering was used in Jain and Govindu (2013) and Chen and Lerman (2009), where one starts with a naive sampling to get approximate partitions and then iteratively improves the result by sampling edges aligned with partitions. Matching algorithms (Duchenne et al., 2011) exploit side information to prioritise edges with significant weights. Other heuristics have also been suggested in some works.

We formally study the following problem. Suppose we are given a certain distribution $(p_e)_{e\in\mathcal{E}}$ on the set of all m-way edges $\mathcal{E}$. Let N edges be sampled with replacement according to the given distribution. We aim to find the minimum sample size required such that corresponding partitioning algorithm (with edge sampling) is still weakly consistent. In this paper, we assume that the core partitioning approach is TTM, and the sampling only affects Step 1 of the algorithm, where we replace A by its sample estimate, denoted by $\widehat{A}$. A requirement of the estimator should be its unbiasedness, *i.e.*, $\mathsf{E}_{S|H}[\widehat{A}] = A$, where the expectation is with respect to the sampling distribution given an instance of the random hypergraph. Based on (17), we propose to use an unbiased estimator of the form

$$\widehat{A} = \frac{(m-2)!}{N}\sum_{e\in\mathcal{I}} \frac{w_e}{p_e} R_e \ , \tag{22}$$

where $\mathcal{I} \subset \mathcal{E}$ with $|\mathcal{I}| = N$ is the collection of sampled edges (with possible duplicates). The matrix $R_e \in \{0,1\}^{n\times n}$ is such that $(R_e)_{ij} = 1$ if $i,j \in e, i \neq j$, and zero otherwise. The overall method is listed below, and one can easily see that its runtime is $O(m^2N + kn^2\ln(kn) + k^2n + k^4)$.

5.1 Consistency of Sampled Variants of Algorithm TTM

We now analyse the performance of Algorithm Sampled TTM for any given edge sampling distribution $(p_e)_{e\in\mathcal{E}}$. The main message of the following result is that the algorithm remains weakly consistent even if we use very small number of sampled edges, *i.e.*, $N = o(n^m)$. However, the minimum sample size required depends on the sampling distribution.

Algorithm Sampled TTM : TTM where a sampled set of edge weights are observed

Input: Distribution $(p_e)_{e\in\mathcal{E}}$ on the set of all edges $\mathcal{E}$;
Affinity tensor $\mathbf{A}$, which is not observed, but requested entries can be observed.

1: Sample a collection of N edges $\mathcal{I} \in \mathcal{E}$ with replacement.
2: Observe entries of $\mathbf{A}$ corresponding to edges in $\mathcal{I}$, and compute $\widehat{A}$ using (22).
3: Run Steps 2-5 of Algorithm TTM using $\widehat{A}$ instead of A.

Output: Partition of $\mathcal{V}$ that correspond to the clusters obtained from k-means.

Theorem 9 *Let N edges be sampled with replacement according to probability distribution $(p_e)_{e\in\mathcal{E}}$, and let $\beta > 0$ be such that $\mathsf{P}_H\left(\max_{e\in\mathcal{E}} \frac{w_e}{p_e} > \beta\right) = o(1)$. Let δ be as defined in (11). There exist absolute constants $C, C' > 0$, such that, if $\delta > 0$,*

$$\delta^2 d > C\frac{kn_1(\ln n)^2}{n_k} \quad \text{and} \quad N > C'\left(1+\frac{2\beta}{d}\right)\frac{kn_1(\ln n)^2}{n_k\delta^2} \tag{23}$$

for all large n, then with probability $(1-o(1))$,

$$\mathsf{Err}(\psi,\psi') = O\left(\frac{kn_1\ln n}{\delta^2}\left(\frac{1}{d}+\frac{1}{N}+\frac{2\beta}{Nd}\right)\right) = o(n). \tag{24}$$

Note that the above probability is with respect to both the randomness of the hypergraph and edge sampling. The above result is similar to Theorem 2 except for the additional condition and error term associated with the number of sampled edges N. We mention here that the constant C in (23) is different from the one used in Theorem 2, but the quantity δ remains the same, and does not depend on the sampling distribution. Since, the above error rate is $o(n)$, we can immediately conclude that the lower bound on N in (23) is sufficient to ensure weak consistency of the sampled variant. The result also shows that if we fix a particular sampling strategy, then smaller N is needed for denser and easier models (large $\delta^2 d$). This can be explained since for sparse hypergraphs, most edges have zero or negligibly small weights, and do not provide 'sufficient information' about the true partition.

On the other hand, the sampling strategy plays a crucial role in the lower bound for N, but the dependence is only via the ratio of the edge weight to the sampling probability. We note that β is a high probability upper limit of this ratio,[6] and (23) suggests that a better sampling distribution is one for which β is smaller. To clarify this observation, we state the result for two particular sampling distributions: (i) uniform sampling, and (ii) sampling each edge e with probability proportional to its weight, *i.e.*,

$$p_e = \frac{w_e}{\sum_{e'\in\mathcal{E}} w_{e'}} \qquad \text{for all } e \in \mathcal{E}. \tag{25}$$

One can easily see that $\beta = \sum_e w_e$ in the latter case, whereas $\beta = \binom{n}{m}\max_e w_e$ for uniform sampling. For ease of exposition, we restrict ourselves to the special case described in Section 4.1, and demonstrate the effect of these distributions on sample size.

6. The probability is with respect to the randomness of the planted model, and arises since the edge weights are random.

Corollary 10 *Consider the setting described in Section 4.1. Define quantity ξ such that $\xi = 1$ for uniform sampling, and $\xi = \alpha_n$ for the weighted sampling of (25). There exist constants $C, C' > 0$, such that, if*

$$\alpha_n > C\frac{k^{2m-1}(\ln n)^2}{n^{m-1}} \quad \text{and} \quad N > C'\frac{\xi nk^{2m-1}(\ln n)^2}{\alpha_n}, \tag{26}$$

then $\mathsf{Err}(\psi,\psi') = o(n)$ with probability $(1-o(1))$.

For simplicity, let us start with the case where $k = O(1)$. Then one has the lower bound $N = \Omega\left(\frac{n(\ln n)^2}{\alpha_n}\right)$ for uniform sampling, and $N = \Omega(n(\ln n)^2)$. Thus, the both sampling techniques have similar performance in the dense case ($\alpha_n = 1$), the gap between the lower bounds increase when α_n decays with n. In fact, in the most sparse setting possible in (23), $\alpha_n = O(\frac{(\ln n)^2}{n^{m-1}})$ and so, uniform sampling works only when one samples $\Omega(n^m)$ edges.[7] But with weighted sampling, one still needs only $\Omega(n(\ln n)^2)$ edges.

Possibility of achieving consistency with such a low sample size is quite remarkable, and has not been yet observed in any other tensor problem. For instance, it may be argued that one can directly use the factorisation techniques for partially observed tensors studied in Jain and Oh (2014) and Bhojanapalli and Sanghavi (2015), to guarantee sampling rates derived in these works. We show here that this may not be a good strategy since such sampling can be often much larger than the rate derived in Corollary 10. We note here that the comparison is not entirely fair since, on one hand, we require only the clusters instead of the complete factorisation, whereas on the other hand, the results in related tensor sampling works are usually tied to an incoherence assumption that is violated in our setting.

For the comparison, we recall that in the setting of Corollary 10, $\mathbf{A}$ has an approximate CP-decomposition of rank $(k+1)$ as shown in (5). Furthermore, most works on tensors do not consider the case where entries decay with dimension, and so, we may assume $\alpha_n = 1$. The aforementioned works consider the problem of tensor factorisation, where the tensor is partly observed by means of some sampling. Jain and Oh (2014) show that to obtain an accurate tensor factorisation, it is suffice to observe $\Omega(k^5 n^{m/2}(\ln n)^4)$ uniformly sampled entries. Bhojanapalli and Sanghavi (2015) use a different sampling distribution, which essentially assigns more weight for larger entries quite similar to (25), and then prove a similar bound on the sample size (upto logarithmic factors). The key difference of such bounds with Corollary 10 is that the m in the exponential is tied to n in other works, whereas it is tied to k in our case—this improves efficiency significantly when k grows much slower than n, which is clearly the case in clustering.

We elaborate on this further by considering the extreme values of k and α_n possible in Corollaries 3 and 4, respectively. First, let $\alpha_n = 1$ and $k = O\left(\frac{n^{1/4}}{\ln n}\right)$, as in Corollary 3. Then both uniform and weighted sampling can guarantee weak consistency if $N = \Omega\left(n^{0.5m+0.75}(\ln n)^{3-2m}\right)$. In contrast, the sample size from (Jain and Oh, 2014) is $N = \Omega(n^{0.5m+1.25}(\ln n)^{-1})$, which is worse by a factor of about $\sqrt{n}$. Turning to the setting of Corollary 4, we have $k = O(\ln n)$ and let α_n be at its lower bound in (15). Then, the above

7. Note that this observation is only true for weighted hypergraphs, where a small α_n implies that most edges have very small, but positive, weights. On the other hand, unweighted hypergraphs with small α_n implies that only few edges are present, and sampling is not required if these edges are given a priori.

result shows that while uniform sampling is poor, by sampling significant edges frequently, one needs only $N = \Omega\left(n(\ln n)^{2m+1}\right)$ edges for consistent partitioning. In contrast, the weighted sampling of Bhojanapalli and Sanghavi (2015) still needs $\Omega(n^{0.5m}(\ln n)^7)$ samples, which is much larger.

5.2 Proof of Theorem 9

We will further discuss the implications and limitations of weighted sampling, but first, we provide an outline for the proof of Theorem 9. Recall that the sampled variant differs from core TTM algorithm only in the use of $\widehat{A}$ (22) instead of A. Let us define $\widehat{D}, \widehat{L}$ for this case corresponding to D, L. That is, $\widehat{D}_{ii} = \sum_j \widehat{A}_{ij}$ and $\widehat{L} = \widehat{D}^{-1/2}\widehat{A}\widehat{D}^{-1/2}$. Note that $\widehat{A}, \widehat{D}$ are both unbiased estimates of A, D. The proof follows the lines of the proof of Theorem 2. It is easy to see that the only difference is in Lemma 6, where instead of $\|L - \mathcal{L}\|_2$, we now need to compute a bound on $\|\widehat{L} - \mathcal{L}\|_2$. Observe that

$$\|\widehat{L} - \mathcal{L}\|_2 \leq \|\widehat{L} - L\|_2 + \|L - \mathcal{L}\|_2 \ ,$$

where the second term is bounded due to Lemma 6. We have the following bound for the first part, which can be derived using matrix Bernstein inequality.

Lemma 11 *For large n and under the conditions in* (23)*, with probability* $1 - o(1)$*,*

$$\|\widehat{L} - L\|_2 \leq 12\sqrt{\frac{\ln n}{N}\left(1 + \frac{2\beta}{d}\right)} \ . \tag{27}$$

This bound combined with Lemma 6 implies

$$\|\widehat{L} - \mathcal{L}\|_2 \leq 12\sqrt{\frac{\ln n}{d}} + 12\sqrt{\frac{\ln n}{N}\left(1 + \frac{2\beta}{d}\right)} \ . \tag{28}$$

Let us denote the above upper bound by γ_n. Then one can restate Lemmas 7 and 8 as follows.

Lemma 7*. If $\delta > 2\gamma_n$ for all large n, then with probability $(1 - o(1))$,

$$\left\|\overline{X} - ZQ\right\|_F \leq \frac{2\gamma_n\sqrt{2kn_1}}{\delta} \ . \tag{29}$$

Lemma 8*. If $\delta \geq 2\gamma_n\sqrt{\frac{8kn_1 \ln n}{n_k}}$, then with probability $1 - o(1)$,

$$\mathsf{Err}(\psi, \psi') = O\left(\frac{kn_1\gamma_n^2}{\delta^2}\right) \ . \tag{30}$$

Here, the stronger condition is required for the k-means error bound. Now, observe that we can bound γ_n^2 as

$$\gamma_n^2 \leq 288\left(\frac{\ln n}{d} + \frac{\ln n}{N}\left(1 + \frac{2\beta}{d}\right)\right).$$

The above bound immediately implies the error bound in (24), whereas the condition in Lemma 8* is satisfied if (23) holds. Thus, the claim of Theorem 9 follows.

5.3 TTM with Iterative Sampling

In this section, we discuss practical strategies for sampling. The purpose of the section is two-fold. We first relate the weighted sampling strategy (25) to heuristics used in practice. We then suggest a practical variant of Algorithm Sampled TTM to solve the problem of subspace clustering. Our experimental results in next section will validate the efficacy of this method in realistic problems.

We recall that Corollary 10 led to the conclusion that, in general, weighted sampling (25) achieves a runtime that is smaller than that of uniform sampling by a factor of α_n. It is obvious that specifying this distribution involves computing all edge weights, which in turn, requires a single pass over the adjacency tensor. Even the weighted sampling of Bhojanapalli and Sanghavi (2015) suffers from the same issue. However, even this is not acceptable in practice as a single pass also has computational complexity of $O(n^m)$, and hence, Sampled TTM based on (25) is mainly of theoretical interest. But our analysis leads to an important conclusion—*sample edges with larger weights more frequently.*

This is essentially the idea commonly used in most tensor based algorithms. In the case of matching algorithms, one uses an efficient nearest neighbour search to sample the larger tensor entries (Duchenne et al., 2011). On the other hand, the subspace clustering literature has acknowledged the idea of iterative sampling (Chen and Lerman, 2009; Jain and Govindu, 2013), where one uses an alternating strategy of finding clusters using a sampled set of edges, and then re-sampling edges for which at least $(m-1)$ nodes belong to a cluster. It is not hard to realise that both sampling techniques give higher preference to edges with large weights, and hence, as a consequence of Corollary 10, both methods are expected to perform better than uniform sampling. Thus Corollary 10 provides a theoretical justification for why such heuristics work, thereby answering an open question posed by Chen and Lerman (2009).

We now turn to the problem of designing a practical variant of TTM based on the above discussion. We use the conclusions of Corollary 10 and present an iterative version of Algorithm TTM for the purpose of subspace clustering. We henceforth refer to this algorithm as *tensor trace maximisation with iterative sampling*, or simply Tetris. An additional reason for presenting this algorithm is to address a paradoxical situation that arose in our previous work (Ghoshdastidar and Dukkipati, 2015b). While the theoretical results suggest that TTM perform better than HOSVD based techniques (Govindu, 2005; Chen and Lerman, 2009), experiments on large benchmark problems did not align with the same conclusion. We later realised that this disparity occurred because we had combined TTM with a naive sampling technique, but had compared with the practical iterative variant of HOSVD. The numerical comparisons in this paper using Tetris resolves this issue, and shows that TTM is indeed more favourable.

We now present Tetris for solving the subspace clustering problem (Soltanolkotabi et al., 2014). In this problem, one is given a collection of n points $Y_1, Y_2, \ldots, Y_n \in \mathbb{R}^{r_a}$ in an high dimensional *ambient* space. However, there are k subspaces, each of dimension at most $r < r_a$, such that one can represent Y_i as

$$Y_i = \widetilde{Y}_i + \eta_i \ ,$$

where $\widetilde{Y}_i$ lies in one of the k subspaces, and η_i is a noise term. The objective of a subspace clustering algorithm is to group $Y_1, \ldots, Y_n$ into k disjoint clusters such that each cluster corresponds to exactly one of the k low-dimensional subspaces. A hypergraph or tensor based

subspace clustering approach (Agarwal et al., 2005; Govindu, 2005) involves construction of a weighted m-uniform hypergraph such that $m \geq (r+2)$ and the weight of an edge $e = \{i_1, \ldots, i_m\}$ is given by

$$w_e = w(\{i_1, \ldots, i_m\}) = \exp\left(-\frac{f_r(Y_{i_1}, \ldots, Y_{i_m})}{\sigma^2}\right) . \tag{31}$$

Here, $f_r(\cdot)$ computes the error of fitting a r-dimensional subspace for the given m points, and σ is a scaling parameter. Different choices for $f_r(\cdot)$ has been considered in the literature based on Euclidean distance of points from the estimated subspace (Govindu, 2005; Jain and Govindu, 2013), polar curvature of the points (Chen and Lerman, 2009) among others. Chen and Lerman (2009) also proposed a heuristic for estimating σ at each iteration.

We present Algorithm Tetris for the subspace clustering problem. We fix the order of the tensor as $m = (r+2)$, and define $f_r(\cdot)$ in terms of polar curvature (see Equations 1-3 of Chen and Lerman, 2009). We also incorporate the convergence criteria and the estimation procedure for σ used by Chen and Lerman (2009), which are not explicitly stated below. Furthermore, to standardise with their approach, Tetris uses a one-sided degree normalisation and computes left singular vectors of the normalised adjacency matrix.

Algorithm Tetris : TTM with iterative sampling for subspace clustering

Input: Dataset $Y = [Y_1, \ldots, Y_n]$; k = Number of subspaces;
r = Maximum subspace dimension; and
c = A hyper-parameter controlling number of sampled edges ($N = nc$)

1: Set $m = r + 2$.
2: Uniformly sample c subsets of Y, each containing $(m-1)$ points.
3: Initialise $\widehat{A} \in \mathbb{R}^{n \times n}$ to a zero matrix.
4: **for** $j = 1$ to c **do**
5: Consider j^{th} subset of Y with the points $Y_{j_1}, \ldots, Y_{j_{m-1}}$.
6: **for** $i = 1$ to n **do**
7: Compute the weight w_e for the edge $e = \{Y_i, Y_{j_1}, \ldots, Y_{j_{m-1}}\}$ using (31).
8: Update $\widehat{A}_{ij_l} = \widehat{A}_{ij_l} + w_e$ for all $l = 1, \ldots, m-1$.
9: **end for**
10: **end for**
11: Let $\widehat{D} \in \mathbb{R}^{n \times n}$ be diagonal with $\widehat{D}_{ii} = \sum_{j=1}^{n} \widehat{A}_{ij}$, and $\widehat{L} = \widehat{D}^{-1}\widehat{A}$.
12: Compute k dominant left singular vectors of $\widehat{L}$, denoted by $\widehat{X} \in \mathbb{R}^{n \times k}$.
13: Normalise rows of $\widehat{X}$ to have unit norm.
14: Run k-means on the rows of the normalised matrix, and partition Y into k clusters.
15: From each obtained cluster, sample c/k subsets, each of size $(m-1)$.
16: Repeat from Step 3, and iterate until convergence.

Output: Clustering of Y into k disjoint clusters.

6. Experimental Validation

In this section, we present numerical illustrations related to uniform hypergraph partitioning. The numerical results are categorised into four parts. The first set of results is based on

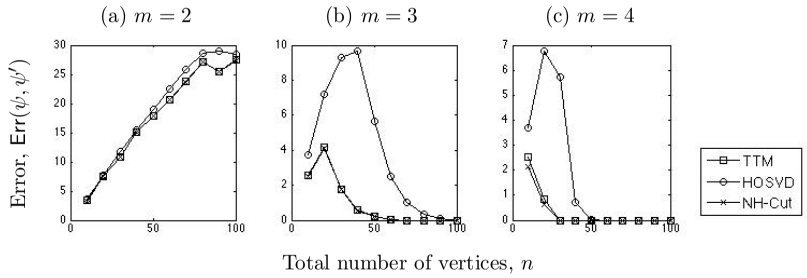

Figure 1: Number of vertices mis-clustered by TTM, HOSVD and NH-Cut as n increases. The figures from left to right correspond to cases with $m = 2$, 3 and 4, respectively.

the setting of Corollary 3, and validates our theoretical observations about TTM. We next compare the performance of TTM with several uniform hypergraph partitioning methods for some small scale problems. The reason for restricting our study to small problems is because, in such cases, the hypergraphs can be completely specified, and edge sampling can be avoided. The rest of the section focuses on practical versions of the subspace clustering problem, where we compare sampled variants of TTM with state of the art subspace clustering algorithms. Our experiments include both synthetic subspace clustering problems (Park et al., 2014) and benchmark motion segmentation problem (Tron and Vidal, 2007).

6.1 Comparison of Spectral Algorithms

We first compare the performance of TTM with the HOSVD based algorithm (Govindu, 2005; Ghoshdastidar and Dukkipati, 2014) and the NH-Cut algorithm (Zhou et al., 2007; Ghoshdastidar and Dukkipati, 2017). This study is based on the model related to Corollary 3, where a m-uniform hypergraph is generated on n vertices. We assume here that $\alpha_n = 1$, $k = 2$, and the true clusters are of equal size. The edges occur with following probabilities. If all vertices in an edge do not belong to the same cluster, then the edge probability is $q = 0.2$, else it is $(p+q)$ for some $p \in (0, 1-q)$ specified below.

In Figure 1, we show results for three examples, where p is fixed at $p = 0.1$, m is varied over $m = 2, 3, 4$, and the total number of vertices n grows from 10 to 100. For each case, 50 planted hypergraphs are generated, and subsequently partitioned by TTM, HOSVD and NH-Cut. The mean error, $\mathsf{Err}(\psi, \psi')$, is reported for each algorithm as a function of n. Figure 1 shows that the performance of TTM and NH-Cut are similar, and the errors incurred by these methods are significantly smaller than that of HOSVD. This observation validates Corollary 3 and Remark 5. It can also be seen empirically that all three methods have a sub-linear error rate for $m = 2$, *i.e.*, they are weakly consistent, whereas, $\mathsf{Err}(\psi, \psi') = o(1)$ for $m \geq 3$.

We consider another example on bi-partitioning 3-uniform hypergraphs, where we fix $q = 0.2$ but the gap p is decreased as 0.1, 0.05 and 0.025. Figure 2 shows the errors, averaged over 50 runs, incurred by the three methods as the hypergraph grows. Note that

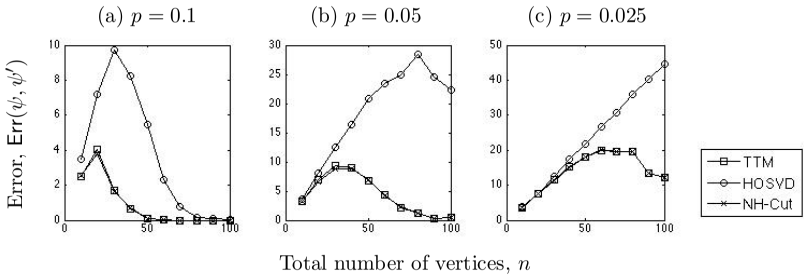

Figure 2: Number of vertices mis-clustered by TTM, HOSVD and NH-Cut as n increases. The figures from left to right correspond to cases with $p = 0.1$, 0.05 and 0.025, respectively.

the problem becomes harder as p reduces, and the performance of HOSVD is highly affected. But, the effect is much less in case of TTM and NH-Cut. This follows from Theorem 2, where one can observe that, in the present context $\mathsf{Err}(\psi, \psi')$ varies as $1/p^2$. Same holds for NH-Cut, but in the case of HOSVD, $\mathsf{Err}(\psi, \psi')$ varies as $1/p^4$ making the algorithm more sensitive to reduction in probability gap.

6.2 Comparison of Hypergraph Partitioning Methods

We consider similar studies with other hypergraph partitioning methods, such as methods based on symmetric non-negative tensor factorisation (SNTF) (Shashua et al., 2006), higher order game theoretic clustering (HGT) (Rota Bulo and Pelillo, 2013) and the hMETIS algorithm widely used in VLSI community (Karypis and Kumar, 2000). For the latter two methods, we have used implementations provided by the authors.

We first compare the different algorithms under a planted model for 3-uniform hypergraphs with $k = 3$ planted clusters of equal size. As before, we assume the hypergraph to be dense, $\alpha_n = 1$, and the inter-cluster edges occur with probability $q = 0.2$. We study the performance of the methods as the number of vertices n, and the probability gap p varies. The fractional clustering error, $\frac{1}{n}\mathsf{Err}(\psi, \psi')$, averaged over 50 runs, is reported in Figure 3.

The figure shows the previously observed trends for TTM, NH-Cut and HOSVD. In addition, it is observed that SNTF and hMETIS provide nearly similar, but marginally worse results than TTM. However, HGT uses a greedy strategy for extracting individual clusters, and hence, often identifies a majority of the vertices as outliers, thereby resulting in poor performance.

Since partitioning algorithms find use in a variety of applications, we compare the performance of the above algorithms for the subspace clustering problem. In particular, we consider the line clustering problem in an ambient space of dimension 3. We randomly generate three one-dimensional subspaces, and sampled n/k random points from each subspace. As mentioned in the previous section, the data points in subspace clustering problems are typically perturbed by noise. To simulate this behaviour, we add a zero mean Gaussian

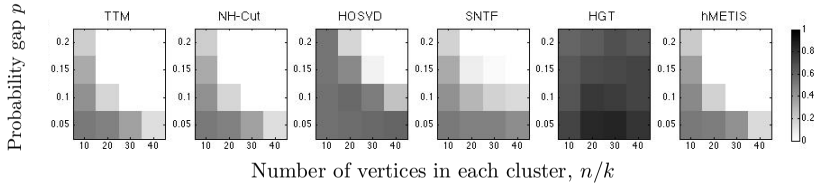

Figure 3: Fractional error incurred by hypergraph partitioning algorithms under a planted model. The cluster size, (n/k), and the probability gap p are varied. The colour bar indicates the shade corresponding to different levels of error, with darker shade representing larger error.

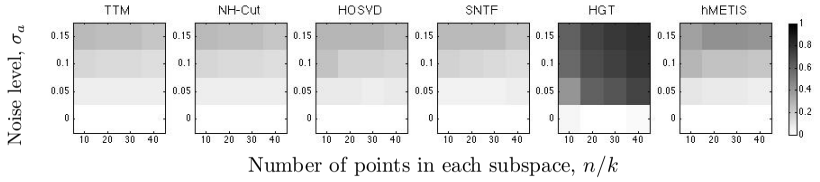

Figure 4: Fractional error incurred by hypergraph partitioning algorithms in clustering noisy points from three intersecting lines. The cluster size, (n/k), and the noise level σ_a are varied. The colour bar indicates the shade corresponding to different levels of error, with darker shade representing larger error.

noise vector to each point. The covariance of the noise vectors is given as $\sigma_a I$, where we vary σ_a to control the difficulty of the problem. We construct a weighted 3-uniform similarity hypergraph based on polar curvature of triplet of points, which is partitioned by the different methods. The fractional clustering errors are presented in Figure 4. As expected, all the methods can identify the exact subspace in the absence of noise, and the errors increase for larger σ_a. Apart from HGT, a good performance is observed from all the methods.

One can observe that the above comparisons were based on very small problems, where the hypergraph consists of at most 120 vertices. This restriction was imposed since specification of the entire affinity tensor is computationally infeasible for large hypergraphs. To demonstrate the performance of TTM in practical settings, we study its sampled variants in the subsequent sections.

6.3 Comparison of Subspace Clustering Algorithms: Synthetic Data

We now compare our method against the state of the art subspace clustering algorithms. We consider sampled variants of the TTM algorithm, *i.e.*, TTM with uniform sampling and TTM with iterative sampling (Tetris). We note that from practical consideration, we do

not consider aforementioned hypergraph partitioning methods that require computation of the entire tensor. The clustering algorithms under consideration include:

- k-means algorithm for clustering based on Euclidean distance,
- k-flats algorithm (Bradley and Mangasarian, 2000) which generalises k-means to subspace clustering,
- sparse subspace clustering (SSC) (Elhamifar and Vidal, 2013), which finds clusters by estimating the subspaces,
- subspace clustering using low-rank representation (LRR) (Liu et al., 2010),
- thresholding based subspace clustering (TSC) (Heckel and Bölcskei, 2013),
- faster variant of SSC using orthogonal matching pursuit (SSC-OMP) (Dyer et al., 2013),
- greedy subspace clustering using nearest subspace neighbour search and spectral clustering (NSN+Spectral) (Park et al., 2014),
- spectral curvature clustering (SCC) (Chen and Lerman, 2009), which is an iterative variant of HOSVD,
- sparse Grassmann clustering (SGC) (Jain and Govindu, 2013),[8] yet another variation of HOSVD where some information about the eigenvectors computed in previous iterations is retained,
- Algorithm Tetris, and
- Algorithm TTM with uniform sampling, which is derived by performing a single iteration of Steps 1-14 of Algorithm Tetris.[9]

We first focus on the problem of clustering randomly generated subspaces.[10] In an ambient space of dimension $r_a = 5$, we randomly generate $k = 5$ subspaces each of dimension $r = 3$. From each subspace, we randomly sample n/k points and perturb every point with a 5-dimensional Gaussian noise vector with mean zero and covariance $\sigma_a I$. In Figure 5, we report the fractional error, $\frac{1}{n}\mathsf{Err}(\psi, \psi')$, incurred by various subspace clustering algorithms when (n/k) and σ_a are varied. The results are averaged over 50 independent trials. We note that for existing methods, we fix the parameters as mentioned in Park et al. (2014). For Tetris and SGC, the parameters are set to the same values as SCC, where $c = 100k$ and σ as in (31) is determined by the algorithm. In case of uniformly sampled TTM, we fix σ to be same as the value determined by Tetris. To demonstrate that sampling more edges lead to error reduction, we consider uniform sampling for two values $c = 100k$ and $200k$.

Figure 5 shows that Tetris and SGC clearly outperform other methods over a wide range of settings. In particular, it can be seen that greedy methods like NSN is accurate

8. For this method, we have used our implementation.
9. Here, the edge sampling is not exactly uniform since we only select the c subsets of size $(m-1)$ uniformly.
10. The experimental setup has been adapted from Park et al. (2014), and the codes are available at: `http://sml.csa.iisc.ernet.in/SML/code/Feb16TensorTraceMax.zip`

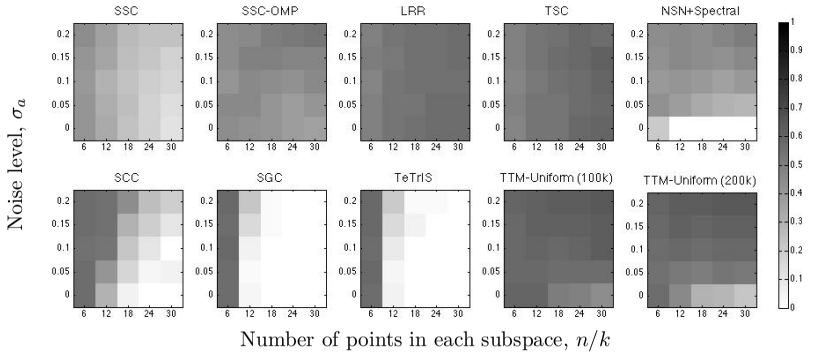

Figure 5: Fractional error incurred by subspace clustering algorithms for synthetic data. The number of points in each subspace, (n/k), and the variance of the noise vector σ_a is varied. The colour bar indicates the shades for different levels of error.

in the absence of noise, but a drastic increase in error occurs when the data is noisy. The effect of noise is much less in hypergraph based methods like SCC, SGC or Tetris. One can also observe that the hypergraph based methods do not work well when there are very few points in each cluster (for example, 6). This is expected since, by definition, these algorithms construct 5-uniform hypergraphs ($m = r + 2$) in this case, and hence, there are very few edges ($\binom{6}{5} = 6$) with large weight for each cluster. However, with increase in number of points, there is a rapid decay in the clustering error. This also shows the consistency of these methods empirically. To this end, it seems that NSN or SSC should be recommended for small scale problems (smaller n/k), whereas Tetris or SGC should be the algorithm of choice for larger n and possible presence of noise. Finally, we also observe that TTM with uniform sampling, even with twice the number of samples, performs quite poorly as compared to Tetris. However, with increase in the number of sampled edges, some extent of error reduction is observed.

6.4 Comparison of Subspace Clustering Algorithms: Motion Segmentation

The Hopkins 155 database (Tron and Vidal, 2007) contains a number of videos capturing motion of multiple objects or rigid bodies. In each video, few features are tracked along the frames, each giving rise to a motion trajectory that resides in a space of dimension twice the number of frames. One can show that under particular camera models, all trajectories corresponding to a particular rigid body motion span a subspace of dimension at most four (Tomasi and Kanade, 1992). Thus, the problem of segmenting different motions in a video can be posed as a subspace clustering problem.

The Hopkins database contains 120 sequences, each containing two motions, and 35 three motion sequences. We run above mentioned subspace clustering algorithms for purpose of

Algorithm	2 motion (120 sequences)			3 motion (35 sequences)		
	Mean (%)	Median (%)	Time (s)	Mean (%)	Median (%)	Time (s)
k-means	19.58	17.92	0.03	26.13	20.48	0.05
k-flats	13.19	10.01	0.38	15.45	14.88	0.76
SSC	1.53	0.00	0.80	4.40	0.56	1.51
LRR	2.13	0.00	0.94	4.03	1.43	1.29
SSC-OMP	16.93	13.28	0.72	27.61	23.79	1.23
TSC	18.44	16.92	0.19	28.58	29.67	0.51
NSN+Spec	3.62	0.00	0.08	8.28	2.76	0.17
SCC	2.53	0.03	0.45	6.40	1.46	0.76
SGC	3.50	0.41	0.54	9.08	5.05	0.89
Tetris	1.31	0.02	0.50	5.71	1.19	0.90

Table 1: Mean and median of clustering error and computational time for different subspace clustering algorithms on Hopkins 155 database.

motion segmentation. For existing approaches, the parameters specified in Park et al. (2014) have been used, and for Tetris and SGC, we use the parameters for SCC. TTM with uniform sampling is not considered due to its higher error rate. Table 1 reports the mean and median of the percentage errors incurred by different algorithms, where these statistics are computed over all 2-motion and 3-motion sequences. In order to remove the effect of randomisation due to sampling (for SCC, SGC, Tetris) or initialisation (for k-means, k-flats, NSN), we average the results over 20 independent trials. The average computational time (in seconds) of each algorithm for each video is also reported.[11]

Table 1 shows that Tetris performs quite well in comparison with state of the art subspace clustering algorithms. In particular, Tetris achieves least mean error for the two motion problem. The computational time for Tetris is also much smaller than other accurate methods like SSC and LRR. The mean error achieved by Tetris is also smaller than SCC in either cases. We note here that the best known results for Hopkins 155 database is achieved by the algorithm in Jung et al. (2014), which uses techniques based on epipolar geometry, and hence, it is not a subspace clustering algorithm. Smaller errors have also been reported in the literature when one construct larger tensors, $m = 8$ (Jain and Govindu, 2013), or uses manual tuning of hyper-parameters (Ghoshdastidar and Dukkipati, 2015a). However, in either cases, computational time increases considerably.

7. Conclusion

In this paper, we studied the problem of partitioning uniform hypergraphs that arises in several applications in computer vision and databases. We formalised the problem by defining a normalised associativity of a partition in a uniform hypergraph that extends a

11. We note that the reported time is based on the fact that we have used Matlab implementations of the algorithms, run on a Mac OS X operating system with 2.2 GHz Intel Core i7 processor and 16 GB memory.

similar notion used in graph literature. We showed that the task of finding a partition that maximises normalised associativity is equivalent to a tensor trace maximisation problem. We proposed a tensor spectral algorithm (TTM) to solve this problem, and following the lines of our previous works, we showed that the TTM algorithm is consistent under a planted partition model. To this end, we extended the existing model of Ghoshdastidar and Dukkipati (2014, 2017) by allowing both sparsity of edges as well as the possibility of weighted edges. Accounting for these factors makes the model more appropriate in the context of computer vision applications. We derived error bounds for the TTM approach under the planted partition model. Our bounds indicate that under mild assumptions on the sparsity of the hypergraph, TTM is weakly consistent, and the error bound for TTM is comparable that of NH-Cut, but better than the error rates for HOSVD. This fact is also validated numerically.

Weighted uniform hypergraphs have been particularly interesting in the computer vision since hypergraphs provide a natural way to represent multi-way similarities. Yet, it is computationally expensive to compute the entire affinity tensor of the hypergraph. As a consequence, several tensor sampling strategies have come into existence. We provide the first theoretical analysis of such sampling techniques in the context of uniform hypergraph partitioning. Our result suggests that consistency can be achieved even with very few sampled edges provided that one assigns a higher sampling probability for edges with larger weight. The derived sampling rate is much lower than that known in tensor literature (Bhojanapalli and Sanghavi, 2015; Jain and Oh, 2014), and our analysis also justifies the superior performance of popular sampling heuristics (Chen and Lerman, 2009; Duchenne et al., 2011). We finally proposed a iteratively sampled variant of TTM, and empirically demonstrated the potential of this method in subspace clustering and motion segmentation applications.

We conclude with the remark that this paper was motivated by practical aspects of hypergraph partitioning, and our aim was to present an approach that can be analysed theoretically, and at the same time, can compete with practical methods. While the paper manages to achieve this goal, there are several questions that still remain unanswered. We list some of the important open problems:

(i) What is the threshold for detecting planted partitions in hypergraphs?
This question was recently answered for a special model in the case of bi-partitioning (Florescu and Perkins, 2016), but more general cases have still not been explored. For instance, it would interesting to know any extension of the results in Abbe and Sandon (2016) for unweighted hypergraphs. However, this would still not provide any information in the weighted case. We noted that one of the reasons for our condition in (12) being worse by logarithmic factors was our analysis is for weighted hypergraphs. It is not known yet whether one can do better for weighted hypergraphs without making distributional assumptions on the edge weights.

(ii) What are the complicated examples? How can we deal with these cases?
Our error bound leads to a counter-intuitive conclusion that even after collapsing the tensor to a matrix, one can get better performance than direct tensor decomposition (HOSVD). The caveat here is that this result is stated for a special case, and still leaves the possibility that that there are models which do not satisfy the condition $\delta > 0$, and hence, TTM does

not work. In Ghoshdastidar and Dukkipati (2017), we constructed few examples, but it is not known whether HOSVD works in these cases. We also mention that the use of other tensor methods (such as power iterations) have not been analysed yet. While we showed that existing results cannot be applied due to the difference in assumptions, we do not claim that alternative tensor methods are inapplicable.

On a similar note, it is known in the case of graph partitioning that the eigen gap (quantified by δ in our results) is not the correct quantity that reflects the presence of a partition. For instance, there are planted graph models, which clearly reflect a separation of the classes, and yet δ is not positive. It would be interesting to see how one can deal with such examples in the case of hypergraphs. An alternative approach in such cases is to quantify the separation by the minimum difference (or distance) between the k rows of $\mathbf{B}$, which is a matrix for graphs. For uniform hypergraphs, a similar quantity would be the difference between the $(m-1)$-order slices of the tensor $\mathbf{B}$, but it is not clear yet how such a condition can be incorporated into the analysis of hypergraph partitioning.

(iii) What is the minimum sample size for achieving weak consistency?
Similar in spirit to the first problem, one can ask what is the minimum sampling rate required to achieve weak consistency irrespective of the partitioning algorithm. We have not made any attempt to answer this question, and surprisingly, the question is open even in graph partitioning. While column sampling techniques (Drineas et al., 2006) are often used in conjunction with spectral clustering, the error rate for this combination is not known.

(iv) How well does TTM extend for other higher order learning problems?
While TTM unifies a wide variety of higher order learning methods, the special cases studies in this paper were restricted to clustering problems. However, other problems like tensor matching can also be modelled as partitioning uniform hypergraph with two partitions of widely different sizes (Duchenne et al., 2011). In principle, this problem has a flavour quite similar to that of the well known planted clique problem (Alon et al., 1998). The state of the art algorithms in tensor matching rely on tensor power iterations, and in Ghoshdastidar and Dukkipati (2017), we showed that a naive use of NH-Cut does not fare well. We feel that in this particular setting, better theoretical guarantees can be achieved by power iteration based approaches.

Appendix A. Proofs of Technical Lemmas and Corollaries

Here, we sequentially present the proofs of lemmas and corollaries stated in the paper. We begin with the calculations that lead to (8).

A.1 Proof of Equation (8)

We recall that the entries of $Y^{(l)}$ is simply $Y^{(l)}_{ij} = \frac{\mathbb{1}\{i \in \mathcal{V}_j\}}{(\mathrm{vol}(\mathcal{V}_j))^{\beta_l}}$. The claimed relation follows by computing diagonal entries of $\mathbf{A} \times_1 {Y^{(1)}}^T \times_2 {Y^{(2)}}^T \times_3 \ldots \times_m {Y^{(m)}}^T$, which are given by

$$\begin{aligned}\left(\mathbf{A} \times_1 {Y^{(1)}}^T \times_2 \ldots \times_m {Y^{(m)}}^T\right)_{j\ldots j} &= \sum_{i_1,\ldots,i_m=1}^{n} \mathbf{A}_{i_1\ldots i_m} Y^{(1)}_{i_1 j} \ldots Y^{(m)}_{i_m j} \\ &= m! \sum_{i_1<\ldots<i_m} \mathbf{A}_{i_1\ldots i_m} \frac{\mathbb{1}\{i_1,\ldots,i_m \in \mathcal{V}_j\}}{(\mathrm{vol}(\mathcal{V}_j))^{\beta_1+\ldots+\beta_m}} ,\end{aligned}$$

where we use the symmetry of the terms to group all $m!$ permutations of every distinct $i_1,\ldots,i_m$. Since $\sum_l \beta_l = 1$, the denominator is simply $\mathrm{vol}(\mathcal{V}_j)$, whereas the indicator in the numerator counts only the edges $e \subset \mathcal{V}_j$ and $\mathbf{A}_{i_1\ldots i_m}$ provides the weights. So the above quantity is simply $m!\frac{\mathrm{assoc}(\mathcal{V}_j)}{\mathrm{vol}(\mathcal{V}_j)}$, and summing over all diagonal entries results in the normalised associativity, scaled by $m!$.

A.2 Proof of Corollary 3

We begin by computing $\mathcal{A}$ as defined in (10)

$$\mathcal{A}_{ij} = \begin{cases} (m-2)!\alpha_n \left(p\binom{\frac{n}{k}-2}{m-2} + q\binom{n-2}{m-2}\right) & \text{if } i \neq j, \psi_i = \psi_j \\ (m-2)!\alpha_n q\binom{n-2}{m-2} & \text{if } i \neq j, \psi_i \neq \psi_j \\ 0 & \text{if } i = j. \end{cases}$$

From the definition of G, $\mathcal{D}_{\min}$ and δ, one can compute that

$$\mathcal{D}_{\min} = (m-1)!\alpha_n \left(p\binom{\frac{n}{k}-1}{m-1} + q\binom{n-1}{m-1}\right) , \tag{32}$$

and

$$\delta = \lambda_k(G)\frac{n}{k\mathcal{D}_{\min}} = \frac{(m-2)!\alpha_n pn}{k\mathcal{D}_{\min}}\binom{\frac{n}{k}-2}{m-2} \tag{33}$$

We need to validate that the conditions in (12), or equivalently (16), are satisfied. Given $\alpha_n = 1$, one can see that $\mathcal{D}_{\min} = \Theta(n^{m-1})$ easily satisfies first condition of (16) for large n.[12] Also

$$\delta^2\mathcal{D}_{\min} = \Theta\left(\left(\frac{n}{k}\right)^{2m-2}\frac{1}{\mathcal{D}_{\min}}\right) = \Theta\left(\frac{n^{m-1}}{k^{2m-2}}\right) = \Omega\left(n^{(m-1)/2}(\ln n)^{2m-2}\right) ,$$

taking into account that $k = O\left(\frac{n^{1/4}}{\ln n}\right)$. Thus, the second condition in (16) also holds for large n and for all $m \geq 2$. Subsequently, one can applying the bound in (13) to claim that $\mathsf{Err}(\psi,\psi') = O\left(\frac{n^{(3-m)/2}}{(\ln n)^{2m-3}}\right)$ with probability $(1-o(1))$.

12. The notation $f_n = \Theta(n)$ denotes that there exists constants c, C such that $cn \leq f_n \leq Cn$ for all large n.

A.3 Proof of Corollary 4

For $k = O(\ln n)$, one can verify that (12) holds if $\mathcal{D}_{\min} = \Omega\left(\frac{(\ln n)^3}{\delta^2}\right)$. From (32) and (33), we have $\mathcal{D}_{\min} = \Theta(\alpha_n n^{m-1})$ and $\delta^2 \mathcal{D}_{\min} = \Omega\left(\alpha_n n^{m-1} (\ln n)^{2-2m}\right)$. Hence, choosing $\alpha_n \geq \frac{C(\ln n)^{2m+1}}{n^{m-1}}$ for sufficiently large C ensures that (16) is satisfied. Subsequently with probability $\left(1 - O\left(n^{-2} + (\ln n)^{-1/4}\right)\right) = (1 - o(1))$, we obtain an error bound

$$\mathsf{Err}(\psi, \psi') = O\left(\frac{n \ln n}{\delta^2 \mathcal{D}_{\min}}\right) = O\left(\frac{n \ln n}{\alpha_n n^{m-1} (\ln n)^{2-2m}}\right) = O\left(\frac{n}{(\ln n)^2}\right) = o(n) \ ,$$

which completes the proof.

A.4 Proof of Lemma 1

The proof is along the lines of the proof of Lemma 4.5 in Ghoshdastidar and Dukkipati (2017). We still include a sketch of the proof since the quantities involved are different from the terms dealt in the mentioned paper. From the discussions following (10), one can see that the matrix $\mathcal{A}$ may be expressed as

$$\mathcal{A} = Z G Z^T - J \ ,$$

where $J \in \mathbb{R}^{n \times n}$ is diagonal with $J_{ii} = G_{\psi_i \psi_i}$. Following the arguments of Ghoshdastidar and Dukkipati (2017), one can show that there is a matrix $\mathcal{G} \in \mathbb{R}^{k \times k}$ with eigen decomposition $\mathcal{G} = U \Lambda_1 U^T$ such that $\mathcal{L}\mathcal{X} = \mathcal{X}\Lambda_1$, where $\mathcal{X} = Z(Z^T Z)^{-1/2} U$, and it satisfies $\mathcal{X}^T \mathcal{X} = I$. Thus, the columns of $\mathcal{X}$ are orthonormal eigenvectors of $\mathcal{L}$ corresponding to the eigenvalues in Λ_1. It is also known that the other $(n-k)$ orthonormal eigenvectors correspond to eigenvalues from the set $\left\{-\frac{J_{ii}}{\mathcal{D}_{ii}} : 1 \leq i \leq n\right\}$.

Thus, to prove the claim we need to ensure that $\mathcal{X}$ corresponds to the dominant eigenvectors of $\mathcal{L}$, or in other words,

$$\lambda_k(\mathcal{G}) > \max_{1 \leq i \leq n} \left(-\frac{J_{ii}}{\mathcal{D}_{ii}}\right) = - \min_{1 \leq i \leq n} \frac{G_{\psi_i \psi_i}}{\mathcal{D}_{ii}} \ . \tag{34}$$

A lower bound on $\lambda_k(\mathcal{G})$ can be derived from Rayleigh's principle and Weyl's inequality as

$$\lambda_k(\mathcal{G}) \geq \lambda_k(G) \min_{1 \leq i \leq n} \frac{(Z^T Z)_{\psi_i \psi_i}}{\mathcal{D}_{ii}} - \max_{1 \leq i \leq n} \frac{G_{\psi_i \psi_i}}{\mathcal{D}_{ii}} \ .$$

Noting that $(Z^T Z)_{jj} = n_j$, size of cluster-j, one can readily see from above that if $\delta > 0$, then (34) is satisfied and hence, $\mathcal{X}$ contains the dominant eigenvectors. It is also useful to note that $\delta \leq \lambda_k(\mathcal{L}) - \lambda_{k+1}(\mathcal{L})$, *i.e.*, δ is a lower bound on the eigen gap between the k^{th} and $(k+1)^{th}$ largest eigenvalues of $\mathcal{L}$. This fact is used later in the proof of Lemma 7.

A.5 Proof of Lemma 6

We begin the proof with the claims that if $\mathcal{D}_{\min} > 9(m-1)! \ln n$, then

$$\mathsf{P}_H \left(\max_{1 \leq i \leq n} \left| \frac{D_{ii}}{\mathcal{D}_{ii}} - 1 \right| > 3 \sqrt{\frac{(m-1)! \ln n}{\mathcal{D}_{\min}}} \right) \leq \frac{2}{n^2} \ , \tag{35}$$

and

$$\mathsf{P}_H \left(\|\mathcal{D}^{-1/2}(A - \mathcal{A})\mathcal{D}^{-1/2}\|_2 > 3 \sqrt{\frac{(m-1)! \ln n}{\mathcal{D}_{\min}}} \right) \leq \frac{2}{n^2} \ . \tag{36}$$

We now bound $\|L - \mathcal{L}\|_2$ as

$$\|L - \mathcal{L}\|_2 \leq \|\mathcal{D}^{-1/2} A \mathcal{D}^{-1/2} - D^{-1/2} A D^{-1/2}\|_2 + \|\mathcal{D}^{-1/2} A \mathcal{D}^{-1/2} - \mathcal{D}^{-1/2} \mathcal{A} \mathcal{D}^{-1/2}\|_2 \ .$$

We expand the first term as

$$\begin{aligned} &\|\mathcal{D}^{-1/2} A \mathcal{D}^{-1/2} - D^{-1/2} A D^{-1/2}\|_2 \\ &\qquad \leq \|(\mathcal{D}^{-1/2} - D^{-1/2}) A \mathcal{D}^{-1/2} + D^{-1/2} A (\mathcal{D}^{-1/2} - D^{-1/2})\|_2 \\ &\qquad \leq \|(\mathcal{D}^{-1} D)^{1/2} - I\|_2 \|(D\mathcal{D}^{-1})^{1/2}\|_2 + \|(\mathcal{D}^{-1} D)^{1/2} - I\|_2, \end{aligned}$$

where the last inequality follows since $\|D^{-1/2} A D^{-1/2}\|_2 = 1$. Also, note that

$$\|(\mathcal{D}^{-1} D)^{1/2} - I\|_2 = \max_{1 \leq i \leq n} \left| \sqrt{\frac{D_{ii}}{\mathcal{D}_{ii}}} - 1 \right| \leq \max_{1 \leq i \leq n} \left| \frac{D_{ii}}{\mathcal{D}_{ii}} - 1 \right| .$$

Combining above arguments, we can write

$$\|L - \mathcal{L}\|_2 \leq \max_{1 \leq i \leq n} \left| \frac{D_{ii}}{\mathcal{D}_{ii}} - 1 \right| \left(2 + \max_{1 \leq i \leq n} \left| \frac{D_{ii}}{\mathcal{D}_{ii}} - 1 \right| \right) + \|\mathcal{D}^{-1/2} A \mathcal{D}^{-1/2} - \mathcal{D}^{-1/2} \mathcal{A} \mathcal{D}^{-1/2}\|_2. \tag{37}$$

Using the bounds in (35) and (36) along with the fact that $3\sqrt{\frac{(m-1)! \ln n}{\mathcal{D}_{\min}}} < 1$, one arrives at the claim.

We now prove the concentration bound in (35). Observe that

$$D_{ii} = \sum_{j=1}^{n} A_{ij} = \sum_{i_2, \ldots, i_m = 1}^{n} \mathbf{A}_{i i_2 \ldots i_m} = (m-1)! \sum_{e \in \mathcal{E} : e \ni i} w_e \ ,$$

where the last equality holds since the summation over all $i_2, \ldots, i_m$ counts each edge containing node-i $(m-1)!$ times. Since, D_{ii} is a sum of independent random variables, we can use Bernstein inequality to obtain for any $t > 0$,

$$\begin{aligned} \mathsf{P}_H \left(|D_{ii} - \mathcal{D}_{ii}| > t \mathcal{D}_{ii} \right) &= \mathsf{P}_H \left(\left| \sum_{e \in \mathcal{E} : e \ni i} w_e - \mathsf{E}_H[w_e] \right| > \frac{t \mathcal{D}_{ii}}{(m-1)!} \right) \\ &\leq 2 \exp \left(\frac{-\left(\frac{t \mathcal{D}_{ii}}{(m-1)!}\right)^2}{2 \sum\limits_{e \in \mathcal{E} : e \ni i} \mathsf{Var}_H(w_e) + \frac{2}{3} \frac{t \mathcal{D}_{ii}}{(m-1)!}} \right) \ . \end{aligned} \tag{38}$$

Since $w_e \in [0, 1]$, we have

$$\sum_{e \in \mathcal{E} : e \ni i} \mathsf{Var}_H(w_e) \leq \sum_{e \in \mathcal{E} : e \ni i} \mathsf{E}_H[w_e] = \frac{\mathcal{D}_{ii}}{(m-1)!} \ .$$

Substituting this in (38), we have

$$\mathsf{P}_H\left(|D_{ii}-\mathcal{D}_{ii}|>t\mathcal{D}_{ii}\right)\leq 2\exp\left(-\frac{t^2\mathcal{D}_{ii}}{3(m-1)!}\right)\leq 2\exp\left(-\frac{t^2\mathcal{D}_{\min}}{3(m-1)!}\right).$$

The bound in (35) follows from above by setting $t=3\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}}$, and using a union bound over all $i=1,\ldots,n$.

Finally, we derive (36) using matrix Bernstein inequality (Tropp, 2012, Theorem 1.4), which states that for independent, symmetric, random matrices $Y_1,\ldots,Y_M\in\mathbb{R}^{n\times n}$ with $\mathsf{E}_H[Y_i]=0$ and $\|Y_i\|_2\leq R$ almost surely, one has

$$\mathsf{P}\left(\left\|\sum_{i=1}^{M}Y_i\right\|_2>t\right)\leq n\exp\left(\frac{-t^2}{2\|\sum_i\mathsf{E}[Y_i^2]\|_2+\frac{2Rt}{3}}\right)\tag{39}$$

for any $t>0$. Owing to the representation in (17), one can write

$$\mathcal{D}^{-1/2}(A-\mathcal{A})\mathcal{D}^{-1/2}=\sum_{e\in\mathcal{E}}(m-2)!\,(w_e-\mathsf{E}_H[w_e])\,\mathcal{D}^{-1/2}R_e\mathcal{D}^{-1/2}$$

as a sum of independent, zero mean random matrices. One can verify that $\|R_e\|_2\leq(m-1)$, and hence,

$$\left\|(m-2)!\,(w_e-\mathsf{E}_H[w_e])\,\mathcal{D}^{-1/2}R_e\mathcal{D}^{-1/2}\right\|_2\leq\frac{(m-1)!}{\mathcal{D}_{\min}}\,.$$

In addition, one can bound

$$\begin{aligned}
&\left\|\sum_{e\in\mathcal{E}}\mathsf{E}_H\left[\left((m-2)!\,(w_e-\mathsf{E}_H[w_e])\,\mathcal{D}^{-1/2}R_e\mathcal{D}^{-1/2}\right)^2\right]\right\|_2\\
&=((m-2)!)^2\left\|\sum_{e\in\mathcal{E}}\mathsf{Var}_H(w_e)\mathcal{D}^{-1/2}R_e\mathcal{D}^{-1}R_e\mathcal{D}^{-1/2}\right\|_2\\
&=((m-2)!)^2\left\|\sum_{e\in\mathcal{E}}\mathsf{Var}_H(w_e)\left(\mathcal{D}^{-1}R_e\right)^2\right\|_2\\
&\leq((m-2)!)^2\max_{1\leq i\leq n}\sum_{j=1}^{n}\sum_{e\in\mathcal{E}}\mathsf{Var}_H(w_e)\left(\left(\mathcal{D}^{-1}R_e\right)^2\right)_{ij}\\
&\leq\frac{((m-2)!)^2}{\mathcal{D}_{\min}}\max_{1\leq i\leq n}\frac{1}{\mathcal{D}_{ii}}\sum_{e\in\mathcal{E}}\mathsf{E}_H(w_e)\sum_{j=1}^{n}\left(R_e^2\right)_{ij}\,.
\end{aligned}$$

Here, the first inequality holds due to Gerschgorin's theorem. Observing that the row sum of R_e^2 is at most $(m-1)^2$, the expression can be simplified to show that the quantity is bounded from above by $\frac{(m-1)!}{\mathcal{D}_{\min}}$. Setting $t=3\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}}$ in (39), and combining above arguments, one arrives at (36). This completes the proof.

A.6 Proof of Corollary 10

We begin by characterising β for either sampling methods. Note that $\beta\geq\max_e\frac{w_e}{p_e}$. Since, $|\mathcal{E}|=\binom{n}{m}$, it follows that for uniform sampling $p_e=\binom{n}{m}^{-1}$ for all e, and hence, an appropriate choice of $\beta=\binom{n}{m}$. On the other hand, for the sampling in (25), $\max_e\frac{w_e}{p_e}=\sum_e w_e$. Using Bernstein inequality, one may easily bound this term from above by $2\sum_e\mathsf{E}_H[w_e]\leq 2\alpha_n\binom{n}{m}$, where the bound holds with probability $(1-n^{-2})$.

Thus, ignoring constants factors, one may set $\beta=\xi n^m$, where $\xi=1$ for uniform sampling and α_n for weighted sampling. The conditions in (26) follow directly from (23) and d,δ computed in the proof of Corollary 3.

A.7 Proof of Lemma 11

Let β be defined as in Theorem 9 and $D_{\min}=\min_{1\leq i\leq n}D_{ii}$. Assume that

$$\mathcal{D}_{\min}>36(m-1)!\ln n\quad\text{and}\quad N>9\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)\ln n\,.\tag{40}$$

Also let Γ denote the event

$$\Gamma=\left\{D_{\min}>\frac{\mathcal{D}_{\min}}{2}\right\}\bigcap\left\{\max_{e\in\mathcal{E}}\frac{w_e}{p_e}\leq\beta\right\}.$$

Then, conditioned on a given random hypergraph and the event Γ, we claim that the following bounds hold with probability $(1-\frac{2}{n^2})$,

$$\max_{1\leq i\leq n}\left|\frac{\widehat{D}_{ii}}{D_{ii}}-1\right|\leq 3\sqrt{\frac{\ln n}{N}\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}\,.\tag{41}$$

and

$$\|D^{-1/2}(\widehat{A}-A)D^{-1/2}\|_2\leq 3\sqrt{\frac{\ln n}{N}\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}\,.\tag{42}$$

Assuming that the above hold, we now derive a bound on $\|\widehat{L}-L\|_2$ in the following way. First, note that the bounds in (41) and (42) are with respect to a conditional probability measure, and need to be converted into a bound with respect to the joint probability measure $\mathsf{P}_{S,H}$. This is not hard to derive as one can see in the case of (42), where one can write

$$\begin{aligned}
&\mathsf{P}_{S,H}\left(\|D^{-1/2}(\widehat{A}-A)D^{-1/2}\|_2>3\sqrt{\frac{\ln n}{N}\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}\right)\\
&=\mathsf{E}_H\left[\mathsf{P}_{S|H}\left(\|D^{-1/2}(\widehat{A}-A)D^{-1/2}\|_2>3\sqrt{\frac{\ln n}{N}\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}\right)\right]\\
&\leq\mathsf{P}_H(\Gamma)\,\mathsf{E}_{H|\Gamma}\left[\mathsf{P}_{S|H,\Gamma}\left(\|D^{-1/2}(\widehat{A}-A)D^{-1/2}\|_2>3\sqrt{\frac{\ln n}{N}\left(1+\frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}\right)\right]+\mathsf{P}_H(\Gamma^c)\\
&=O\left(\frac{1}{n^2}\right)+\mathsf{P}_H(\Gamma^c)\,,
\end{aligned}\tag{43}$$

where the inequalities follow by observing that all the quantities are smaller than one, and the first term is bounded due to (42). For bounding $\mathsf{P}_H(\Gamma^c)$, note that from (35), it follows that with probability $(1 - O(n^{-2}))$, for all $i = 1, \ldots, n$,

$$D_{ii} > \mathcal{D}_{ii}\left(1 - 3\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}}\right).$$

Hence, if $\mathcal{D}_{\min} > 36(m-1)!\ln n$, then

$$D_{\min} > \mathcal{D}_{\min}\left(1 - 3\sqrt{\frac{(m-1)!\ln n}{\mathcal{D}_{\min}}}\right) > \frac{\mathcal{D}_{\min}}{2}.$$

This fact, along with the assumption on β, shows that $\mathsf{P}_H(\Gamma^c) = o(1)$, and so, the upper bound on $\|D^{-1/2}(\widehat{A} - A)D^{-1/2}\|_2$ holds with probability $(1 - o(1))$ even with respect to joint probability measure. Similar result also holds for (41). Subsequently, we follow the arguments leading to (37) to conclude that

$$\begin{aligned}\|\widehat{L} - L\|_2 &\le \max_{1\le i\le n}\left|\frac{\widehat{D}_{ii}}{D_{ii}} - 1\right|\left(2 + \max_{1\le i\le n}\left|\frac{\widehat{D}_{ii}}{D_{ii}} - 1\right|\right) + \|D^{-1/2}(\widehat{A} - A)D^{-1/2}\|_2 \\ &\le 12\sqrt{\frac{\ln n}{N}\left(1 + \frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)},\end{aligned}$$

where the last inequality holds with probability $(1 - O(n^{-2}))$ under the conditions stated in (40). To complete the proof, we derive the bounds (41) and (42), which again rely on the use of Bernstein inequality. For this, observe that

$$\widehat{D}_{ii} = \frac{(m-2)!}{N}\sum_{j=1}^{n}\sum_{e\in\mathcal{I}}\frac{w_e}{p_e}(R_e)_{ij} = \frac{(m-1)!}{N}\sum_{e\in\mathcal{I}}\frac{w_e}{p_e}\mathbb{1}\{i\in e\},$$

where for each $e \in \mathcal{I}$,

$$\begin{aligned}\mathsf{E}_{S|H,\Gamma}\left[\frac{w_e}{p_e}\mathbb{1}\{i\in e\}\right] &= \sum_{e'\in\mathcal{E}:e'\ni i} p_{e'}\frac{w_{e'}}{p_{e'}} = \frac{D_{ii}}{(m-1)!}, \\ \mathsf{Var}_{S|H,\Gamma}\left[\frac{w_e}{p_e}\mathbb{1}\{i\in e\}\right] &= \sum_{e'\in\mathcal{E}:e'\ni i}\frac{w_{e'}^2}{p_{e'}} - \left(\frac{D_{ii}}{(m-1)!}\right)^2 \le \left(\beta - \frac{D_{ii}}{(m-1)!}\right)\frac{D_{ii}}{(m-1)!},\end{aligned}$$

and almost surely with respect to $\mathsf{P}_{S|H,\Gamma}$,

$$\left|\frac{w_e}{p_e}\mathbb{1}\{i\in e\} - \frac{D_{ii}}{(m-1)!}\right| \le \left(\beta + \frac{D_{ii}}{(m-1)!}\right).$$

Define $t = 3\sqrt{\frac{\ln n}{N}\left(1 + \frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right)}$. Since the samples $e \in \mathcal{I}$ are independent and identically distributed, we can use Bernstein inequality to write

$$\begin{aligned}&\mathsf{P}_{S|H,\Gamma}\left(|\widehat{D}_{ii} - D_{ii}| > tD_{ii}\right) \\ &\quad= \mathsf{P}_{S|H,\Gamma}\left(\left|\sum_{e\in\mathcal{I}}\frac{w_e}{p_e}\mathbb{1}\{i\in e\} - \frac{D_{ii}}{(m-1)!}\right| > \frac{NtD_{ii}}{(m-1)!}\right) \\ &\quad\le 2\exp\left(\frac{-\frac{N^2t^2D_{ii}^2}{(m-1)!}}{2N\left(\beta - \frac{D_{ii}}{(m-1)!}\right)\frac{D_{ii}}{(m-1)!} + \frac{2}{3}\frac{NtD_{ii}}{(m-1)!}\left(\beta + \frac{D_{ii}}{(m-1)!}\right)}\right) \\ &\quad\le 2\exp\left(\frac{-\frac{ND_{ii}t^2}{(m-1)!}}{\frac{2}{3}\left(4\beta - 2\frac{D_{ii}}{(m-1)!}\right)}\right) \\ &\quad\le 2\exp\left(\frac{-\frac{N\mathcal{D}_{\min}t^2}{2(m-1)!}}{\frac{2}{3}\left(4\beta + 2\frac{\mathcal{D}_{\min}}{(m-1)!}\right)}\right) \le \frac{2}{n^3}.\end{aligned}$$

The inequalities are derived using above relations, and the definition of Γ. From above, (41) follows from union bound.

To prove (42), observe from (22) that

$$D^{-1/2}\widehat{A}D^{-1/2} = \frac{1}{N}\sum_{e\in\mathcal{I}}(m-2)!\frac{w_e}{p_e}D^{-1/2}R_eD^{-1/2}$$

is a sum of independent random matrices with

$$\mathsf{E}_{S|H,\Gamma}\left[(m-2)!\frac{w_e}{p_e}D^{-1/2}R_eD^{-1/2}\right] = D^{-1/2}AD^{-1/2}$$

and

$$\begin{aligned}\left\|(m-2)!\frac{w_e}{p_e}D^{-1/2}R_eD^{-1/2} - D^{-1/2}AD^{-1/2}\right\|_2 &\le (m-2)!\beta\|D^{-1/2}R_eD^{-1/2}\|_2 + 1 \\ &\le \left(\frac{2\beta(m-1)!}{\mathcal{D}_{\min}} + 1\right).\end{aligned}$$

The first bound uses the fact $\|D^{-1/2}AD^{-1/2}\|_2 = 1$ and the second follows since $D_{\min} > \frac{1}{2}\mathcal{D}_{\min}$ and $\|R_e\|_2 \le (m-1)$. We can also bound the norm of the variance term as

$$\begin{aligned}&\left\|\mathsf{E}_{S|H,\Gamma}\left[\left((m-2)!\frac{w_e}{p_e}D^{-1/2}R_eD^{-1/2} - D^{-1/2}AD^{-1/2}\right)^2\right]\right\|_2 \\ &= \left\|-\left(D^{-1/2}AD^{-1/2}\right)^2 + ((m-2)!)^2\sum_{e\in\mathcal{E}}\frac{w_e^2}{p_e}D^{-1/2}R_eD^{-1}R_eD^{-1/2}\right\|_2 \\ &\le 1 + \frac{((m-2)!)^2\beta}{D_{\min}}\left\|\sum_{e\in\mathcal{E}}w_eD^{-1}(R_e)^2\right\|_2 \le \left(1 + \frac{2\beta(m-1)!}{\mathcal{D}_{\min}}\right).\end{aligned}$$

Using these relations and the matrix Bernstein inequality, the bound in (42) can be derived quite similar to the derivation of (36).

Abstract

We aim at recovering the weighted adjacency matrix W of an undirected graph from a perturbed version of its eigenspaces. This situation arises for instance when working with stationary signals on graphs or Markov chains observed at random times. Our approach relies on minimizing a cost function based on the Frobenius norm of the commutator $\mathsf{AB}-\mathsf{BA}$ between symmetric matrices A and B. We describe a particular framework in which we have access to an estimation of the eigenspaces and provide support selection procedures from theoretical and practical points of view. In the Erdős-Rényi model on N vertices with no self-loops, we show that identifiability (*i.e.*, the ability to reconstruct W from the knowledge of its eigenspaces) follows a sharp phase transition on the expected number of edges with threshold function $N\log N/2$. Simulated and real life numerical experiments assert our methodology.

Keywords: Support recovery; Identifiability; Stationary signal processing; Graphs; Backward selection algorithm

1. Presentation

Networks have become a natural and popular way to model interactions in applications such as information technology (Rossi and Latouche, 2013), social life (Jiang et al., 2013; Matias et al., 2015), genetics (Giraud et al., 2012) or ecology (Thomas et al., 2015; Miele and Matias, 2017). In this paper, we investigate the reconstruction of an undirected weighted graph of size N from incomplete information on its set of edges (for instance, one knows that the target graph has no self-loops) and an estimation of the eigenspaces of its adjacency matrix W. This situation depicts any model where one knows in advance a linear operator K that commutes with W.

For instance, several authors (Espinasse et al., 2014; Girault, 2015; Perraudin and Vandergheynst, 2016; Marques et al., 2016) have introduced a definition of stationarity for signal processing on graphs. In the Gaussian framework, they have shown that this definition implies that the covariance operator K is jointly diagonalizable with the Laplacian (Perraudin and Vandergheynst, 2016) or some weighted symmetric adjacency matrix W supported on the graph (Espinasse et al., 2014; Marques et al., 2016).

Another framework adapted to our methodology concerns time-varying Markov processes, which are used to model numerous phenomena such as chemical reactions (Anderson and Kurtz, 2011) or waiting lines in queuing theory (Gaver Jr, 1959), see also Pittenger (1982); MacRae (1977); Barsotti et al. (2014). In some cases, one may observe at random times a Markov chain with transition matrix P. The transition matrix Q of the resulting Markov chain can be shown to be a function of P. Thus, the transitions on the original process can be recovered from an estimation of Q given that P and Q commute. Several models are presented in Section 3 while the general model is given in Section 2.1.

Section 2.2 is concerned with identifiability issues, *i.e.*, the capacity to solve such problems. We exhibit sufficient and necessary conditions on the ability to reconstruct an undirected graph with no self-loops from the knowledge of the eigenspaces of W. These conditions allow us to derive a sharp phase transition on identifiability in the Erdős-Rényi model.

In Section 4.1, we introduce and theoretically assert new estimation schemes based on the Frobenius norm of the commutator $\mathsf{AB}-\mathsf{BA}$ between symmetric matrices A and B. More precisely, we assume that we have access to an estimation $\widehat{\mathsf{K}}$ of K and we consider the empirical contrast given by the commutator, namely $\mathsf{A}\mapsto\|\widehat{\mathsf{K}}\mathsf{A}-\mathsf{A}\widehat{\mathsf{K}}\|$, where $\|\cdot\|$ denotes the Frobenius norm. Using backward-type procedures based on this empirical contrast, we build in Section 4 an estimator of the graph structure, *i.e.*, its set of edges $S^\star$ referred to as the support. Numerical experiments on simulated data (Section 5) and actual data (Section 6) assess the performances of our new estimation method. A discussion and related questions are presented in Section 7.

Related topics encompass spectral, least-squares and moment methods for graph reconstruction (Verzelen et al., 2015; Guédon and Vershynin, 2015; Klopp et al., 2017; Bubeck et al., 2016), Graphical Models (Verzelen, 2008; Giraud et al., 2012), or Vectorial AutoRegressive process (Hyvärinen et al., 2010). In the specific cases of Ornstein-Uhlenbeck processes and non-linear diffusions, the interesting papers Bento et al. (2010) and Bento and Ibrahimi (2014) tackle a related problem which is to estimate W along a trajectory, see Section 3.6 for further details. Note that the framework of the present paper addresses processes observed at random times—with possibly unknown distribution—which are not covered by Bento et al. (2010) and Bento and Ibrahimi (2014).

2. Model and Identifiability

2.1 The Model

Consider a symmetric matrix $\mathsf{W}\in\mathbb{R}^{N\times N}$, viewed as the weighted adjacency matrix of an undirected graph with N vertices. We investigate the eigenspaces of W in a situation where we have no direct information on the spectrum of the graph. Depicting this situation, we assume that the information on the target W stems from an unknown transformation $\mathsf{K}=f(\mathsf{W})\in\mathbb{R}^{N\times N}$ or, in more realistic scenarios, from a perturbed version $\widehat{\mathsf{K}}$ of K. Precisely, let $f:x\mapsto\sum_{n=0}^{\infty}a_nx^n$ be an injective function, analytical on the spectrum of W, the matrix K is given by

$$\mathsf{K}=f(\mathsf{W}):=\sum_{n=0}^{\infty}a_n\mathsf{W}^n. \tag{1}$$

In this setting, the transformation $\mathsf{K}=f(\mathsf{W})$ preserves the eigenspaces. In particular, W and K commute, *i.e.*, $\mathsf{WK}=\mathsf{KW}$, since they share the same eigenspaces.

Our goal is to reconstruct W from a perturbed observation of its eigenspaces, provided by an estimator $\widehat{\mathsf{K}}$ of K. The key point is then to use extra information given by the location of some zero entries of W. Hence, we assume that one knows in advance a set $F\subset[1,N]^2$ of "forbidden" entries such that

$$\forall(i,j)\in F,\quad \mathsf{W}_{ij}=0 \tag{$\mathbf{H}_\mathrm{F}$}$$

Equivalently, the set F is disjoint from the set of edges of the target graph. Throughout this paper, a special interest is given to the case $F=F_{\mathrm{diag}}:=\{(i,i)\ :\ 1\le i\le N\}$ conveying that there are no self-loops in W.

2.2 Identifiability

For $S \subseteq [1,N]^2$, denote by $\mathcal{E}(S)$ the set of symmetric matrices A whose support is included in S, which we write $\mathrm{Supp}(\mathsf{A}) \subseteq S$. Given the set F of forbidden entries defined via ($\mathbf{H}_{\mathrm{F}}$), the matrix of interest W is sought in the set $\mathcal{E}(\overline{F})$ with $\overline{F}$ the complement of F. In some cases, typically for F sufficiently large, most matrices $\mathsf{W} \in \mathcal{E}(\overline{F})$ are uniquely determined by their eigenspaces. For those $\mathsf{W} \in \mathcal{E}(\overline{F})$, there is no matrix $\mathsf{A} \in \mathcal{E}(\overline{F})$ non collinear with W that commutes with W. This property is encapsulated by the notion of *F-identifiability* as follows.

Definition 1 (F-identifiability) *We say that a symmetric matrix W is F-identifiable if, and only if, the only solutions A with $\mathrm{Supp}(\mathsf{A}) \subseteq \overline{F}$ to $\mathsf{AW} = \mathsf{WA}$ are of the form $\mathsf{A} = t\mathsf{W}$ for some $t \in \mathbb{R}$. Equivalently,*

$$\left\{\mathsf{A} \in \mathbb{R}^{N\times N} \ : \ \mathsf{A} = \mathsf{A}^\top,\ \mathsf{AW} = \mathsf{WA} \text{ and } \mathrm{Supp}(\mathsf{A}) \subseteq \overline{F}\right\} = \left\{t\mathsf{W} \ : \ t \in \mathbb{R}\right\} \tag{2}$$

A matrix W is F-identifiable if the set of symmetric matrices with the same eigenvectors as W and whose support is included in $\overline{F}$ is the line spanned by W.

Remark 2 *The dimension of the commutant, defined by*

$$\mathrm{Com}(\mathsf{W}) := \left\{\mathsf{A} \in \mathbb{R}^{N\times N} \ : \ \mathsf{A} = \mathsf{A}^\top,\ \mathsf{AW} = \mathsf{WA}\right\},$$

is entirely determined by the multiplicity of the eigenvalues of W. Indeed, letting $\lambda_1, \dots, \lambda_s$ denote the different eigenvalues of W and $\ell_1, \dots, \ell_s$ their multiplicities, one can show that

$$N \leq \dim\left(\mathrm{Com}(\mathsf{W})\right) = \sum_{j=1}^{s} \frac{\ell_j(\ell_j+1)}{2} \leq \frac{N(N+1)}{2}.$$

Now, the F-identifiability of W can be stated equivalently as $\dim\left(\mathrm{Com}(\mathsf{W}) \cap \mathcal{E}(\overline{F})\right) = 1$, observing that the left hand side of (2) is exactly $\mathrm{Com}(\mathsf{W}) \cap \mathcal{E}(\overline{F})$. Using a simple inclusion/exclusion formula, one can check that the condition

$$|F| \geq \dim\left(\mathrm{Com}(\mathsf{W})\right) - 1$$

is necessary for the F-identifiability, where $|F|$ denotes the cardinality of F. In particular, a matrix W with repeated eigenvalues requires a large set F of forbidden entries to be F-identifiable.

Proposition 3 (Lemma 2.1 in Barsotti et al. (2014)) *Let $S \subseteq \overline{F}$, the set of F-identifiable matrices in $\mathcal{E}(S)$ is either empty or a dense open subset of $\mathcal{E}(S)$.*

This proposition conveys that the F-identifiability of a matrix W is essentially a condition on its support S. The proof uses the fact that non F-identifiable matrices in $\mathcal{E}(S)$ can be expressed as the zeros of a particular analytic function, we refer to Barsotti et al. (2014) for further details. By abuse of notation, we say that a support $S \subseteq \overline{F}$ is *F-identifiable* if almost every matrix in $\mathcal{E}(S)$ is F-identifiable.

Characterizing the F-identifiability appears to be a challenging issue since it can be viewed as understanding the eigen-structure of graphs through their common support. The special case of the diagonal F_{diag} as the set of forbidden entries turns out to be particularly interesting. Indeed, the F_{diag}-identifiability, or diagonal identifiability, can be reasonably assumed in many practical situations since it entails that W lives on a simple graph, with no self-loops. In Theorem 16 (see Appendix A.1), we introduce necessary and sufficient conditions on the target support $\mathrm{Supp}(\mathsf{W})$ for diagonal identifiability. Defining the *kite* graph ∇_N of size $N \geq 3$ as the graph (V,E) with vertices $V = [1,N]$ and edges $E = \{(k,k+1),\ 1 \leq k \leq N-1\} \cup \{(N-2,N)\}$ (see Figure 1), one simple sufficient condition on diagonal identifiability reads as follows—a proof in given in Section A.2.

Proposition 4 *If the graph $G = ([1,N],S)$ contains the kite graph ∇_N as a subgraph, then S is diagonally identifiable.*

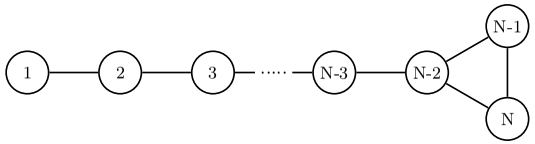

Figure 1: The kite graph ∇_N on N vertices.

Denote $G(N,p)$ the Erdős-Rényi model on graphs of size N where the edges are drawn independently with respect to the Bernoulli law of parameter p. Using Theorem 16, one can prove that $\log N/N$ is a sharp threshold for diagonal identifiability in the Erdős-Rényi model (see Section A.4). This can be stated as follows.

Theorem 5 *Diagonal identifiability in the Erdős-Rényi model occurs with a sharp phase transition with threshold function $\log N/N$: for any $\varepsilon > 0$, it holds*

- *If $p_N \geq (1+\varepsilon)\log N/N$ and $G_N \sim G(N,p_N)$ then the probability that $\mathrm{Supp}(G_N)$ is diagonally identifiable tends to 1 as N goes to infinity.*
- *If $p_N \leq (1-\varepsilon)\log N/N$ and $G_N \sim G(N,p_N)$ then the probability that $\mathrm{Supp}(G_N)$ is diagonally identifiable tends to 0 as N goes to infinity.*

In practice, one may expect that any target graph of size N with no self-loops and degree bounded from below by $\log N$ is diagonally identifiable. In this case, it might be recovered from its eigenspaces. Conversely, small degree graphs (*i.e.*, graphs with some vertices of degree much smaller than $\log N$) may not be identifiable. In this case, there is no hope to reconstruct it from its eigenspaces since there exists another small degree undirected weighted graph with the same eigenspaces.

3. Some Concrete Models

3.1 Markov chains

We begin with an example treated in the companion papers Barsotti et al. (2014, 2016). Consider a Markov chain $(X_n)_{n\in\mathbb{N}}$ with finite state space $[1,N]$ and transition matrix $\mathsf{P} \in \mathbb{R}^{N\times N}$. Let $(T_k)_{k\geq 1}$ be a sequence of random times such that the time gaps $\tau_k := T_{k+1} - T_k$ are i.i.d random variables independent of $(X_n)_{n\in\mathbb{N}}$. One can show that the sequence $Y_k = X_{T_k}$ is also a Markov chain with transition matrix $\mathsf{Q} = \mathbb{E}[\mathsf{P}^{\tau_1}] =: f(\mathsf{P})$ where f is the generating function of τ_k. Indeed, this follows from noticing that

$$\begin{aligned}
\mathbb{P}[Y_{k+1} = j | Y_k = i] &= \mathbb{P}[X_{T_{k+1}} = j | X_{T_k} = i] \\
&= \sum_{t\geq 0} \mathbb{P}[X_{T_k+t} = j, \tau_k = t | X_{T_k} = i] \\
&= \sum_{t\geq 0} \mathbb{P}[X_t = j | X_0 = i]\mathbb{P}[\tau_k = t] \\
&= \sum_{t\geq 0} \mathbb{P}[\tau_1 = t](\mathsf{P}^t)_{ij}.
\end{aligned}$$

Under regularity conditions, $\mathsf{Q} = f(\mathsf{P})$ can be estimated from the Y_k's and one may recover P from Q without any information on the distribution of the time gaps τ_k.

3.2 Vectorial AutoRegressive process

Consider a stationary Vectorial AutoRegressive process of order one $(X_n)_{n\in\mathbb{Z}}$ verifying

$$X_{n+1} = \mathsf{W}X_n + \varepsilon_n\,,$$

with ε_i i.i.d. centered random variables. Define as above $Y_k = X_{T_k}$ where again T_k are random times such that the time gaps $\tau_k = T_{k+1} - T_k$ are i.i.d. with generating function f and independent of $(X_n)_{n\in\mathbb{Z}}$. Then, it holds

$$\mathbb{E}[Y_{k+1}|Y_k] = \mathbb{E}[\mathbb{E}[Y_{k+1}|Y_k,\tau_k]|Y_k] = \sum_{j=0}^{\infty} \mathsf{W}^j Y_k \mathbb{P}(\tau_k = j) = f(\mathsf{W})Y_k,$$

which allows us to estimate $\mathsf{K} = f(\mathsf{W})$ and ultimately recover W.

3.3 Ornstein-Uhlenbeck process

The same property holds for the continuous time version of this process, namely a vectorial Ornstein-Uhlenbeck process observed at random times verifying

$$\mathrm{d}X_t = \mathsf{W}X_t\mathrm{d}t + \mathrm{d}B_t.$$

In this case, one can check that the random process $Y_k := X_{T_k}$ where the T_k's are random times with i.i.d. gaps $\tau_k = T_{k+1} - T_k$ satisfies

$$\mathbb{E}[Y_{k+1}|Y_k] = f(\mathsf{W})Y_k\,,$$

for f the Laplace transform of τ_1, that is, $f(\mathsf{W}) = \mathbb{E}[\exp(-\tau_1\mathsf{W})]$. Indeed, note that

$$\forall t,u\in\mathbb{R},\quad \mathbb{E}[X_{t+u}|X_u] = \exp(-t\mathsf{W})X_u$$

so that

$$\mathbb{E}[Y_{k+1}|Y_k] = \mathbb{E}[\mathbb{E}[X_{T_k+\tau_k}|X_{T_k},\tau_k]|X_{T_k}] = \mathbb{E}[\exp(-\tau_k\mathsf{W})X_{T_k}|X_{T_k}] = \mathbb{E}[\exp(-\tau_k\mathsf{W})]Y_k\,,$$

by independence of τ_k and Y_{k-1}.

3.4 Seasonal VAR structure

Consider a seasonal VAR structure: let T be a positive integer, $(u_k)_{k\in\mathbb{Z}}, (v_k)_{k\in\mathbb{Z}}$ periodic sequences of period T and

$$\forall k\in\mathbb{Z}\,,\quad Y_{k+1} = u_kY_k + v_k\mathsf{W}Y_k + \varepsilon_k\,,$$

where ε_k are independent and centered random variables. We may observe the model only at time gap intervals T with some error, *i.e.*, $X_t = Y_{tT+k_0} + \eta_t$ with η_t centered and independent random variables. This falls into the general frame

$$\mathbb{E}[X_t|X_{t-1}] = f(\mathsf{W})X_{t-1}\quad\text{where}\quad f(x) := \prod_{k=1}^{T}(u_k - v_kx)\,.$$

In this case, $\mathsf{K} = f(\mathsf{W})$ can be estimated from the observations.

3.5 Gaussian Graphical models

Our model is related to Gaussian Graphical models for which an overview can be found in the thesis Verzelen (2008). The reader may also consult the pioneering paper Friedman et al. (2008). One may consider the target W as the precision matrix, *i.e.*, the inverse of the covariance matrix K, having some non zero entries described by a graph of dependencies. Using $f(x) = x^{-1}$, this falls into our setting, trying to recover the "dependency" graph given by the precision matrix W from the estimation of the covariance matrix K. Of course, in this case, it is better to use the knowledge of f, which certainly improves estimation. Nevertheless, our procedure allows us to estimate the function f and heuristically validate the hypothesis $f(x) = x^{-1}$.

3.6 Spatial AutoRegressive Gaussian fields

Note that Gaussian AutoRegressive processes on $\mathbb{Z}$ verify that the precision operator may be written as a polynomial of the adjacency operator of $\mathbb{Z}$. One natural way to extend this property (see for instance Espinasse et al. (2014)) is to define centered Gaussian AutoRegressive fields on a graph through the same relation between the covariance operator K and the adjacency operator W (or the discrete Laplacian, depending on the framework) : $\mathsf{K}^{-1} = P(\mathsf{W})$, with P a polynomial of degree p. In this framework, Graphical models methods will infer the graph of path of length p, whereas our method aims at recovering W. Note that this framework extends to ARMA spatial fields where K writes as a rational fraction of W, and the property of commutativity between W and K still holds.

In the previous cases, we assumed that we can not estimate directly W. For spatio-temporal processes, this means that we do not have access to a full trajectory. It may be the case when the sample is drawn at random times, or when we sample with respect to the stationary measure of the process—for instance when observation times are a lot larger than the typical evolution time's scale of the process. If the whole trajectory is available, it is better to use this extra information, see for instance Bento et al. (2010) for the Ornstein-Uhlenbeck case and Bento and Ibrahimi (2014) for the non-linear diffusion case.

4. Estimating the Support

4.1 Empirical Contrast: the Commutator

The methodology presented in the paper relies on the fact that the target matrix W commutes with the matrix K, in view of $\mathsf{K} := f(\mathsf{W})$, as defined in Eq. (1). Because W is symmetric, it has real eigenvalues $\lambda_1,...,\lambda_N$ (here listed with repetitions, if any) and is diagonalizable in an orthogonal basis. That is, letting Λ denote the diagonal matrix with diagonal entries λ_k, there exists an orthogonal matrix U such that $\mathsf{W} = \mathsf{U}\Lambda\mathsf{U}^\top$. With this notation, one verifies easily from Eq. (1) that $\mathsf{K} = \mathsf{U}\mathsf{D}\mathsf{U}^\top$, where $\mathsf{D} := f(\Lambda)$ is the diagonal matrix with diagonal entries $f(\lambda_i), i = 1,\dots,N$. Since f is assumed one-to-one on the spectrum of W, the matrices W and K share the same eigenspaces associated to λ_k and $f(\lambda_k)$ respectively :

$$\{v\in\mathbb{R}^N : \mathsf{W}v = \lambda_k v\} = \{v\in\mathbb{R}^N : \mathsf{K}v = f(\lambda_k)v\},$$

for all λ_k. Moreover, the dimension of each eigenspace is equal to the multiplicity of the corresponding eigenvalue λ_k in the spectrum of W. Additionally, when F-identifiability holds, the only solutions A with $\mathrm{Supp}(\mathsf{A}) \subseteq \overline{F}$ to $\mathsf{A}\mathsf{K} = \mathsf{K}\mathsf{A}$ are of the form $\mathsf{A} = t\mathsf{W}$ for some $t\in\mathbb{R}$.

Remark 6 (Matrix perturbation theory) *In practice, we do not observe* K *but an estimation* $\widehat{\mathsf{K}}$ *(which we assume symmetric) with perturbed eigen-decomposition* $\widehat{\mathsf{K}} = \widehat{\mathsf{U}}\widehat{\mathsf{D}}\widehat{\mathsf{U}}^\top$. *Nevertheless, by continuity of the eigen-decomposition, we know that* $\widehat{\mathsf{K}}$ *being close to* K *implies*

simultaneously the proximity of their eigenvalues and eigenspaces (see for instance Mirsky's inequality (Stewart and Sun, 1990, Corollary 4.12) and Wedin's $\sin(\theta)$ theorem (Stewart and Sun, 1990, P. 260) for the details). Thus, if we consider A such that $\mathsf{A}\widehat{\mathsf{K}} = \widehat{\mathsf{K}}\mathsf{A}$, then A has the same eigenspaces as $\widehat{\mathsf{K}}$ which in turns, are expected to be close to the eigenspaces of W.

Given an estimator $\widehat{\mathsf{K}}$ of K, remark that W verifies

$$\frac{\|\mathsf{W}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{W}\|}{\|\mathsf{W}\|} = \frac{\|\mathsf{W}(\widehat{\mathsf{K}} - \mathsf{K}) - (\widehat{\mathsf{K}} - \mathsf{K})\mathsf{W}\|}{\|\mathsf{W}\|} \leq 2\|\widehat{\mathsf{K}} - \mathsf{K}\|\,. \tag{3}$$

Hence, in view of (3) and the discussion above, we aim to estimate W by minimizing the following cost function

$$\mathsf{A} \mapsto \frac{\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|}{\|\mathsf{A}\|}, \quad \mathsf{A} \in \mathcal{E}(\overline{F}) \setminus \{0\}.$$

This empirical criterion was first used in Barsotti et al. (2014), in a Markov Chain context, to reflect that W is expected to nearly commute with $\widehat{\mathsf{K}}$.

4.2 The ℓ_0-approach

Given an estimator $\widehat{\mathsf{K}}$ of K build from a sample of size n and a set of forbidden entries F reflecting ($\mathbf{H}_{\mathrm{F}}$), we construct an estimator $\widehat{S}$ of the target support $S^\star := \mathrm{Supp}(\mathsf{W})$ as a minimizer of the criterion Q given by

$$\forall S \subseteq \overline{F}, \quad Q(S) := \min_{\mathsf{A} \in \mathcal{E}(S)\setminus\{0\}} \frac{\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|}{\|\mathsf{A}\|} + \lambda_n |S|,$$

for some tuning parameter $\lambda_n > 0$ and defining the minimum of an empty set as ∞. Recall that $\mathcal{E}(S)$ is the set of symmetric matrices A such that $\mathrm{Supp}(\mathsf{A}) \subseteq S$. Our estimator of the true support $S^\star$ is defined as

$$\widehat{S} \in \arg\min_{S \subseteq \overline{F}} Q(S)$$

Furthermore, we assume that the estimator $\widehat{\mathsf{K}}$ converges toward K in probability with

$$\forall t > 0\,, \quad \mathbb{P}\big\{\|\widehat{\mathsf{K}} - \mathsf{K}\| \geq t\big\} \leq R_n(t), \tag{$\mathbf{H}_2$}$$

where $R_n, n \in \mathbb{N}$ is a sequence of non-increasing functions that converge pointwise toward 0 as n goes to ∞.

Theorem 7 *Assume that ($\mathbf{H}_2$) and ($\mathbf{H}_{\mathrm{F}}$) hold. If W is F-identifiable, then*

$$\mathbb{P}\big\{\widehat{S} \neq S^\star\big\} \leq R_n\Big(\frac{c_0(S^\star) - \lambda_n |S^\star|}{4}\Big) + R_n\Big(\frac{\lambda_n}{2}\Big)\,,$$

where

$$c_0(S^\star) := \min_{\substack{S \neq S^\star \\ |S| \leq |S^\star|}} \min_{\mathsf{A} \in \mathcal{E}(S)} \frac{\|\mathsf{A}\mathsf{K} - \mathsf{K}\mathsf{A}\|}{\|\mathsf{A}\|} > 0\,. \tag{4}$$

A proof of Theorem 7 is given in Section B.1.

Corollary 8 *Under the assumptions of Theorem 7, if*

$$\lambda_n \to 0 \quad \text{and} \quad \sum_{n \in \mathbb{N}} R_n\Big(\frac{\lambda_n}{2}\Big) < +\infty\,,$$

then $\widehat{S} \to S^\star$ almost surely.

Note that, based on the upper bound in Theorem 7, a good scaling may be $\lambda_n^\star = \frac{c_0(S^\star)}{|S^\star|+4}$ which interestingly does not depend on n. This leads to the upper bound

$$\mathbb{P}\big\{\widehat{S} \neq S^\star\big\} \leq 2R_n\Big(\frac{c_0(S^\star)}{2|S^\star| + 8}\Big) \xrightarrow{n\to\infty} 0$$

which is optimal up to a constant less than 2. This oracle choice $\lambda_n^\star$ is of course irrelevant in practice since both $c_0(S^\star)$ and $|S^\star|$ are unknown. Alternatively, we may choose a sequence λ_n decreasing slowly to 0 to ensure both conditions of Corollary 8.

4.3 Edge significance based on the commutator criterion

The exponential complexity of the ℓ_0-approach making it generally infeasible in practice, a backward methodology provides a computationally feasible alternative to the support reconstruction problem. Starting from the maximal acceptable support $\overline{F}$, the idea of the backward procedure is to remove the least significant entries one at a time and stop when every entry is significant. Using the corresponding small case letter to denote the vectorization of a matrix, *e.g.*, $a = \mathrm{vec}(\mathsf{A}) = (\mathsf{A}_{11}, ..., \mathsf{A}_{N1}, ..., \mathsf{A}_{1N}, ..., \mathsf{A}_{NN})^\top$, significancy can be leveraged using the Frobenius norm of the commutator operator $a \mapsto \Delta(\mathsf{K})a = \mathrm{vec}(\mathsf{K}\mathsf{A} - \mathsf{A}\mathsf{K})$, where

$$\Delta(\mathsf{K}) = \mathrm{I} \otimes \mathsf{K} - \mathsf{K} \otimes \mathrm{I} \quad \in \mathbb{R}^{N^2 \times N^2}$$

and $\otimes$ denotes the Kronecker product. Indeed, searching for the target W in the commutant of K reduces to searching for $w = \mathrm{vec}(\mathsf{W})$ in $\ker(\Delta(\mathsf{K}))$, the kernel of $\Delta(\mathsf{K})$. Because the Frobenius norm coincides with the Euclidean norm of the vectorization, the functions $\mathsf{A} \mapsto \|\widehat{\mathsf{K}}\mathsf{A} - \mathsf{A}\widehat{\mathsf{K}}\|^2$ and $a \mapsto \|\Delta(\widehat{\mathsf{K}})a\|^2$ can be used indistinctly as cost functions.

Assumptions

Assume the three following hypotheses ($\mathbf{H}_\Sigma$), ($\mathbf{H}_1$) and ($\mathbf{H}_{\mathrm{Id}}$).

∘ Deriving the asymptotic law of least-squares estimators, we may assume that the estimate $\widehat{\mathsf{K}}$ is such that

$$\sqrt{n}(\widehat{k} - k) \xrightarrow[n\to\infty]{d} \mathcal{N}(0, \Sigma), \tag{$\mathbf{H}_\Sigma$}$$

where Σ is a $N^2 \times N^2$ covariance matrix (either known or that can be estimated). For instance, one can think of $\widehat{\mathsf{K}}$ as the empirical covariance when observing a sample of vectors of covariance K. This condition is verified for instance in the framework considered in Barsotti et al. (2014, 2016). Note that asymptotic normality is a standard ground base investigating any least-squares procedure.

∘ In order to exclude the trivial solution $a = 0$, the target W is assumed normalized

$$\mathbf{1}^\top w = 1, \tag{$\mathbf{H}_1$}$$

where $\mathbf{1}$ has all its entries equal to one. Because the available information on W is of spectral nature and as such, is scale-invariant, a normalization of some kind is crucial for the reconstruction. Here, the condition $\mathbf{1}^\top w = 1$ achieves two goals: preventing the null matrix form being a solution and making the problem identifiable.

Remark 9 *The main drawback of this normalization concerns the situation where the entries of W sum up to zero, in which case the normalization is impossible. If the context suggests that the solution may be such that $\mathbf{1}^\top w = 0$, a different affine normalization $\mathbf{v}^\top w = 1$ (with any fixed vector $\mathbf{v}$) must be used, without major changes in the methodology. In practice, one may consider the vector $\mathbf{v}$ at random (for instance with isotropic law), so that ($\mathbf{H}_1$) is almost surely fulfilled for any fixed target w. Finally, observe that if W has non-negative entries, then the normalization ($\mathbf{H}_1$) is always feasible.*

◦ For S a support included in $\overline{F}$, we aim at a solution in the affine space

$$\mathcal{A}_S := \{a = \mathrm{vec}(\mathsf{A}) : \mathrm{Supp}(\mathsf{A}) \subseteq S,\ \mathsf{A} = \mathsf{A}^\top\ ,\ \mathbf{1}^\top a = 1\}.$$

with linear difference space given by

$$\mathcal{L}_S := \{a = \mathrm{vec}(\mathsf{A}) : \mathrm{Supp}(\mathsf{A}) \subseteq S,\ \mathsf{A} = \mathsf{A}^\top\ ,\ \mathbf{1}^\top a = 0\}\,.$$

By abuse of notation, $\mathcal{A}_S$ may refer both to the space of matrices or their vectorizations. To find the target support $S^\star$, one must exploit the fact that the vector w lies in the intersection of $\ker(\Delta(\mathsf{K}))$ and $\mathcal{A}_{\overline{F}}$. Actually, w can be recovered if the intersection is reduced to the singleton $\{w\}$. In this case, the matrix W and its support $S^\star$ are F-identifiable. Hence, we assume that

$$\ker(\Delta(\mathsf{K})) \cap \mathcal{L}_{\overline{F}} = \{0\}, \tag{$\mathbf{H}_{\mathrm{Id}}$}$$

which is implied by F-identifiability, see Definition 1.

Asymptotic normality and significance test

The framework under consideration can be viewed as a heteroscedastic linear regression model with noisy design for which $w = \mathrm{vec}(\mathsf{W})$ is the parameter of interest. Indeed, consider for each support $S \subseteq \overline{F}$ a full-ranked matrix $\Phi_S \in \mathbb{R}^{N^2 \times \dim(\mathcal{A}_S)}$ whose column vectors form a basis of $\mathcal{L}_S$. Assuming that W is F-identifiable and taking $S \subseteq \overline{F}$, the operator $\Delta(\mathsf{K})\Phi_S$ is one-to-one. In this case, evaluating the commutator $a \mapsto \Delta(\mathsf{K})a$ over $\mathcal{A}_S$ reduces to considering the map

$$b \mapsto \Delta(\mathsf{K})(a_0 - \Phi_S b)\,, \quad b \in \mathbb{R}^{\dim(\mathcal{A}_S)},$$

with a_0 chosen arbitrarily in $\mathcal{A}_S$. When replacing the unknown $\Delta(\mathsf{K})$ with its estimate $\Delta(\widehat{\mathsf{K}})$, the minimization of the criterion $a \mapsto \|\Delta(\widehat{\mathsf{K}})a\|^2$ over $\mathcal{A}_S$ can be written similarly as a linear regression framework where the parameter of interest is estimated by

$$\widehat{\beta}_S \in \arg\min_{b \in \mathbb{R}^{\dim(\mathcal{A}_S)}} \|\Delta(\widehat{\mathsf{K}})(a_0 - \Phi_S b)\|^2. \tag{5}$$

We recognize a linear model with response $y = \Delta(\widehat{\mathsf{K}})a_0$ and noisy design matrix $X = \Delta(\widehat{\mathsf{K}})\Phi_S$. In this setting, remark that $w = a_0 - \Phi_S\beta$ with β the unique solution to $\Delta(\mathsf{K})(a_0 - \Phi_S\beta) = 0$. Denoting by $\mathsf{M}^\dagger$ the pseudo-inverse of a matrix M, we deduce the following result.

Theorem 10 *If $S^\star \subseteq S$, the estimator $\widehat{\beta}_S$ is asymptotically Gaussian with*

$$\sqrt{n}(\widehat{\beta}_S - \beta) \xrightarrow[n\to\infty]{d} \mathcal{N}(0, \Omega_S),$$

where $\Omega_S := \big(\Phi_S^\top \Delta(\mathsf{K})\big)^\dagger \Delta(\mathsf{W})\Sigma\Delta(\mathsf{W})\big(\Delta(\mathsf{K})\Phi_S\big)^\dagger$.

We then have

$$\widehat{w}_S = \mathrm{vec}(\widehat{\mathsf{W}}_S) = \arg\min_{a \in \mathcal{A}_S} \|\Delta(\widehat{\mathsf{K}})a\|^2 = a_0 - \Phi_S\widehat{\beta}_S\,. \tag{6}$$

The asymptotic distribution of $\widehat{w}_S$ follows directly from Theorem 10,

$$\sqrt{n}(\widehat{w}_s - w) \xrightarrow[n\to\infty]{d} \mathcal{N}\big(0, \Phi_S\Omega_S\Phi_S^\top\big). \tag{7}$$

The limit covariance matrix is unknown, but plugging the estimates $\widehat{\mathsf{W}}_S$, $\widehat{\mathsf{K}}$ and $\widehat{\Sigma}$ yields an estimator $\Phi_S\widehat{\Omega}_S\Phi_S^\top$, which is consistent under the F-identifiability assumption. In particular,

the diagonal entry of $\Phi_S\widehat{\Omega}_S\Phi_S^\top$ associated to the (i,j)-entry of W, which we denote $\widehat{\sigma}^2_{S,ij}$, provides a consistent estimator for the asymptotic variance of $\widehat{\mathsf{W}}_{S,ij}$. As a result, the statistic

$$\tau_{ij}(S) := \sqrt{n}\frac{\widehat{\mathsf{W}}_{S,ij}}{\widehat{\sigma}_{S,ij}} \tag{8}$$

can be used to measure the relative significance of the estimated entry $\widehat{\mathsf{W}}_{S,ij}$. The backward support selection procedure is then implemented by the recursive algorithm as follows.

Algorithm 1: Backward algorithm for support selection

Data: A set of forbidden entries F, a matrix $\widehat{\mathsf{K}}$.
Result: A sequence of estimators $\widehat{\mathsf{W}}_{S_1}, \widehat{\mathsf{W}}_{S_2}, \ldots$ with nested supports $S_1 \supset S_2 \supset \ldots$.

1: Start with the maximal acceptable support $S_1 = \overline{F}$,
2: At each step k, compute the statistics $\tau_{ij}(S_k)$ for all $(i,j) \in S_k$,
3: Remove the least significant edge (i,j) which minimizes $|\tau_{ij}(S_k)|$ for $(i,j) \in S_k$, and set $S_{k+1} = S_k \setminus \{(i,j),(j,i)\}$,
4: Stop when all edges have been removed.

The backward algorithm produces a sequence of nested supports that one can choose to stop once all the edges are judged significant, that is, when all the statistics $\tau_{ij}(S_k)$, $(i,j) \in S_k$ exceed in absolute value some fixed threshold τ_0. Owing to the asymptotic normality of $\widehat{\mathsf{W}}_{S,ij}$ shown in Eq. (7), the $(1 - \frac{\alpha}{2})$-quantile of the standard Gaussian distribution would appear as a reasonable choice for the threshold τ_0, as it boils down to performing an asymptotic significance test of level α. However, due to the slow convergence to the limit distribution and the tendency to overestimate the variance for small sample sizes (see Figure 2), a threshold based on the Gaussian quantile inevitably leads to an overly large estimated support. Nevertheless, we show that an adaptive calibration of the threshold can be achieved by considering the overall behavior of the commutator $\Delta(\widehat{\mathsf{K}})\widehat{w}_{S_m}$ computed over the nested sequence of active supports.

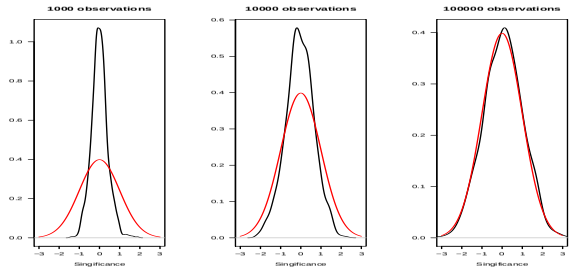

Figure 2: Estimated density of the statistic $\tau_{ij}(S)$ for an edge $(i,j) \in S \setminus S^\star$ compared to its theoretical Gaussian limit distribution, for samples of size $n = 1000$ (left), $n = 10000$ (center) and $n = 100000$ (right).

Calibration of the threshold by cross-validation

By removing the least significant edge at each step, the backward algorithm generates a sequence of nested active supports $S_1 \supset \cdots \supset S_\ell$, that we refer to as a "trajectory". Along this trajectory, we compute the empirical contrast defined by

$$\forall S \subseteq \overline{F}, \quad S \mapsto \mathrm{Crit}(\widehat{\mathsf{W}}_S, \widehat{\mathsf{K}}) := \frac{\|\widehat{\mathsf{W}}_S\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\widehat{\mathsf{W}}_S\|}{\|\widehat{\mathsf{W}}_S\|}\,. \tag{9}$$

Note that computing this criterion boils down to compute $\widehat{\mathsf{W}}_S$ which is a simple projection onto $\mathcal{A}_S$ as shown in (6).

When the true support $S^\star$ lies in the trajectory, one expects to observe a "gap" in the sequence $j \mapsto \mathrm{Crit}(\widehat{\mathsf{W}}_{S_j}, \widehat{\mathsf{K}})$ when S_j goes from $S^\star$ to a smaller support. Indeed:

- For $S^\star \subseteq S$, the target W is consistently estimated by $\widehat{\mathsf{W}}_S$ so that $\mathrm{Crit}(\widehat{\mathsf{W}}_S, \widehat{\mathsf{K}})$ tends to zero at rate $\sqrt{n}$,
- For $S \subsetneq S^\star$, the lower bound $\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\| \geq \|\mathsf{A}\mathsf{K} - \mathsf{K}\mathsf{A}\| - 2\|\widehat{\mathsf{K}} - \mathsf{K}\|\|\mathsf{A}\|$ yields

$$\mathrm{Crit}(\widehat{\mathsf{W}}_S, \widehat{\mathsf{K}}) = \frac{\|\widehat{\mathsf{W}}_S\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\widehat{\mathsf{W}}_S\|}{\|\widehat{\mathsf{W}}_S\|} \geq c(S) - 2\|\widehat{\mathsf{K}} - \mathsf{K}\| \tag{10}$$

  with $c(S) := \min_{A \in \mathcal{A}_S} \|\mathsf{A}\mathsf{K} - \mathsf{K}\mathsf{A}\|/\|\mathsf{A}\|$ a positive constant. In particular, one has

$$\min_{S \subsetneq S^\star} c(S) \geq \min_{\substack{S \neq S^\star \\ |S| \leq |S^\star|}} c(S) = c_0(S^\star) > 0$$

  where $c_0(S^\star)$ is defined in (4).

In some way, $c_0(S^\star)$ measures the amplitude of the signal: one expects to be able to recover the target W when the estimation error $\|\widehat{\mathsf{K}} - \mathsf{K}\|$ reaches at least the same order as $c_0(S^\star)$. The true support $S^\star$ then corresponds to a transitional gap in the contrast curve that can be captured by a suitably chosen threshold $t > 0$. Since $\widehat{\mathsf{K}}$ converges toward K in probability, any threshold $0 < t < c_0(S^\star)$ will work with probability one asymptotically.

Remark 11 *The condition that $S^\star$ lies in the trajectory of nested supports is crucial to detect the commutation gap, although seldom verified in practice due to the tremendous amount of testable supports. This issue is specifically targeted by the bagging version of the backward algorithm discussed in Section 4.4.*

An obstacle to the detection of the commutation gap is the increasing behavior of the commutator over the nested trajectory $S_1 \supset \cdots \supset S_\ell$. This phenomenon, indirectly caused by the dependence between the trajectory and $\widehat{\mathsf{K}}$, can be annihilated when considering the empirical contrast over a trajectory built from a training sample. In fact, the monotonicity can even be "reversed" before reaching the true support if the $\widehat{\mathsf{W}}_{S_j}$ are estimated independently from $\widehat{\mathsf{K}}$. This can be explained as follows. Consider the ideal scenario where estimators $\widetilde{\mathsf{W}}_{S_1}, ..., \widetilde{\mathsf{W}}_{S_\ell}$ are built from the backward algorithm using an estimator $\widetilde{\mathsf{K}}$ independent from $\widehat{\mathsf{K}}$. We assume moreover that the true support $S^\star$ lies in the trajectory $S_1 \supset ... \supset S_\ell$. The trick is to write

$$\Delta(\widehat{\mathsf{K}})\widetilde{w}_{s_j} = \Delta(\widetilde{\mathsf{K}})w + \Delta(\mathsf{K})\widetilde{w}_{S_j} + \Delta(\widehat{\mathsf{K}} - \mathsf{K})(\widetilde{w}_{S_j} - w),$$

and to analyze the three terms separately:

- The term $\Delta(\widehat{\mathsf{K}})w$ has no influence as it is common to all supports in the trajectory.

- The term $\Delta(\mathsf{K})\widetilde{w}_{S_j}$ approaches zero as $\widetilde{w}_{S_j}$ gets closer to w. Heuristically, the variance of $\widetilde{w}_{S_j}$, and incidentally that of $\Delta(\mathsf{K})\widetilde{w}_{S_j}$, is larger for over-fitting supports $S \supseteq S^\star$. This results in the sequence $j \mapsto \Delta(\mathsf{K})\widetilde{w}_{S_j}$ being stochastically decreasing as S_j approaches $S^\star$ from above. On the other hand, the bias of order $O(1)$ is expected to dominate once the trajectory passes through the true value $S^\star$, making the remaining of the sequence $\Delta(\mathsf{K})\widetilde{w}_{S_j}$increase stochastically.
- The term $\Delta(\widehat{\mathsf{K}} - \mathsf{K})(\widetilde{w}_{S_j} - w)$ is negligible for $S \supseteq S^\star$, as both $\widehat{\mathsf{K}} - \mathsf{K}$ and $\widetilde{w}_{S_j} - w$ tend to zero independently. We emphasize that this argument no longer holds without the independence of $\widetilde{w}_{S_j}$ and $\widehat{\mathsf{K}}$. This is precisely why we use a training sample.

Thus, the sequence $j \mapsto \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_j}, \widehat{\mathsf{K}}) = \|\Delta(\widehat{\mathsf{K}})\widetilde{w}_{S_j}\|/\|\widetilde{w}_{S_j}\|$ is expected to achieve its minimum for the best estimator $\widetilde{w}_{S_j}$ in the trajectory, that is for $S_j = S^\star$. Furthermore, beyond the true support (for small active supports), $\widetilde{w}_{S_j}$ is not a consistent estimator of w so that the criterion no longer approaches zero, resulting in the so-called commutation gap.

The "reversed" monotonicity provides an easy way to calibrate the threshold in the backward algorithm. Indeed, since $S_j \mapsto \Delta(\widehat{\mathsf{K}})\widetilde{w}_{S_j}$ is expected to decrease when approaching the true support (coming from larger active supports along a trajectory), the estimated support can be heuristically chosen as the last time the criterion is below an adaptive threshold, see Figure 3. In particular, $\mathrm{Crit}(\widetilde{\mathsf{W}}_{S_1}, \widehat{\mathsf{K}})$ can be used as an adaptive threshold for the backward algorithm when the estimator $\widehat{\mathsf{K}}$ and the trajectory $S_1 \supset \cdots \supset S_\ell$ are obtained from independent samples.

Of course, to afford splitting the sample to build the $\widetilde{\mathsf{W}}_{S_j}$ independent from $\widehat{\mathsf{K}}$ may be unrealistic. Nevertheless, the numerical study suggests that the independence is well mimicked when $\widehat{\mathsf{K}}$ is built from the whole dataset but the backward algorithm sequence $\widetilde{\mathsf{W}}_{S_1}, ..., \widetilde{\mathsf{W}}_{S_\ell}$ is obtained from a learning sub-sample, as illustrated in Figure 3. Empirically, the optimal size of training samples could be calibrated in function of the number of observations using the robustness of the outputs of the algorithm. In this paper, we always draw training samples by taking each observation with probability 1/2, with no consideration regarding the size of the whole sample.

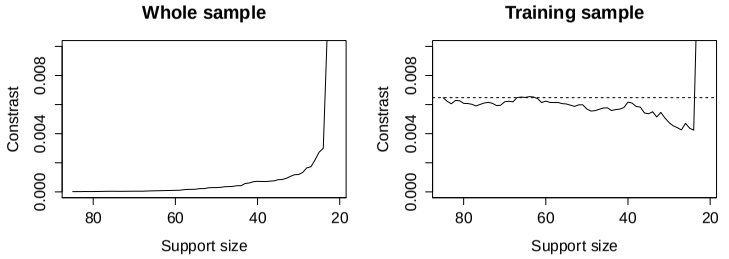

Figure 3: The contrast sequence $j \mapsto \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_j}, \widehat{\mathsf{K}})$ computed in the example of Section 5.2. The nested support sequence and estimators $\widetilde{\mathsf{W}}_{S_j}$ are obtained from the backward algorithm implemented on the whole sample (left) and on a training sample of half size (right). In both cases, $\widehat{\mathsf{K}}$ is constructed from the whole sample. Using a training sample manages to reverse the monotonicity in the first part of the sequence, thus making the commutation gap easier to locate. The initial value of the sequence $t = \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_1}, \widehat{\mathsf{K}})$ then provides a tractable adaptive choice for the threshold.

4.4 Improving the backward algorithm by bagging

The main weakness of the backward procedure remains that it requires the true support $S^\star$ to lie in the trajectory $S_1 \supset \cdots \supset S_\ell$ obtained from removing the least significant edge one at a time. In practice, this condition is rarely verified, especially with small datasets. A way to solve this issue is to replicate the backward algorithm over a collection of random sub-samples, a process commonly known to as Bootstrap Aggregating, or bagging. The description of this algorithm is given in Algorithm 2.

Algorithm 2: Bagging backward algorithm

Data: A set of forbidden entries F, a sample X.
Result: A collection of estimated supports $\widehat{S}_m, m = 1, ..., M$.

1: Build M bootstrapped samples without replacement.
2: For each sub-sample $m = 1, ..., M$, build an estimator $\widetilde{\mathsf{K}}_m$ of K.
3: For all m, run Algorithm 1 without stopping condition and return M trajectories $S_{1m} \supset \cdots \supset S_{\ell m}$ and the corresponding estimators $\widetilde{\mathsf{W}}_{S_{km}}$.
4: Evaluate the empirical contrast $\mathrm{Crit}(\widetilde{\mathsf{W}}_{S_{km}}, \widehat{\mathsf{K}})$ over each trajectory with the estimator $\widehat{\mathsf{K}}$ calculated from the whole sample.
5: For each trajectory, return the estimated support $\widehat{S}_m := S_{\hat{k}_m m}$ as the last support whose contrast lies below the initial value:

$$\hat{k}_m := \max\big\{k = 1, ..., \ell : \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_{km}}, \widehat{\mathsf{K}}) \leq \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_{1m}}, \widehat{\mathsf{K}})\big\}.$$

The bagging algorithm produces a collection of estimated supports in a way to make the final decision more robust. At this point, several solutions are possible: select the most represented support among the $\widehat{S}_m$'s, keep the edges present in the most supports etc... A preliminary detection of the outliers among the $\widehat{S}_m$'s, e.g. by removing beforehand the supports $\widehat{S}_m$'s that are either too big or too small, might also considerably improve the method, as we illustrate on actual examples in Section 5.

5. Numerical study

5.1 Toy example

In the previous section, we have introduced different algorithms. To emphasize the motivation of the bagging algorithm, we consider a simple example, and implement the different algorithms for support recovery. To check the performances of the ℓ_0 procedure, we need to consider a graph with a small number of vertices (since the ℓ_0 complexity grows with $2^{N(N-1)/2}$ where N denotes the number of vertices). Here, we consider the graph G_1 represented in Figure 4, the kite graph on 5 vertices.

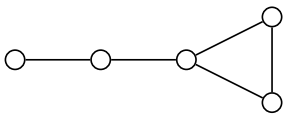

Figure 4: The kite graph $G_1 = \nabla_5$.

We choose W as the (normalized) adjacency matrix of G_1 then draw a sample of size $n = 500$ of centered Gaussian vectors $X_1, \cdots X_n$ of $\mathbb{R}^5$ with covariance matrix $\mathsf{K} = \exp(\mathsf{W})$. We assume

known that G_1 contains no self-loop so that we take $F = F_{diag}$ as the set of forbidden values. In this simple example, the constant $c_0(S^\star)$ (see Eq. (4)) can be calculated explicitly, yielding $c_0(S^\star) \approx 0.12$. In comparison, for $n = 500$, $\mathbb{E}\|\widehat{\mathsf{K}} - \mathsf{K}\|$ is evaluated to approximately 0.27 by Monte-Carlo. We expect to be able to recover the true support when the noise level drops below the signal amplitude. Based on the bound of Eq. (10), this occurs as soon as $\|\widehat{\mathsf{K}} - \mathsf{K}\| \leq c_0(S^\star)/2$. However, because this bound is not sharp, a lesser level of precision is required in practice.

We compare the following algorithms:

1. *Contrast penalized ℓ_0 minimization with optimal penalization constant.* We compute

$$\widehat{S} = \arg\min_{S \subseteq \overline{F}_{diag}} \left\{ \min_{\mathsf{A} \in \mathcal{E}(S)\setminus\{0\}} \frac{\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|}{\|\mathsf{A}\|} + \lambda|S| \right\}.$$

   The constant λ is chosen as the best possible value, minimizing the oracle error $\delta(\widehat{S})$ measured by the symmetric difference between $\widehat{S}$ and $S^\star$, namely

$$\delta(\widehat{S}) := |\widehat{S} \cup S^\star \setminus \widehat{S} \cap S^\star|.$$

   Note that the calibration parameter λ is chosen optimally. Hence, the numerical performances of the method can be expected to be overestimated compared to a fully data-driven procedure.

2. *Thresholding contrast minimization with optimal threshold.* The target matrix W is estimated over the maximal acceptable support $\overline{F}_{diag}$. We then compute

$$\widehat{S} = \{(i, j) : |\widehat{\mathsf{W}}_{ij}| > t\},$$

   where the threshold t is chosen so as to minimize the oracle error $\delta(\widehat{S})$. Here again, the performances are expected to be overestimated compared to a data-driven threshold.

3. *Backward algorithm.* We generate a training sample by taking each observation with probability 1/2 independently, from the whole sample. The estimator of K in this sub-sample is denoted $\widetilde{\mathsf{K}}$. We implement Algorithm 1 on $\widetilde{\mathsf{K}}$, yielding a trajectory $S_1 \supset ... \supset S_\ell$ of nested supports whose sizes vary from $|S_1| = 20$ (the full off-diagonal support) to $|S_\ell| = 12$ (the minimal size required for diagonal identifiability), along with the associated estimators $\widetilde{\mathsf{W}}_{S_k}, k = 1, ..., \ell$. Remark that the supports are symmetric, hence two entries are removed at each step so that $\ell = 5$ in this case. We then compute the threshold $t = \mathrm{Crit}(\widetilde{\mathsf{W}}_{S_1}, \widehat{\mathsf{K}})$ corresponding to the initial value of the contrast. The estimated support $\widehat{S}$ is defined as the smallest support S in the trajectory such that $\mathrm{Crit}(\widehat{\mathsf{W}}_S, \widehat{\mathsf{K}}) \leq t$. Here, the choice of t is adaptive in a fully data driven manner.

4. *Bagging backward algorithm.* The previous algorithm is implemented over $M = 100$ training samples drawn keeping observations with probability 1/2. For each $m = 1, ..., M$, we retain

   - the threshold $t_m = \mathrm{Crit}(\widehat{\mathsf{W}}_{S_{1m}}, \widehat{\mathsf{K}})$ corresponding to the initial value of the contrast,
   - the estimated support, that is, the smallest support $\widehat{S}_m$ in the trajectory such that $\mathrm{Crit}(\widehat{\mathsf{W}}_{\widehat{S}_m}, \widehat{\mathsf{K}}) \leq t_m$.

   The estimated support $\widehat{S}$ is obtained as follows. Only a proportion q of the training samples m with a small initial contrast t_m are kept, they are expected to provide better results—in the whole paper, we chose $q = 2/\sqrt{M}$ empirically. Then, the smallest support among the remaining candidates is retained, breaking ties arbitrarily.

Remark 12 *Using a ℓ_1-penalized contrast*

$$\mathsf{A} \mapsto \|\widehat{\mathsf{K}}\mathsf{A} - \mathsf{A}\widehat{\mathsf{K}}\|^2 + \lambda\|\mathsf{A}\|_1$$

(subject to a normalizing condition so as to rule out the trivial solution $\mathsf{A} = 0$) tends to overestimate the support. In fact, any conservative choice of λ will lead to false positives in the estimated support (typically, a full support matrix may commute with $\widehat{\mathsf{K}}$ while still having a small ℓ_1 norm). Hence, when aiming for support recovery, the typical solution is to vanish the small entries of the minimizer, making it no more efficient than the thresholded ℓ_2 procedure considered in Algorithm 2. For this reason, the numerical performances of the Lasso procedure are not included in the study.

The next table compares the performances of the four algorithms. We calculated the Monte-Carlo estimated mean error $\mathbb{E}(\delta(\widehat{S}))$ and probability of exact recovery $\mathbb{P}\{\widehat{S} = S^\star\}$ for 1000 repetitions of the experiment. The average computational time (obtained with the function `timer` of Scilab) on a processor Intel Xeon @2.6 GHz are shown, using the oracle values of λ and t for the first two algorithms (the calibration of these parameters is thus not accounted for in the computation time).

Algorithm	ℓ_0	ℓ_2-thresholding	Backward	Bagging Backward
Mean Error	0.45	0.37	1.95	0.68
Exact recoverery	68%	75%	23%	61%
CPU time (s)	0.32	0.002	0.009	0.59

In this example, the first two algorithms are the more accurate. The percentage of successful recoveries for the bagging backward algorithm is nonetheless competitive given that the first two procedures have been calibrated optimally for each experiment, which would be highly infeasible in practice. Finally, we observe that although it is much more expensive computationally, the bagging version of the backward algorithm yields an undeniable improvement.

Upper bounds for the time and space complexity of the algorithms are given in the next table. The time complexity is calculated as the number of different supports S considered to lead to the solution in function of the size N of the graph and the number M of training samples. The spatial complexity measures the memory size needed to compute the solution. In this setting, it is the main limitation for applying the procedures to large graphs. The N^4 comes from the computation of $\Delta(\mathsf{K}) = \mathsf{K} \otimes \mathrm{I} - \mathrm{I} \otimes \mathsf{K}$ in the solver. Admittedly, the complexity could be improved by using sparse matrix encoding although this was not implemented.

Algorithm	ℓ_0	ℓ_2-thresholding	Backward	Bagging Backward
Space Complexity	$O(N^4)$	$O(N^4)$	$O(N^4)$	$O(N^4)$
Time Complexity	$O(2^{N(N-1)/2})$	$O(1)$	$O(N^2)$	$O(N^2.M)$

On the current version, the bagging backward algorithm contains scalability issues for big graphs due to its space complexity. Leads to reduce the spatial complexity include using sparse matrix encoding or the use of cheap approximations of the criterion. These shall be investigated in future works.

5.2 A diagonally identifiable matrix

The advantages of the bagging backward algorithm are highlighted for larger graphs. In the next example, we consider the graph G_2 on $N = 15$ vertices represented in Figure 5. The experimental conditions are similar to that of the previous example, a sample of size $n = 10000$ is drawn from

a centered Gaussian vector of variance $\mathsf{K} = \exp(\mathsf{W})$ where W is the normalized adjacency matrix of G_2, with normalizing constant chosen such that $\mathbf{1}^\top w = 1$. The implementation of the different algorithms follow the description of the previous example.

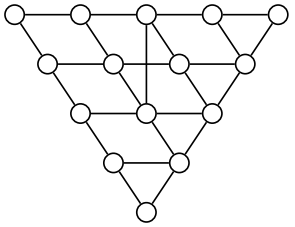

Figure 5: The graph G_2 is diagonally identifiable.

In this case, the number of possible supports is too large for the ℓ_0 method to be implementable while the accuracy of the thresholded ℓ_2 drops considerably compared to smaller cases. We summarize the results in the following table.

Algorithm	ℓ_2-thresholding	Backward	Bagging Backward
Mean Error	10	25	1
Exact recoverery	22%	26%	69%
CPU time (s)	0.04	2.5	256

A drawback of the bagging backward algorithm is the larger computational time: it takes around 4 minutes in average to estimate the support. Being essentially $M = 100$ repetitions of the backward algorithm, the numerical complexity of the bagging version is roughly M times that of the simple backward algorithm, although the improvement is, here again, clear.

To illustrate the influence of the unknown function f, we consider $f : t \mapsto (1-t)^{-2}$ and reproduce the numerical study for $\mathsf{K} = f(\mathsf{W})$. The results for various sample sizes are gathered in the next table, for $M = 100$ bagging runs.

n	10000	5000	2000	1000
Exact recovery	97%	87%	83%	13%
Mean error	0.05	0.33	0.9	8.5

The probability of recovering the true support appears to be greater than in the previous example (97% against 69% previously for $n = 10000$). This sheds lights on another important factor in the efficiency of the methods which is the separability of the spectrum of K. Indeed, in this framework, the information needed to recover W lies in its eigenspaces, which are estimated via $\widehat{\mathsf{K}}$. The accuracy of these estimates depends on the distance between the different eigenvalues (see e.g. Corollary 4.12 in Stewart and Sun (1990) and Wedin's $\sin(\theta)$ theorem in Stewart and Sun (1990)). Thus, for the spectrum $\lambda_1, ..., \lambda_N$ of W, the ability to recover W from $\mathsf{K} = f(\mathsf{W})$ essentially relies on how far the $f(\lambda_i)$'s are from each other. For the sake of comparison, the spectrum of W which lies in the interval $[-0.5, 0.5]$ is more "spread" by the function $t \mapsto (1-t)^{-2}$ than by the exponential, as we can see in Figure 6.

Remark 13 *We also implemented the procedure in a random setting where W is drawn from an Erdös-Rényi graph with binomial entries. The conclusions obtained in this case are similar to those already discussed and shall not be presented to avoid redundancy.*

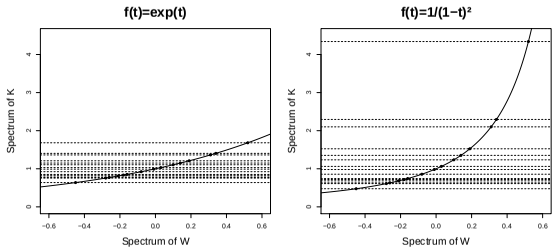

Figure 6: Separability of the spectrum of $\mathsf{K} = f(\mathsf{W})$ for $f : t \mapsto \exp(t)$ (left) and $f : t \mapsto (1-t)^{-2}$ (right). The eigenvalues of K are more separated in the second case, making it easier to approximate its eigenspaces from the estimator $\widehat{\mathsf{K}}$.

6. Real life application

We now implement the bagging backward algorithm on real life data provided by Météorage and Météo France. The data contain the daily number of lightnings during a 3 year period in 16 regions of France localized on a 4×4 grid. We expect to recover the spatial structure of the graph from the dependence of the lightning occurrences between the regions.

The data are refined as follows. We first eliminate the days without any lighting, leaving 950 vectors X_i of length 16 that contain the number of impacts at day i in each of the 16 regions. This numbers are highly non Gaussian, contain many zeros, and show a clear south-east/north-west tendency, with much more lightning in the south east. As a pre-processing, we apply the transformation $x \mapsto \log(1+x)$ to the data and subtract the spatial tendency estimated by linear regression. The process is then normalized in such manner that the conditional variance at each vertex conditionally to all the others is 1. This way, the precision matrix K^{-1}, with K the covariance matrix, has diagonal 1.

We model the resulting process as a spatial AutoRegressive process of order $p > 1$ on a 4×4 grid, as described in Section 3.6. In this setting, K^{-1} writes as a degree p polynomial of a matrix W supported on the 4×4 grid. Using only the information that W has zero diagonal, we aim to recover this dependency from the empirical estimator $\widehat{\mathsf{K}}$ of the covariance, using that K and W commute. Remark that, because the target graph is bipartite, the model is not diagonally identifiable—for instance W^3 also has zero diagonal. However, we still manage to recover the support from the fact that W is the *sparsest* matrix that commute with K. We run our algorithm 100 times and we show in Figure 7 the most frequent edges appearing in the output graph.

To the best of our knowledge, this exact framework has not been tackled in the literature. For this reason, it is difficult to compare the performances of our algorithm to other existing methods. For instance, while being a reference in Graphical Models, the package `GGMselect` (see Giraud et al. (2012)) fails to uncover the dependence structure in this case, as we see in Figure 8. The reason is simple: the package `GGMselect` aims to estimate the precision matrix, which is a polynomial of W. Thus, while GGM inference may be more stable, faster ($0.3s$ for `GGMselect` and $400s$ for our algorithm) and easily interpretable, it is only adapted to recover the dependence structure if $p = 1$, in which case K^{-1} is an affine function of W.

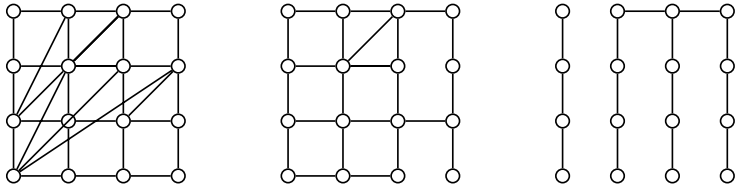

Figure 7: Edges that appear 30%, 50%, and 70% of the time when running the bagging backward algorithm 100 times. The spatial dependency becomes apparent around the 50% mark.

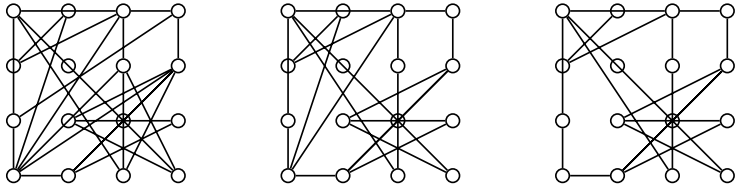

Figure 8: Edges that appear 30%, 50%, and 70% of the time using the `GGMselect` package with family `CO1` and maximal degree `dmax` $= 5$.

7. Discussion

In this paper, we develop a new method to recover hidden graphical structures in different models. We consider a general framework in which we have access to an approximation of the eigen-structure of an unknown graph, via an operator that commutes with its weighted adjacency matrix W. We are able to recover the support of W from an estimate of $\mathsf{K} = f(\mathsf{W})$ with f an unknown function, under the sole assumption that the location of some zeros of W are known. We tackle two situations where this condition may arise: Markov processes observed at random times and stationary signals on graphs. We focus on the particular case of a weighted adjacency matrix W with zero diagonal, indicating that the underlying graph has no self-loop.

A main limitation of our method lies in the large amount of data necessary to recover the true support with high probability. Arguably, this limitation is intrinsic to our model and is a matter of comparison between the estimation error $\|\widehat{\mathsf{K}} - \mathsf{K}\|$ and the signal strength, measured by the constant $c_0(S^\star)$ in (4) and (10). Even under the assumption that the estimation error has order $1/\sqrt{n}$, the difficulties stem from the constant $c_0(S^\star)$ being extremely small in some cases.

For practical issues, there remain three main challenges to be addressed. The first one concerns the symmetry of W, that once relaxed, would offer a wider range of applications. The second concerns the generalization and applications to identifiability conditions other than W having zero diagonal. Finally, our algorithm is greedy when the size of the graph increases. For large graphs, it remains to find a way to compute more efficiently the criterion and significance of the variables.

Acknowledgement

We would like to warmly thank Météo France and Météorage for providing us the data used in Section 6. We also thank Dieter Mitsche for fruitful discussions, as well as the Universidad de la Habana (Cuba) and the Centro de Modelamiento Matematico (Chile) for their hospitality.

Appendix A. Asserting the Diagonal Identifiability

A.1 Necessary and sufficient conditions

In this section, we focus on the F-identifiability in the special case where the set of forbidden entries is the diagonal $F_{\rm diag} := \{(i,i) : i \in [1,N]\}$. Recall that a support S is $F_{\rm diag}$-identifiable, or simply diagonally identifiable (DI), if for almost every matrix $\mathsf{A} \in \mathcal{E}(S)$,

$$\mathsf{BA} = \mathsf{AB}\ ,\ \mathrm{diag}(\mathsf{B}) = 0\ ,\ \mathsf{B} = \mathsf{B}^\top \implies \mathsf{B} = \lambda \mathsf{A}$$

for some $\lambda \in \mathbb{R}$. In other words, a support S is diagonally identifiable if almost every symmetric matrix A with support in S is uniquely determined, up to scaling, by its eigenspaces among symmetric matrices with zero diagonal. In this section, we provide both sufficient and necessary conditions on a support S to ensure the $F_{\rm diag}$-identifiability. For this, we consider a simple undirected graph $G_S = ([1,N], S)$ on N vertices with edge set S.

Definition 14 (Induced subgraph) *For $V \subseteq [1,N]$, the induced subgraph $G_S(V) = (V, S(V))$ is the graph on V with edge set $S(V) = S \cap V^2$.*

Proposition 15 *For all support $S \subseteq [1,N]^2$, the set of invertible matrices in $\mathcal{E}(S)$ is either empty or a dense open subset of $\mathcal{E}(S)$.*

The proof is straightforward when writing the determinant of $\mathsf{A} \in \mathcal{E}(S)$ as a polynomial in its entries. Observe that by this property, finding one invertible matrix A in $\mathcal{E}(S)$ guarantees that almost every matrix in $\mathcal{E}(S)$ is invertible. In this case, we say that the graph G_S is invertible. Similarly, we say that G_S is diagonally identifiable if S is diagonally identifiable.

Theorem 16 (Conditions for $F_{\rm diag}$-identifiability) *Let $S \subseteq \overline{F}_{\rm diag}$ and $G_S = ([1,N], S)$.*

1. ***Necessary condition:*** *If S is diagonally identifiable then there exists a sequence of subsets $V_3, ..., V_{N-1} \subset [1,N]$ such that $|V_k| = k$ and $G_S(V_k)$ is invertible for all $k = 3, ..., N-1$.*
2. ***Sufficient condition:*** *If there exists a nested sequence $V_3 \subset ... \subset V_{N-1} \subset [1,N]$ with $|V_k| = k$ such that $G_S(V_k)$ is invertible for all $k = 3, ..., N-1$, then S is diagonally identifiable.*

The gap between the sufficient and necessary conditions lies in the fact that the sequence $V_3, ..., V_{N-1}$ need to be nested for the sufficient condition.

Proof We proceed by contradiction. For the necessary condition, let $k \geq 3$ be such that $G_S(V_k)$ is not invertible, for all $V_k \subset [1,N]$ of size k. For $\mathsf{A} \in \mathcal{E}(S)$, denote by $\psi_0(\mathsf{A}), \psi_1(\mathsf{A}), \ldots, \psi_N(\mathsf{A})$ the coefficients of the characteristic polynomial

$$\det(z\,\mathrm{I} - \mathsf{A}) = \sum_{j=0}^{N} \psi_j(\mathsf{A})\ z^j, \quad z \in \mathbb{R}.$$

Consider the matrix $M_k(\mathsf{A}) := \sum_{j=0}^{k} \psi_j(\mathsf{A})\ \mathsf{A}^j$. By Eq. (14) in Espinasse and Rochet (2016), we see that the (i,i)-entry of $M_k(\mathsf{A})$ equals the sum of all minors of size k that do not contain the vertex i. Since for all subset V_k of size k, $G_S(V_k)$ is not invertible, this implies that $M_k(\mathsf{A})$ has zero diagonal. On the other hand, the non-zero entries of $M_k(\mathsf{A})$ are degree k polynomials in the variables $\mathsf{A}_{ij}, (i,j) \in \mathrm{Supp}(\mathsf{A})$. Therefore, the equality $M_k(\mathsf{A}) = \lambda \mathsf{A}$ for some $\lambda \in \mathbb{R}$ occurs for at most a countable number of $\mathsf{A} \in \mathcal{E}(S)$. Since $M_k(\mathsf{A})$ commutes with A, we deduce that S is not diagonally identifiable.

For the sufficient condition, we will need the following lemma.

Lemma 17 *If there exists a subset $V' \subset [1,N]$ of size $N-1$ such that $G_S(V')$ is both DI and invertible, then G_S is DI.*

Proof We may assume that $V' = [1, N-1]$ without loss of generality. Let M' denote a symmetric $(N-1)\times(N-1)$ matrix indexed on V' that is both invertible and diagonally identifiable, *i.e.*, for all non-zero matrix $\mathsf{A}' \neq \lambda \mathsf{M}'$,

$$\mathsf{M}'\mathsf{A}' = \mathsf{A}'\mathsf{M}' \implies \mathrm{diag}(\mathsf{A}') \neq 0.$$

To prove that G_S is DI, it suffices to find a symmetric matrix M with support S that is diagonally identifiable. Consider M defined by

$$\mathsf{M} = \begin{bmatrix} \mathsf{M}' & 0 \\ 0 & 0 \end{bmatrix}.$$

Let A be a matrix with zero diagonal that commutes with M and write

$$\mathsf{A} = \begin{bmatrix} \mathsf{A}' & a \\ a^\top & 0 \end{bmatrix}$$

for some $a \in \mathbb{R}^{N-1}$, with $\mathrm{diag}(\mathsf{A}') = 0$. The condition $\mathsf{MA} = \mathsf{AM}$ can be stated equivalently as

$$\begin{cases} \mathsf{M}'\mathsf{A}' = \mathsf{A}'\mathsf{M}' \\ \mathsf{M}'a = 0 \end{cases}$$

Since M' is invertible by assumption, $a = 0$ and the only matrix A with zero diagonal that commutes with M is the null matrix. Thus, M is diagonally identifiable. ■

We now go back to prove the sufficient condition in Theorem 16. Assume that G_S is not diagonally identifiable, then by Lemma 17, neither is $G_S(V_{N-1})$. By iterating the argument, we conclude that $G_S(V_3)$ is not diagonally identifiable. However, the only invertible graph on three vertices is the triangle graph, which is diagonally identifiable, leading to a contradiction. ■

Remark 18 *The proof of Theorem 16 combines the results of Lemma 2.1 in Barsotti et al. (2014) and Eq. (14) in Espinasse and Rochet (2016). The first one is of topological flavor proving that the set of identifiable matrices is either dense or empty in the set of matrices with prescribed support. The second ingredient is Eq. (14) in Espinasse and Rochet (2016) which contains a key combinatorial computation on the adjugate matrix of weighted graphs. Admittedly, its purpose was to provide the first step to prove the necessary condition for identifiability in the present article (precisely, that $M_k(\mathsf{A})$ has zero diagonal). The proof of the sufficient condition does not, however, involve this result.*

A.2 Proof of Proposition 4

From Claim (*ii*) in Theorem 16 and considering the nested sequence $V_{N-1} \supset ... \supset V_3$ obtained by removing the last vertex on the tail of the kite at each step, we deduce a simple and tractable sufficient condition for a graph G_S to be diagonally identifiable, namely that G_S contains the kite graph as a vertex covering (possibly not induced) subgraph.

A.3 Existence of kites

The condition on containing the kite graph ∇_N as a subgraph is mild in the sense that it is satisfied in the dense regime $\log n/n$ by random graphs, as depicted in the following proposition.

Proposition 19 *The existence of kite graphs in the Erdős-Rényi model occurs as follows. For any $\omega(N) \to \infty$ and for $G_N \sim G(N, p_N)$, if $p_N \geq (1/N)(\log N + \log\log N + \omega(N))$ then $\mathbb{P}\{G_N$ has a kite of length $N\}$ tends to 1 as N goes to infinity.*

The proof makes use of the existence of a hamiltonian cycle which is a standard result in Random Graph Theory, see Corollary 8.12 in Bollobás (1998) for instance. This results shows that in the regime $(\log N + \log\log N)/N$ an Erdős-Rényi graph is diagonally identifiable.

Proof We now present the proof of this fact. Let $\omega(n) \to \infty$ and set

$$p_1 := (1/n)(\log n + \log\log n + \omega(n)/2),$$
$$p_2 := \omega(n)/(2n)\,.$$

Let $G^{(1)}$ and $G^{(2)}$ be two independent Erdős-Rényi graphs such that

$$G_n^{(1)} \sim G(n, p_1) \quad \perp\!\!\!\perp \quad G_n^{(2)} \sim G(n, p_2)\,.$$

As shown in Corollary 8.12 in Bollobás (1998) for instance, $\mathbb{P}\{G_n^{(1)}$ is hamiltonian$\}$ tends to 1 as n goes to infinity. Given a hamiltonian cycle C_n of length n in $G^{(1)}$ one can construct a kite of length n using edges of $G^{(2)}$ to connect a pair of vertices at distance 2 on the cycle C_n. Invoke the independence of $G^{(1)}$ and $G^{(2)}$ to get that this latter probability is

$$\mathbb{P}\{\{k, k+2\} \text{ is an edge of } G^{(2)} \text{ for some } k\} = \mathbb{P}\{B(n, p_2) > 0\}\,,$$

where $B(n, p_2)$ denotes the binomial law. Using Poisson approximation one gets that this probability tends to 1 as n goes to infinity. We deduce that the probability that the graph $G = G_n^{(1)} + G_n^{(2)}$ has at least a kite tends to 1. Observe that G is an Erdős-Rényi graph of size n and parameter $p = p_1 + p_2 - p_1 p_2 \leq p_n$ which concludes the proof. ∎

A.4 Proof of Theorem 5

Combining Proposition 19 and Theorem 16, we deduce the first point. From the necessary condition in Theorem 16, we see that it is sufficient to find two isolated vertices to prove non-identifiability. Indeed, in this case, the kernel of the adjacency matrix has co-dimension at least 2 showing that all sub-graphs of size $N-1$ are not invertible. Furthermore, one knows (see Theorem 3.1 in Bollobás (1998) for instance) that the event "there is at least two isolated points" has sharp threshold function $\log n/n$. This proves the second point.

Appendix B. Support reconstruction

B.1 Proof of Theorem 7

Define $\mathcal{S}_1 := \{S \in \mathcal{S} : |S| \leq |S^\star|, S \neq S^\star\}$ and $\mathcal{S}_2 := \{S \in \mathcal{S} : |S| > |S^\star|\}$, clearly it holds $\mathcal{S} = \{S^\star\} \cup \mathcal{S}_1 \cup \mathcal{S}_2$. We want to control the terms $\mathbb{P}\{\widehat{S} \in \mathcal{S}_1\}$ and $\mathbb{P}\{\widehat{S} \in \mathcal{S}_2\}$ separately and conclude in view of

$$\mathbb{P}\{\widehat{S} \neq S^\star\} = \mathbb{P}\{\widehat{S} \in \mathcal{S}_1\} + \mathbb{P}\{\widehat{S} \in \mathcal{S}_2\}\,.$$

Since the Frobenius norm is sub-multiplicative, it holds, for all $\mathsf{A} \in \mathcal{E}(\overline{F})$,

$$\|\mathsf{A}(\widehat{\mathsf{K}} - \mathsf{K}) - (\widehat{\mathsf{K}} - \mathsf{K})\mathsf{A}\| \leq \|\mathsf{A}(\widehat{\mathsf{K}} - \mathsf{K})\|_2 + \|(\widehat{\mathsf{K}} - \mathsf{K})\mathsf{A}\| \leq 2\|\mathsf{A}\|\|\widehat{\mathsf{K}} - \mathsf{K}\|\,.$$

Thus, the quantity $\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|$ for $\mathsf{A} \in \mathcal{E}(\overline{F})$ can be bounded from below and above by

$$\|\mathsf{AK} - \mathsf{KA}\| - 2\|\mathsf{A}\|\|\widehat{\mathsf{K}} - \mathsf{K}\| \leq \|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\| \leq \|\mathsf{AK} - \mathsf{KA}\| + 2\|\mathsf{A}\|\|\widehat{\mathsf{K}} - \mathsf{K}\|. \tag{11}$$

To bound the term $\mathbb{P}\{\widehat{S} \in \mathcal{S}_1\}$, we use (11) to remark that for all $S \in \mathcal{S}_1$,

$$Q(S) = \min_{\mathsf{A} \in \mathcal{E}(S)\setminus\{0\}} \frac{\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|}{\|\mathsf{A}\|} + \lambda_n|S| \geq \min_{\mathsf{A} \in \mathcal{E}(S)\setminus\{0\}} \frac{\|\mathsf{AK} - \mathsf{KA}\|}{\|\mathsf{A}\|} - 2\|\widehat{\mathsf{K}} - \mathsf{K}\|\,.$$

It follows

$$\min_{S \in \mathcal{S}_1} Q(S) \geq \min_{S \in \mathcal{S}_1} \min_{\mathsf{A} \in \mathcal{E}(S)\setminus\{0\}} \frac{\|\mathsf{AK} - \mathsf{KA}\|}{\|\mathsf{A}\|} - 2\|\widehat{\mathsf{K}} - \mathsf{K}\| = c_0(S^\star) - 2\|\widehat{\mathsf{K}} - \mathsf{K}\|. \tag{12}$$

The constant $c_0(S^\star)$ is positive by F-identifiability of W. Moreover, observe that

$$Q(S^\star) = \min_{\mathsf{A} \in \mathcal{E}(S^\star)\setminus\{0\}} \frac{\|\mathsf{A}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{A}\|}{\|\mathsf{A}\|} + \lambda_n|S^\star| \leq \frac{\|\mathsf{W}\widehat{\mathsf{K}} - \widehat{\mathsf{K}}\mathsf{W}\|}{\|\mathsf{W}\|} + \lambda_n|S^\star| \leq 2\|\widehat{\mathsf{K}} - \mathsf{K}\| + \lambda_n|S^\star|, \tag{13}$$

where we used both Eq. (11) and the fact that $\mathsf{WK} - \mathsf{KW} = 0$. Combining (12) and (13), we get

$$\mathbb{P}\{\widehat{S} \in \mathcal{S}_1\} \leq \mathbb{P}\Big\{\min_{S \in \mathcal{S}_1} Q(S) \leq Q(S^\star)\Big\} \leq \mathbb{P}\Big\{\|\widehat{\mathsf{K}} - \mathsf{K}\| \geq \frac{c_0(S^\star) - \lambda_n|S^\star|}{4}\Big\}\,.$$

To control the term $\mathbb{P}(\widehat{S} \in \mathcal{S}_2)$, we use that $\min_{S \in \mathcal{S}_2} Q(S) \geq \lambda_n \min_{S \in \mathcal{S}_2} |S| \geq \lambda_n(|S^\star| + 1)$. By Eq. (13), it follows

$$\begin{aligned}\mathbb{P}\big\{\widehat{S} \in \mathcal{S}_2\big\} &\leq \mathbb{P}\Big\{\min_{S \in \mathcal{S}_2} Q(S) \leq Q(S^\star)\Big\} \\ &\leq \mathbb{P}\Big\{\lambda_n(|S^\star| + 1) \leq 2\|\widehat{\mathsf{K}} - \mathsf{K}\| + \lambda_n|S^\star|\Big\} \\ &= \mathbb{P}\Big\{\|\widehat{\mathsf{K}} - \mathsf{K}\| \geq \frac{\lambda_n}{2}\Big\}\,.\end{aligned}$$

The proof of Theorem 7 follows directly by ($\mathbf{H}_2$). The corollary is a direct consequence using Borel-Cantelli's Lemma.

B.2 Proof of Theorem 10

Since $\Delta(\mathsf{K})\Phi_S$ is of full rank, the value $\widehat{\beta}_S = \big(\Delta(\widehat{\mathsf{K}})\Phi_S\big)^\dagger \Delta(\widehat{\mathsf{K}})a_0$ is the unique solution to Eq. (5) with probability tending to one asymptotically. Since the value of $\widehat{\beta}_S$ does not depend on $a_0 \in \mathcal{A}_S$, one can take $a_0 = w$ in view of $S^\star \subseteq S$. We obtain

$$\widehat{\beta}_S = \big(\Delta(\widehat{\mathsf{K}})\Phi_S\big)^\dagger \Delta(\widehat{\mathsf{K}})w = -\big(\Delta(\widehat{\mathsf{K}})\Phi_S\big)^\dagger \Delta(\mathsf{W})\widehat{k}.$$

The result follows from Slutsky's lemma, using that $(\Delta(\widehat{\mathsf{K}})\Phi_S)^\dagger$ converges in probability towards $(\Delta(K)\Phi_S)^\dagger$ and

$$\sqrt{n}\,\big(\Delta(\mathsf{W})\widehat{k} - \Delta(\mathsf{W})k\big) \xrightarrow[n\to\infty]{d} \mathcal{N}\big(0, \Delta(\mathsf{W})\Sigma\Delta(\mathsf{W})^\top\big).$$

Abstract

We consider the closely related problems of bandit convex optimization with two-point feedback, and zero-order stochastic convex optimization with two function evaluations per round. We provide a simple algorithm and analysis which is optimal for convex Lipschitz functions. This improves on Duchi et al. (2015), which only provides an optimal result for smooth functions; Moreover, the algorithm and analysis are simpler, and readily extend to non-Euclidean problems. The algorithm is based on a small but surprisingly powerful modification of the gradient estimator.

Keywords: zero-order optimization, bandit optimization, stochastic optimization, gradient estimator

1. Introduction

We consider the problem of bandit convex optimization with two-point feedback Agarwal et al. (2010). This problem can be defined as a repeated game between a learner and an adversary as follows: At each round t, the adversary picks a convex function f_t on $\mathbb{R}^d$, which is not revealed to the learner. The learner then chooses a point $\mathbf{w}_t$ from some known and closed convex set $\mathcal{W} \subseteq \mathbb{R}^d$, and suffers a loss $f_t(\mathbf{w}_t)$. As feedback, the learner may choose two points $\mathbf{w}'_t, \mathbf{w}''_t \in \mathcal{W}$ and receive[1] $f_t(\mathbf{w}'_t), f_t(\mathbf{w}''_t)$. The learner's goal is to minimize average regret, defined as

$$\frac{1}{T}\sum_{t=1}^{T} f_t(\mathbf{w}_t) - \min_{\mathbf{w}\in\mathcal{W}} \frac{1}{T}\sum_{t=1}^{T} f_t(\mathbf{w}).$$

In this paper, we focus on obtaining bounds on the expected average regret (with respect to the learner's randomness).

A closely-related and easier setting is zero-order stochastic convex optimization. In this setting, our goal is to approximately solve $F(\mathbf{w}) = \min_{\mathbf{w}\in\mathcal{W}} \mathbb{E}_\xi[f(\mathbf{w};\xi)]$, given limited access to $\{f(\cdot;\xi_t)\}_{t=1}^T$ where ξ_t are i.i.d. instantiations. Specifically, we assume that each $f(\cdot,\xi_t)$ is not directly observed, but rather can be queried at two points. This models situations where computing gradients directly is complicated or infeasible. It is well-known (Cesa-Bianchi et al., 2004) that given an algorithm with expected average regret R_T in the bandit optimization setting above, if we feed it with the functions $f_t(\mathbf{w}) = f(\mathbf{w};\xi_t)$, then the average $\bar{\mathbf{w}}_T = \frac{1}{T}\sum_{t=1}^T \mathbf{w}_t$ of the points generated satisfies the following bound on the expected optimization error:

$$\mathbb{E}[F(\bar{\mathbf{w}}_T)] - \min_{\mathbf{w}\in\mathcal{W}} F(\mathbf{w}) \leq R_T.$$

Thus, an algorithm for bandit optimization can be converted to an algorithm for zero-order stochastic optimization with similar guarantees.

The bandit optimization setting with two-point feedback was proposed and studied in Agarwal et al. (2010). Independently, Nesterov (2011) and considered two-point methods for stochastic optimization. Both papers are based on randomized gradient estimates which are then fed into standard first-order algorithms (e.g. gradient descent, or more generally mirror descent). However, the regret/error guarantees in both papers were suboptimal in terms of the dependence on the dimension. Recently, Duchi et al. (2015) considered a similar approach for the stochastic optimization setting, attaining an optimal error guarantee when $f(\cdot;\xi)$ is a smooth function (differentiable and with Lipschitz-continuous gradients). Related results in the smooth case were also obtained by Ghadimi and Lan (2013). However, to tackle the general case, where $f(\cdot;\xi)$ may be non-smooth, Duchi et al. (2015) resorted to a non-trivial smoothing scheme and a significantly more involved analysis. The resulting bounds have additional factors (logarithmic in the dimension) compared to the guarantees in the smooth case. Moreover, an analysis is only provided for Euclidean problems (where the domain $\mathcal{W}$ and Lipschitz parameter of f_t scale with the L_2 norm).

In this note, we present and analyze a simple algorithm with the following properties:

- For Euclidean problems, it is optimal up to constants for both smooth and non-smooth functions. This closes the gap between the smooth and non-smooth Euclidean problems in this setting.
- The algorithm and analysis are readily applicable to non-Euclidean problems. We give an example for the 1-norm, with the resulting bound optimal up to logarithmic factors.
- The algorithm and analysis are simpler than those proposed in Duchi et al. (2015). They apply equally to the bandit and zero-order optimization setting, and can be readily extended using standard techniques, e.g. improved bounds for strongly-convex functions; regret/error bounds holding with high-probability rather than just in expectation; and improved bounds if allowed $k > 2$ observations per round instead of just two (Hazan et al., 2007; Shalev-Shwartz, 2007; Agarwal et al., 2010).

Like previous algorithms, our algorithm is based on a random gradient estimator, which given a function f and point $\mathbf{w}$, queries f at two random locations close to $\mathbf{w}$, and computes a random vector whose expectation is a gradient of a smoothed version of f. The papers Nesterov (2011); Duchi et al. (2015); Ghadimi and Lan (2013) essentially use the estimator

1. This is slightly different than the model of Agarwal et al. (2010), where the learner only chooses $\mathbf{w}'_t, \mathbf{w}''_t$ and the loss is $\frac{1}{2}(f_t(\mathbf{w}'_t) + f_t(\mathbf{w}''_t))$. However, our results and analysis can be easily translated to their setting, and the model we discuss translates more directly to the zero-order stochastic optimization considered later.

which queries at $\mathbf{w}$ and $\mathbf{w}+\delta\mathbf{u}$ (where $\mathbf{u}$ is a random unit vector and $\delta>0$ is a small parameter), and returns

$$\frac{d}{\delta}\left(f(\mathbf{w}+\delta\mathbf{u})-f(\mathbf{w})\right)\mathbf{u}. \tag{1}$$

The intuition is readily seen in the one-dimensional ($d=1$) case, where the expectation of this expression equals

$$\frac{1}{2\delta}\left(f(w+\delta)-f(w-\delta)\right), \tag{2}$$

which indeed approximates the derivative of f (assuming f is differentiable) at w, if δ is small enough.

In contrast, our algorithm uses a slightly different estimator (also used in Agarwal et al., 2010), which queries at $\mathbf{w}-\delta\mathbf{u},\mathbf{w}+\delta\mathbf{u}$, and returns

$$\frac{d}{2\delta}\left(f(\mathbf{w}+\delta\mathbf{u})-f(\mathbf{w}-\delta\mathbf{u})\right)\mathbf{u}. \tag{3}$$

Again, the intuition is readily seen in the case $d=1$, where the expectation of this expression also equals Eq. (2).

When δ is sufficiently small and f is differentiable at $\mathbf{w}$, both estimators compute a good approximation of the true gradient $\nabla f(\mathbf{w})$. However, when f is not differentiable, the variance of the estimator in Eq. (1) can be quadratic in the dimension d, as pointed out by Duchi et al. (2015): For example, for $f(\mathbf{w})=\|\mathbf{w}\|_2$ and $\mathbf{w}=0$, the second moment equals

$$\mathbb{E}\left[\left\|\frac{d}{\delta}\left(f(\delta\mathbf{u})-f(\mathbf{0})\right)\mathbf{u}\right\|_2^2\right] \;=\; \mathbb{E}\left[d^2\|\mathbf{u}\|_2^4\right] \;=\; d^2.$$

Since the performance of the algorithm crucially depends on the second moment of the gradient estimate, this leads to a highly sub-optimal guarantee. In Duchi et al. (2015), this was handled by adding an additional random perturbation and using a more involved analysis. Surprisingly, it turns out that the slightly different estimator in Eq. (3) does not suffer from this problem, and its second moment is essentially *linear* in the dimension d.

We note that in this work, we assume that $\mathbf{u}$ is a random unit vector, similar to previous works. However, our results can be readily extended to other distributions, such as uniform in the Euclidean unit ball, or a Gaussian distribution.

2. Algorithm and Main Results

We consider the algorithm described in Figure 1, which performs standard mirror descent using a randomized gradient estimator $\tilde{\mathbf{g}}_t$ of a (smoothed) version of f_t at point $\mathbf{w}_t$. Following Duchi et al. (2015), we assume that one can indeed query f_t at any point $\mathbf{w}_t+\delta_t\mathbf{u}_t$ as specified in the algorithm[2].

The analysis of the algorithm is presented in the following theorem:

2. This may require us to query at a distance δ_t outside $\mathcal{W}$. If we must query within $\mathcal{W}$, then a standard technique (see Agarwal et al., 2010) is to simply run the algorithm on a slightly smaller set $(1-\epsilon)\mathcal{W}$, where $\epsilon>0$ is sufficiently large so that $\mathbf{w}_t+\delta_t\mathbf{u}_t$ must be in $\mathcal{W}$. Since the formal guarantee in Thm. 1 holds for arbitrarily small δ_t, and each f_t is Lipschitz, we can generally take δ_t (and hence ϵ) sufficiently small so that the additional regret/error incurred is arbitrarily small.

Algorithm 1 Two-Point Bandit Convex Optimization Algorithm

Input: Step size η, function $r:\mathcal{W}\mapsto\mathbb{R}$, exploration parameters $\delta_t>0$
Initialize $\boldsymbol{\theta}_1=\mathbf{0}$.
for $t=1,\ldots,T-1$ **do**
  Predict $\mathbf{w}_t=\arg\max_{\mathbf{w}\in\mathcal{W}}\langle\boldsymbol{\theta}_t,\mathbf{w}\rangle-r(\mathbf{w})$
  Sample $\mathbf{u}_t$ uniformly from the Euclidean unit sphere $\{\mathbf{w}:\|\mathbf{w}\|_2=1\}$
  Query $f_t(\mathbf{w}_t+\delta_t\mathbf{u}_t)$ and $f_t(\mathbf{w}_t-\delta_t\mathbf{u}_t)$
  Set $\tilde{\mathbf{g}}_t=\frac{d}{2\delta_t}\left(f_t(\mathbf{w}_t+\delta_t\mathbf{u}_t)-f_t(\mathbf{w}_t-\delta_t\mathbf{u}_t)\right)\mathbf{u}_t$
  Update $\boldsymbol{\theta}_{t+1}=\boldsymbol{\theta}_t-\eta\tilde{\mathbf{g}}_t$
end for

Theorem 1 *Assume the following conditions hold:*

1. *r is 1-strongly convex with respect to a norm $\|\cdot\|$, and $\sup_{\mathbf{w}\in\mathcal{W}}r(\mathbf{w})\leq R^2$ for some $R<\infty$.*
2. *f_t is convex and G_2-Lipschitz with respect to the 2-norm $\|\cdot\|_2$.*
3. *The dual norm $\|\cdot\|_*$ of $\|\cdot\|$ is such that $\sqrt[4]{\mathbb{E}_{\mathbf{u}_t}\|\mathbf{u}_t\|_*^4}\leq p_*$ for some $p_*<\infty$.*

If $\eta=\frac{R}{p_*G_2\sqrt{dT}}$, and δ_t chosen such that $\delta_t\leq p_*R\sqrt{\frac{d}{T}}$, then the sequence $\mathbf{w}_1,\ldots,\mathbf{w}_T$ generated by the algorithm satisfies the following for any T and $\mathbf{w}^*\in\mathcal{W}$:

$$\mathbb{E}\left[\frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}_t)-\frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}^*)\right]\leq c\;p_*G_2R\sqrt{\frac{d}{T}},$$

where c is some numerical constant.

We note that condition 1 is standard in the analysis of the mirror-descent method (see the specific corollaries below), whereas conditions 2 and 3 are needed to ensure that the variance of our gradient estimator is controlled.

As mentioned earlier, the bound on the average regret which appears in Thm. 1 immediately implies a similar bound on the error in a stochastic optimization setting, for the average point $\bar{\mathbf{w}}_T=\frac{1}{T}\sum_{t=1}^T\mathbf{w}_t$. We note that the result is robust to the choice of η, and is the same up to constants as long as $\eta=\Theta(R/p_*G_2\sqrt{dT})$. Also, the constant c, while always strictly positive, shrinks as $\delta_t\to 0$ (see the proof below for details).

As a first application of the theorem, let us consider the case where $\|\cdot\|$ is the Euclidean norm $\|\cdot\|_2$. In this case, we can take $r(\mathbf{w})=\frac{1}{2}\|\mathbf{w}\|_2^2$, and the algorithm reduces to a standard variant of online gradient descent, defined as $\boldsymbol{\theta}_{t+1}=\boldsymbol{\theta}_t-\tilde{\mathbf{g}}_t$ and $\mathbf{w}_t=\arg\min_{\mathbf{w}\in\mathcal{W}}\|w-\boldsymbol{\theta}_t\|_2$. In this case, we get the following corollary:

Corollary 2 *Suppose f_t for all t is G_2-Lipschitz with respect to the Euclidean norm, and $\mathcal{W}\subseteq\{\mathbf{w}:\|\mathbf{w}\|_2\leq R\}$. Then using $\|\cdot\|=\|\cdot\|_2$ and $r(\mathbf{w})=\frac{1}{2}\|\mathbf{w}\|_2^2$, it holds for some constant c and any $\mathbf{w}^*\in\mathcal{W}$ that*

$$\mathbb{E}\left[\frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}_t)-\frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}^*)\right]\leq c\;G_2R\sqrt{\frac{d}{T}},$$

The proof is immediately obtained from Thm. 1, noting that $p_* = 1$ in our case. This bound matches (up to constants) the lower bound in Duchi et al. (2015), hence closing the gap between upper and lower bounds in this setting.

As a second application, let us consider the case where $\|\cdot\|$ is the 1-norm, $\|\cdot\|_1$, the domain $\mathcal{W}$ is the simplex in $\mathbb{R}^d$, $d > 1$ (although our result easily extends to any subset of the 1-norm unit ball), and we use a standard entropic regularizer:

Corollary 3 *Suppose f_t for all t is G_1-Lipschitz with respect to the L_1 norm. Then using $\|\cdot\| = \|\cdot\|_1$ and $r(\mathbf{w}) = \sum_{i=1}^d w_i \log(dw_i)$, it holds for some constant c and any $\mathbf{w}^* \in \mathcal{W}$ that*

$$\mathbb{E}\left[\frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}_t) - \frac{1}{T}\sum_{t=1}^T f_t(\mathbf{w}^*)\right] \leq c\, G_1 \sqrt{\frac{d\log^2(d)}{T}}.$$

This bound matches (this time up to a factor polylogarithmic in d) the lower bound in Duchi et al. (2015) for this setting.

Proof The function r is 1-strongly convex with respect to the 1-norm (see for instance Shalev-Shwartz, 2012, Example 2.5), and has value at most $\log(d)$ on the simplex. Also, if f_t is G_1-Lipschitz with respect to the 1-norm, then it must be $\sqrt{d}G_1$-Lipschitz with respect to the Euclidean norm. Finally, to satisfy condition 3 in Thm. 1, we upper bound $\sqrt[4]{\mathbb{E}[\|\mathbf{u}_t\|_\infty^4]}$ using the following lemma, whose proof is given in the appendix:

Lemma 4 *If $\mathbf{u}$ is uniformly distributed on the unit sphere in $\mathbb{R}^d$, $d > 1$, then $\sqrt[4]{\mathbb{E}[\|\mathbf{u}\|_\infty^4]} \leq c\sqrt{\frac{\log(d)}{d}}$ where c is a positive numerical constant independent of d.*

Plugging these observations into Thm. 1 leads to the desired result. ■

Finally, we make two additional remarks on possible extensions and improvements to Thm. 1.

Remark 5 (Querying at $k > 2$ points) *If the algorithm is allowed to query f_t at $k > 2$, then it can be modified to attain an improved regret bound, by computing $\lfloor k/2 \rfloor$ independent estimates of $\tilde{g}_t$ at every round (using a freshly sampled $\mathbf{u}_t$ each time), and using their average. This leads to a new gradient estimator $\tilde{\mathbf{g}}_t^k$, which satisfies $\mathbb{E}[\|\tilde{\mathbf{g}}_t^k\|^2] \leq \frac{1}{k}\mathbb{E}[\|\tilde{\mathbf{g}}_t\|^2] + \|\mathbb{E}[\tilde{\mathbf{g}}_t]\|^2$. Based on the proof of Thm. 1, it is easily verified that this leads to an average expected regret bound of $\frac{cG_2R}{\sqrt{T}}\left(1 + p_*\sqrt{d/k}\right)$ for some numerical constant c.*

Remark 6 (Non-Euclidean Geometries) *When considering norms other than the Euclidean norm, it is tempting to conjecture that our algorithm and analysis can be improved, by sampling $\mathbf{u}_t$ from a distribution adapted to the geometry of that norm (not necessarily the Euclidean ball), and assuming f_t is Lipschitz w.r.t. the dual norm. However, adapting the proof (and in particular getting appropriate versions of Lemma 8 and Lemma 9) does not appear straightforward, and the potential performance improvement is currently unclear.*

3. Proof of Theorem 1

As discussed in the introduction, the key to getting improved results compared to previous papers is the use of a slightly different random gradient estimator, which turns out to have significantly less variance. The formal proof relies on a few simple lemmas listed below. The key lemma is Lemma 10, which establishes the improved variance behavior.

Lemma 7 *For any $\mathbf{w}^* \in \mathcal{W}$, it holds that*

$$\sum_{t=1}^T \langle \tilde{\mathbf{g}}_t, \mathbf{w}_t - \mathbf{w}^* \rangle \leq \frac{1}{\eta}R^2 + \eta\sum_{t=1}^T \|\tilde{\mathbf{g}}_t\|_*^2.$$

This lemma is the canonical result on the convergence of online mirror descent, and the proof is standard (see e.g. Shalev-Shwartz, 2012).

Lemma 8 *Define the function*

$$\hat{f}_t(\mathbf{w}) = \mathbb{E}_{\mathbf{u}_t}\left[f_t(\mathbf{w} + \delta_t\mathbf{u}_t)\right],$$

over $\mathcal{W}$, where $\mathbf{u}_t$ is a vector picked uniformly at random from the Euclidean unit sphere. Then the function is convex, Lipschitz with constant G_2, satisfies

$$\sup_{\mathbf{w}\in\mathcal{W}} |\hat{f}_t(\mathbf{w}) - f_t(\mathbf{w})| \leq \delta_t G_2,$$

and is differentiable with the following gradient:

$$\nabla\hat{f}_t(\mathbf{w}) = \mathbb{E}_{\mathbf{u}_t}\left[\frac{d}{\delta_t}f_t(\mathbf{w} + \delta_t\mathbf{u}_t)\mathbf{u}_t\right].$$

Proof The fact that the function is convex and Lipschitz is immediate from its definition and the assumptions in the theorem. The inequality follows from $\mathbf{u}_t$ being a unit vector and that f_t is assumed to be G_2-Lipschitz with respect to the 2-norm. The differentiability property follows from Lemma 2.1 in Flaxman et al. (2005). ■

Lemma 9 *For any function g which is L-Lipschitz with respect to the 2-norm, it holds that if $\mathbf{u}$ is uniformly distributed on the Euclidean unit sphere, then*

$$\sqrt{\mathbb{E}\left[\left(g(\mathbf{u}) - \mathbb{E}[g(\mathbf{u})]\right)^4\right]} \leq c\frac{L^2}{d}.$$

for some numerical constant c.

Proof A standard result on the concentration of Lipschitz functions on the Euclidean unit sphere implies that

$$\Pr(|g(\mathbf{u}) - \mathbb{E}[g(\mathbf{u})]| > t) \leq 2\exp\left(-c'dt^2/L^2\right)$$

for some numerical constant $c' > 0$ (see the proof of Proposition 2.10 and Corollary 2.6 in Ledoux, 2005). Therefore,

$$\sqrt{\mathbb{E}\left[(g(\mathbf{u}) - \mathbb{E}[g(\mathbf{u})])^4\right]} = \sqrt{\int_{t=0}^{\infty} \Pr\left((g(\mathbf{u}) - \mathbb{E}[g(\mathbf{u})])^4 > t\right) dt}$$
$$= \sqrt{\int_{t=0}^{\infty} \Pr\left(|g(\mathbf{u}) - \mathbb{E}[g(\mathbf{u})]| > \sqrt[4]{t}\right) dt} \leq \sqrt{\int_{t=0}^{\infty} 2\exp\left(-\frac{c'd\sqrt{t}}{L^2}\right) dt} = \sqrt{2\frac{L^4}{(c'd)^2}},$$

where in the last step we used the fact that $\int_{x=0}^{\infty} \exp(-\sqrt{x})dx = 2$. The expression above equals cL^2/d for some numerical constant c. ■

Lemma 10 *It holds that $\mathbb{E}[\tilde{\mathbf{g}}_t|\mathbf{w}_t] = \nabla \hat{f}_t(\mathbf{w}_t)$ (where $\hat{f}_t(\cdot)$ is as defined in Lemma 8), and $\mathbb{E}[\|\tilde{\mathbf{g}}_t\|^2|\mathbf{w}_t] \leq cdp_*^2 G_2^2$ for some numerical constant c.*

Proof For simplicity of notation, we drop the t subscript. Since $\mathbf{u}$ has a symmetric distribution around the origin,

$$\begin{aligned}
\mathbb{E}[\tilde{\mathbf{g}}|\mathbf{w}] &= \mathbb{E}_{\mathbf{u}}\left[\frac{d}{2\delta}\left(f(\mathbf{w}+\delta\mathbf{u}) - f(\mathbf{w}-\delta\mathbf{u})\right)\mathbf{u}\right] \\
&= \mathbb{E}_{\mathbf{u}}\left[\frac{d}{2\delta}\left(f(\mathbf{w}+\delta\mathbf{u})\right)\mathbf{u}\right] + \mathbb{E}_{\mathbf{u}}\left[\frac{d}{2\delta}f(\mathbf{w}-\delta\mathbf{u})(-\mathbf{u})\right] \\
&= \mathbb{E}_{\mathbf{u}}\left[\frac{d}{2\delta}\left(f(\mathbf{w}+\delta\mathbf{u})\right)\mathbf{u}\right] + \mathbb{E}_{\mathbf{u}}\left[\frac{d}{2\delta}f(\mathbf{w}+\delta\mathbf{u})(\mathbf{u})\right] \\
&= \mathbb{E}_{\mathbf{u}}\left[\frac{d}{\delta}f(\mathbf{w}+\delta\mathbf{u})\mathbf{u}\right]
\end{aligned}$$

which equals $\nabla\hat{f}(\mathbf{w})$ by Lemma 8.

As to the second part of the lemma, we have the following, where α is an arbitrary parameter and where we use the elementary inequality $(a-b)^2 \leq 2(a^2+b^2)$.

$$\begin{aligned}
\mathbb{E}[\|\tilde{\mathbf{g}}\|_*^2|\mathbf{w}] &= \mathbb{E}_{\mathbf{u}}\left[\left\|\frac{d}{2\delta}\left(f(\mathbf{w}+\delta\mathbf{u}) - f(\mathbf{w}-\delta\mathbf{u})\right)\mathbf{u}\right\|_*^2\right] \\
&= \frac{d^2}{4\delta^2}\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}+\delta\mathbf{u}) - f(\mathbf{w}-\delta\mathbf{u})\right)^2\right] \\
&= \frac{d^2}{4\delta^2}\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right) - \left(f(\mathbf{w}-\delta\mathbf{u}) - \alpha\right)\right)^2\right] \\
&\leq \frac{d^2}{2\delta^2}\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^2 + \left(f(\mathbf{w}-\delta\mathbf{u}) - \alpha\right)^2\right)\right] \\
&= \frac{d^2}{2\delta^2}\left(\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^2\right] + \mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}-\delta\mathbf{u}) - \alpha\right)^2\right]\right).
\end{aligned}$$

Again using the symmetric distribution of $\mathbf{u}$, this equals

$$\begin{aligned}
&\frac{d^2}{2\delta^2}\left(\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^2\right] + \mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^2\right]\right) \\
&\quad = \frac{d^2}{\delta^2}\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^2\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^2\right].
\end{aligned}$$

Applying Cauchy-Schwartz and using the condition $\sqrt[4]{\mathbb{E}_{\mathbf{u}}\|\mathbf{u}\|_*^4} \leq p_*$ stated in the theorem, we get the upper bound

$$\frac{d^2}{\delta^2}\sqrt{\mathbb{E}_{\mathbf{u}}\left[\|\mathbf{u}\|_*^4\right]}\sqrt{\mathbb{E}_{\mathbf{u}}\left[\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^4\right]} = \frac{p_*^2 d^2}{\delta^2}\sqrt{\mathbb{E}_{\mathbf{u}}\left[\left(f(\mathbf{w}+\delta\mathbf{u}) - \alpha\right)^4\right]}.$$

In particular, taking $\alpha = \mathbb{E}_{\mathbf{u}}[f(\mathbf{w}+\delta\mathbf{u})]$ and using Lemma 9 (noting that $f(\mathbf{w}+\delta\mathbf{u})$ is $G_2\delta$-Lipschitz w.r.t. $\mathbf{u}$ in terms of the 2-norm), this is at most $\frac{p_*^2 d^2}{\delta^2} c\frac{(G_2\delta)^2}{d} = cdp_*^2 G_2^2$ as required. ■

We are now ready to prove the theorem. Taking expectations on both sides of the inequality in Lemma 7, we have

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle\tilde{\mathbf{g}}_t, \mathbf{w}_t - \mathbf{w}^*\rangle\right] \leq \frac{1}{\eta}R^2 + \eta\sum_{t=1}^{T}\mathbb{E}\left[\|\tilde{\mathbf{g}}_t\|_*^2\right] = \frac{1}{\eta}R^2 + \eta\sum_{t=1}^{T}\mathbb{E}\left[\mathbb{E}\left[\|\tilde{\mathbf{g}}_t\|_*^2|\mathbf{w}_t\right]\right]. \quad (4)$$

Using Lemma 10, the right hand side is at most

$$\frac{1}{\eta}R^2 + \eta cdp_*^2 G_2^2 T$$

The left hand side of Eq. (4), by Lemma 10 and convexity of $\hat{f}_t$, equals

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle\mathbb{E}[\tilde{\mathbf{g}}_t|\mathbf{w}_t], \mathbf{w}_t - \mathbf{w}^*\rangle\right] = \mathbb{E}\left[\sum_{t=1}^{T}\langle\nabla\hat{f}_t(\mathbf{w}_t), \mathbf{w}_t - \mathbf{w}^*\rangle\right] \geq \mathbb{E}\left[\sum_{t=1}^{T}\left(\hat{f}_t(\mathbf{w}_t) - \hat{f}_t(\mathbf{w}^*)\right)\right].$$

By Lemma 8, this is at least

$$\mathbb{E}\left[\sum_{t=1}^{T}\left(f_t(\mathbf{w}_t) - f_t(\mathbf{w}^*)\right)\right] - 2G_2\sum_{t=1}^{T}\delta_t.$$

Combining these inequalities and plugging back into Eq. (4), we get

$$\mathbb{E}\left[\sum_{t=1}^{T}\left(f_t(\mathbf{w}_t) - f_t(\mathbf{w}^*)\right)\right] \leq 2G_2\sum_{t=1}^{T}\delta_t + \frac{1}{\eta}R^2 + cdp_*^2 G_2^2\eta T.$$

Choosing $\eta = R/(p_* G_2\sqrt{dT})$, and any $\delta_t \leq p_* R\sqrt{d/T}$, we get

$$\mathbb{E}\left[\sum_{t=1}^{T}\left(f_t(\mathbf{w}_t) - f_t(\mathbf{w}^*)\right)\right] \leq (c+3)p_* G_2 R\sqrt{dT}.$$

Dividing both sides by T, the result follows.

Appendix A. Proof of Lemma 4

We note that the distribution of $\|\mathbf{u}\|_\infty^4$ is identical to that of $\frac{\|\mathbf{n}\|_\infty^4}{\|\mathbf{n}\|_2^4}$, where $\mathbf{n} \sim \mathcal{N}(\mathbf{0}, I_d)$ is a standard Gaussian random vector. Moreover, by a standard concentration bound on the norm of Gaussian random vectors (e.g. Corollary 2.3 in Barvinok, 2005, with $\epsilon = 1/2$):

$$\max\left\{\Pr\left(\|\mathbf{n}\|_2 \leq \sqrt{\frac{d}{2}}\right), \Pr\left(\|\mathbf{n}\|_2 \geq \sqrt{2d}\right)\right\} \leq \exp\left(-\frac{d}{16}\right).$$

Finally, for any value of $\mathbf{n}$, we always have $\frac{\|\mathbf{n}\|_\infty}{\|\mathbf{n}\|_2} \leq 1$, since the Euclidean norm is always larger than the infinity norm. Combining these observations, and using $\mathbf{1}_A$ for the indicator function of the event A, we have

$$\begin{aligned}
\mathbb{E}[\|\mathbf{u}\|_\infty^4] &= \mathbb{E}\left[\frac{\|\mathbf{n}\|_\infty^4}{\|\mathbf{n}\|_2^4}\right] \\
&= \Pr\left(\|\mathbf{n}\|_2 \leq \sqrt{\frac{d}{2}}\right)\mathbb{E}\left[\frac{\|\mathbf{n}\|_\infty^4}{\|\mathbf{n}\|_2^4} \;\middle|\; \|\mathbf{n}\|_2 \leq \sqrt{\frac{d}{2}}\right] \\
&\quad + \Pr\left(\|\mathbf{n}\|_2 > \sqrt{\frac{d}{2}}\right)\mathbb{E}\left[\frac{\|\mathbf{n}\|_\infty^4}{\|\mathbf{n}\|_2^4} \;\middle|\; \|\mathbf{n}\|_2 > \sqrt{\frac{d}{2}}\right] \\
&\leq \exp\left(-\frac{d}{16}\right) * 1 + \Pr\left(\|\mathbf{n}\|_2 > \sqrt{\frac{d}{2}}\right)\mathbb{E}\left[\frac{\|\mathbf{n}\|_\infty^4}{\left(\sqrt{d/2}\right)^4} \;\middle|\; \|\mathbf{n}\|_2 > \sqrt{\frac{d}{2}}\right] \\
&= \exp\left(-\frac{d}{16}\right) + \left(\frac{2}{d}\right)^2 \mathbb{E}\left[\|\mathbf{n}\|_\infty^4 \mathbf{1}_{\|\mathbf{n}\|_2 > \sqrt{d/2}}\right] \\
&\leq \exp\left(-\frac{d}{16}\right) + \frac{4}{d^2}\mathbb{E}\left[\|\mathbf{n}\|_\infty^4\right]. \qquad (5)
\end{aligned}$$

Thus, it remains to upper bound $\mathbb{E}\left[\|\mathbf{n}\|_\infty^4\right]$ where $\mathbf{n}$ is a standard Gaussian random variable. Letting $\mathbf{n} = (n_1, \ldots, n_d)$, and noting that $n_1, \ldots, n_d$ are independent and identically

distributed standard Gaussian random variables, we have for any scalar $z \geq 1$ that

$$\begin{aligned}
\Pr(\|\mathbf{n}\|_\infty \leq z) = \prod_{i=1}^n \Pr(|n_i| \leq z) &= (\Pr(|n_1| \leq z))^d \\
&= (1 - \Pr(|n_1| > z))^d \overset{(1)}{\geq} 1 - d\Pr(|n_1| > z) \\
&= 1 - 2d\Pr(n_1 > z) \overset{(2)}{\geq} 1 - d\exp(-z^2/2),
\end{aligned}$$

where (1) is Bernoulli's inequality, and (2) is using a standard tail bound for a Gaussian random variable. In particular, the above implies that

$$\Pr\left(\|\mathbf{n}\|_\infty > z\right) \leq d\exp(-z^2/2).$$

Therefore, for an arbitrary positive scalar $r \geq 1$,

$$\begin{aligned}
\mathbb{E}\left[\|\mathbf{n}\|_\infty^4\right] &= \int_{z=0}^\infty \Pr\left(\|\mathbf{n}\|_\infty^4 > z\right) dz \\
&\leq \int_{z=0}^r 1 dz + \int_{z=r}^\infty \Pr\left(\|\mathbf{n}\|_\infty > \sqrt[4]{z}\right) dz \\
&\leq r + \int_{z=r}^\infty d\exp\left(-\frac{\sqrt{z}}{2}\right) dz \\
&= r + 4d(2 + \sqrt{r})\exp\left(-\frac{\sqrt{r}}{2}\right).
\end{aligned}$$

In particular, plugging $r = 4\log^2(d)$ (which is larger than 1, since we assume $d > 1$), we get $4(2 + 2\log(d) + \log^2(d))$. Plugging this back into Eq. (5), we get that

$$\mathbb{E}[\|\mathbf{u}\|_\infty^4] \;\leq\; \exp\left(-\frac{d}{16}\right) + 16\frac{2 + 2\log(d) + \log^2(d)}{d^2},$$

which can be shown to be at most $c'\left(\frac{\log(d)}{d}\right)^2$ for all $d > 1$, where $c' < 150$ is a numerical constant. In particular, this means that $\sqrt[4]{\mathbb{E}[\|\mathbf{u}\|_\infty^4]} \leq \sqrt[4]{c'}\sqrt{\frac{\log(d)}{d}}$ as required.

Abstract

We consider a firm that sells a large number of products to its customers in an online fashion. Each product is described by a high dimensional feature vector, and the market value of a product is assumed to be linear in the values of its features. Parameters of the valuation model are unknown and can change over time. The firm sequentially observes a product's features and can use the historical sales data (binary sale/no sale feedbacks) to set the price of current product, with the objective of maximizing the collected revenue. We measure the performance of a dynamic pricing policy via regret, which is the expected revenue loss compared to a clairvoyant that knows the sequence of model parameters in advance.

We propose a pricing policy based on projected stochastic gradient descent (PSGD) and characterize its regret in terms of time T, features dimension d, and the temporal variability in the model parameters, δ_t. We consider two settings. In the first one, feature vectors are chosen antagonistically by nature and we prove that the regret of PSGD pricing policy is of order $O(\sqrt{T}+\sum_{t=1}^{T}\sqrt{t}\delta_t)$. In the second setting (referred to as stochastic features model), the feature vectors are drawn independently from an unknown distribution. We show that in this case, the regret of PSGD pricing policy is of order $O(d^2\log T+\sum_{t=1}^{T}t\delta_t/d)$.

Keywords: Dynamic Pricing, Revenue Management, Varying-Coefficient Models, Regret, Stochastic Gradient Descent, Hypothesis Testing

1. Introduction

Motivated by the prevalence of online marketplaces, we consider the problem of a firm selling a large number of products, that are significantly differentiated from each other, to customers that arrive over time. The firm needs to price the products in a dynamic manner, with the objective of maximizing the expected revenue.

The majority of work in dynamic pricing assume that a retailer sells *identical* items to its customers (Besbes and Zeevi, 2009; Farias and Van Roy, 2010; Broder and Rusmevichientong, 2012; den Boer and Zwart, 2013; Wang et al., 2014). Recently, feature-based models have been used to model the products differentiation by assuming that each product is described by vectors of high-dimensional features. These models are suitable for business settings where there are an enormous number of distinct products. One important example is online ad markets. In this context, products are the impressions (user view) that are sold by the web publisher to advertisers. Due to the ever-growing amount of data that is available on the Internet, for each impression there is large number of associated features, including demographic information, browsing history of the user, and context of the webpage. Many other online markets, such as Airbnb, eBay and Etsy also have a similar setting in which products to be sold are highly differentiated. For example, in the case of Aribnb, the products are "stays" and each is characterized by a large number of features including space properties, location, amenities, house rules, as well as arrival dates, events in the area, availability of near-by hotels, etc (Airbnb Documentation, 2015).

Here, we consider a feature-based model that postulates a linear relation between the market value of each product and its feature values. Further, from the firm's perspective, we treat distinct buyers independently, and hereafter focus on a single buyer. Put it formally, we start with the following model for the buyer's valuation:

$$v(x_t) = \langle x_t, \theta\rangle + z_t\,, \tag{1}$$

where $x_t \in \mathbb{R}^d$ denotes the product feature vector, θ represents the buyer's preferences and z_t, $t \geq 1$ are idiosyncratic shocks, referred to as noise, which are drawn independently and identically from a zero mean distribution. For two vectors a, b, we write $\langle a, b\rangle$ to refer to their inner product. Feature vectors x_t are observable, while model parameter θ is a-priori unknown to the firm (seller). Therefore, the buyer's valuation $v(x_t)$ is also hidden from the firm.

Parameters of the above model represents how different features are weighted by the buyer in assessing the product. Considering such model, a firm can use historical sales data to estimate parameters of the valuation model, while concurrently collecting revenue from new sales. In practice, though, the buyer's valuation of a product will change over time and this raises the concern of *perishability* of sales data.

In order to capture this point, we consider a richer model with varying coefficients:

$$v_t(x_t) = \langle x_t, \theta_t\rangle + z_t\,. \tag{2}$$

Model parameters θ_t may change over time and as a result, valuation of a product depends on both the product feature vector and the time index.

We study a dynamic pricing problem, where at each time period t, the firm has a product to sell and after observing the product feature vector x_t, posts a price p_t. If the buyer's valuation is above the posted price, $v_t(x_t) \geq p_t$, a sale occurs and the firm collects a revenue of p_t. If the posted price exceeds the buyer's valuation, $p_t > v_t(x_t)$, no sale occurs. Note that at each step, the firm has access to the previous feedbacks (sale/no sale) from the buyer and can use this information in setting the current price.

In this paper, we will analyze the varying-coefficient model (2) and answer two fundamental questions:

> First, what is the value of knowing the sequence of model parameters θ_t; in other words, what is the expected revenue loss (regret) compared to the clairvoyant policy that knows the parameters of the valuation model in advance? Second, what is a good pricing policy?

The answer to the first question intrinsically depends on the temporal variability in the sequence θ_t. If this variation is very large, then there is not much that can be learnt

from previous feedback on the buyer's behavior and the problem turns into a random price experimentation. On the other hand, if all of the parameters θ_t are the same, then this feedback information can be used to learn the model parameters, which in turn helps in setting the future prices. In this case, an algorithm that performs a good balance between price exploration and best-guess pricing (exploitation) can lead to a small regret. In this work, we study this trade-off through a projected stochastic gradient descent algorithm and investigate the effect of variations of the sequence of θ_t on the regret bounds.

Feature-based models have recently attracted interest in dynamic pricing. (Amin et al., 2014) studied a similar model to (1) (without the noise terms z_t), where the features x_t are drawn from an unknown i.i.d distribution. A pricing strategy was proposed based on stochastic gradient descent, which results in a regret of the form $O(T^{2/3}\sqrt{\log T})$. This work also studied the problem of dynamic incentive compatibility in repeated posted-price auctions. Subsequently, (Cohen et al., 2016) studied model (1), wherein the feature vectors x_t are chosen antagonistically by nature and not sampled i.i.d. This work proposes a pricing policy based on the ellipsoid method from convex optimization (Boyd and Vandenberghe, 2004) with a regret bound of $O(d^2\log(T/d))$, under a low-noise setting. More accurately, the regret scales as $O(d^2\log(\min\{T/d, 1/\delta\}) + d\delta T)$, where δ measures the noise magnitude: in case of bounded noise, δ represents the uniform bound on noise and in case of gaussian noise with variance σ^2, it is defined as $\delta = 2\sigma\sqrt{\log(T)}$. In (Lobel et al., 2016), the regret bound of this policy was improved to $O(d\log T)$, under the noiseless setting. In (Javanmard and Nazerzadeh, 2016), authors study and highlight the role of the structure of demand curve in dynamic pricing. They introduce model (1), and assume that the feature vectors x_t are drawn i.i.d. from an unknown distribution. Further, motivated by real-world applications, it is assumed that the parameter vector θ is sparse in the sense that only a few of its entries are nonzero. A regularized log-likelihood approach is taken to get an improved regret bound of order $s_0(\log(d)+\log(T))$. We add to this body of work by considering feature-based models for valuation of products whose parameters vary over time.

Time-varying demand environments have also been studied recently by (Keskin and Zeevi, 2016). Explicitly, they consider a firm that sells one type of product to customers that arrive over a time horizon. After setting price p_t, the firm observes demand D_t given by $D_t = \alpha_t + \beta_t p_t + \epsilon_t$, where $\alpha_t, \beta_t \in \mathbb{R}$ are the unknown parameters of the demand model and ϵ_t are the unobserved demand shocks (noise). By contrast, in this work we consider different products, each characterized by a high-dimensional feature vector. Further, the seller only receives a binary feedback (sale/no sale) of the customer's behavior at each step, rather than observing the customer's valuation.

1.1 Organization of paper and our main contributions

The remainder of this paper is structured as follows. In Section 2, we formally define the model and formulate the problem. Technical assumptions and the notion of regret will be discussed in this section. We next propose a pricing policy based on projected stochastic gradient descent (PSGD) applied to the log-likelihood function. At each time period t, it returns an estimate $\widehat{\theta}_t$. The price p_t is then set to the optimal price as if $\widehat{\theta}_t$ was the actual parameter θ_t. We next analyze the regret of our PSGD algorithm. Let $\delta_t = \|\theta_{t+1} - \theta_t\|$ be the variation in model parameters at time period t. In Section 3.1, we consider the setting where the product feature vectors x_t are chosen antagonistically by nature and show that the regret of PSGD algorithm is of order $O(\sqrt{T} + \sum_{t=1}^{T}\sqrt{t}\delta_t)$. Interestingly, this bound is independent of the dimension d, which is a desirable property of our policy for high-dimensional applications. We next, in Section 4, consider a stochastic features model, where the feature vectors x_t are drawn independently from an unknown distribution (cf. Assumption 6). Under this setting, we show that the regret of PSGD is of order $O(d^2\log T + \sum_{t=1}^{T} t\delta_t/d)$. Note that setting $\delta_t = 0$ corresponds to model (1) and our PSGD pricing obtains a logarithmic regret in T. Section 7 is devoted to the proof of main theorems and the main lemmas are proved in Section 8. Finally, proof of several technical steps are deferred to Appendices.

1.2 Related literature

Our works is at the intersection of dynamic pricing, online optimization and high-dimensional statistics. In the following, we briefly discuss the work most related to ours from these contexts.

Feature-based dynamic pricing. Recent papers on dynamic pricing consider models with features/covariates, motivated in part by new advances in big data technology that allow firms to collect large amount of fine-grained information. In the introduction, we discussed the work (Amin et al., 2014; Javanmard and Nazerzadeh, 2016; Cohen et al., 2016) which are closely related to our setting. Another recent work on feature-based dynamic pricing is (Qiang and Bayati, 2016). In this work, authors consider a model where the seller observes the demand entirely, rather than a binary feedback as in our setting. A greedy iterative least squares (GILS) algorithm is proposed that at each time period estimates the demand as a linear function of price by applying least squares to the set of prior prices and realized demands. The work underscores the role of feature-based approaches and show that they create enough price dispersion to achieve a regret of $O(\log(T))$. This is closely related to the work of (den Boer and Zwart, 2013) and (Keskin and Zeevi, 2014) in dynamic pricing (without demand covariates) that demonstrate the GILS is suboptimal and propose methods to integrate forced price-dispersion with GILS to achieve optimal regret.

Online optimization. This field offers a variety of tools for sequential prediction, where an agent measures its predictive performance according to a series of convex functions. Specifically, there is a sequence of a priori unknown reward functions $f_1, f_2, f_3, \dots$ and an agent must make a sequence of decisions: at each time period t, he selects a point z_t and a loss $f_t(z_t)$ is incurred. Note that the function f_t is not known to agent at step t, but he has access to all previous functions $f_1, \dots, f_{t-1}$. First order methods, like online gradient descent (OGD) or online mirror descent (OMD) only use the gradient of previous function at the selected points, i.e., $\partial f_t(z_t)$. The notion of regret here is defined by comparing the agent with the best fixed comparator (Shalev-Shwartz, 2011).

(Hall and Willett, 2015) proposed dynamic mirror descent that is capable of adapting adapts to a possibly non-stationary environment. In contrast to OMD (Beck and Teboulle, 2003; Shalev-Shwartz, 2011), the notion of regret is defined more generally with respect to the best comparator "sequence".

It is worth noting that the general framework of online learning does not directly apply to our problem. To see this, we define the the loss f_t to be the negative of the revenue obtained

in time period t, i.e., $f_t = -p_t \mathbb{I}(p_t \geq v_t)$. Then (i) the loss functions are not convex; (ii) the (first order information) of previous loss functions depend on the corresponding valuations $v_1, \ldots, v_{t-1}$ which are never revealed to the seller. That said, we borrow some of the techniques from online optimization in proving our results. (See proof of Lemma 3.)

High-dimensional statistics. Among the work in this area, perhaps the most related one to our setting is the problem of 1-bit compressed sensing (Plan and Vershynin, 2013a,b; Ai et al., 2014; Bhaskar and Javanmard, 2015). In this problem, a set of linear measurements are taken from an unknown vector and the goal is to recover this vector having access to the sign of these measurements (1-bit information). This is related to the dynamic pricing problem on model (1), as the seller observes 1-bit feedback (sale/no sale from previous time periods). However, there are a few important differences between these two problem that are worth noting: 1) In dynamic pricing, the crux of the matter is the decisions (prices) made by the firm. Of course this task entails learning the model parameters and therefore the firm gets into the realm of exploration (learning) and exploitation (earning revenue). By contrast, 1-bit compressed sensing is only a learning task; 2) In dynamic pricing, the prices are set based on the previous (sale/no sale) feedbacks. Therefore, the feedbacks are inherently correlated and this makes the learning task challenging. However, in 1-bit compressed sensing it is assumed that the measurements (and therefore the observed signs) are independent; 3) The majority of work on 1-bit compressed sensing consider an offline setting, while in the dynamic pricing, decision are made in an online manner.

2. Model

We consider a pricing problem faced by a firm that sells products in a sequential manner. At each time period $t = 1, 2, \cdots, T$ the firm has a product to sell and the product is represented by an *observable* vector of features (covariates) $x_t \in \mathcal{X} \subseteq \mathbb{R}^d$. The length of the time horizon, denoted by T, is *unknown* the to the firm and the set $\mathcal{X}$ is bounded.

The product at time t has a market value $v_t = v_t(x_t)$, depending on both t and x_t, which is *unobservable*. At each period t, the firm (seller) posts a price p_t. If $p_t \leq v_t$, a sale occurs, and the firm collects revenue p_t. If the price is set higher than the market value, $p_t > v_t$, no sale occurs and no revenue is generated. The goal of the firm is to design a pricing policy that maximizes the collected revenue.

We assume that the market value of a product is a linear function of its covariates, namely

$$v_t(x_t) = \langle \theta_t, x_t \rangle + z_t \,. \tag{3}$$

Here, θ_t and x_t are d-dimensional and $\{z_t\}_{t\geq 1}$ are idiosyncratic shocks, referred to as noise, which are drawn independently and identically from a zero-mean distribution over $\mathbb{R}$. We denote its cumulative distribution function by F, and the corresponding density by $f(x) = F'(x)$. Note that the noise can account for the features that are not measured. We refer to (Keskin and Zeevi, 2014; den Boer and Zwart, 2014; Qiang and Bayati, 2016) for a similar notion of demand shocks.

The sequence of parameters $\boldsymbol{\theta} = (\theta_1, \theta_2, \ldots)$ is *unknown* to the firm and it may vary across time. This paper focuses on arbitrary sequences $\boldsymbol{\theta}$ and propose an efficient algorithm whose regret scale gracefully in time and the temporal variability in the sequences of θ_t.

The regret is measured with respect to the clairvoyant policy that knows the sequence $\boldsymbol{\theta}$ in advance. We will formally define the regret in Section 2.2.

Let y_t be the response variable that indicates whether a sale has occurred at period t:

$$y_t = \begin{cases} +1 & \text{if } v_t \geq p_t \,, \\ -1 & \text{if } v_t < p_t \,. \end{cases} \tag{4}$$

Note that the above model for y_t can be represented as the following probabilistic model:

$$y_t = \begin{cases} +1 & \text{with probability } \; 1 - F\left(p_t - \langle \theta_t, x_t \rangle\right) \\ -1 & \text{with probability } \; F\left(p_t - \langle \theta_t, x_t \rangle\right) \end{cases} \tag{5}$$

2.1 Technical assumptions and notations

For a vector v, we write $\|v\|_p$ for the standard ℓ_p norm of a vector v, i.e., $\|v\|_p = (\sum_i |v_i|^p)^{1/p}$. Whenever the subscript p is not mentioned it is deemed as the ℓ_2 norm. For a matrix A, $\|A\|$ denotes its ℓ_2 operator norm. For two vectors a, b, we use the notation $\langle a, b \rangle$ to refer to their inner product.

To simplify the presentation, we assume that $\|x_t\| \leq 1$, for all $x_t \in \mathcal{X}$, and $\|\theta_t\| \leq W$ for a known constant W. We denote by Θ the d-dimensional ℓ_2 ball of radius W (In fact, we can take Θ to be any convex set that contains parameters θ_t. The size of Θ effects our regret bounds up to a constant factor.)

We also make the following assumption on the distribution of noise F.

Assumption 1 *The function $F(v)$ is strictly increasing. Further, $F(v)$ and $1 - F(v)$ are log-concave in v.*

Log-concavity is a widely-used assumption in the economics literature (Bagnoli and Bergstrom, 2005). Note that if the density f is symmetric and the distribution F is log-concave, then $1 - F$ is also log-concave. Assumption 1 is satisfied by several common probability distributions including normal, uniform, Laplace, exponential, and logistic. Note that the cumulative distribution function of all log-concave densities is also log-concave (Boyd and Vandenberghe, 2004).

We use the standard big-O notation. In particular $f(n) = O(g(n))$ if there exists a constant $C > 0$ such that $|f(n)| \leq Cg(n)$ for all n large enough. We also use $\mathbb{R}_{\geq 0}$ to refer to the set of non-negative real-valued numbers.

2.2 Benchmark policy and regret minimization

For a pricing policy, we measures its performance via the notion of regret, which is the expected revenue loss compared to an oracle that knows the sequence of model parameters in advance (but not the realizations of $\{z_t\}_{t\geq 1}$).We first characterize this benchmark policy.

Using Eq. (3), the expected revenue from a posted price p is equal to $p \times \mathbb{P}(v_t \geq p) = p(1 - F(p - \theta_t \cdot x_t))$. First order condition for the optimal price $p^*(x_t, \theta_t)$ reads

$$p^*(x_t, \theta_t) = \frac{1 - F\left(p^*(x_t, \theta_t) - \langle \theta_t, x_t \rangle\right)}{f\left(p^*(x_t, \theta_t) - \langle \theta_t, x_t \rangle\right)} \,. \tag{6}$$

To lighten the notation, we drop the arguments x_t, θ_t and denote by p_t^* the optimal price at time t.

We next recall the *virtual valuation* function, commonly used in mechanism design (Myerson, 1981):

$$\varphi(v) \equiv v - \frac{1 - F(v)}{f(v)}\,.$$

Writing Eq. (6) in terms of function φ, we get

$$\langle \theta_t, x_t \rangle + \varphi\left(p_t^* - \langle \theta_t, x_t \rangle\right) = 0\,.$$

In order to solve for p_t^*, we define the pricing function g as follows:

$$g(v) \equiv v + \varphi^{-1}(-v)\,. \tag{7}$$

By Assumption 1, φ is injective and hence g is well-defined. Further, it is easy to verify that g is non-negative. Using the definition of g and rearranging the terms we obtain

$$p_t^* = g(\langle \theta_t, x_t \rangle)\,. \tag{8}$$

The performance metric we use in this paper is the worst-case regret with respect to a clairvoyant policy that knows the sequence $\boldsymbol{\theta}$ in advance. Formally, for a policy π to be the seller's policy that sets price p_t at period t, the worst-case regret is defined over T periods is defined as:

$$\mathsf{Regret}^{\pi}(T) \equiv \sup\left\{\Delta^{\pi}_{\boldsymbol{\theta},\boldsymbol{x}} : \theta_t \in \Theta,\, x_t \in \mathcal{X}\right\}\,, \tag{9}$$

where for $T \geq 1$, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_T)$ and $\boldsymbol{x} = (x_1, x_2, \ldots, x_T)$,

$$\Delta^{\pi}_{\boldsymbol{\theta},\boldsymbol{x}}(T) = \mathbb{E}_{\boldsymbol{\theta},\boldsymbol{x}}\left[\sum_{t=1}^{T}\left(p_t^*\mathbb{I}(v_t \geq p_t^*) - p_t\mathbb{I}(v_t \geq p_t)\right)\right]\,. \tag{10}$$

Here the expectation $\mathbb{E}_{\boldsymbol{\theta},\boldsymbol{x}}$ is with respect to the distributions of idiosyncratic noise, z_t. Note that v_t, p_t, and p_t^* depend on $\boldsymbol{\theta}$ and $\boldsymbol{x}$.

3. Pricing policy

Our dynamic pricing policy consists of a projected gradient descent algorithm to predict parameters $\widehat{\theta}_t$. With each new product, it computes the negative gradient of the loss and shirts its prediction in that direction. The result is projected onto set Θ to produce the next prediction. The policy then sets the prices as $p_t = g(\langle x_t, \widehat{\theta}_t \rangle)$. Note that by Eq. (7), p_t is the optimal price if $\widehat{\theta}_t$ was the true parameter θ_t. Also, by log-concavity assumption on F and $1 - F$, the function $\ell_t(\theta)$ is convex.

In projected gradient descent, the sequence of step sizes $\{\eta_t\}_{t\geq 1}$ is an arbitrary sequence of non-increasing values. In Sections 3.1 and 4, we analyze the regret of our pricing policy and provide guidelines for choosing step sizes.

PSGD (Projected stochastic gradient descent) pricing policy

Input: **(at time** 0**)** function g, set Θ,
Input: **(arrives over time)** covariate vectors $\{x_t\}_{t\in\mathbb{N}}$
Output: prices $\{p_t\}_{t\in\mathbb{N}}$

1: $p_1 \leftarrow 0$ and initialize $\widehat{\theta}_1 \in \Theta$
2: **for** $t = 1, 2, 3, \ldots$ **do**
3: Set $\widehat{\theta}_{t+1}$ according to the following rule:

$$\widehat{\theta}_{t+1} = \Pi_{\Theta}(\widehat{\theta}_t - \eta_t \nabla \ell_t(\widehat{\theta}_t)) \tag{11}$$

with

$$\ell_t(\theta) = -\mathbb{I}(y_t = 1)\log(1 - F(p_t - \langle x_t, \theta\rangle)) - \mathbb{I}(y_t = -1)\log(F(p_t - \langle x_t, \theta\rangle)) \tag{12}$$

4: Set price p_{t+1} as

$$p_{t+1} \leftarrow g(\langle x_{t+1}, \widehat{\theta}_{t+1}\rangle) \tag{13}$$

3.1 Regret analysis

We first define a few useful quantities that appear in our regret bounds. Define

$$M \equiv W + \varphi^{-1}(0)\,, \tag{14}$$

$$u_M \equiv \sup_{|x|\leq M}\left\{\max\left\{-\frac{\mathrm{d}}{\mathrm{d}x}\log F(x), -\frac{\mathrm{d}}{\mathrm{d}x}\log(1 - F(x))\right\}\right\}\,, \tag{15}$$

$$\ell_M \equiv \inf_{|x|\leq M}\left\{\min\left\{-\frac{\mathrm{d}^2}{\mathrm{d}x^2}\log F(x), -\frac{\mathrm{d}^2}{\mathrm{d}x^2}\log(1 - F(x))\right\}\right\}\,, \tag{16}$$

where the derivatives are with respect to x. We note that M is an upper-bound on the maximum price offered and also, by the log-concavity property of F and $1 - F$, we have

$$u_M = \max\left\{-\frac{\mathrm{d}}{\mathrm{d}x}\log F(-M), -\frac{\mathrm{d}}{\mathrm{d}x}\log(1 - F(M))\right\}.$$

Further, by log-concavity property of F and $1 - F$, we have $\ell_M > 0$.

We also let $B = \max_v f(v)$ and $B' = \max_v f'(v)$, respectively denote the maximum value of the density function f and the its derivative f'.

The following theorem bounds the regret of our PSGD policy.

Theorem 2 *Consider model* (3) *for the product market values and let Assumption 1 hold. Set* $M = 2W + \varphi^{-1}(0)$*, with* φ *being the virtual valuation function w.r.t distribution* F*. Then, the regret of PSGD pricing policy using a non-increasing sequence of step sizes* $\{\eta_t\}_{t\geq 1}$ *is bounded as follows:*

$$\mathsf{Regret}(T) \leq \frac{2(2B + MB')}{\ell_M}\max\left\{\frac{16}{\ell_M}\log T,\, \frac{2W^2}{\eta_{T+1}} + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t}\right\} + \frac{M}{T}\,, \tag{17}$$

where $\delta_t \equiv \|\theta_{t+1} - \theta_t\|$.

In particular, if $\eta_t \propto \frac{1}{\sqrt{t}}$, then there exists a constant $C = C(B, M, W, \ell_M, u_M) > 0$, independent of T, such that

$$\mathsf{Regret}(T) \leq C\Big(\sqrt{T} + \sum_{t=1}^{T} \sqrt{t}\delta_t\Big)\,. \tag{18}$$

At the core of our regret analysis (proof of Theorem 2) is the following Lemma that provides a prediction error bound for the customer's valuations.

Lemma 3 *Consider model* (3) *for the product market values and let Assumption 1 hold. Set* $M = 2W + \varphi^{-1}(0)$*, with* φ *being the virtual valuation function w.r.t distribution* F*. Let* $\{\widehat{\theta}_t\}_{t\geq 1}$ *be generated by PSGC pricing policy, using a non-increasing positive series* $\eta_{t+1} \leq \eta_t$*. Then, with probability at least* $1 - \frac{1}{T^2}$ *the following holds true:*

$$\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \leq \frac{4}{\ell_M}\max\Bigg\{\frac{16}{\ell_M}\log T, \frac{2W^2}{\eta_1} + \sum_{t=1}^{T}\Big(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\Big)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t}\Bigg\}\,, \tag{19}$$

where u_M, ℓ_M *are given by Equations* (15), (16)*, respectively.*

Lemma 3 is presented in a form that can also be used in proving our next results under the stochastic features model. For proving Theorem 2, we simplify bound (19) as follows. Given that $\theta_{t+1}, \widehat{\theta}_{t+1} \in \Theta$, we have $\|\theta_{t+1} - \widehat{\theta}_{t+1}\| \leq 2W$. Using the non-increasing property of sequence η_t, we write

$$\frac{2W^2}{\eta_1} + \sum_{t=1}^{T}\left(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\right)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 \leq \frac{2W^2}{\eta_1} + \sum_{t=1}^{T}\left(\frac{2W^2}{\eta_{t+1}} - \frac{2W^2}{\eta_t}\right) \leq \frac{2W^2}{\eta_{T+1}}\,.$$

Therefore, bound (19) simplifies to:

$$\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \leq \frac{4}{\ell_M}\max\Big\{\frac{16}{\ell_M}\log T, \frac{2W^2}{\eta_{T+1}} + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t}\Big\}, \tag{20}$$

The regret bound (17) is derived by relating regret at each time period to the prediction error at that time. We refer to Section 7 for the proof of Theorem 2.

Remark 4 *The regret bound* (17) *does not depend on the dimension* d*, which makes our pricing policy desirable for high-dimensional applications. Also, note that the temporal variation* δ_t *appears in our bound with coefficient* $\sqrt{t}$*. Therefore, variations at later times are more impactful on the regret of PSGD pricing policy. This is expected because at later times, the pricing policy is more relied on the accumulated information about the valuation model and an abrupt change in the model parameters can make this information worthless. On the other side, temporal changes at the beginning steps are not that effective since the policy is still experimenting different prices to learn the customer's behavior.*

Remark 5 *While the regret bound is dimension-free, the computational complexity of PSGD pricing policy scales with dimension* d*. Specifically, the complexity of each step is* $O(d)$*. To see this, we note that the gradient* $\nabla\ell_t(\theta)$ *can be computed in* $O(d)$ *by Equations* (70) *and* (71)*. Projection onto set* Θ *(*ℓ_2 *projection) is also* $O(d)$*.*

4. Stochastic features model

In Theorem 2, we showed that our PSGD pricing policy achieves regret of order $O(\sqrt{T} + \sum_{t=1}^{T}\sqrt{t}\delta_t)$. Let us point out that in Theorem 2 the arrivals (feature vectors x_t) are modeled as adversarial. In this section, we assume that features x_t are independent and identically distributed according to a probability distribution on $\mathbb{R}^d$. Under such stochastic model, we show that the regret of PSGD pricing scales at most of order $O(d^2\log T + \sum_{t=1}^{T} t\delta_t/d)$.

We proceed by formally defining the stochastic features model.

Assumption 6 *(*Stochastic features model*). Feature vectors* x_t *are generated independently according to a probability distribution* $\mathbb{P}_{\boldsymbol{x}}$*, with a bounded support in* $\mathbb{R}^d$*. We denote by* Σ *the covariance matrix of distribution* $\mathbb{P}_{\boldsymbol{x}}$ *and assume that* Σ *has bounded eigenvalues. Specifically, there exist constants* $C_{\min}$ *and* $C_{\max}$ *such that for every eigenvalue* σ *of* Σ*, we have* $0 < \frac{1}{d}C_{\min} \leq \sigma < \frac{1}{d}C_{\max}$*.*

Without loss of generality and to simplify the presentation, we assume that $\mathbb{P}_{\boldsymbol{x}}$ is supported on the unit ℓ_2 ball in $\mathbb{R}^d$. The rationale behind the above assumption on the scaling of eigenvalues is that $\mathrm{Trace}(\Sigma) = \mathbb{E}(\|x_t\|^2) \leq 1$. Therefore, the assumption above on the eigenvalues of Σ states that all the eigenvalues are of the same order.

Under the stochastic features model, we define the notion of worst-case regret as follows. For a policy π be the seller's policy that sets price p_t at period t, the T-period regret is defined as:

$$\mathsf{Regret}^{\pi}(T) \equiv \sup\left\{\Delta^{\pi}_{\boldsymbol{\theta},\mathbb{P}_{\boldsymbol{x}}} : \theta_t \in \Theta, \mathbb{P}_{\boldsymbol{x}} \in Q\right\}\,, \tag{21}$$

where Q denotes the set of probability distribution supported on ℓ_2 unit ball satisfying Assumption 6 (bounded eigenvalues). Further, for $T \geq 1$, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_T)$ and probability measure $\mathbb{P}_{\boldsymbol{x}}$, we define

$$\Delta^{\pi}_{\boldsymbol{\theta},\mathbb{P}_{\boldsymbol{x}}}(T) = \mathbb{E}_{\boldsymbol{\theta},\mathbb{P}_{\boldsymbol{x}}}\left[\sum_{t=1}^{T}\Big(p_t^*\mathbb{I}(v_t \geq p_t^*) - p_t\mathbb{I}(v_t \geq p_t)\Big)\right]\,. \tag{22}$$

where the expectation is with respect to the distributions of idiosyncratic noise, z_t, and $\mathbb{P}_{\boldsymbol{x}}$, the distribution of feature vectors. Note the subtle difference with definition (9), in that the worst case is computed over Q rather than $\mathcal{X}$.

We propose a similar PSGD pricing policy for this setting, with a specific choice of the step sizes. Ideally, we want to set $\eta_t = 6/(\ell_M C t)$, where C is an arbitrary fixed constant such that $0 < C < \sigma_{\min}$, with $\sigma_{\min}$ being the minimum eigenvalue of population covariance Σ. Of course, Σ is unknown and therefore we proceed as follows. We let $Q_t = (1/t)\sum_{\ell=1}^{t} x_\ell x_\ell^{\mathsf{T}}$ be the empirical covariance based on the first t features. Denote by σ_t the minimum eigenvalue of Q_t. We then use the sequence σ_t, and set the step size η_t as

$$\eta_t = \frac{1}{\lambda_t \cdot t}\,, \qquad \lambda_t = \frac{\ell_M}{6}\left\{\frac{1}{t}\Big(1 + \sum_{\ell=1}^{t}\sigma_\ell\Big)\right\}\,.$$

PSGD pricing policy for stochastic features model

Input: (at time 0) function g, set Θ,
Input: (arrives over time) covariate vectors $\{x_t\}_{t\in\mathbb{N}}$
Output: prices $\{p_t\}_{t\in\mathbb{N}}$

1: $p_1 \leftarrow 0$ and initialize $\widehat{\theta}_1 \in \Theta$
2: $Q_1 \leftarrow x_1 x_1^{\mathsf{T}}$
3: **for** $t = 1, 2, 3, \ldots$ **do**
4: Define σ_t as the minimum eigenvalue of Q_t.
5: Set

$$\lambda_t = \frac{\ell_M}{6t}(1 + \sum_{\ell=1}^{t} \sigma_\ell)\,. \tag{23}$$

6: Set

$$\eta_t = \frac{1}{\lambda_t \cdot t} \tag{24}$$

7: Set $\widehat{\theta}_{t+1}$ according to the following rule:

$$\widehat{\theta}_{t+1} = \Pi_\Theta(\widehat{\theta}_t - \eta_t \nabla \ell_t(\widehat{\theta}_t)) \tag{25}$$

with

$$\ell_t(\theta) = -\mathbb{I}(y_t = 1)\log(1 - F(p_t - \langle x_t, \theta\rangle)) - \mathbb{I}(y_t = -1)\log(F(p_t - \langle x_t, \theta\rangle)) \tag{26}$$

8: $Q_{t+1} \leftarrow (\frac{t}{t+1})Q_t + (\frac{1}{t+1})x_{t+1}x_{t+1}^{\mathsf{T}}$
9: Set price p_{t+1} as

$$p_{t+1} \leftarrow g(\langle x_{t+1}, \widehat{\theta}_{t+1}\rangle) \tag{27}$$

Description of the PSGD pricing policy is given in Table above.

4.1 Logarithmic regret bound

The following theorem bounds the regret of our dynamics pricing policy.

Theorem 7 *Consider model* (3) *for the product market values and suppose Assumption 1 holds. Let* $M = 2W + \varphi^{-1}(0)$*, with* φ *being the virtual valuation function w.r.t distribution* F*. Under the stochastic features model (Assumption 6), the regret of PSGD pricing policy is bounded as follows:*

$$\mathsf{Regret}(T) \le C_1 d^2 \log T + C_2 \sum_{t=1}^{T} \frac{t}{d}\delta_t\,, \tag{28}$$

where $\delta_t \equiv \|\theta_{t+1} - \theta_t\|$ *and* C_1, C_2 *are constants that depend on* $C_{\max}, C_{\min}, u_M, \ell_M, M, B, W$ *but are independent of dimension* d*.*

Proof of Theorem 7 relies on the following lemma that is analogous to Lemma 3 and establishes a prediction error bound for the customer's valuations.

Lemma 8 *Consider model* (3) *for the product market values and the stochastic features model (Assumption 6). Suppose that Assumption 1 holds and set* $M = 2W + \varphi^{-1}(0)$*, with* φ *being the virtual valuation function w.r.t distribution* F*. Let* $\{\widehat{\theta}_t\}_{t\ge 1}$ *be generated by PSGD pricing policy. Then,*

$$C_{\min}\sum_{t=1}^{T}\mathbb{E}(\|\theta_t - \widehat{\theta}_t\|^2) \le \left[\frac{128}{\ell_M^2} + \frac{24u_M^2}{\ell_M^2}\left(\tilde{c} + \frac{4}{C_{\min}d}\right)\right]\cdot d^3 \log T + 8W^2 d\left(\frac{1}{T} + \frac{12}{\ell_M^2} + \frac{1}{c_2 d}\right) + 4W\sum_{t=1}^{T} t\delta_t\,.$$

Here $\sigma_{\min}$ *denotes the minimum eigenvalue of covariance* Σ*. (See Assumption 6.)*

4.2 A lower bound on regret

In this section, we provide a theoretical lower bound on the minimum achievable regret of any pricing policy under the stochastic features model. Prior to that, we need to adopt a few notations.

For a given time horizon T and a sequence of valuations parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_T)$, let

$$V_{\boldsymbol{\theta}}(T) \equiv \sum_{t=1}^{T} t\|\theta_{t+1} - \theta_t\|\,. \tag{29}$$

We also define, for $\nu \in [1/2, 2]$,

$$\mathcal{V}(T, B, \nu) \equiv \{\boldsymbol{\theta} :\ \theta_t \in \Theta,\, V_{\boldsymbol{\theta}}(T) \le BdT^\nu\}\,. \tag{30}$$

By assuming $\boldsymbol{\theta} \in \mathcal{V}(T, B, \nu)$ for all T, we are assuming that nature has a finite temporal variation budget to use in changing the valuation parameters throughout the time horizon. Of course, different variation metrics can be considered such as total variation $\sum_{t=1}^{T}\delta_t$ or the maximum temporal variation $\sup_{1\le t\le T}\delta_t$ and the performance of a pricing policy can be studied under different variation budget constraints. The specific choice of (29) is putting higher weights at later variations in the sequence $\boldsymbol{\theta}$ and is reasonable for applications where one expects the buyer's preferences (valuation parameters) become stable over time. Note that designing favorable pricing policy for applications with gradual changes in buyer's preferences is more challenging than that for environments with bursty changes. This might look counterintuitive at first glance because at any time, the accumulated information about valuations can become useless by an abrupt change in the valuation model. However, as noticed and analyzed in (Keskin and Zeevi, 2016), this is not that case because, intuitively, gradual changes can be undetectable and lead to significant revenue loss, while for bursty

changes, the policy can be designed in a way to detect the changes and reset its estimate of the valuation model after each change to avoid large estimation error and revenue loss. For a pricing policy π, consider the T-period regret, defined as

$$\mathsf{Regret}^{\pi}(T, B, \nu) \equiv \max \left\{ \Delta^{\pi}_{\boldsymbol{\theta}, \mathbb{P}_{\boldsymbol{x}}}(T) : \boldsymbol{\theta} \in \mathcal{V}(T, B, \nu),\, \mathbb{P}_{\boldsymbol{x}} \in Q \right\} \tag{31}$$

where we recall that

$$\Delta^{\pi}_{\boldsymbol{\theta}, \mathbb{P}_{\boldsymbol{x}}}(T) \equiv \sum_{t=1}^{T} \mathbb{E}_{\boldsymbol{\theta}, \mathbb{P}_{\boldsymbol{x}}} \Big(p_t^* \mathbb{I}(v_t \geq p_t^*) - p_t \mathbb{I}(v_t \geq p_t) \Big) \,. \tag{32}$$

Note that this is the same regret notion defined in (21), where we just make the variation budget constraint explicit in the notation.

Rephrasing the statement of Theorem 7, for PSGD pricing policy we have $\mathsf{Regret}^{\pi}(T, B, \nu) \leq C_1 d^2 \log T + C_2 B T^{\nu}$. We next provide a lower bound on the regret of any pricing policy. Indeed this lower bound applies to a powerful clairvoyant who fully observes the market values after the price is either accepted or rejected.

Theorem 9 *Consider linear model* (3) *where the market values $v_t(x_t)$, $1 \leq t \leq T$, are fully observed. We further assume that market value noises are generated as $z_t \sim \mathsf{N}(0, \sigma^2)$. There exists a constant c, depending on σ, $C_{\max}$, such that*

$$\mathsf{Regret}^{\pi}(T, B, \nu) \geq c \min \Big(\big(B^2 d T^{2\nu-1}\big)^{1/3}, T/d \Big) \,,$$

for any pricing policy π and time horizon T.

The high-level intuition behind this result is that the nature can change the valuation parameters in a gradual manner such that the seller should pay a revenue loss in order to detect the changes and learn the new valuation parameter after a change. To be more specific, we divide the time horizon into cycles of length N periods, where N is of order $(T^{4-2\nu}/d)^{1/3}$ and consider a setting where the value of θ_t can change to one of two options θ^0, θ^1, only in the first period of a cycle. We choose the parameter change $\delta = \|\theta^1 - \theta^0\|$ of order $\sqrt{d/N}$ to ensure that (i) no policy can identify the change without incurring a revenue loss of order $N\delta^2/d$ (ii) The variation metric $V_{\boldsymbol{\theta}}(T)$ remains below the allowable limit of BdT^{ν}. Therefore, the total regret over T periods works out at $T\delta^2/d$. In particular, for proving point (i) we quantify the likelihood of valuations under the probability measures corresponding to θ^0 and θ^1, using Kullback-Leibler divergence. We use Pinsker inequality form probability theory and hypothesis testing results from information theory to show that there is a significant probability of not detecting the (potential) change, which consequently yields a revenue loss of order $N\delta^2/d$, over each cycle.

We refer to Section 7.3 for the proof of Theorem 9.

5. Numerical experiments

We numerically study the performance of our PSGD pricing policy on synthetic data. In our experiments, we set $W = 5$ and set $\theta_1 = (W/2)(Z/\|Z\|)$, with $Z \sim \mathsf{N}(0, \mathrm{I}_d)$ a multivariate normal variable. We then generate a sequence of parameters θ_t as follows:

$$\theta_{t+1} = \theta_t + r_t \,,$$

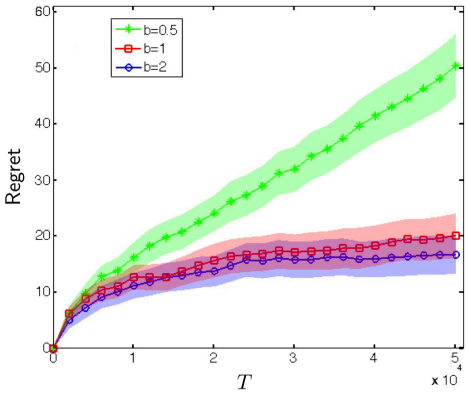

Figure 1: Cumulative regret of PSGD pricing policy for the synthetic data in Section 5. Temporal variations are $\delta_t = t^{-b}$ and the curves are obtained by averaging across 80 trials. Shaded region around each curve is the 95% confidence interval.

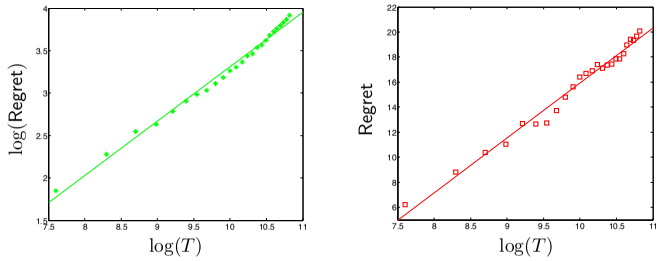
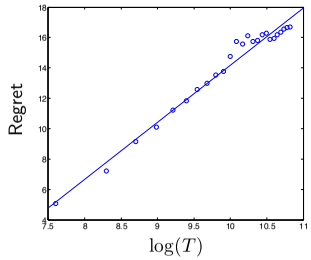
where $r_t = t^{-b}(\tilde{Z}/\|\tilde{Z}\|)$, with $\tilde{Z} \sim \mathsf{N}(0, \mathrm{I}_d)$. Note that $\delta_t = \|\theta_{t+1} - \theta_t\| = \|r_t\| = t^{-b}$.

Next, at each time t, product covariates x_t are independently sampled from a Gaussian distribution $\mathsf{N}(0, \mathrm{I}_d)$ and normalized so that $\|x_t\| = 1$. Further, the market shocks are generated as $z_t \sim \mathsf{N}(0, \sigma^2)$, with $\sigma = 1$. We run the PSGD pricing policy for stochastic features model.



Results. Figure 1 compares the cumulative regret (averaged over 80 trials) of the PSGD policy, for $b = 0.5, 1, 2$, on the aforementioned synthetic data for $T = 50,000$ steps. The shaded region around each curve correspond to the 95% confidence interval across the 80 trials. As expected, increase in b results in larger temporal variations and larger regret.

To better understand the behavior of regret for different values of b, we plotted the regret bounds in various scales in Figure 2. For $b = 0.5$, we have $\mathsf{Regret}(T) \sim T^{2/3}$, and for $b = 1, 2$, we have $\mathsf{Regret} \sim \log(T)$. Comparing with Theorem 7, we see that the empirical regret in case of $b = 0.5$, 1, is smaller than the upper bound given by Equation (28), order-wise. However, it is worth noting that bound given in Theorem 7 applies to any adversarial choice of temporal variations r_t, while in our experiments we generated these terms independently at random.



6. Extension to nonlinear model

Throughout the paper, we exclusively focused on linear models for buyer's valuation with varying coefficients. In order to generalize our results to nonlinear models, we consider a setting where the market value of a product with feature vector x_t is given by

$$v_t(x_t) = \psi(\langle x_t, \theta_t \rangle + z_t) \,. \tag{33}$$

(a) $b = 0.5$ (b) $b = 1$

(c) $b = 2$

Figure 2: Cumulative regrets of PSGD for different values of b. For $b = 0.5$, $\mathsf{Regret}(T) \sim T^{2/3}$; for $b = 1, 2$, $\mathsf{Regret}(T) \sim \log(T)$.

This model is often referred to as generalized linear model and captures nonlinear dependencies on features to some extent. We assume that the link function $\psi : \mathbb{R} \mapsto \mathbb{R}$ is a general log-concave function and is strictly increasing.

We next compute the pricing function. Since ψ is strictly increasing, the expected revenue at a price p amounts to $p\left(1 - F\left(\psi^{-1}(p) - \langle x_t, \theta_t\rangle\right)\right)$. First order condition for the optimal price $p_t^*(x_t)$ reads as

$$\psi'(\psi^{-1}(p_t^*)) = \frac{pf\left(\psi^{-1}(p_t^*) - \langle x_t, \theta_t\rangle\right)}{1 - F\left(\psi^{-1}(p_t^*) - \langle x_t, \theta_t\rangle\right)}\,. \tag{34}$$

Define $\lambda(v) = f(v)/(1 - F(v))$ the hazard rate function for distribution F, and let $\tilde{p} = \psi^{-1}(p)$. Writing (34) in terms of λ function, we get

$$\langle x_t, \theta_t\rangle = \tilde{p}_t^* - \lambda^{-1}\left(\frac{\psi'(\tilde{p}_t^*)}{\psi(\tilde{p}_t^*)}\right)\,. \tag{35}$$

For real-valued v, define

$$g_\psi^{-1}(v) \equiv v - \lambda^{-1}\left(\frac{\psi'(v)}{\psi(v)}\right)\,. \tag{36}$$

Note that by log-concavity of $1 - F$, the hazard function λ is increasing. Also, by log-concavity of ψ, the term $\frac{\mathrm{d}}{\mathrm{d}v}\log\psi(v) = \psi'(v)/\psi(v)$ is decreasing. Putting these together, we obtain that $-\lambda^{-1}(\psi'(v)/\psi(v))$ is increasing. Therefore, the right-hand side of (36) is strictly increasing and the function g_ψ is well-defined. Invoking Equation (35), we derive the optimal price as

$$p_t^* = \psi\left(g_\psi(\langle x_t, \theta_t\rangle)\right)\,. \tag{37}$$

As noted before, since ψ is increasing, at each period t, a sale happens if $z_t \geq \psi^{-1}(p_t) - \langle x_t, \theta_t\rangle$. Hence, the log-likelihood function reads as

$$\ell_t(\theta) = -\mathbb{I}(y_t = 1)\log\left(1 - F\left(\psi^{-1}(p_t) - \langle x_t, \theta\rangle\right)\right) - \mathbb{I}(y_t = -1)\log\left(F\left(\psi^{-1}(p_t) - \langle x_t, \theta\rangle\right)\right)\,. \tag{38}$$

In PSGD pricing policy, we run gradient step with this log-likelihood function and then set price p_{t+1} at next step as $p_{t+1} = \psi\left(g_\psi(\langle x_{t+1}, \theta_{t+1}\rangle)\right)$.

The results on the regret of PSGD pricing policy carries over to the generalized linear model as well. The analysis goes along the same lines and is omitted.

7. Proof of main theorems

7.1 Proof of Theorem 2

Lemma 10 *Set $M = 2W + \varphi^{-1}(0)$, and for $\theta \in \Theta$ define $u_t(\theta) = p_t - \langle x_t, \theta\rangle$, where $p_t = g(\langle x_t, \widehat{\theta}_t\rangle)$ is the posted price at time t. Then $|u_t(\theta)| \leq M$ for all $t \geq 1$.*

Define function $h(\,;u)$ from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}_{\geq 0}$ as

$$h(p;u) = p(1 - F(p - u))$$

This is the expected revenue at price p when the noiseless valuation is u, i.e., $\langle x_t, \theta_t\rangle = u$. We let

$$R_t \equiv p_t^* \mathbb{I}(v_t \geq p_t^*) - p_t \mathbb{I}(v_t \geq p_t) \tag{39}$$

be the regret incurred at time t, and define $\mathcal{F}_t$ as the history up to time t (Formally, $\mathcal{F}_t$ is the σ-algebra generated by market noise $\{z_\ell\}_{\ell=1}^t$.) Then,

$$\mathbb{E}(R_t|\mathcal{F}_{t-1}) = p_t^* \mathbb{P}(v_t \geq p_t^*) - p_t \mathbb{P}(v_t \geq p_t) = h(p_t^*; \langle x_t, \theta_t\rangle) - h(p_t; \langle x_t, \widehat{\theta}_t\rangle)\,. \tag{40}$$

The optimal price p_t^* is the maximizer of $h(p; \langle x_t, \theta_t\rangle)$ and thus $h'(p_t^*; \langle x_t, \theta_t\rangle) = 0$. By Taylor expansion of function h, there exists a value p between p_t and p_t^*, such that,

$$h(p_t; \langle x_t, \theta_t\rangle) - h(p_t^*; \langle x_t, \theta_t\rangle) = \frac{1}{2} h''(p; \langle x_t, \theta_t\rangle)(p_t - p_t^*)^2\,. \tag{41}$$

We next show that $|h''(p; \langle x_t, \theta_t\rangle)| \leq C$ with $C = 2B + MB'$. Recall that $B = \max_v f(v)$ and $B' = \max_v f'(v)$. To see this, we write

$$|h''(p; \langle x_t, \theta_t\rangle)| = \Big|2f(p - \langle x_t, \theta_t\rangle) + pf'(p - \langle x_t, \theta_t\rangle)\Big| \leq 2B + MB'\,. \tag{42}$$

Putting Equations (39), (41), (42) and using the 1-Lipschitz property of price function g, we conclude:

$$\begin{aligned}\mathbb{E}[R_t|\mathcal{F}_{t-1}] &= h(p_t^*; \langle x_t, \theta_t\rangle) - h(p_t; \langle x_t, \widehat{\theta}_t\rangle) \leq \frac{2B + MB'}{2}(p_t - p_t^*)^2 \\ &= \frac{2B + MB'}{2}\Big(g(\langle x_t, \widehat{\theta}_t\rangle) - g(\langle x_t, \theta_t\rangle)\Big)^2 \leq \frac{2B + MB'}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \end{aligned} \tag{43}$$

To ease the presentation, define the shorthand

$$A(T) \equiv \frac{4}{\ell_M} \max\left\{\frac{16}{\ell_M}\log T,\, \frac{2W^2}{\eta_{T+1}} + \frac{u_M^2}{2}\sum_{t=1}^T \eta_t + 2W\sum_{t=1}^T \frac{\delta_t}{\eta_t}\right\}.$$

We further let $\mathcal{G}$ be the probabilistic event that $\sum_{t=1}^T \langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \leq A(T)$. Employing Lemma 3 and using the fact that $\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 \leq 4W^2$, we obtain that $\mathbb{P}(\mathcal{G}) \geq 1 - \frac{1}{T^2}$.

We continue by bounding $E(R_t)$ as follows:

$$\begin{aligned}\mathbb{E}[R_t] &= \mathbb{E}[\mathbb{E}[R_t|\mathcal{F}_{t-1}]] = \mathbb{E}\Big[\mathbb{E}[R_t|\mathcal{F}_{t-1}]\cdot\Big(\mathbb{I}(\mathcal{G}) + \mathbb{I}(\mathcal{G}^c)\Big)\Big] \\ &= \frac{2B + MB'}{2}\mathbb{E}\Big[\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \cdot \mathbb{I}(\mathcal{G})\Big] + M\mathbb{P}(\mathcal{G}^c)\,.\end{aligned}$$

Consequently,

$$\mathsf{Regret}(T) \leq \sum_{t=1}^T \mathbb{E}[R_t] \leq \frac{2B + MB'}{2}\mathbb{E}\Big[\sum_{t=1}^T \langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \cdot \mathbb{I}(\mathcal{G})\Big] + MT\,\mathbb{P}(\mathcal{G}^c) \leq \frac{2B + MB'}{2}A(T) + \frac{M}{T}\,.$$

The proof is complete.

7.2 Proof of Theorem 7

Proof of Theorem 7 follows along the same lines as proof of Theorem 2. Let $\tilde{\mathcal{F}}_t$ be the σ-algebra generated by market noises $\{z_\ell\}_{\ell=1}^t$ and feature vectors $\{x_\ell\}_{\ell=1}^t$. Further, let $\mathcal{F}_t$ be the σ-algebra generated by $\tilde{\mathcal{F}}_t \cup \{x_{t+1}\}$. For term R_t defined by (39) and following the chain of inequalities as in (43),

$$\mathbb{E}[R_t|\mathcal{F}_{t-1}] \leq \frac{2B + MB'}{2}\,\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\,. \tag{44}$$

For brevity in notation, let $\bar{B} = (2B + MB')/2$. Since, $\mathcal{F}_t \supseteq \tilde{\mathcal{F}}_t$, by iterated law of iteration,

$$\mathbb{E}(R_t|\tilde{\mathcal{F}}_{t-1}) = \mathbb{E}(\mathbb{E}(R_t|\mathcal{F}_{t-1})|\tilde{\mathcal{F}}_{t-1}) \leq \bar{B}\langle \theta_t - \widehat{\theta}_t, \Sigma(\theta_t - \widehat{\theta}_t)\rangle \leq \frac{1}{d}\bar{B}C_{\max}\|\theta_t - \widehat{\theta}_t\|^2 \tag{45}$$

Applying Lemma 8, we get

$$\begin{aligned}\mathsf{Regret}(T) &\leq \sum_{t=1}^T \mathbb{E}[R_t] \leq \frac{1}{d}\bar{B}C_{\max}\sum_{t=1}^T \mathbb{E}(\|\theta_t - \widehat{\theta}_t\|^2) \\ &\leq \bar{B}\frac{C_{\max}}{C_{\min}}\left[\frac{128}{\ell_M^2} + \frac{24u_M^2}{\ell_M^2}\left(\tilde{c} + \frac{4}{C_{\min}d}\right)\right]\cdot d^2\log T \\ &\quad + 8W^2\bar{B}\frac{C_{\max}}{C_{\min}}\left(\frac{1}{T} + \frac{12}{\ell_M^2} + \frac{1}{c_2 d}\right) + \bar{B}\frac{C_{\max}}{C_{\min}}\Big(\frac{4W}{d}\Big)\sum_{t=1}^T t\delta_t\,.\end{aligned}$$

The result follows by taking

$$\begin{aligned}C_1 &= \bar{B}\frac{C_{\max}}{C_{\min}}\left[8W^2\left(\frac{1}{T} + \frac{12}{\ell_M^2} + \frac{1}{c_2 d}\right) + \frac{128}{\ell_M^2} + \frac{24u_M^2}{\ell_M^2}\left(\tilde{c} + \frac{4}{C_{\min}d}\right)\right]\,, \\ C_2 &= 4W\bar{B}\frac{C_{\max}}{C_{\min}}\,.\end{aligned}$$

7.3 Proof of Theorem 9

The proof methodology is similar to the proof of (Keskin and Zeevi, 2016, Theorem 1).

We first propose a setting for constructing the sequence of valuation parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_T)$. Divide the time horizon into cycles of length $N = \lceil m_0 T^{(4-2\nu)/3}\rceil$, where $m_0 = (\frac{\sigma^2}{C_{\max}B^2 d})^{1/3}$. Consider a setting wherein the noise markets are generated as $z_t \sim \mathsf{N}(0, \sigma^2)$ and the value of θ_t can change only in the first period of a cycle, taking one of the two values $\{\theta^0, \theta^1\}$. Here, $\theta^0, \theta^1 \in \mathbb{R}^d$ are two arbitrary vectors such that $\|\theta^0 - \theta^1\| = \delta$, with $\delta = \min(\sigma\sqrt{d/(C_{\max}N)}, \sqrt{c_2})$. Note that for this sequence of $\boldsymbol{\theta}$, we have

$$V_{\boldsymbol{\theta}}(T) \leq \sum_{k=1}^{\lceil T/N\rceil}(kN)\delta \leq \frac{T^2}{N}\delta \leq BdT^\nu \tag{46}$$

We consider a clairvoyant who fully observes the market values $v_t(x_t)$. Focus on a single cycle and let $\mathbb{P}_0^\pi$ (resp. $\mathbb{P}_1^\pi$) denote the probability distribution of valuations $(v_1, v_2, \ldots, v_N)$

when all the parameters θ_t are equal to θ^0 (resp. θ^1), for $1 \le t \le N$. The KL divergence between $\mathbb{P}_0^\pi$ and $\mathbb{P}_1^\pi$ amounts to

$$D_{\mathrm{KL}}(\mathbb{P}_0^\pi, \mathbb{P}_1^\pi) \equiv \mathbb{E}_0^\pi \log \left(\frac{\prod_{t=1}^N \phi\left(\frac{v_t - \langle x_t, \theta_0 \rangle}{\sigma}\right)}{\prod_{t=1}^N \phi\left(\frac{v_t - \langle x_t, \theta_1 \rangle}{\sigma}\right)} \right) . \tag{47}$$

where $\mathbb{E}_0^\pi$ denotes expectation w.r.t $\mathbb{P}_0^\pi$ and $\phi(s) = 1/(\sqrt{2\pi})e^{-s^2/2}$ is the standard Gaussian density. After simple algebraic manipulation, we obtain

$$\begin{aligned} D_{\mathrm{KL}}(\mathbb{P}_0^\pi, \mathbb{P}_1^\pi) &= -\frac{1}{2\sigma^2}\mathbb{E}_0^\pi \Big\{ \sum_{t=1}^N (2z_t - \langle x_t, \theta^1 - \theta^0 \rangle) \langle x_t, \theta^1 - \theta^0 \rangle \Big\} \\ &= \frac{1}{2\sigma^2} \sum_{t=1}^N \mathbb{E}_0^\pi (\langle x_t, \theta^1 - \theta^0 \rangle^2) \le \frac{1}{2\sigma^2 d} \sum_{t=1}^N C_{\max} \|\theta^1 - \theta^0\|^2 \\ &= \frac{1}{2\sigma^2} C_{\max} \frac{\delta^2 N}{d} . \end{aligned}$$

We next relate the expected regret to the KL divergence between $\mathbb{P}_0^\pi$ and $\mathbb{P}_1^\pi$.

Lemma 11 *Let R_t be the regret incurred at time t, defined as $R_t \equiv p_t^* \mathbb{I}(v_t \ge p_t^*) - p_t \mathbb{I}(v_t \ge p_t)$. Then, there exist constants c_1, c_2 depending on σ, W, and $C_{\min}$, such that*

$$\mathbb{E}(R_t) \ge \frac{c_1}{d} \mathbb{E}\Big\{ \min\Big(\|\widehat{\theta}_t - \theta_t\|_2^2, c_2 \Big) \Big\} . \tag{48}$$

Proof of Lemma 11 goes along the proof of (Javanmard and Nazerzadeh, 2016, Equation (55)) and is omitted.

By applying Lemma 11, we have

$$\Delta_{\boldsymbol{\theta}, \mathbb{P}_{\boldsymbol{x}}}^\pi(N) = \sum_{t=1}^N \mathbb{E}_{\boldsymbol{\theta}}(R_t) \ge \frac{c_1}{d} \sum_{t=1}^N \mathbb{E}\Big\{ \min\Big(\|\widehat{\theta}_t - \theta_t\|_2^2, c_2 \Big) \Big\} . \tag{49}$$

For brevity in notations, for the sequence $\boldsymbol{\theta} = (\theta_1, \dots, \theta_N)$, we define $\mathsf{d}_a(\boldsymbol{\theta}) = c_1 \sum_{t=1}^N \min(\|\theta_t - \theta^a\|_2^2, c_2)$, for $a = 1, 2$. Define two sets J_a, for $a = 1, 2$ as follows:

$$J_a = \Big\{ \boldsymbol{\theta} = (\theta_1, \dots, \theta_N) : \theta_i \in \mathbb{R}^d , \mathsf{d}_a(\boldsymbol{\theta}) < \frac{1}{4} N \delta^2 \Big\} . \tag{50}$$

Then,

$$\begin{aligned} \max\big(\Delta_{0,\mathbb{P}_{\boldsymbol{x}}}^\pi(N), \Delta_{1,\mathbb{P}_{\boldsymbol{x}}}^\pi(N)\big) &\ge \frac{1}{d} \max\Big(\mathbb{E}_0^\pi(\mathsf{d}_0(\boldsymbol{\theta})), \mathbb{E}_1^\pi(\mathsf{d}_1(\boldsymbol{\theta})) \Big) \\ &\ge \frac{N}{4d}\delta^2 \max\Big(\mathbb{P}_0^\pi(\boldsymbol{\theta} \notin J_0), \mathbb{P}_1^\pi(\boldsymbol{\theta} \notin J_1) \Big) \\ &\overset{(a)}{\ge} \frac{N}{4d}\delta^2 \max\Big(\mathbb{P}_0^\pi(\boldsymbol{\theta} \notin J_0), \mathbb{P}_1^\pi(\boldsymbol{\theta} \in J_0) \Big) \\ &\ge \frac{N}{8d}\delta^2 \Big(\mathbb{P}_0^\pi(\boldsymbol{\theta} \notin J_0) + \mathbb{P}_1^\pi(\boldsymbol{\theta} \in J_0) \Big) \\ &\ge \frac{N}{8d}\delta^2 \Big(1 - \mathbb{P}_0^\pi(\boldsymbol{\theta} \in J_0) + \mathbb{P}_1^\pi(\boldsymbol{\theta} \in J_0) \Big) \\ &\ge \frac{N}{8d}\delta^2 \Big(1 - \sqrt{\frac{1}{2} D_{\mathrm{KL}}(\mathbb{P}_0^\pi, \mathbb{P}_1^\pi)} \Big) \quad \text{(By Pinsker inequality)} \\ &\ge \frac{N}{8d}\delta^2 \left(1 - \frac{1}{2\sigma}\delta \sqrt{C_{\max}\frac{N}{d}} \right) \ge \frac{N\delta^2}{16d} . \end{aligned}$$

Here (a) holds because $\boldsymbol{\theta} \in J_0$ implies $\boldsymbol{\theta} \notin J_1$. Otherwise, $\mathsf{d}_0(\boldsymbol{\theta}) < N\delta^2/4$ and $\mathsf{d}_1(\boldsymbol{\theta}) < N\delta^2/4$. Using the inequality $\min(a+b, c) \le \min(a, c) + \min(b, c)$ for $a, b, c \ge 0$, and applying triangle inequality, we get

$$N \min(\|\theta^0 - \theta^1\|^2, c_2) \le 2\mathsf{d}_0(\boldsymbol{\theta}) + 2\mathsf{d}_1(\boldsymbol{\theta}) < N\delta^2 , \tag{51}$$

which is a contradiction because $\delta^2 = \|\theta^0 - \theta^1\|^2 \le c_2$. Therefore, we conclude that

$$\begin{aligned} \mathsf{Regret}^\pi(T, B, \nu) &\ge \Big\lfloor \frac{T}{N} \Big\rfloor \max\big(\Delta_{0,\mathbb{P}_{\boldsymbol{x}}}^\pi(N), \Delta_{1,\mathbb{P}_{\boldsymbol{x}}}^\pi(N)\big) \\ &\ge \frac{T\delta^2}{16d} = \frac{T}{16} \min\Big(\frac{\sigma^2}{C_{\max} N}, \frac{c_2}{d} \Big) \\ &= \frac{1}{16} \min\left\{ \Big(\frac{\sigma^2}{C_{\max}} \Big)^{2/3} (B^2 d T^{2\nu-1})^{1/3}, \frac{c_2 T}{d} \right\} . \end{aligned} \tag{52}$$

The result follows.

8. Proof of main lemmas

8.1 Proof of Lemma 3

We prove Lemma 3 by developing an upper bound and a lower bound for the quantity $\sum_{t=1}^T \ell_t(\widehat{\theta}_t) - \sum_{t=1}^T \ell_t(\theta_t)$. The result follows by combining these two bounds.

Lemma 12 (*Upper bound*) *Suppose $\{\theta_t\}_{t \ge 1}$ is an arbitrary sequence in Θ, and $\|\theta\| \le W$ for all $\theta \in \Theta$. Set $M = 2W + \varphi^{-1}(0)$, with φ being the virtual valuation function w.r.t distribution F. Further, let $\{\widehat{\theta}_t\}_{t \ge 1}$ be generated by PSGD policy using a non-increasing*

positive series $\eta_{t+1} \le \eta_t$. *Then*

$$\sum_{t=1}^{T} \ell_t(\widehat{\theta}_t) - \sum_{t=1}^{T} \ell_t(\theta_t) \le \frac{2W^2}{\eta_1} + \sum_{t=1}^{T} \Big(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\Big)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t} - \frac{\ell_M}{2}\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\,, \tag{53}$$

where $\delta_t \equiv \|\theta_{t+1} - \theta_t\|$ *and we recall* u_M *from Equation* (15).

The proof of Lemma 12 uses similar ideas to the regret bounds established in (Hall and Willett, 2015), but uses the log-concavity of F and $1-F$ and also definition of u_M and ℓ_M as per Equations (15) and (16) to get a more refined bound including quadratic terms $\langle x_t, \widehat{\theta}_t - \theta_t\rangle^2$. We refer to Appendix B for the proof of Lemma 12.

Our next Lemma provides a probabilistic lower bound on $\sum_{t=1}^{T} \ell_t(\widehat{\theta}_t) - \sum_{t=1}^{T} \ell_t(\theta_t)$.

Lemma 13 (*Lower bound*) *Consider model* (3) *for the product market values and suppose Assumption 1 holds. Let* $\{\widehat{\theta}_t\}_{t\ge 1}$ *be an arbitrary sequence in* Θ. *Then with probability at least* $1 - \frac{1}{T^2}$ *the following holds true*

$$\sum_{t=1}^{T} \ell_t(\widehat{\theta}_t) - \sum_{t=1}^{T} \ell_t(\theta_t) \ge -2\sqrt{\log T}\Big\{\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\Big\}^{1/2}. \tag{54}$$

Proof of Lemma 13 is given in Appendix C. It uses convexity of $\ell_t(\widehat{\theta})$ and an application of a concentration bound on martingale difference sequences.

Combining Equations (53) and (54) we obtain that with probability at least $1 - \frac{1}{T^2}$ the following holds true

$$-2\sqrt{\log T}\Big\{\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\Big\}^{1/2} \le \frac{2W^2}{\eta_1} + \sum_{t=1}^{T} \Big(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\Big)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t} - \frac{\ell_M}{2}\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \tag{55}$$

Rearranging the terms, we get

$$\frac{\ell_M}{2}\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 - 2\sqrt{\log T}\Big\{\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\Big\}^{1/2} \le \frac{2W^2}{\eta_1} + \sum_{t=1}^{T} \Big(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\Big)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t} \tag{56}$$

Define $A \equiv \sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2$ and denote by B the right-hand side of Equation (56).

Writing in terms of A and B, we have

$$A - \frac{4}{\ell_M}\sqrt{A\log T} \le \frac{2B}{\ell_M}\,. \tag{57}$$

We next upper bound A as follows. Consider two cases:

Case 1: Assume that

$$\sqrt{A\log T} \le \frac{\ell_M}{8}A\,.$$

Using this in Equation (57), we get $A \le 4B/\ell_M$.

Case 2: Assume that

$$\sqrt{A\log T} > \frac{\ell_M}{8}A\,.$$

Then, $A < (64/\ell_M^2)\log T$.

Combining the above two cases, we obtain

$$A \le \frac{4}{\ell_M}\max\Big(\frac{16}{\ell_M}\log T, B\Big)\,.$$

Substituting for A and B, we have

$$\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \le \frac{4}{\ell_M}\max\Big\{\frac{16}{\ell_M}\log T, \frac{2W^2}{\eta_1} + \sum_{t=1}^{T}\Big(\frac{1}{2\eta_{t+1}} - \frac{1}{2\eta_t}\Big)\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t}\Big\}$$

The proof is complete.

8.2 Proof of Lemma 8

theorem 8.1 *Let* σ_t *denote the minimum eigenvalue of* $Q_t \equiv (1/t)\sum_{\ell=1}^{t} x_\ell x_\ell^{\mathsf{T}}$. *Further, let* $\sigma_{\min}$ *be the minimum eigenvalue of* Σ, *where* Σ *is the population covariance of feature vectors as in Assumption 6. Then, there exist constants* $c_1, c_2 > 0$, *such that*

$$\forall t \ge c_1 d:\ \mathbb{P}\Big(\frac{1}{2}\sigma_{\min} \le \sigma_t \le \frac{3}{2}\sigma_{\min}\Big) \ge 1 - 2e^{-c_2 t/d}\,. \tag{58}$$

Further, $\sigma_t \le 1$, *for all* $t \ge 1$.

Let $\mathcal{F}_t$ be the σ algebra generated by market shocks $\{z_\ell\}_{\ell=1}^{t}$ and features $\{x_\ell\}_{\ell=1}^{t}$. We further define $D_t = \langle x_t, \widehat{\theta}_t - \theta_t\rangle^2 - \|\Sigma^{1/2}(\widehat{\theta}_t - \theta_t)\|^2$. Note that $\widehat{\theta}_t$ is $\mathcal{F}_{t-1}$ measurable and x_t is independent of $\mathcal{F}_{t-1}$, which implies $\mathbb{E}(D_t|\mathcal{F}_{t-1}) = 0$. Hence, $\mathbb{E}(D_t) = 0$ by iterated law of expectation and therefore $\sum_{t=1}^{T}\mathbb{E}(D_t) = 0$. Equivalently,

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t, \widehat{\theta}_t - \theta_t\rangle^2\right] = \sum_{t=1}^{T}\mathbb{E}\left[\|\Sigma^{1/2}(\widehat{\theta}_t - \theta_t)\|^2\right] \ge \sigma_{\min}\,\mathbb{E}\left[\sum_{t=1}^{T}\|\widehat{\theta}_t - \theta_t\|^2\right] \tag{59}$$

Define $\mathcal{G}_T$ the event that bound (19) holds true. Then,

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\right]=\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\cdot(\mathbb{I}_{\mathcal{G}}+\mathbb{I}_{\mathcal{G}^c})\right]$$
$$\le\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\cdot\mathbb{I}_{\mathcal{G}}\right]+4W^2T\,\mathbb{P}(\mathcal{G}^c)$$
$$\le\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\cdot\mathbb{I}_{\mathcal{G}}\right]+\frac{4W^2}{T}\,. \tag{60}$$

Further, using inequality $\max(a,b)\le|a|+|b|$, we get

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\cdot\mathbb{I}_{\mathcal{G}}\right]\le\frac{4}{\ell_M}\Big\{\frac{16}{\ell_M}\log T+\frac{12W^2}{\ell_M}+\frac{1}{2}\sum_{t=1}^{T}\mathbb{E}\Big[\Big((t+1)\lambda_{t+1}-t\lambda_t\Big)\cdot\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\Big]$$
$$+\frac{u_M^2}{2}\sum_{t=1}^{T}\mathbb{E}\left[\frac{1}{t\lambda_t}\right]+2W\sum_{t=1}^{T}\mathbb{E}[t\lambda_t]\delta_t\Big\}\,. \tag{61}$$

We next bound the terms on the right-hand side individually.

$$\sum_{t=1}^{T}\mathbb{E}\Big[\Big((t+1)\lambda_{t+1}-t\lambda_t\Big)\cdot\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\Big]\le\frac{\ell_M}{6}\sum_{t=1}^{T}\mathbb{E}\Big[\sigma_{t+1}\cdot\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\Big]$$
$$\le\frac{\ell_M}{6}\sum_{t=1}^{T}\mathbb{E}\Big[\sigma_{t+1}\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\,\mathbb{I}(\sigma_{t+1}<3\sigma_{\min}/2)\Big]+\frac{\ell_M}{6}\sum_{t=1}^{T}\mathbb{E}\Big[\sigma_{t+1}\,\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\,\mathbb{I}(\sigma_{t+1}>3\sigma_{\min}/2)\Big]$$
$$\le\frac{\ell_M}{4}\sigma_{\min}\sum_{t=1}^{T}\mathbb{E}\Big(\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\Big)+\sum_{t=1}^{T}2\ell_MW^2e^{-c_2t/d}$$
$$\le\frac{\ell_M}{4}\sigma_{\min}\sum_{t=1}^{T}\mathbb{E}\Big(\|\theta_{t+1}-\widehat{\theta}_{t+1}\|^2\Big)+\frac{2\ell_M}{c_2d}W^2\,, \tag{62}$$

where in the last inequality, we used $\mathbb{P}(\sigma_{t+1}>3\sigma_{\min}/2)\le 2e^{-c_2dt}$, $\sigma_t\le 1$ and $\|\widehat{\theta}_t-\theta_t\|\le 2W$, according to Proposition 8.1.

The next term on the right-hand side of (61) is bounded in the following proposition.

theorem 8.2 *Using rule* (23) *for* λ_t*, we have*

$$\mathbb{E}\left[\frac{1}{t\lambda_t}\right]\le\frac{6}{\ell_M}\left(\tilde{c}d^2\log T+\frac{4d}{C_{\min}}\log T\right)\,, \tag{63}$$

where $\tilde{c}=\max(c_1,1/c_2)$ *and constants* c_1 *and* c_2 *are defined in Proposition 8.1 .*

Finally, for the last term, we note that Q_t is rank deficient for $t\le d$ and hence $\sigma_t=0$, for $1\le t\le d$. Further, the minimum eigenvalue of a matrix is a concave function over PSD matrices. By Jensen inequality, we have

$$\mathbb{E}(\lambda_t)=\frac{\ell_M}{6t}(1+\sum_{\ell=1}^{t}\mathbb{E}(\sigma_\ell))=\frac{\ell_M}{6t}\Big(1+\sum_{\ell=d+1}^{t}\mathbb{E}(\sigma_\ell)\Big)$$
$$\le\frac{\ell_M}{6t}\Big(1+\sum_{\ell=d+1}^{t}\sigma_{\min}\Big)\le\frac{\ell_M}{6t}\Big(1+\frac{t-d}{d}\Big)=\frac{\ell_M}{6d}\,. \tag{64}$$

In the last inequality, we used the fact that $\mathrm{Trace}(\Sigma)=\mathbb{E}(\|x_t\|^2)=1$, and thus $\sigma_{\min}\le 1/d$. Hence,

$$\sum_{t=1}^{T}\mathbb{E}[t\lambda_t]\delta_t\le\frac{\ell_M}{6d}\sum_{t=1}^{T}t\delta_t\,, \tag{65}$$

Using Equations (62), (63), (65) to bound the right-hand side of (61), we get

$$\mathbb{E}\left[\sum_{t=1}^{T}\langle x_t,\widehat{\theta}_t-\theta_t\rangle^2\cdot\mathbb{I}_{\mathcal{G}}\right]\le\left[\frac{64}{\ell_M^2}+\frac{12u_M^2}{\ell_M^2}\left(\tilde{c}+\frac{4}{C_{\min}d}\right)\right]\cdot d^2\log T$$
$$+\frac{48W^2}{\ell_M^2}+\frac{4W^2}{c_2d}+\frac{2W}{d}\sum_{t=1}^{T}t\delta_t+\frac{\sigma_{\min}}{2}\sum_{t=1}^{T}\mathbb{E}(\|\theta_t-\widehat{\theta}_t\|^2)\,. \tag{66}$$

Combining bounds (59),(60) and (65), we obtain

$$\frac{\sigma_{\min}}{2}\sum_{t=1}^{T}\mathbb{E}(\|\theta_t-\widehat{\theta}_t\|^2)\le\left[\frac{64}{\ell_M^2}+\frac{12u_M^2}{\ell_M^2}\left(\tilde{c}+\frac{4}{C_{\min}d}\right)\right]\cdot d^2\log T$$
$$+4W^2\left(\frac{1}{T}+\frac{12}{\ell_M^2}+\frac{1}{c_2d}\right)+\frac{2W}{d}\sum_{t=1}^{T}t\delta_t\,.$$

The result follows by recalling that $\sigma_{\min}\ge C_{\min}/d$ as stated by Assumption 6.

Appendix A. Proof of Lemma 10

We first state some properties of the the virtual valuation function φ and the price function g, given by Equation (7).

theorem A.1 *If $1-F$ is log-concave, then the virtual valuation function φ is strictly monotone increasing and the price function g satisfies $0 < g'(v) < 1$, for all values of $v \in \mathbb{R}$.*

We refer to (Javanmard and Nazerzadeh, 2016) (Lemmas 1 and 2 in Appendix A therein) for a proof of Proposition A.1.

For $\theta \in \Theta$ we have $\|\theta\| \le W$ and hence $|\langle x_t, \theta\rangle| \le \|x_t\|\|\theta\| \le W$ for all t. Applying Proposition A.1 (1-Lipschitz property of g),

$$p_t = g(\langle x_t, \theta_t\rangle) \le g(0) + |\langle x_t, \theta_t\rangle| \le \varphi^{-1}(0) + W\,.$$

Therefore,

$$|u_t(\theta)| \le |p_t| + |\langle x_t, \theta\rangle| \le \varphi^{-1}(0) + 2W\,. \tag{67}$$

Appendix B. Proof of Lemma 12

We note that the update rule (11) can be recast as $\widehat{\theta}_{t+1} = \arg\min_{\theta\in\Theta} \mathcal{C}_t(\theta)$, where

$$\mathcal{C}_t(\theta) = \eta_t \langle \nabla \ell_t(\widehat{\theta}_t), \theta\rangle + \frac{1}{2}\|\theta - \widehat{\theta}_t\|^2\,.$$

By convexity of $\mathcal{C}_t$ and optimality of $\widehat{\theta}_{t+1}$, we have $\langle \theta - \widehat{\theta}_{t+1}, \nabla \mathcal{C}_t(\widehat{\theta}_{t+1})\rangle \ge 0$ for all $\theta \in \Theta$. Setting $\theta = \theta_t$,

$$\langle \theta_t - \widehat{\theta}_{t+1}, \eta_t \nabla \ell_t(\widehat{\theta}_t) + \widehat{\theta}_{t+1} - \widehat{\theta}_t\rangle \ge 0\,. \tag{68}$$

Expanding $\ell_t(\theta)$ around $\widehat{\theta}_t$, we have

$$\ell_t(\widehat{\theta}_t) - \ell(\theta_t) = \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \theta_t\rangle - \frac{1}{2}\langle \theta_t - \widehat{\theta}_t, \nabla^2 \ell_t(\tilde{\theta})(\theta_t - \widehat{\theta}_t)\rangle\,, \tag{69}$$

for some $\tilde{\theta}$ on the line segment between $\widetilde{\theta}_t$ and $\widehat{\theta}_t$. Recalling (12), the gradient and the hessian of ℓ_t read as

$$\nabla \ell_t(\theta) = \mu_t(\theta) x_t\,, \quad \nabla^2 \ell_t(\theta) = \eta_t(\theta) x_t x_t^{\mathsf{T}}\,, \tag{70}$$

with,

$$\begin{aligned}\mu_t(\theta) &= -\frac{f(u_t(\theta))}{F(u_t(\theta))}\mathbb{I}(y_t = -1) + \frac{f(u_t(\theta))}{1 - F(u_t(\theta))}\mathbb{I}(y_t = +1)\\ &= -\frac{\mathrm{d}}{\mathrm{d}x}\log F(u_t(\theta))\mathbb{I}(y_t = -1) - \frac{\mathrm{d}}{\mathrm{d}x}\log(1 - F(u_t(\theta)))\mathbb{I}(y_t = +1)\end{aligned} \tag{71}$$

$$\begin{aligned}\eta_t(\theta) &= \left(\frac{f(u_t(\theta))^2}{F(u_t(\theta))^2} - \frac{f'(u_t(\theta))}{F(u_t(\theta))}\right)\mathbb{I}(y_t = -1) + \left(\frac{f(u_t(\theta))^2}{(1 - F(u_t(\theta)))^2} + \frac{f'(u_t(\theta))}{1 - F(u_t(\theta))}\right)\mathbb{I}(y_t = +1)\\ &= -\frac{\mathrm{d}^2}{\mathrm{d}x^2}\log F(u_t(\theta))\mathbb{I}(y_t = -1) - \frac{\mathrm{d}^2}{\mathrm{d}x^2}\log(1 - F(u_t(\theta)))\mathbb{I}(y_t = +1)\,.\end{aligned} \tag{72}$$

Here, $u_t(\theta) = p_t - \langle x_t, \theta\rangle$, and $\frac{\mathrm{d}}{\mathrm{d}x}\log F(x)$ and $\frac{\mathrm{d}^2}{\mathrm{d}x^2}\log F(x)$ represent first and second derivative w.r.t x, respectively. In addition, using Equation (73)

$$|u_t(\theta)| \le \varphi^{-1}(0) + 2W = M\,, \quad \forall \theta \in \Theta\,. \tag{73}$$

Hence, invoking the definition of ℓ_M, as per Equation (16), we get that $\eta_t(\theta) \ge \ell_M$ and hence $\nabla^2 \ell_t(\tilde{\theta}) \succeq \ell_M x_t x_t^{\mathsf{T}}$.

Continuing from Equation (69), we get

$$\begin{aligned}\ell_t(\widehat{\theta}_t) - \ell(\theta_t) &\le \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \theta_t\rangle - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\\ &= \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_{t+1} - \theta_t\rangle + \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \widehat{\theta}_{t+1}\rangle - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\\ &\le \frac{1}{\eta_t}\langle \theta_t - \widehat{\theta}_{t+1}, \widehat{\theta}_{t+1} - \widehat{\theta}_t\rangle + \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \widehat{\theta}_{t+1}\rangle - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\\ &= \frac{1}{2\eta_t}\Big\{\|\theta_t - \widehat{\theta}_t\|^2 - \|\theta_t - \widehat{\theta}_{t+1}\|^2 - \|\widehat{\theta}_{t+1} - \widehat{\theta}_t\|^2\Big\}\\ &\quad + \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \widehat{\theta}_{t+1}\rangle - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\\ &= \frac{1}{2\eta_t}\Big\{\|\theta_t - \widehat{\theta}_t\|^2 - \|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2\Big\} + \frac{1}{2\eta_t}\Big\{\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 - \|\theta_t - \widehat{\theta}_{t+1}\|^2\Big\}\\ &\quad - \frac{1}{2\eta_t}\|\widehat{\theta}_{t+1} - \widehat{\theta}_t\|^2 + \langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \widehat{\theta}_{t+1}\rangle - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\end{aligned} \tag{74}$$

We next note that the second term above can be bounded as

$$\frac{1}{2\eta_t}\Big\{\|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2 - \|\theta_t - \widehat{\theta}_{t+1}\|^2\Big\} = \frac{1}{\eta_t}\langle \theta_{t+1} - \widehat{\theta}_{t+1}, \theta_{t+1} - \theta_t\rangle \le \frac{2}{\eta_t} W\delta_t\,, \tag{75}$$

because $\theta_{t+1}, \widehat{\theta}_{t+1} \in \Theta$ and hence $\|\theta_{t+1} - \widehat{\theta}_{t+1}\| \le 2W$ by triangle inequality.

Further,

$$\begin{aligned}\langle \nabla \ell_t(\widehat{\theta}_t), \widehat{\theta}_t - \widehat{\theta}_{t+1}\rangle &\le \frac{1}{2\eta_t}\|\widehat{\theta}_{t+1} - \widehat{\theta}_t\|^2 + \frac{\eta_t}{2}\|\nabla \ell_t(\widehat{\theta}_t)\|^2\\ &\le \frac{1}{2\eta_t}\|\widehat{\theta}_{t+1} - \widehat{\theta}_t\|^2 + \frac{\eta_t}{2}|\mu(\widehat{\theta}_t)|^2\|x_t\|^2 \le \frac{1}{2\eta_t}\|\widehat{\theta}_{t+1} - \widehat{\theta}_t\|^2 + \frac{\eta_t}{2}u_M^2\,,\end{aligned} \tag{76}$$

where we used the inequality $2ab \le a^2 + b^2$ and the characterization of gradient (70). Note that by (73), $|u_t(\widehat{\theta})| \le M$ and by definition (15), $|\mu_t(\widehat{\theta}_t)| \le u_M$. Plugging in bounds from (75) and (76) in Equation (74), we arrive at

$$\ell_t(\widehat{\theta}_t) - \ell(\theta_t) \le \frac{1}{2\eta_t}\Big\{\|\theta_t - \widehat{\theta}_t\|^2 - \|\theta_{t+1} - \widehat{\theta}_{t+1}\|^2\Big\} + \frac{2}{\eta_t}W\delta_t + \frac{\eta_t}{2}u_M^2 - \frac{\ell_M}{2}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 \tag{77}$$

We use the shorthand $D_t = \frac{1}{2}\|\theta_t - \widehat{\theta}_t\|^2$. The result follows by summing the above bound over time:

$$\sum_{t=1}^{T} \ell_t(\widehat{\theta}_t) - \sum_{t=1}^{T} \ell_t(\theta_t) = \sum_{t=1}^{T} \Big(\frac{D_t}{\eta_t} - \frac{D_{t+1}}{\eta_{t+1}}\Big) + \sum_{t=1}^{T} D_{t+1}\Big(\frac{1}{\eta_{t+1}} - \frac{1}{\eta_t}\Big) + \frac{u_M^2}{2}\sum_{t=1}^{T}\eta_t + 2W\sum_{t=1}^{T}\frac{\delta_t}{\eta_t} - \frac{\ell_M}{2}\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2 .$$

The proof is concluded because $D_1 \le 2W^2$ as $\widehat{\theta}_1, \theta_1 \in \Theta$; therefore

$$\sum_{t=1}^{T} \Big(\frac{D_t}{\eta_t} - \frac{D_{t+1}}{\eta_{t+1}}\Big) = \frac{D_1}{\eta_1} - \frac{D_{T+1}}{\eta_{T+1}} \le \frac{D_1}{\eta_1} \le \frac{2W^2}{\eta_1} .$$

Appendix C. Proof of Lemma 13

By convexity of $\ell_t(\theta)$, we have

$$\ell_t(\theta_t) - \ell_t(\widehat{\theta}_t) \le \langle \nabla \ell_t(\theta_t), \widehat{\theta}_t - \theta_t\rangle = \mu_t(\theta_t)\langle x_t, \theta_t - \widehat{\theta}_t\rangle . \tag{78}$$

We denote $D_t = \mu_t(\theta_t)\langle x_t, \theta_t - \widehat{\theta}_t\rangle$ and let $\mathcal{F}_t$ be the σ-algebra generated by $\{z_t\}_{t=1}^T$. Since $\widehat{\theta}_t$ is $\mathcal{F}_{t-1}$ measurable, we have

$$\mathbb{E}(D_t|\mathcal{F}_{t-1}) = \mathbb{E}(\mu_t(\theta_t)|\mathcal{F}_{t-1})\langle x_t, \theta_t - \widehat{\theta}_t\rangle = 0 , \tag{79}$$

where $\mathbb{E}(\mu_t(\theta_t)|\mathcal{F}_{t-1}) = 0$ follows readily from Equation (71). Therefore, $D(T) \equiv \sum_{t=1}^T D_t$ is a martingale adapted to the filtration $\mathcal{F}_t$.

We next bound $\mathbb{E}[e^{\lambda D_t}|\mathcal{F}_{t-1}]$ for any $\lambda \in \mathbb{R}$. Conditional on $\mathcal{F}_{t-1}$, we have $|D_t| \le \beta_t$, with $\beta_t \equiv u_M|\langle x_t, \theta_t - \widehat{\theta}_t\rangle|$. Since $e^{\lambda z}$ is convex,

$$\begin{aligned}\mathbb{E}[e^{\lambda D_t}|\mathcal{F}_{t-1}] &\le \mathbb{E}\left[\frac{\beta_t - D_t}{2\beta_t}e^{-\lambda\beta_t} + \frac{\beta_t + D_t}{2\beta_t}e^{\lambda\beta_t}\middle|\mathcal{F}_{t-1}\right] \\ &= \mathbb{E}\left[\frac{e^{-\lambda\beta_t} + e^{\lambda\beta_t}}{2}\right] + \mathbb{E}[D_t|\mathcal{F}_{t-1}]\left(\frac{e^{-\lambda\beta_t} + e^{\lambda\beta_t}}{2\beta_t}\right) = \cosh(\lambda\beta_t) \le e^{\lambda^2\beta_t^2/2} .\end{aligned} \tag{80}$$

We are now ready to apply the following Bernstein-type concentration bound for martingale difference sequences, whose proof is given in Appendix D for the reader's convenience.

theorem C.1 *Consider a martingale difference sequence D_t adapted to a filtration $\mathcal{F}_t$, such that for any $\lambda \ge 0$, $\mathbb{E}[e^{\lambda D_t}|\mathcal{F}_{t-1}] \le e^{\lambda^2\sigma_t^2/2}$. Then, for $D(T) = \sum_{t=1}^T D_t$, the following holds true:*

$$\mathbb{P}(D(T) \ge \xi) \le e^{-\xi^2/(2\sum_{t=1}^T \sigma_t^2)} . \tag{81}$$

Combining Equation (78) and the result of Proposition C.1 we obtain

$$\mathbb{P}\Bigg(\sum_{t=1}^{T}\ell_t(\widehat{\theta}_t) - \sum_{t=1}^{T}\ell_t(\theta_t) \le -2\sqrt{\log T}\Big\{\sum_{t=1}^{T}\langle x_t, \theta_t - \widehat{\theta}_t\rangle^2\Big\}^{1/2}\Bigg) \le \frac{1}{T^2} . \tag{82}$$

The result follows.

Appendix D. Proof of Proposition C.1

We follow the standard approach of controlling the moment generating function of $D(T)$.Conditioning on $\mathcal{F}_{t-1}$ and applying iterated expectation yields

$$\mathbb{E}[e^{\lambda D(T)}] = \mathbb{E}\left[e^{\lambda\sum_{t=1}^{T-1}D_t}\cdot\mathbb{E}[e^{\lambda D_T}|\mathcal{F}_{T-1}]\right] \le \mathbb{E}\left[e^{\lambda\sum_{t=1}^{T-1}D_t}\right]e^{\lambda^2\sigma_T^2/2} . \tag{83}$$

Iterating this procedure gives the bound $\mathbb{E}[e^{\lambda\sum_{t=1}^T D_t}] \le e^{\lambda^2\sum_{t=1}^T\sigma_t^2/2}$, for all $\lambda \ge 0$.

Now by applying the exponential Markov inequality we get

$$\mathbb{P}(D(T) \ge \xi) = \mathbb{P}(e^{\lambda D(T)} \ge e^{\lambda\xi}) \le e^{-\lambda\xi}\mathbb{E}[e^{\lambda\sum_{t=1}^T D_t}] \le e^{-\lambda\xi}e^{\lambda^2(\sum_{t=1}^T\sigma_t^2)/2} . \tag{84}$$

Choosing $\lambda = \xi/(\sum_{t=1}^T\sigma_t^2)$ gives the desired result.

Appendix E. Proof of Proposition 8.1

We prove the result in a more general case, namely when the features are independent random vectors with bounded subgaussian norms.

Definition 14 *For a random variable z, its subgaussian norm, denoted by $\|z\|_{\psi_2}$ is defined as*

$$\|z\|_{\psi_2} = \sup_{p\ge 1} p^{-1/2}(\mathbb{E}|z|^p)^{1/p} . \tag{85}$$

Further, for a random vector z its subgaussian norm is defined as

$$\|z\|_{\psi_2} = \sup_{\|u\|\ge 1} \|\langle z, u\rangle\|_{\psi_2} . \tag{86}$$

We next recall the following result from (Vershynin, 2012) about random matrices with independent rows.

theorem E.1 *Suppose $x_\ell \in \mathbb{R}^d$ are independent random vectors generated from a distribution with covariance Σ and their subgaussian norms are bounded by K. Further, let $Q_t = (1/t)\sum_{\ell=1}^t x_\ell x_\ell^\mathsf{T}$. Then for every $s \ge 0$, the following inequality holds with probability at least $1 - 2\exp(-cs^2)$:*

$$\Big\|Q_t - \Sigma\Big\| \le \max(\delta, \delta^2) \qquad \text{where } \delta = C\sqrt{\frac{d}{t}} + \frac{s}{\sqrt{t}} . \tag{87}$$

Here C and $c > 0$ are constants that depend solely on K.

We next show that the feature vectors in our problem have bounded subgaussian norm. Given that $\|x_\ell\| \le 1$, for $\|u\| \le 1$, we have

$$\|\langle x_\ell, u\rangle\|_{\psi_2} = \sup_{p\ge1} p^{-1/2}(\mathbb{E}|\langle x_\ell, u\rangle|^p)^{1/p} \le \sup_{p\ge1} p^{-1/2}(\mathbb{E}[\|x_\ell\|\|u\|]^p)^{1/p} \le 1 .$$

Applying Proposition (E.1) with $K = 1$, there exist constants c_1, c_2 (depending on $C_{\min}$), such that for $t \geq c_1 d^2$, we have

$$\|Q_t - \Sigma\| \leq \frac{1}{2d} C_{\min} \leq \frac{1}{2}\sigma_{\min}\,, \tag{88}$$

with probability at least $1 - 2e^{-c_2 t/d}$. Weyl's inequality then implies that $|\sigma_t - \sigma_{\min}| \leq \sigma_{\min}/2$.

Also note that for $t \geq 1$,

$$\sigma_t \leq \|Q_t\| \leq \frac{1}{t}\sum_{\ell=1}^{t} \|x_\ell x_\ell^{\mathsf{T}}\| = \frac{1}{t}\sum_{\ell=1}^{t} \|x_\ell\|^2 = 1\,.$$

The proof is complete.

Appendix F. Proof of Lemma 8.2

The way we set λ_t (see Equation (23)), we have

$$\frac{1}{t\lambda_t} = \left(\frac{6}{\ell_M}\right) \frac{1}{1 + \sigma_1 + \sigma_2 + \ldots + \sigma_t}$$

Clearly, for $t \geq 1$, $1/(t\lambda_t) \leq 6/\ell_M$. Let $t_0 = \tilde{c} d^2 \log T$, with $\tilde{c} = \max(c_1, 1/c_2)$. For $T \geq t_0$, define the event $\mathcal{E}_T$ as follows

$$\mathcal{E}_T = \{\sigma_t \geq \sigma_{\min}/2, \text{ for } t_0 \leq t \leq T\}\,. \tag{89}$$

By applying Proposition 8.1 and union bounding over t, we get

$$\mathbb{P}(\mathcal{E}_T) \geq 1 - \sum_{t=t_0}^{T} 2e^{-c_2 t/d} \geq 1 - \frac{2d}{c_2} e^{-c_2 t_0/d} \tag{90}$$

Therefore,

$$\begin{aligned}
\sum_{t=t_0}^{T} \mathbb{E}\left[\frac{1}{t\lambda}\right] &\leq \mathbb{E}\left[\left(\sum_{t=t_0}^{T} \frac{1}{t\lambda}\right)\mathbb{I}(\mathcal{E}_T)\right] + \frac{6T}{\ell_M}\mathbb{P}(\mathcal{E}_T^c) \\
&= \frac{6}{\ell_M}\mathbb{E}\left[\left(\sum_{t=t_0}^{T} \frac{1}{1 + \sigma_1 + \ldots + \sigma_t}\right)\cdot \mathbb{I}(\mathcal{E}_T)\right] + \frac{6T}{\ell_M}\mathbb{P}(\mathcal{E}_T^c) \\
&\leq \frac{6}{\ell_M}\left(\sum_{t=1}^{T} \frac{1}{1 + \frac{t}{2}\sigma_{\min}} + \frac{2d}{c_2} T^{1 - c_2\tilde{c}d}\right) \\
&\leq \frac{12}{\ell_M}\left(\frac{1}{\sigma_{\min}}\log T + \frac{d}{c_2} T^{1-d}\right) \leq \frac{24d}{\ell_M C_{\min}}\log T\,.
\end{aligned} \tag{91}$$

For $t \geq 1$, we use the bound $1/(t\lambda_t) \leq 6/\ell_M$. Hence,

$$\sum_{t=1}^{T} \mathbb{E}\left[\frac{1}{t\lambda}\right] \leq \frac{6}{\ell_M}\left(t_0 + \frac{4d}{C_{\min}}\log T\right) \leq \frac{6}{\ell_M}\left(\tilde{c}d^2 \log T + \frac{4d}{C_{\min}}\log T\right) \tag{92}$$

The proof is complete.

Abstract

In this paper we introduce a new optimization formulation for sparse regression and compressed sensing, called CLOT (Combined L-One and Two), wherein the regularizer is a convex combination of the ℓ_1- and ℓ_2-norms. This formulation differs from the Elastic Net (EN) formulation, in which the regularizer is a convex combination of the ℓ_1- and ℓ_2-norm *squared*. It is shown that, in the context of compressed sensing, the EN formulation *does not achieve* robust recovery of sparse vectors, whereas the new CLOT formulation achieves robust recovery. Also, like EN but unlike LASSO, the CLOT formulation achieves the grouping effect, wherein coefficients of highly correlated columns of the measurement (or design) matrix are assigned roughly comparable values. It is already known LASSO does not have the grouping effect. Therefore the CLOT formulation combines the best features of both LASSO (robust sparse recovery) and EN (grouping effect).

The CLOT formulation is a special case of another one called SGL (Sparse Group LASSO) which was introduced into the literature previously, but without any analysis of either the grouping effect or robust sparse recovery. It is shown here that SGL achieves robust sparse recovery, and also achieves a version of the grouping effect in that coefficients of highly correlated columns belonging to the same group of the measurement (or design) matrix are assigned roughly comparable values.

Keywords: Sparse regression, compressed sensing, LASSO, Sparse Group LASSO, Elastic Net

1. Introduction

The LASSO and the Elastic Net (EN) formulations are among the most popular approaches for sparse regression and compressed sensing. In this section, we briefly review these two problems and their current status, so as to provide the background for the remainder of the paper.

1.1 Sparse Regression

In sparse regression, one is given a measurement matrix (also called a design matrix in statistics) $A \in \mathbb{R}^{m \times n}$ where $m \ll n$, together with a measurement or measured vector $y \in \mathbb{R}^m$. The objective is to choose a vector $x \in \mathbb{R}^n$ such that x is rather sparse, and Ax is either exactly or approximately equal to y. The problem of finding the most sparse x that satisfies $Ax = y$ is known to be NP-hard (Natarajan, 1995); therefore it is necessary to find alternate approaches.

For the sparse regression problem, the general approach is to determine the estimate $\hat{x}$ by solving the minimization problem

$$\hat{x} = \underset{z}{\operatorname{argmin}} \|y - Az\|_2^2 \text{ s.t. } \mathcal{R}(z) \leq \gamma, \tag{1}$$

or in Lagrangian form,

$$\hat{x} = \underset{z}{\operatorname{argmin}} \|y - Az\|_2^2 + \lambda \mathcal{R}(z), \tag{2}$$

where $\mathcal{R} : \mathbb{R}^n \to \mathbb{R}$ is known as a "regularizer," and γ, λ are adjustable parameters. Different choices of the regularizer lead to different approaches. With the choice $\mathcal{R}_{\text{ridge}}(z) = \|z\|_2^2$, the approach is known as ridge regression (Hoerl and Kennard, 1970), which builds on earlier work (Tikhonov, 1943). The LASSO approach (Tibshirani, 1996) results from choosing $\mathcal{R}_{\text{LASSO}}(z) = \|z\|_1$, while the Elastic Net (EN) approach (Zou and Hastie, 2005) results from choosing

$$\mathcal{R}_{\text{EN}}(z) = \alpha_1 \|z\|_1 + \alpha_2 \|z\|_2^2, \tag{3}$$

where α_1, α_2 are adjustable parameters. For later use, we redefine the EN regularizer as

$$\mathcal{R}_{\text{EN}}(z) = (1 - \mu)\|z\|_1 + \mu \|z\|_2^2, \tag{4}$$

where

$$\mu = \frac{\alpha_2}{\alpha_1 + \alpha_2} \in [0, 1]$$

is an adjustable parameter, and the constant $\alpha_1 + \alpha_2$ can be absorbed into the Lagrange multiplier λ in (2). Note that the EN regularizer function interpolates ridge regression and LASSO, in the sense that EN reduces to LASSO if $\mu = 0$ and to ridge regression if $\mu = 1$. A very general approach to regression using a convex regularizer is given in (Negabhan et al., 2012).

The LASSO approach can be shown to return a solution $\hat{x}$ with no more than m nonzero components, under mild regularity conditions; see (Osborne et al., 2000). There is no such bound on the number of components of $\hat{x}$ when EN is used. However, when the columns of the matrix A are highly correlated, then LASSO chooses just one of these columns and ignores the rest. Measurement matrices with highly correlated columns occur in many

practical situations, for example, in microarray measurements of messenger RNA, otherwise known as gene expression data. The EN approach was proposed at least in part to overcome this undesirable behavior of the LASSO formulation. It is shown in (Zou and Hastie, 2005, Theorem 1) that if two columns (say i and j) of the matrix A are highly correlated, then the corresponding components $\hat{x}_i$ and $\hat{x}_j$ of the EN solution are nearly equal. This is known as the "grouping effect", and the point is that EN demonstrates the grouping effect whereas LASSO does not.

1.2 Compressed Sensing

In compressed sensing, the objective is to *choose* the measurement matrix A (which is part of the data in sparse regression), such that whenever the vector x is nearly sparse, it is possible to nearly recover x from noise-corrupted measurements of the form $y = Ax + \eta$. Let us make the problem formulation precise. For this purpose we begin by introducing some notation.

Throughout, the symbol $[n]$ denotes the index set $\{1, \ldots, n\}$. The **support** of a vector $x \in \mathbb{R}^n$ is denoted by $\text{supp}(x)$ and is defined as

$$\text{supp}(x) := \{i \in [n] : x_i \neq 0\}.$$

A vector $x \in \mathbb{R}^n$ is said to be k-**sparse** if $|\text{supp}(x)| \leq k$. The set of all k-sparse vectors is denoted by Σ_k. The k-**sparsity index** of a vector x with respect to a given norm $\|\cdot\|$ is defined as

$$\sigma_k(x, \|\cdot\|) := \min_{z \in \Sigma_k} \|x - z\|. \tag{5}$$

It is obvious that $x \in \Sigma_K$ if and only if $\sigma_k(x, \|\cdot\|) = 0$ for every norm.

The general formulation of the compressed sensing problem given below is essentially taken from (Cohen et al., 2009). Suppose that $A \in \mathbb{R}^{m \times n}$ is the "measurement matrix", and $\Delta : \mathbb{R}^m \to \mathbb{R}^n$ is the "decoder map", where $m \ll n$. Suppose $x \in \mathbb{R}^n$ is an unknown vector that is to be recovered. The input to the decoder consists of $y = Ax + \eta$ where η denotes the measurement noise, and a prior upper bound in the form $\|\eta\|_2 \leq \epsilon$ is available; in other words, ϵ is a known number. In this set-up, the vector $\hat{x} = \Delta(y)$ is the approximation to the original vector x. With these conventions, we can now state the following.

Definition 1 *Suppose $p \in [1, 2]$. The pair (A, Δ) is said to achieve **robust sparse recovery** of order k with respect to $\|\cdot\|_p$ if there exist constants C and D that might depend on A and Δ but not on x or η, such that*

$$\|\hat{x} - x\|_p \leq \frac{1}{k^{1-1/p}}[C\sigma_k(x, \|\cdot\|_1) + D\epsilon]. \tag{6}$$

The restriction that $p \in [1, 2]$ is tied up with the fact that the bound on the noise is for the Euclidean norm $\|\eta\|_2$. The usual choices for p in (6) are $p = 1$ and $p = 2$.

Among the most popular approaches to compressed sensing is ℓ_1-norm minimization, which was popularized in a series of papers, of which we cite only (Candès and Tao, 2005; Candès et al., 2006; Candès, 2008; Donoho, 2006). The survey paper (Davenport et al.,

2012) has an extensive bibliography on the topic, as does the recent book (Foucart and Rauhut, 2013). In this approach, the estimate $\hat{x}$ is defined as

$$\hat{x} := \underset{z}{\text{argmin}} \|z\|_1 \text{ s.t. } \|Az - y\|_2 \leq \epsilon. \tag{7}$$

Note that the above definition does indeed define a decoder map $\Delta : \mathbb{R}^m \to \mathbb{R}^n$. In order for the above pair (A, Δ) to achieve robust sparse recovery, the matrix A is chosen so as to satisfy a condition defined next.

Definition 2 *A matrix $A \in \mathbb{R}^{m \times n}$ is said to satisfy the **Restricted Isometry Property (RIP)** of order k with constant δ_k if*

$$(1 - \delta_k)\|u\|_2^2 \leq \|Au\|_2^2 \leq (1 + \delta_k)\|u\|_2^2, \ \forall u \in \Sigma_k. \tag{8}$$

Starting with (Candès and Tao, 2005), several papers have derived sufficient conditions that the RIP constant of the matrix A must satisfy in order for ℓ_1-norm minimization to achieve robust sparse recovery. Recently, the "best possible" bound has been proved in (Cai and Zhang, 2014). These results are stated here for the convenience of the reader.

Theorem 3 *(See (Cai and Zhang, 2014, Theorem 2.1)) Suppose A satisfies the RIP of order tk for some number $t \geq 4/3$ such that tk is an integer, with $\delta_{tk} < \sqrt{(t-1)/t}$. Then the recovery procedure in (7) achieves robust sparse recovery of order k.*

Theorem 4 *(See (Cai and Zhang, 2014, Theorem 2.2)) Let $t \geq 4/3$. For all $\gamma > 0$ and all $k \geq 5/\gamma$, there exists a matrix A satisfying the RIP of order tk with constant $\delta_{tk} \leq \sqrt{(t-1)/t} + \gamma$ such that the recovery procedure in (7) fails for some k-sparse vector.*

Observe that the Lagrangian formulation of the LASSO approach is

$$\hat{x} := \underset{z}{\text{argmin}}[\|Az - y\|_2^2 + \lambda\|z\|_1],$$

whereas the Lagrangian formulation of (7) is

$$\hat{x} := \underset{z}{\text{argmin}}[\|z\|_1 + \beta\|Az - y\|_2],$$

which is essentially the same as the Lagrangian formulation of

$$\hat{x} = \underset{z}{\text{argmin}} \|Az - y\|_2 \text{ s.t. } \|z\|_1 \leq \gamma.$$

This last formulation of sparse regression is known as "square-root LASSO" (Belloni et al., 2014). Therefore the community refers to the approach to compressed sensing given in (7) as the LASSO, though this may not be strictly accurate.

1.3 Compressed Sensing with Group Sparsity

Over the years some variants of LASSO have been proposed for compressed sensing, such as the Group LASSO (GL) (Yuan and Lin, 2006) and the Sparse Group LASSO (SGL) (Simon et al., 2013). In the GL formulation, the index set $\{1, \ldots, n\}$ is partitioned into g disjoint sets $G_1, \ldots, G_g$, and the associated norm is defined as

$$\|z\|_{\mathrm{GL}} := \sum_{i=1}^{g} \|z_{G_i}\|_2, \tag{9}$$

where z_{G_i} denotes the projection of the vector z onto the components in G_i. The notation is intended to remind us that the norm depends on the specific partitioning $\mathcal{G}$. Some authors divide the term $\|z_{G_i}\|_2$ by $|G_i|$, but we do not do that. A further refinement of GL is the sparse group LASSO (SGL), in which the group structure is as before, but the norm is now defined as

$$\|z\|_{\mathrm{SGL},\mu} := \sum_{i=1}^{g} (1-\mu)\|z_{G_i}\|_1 + \mu\|z_{G_i}\|_2, \tag{10}$$

where as before $\mu \in [0,1]$. If $x \in \mathbb{R}^n$ is an unknown vector, then recovery of x is attempted via

$$\hat{x} = \underset{z}{\operatorname{argmin}} \|z\|_{\mathrm{GL}} \text{ s.t. } \|Az - y\|_2 \leq \epsilon \tag{11}$$

in Group LASSO, and via

$$\hat{x} = \underset{z}{\operatorname{argmin}} \|z\|_{\mathrm{SGL},\mu} \text{ s.t. } \|Az - y\|_2 \leq \epsilon \tag{12}$$

in Sparse Group LASSO.

The main idea behind GL is that one is less concerned about the number of nonzero components of $\hat{x}$, and more concerned about the number of distinct groups containing these nonzero components. Therefore GL attempts to choose an estimate $\hat{x}$ that has nonzero entries in as few distinct sets as possible. In principle, SGL tries to choose an estimate $\hat{x}$ that not only has nonzero components within as few groups as possible, but within those groups, has as few nonzero components as possible. Note that if $\mu = 0$, then SGL reduces to LASSO (because of the summability of the ℓ_1-norm), whereas if $\mu = 1$, then SGL reduces to GL. Note too that if $g = n$ and every set G_i is a singleton $\{i\}$, then GL reduces to LASSO.

1.4 Motivation and Contributions of the Paper

Now we come to the motivation and contributions of the present paper. The LASSO formulation is well-suited for compressed sensing (see Theorem 3), but not so well-suited for sparse regression, because it lacks the grouping effect. The EN formulation is well-suited for sparse regression as it exhibits the grouping effect, but it is not known whether it can achieve compressed sensing.

The first result presented in the paper is that if the EN regularizer of (4) is used instead of the ℓ_1-norm in (7), then the resulting approach *does not achieve* robust sparse recovery unless $m \geq n/4$, that is, the number of measurements grows linearly with respect to the size

of the vector. This would not be considered "compressed" sensing. This led us to formulate another regularizer, namely

$$\|z\|_{C,\mu} = (1-\mu)\|z\|_1 + \mu\|z\|_2. \tag{13}$$

Note that, while the EN regularizer in (4) is a convex function, it is not a norm. In contrast, $\|\cdot\|_{C,\mu}$ is not just convex but is also a norm. Also, the EN regularizer in its original form in (3) is intended to have *two* adjustable parameters. Our intent is that, in compressed sensing applications, the constant μ in (13) is a *fixed constant*, and not intended to be varied. Therefore, if the ℓ_1-norm in (7) is replaced by $\|\cdot\|_{C,\mu}$, then there is only one adjustable parameter, namely the Lagrange multiplier associated with the constraint. The same remark applies also to GL and SGL, that is, (11) and (12) respectively. We refer to $\|\cdot\|_{C,\mu}$ as the CLOT norm, with CLOT standing for Combined L-One and Two. It is shown that the CLOT norm combines the best features of both LASSO and EN, in that

- When the CLOT norm is used as the regularizer in sparse regression, the resulting solution exhibits the grouping effect.
- When the ℓ_1-norm is replaced by the CLOT norm in (7), the resulting solution achieves robust sparse recovery if the matrix A satisfies the RIP.
- Moreover, if μ in CLOT is set to zero so that CLOT becomes LASSO, the bound on the RIP constant reduces to the "best possible" bound in Theorem 3.

Clearly the CLOT norm is a special case of the SGL norm with the entire index set $[n]$ being taken as a single group (though the adjective "sparse" is no longer appropriate). This led us to explore whether the SGL norm achieves either grouping effect or robust sparse recovery. We are able to show that SGL does indeed achieve both.

Now we place these contributions in perspective. There is empirical evidence to support the belief that both the GL and the SGL formulations work well for compressed sensing. However, until the publication of a companion paper by a subset of the present authors (Ahsen and Vidyasagar, 2016), there were no proofs that either of these formulations achieved robust sparse recovery. In (Ahsen and Vidyasagar, 2016), it is shown that both the GL and SGL formulations achieve robust sparse recovery *provided the group sizes are sufficiently small*. This restriction on group sizes is removed in the present paper. Moreover, so far as the authors are aware, until now there are no results on the grouping effect for either of these formulations. In the present paper, it is shown that if two columns of the measurement matrix A *that belong to the same group* are highly correlated, then the corresponding components of the estimate $\hat{x}$ have nearly equal values. However, if two columns that belong to different groups are highly correlated, then their coefficients need not be nearly equal. From the standpoint of applications, this is a highly desirable property. To illustrate, suppose the groups represent biological pathways. Then one would wish to assign roughly similar weights to genes in the same pathway, but not necessarily to those in disjoint pathways.

Thus the contributions of the present paper are:

- To show that the EN *does not achieve* robust sparse recovery.
- To show that both the CLOT and SGL formulations achieve both robust sparse recovery as well as the grouping effect.

- To derive a condition under which CLOT achieves robust sparse recovery, which reduces to the "best possible" condition in Theorem 3 when μ is set to zero, so that CLOT becomes LASSO.

Taken together, these results might indicate that CLOT and SGL are attractive alternatives to the LASSO and EN formulations.

2. Main Theoretical Results

This section contains the main contributions of the paper. We begin by showing in Section 2.1 that the solution paths of EN and CLOT are identical if both λ_1 and λ_2 are treated as adjustable parameters. Therefore further research would be needed to establish whether CLOT offers any advantages over EN in numerical performance in sparse regression.

Then we present several theoretical advantages of CLOT over both EN and LASSO. First it is shown in Section 2.2 that the EN approach does not achieve robust sparse recovery, and is therefore not suitable for compressed sensing applications. Next, it is shown in Section 2.3 that the SGL formulation assigns nearly equal weights to highly correlated features *within the same group*, though not necessarily to highly correlated features from different groups. It follows as a corollary that CLOT assigns nearly equal weights to highly correlated features. Then it is shown in Section 2.4 that the SGL formulation achieves robust sparse recovery. The contents of a companion paper by a subset of the present authors Ahsen and Vidyasagar (2016) establish that SGL achieves robust sparse recovery of order k *provided that each group size is smaller than* k. There is no such restriction here. It follows as a corollary that CLOT also achieves robust sparse recovery.

2.1 Relationship Between Solution Paths of EN and CLOT

In this subsection, it is shown that if both μ and λ are tuned via cross-validation in (3), then the solution paths of CLOT are identical to those of EN when both λ_1 and λ_2 are tuned. However, it is shown via an example that if μ is kept fixed and *only* λ is tuned in (3), then CLOT and EN have different solution paths.

Towards this end, we rewrite the CLOT formulation with both μ and λ being tuned in the form

$$\hat{x}_{\rm CLOT} := \underset{z}{\rm argmin}[\|y - Ax\|_2^2 + \lambda_1\|z\|_1 + \lambda_2\|z\|_2]. \tag{14}$$

It is easy to see that the transformation

$$\mu = \frac{\lambda_2}{\lambda_1 + \lambda_2}, \lambda = \lambda_1 + \lambda_2$$

maps (14) into (3). In the other direction, we would define

$$\lambda_1 = (1 - \mu)\lambda, \lambda_2 = \mu\lambda.$$

We are grateful to one of the reviewers for pointing out the result as described in Theorem 5, and providing a proof.

Theorem 5 *Given $y \in \mathbb{R}^m$ and $A \in \mathbb{R}^{m\times n}$, define two vectors:*

$$\hat{x}_{\rm CLOT}(\lambda_1, \tilde{\lambda}_2) = \underset{z}{\rm argmin}[\|y - Az\|_2^2 + \lambda_1\|z\|_1 + \tilde{\lambda}_2\|z\|_2],$$

$$\hat{x}_{\rm EN}(\lambda_1, \hat{\lambda}_2) = \underset{z}{\rm argmin}[\|y - Az\|_2^2 + \lambda_1\|z\|_1 + \hat{\lambda}_2\|z\|_2^2].$$

Then for each fixed $\lambda_1 > 0$ and each $\tilde{\lambda}_2 > 0$, there exists a $\hat{\lambda}_2 > 0$ such that

$$\hat{x}_{\rm CLOT}(\lambda_1, \tilde{\lambda}_2) = \hat{x}_{\rm EN}(\lambda_1, \hat{\lambda}_2),$$

and vice versa.

Proof We begin with the following rather obvious observation. Suppose $f(\cdot)$ and $g(\cdot)$ are convex functions, and consider two problems:

$$\text{(P1)} \quad \hat{x}_1(\lambda) = \underset{z}{\rm argmin}[f(z) + \lambda g(z)],$$

$$\text{(P2)} \quad \hat{x}_2(c) = \underset{z}{\rm argmin}\, f(z) \text{ s.t. } g(z) \le c.$$

Then for each λ there exists a c such that $\hat{x}_1(\lambda) = \hat{x}_2(c)$, and vice versa. To establish this, write down the optimality conditions for the two problems, with $\partial f(\cdot)$, $\partial g(\cdot)$ denoting the subgradient sets of $f(\cdot)$, $g(\cdot)$ respectively. Then a necessary and sufficient condition for $\hat{x}_1(\lambda)$ to be the solution of (P1) is:

$$\mathbf{0} \in \partial f(\hat{x}_1(\lambda)) + \lambda\partial g(\hat{x}_1(\lambda)), \tag{15}$$

where $\mathbf{0}$ denotes the zero vector. Similarly, for (P2) the necessary and sufficient conditions are the existence of a constant λ^* such that

$$\mathbf{0} \in \partial f(\hat{x}_1(\lambda^*)) + \lambda\partial g(\hat{x}_1(\lambda^*)), \text{ and } \lambda^*(g(\hat{x}_1(\lambda^*)) - c) = 0. \tag{16}$$

Suppose (15) holds; then (16) holds with $c = g(\hat{x}_1(\lambda))$. Conversely, suppose (16) holds; then (15) holds with $\lambda = \lambda^*$.

Now apply this reasoning with $f(z) = \|y - Az\|_2^2 + \lambda_1\|z\|_1$, $g_1(z) = \|z\|_2$, $g_2(z) = \|z\|_2^2$. Then each $\hat{x}_{\rm CLOT}(\lambda_1, \tilde{\lambda}_2)$ equals the minimizer of $f(z)$ subject to $\|z\|_2 \le c$ for some c, while each $\hat{x}_{\rm EN}(\lambda_1, \hat{\lambda}_2)$ equals the minimizer of $f(z)$ subject to $\|z\|_2^2 \le c'$ for some c'. However, it is obvious that

$$[\|z\|_2 \le c] \iff [\|z\|_2^2 \le c^2].$$

Therefore the theorem is proved. □ ■

2.2 Lack of Robust Sparse Recovery of the Elastic Net Formulation

The first result of this section shows that EN formulation does not achieve robust sparse recovery, and therefore is not suitable for compressed sensing applications.

Theorem 6 *Suppose a matrix $A \in \mathbb{R}^{m\times n}$ has the following property: There exist constants C and D such that, whenever $y = Ax + \eta$ for some $x \in R^n$ and $\eta \in \mathbb{R}^m$ with $\|\eta\|_2 \leq \epsilon$, the solution*

$$\hat{x}_{\text{EN}} := \underset{z\in\mathbb{R}^n}{\text{argmin}}[(1-\mu)\|z\|_1 + \mu\|z\|_2^2] \text{ s.t. } \|y - Az\|_2 \leq \epsilon$$

satisfies

$$\|\hat{x}_{\text{EN}} - x\|_2 \leq C\sigma_k(x, \|\cdot\|_1) + D\epsilon. \tag{17}$$

Then

$$m \geq n/4. \tag{18}$$

Proof: Let $\mathcal{N}(A)$ denote the null space of the matrix A, that is, the set of all $h \in \mathbb{R}^n$ such that $Ah = 0$. Let $h \in \mathcal{N}(A)$ be arbitrary, and let $\Lambda \subseteq \{1, \ldots, n\}$ denote the index set of the k largest components of h by magnitude. Therefore

$$\|h_{\Lambda^c}\|_2 = \sigma_k(h, \|\cdot\|_2).$$

Next, (17) implies that, if $\eta = 0$, then $\hat{x}_{\text{EN}} = x$ for all $x \in \Sigma_k$. In other words,

$$x = \underset{z\in\mathbb{R}^n}{\text{argmin}}[(1-\mu)\|z\|_1 + \mu\|z\|_2^2] \text{ s.t. } Az = Ax,$$

or equivalently,

$$(1-\mu)\|x\|_1 + \mu\|x\|_2^2 \leq (1-\mu)\|z\|_1 + \mu\|z\|_2^2, \ \forall z \in A^{-1}(\{Ax\}), \ \forall x \in \Sigma_k. \tag{19}$$

Now observe that, because $h \in \mathcal{N}(A)$, we have that

$$Ah_\Lambda = -Ah_{\Lambda^c},$$

and more generally,

$$A(\beta h_\Lambda) = A(-\beta h_{\Lambda^c}), \ \forall \beta > 0.$$

Apply (19) with $x = \beta h_\Lambda \in \Sigma_k$ and $z = -A\beta h_{\Lambda^c} \in A^{-1}(\{Ax\})$. This leads to

$$(1-\mu)\beta\|h_\Lambda\|_1 + \beta^2\mu\|h_\Lambda\|_2^2 \leq (1-\mu)\beta\|h_{\Lambda^c}\|_1 + \beta^2\mu\|h_{\Lambda^c}\|_2^2.$$

Now divide both sides by $\beta^2\mu$, and observe that, for each fixed $\mu > 0$,

$$\frac{1-\mu}{\beta\mu} \to 0 \text{ as } \beta \to \infty.$$

Therefore

$$\|h_\Lambda\|_2^2 \leq \|h_{\Lambda^c}\|_2^2, \text{ or } \|h_\Lambda\|_2 \leq \|h_{\Lambda^c}\|_2, \ \forall h \in \mathcal{N}(A).$$

Next

$$\|h\|_2 \leq \|h_\Lambda\|_2 + \|h_{\Lambda^c}\|_2 \leq 2\|h_{\Lambda^c}\|_2, \ \forall h \in \mathcal{N}(A).$$

Equivalently

$$\|h\|_2 \leq 2\sigma_k(h, \|\cdot\|_2), \ \forall h \in \mathcal{N}(A).$$

This is Equation (5.2) of Cohen-Dahmen-Devore (2009) with $C_0 = 2$. As shown in Theorem 5.1 of that paper, this implies that $m \geq n/C_0^2 = n/4$, which is the desired conclusion. □

Note that the proof of Theorem 6 remains valid even if we were to allow the constant μ to be "tuned", provided that it is bounded away from zero. In other words, the proof does not make use of the fact that μ is a fixed constant. Therefore even in the "naive" version of EN, in which the regularizer is defined as in (3), and both constants α_1 and α_2 are adjusted, robust sparse recovery requires that $m \geq n/4$ provided only that the ratio α_1/α_2 remains bounded away from zero as both parameters are tuned.

2.3 Grouping Property of the SGL and CLOT Formulations

One advantage of the EN over LASSO is that the former assigns roughly equal weights to highly correlated features, as shown in (Zou and Hastie, 2005, Theorem 1) and referred to as the grouping effect. In contrast, if LASSO chooses one feature among a set of highly correlated features, then generically it assigns a zero weight to all the rest. To illustrate, if two columns of A are identical, then in principle LASSO could assign nonzero weights to both columns; however, the slightest perturbation in the data would cause one or the other weight to become zero. The drawback of this is that the finally selected feature set is very sensitive to noise in the measurements. In this section we prove an analog of (Zou and Hastie, 2005, Theorem 1) for SGL formulation. Our result states that if two highly correlated features *within the same group* are chosen by SGL, then they will have roughly similar weights. Since CLOT is a special case of SGL with the entire feature set treated as one group, it follows that CLOT assigns roughly similar weights to highly correlated features in the entire set of features. As a result, the final feature sets obtained using SGL or CLOT are less sensitive to noise in measurements than the ones obtained using LASSO.

Theorem 7 *Let $y \in \mathbb{R}^m, A \in \mathbb{R}^{m\times n}$ be some vector and matrix respectively. Without loss of generality, suppose that y is centered, i.e. $y^t\mathbf{e}_m = 0$, where $\mathbf{e}_m$ denotes a column vector consisting of m ones, and that A is standardized, i.e. $\|a_j\|_2 = 1$ where a_j denotes the j-th column of A. Suppose $\mu > 0$, and let $\mathcal{G}$ denote a partition of $\{1, \ldots, n\}$ into g disjoint subsets. Define*

$$\hat{x} := \underset{z}{\text{argmin}}\, \lambda\|y - Az\|_2^2 + \|z\|_{\text{SGL},\mu}, \tag{20}$$

where $\lambda > 0$ is a Lagrange multiplier. Suppose that, for two indices i, j belonging to the same group G_s, we have that $\hat{x}_i\hat{x}_j \neq 0$, where $\hat{x}_i, \hat{x}_j$ denote the components of the vector $\hat{x}$. By changing the sign of one of the columns of A if necessary, it can be assumed that $\hat{x}_i\hat{x}_j > 0$. Define

$$d(i,j) := \frac{|\hat{x}_i - \hat{x}_j|}{2\lambda\|y\|_2}, \rho(i,j) = a_i^t a_j.$$

Then

$$d(i,j) \leq \frac{\sqrt{2(1-\rho(i,j))}\|\hat{x}^s\|_2}{\mu}, \tag{21}$$

where $\hat{x}^s$ is shorthand for $\hat{x}_{G_s}$.

Proof: Define

$$\begin{aligned} L(z,\mu) &:= \lambda\|y-Az\|_2^2 + \|z\|_{\text{SGL},\mu} \\ &= \lambda\|y-Az\|_2^2 + (1-\mu)\|z\|_1 + \mu\sum_{s=1}^{g}\|z^s\|_2, \end{aligned}$$

where, as above, z^s denotes Z_{G_s}. Then L is differentiable with respect to z_i whenever $z_i \neq 0$. In particular, since both $\hat{x}_i$ and $\hat{x}_j$ are nonzero by assumption, it follows that

$$\left.\frac{\partial L}{\partial z_i}\right|_{z=\hat{x}} = \left.\frac{\partial L}{\partial z_j}\right|_{z=\hat{x}} = 0.$$

Expanding the partial derivatives leads to

$$-2\lambda a_i^t(y-A\hat{x}) + (1-\mu)\text{sign}(\hat{x}_i) + \mu\frac{\hat{x}_i}{\|\hat{x}^s\|_2} = 0,$$

$$-2\lambda a_j^t(y-A\hat{x}) + (1-\mu)\text{sign}(\hat{x}_j) + \mu\frac{\hat{x}_j}{\|\hat{x}^s\|_2} = 0.$$

Subtracting one equation from the other gives

$$2\lambda(a_j^t - a_i^t)(y-A\hat{x}) + \mu\frac{\hat{x}_i - \hat{x}_j}{\|\hat{x}^s\|_2} = 0.$$

Hence

$$\begin{aligned} \frac{|\hat{x}_i - \hat{x}_j|}{\|\hat{x}^s\|_2} &= \frac{2\lambda}{\mu}|(a_j^t - a_i^t)(y-A\hat{x})| \\ &\leq \frac{2\lambda}{\mu}\|a_j - a_i\|_2\|y-A\hat{x}\|_2 \\ &\leq \frac{2\lambda}{\mu}\sqrt{2(1-\rho(i,j))}\|y\|_2. \end{aligned}$$

In the last step, we use the fact that

$$\|y-A\hat{x}\|_2 \leq \|y-A\mathbf{0}\|_2 = \|y\|_2.$$

Rearranging gives

$$\frac{1}{2\lambda}\frac{|\hat{x}_i - \hat{x}_j|}{\|y\|_2} \leq \frac{\sqrt{2(1-\rho(i,j))}\|\hat{x}^s\|_2}{\mu},$$

which is the desired conclusion. □

Let us illustrate the above result using the CLOT formulation. In the case of CLOT formulation we have $g = 1$, $\mathcal{G} = \{G_1\}$, $G_1 = \{1, \cdots, n\}$, and the inequality in (21) becomes

$$d(i,j) \leq \frac{\sqrt{2(1-\rho(i,j))}\|\hat{x}\|_2}{\mu}, \tag{22}$$

where $\hat{x}$ is the solution of the CLOT formulation, and

$$d(i,j) = \frac{|\hat{x}_i - \hat{x}_j|}{2\lambda\|y\|_2}. \tag{23}$$

Now suppose that two indices i and j are highly correlated such that $\rho(i,j) \approx 1$, so that the right hand side of the inequality in (22) is almost equal to zero. Combining this with (23) we can conclude $\hat{x}_i \approx \hat{x}_j$, so CLOT assigns similar weights to highly correlated variables. □

Though the focus of the present paper is not on the GL formulation, we digress briefly to discuss the implications of Theorem 7 for GL. This theorem also implies that the GL formulation exhibits the grouping effect, because GL is a special case of SGL with $\mu = 1$. Indeed, it can be observed from (21) that the bound on the right side is minimized by setting $\mu = 1$, that is, using GL instead of SGL. This is not surprising, because SGL not only tries to minimize the number of distinct groups containing the support of $\hat{x}$, but within each group, tries to choose as few elements as possible. Thus, within each group, SGL inherits the weaknesses of LASSO. Thus one would expect that, within each group, the feature set chosen would become more sensitive as we decrease μ.

2.4 Robust Sparse Recovery of the SGL and CLOT Formulations

In this subsection, we present some sufficient conditions for the SGL and CLOT formulations to achieve robust sparse recovery. When CLOT is specialized to LASSO by setting $\mu = 0$, the sufficient condition reduces to the "tight" bound given in Theorem 3.

Recall the definitions. The CLOT norm with parameter μ is given by

$$\|z\|_{C,\mu} := (1-\mu)\|z\|_1 + \mu\|z\|_2,$$

while the SGL norm is given by

$$\|z\|_{SGL,\mu} := \sum_{i=1}^{g}[(1-\mu)\|z_{G_i}\|_1 + \mu\|z_{G_i}\|_2]$$

Recall also the problem set-up. The measurement vector y equals $Ax + \eta$ where $\|\eta\|_2 \leq \epsilon$, a known upper bound. The recovered vector $\hat{x}$ is defined as

$$\hat{x} = \underset{z}{\text{argmin}}\,\|z\|_{\text{SGL},\mu} \text{ s.t. } \|Az - y\|_2 \leq \epsilon \tag{24}$$

if SGL is used, and as

$$\hat{x} = \underset{z}{\text{argmin}}\,\|z\|_{C,\mu} \text{ s.t. } \|Az - y\|_2 \leq \epsilon \tag{25}$$

if CLOT is used.

Definition 8 *A matrix $A \in \mathbb{R}^{m\times n}$ is said to satisfy the ℓ_2* ***robust null space property (RNSP)*** *if there exist constants $\rho \in (0,1)$ and $\tau \in \mathbb{R}_+$ such that, for all sets $S \subseteq [n]$ with $|S| \leq k$, we have*

$$\|h_S\|_2 \leq \frac{\rho}{\sqrt{k}}\|h_{S^c}\|_1 + \frac{\tau}{\sqrt{k}}\|Ah\|_2. \tag{26}$$

This property was apparently first introduced in (Foucart and Rauhut, 2013, Definition 4.21). Note that the definition in Foucart and Rauhut (2013) has just τ in place of $\tau/\sqrt{k}$. It is easy to show that, if (26) holds, then

$$\|h_S\|_1 \leq \rho\|h_{S^c}\|_1 + \tau\|Ah\|_2.$$

The following result is established in Ranjan and Vidyasagar (2016) in the context of group sparsity, but is new even for conventional sparsity. The reader is directed to that source for the proof.

Theorem 9 *((Ranjan and Vidyasagar, 2016, Theorem 5)) Suppose that, for some number $t > 1$, the matrix A satisfies the RIP of order tk with constant $\delta_{tk} < \sqrt{(t-1)/t}$. Let δ be an abbreviation for δ_{tk}, and define the constants*

$$\nu := \sqrt{t(t-1)} - (t-1) \in (0, 0.5), \tag{27}$$

$$a := [\nu(1-\nu) - \delta(0.5 - \nu + \nu^2)]^{1/2}, \tag{28}$$

$$b := \nu(1-\nu)\sqrt{1+\delta}, \tag{29}$$

$$c := \left[\frac{\delta\nu^2}{2(t-1)}\right]^{1/2}. \tag{30}$$

Then A satisfies the ℓ_2-robust null space property with

$$\rho = \frac{c}{a} < 1, \tau = \frac{b\sqrt{k}}{a^2}. \tag{31}$$

In Theorem 10 below, it is assumed that the matrix A satisfies the RIP of order tk with $\delta_{tk} < \sqrt{(t-1)/t}$, in accordance with Theorem 3. With this assumption, we prove bounds on the residual error $\|\hat{x} - x\|_1$ with SGL; the bounds for CLOT can be obtained simply by setting $g = 1$ in the SGL bounds. Note that, once bounds for $\|\hat{x} - x\|_1$ are proved, it is possible to extend the bounds to $\|\hat{x} - x\|_p$ for all $p \in [1, 2]$; see (Foucart and Rauhut, 2013, Theorem 4.22).

Theorem 10 *Suppose $x \in \mathbb{R}^n$ and that $A \in \mathbb{R}^{m\times n}$ satisfies the RIP of order tk with constant $\delta = \delta_{tk} < \sqrt{(t-1)/t}$, and define constants ρ, τ as in* (31)*. Suppose that*

$$\mu < \frac{1-\rho}{\sqrt{g}(1+\rho)}. \tag{32}$$

Define

$$\gamma = \frac{\mu\sqrt{g}}{1-\mu}. \tag{33}$$

With these assumptions,

$$\|\hat{x} - x\|_1 \leq C\sigma_k(x, \|\cdot\|_1) + D\epsilon, \tag{34}$$

$$\|\hat{x} - x\|_p \leq \frac{1}{k^{1-1/p}}[(1+\rho)C\sigma_k(x, \|\cdot\|_1) + ((1+\rho)D + 2\tau)\epsilon], \ \forall p \in (1, 2], \tag{35}$$

where

$$C = \frac{2(1+\rho)}{(1-\gamma) - (1+\gamma)\rho}, D = \frac{4\tau}{(1-\gamma) - (1+\gamma)\rho}. \tag{36}$$

The proof of the above theorem is presented in an appendix, due to its length.

In the above theorem, we started with the restricted isometry constant δ and computed an upper bound on μ in order for SGL and CLOT to achieve robust sparse recovery. As δ_{tk} gets closer to the limit $\delta_{tk} < \sqrt{(t-1)/t}$ (which is known to be the best possible in view of Theorem 4), the limit on μ would approach zero. It is also possible to start with μ and find an upper bound on δ, by rearranging the inequalities. As this involves just routine algebra, we simply present the final bound. Given the number $t \geq 4/3$, define ν as in (27), and define

$$\theta_1 := \nu(1-\nu) \in (0, 0.25), \theta_2 := 0.5 - \theta_1 \in (0.25, 0.5), \tag{37}$$

$$\theta_3 := \frac{\nu^2}{2(t-1)}. \tag{38}$$

Given $\mu > 0$, define γ as in (33), and define

$$\bar{\rho} := \frac{1-\gamma}{1+\gamma}.$$

If the matrix A satisfies the RIP of order tk with a constant $\delta = \delta_{tk}$, then SGL achieves robust sparse recovery of order k provided

$$\delta < \bar{\rho}^2 \frac{\theta_1}{\theta_3 + \bar{\rho}^2\theta_2}, \tag{39}$$

3. Numerical Examples

In this section we present two simulation studies, to demonstrate the the grouping effect of CLOT and the lack of robust sparse recovery of EN, respectively.

3.1 Grouping Effect of CLOT

To illustrate that CLOT demonstrates the grouping effect as does EN (see Theorem 7), we ran the same example as at the end of (Zou and Hastie, 2005, Section 5). Specifically, we chose Z_1 and Z_2 to be two independent $U(0, 20)$ random variables, and the observation y as $N(Z_1 + 0.1Z_2, 1)$. The six observations were

$$x_1 = Z_1 + \epsilon_1, x_2 = -Z_1 + \epsilon_2, x_3 = Z_1 + \epsilon_3, x_4 = Z_2 + \epsilon_4, x_5 = -Z_2 + \epsilon_5, x_6 = Z_2 + \epsilon_6,$$

where the ϵ_i are i.i.d. $N(0, 1/16)$. The objective was to express y as a linear combination of x_1 through x_6. In other words, we wished to express $y = X\boldsymbol{\beta}$, where X is the matrix with the x_i as columns, and $\boldsymbol{\beta}$ is a 6×1 vector. Ideally the outcome should be to assign

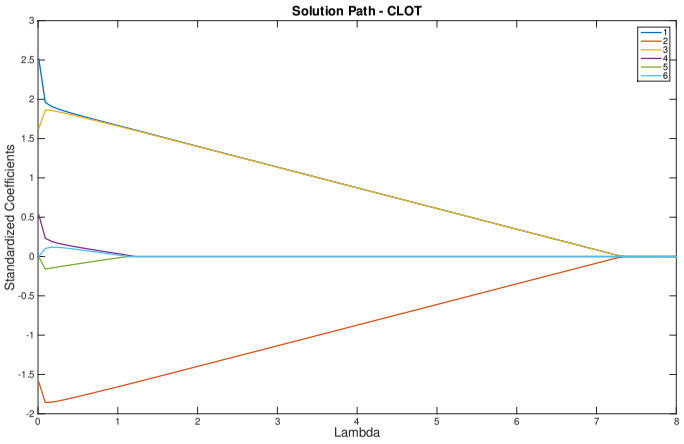

Figure 1: Solution Paths for CLOT

high weights to the correlated group x_1, x_2, x_3 and low weights to x_4, x_5, x_6. Therefore, if $\boldsymbol{\beta}$ denotes the six-dimensional coefficient vector, we should have that

$$\beta_1 \approx -\beta_2 \approx \beta_3,$$

and that β_4 through β_6 are much smaller than β_1 through β_3.

The three algorithms LASSO, EN, and CLOT were implemented via the Lagrangian formulation in (2), with λ being increased. Clearly, when λ is sufficiently large, the optimal value of $\boldsymbol{\beta}$ is the zero vector. The "sufficiently large" value of λ varies from one algorithm to the next. Figures 1 through 3 show the solution trajectories of the three algorithms as functions of λ, with μ set equal to 0.5. From Figures 1 and 2, it is clear that both CLOT and EN very quickly reach the correct proportionalities between the large coefficient values, which eventually become smaller and go to zero as λ becomes larger. In contrast, the LASSO solutions are quite inaccurate.

3.2 Lack of Robust Sparse Recovery by EN

In this subsection we illustrate Theorem 6. In this set-up, $n = 4,000$ and $k = 3$. The first three components of the vector x are assigned values at random using the `Matlab rand` function, which resulted in [0.8147 0.9058 0.1270]. The remaining components of x were set equal to zero. We could have chosen not just the values but also the location of the nonzero components at random; but this would have been just a permuation of the above example.

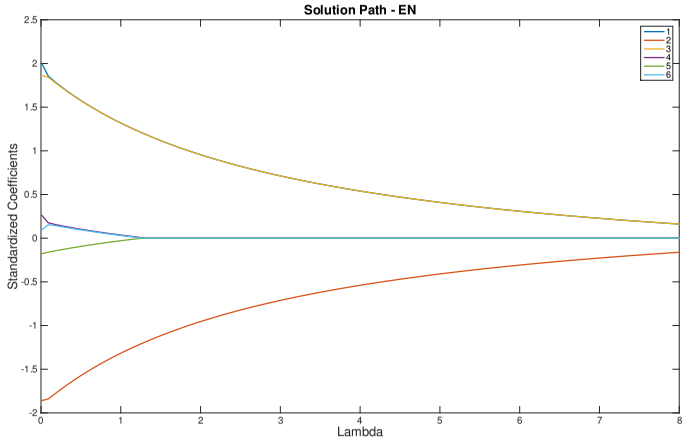

Figure 2: Solution Path for EN

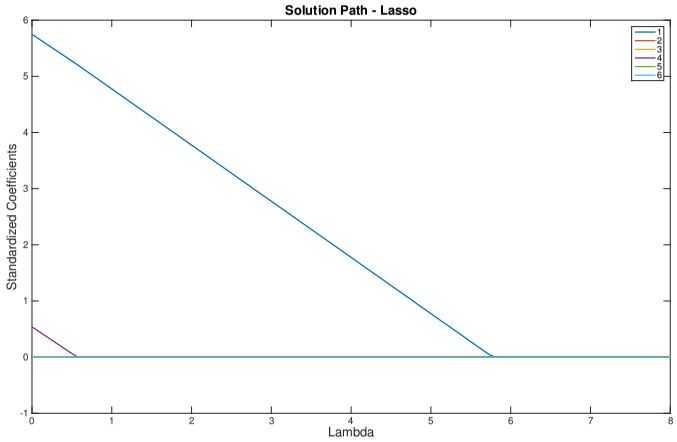

Figure 3: Solution Path for LASSO

Next, in order to achieve robust sparse recovery of order k, following Theorem 3 we needed to choose a $t \geq 4/3$ and then choose a matrix A such that A satisfied the RIP of order $\lceil tk \rceil$ with constant $\delta < \sqrt{(t-1)/t}$. We chose $t = 1.5$, which resulted in $\lceil tk \rceil = 5$, and $\delta_5 < \sqrt{1/3} \approx 0.5774$. We chose $\delta_5 = 0.4$. Therefore we had to choose an integer m and a matrix $A \in \mathbb{R}^{m \times n}$ such that A satisfied the RIP of order 5 with constant $\delta_5 \leq 0.4$. Such a matrix was constructed using the deterministic procedure suggested in (DeVore, 2007). This required the choice of an integer $r \geq 2$ and a prime number p such that

$$p \geq \max \left\{ \frac{(\lceil tk \rceil - 1)r}{\delta}, n^{1/(r+1)} \right\} = \max\{20, 15.87\} = 20.$$

and led to a binary matrix of dimensions $p^2 \times p^{r+1}$. The smallest prime number greater than 20 is $p = 23$, and $m = p^2 = 529$. Note that $m < n/4$. The main advantages of the construction in (DeVore, 2007) are that (i) the construction is deterministic, (ii) the matrix A is binary, and (iii) only a fraction $1/p$ of the elements of A are equal to 1, and the rest are equal to zero. This makes computation very fast.

Once the matrix A was chosen, we defined the measured vector as $y = Ax$; that is, we did not introduce any measurement noise. Then we computed estimates of x using both CLOT and EN. With $\delta = 0.4$, the constant ρ defined in (31) becomes 0.6551, and the bound in (32), after substituting $g = 1$, becomes $\mu < 0.2084$. Therefore we chose $\mu = 0.2$, and defined

$$\hat{x}_{\text{CLOT}} = \underset{z}{\text{argmin}} \, \|z\|_{C,\mu} \text{ s.t. } Az = y,$$

$$\hat{x}_{\text{EN}} = \underset{z}{\text{argmin}} (1-\mu)\|z\|_1 + \mu\|z\|_2^2 \text{ s.t. } Az = y,$$

with the same value of $\mu = 0.2$ in both cases. Then we replaced x by $10^c x$ for $c = 1, 2, 3, 4$ and recomputed the estimates. Because $m < n/4$, according to Theorem 7, EN should fail as the norm of the vector x is increased.

The above constrained optimization problems were solved using the cvx package in `Matlab`, on an HP Pavilion laptop. The actual results are shown in Table 1. For compactness only the first three components of $\hat{x}$ are shown. As can be seen, when $c = 0$ or $c = 1$, both CLOT and EN give the correct answer. However, for larger values of c, the CLOT estimate simply got multiplied by the same scale factor, whereas the EN estimate started diverging from the true value with $c = 2$; the algorithm failed to converge with $c = 4$.

4. Discussion and Concluding Remarks

In this paper we have introduced a new optimization formulation called CLOT (Combined L-One and Two), wherein the regularizer is a convex combination of the ℓ_1- and ℓ_2-norms. This formulation differs from the Elastic Net (EN) formulation, in which the regularizer is a convex combination of the ℓ_1- and ℓ_2-norm *squared*. This seemingly simple modification has fairly significant consequences. In particular, it is shown in this paper that the EN formulation *does not achieve* robust recovery of sparse vectors in the context of compressed sensing, whereas the new CLOT formulation does so. Also, like EN but unlike LASSO, the CLOT formulation achieves the grouping effect, wherein coefficients of highly correlated columns of the measurement (or design) matrix are assigned roughly comparable values. It

c	$\hat{x}_{\text{CLOT}}$	$\hat{x}_{\text{EN}}$
0	0.8147	0.8147
	0.9058	0.9058
	0.1270	0.1270

	126.9868	15.3818
4	8.1472×10^3	NaN
	9.0579×10^3	NaN
	1.2699×10^3	NaN

Table 1: Comparison of solutions of the CLOT and EN algorithms as the unknown vector is scaled by successive powers of 10. The CLOT output simply scales by the same factor, whereas the EN output begins to be incorrect already when the scale factor is 100. For a scale factor of 10^4, the algorithm fails.

is noteworthy that LASSO does not have the grouping effect and EN (as shown here) does not achieve robust sparse recovery. Therefore the CLOT formulation combines the best features of both LASSO (robust sparse recovery) and EN (grouping effect).

The CLOT formulation is a special case of another one called SGL (Sparse Group LASSO) which was introduced into the literature previously, but without any analysis of either the grouping effect or robust sparse recovery (Simon et al., 2013). It is shown here that SGL achieves robust sparse recovery, and also achieves a version of the grouping effect in that coefficients of highly correlated columns of the measurement (or design) matrix are assigned roughly comparable values, *if the columns belong to the same group*.

There are several papers in the literature that discuss LASSO-like formulations for group sparsity; some of these are discussed here. First, there is a companion paper by a subset of the present authors (Ahsen and Vidyasagar, 2016), which studies the problem of robust sparse recovery with SGL-like formulations, *but with restrictions on the group size*. In contrast, in the present paper, there is no such restriction, which is why the results derived here for the SGL formulation can be directly applied to the CLOT formulation. Second, for the case where several columns of the matrix A are highly correlated, (Bühlmann et al., 2013) suggests a two-stage process whereby first correlated columns are clustered, and second, a variant of LASSO is applied. In a discussion of this paper, namely (Bien and Wegkamp, 2013), all the LASSO variants together with EN are run on various test data. For the purposes of the present discussion, the salient observation is that the EN formulation performed roughly as well – no better and no worse – compared almost all the

LASSO variants. Finally, in (van de Geer, 2014), a general theory is presented whereby the fully decomposable ℓ_1-norm is replaced by a weakly decomposable norm, and oracle bounds are derived for $\|\hat{x} - x\|$ provided that the index set $[n]$ is divided into an "allowed set" and its complement. There is also some discussion of overlapping group decompositions. Specifically, when an element of the index set $[n]$ appears in two groups, the corresponding column of A is simply replicated to remove the overlap. However, if two columns of A are identical (and normalized), then the RIP constant δ_2 would equal zero, as would δ_k for $k \geq 2$. Therefore, if the case of overlapping groups is handled in this manner, then any analysis based on RIP would be infructuous. The above discussion is quite cursory, and the reader may consult these references for fuller details.

It would be worthwhile to study the behavior of SGL with overlapping groups. There are variants of SGL with overlapping groups, provided they satisfy some additional constraints; see (Jenetton et al., 2011; Obozinski et al., 2011) for example. However, in a companion paper (Ahsen and Vidyasagar, 2016), it is shown that the assumptions of (Jenetton et al., 2011; Obozinski et al., 2011) still enforce a nonoverlap constraint, but in a nonobvious fashion. As pointed out in the previous paragraph, the approach of introducing duplicate columns into A to eliminate overlap would render any analysis based on RIP impossible. Thus a suitable approach remains to be discovered.

Appendix A: Proof of Theorem 10

Proof Hereafter we write z^i instead of z_{G_i} in the interests of brevity.

Define $h = \hat{x} - x \in \mathbb{R}^n$. From the definition of the estimate, we have that

$$\|x\|_{SGL,\mu} \geq \|\hat{x}\|_{SGL,\mu} = \|x + h\|_{SGL,\mu}$$

From the definition of the SGL norm, this expands to

$$(1-\mu)\|x\|_1 + \mu \sum_{j=1}^{g} \|x^j\|_2 \geq (1-\mu)\|x+h\|_1 + \mu \sum_{j=1}^{g} \|x^j + h^j\|_2.$$

This can be rearranged as

$$(1-\mu)(\|x\|_1 - \|x+h\|_1) + \mu \sum_{j=1}^{g} (\|x^j\|_2 - \|(x^j + h^j\|_2) \geq 0. \tag{40}$$

We will work separately on each of the two terms separately. First, by the triangle inequality, we have that

$$\|x^j + h^j\|_2 \geq \|x^j\|_2 - \|h^j\|_2, \text{ or } \|h^j\|_2 \geq \|x^j\|_2 - \|x^j + h^j\|_2.$$

As a consequence,

$$\sum_{j=1}^{g} \|h^j\|_2 \geq \sum_{j=1}^{g} [\|x^j\|_2 - \|x^j + h^j\|_2]$$

From Schwarz' inequality, we get

$$\sum_{j=1}^{g} \|h^j\|_2 \leq \sqrt{g}\|h\|_2 \leq \sqrt{g}\|h\|_1 \leq \sqrt{g}(\|h_S\|_1 + \|h_{S^c}\|_1),$$

for any $S \subseteq [n]$. Combining everything gives

$$\sum_{j=1}^{g} [\|x^j\|_2 - \|x^j + h^j\|_2] \leq \sqrt{g}(\|h_S\|_1 + \|h_{S^c}\|_1), \tag{41}$$

for any subset $S \subseteq [n]$. Second, for any subset $S \subseteq [n]$, the decomposability of $\|\cdot\|_1$ implies that

$$\|x\|_1 = \|x_S\| + \|x_{S^c}\|_1,$$

while the triangle inequality implies that

$$\begin{aligned} \|x+h\|_1 &= \|x_S + h_S\|_1 + \|x_{S^c} + h_{S^c}\|_1 \\ &\geq \|x_S\|_1 - \|h_S\|_1 + \|h_{S^c}\|_1 - \|x_{S^c}\|_1. \end{aligned}$$

Therefore

$$\|x\|_1 - \|x+h\|_1 \leq \|h_S\|_1 - \|h_{S^c}\|_1 + 2\|x_{S^c}\|_1. \tag{42}$$

If we now choose S to be the set corresponding to the k largest elements of x by magnitude, then

$$\|x_{S^c}\|_1 = \sigma_k(x, \|\cdot\|_1) =: \sigma_k.$$

With this choice of S, (42) becomes

$$\|x\|_1 - \|x+h\|_1 \leq \|h_S\|_1 - \|h_{S^c}\|_1 + 2\sigma_k. \tag{43}$$

Substituting the bounds (41) and (42) into (40) gives

$$0 \leq \mu\sqrt{g}(\|h_S\|_1 + \|h_{S^c}\|_1) + (1-\mu)(\|h_S\|_1 - \|h_{S^c}\|_1 + 2\sigma_k).$$

Now recall the definition of the constant γ from (33). Using this definition, the above inequality can be rearranged as

$$0 \leq \gamma(\|h_S\|_1 + \|h_{S^c}\|_1) + (\|h_S\|_1 - \|h_{S^c}\|_1 + 2\sigma_k).$$

and equivalently as

$$(1-\gamma)\|h_{S^c}\|_1 - (1+\gamma)\|h_S\|_1 \leq 2\sigma_k. \tag{44}$$

This is the first of two equations that we need.

Now we derive the second equation. From Theorem 9, we know that the matrix A satisfies the l_2-robust null space property, namely (26). An application of Schwarz' inequality shows that

$$\|h_S\|_1 \leq \rho\|h_{S^c}\|_1 + \tau\|Ah\|_2.$$

However, because both x and $\hat{x}$ are feasible for the optimization problem in (24), we get

$$\|Ah\|_2 = \|A\hat{x} + \eta - (Ax + \eta)\|_2 \leq 2\epsilon.$$

Substituting this bound for $\|Ah\|_2$ gives us the second equation we need, namely

$$\|h_S\|_1 \leq \rho\|h_{S^c}\|_1 + 2\tau\epsilon,$$

or equivalently

$$-\rho\|h_{S^c}\|_1 + \|h_S\|_1 \leq 2\tau\epsilon. \tag{45}$$

The two inequalities (44) and (45) can be written compactly as

$$M\begin{bmatrix}\|h_{S^c}\|_1 \\ \|h_S\|_1\end{bmatrix} \leq \left\{\begin{bmatrix}2\\0\end{bmatrix}\sigma_k + \begin{bmatrix}0\\2\tau\end{bmatrix}\epsilon\right\}, \tag{46}$$

where the coefficient matrix M is given by

$$M = \begin{bmatrix}(1-\gamma) & -(1+\gamma)\\ -\rho & 1\end{bmatrix}$$

The matrix M has positive diagonal elements (recall that $\gamma < 1$), and negative off-diagonal elements. Therefore, if $\det(M) > 0$, then every element of M^{-1} is positive, in which we can multiply both sides of (46) by M^{-1}. Now

$$\det(M) = 1 - \gamma - \rho(1+\gamma) > 0 \iff \rho < \frac{1-\gamma}{1+\gamma}.$$

Recall the definition of γ from (33). Now routine algebra shows that

$$\rho < \frac{1-\gamma}{1+\gamma} \iff \rho < \frac{1-\mu\sqrt{g}}{1+\mu\sqrt{g}} \iff \mu < \frac{1-\rho}{\sqrt{g}(1+\rho)},$$

which is precisely (32). Thus we can multiply both sides of (46) by M^{-1}, which gives

$$\begin{bmatrix}\|h_{S^c}\|_1 \\ \|h_S\|_1\end{bmatrix} \leq \frac{1}{\det(M)}\begin{bmatrix}1 & (1+\gamma)\\ \rho & (1-\gamma)\end{bmatrix}\left\{\begin{bmatrix}2\\0\end{bmatrix}\sigma_k + \begin{bmatrix}0\\2\tau\end{bmatrix}\epsilon\right\}.$$

Clearing out the matrix multiplication gives

$$\begin{bmatrix}\|h_{S^c}\|_1 \\ \|h_S\|_1\end{bmatrix} \leq \frac{1}{\det(M)}\left\{\begin{bmatrix}2\\2\rho\end{bmatrix}\sigma_k + \begin{bmatrix}2\tau(1+\gamma)\\2\tau(1-\gamma)\end{bmatrix}\epsilon\right\}. \tag{47}$$

Now the triangle inequality states that

$$\|h\|_1 \leq \|h_{S^c}\|_1 + \|h_S\|_1 = \begin{bmatrix}1 & 1\end{bmatrix}\begin{bmatrix}\|h_{S^c}\|_1 \\ \|h_S\|_1\end{bmatrix}$$

Substituting from (47) gives

$$\|h\|_1 \leq \frac{1}{\det(M)}[2(1+\rho)\sigma_k + 4\tau\epsilon].$$

By substituting that $\det(M) = (1-\gamma) - (1+\gamma)\rho$, we get (34) with the constants as defined in (36).

To prove (35), suppose $p \in (1, 2]$. This part of the proof closely follows that of (Foucart and Rauhut, 2013, Theorem 4.22), except that we provide explicit values for the constants. Let Λ_0 denote the index set of the k largest components of h by magnitude. Then

$$\|h\|_p \leq \|h_{\Lambda_0}\|_p + \|h_{\Lambda_0^c}\|_p.$$

We will bound each term separately. First, by (Foucart and Rauhut, 2013, Theorem 2.5) and (34), we get

$$\|h_{\Lambda_0^c}\|_p \leq \frac{1}{k^{1-1/p}}\|h\|_1 \leq \frac{1}{k^{1-1/p}}(C\sigma_k + D\epsilon). \tag{48}$$

Now we apply in succession Hölder's inequality, the robust null space property, the fact that $\|Ah\|_2 \leq 2\epsilon$, and (34). This gives

$$\begin{aligned}\|h_{\Lambda_0}\|_p &\leq k^{1/p-1/2}\|h_{\Lambda_0}\|_2\\ &\leq \frac{k^{1/p-1/2}}{\sqrt{k}}[\rho\|h_{\Lambda_0^c}\|_1 + \tau\|Ah\|_2]\\ &\leq \frac{1}{k^{1-1/p}}[\rho(C\sigma_k + D\epsilon) + 2\tau\epsilon]\\ &= \frac{1}{k^{1-1/p}}[\rho C\sigma_k + (\rho D + 2\tau)\epsilon]. \end{aligned}\tag{49}$$

Adding (48) and (49) gives (35).

Abstract

Many of the ordinal regression models that have been proposed in the literature can be seen as methods that minimize a convex surrogate of the zero-one, absolute, or squared loss functions. A key property that allows to study the statistical implications of such approximations is that of *Fisher consistency*. Fisher consistency is a desirable property for surrogate loss functions and implies that in the population setting, i.e., if the probability distribution that generates the data were available, then optimization of the surrogate would yield the best possible model. In this paper we will characterize the Fisher consistency of a rich family of surrogate loss functions used in the context of ordinal regression, including support vector ordinal regression, ORBoosting and least absolute deviation. We will see that, for a family of surrogate loss functions that subsumes support vector ordinal regression and ORBoosting, consistency can be fully characterized by the derivative of a real-valued function at zero, as happens for convex margin-based surrogates in binary classification. We also derive excess risk bounds for a surrogate of the absolute error that generalize existing risk bounds for binary classification. Finally, our analysis suggests a novel surrogate of the squared error loss. We compare this novel surrogate with competing approaches on 9 different datasets. Our method shows to be highly competitive in practice, outperforming the least squares loss on 7 out of 9 datasets.

Keywords: Fisher consistency, ordinal regression, calibration, surrogate loss, excess risk bound.

1. Introduction

In ordinal regression the goal is to learn a rule to predict labels from an ordinal scale, i.e., labels from a discrete but ordered set. This arises often when the target variable consists of human generated ratings, such as ("do-not-bother" $\prec$ "only-if-you-must" $\prec$ "good" $\prec$ "very-good" $\prec$ "run-to-see") in movie ratings (Crammer and Singer, 2001), ("absent" $\prec$ "mild" $\prec$ "severe") for the symptoms of a physical disease (Armstrong and Sloan, 1989) and the NRS-11 numeric rating scale for clinical pain measurement (Hartrick et al., 2003). Ordinal regression models have been successfully applied to fields as diverse as econometrics (Greene, 1997), epidemiology (Ananth and Kleinbaum, 1997), fMRI-based brain decoding (Doyle et al., 2013) and collaborative filtering (Rennie and Srebro, 2005).

Ordinal regression shares properties–and yet is fundamentally different–from both multiclass classification and regression. As in the multiclass classification setting, the target variables consist of discrete values, and as in the regression setting (but unlike the multiclass setting) there is a meaningful order between the classes. If we think of the symptoms of a physical disease, it is clear that if the true label is "severe" it is preferable to predict "mild" than "absent". Ordinal regression models formalize this notion of order by ensuring that predictions farther from the true label incur a greater penalty than those closer to the true label.

The ordinal regression approach also shares properties with the learning-to-rank problem (Liu, 2011), in which the goal is to predict the relative order of a sequence of instances. Hence, this approach focuses on predicting a relative order while ordinal regression focuses on predicting a label for each instance. In this sense, it is possible for a ranking model (but not for an ordinal regression one) that predicts the wrong labels to incur no loss at all, as long as the relative order of those labels are correct, e.g. if the prediction is given by the true label plus an additive bias. Although ordinal regression and ranking are different problems, the distinction between both has not always been clear, generating some confusion. For example, in the past some methods presented with the word "ranking" in the title would be considered today ordinal regression methods (Crammer and Singer, 2001; Shashua and Levin, 2003; Crammer and Singer, 2005) and likewise some of the first pairwise ranking methods (Herbrich et al., 1999) featured the word ordinal regression in the title.

Despite its widespread applicability, there exists a relative paucity in the understanding of the theoretical properties behind ordinal regression methods, at least compared to that of binary and multiclass classification. One such example is the notion of *Fisher consistency*, which relates the minimization of a given loss to the minimization of a surrogate with better computational properties. The importance of this property stems from the fact that many supervised learning methods, such as support vector machines, boosting and logistic regression for binary classification, can be seen as methods that minimize a convex surrogate on the 0-1 loss. Such results have emerged in recent years for classification (Bartlett et al., 2003; Zhang, 2004a; Tewari and Bartlett, 2007), ranking (Duchi et al., 2010; Calauzenes et al., 2012), structured prediction (Ciliberto et al., 2016; Osokin et al., 2017) and multiclass classification with an arbitrary loss function (Ramaswamy and Agarwal, 2012, 2016), a setting that subsumes ordinal regression. Despite these recent progress, the Fisher consistency of most surrogates used within the context of ordinal regression remains elusive. The aim of this paper is to bridge the gap by providing an analysis of Fisher consistency for a wide family of ordinal regression methods that parallels the ones that already exist for other multiclass classification and ranking.

Notation. Through the paper, we will use k to denote the number of classes (i.e., labels) in the learning problem. We will denote by $\mathcal{S}$ the subset of $\mathbb{R}^{k-1}$ for which the

components are non-decreasing, that is,

$$\mathcal{S} := \left\{ \alpha : \alpha \in \mathbb{R}^{k-1} \text{ and } \alpha_i \leq \alpha_{i+1} \text{ for } 1 \leq i \leq k-2 \right\} \quad .$$

Δ^p denotes the p-dimensional simplex, defined as

$$\Delta^p := \left\{ x \in \mathbb{R}^p : x_i \geq 0 \text{ and } \sum_{i=1}^{p} x_i = 1 \right\} \quad .$$

Following Knuth (1992) we use the Iverson bracket $[\![\cdot]\!]$ as

$$[\![q]\!] := \begin{cases} 1 \text{ if q is true} \\ 0 \text{ otherwise} \end{cases} \quad .$$

We will also make reference to loss functions commonly used in binary classification. These are the hinge loss ($\varphi(t) = \max(1-t, 0)$), the squared hinge loss ($\varphi(t) = \max(1-t, 0)^2$), the logistic loss ($\varphi(t) = \log(1+e^{-t})$), exponential loss ($\varphi(t) = e^{-t}$) and the squared loss ($\varphi(t) = (1-t)^2$).

1.1 Problem setting

Here we present the formalism that we will be using throughout the paper. Let $(\mathcal{X}, \mathcal{A})$ be a measurable space. Let (X, Y) be two random variables with joint probability distribution P, where X takes its values in $\mathcal{X}$ and Y is a random label taking values in a finite set of k *ordered categories* that we will denote $\mathcal{Y} = \{1, \ldots, k\}$. In the ordinal regression problem, we are given a set of n observations $\{(X_1, Y_1), \ldots, (X_n, Y_n)\}$ drawn i.i.d. from $X \times Y$ and the goal is to learn from the observations a measurable mapping called a *decision function* $f : \mathcal{X} \to \mathcal{S} \subseteq \mathbb{R}^{k-1}$ so that the *risk* given below is as small as possible:

$$\mathcal{L}(f) := \mathbb{E}(\ell(Y, f(X))) \quad , \tag{1}$$

where $\ell : \mathcal{Y} \times \mathcal{S}$ is a *loss function* that measures the disagreement between the true label and the prediction. For ease of optimization, the decision function has its image in a subset of $\mathbb{R}^{k-1}$, and the function that converts an element of $\mathcal{S}$ into a class label is called a *prediction function*. The prediction function that we will consider through the paper is given for $\alpha \in \mathcal{S}$ by the number of coordinates below zero plus one, that is,

$$\text{pred}(\alpha) := 1 + \sum_{i=1}^{k-1} [\![\alpha_i < 0]\!] \quad . \tag{2}$$

Note that for the case of two classes $\mathcal{Y} = \{1, 2\}$, the decision function is real-valued and the prediction defaults the common binary classification rule in which prediction depends on the sign of this decision function.

Different loss functions can be used within the context of ordinal regression. The most commonly used one is the absolute error, which measures the absolute difference between the predicted and true labels. For $\alpha \in \mathcal{S}$, this is defined as

$$\ell(y, \alpha) := \left| y - \text{pred}(\alpha) \right| \quad . \tag{3}$$

The absolute error loss is so ubiquitous in ordinal regression that some authors refer to it simply as *the* ordinal regression loss (Agarwal, 2008; Ramaswamy and Agarwal, 2012). For this reason we give special emphasis on this loss. However, we will also describe methods that minimize the 0-1 loss (i.e., the classification error) and in Section 3.4 we will see how some results can be generalized beyond these and to general loss functions that verify a certain admissibility criterion.

In order to find the decision function with minimal risk it might seem appropriate to minimize Eq. (1). However, this is not feasible in practice for two reasons. First, the probability distribution P is unknown and the risk must be minimized approximately based on the observations. Second, ℓ is typically discontinuous in its second argument, hence the empirical approximation to the risk is difficult to optimize and can lead to an NP-hard problem (Feldman et al., 2012; Ben-David et al., 2003)[1]. It is therefore common to approximate ℓ by a function $\psi : \mathcal{Y} \times \mathcal{S} \to \mathbb{R}$, called a *surrogate loss function*, which has better computational properties. The goal becomes then to find the decision function that instead minimizes the *surrogate risk*, defined as

$$\mathcal{A}(f) := \mathbb{E}(\psi(Y, f(X))) \ . \tag{4}$$

We are interested by the statistical implications of such approximation. Assuming that we have full knowledge of the probability distribution that generates the data P, what are the consequences of optimizing a convex surrogate of the risk instead of the true risk?

The main property that we will study in order to answer this question is that of *Fisher consistency*. Fisher consistency is a desirable property for surrogate loss functions (Lin, 2004) and implies that in the population setting, i.e., if the probability distribution P were available, then optimization of the surrogate would yield a function with minimal risk. From a computational point of view, this implies that the minimization of the surrogate risk, which is usually a convex optimization problem and hence easier to solve than the minimization of the risk, does not penalize the quality (always in the population setting) of the obtained solution.

We will use the following notation for the optimal risk and optimal surrogate risk:

$$\mathcal{L}^* := \inf_f \mathcal{L}(f) \quad \text{and} \quad \mathcal{A}^* := \inf_f \mathcal{A}(f) \quad ,$$

where the minimization is done over all measurable functions $\mathcal{X} \to \mathcal{S}$. $\mathcal{L}^*$ is sometimes referred to as the *Bayes risk*, and a decision function (not necessarily unique) that minimizes the risk is called a *Bayes decision function*.

We will now give a precise definition of Fisher consistency. This notion originates from a classical parameter estimation setting. Suppose that an estimator T of some parameter θ is defined as a functional of the empirical distribution P_n. We denote it $T(P_n)$. The estimator is said to be Fisher consistent if its population analog, $T(P)$, coincides with the parameter θ. Adapting this notion to the context of risk minimization (in which the optimal risk is the parameter to estimate) yields the following definition, adapted from Lin (2004) to an arbitrary loss function ℓ:

1. Note that binary classification can be seen as a particular case of ordinal regression.

Definition 1 ***(Fisher consistency)*** *Given a surrogate loss function $\psi : \mathcal{Y} \times \mathcal{S} \to \mathbb{R}$, we will say that the surrogate loss function ψ is consistent with respect to the loss $\ell : \mathcal{Y} \times \mathcal{S} \to \mathbb{R}$ if for every probability distribution over $X \times Y$ it is verified that every minimizer f of the surrogate risk reaches Bayes optimal risk, that is,*

$$\mathcal{A}(f) = \mathcal{A}^* \implies \mathcal{L}(f) = \mathcal{L}^* \quad .$$

For some surrogates we will be able to derive not only Fisher consistency, but also *excess risk bounds*. These are bounds of the form

$$\gamma(\mathcal{L}(f) - \mathcal{L}^*) \leq \mathcal{A}(f) - \mathcal{A}^* \quad ,$$

for some real-valued function γ with $\gamma(0) = 0$. These inequalities not only imply Fisher consistency, but also allow to bound the excess risk by the excess in surrogate risk. These inequalities play an important role in different areas of learning theory, as they can be used for example to obtain rates of convergence (Bartlett et al., 2003) and oracle inequalities (Boucheron et al., 2005).

1.2 Full and conditional risk

The above definition of Fisher consistency is often replaced by a point-wise version that is easier to verify in practice. Two key ingredients of this characterization are the notions of *conditional risk* and *surrogate conditional risk* that we will now define. These are denoted by L and A respectively, and defined for any $\alpha \in \mathcal{S}$, $p \in \Delta^k$ by

$$L(\alpha, p) := \sum_{i=1}^{k} p_i \ell(i, \alpha) \quad \text{and} \quad A(\alpha, p) := \sum_{i=1}^{k} p_i \psi(i, \alpha) \quad . \tag{5}$$

The full and conditional risk are then related by the equations

$$\begin{aligned} \mathcal{L}(f) &= \mathbb{E}_{X\times Y}(\ell(Y, f(X))) = \mathbb{E}_X \mathbb{E}_{Y|X}(\ell(Y, f(X))) = \mathbb{E}_X(L(f(X), \eta(X))) \\ \mathcal{A}(f) &= \mathbb{E}_{X\times Y}(\psi(Y, f(X))) = \mathbb{E}_X \mathbb{E}_{Y|X}(\psi(Y, f(X))) = \mathbb{E}_X(A(f(X), \eta(X))) \quad , \end{aligned}$$

where $\eta : \mathcal{X} \to \Delta^k$ is the vector of conditional probabilities given by $\eta_i(x) = P(y = i|X = x)$. As for the full risk, we will denote by L^*, A^* the infimum of its value for a given $p \in \Delta^k$, i.e.,

$$L^*(p) = \inf_{\alpha \in \mathcal{S}} L(\alpha, p) \quad \text{and} \quad A^*(p) = \inf_{\alpha \in \mathcal{S}} A(\alpha, p) \quad .$$

When the risk infimum over functions that can be defined independently at every $x \in \mathcal{X}$, it is possible to relate the minimization of the risk with that of the conditional risk since

$$\begin{aligned} \inf_f \mathcal{L}(f) &= \inf_f \mathbb{E}_{X\times Y}\left(\ell(Y, f(X))\right) = \mathbb{E}_X\left[\inf_f \mathbb{E}_{Y|X}(\ell(Y, f(X)))\right] \\ &= \mathbb{E}_X\left[\inf_\alpha L(\alpha, \eta(X))\right] \quad . \end{aligned} \tag{6}$$

This equation implies that the minimal risk can be achieved by minimizing pointwise the conditional risk $L(\cdot)$, which–in general–will be easier that direct minimization of the full risk.

The condition for this, i.e., that the functions be estimated independently at every sample point, is verified by the set of measurable functions from the sample space into a subset of $\mathbb{R}^k$ (in this case $\mathcal{S}$), which is the typical setting in studies of Fisher consistency. However, this is no longer true when inter-observation constraints are enforced (e.g. smoothness). As is common in studies of Fisher consistency, we will suppose that the function class verifies the property of Eq. (6) and we will discuss in Section 4 an important family of functions in which this requisite is not met.

We will now present a characterization of Fisher consistency based on the pointwise risk which we will use throughout the paper. Equivalent forms of this characterization have appeared under a variety of names in the literature, such as classification calibration (Bartlett et al., 2003; Ramaswamy and Agarwal, 2012), infinite sample consistency (Zhang, 2004b) and proper surrogates (Buja et al., 2005; Gneiting and Raftery, 2007).

Lemma 2 (Pointwise characterization of Fisher consistency) *Let A and L be defined as in Eq (5). Then ψ is Fisher consistent with respect to ℓ if and only if for all $p \in \Delta^k$ it is verified that*

$$A(\alpha, p) = A^*(p) \implies L(\alpha, p) = L^*(p) \quad . \tag{7}$$

Proof Let $\mathcal{L}$ and $\mathcal{A}$ denote the expected value of ℓ and ψ, as defined in Equations (1) and (4) respectively.

($\Longleftarrow$) We prove that Eq. (7) implies Fisher consistency. Let f be such that $\mathcal{A}(f) = \mathcal{A}^*$. Then it is verified that

$$\mathcal{A}(f) - \mathcal{A}^* = \mathbb{E}_X(A(f(X), \eta(X)) - A^*(\eta(X))) = 0 \quad .$$

The value inside the expectation is non-negative by definition of A^*. Since this is verified for all probability distributions over $X \times Y$, then it must be true that $A(f(x), \eta(x)) = A^*(\eta(x))$ for all $x \in \mathcal{X}$. By assumption $L(f(X), \eta(X)) = L^*(\eta(X))$. Hence the excess risk verifies

$$\mathcal{L}(f) - \mathcal{L}^* = \mathbb{E}_X(L(f(X), \eta(X)) - L^*(\eta(X))) = \mathbb{E}(0) = 0 \quad .$$

and so ψ is Fisher consistent with respect to ℓ.

($\Longrightarrow$) We prove that Fisher consistency implies Eq. (7). We do so by contradiction: first suppose that there exists a surrogate that is Fisher consistent but Eq. (7) is not verified and arrive to a contradiction. If Eq. (7) is not verified then there exists $\tilde{\alpha} \in \mathcal{S}$ and $\tilde{p} \in \Delta^k$ such that

$$A(\tilde{\alpha}, \tilde{p}) = A^*(\tilde{p}) \text{ and } L(\tilde{\alpha}, \tilde{p}) > L^*(\tilde{p}) \quad .$$

We now construct a probability distribution (X, Y) such that the Fisher consistency characterization is not verified in order to arrive to a contradiction. For this, consider the probability distribution P such that $\eta(x) = \tilde{p}$ for all $x \in \mathcal{X}$. Consider also $f : \mathcal{X} \to \mathcal{S}$, the mapping that is constantly $\tilde{\alpha}$. Then it is verified that

$$\mathcal{A}(f) - \mathcal{A}^* = \mathbb{E}_X(A(f(X), \eta(X)) - A^*(\eta(X))) = \mathbb{E}_X(A(\tilde{\alpha}, \tilde{p}) - A^*(\tilde{p})) = 0 \quad ,$$

and so $\mathcal{A}(f) = \mathcal{A}^*$. Likewise, the excess risk verifies

$$\mathcal{L}(f) - \mathcal{L}^* = \mathbb{E}_X(L(f(X), \eta(X)) - L^*(\eta(X))) = \mathbb{E}_X(L(\tilde{\alpha}, \tilde{p}) - L^*(\tilde{p})) > 0$$

and so ψ cannot be Fisher consistent with respect to ℓ. This is a contradiction, and concludes the proof.

■

1.3 Summary of main results

The main contribution of this paper is to characterize the Fisher consistency of a wide family of surrogate loss functions used for the task of ordinal regression. Contrary to known results for multiclass classification and ranking, where One-vs-All and RankSVM have been proven to be inconsistent, in the ordinal regression setting common surrogates such as ORSVM and proportional odds will be proven to be Fisher consistent. One of the most surprising results of this paper is that for a particular class of surrogates that verify a *decomposability* property, it is possible to provide a characterization of Fisher consistency and excess risk bounds that generalize those known for convex margin-based surrogates (loss functions of the form $\varphi(Yf(X))$) in binary classification.

We will introduce the surrogate loss functions that we consider in Section 2. These will be divided between surrogates of the absolute error and surrogate of the 0-1 loss. We organize their study as follows:

- In Sections 3.1 and 3.2 we characterize the **Fisher consistency for surrogates of the absolute and squared error**. The surrogates that we consider in this section are the all threshold (AT), the cumulative link (CL), the least absolute deviation (LAD) and the least squares (LS). Besides Fisher consistency, a decomposability of the AT loss will allow us to provide excess risk bounds for this surrogate.

- In Section 3.3 we characterize the **Fisher consistency of the surrogates of the 0-1 loss**. For this loss, denoted immediate threshold (IT), its Fisher consistency will depend on the derivative at zero of a real-valued convex function.

- In Section 3.4 we **construct a surrogate for an arbitrary loss function** that verifies an admissibility condition. We name this surrogate generalized all threshold (GAT). This loss function generalizes the AT and IT loss functions introduced earlier. We will characterize the Fisher consistency of this surrogate.

- Turning back to one of the topics mentioned in the introduction, we discuss in Section 4 the **implications of inter-observational constraints in Fisher consistency**. Following Shi et al. (2015), we define a restricted notion of consistency known as $\mathcal{F}$-consistency of parametric consistency and give sufficient conditions for the $\mathcal{F}$-consistency of two surrogates.

- In Section 5 we **examine the empirical performance of a novel surrogate**. This novel surrogate is a particular instance of the GAT loss function introduced in Section 3.4 when considering the squared error as evaluation metric. We compare this novel surrogate against a least squares model on 9 different datasets, where the novel surrogate outperforms the least squares estimate on 7 out of the 9 datasets.

1.4 Related work

Fisher consistency of binary and multiclass classification for the zero-one loss has been studied for a variety of surrogate loss functions, see e.g. (Bartlett et al., 2003; Zhang, 2004a; Tewari and Bartlett, 2007; Reid and Williamson, 2010). Some of the results in this paper generalize known results for binary classification to the ordinal regression setting. In particular, Bartlett et al. (2003) provide a characterization of the Fisher consistency for convex margin-based surrogates that we extend to the all threshold (AT) and immediate threshold (IT) family of surrogate loss functions. The excess error bound that we provide for the AT surrogate also generalizes the excess error bound given in (Bartlett et al., 2003, Section 2.3).

Fisher consistency of arbitrary loss functions (a setting that subsumes ordinal regression) has been studied for some surrogates. Lee et al. (2004) proposed a surrogate that can take into account generic loss functions and for which Fisher consistency was proven by Zhang (2004b). In a more general setting, Ramaswamy and Agarwal (2012, 2016) provide necessary and sufficient conditions for a surrogate to be Fisher consistent with respect to an arbitrary loss function. Among other results, they prove consistency of least absolute deviation (LAD) and an ε-insensitive loss with respect to the absolute error for the case of three classes ($k = 3$). In this paper, we extend the proof of consistency for LAD to an arbitrary number of classes. Unlike previous work, we consider the so-called *threshold-based surrogates* (AT, IT and CL), which rank among the most popular ordinal regression loss functions and for which its Fisher consistency has not been studied previously.

Fisher consistency has also been studied in the pairwise ranking setting, where it has been proven (Duchi et al., 2010; Calauzenes et al., 2012) that some models (such as RankSVM) are not consistent. Despite similarities between ranking and ordinal regression, we will see in this paper that most popular ordinal regression models are Fisher consistent under mild conditions.

There are few studies on the theoretical properties of ordinal regression methods. A notable example comes from Agarwal (2008), where the authors study generalization bounds for some ordinal regression algorithms. Some of the surrogate loss functions used by these models (such as the support vector ordinal regression of Chu and Keerthi (2005)) are analyzed in this paper. In that work, the authors outline the study of consistency properties of ordinal regression models as an important question to be addressed in the future.

A related, yet different, notion of consistency is *asymptotic consistency*. A surrogate loss is said to be asymptotically consistent if the minimization of the ψ-risk converges to the optimal risk as the number of samples tends to infinity. It has also been studied in the setting of supervised learning (Stone, 1977; Steinwart, 2002). This paper focuses solely on Fisher consistency, to whom we will refer simply as consistency from now on.

2. Ordinal regression models

We introduce the different ordinal regression models that we will consider within this paper. Considering first the absolute error, we will write this loss as a sum of binary 0-1 loss

functions[2]. This is a key reformulation of the absolute error that we will use throughout the paper. For any $y \in \mathcal{Y}$ and $\alpha \in \mathcal{S}$ we have the following sequence of equivalences

$$\begin{aligned}\ell(y,\alpha) &= \big|y - \text{pred}(\alpha)\big| = \left|y - 1 - \sum_{i=1}^{k-1} [\![\alpha_i < 0]\!]\right| \\ &= \left|y - 1 - \sum_{i=1}^{y-1} [\![\alpha_i < 0]\!] - \sum_{i=y}^{k-1} [\![\alpha_i < 0]\!]\right| \\ &= \left|\sum_{i=1}^{y-1} [\![\alpha_i \geq 0]\!] - \sum_{i=y}^{k-1} [\![\alpha_i < 0]\!]\right| \quad .\end{aligned} \tag{8}$$

If $\alpha_y \geq 0$ then the second summand of the last equation equals zero. Otherwise, if $\alpha_y < 0$, then the first summand equals zero. In either case, we have

$$\ell(y,\alpha) = \sum_{i=1}^{y-1} [\![\alpha_i \geq 0]\!] + \sum_{i=y}^{k-1} [\![\alpha_i < 0]\!] \quad . \tag{9}$$

This expression suggests that a natural surrogate can be constructed by replacing the binary 0-1 loss in the above expression function by a convex surrogate such as the logistic or hinge loss. Denoting by $\varphi : \mathbb{R} \to \mathbb{R}$ such surrogate, we obtain the following loss function that we denote *all threshold (AT)*:

$$\psi_{\text{AT}}(y,\alpha) := \sum_{i=1}^{y-1} \varphi(-\alpha_i) + \sum_{i=y}^{k-1} \varphi(\alpha_i) \quad . \tag{10}$$

This function has appeared under different names in the literature. When φ is the hinge loss, this model is known as support vector ordinal regression with implicit constraints (Chu and Keerthi, 2005) and support vector with sum-of-margins strategy (Shashua and Levin, 2003). When φ is the exponential loss, this model has been described in (Lin and Li, 2006) as ordinal regression boosting with all margins. Finally, Rennie and Srebro (2005) provided a unifying formulation for this approach considering for the hinge, logistic and exponential loss under the name of All-Threshold loss, a name that we will adopt in this paper.

The name *thresholds* comes from the fact that in the aforementioned work, the decision function is of the form $\alpha_i = \theta_i - f(\cdot)$, where $(\theta_1, \ldots, \theta_{k-1})$ is a vector estimated from the data known as the vector of thresholds. We will discuss in Section 4 the implications of such decision function. For the prediction rule to give meaningful results it is important to ensure that the thresholds are ordered, i.e., $\theta_1 \leq \theta_2, \leq \cdots, \leq \theta_{k-1}$ (Chu and Keerthi, 2005). In our setting, we enforce this through the constraint $\alpha \in \mathcal{S}$, hence the importance of restricting the problem to this subset of $\mathbb{R}^{k-1}$.

Another family of surrogate loss functions takes a probabilistic approach and models instead the posterior probability. This is the case of the *cumulative link* models of McCullagh

2. The 0-1 loss, defined as the function that is 1 for negative values and 0 otherwise can be defined in bracket notation as $\ell_{0-1}(t) = [\![\alpha_i \leq 0]\!]$.

(1980). In such models the decision function f is selected to approximate $\sigma(f_i(x)) = P(Y \leq i | X = x)$, where $\sigma : \mathbb{R} \to [0,1]$ is a function referred to as *link function*. Several functions can be used as link function, although the most common ones are the sigmoid function and the Gaussian cumulative distribution. The sigmoid function, i.e., $\sigma(t) = 1/(1+\exp(-t))$, leads to a model sometimes referred as proportional odds (McCullagh, 1980) and cumulative logit (Agresti, 2010), although for naming consistency we will refer to it as *logistic cumulative link*. Another important link function is given by the Gaussian cumulative distribution, $\sigma(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-x^2/2}$, used in the Gaussian process ordinal regression model of Chu and Ghahramani (2004). The cumulative link (CL) loss function is given by its negative likelihood, that is,

$$\psi_{\text{CL}}(y,\alpha) := \begin{cases} -\log(\sigma(\alpha_1)) & \text{if } y = 1 \\ -\log(\sigma(\alpha_y) - \sigma(\alpha_{y-1})) & \text{if } 1 < y < k \\ -\log(1 - \sigma(\alpha_{k-1})) & \text{if } y = k \quad . \end{cases} \tag{11}$$

We will now consider the multiclass 0-1 loss. In this case, the loss will be 1 if the prediction is below or above y (i.e., if $\alpha_{y-1} \geq 0$ or $\alpha_y < 0$) and 0 otherwise. Hence, it is also possible to write the multiclass 0-1 loss as a sum of binary 0-1 loss functions:

$$\ell(y,\alpha) = \begin{cases} [\![\alpha_1 < 0]\!] & \text{if } y = 1 \\ [\![\alpha_{y-1} \geq 0]\!] + [\![\alpha_y < 0]\!] & \text{if } 1 < y < k \\ [\![\alpha_{k-1} \geq 0]\!] & \text{if } y = k \quad . \end{cases}$$

Given this expression, a natural surrogate is given by replacing the binary 0-1 loss by a convex surrogate as the hinge or logistic function. Following Rennie and Srebro (2005), we will refer to this loss function as *immediate threshold (IT)*:

$$\psi_{\text{IT}}(y,\alpha) := \begin{cases} \varphi(\alpha_1) & \text{if } y = 1 \\ \varphi(-\alpha_{y-1}) + \varphi(\alpha_y) & \text{if } 1 < y < k \\ \varphi(-\alpha_{k-1}) & \text{if } y = k \quad . \end{cases} \tag{12}$$

As with the AT surrogate, this loss has appeared under a variety of names in the literature. When φ is the hinge loss, this model is known as support vector ordinal regression with explicit constraints (Chu and Keerthi, 2005) and support vector with fixed-margins strategy (Shashua and Levin, 2003). When φ is the exponential loss, this model has been described by Lin and Li (2006) as ordinal regression boosting with left-right margins. We note that the construction of the AT and IT surrogates are similar, and in fact, we will see in Section 3.4 that both can be seen as a particular instance of a more general family of loss functions.

The aforementioned approaches can be seen as methods that adapt known binary classification methods to the ordinal regression setting. A different approach consists in treating the labels as real values and use regression algorithms to learn a real-valued mapping between the samples and the labels. This ignores the discrete nature of the labels, thus it is

necessary to introduce a prediction function that converts this real value into a label in $\mathcal{Y}$. This prediction function is given by rounding to the closest label (see, e.g., (Kramer et al., 2001) for a discussion of this method using regression trees). This approach is commonly referred to as the *regression-based* approach to ordinal regression. If we are seeking to minimize the absolute error, a popular loss function is to minimize the least absolute deviation (LAD). For any $\beta \in \mathbb{R}$, this is defined as

$$\psi_{\text{LAD}}(y, \beta) := |y - \beta| \quad ,$$

and prediction is then given by rounding β to the closest label. This setting departs from the approaches introduced earlier by using a different prediction function. However, via a simple transformation it is possible to convert this prediction function (rounding to the closest label) to the prediction function that counts the number of non-zero components defined in Eq. (2). For a given $\beta \in \mathbb{R}$, this transformation is given by

$$\alpha_1 = \frac{3}{2} - \beta, \quad \alpha_2 = \frac{5}{2} - \beta, \quad \ldots, \quad \alpha_i = i + \frac{1}{2} - \beta \quad . \tag{13}$$

It is immediate to see that this vector α belongs to $\mathcal{S}$ and

$$\begin{aligned}
\text{pred}(\alpha) &= 1 + \sum_{i=1}^{k-1} [\![i + \frac{1}{2} < \beta]\!] \\
&= \begin{cases} 1 & \text{if } \beta \leq 1 + \frac{1}{2} \\ i & \text{if } i - \frac{1}{2} \leq \beta < i + \frac{1}{2}, 1 < i < k \\ k & \text{if } \beta \geq k - \frac{1}{2} \end{cases} \\
&= \arg\min_{1 \leq i \leq k} |\beta - i| \quad \text{(rounding to the lower label in case of ties)} \quad ,
\end{aligned}$$

hence predicting in the transformed vector α is equivalent to the closest label to β. We will adopt this transformation when considering LAD for convenience, in order to analyze it within the same framework as the rest. With the aforementioned transformation, the least absolute deviation surrogate is given by

$$\psi_{\text{LAD}}(y, \alpha) = \left| y + \alpha_1 - \frac{3}{2} \right| \tag{14}$$

Although the surrogate loss function LAD and the absolute loss of Eq. (3) look very similar, they differ in that the LAD surrogate is convex on α, while the absolute error is not, due to the presence of the discontinuous function $\text{pred}(\cdot)$.

In this section we have introduced some of the most common ordinal regression methods based on the optimization of a convex loss function. These are summarized in Table 1.

3. Consistency results

In this section we present consistency results for different surrogate loss functions. We have organized this section by the different loss functions against which we test for consistency.

Table 1: Surrogate loss functions considered in this paper.

Model	**Loss Function**	**Also known as**
All thresholds (AT)	$\sum_{i=1}^{y-1} \varphi(-\alpha_i) + \sum_{i=y}^{k-1} \varphi(\alpha_i)$	Implicit constraints (Chu and Keerthi, 2005), all margins (Lin and Li, 2006).
Cumulative link (CL)	$-\log(\sigma(\alpha_y) - \sigma(\alpha_{y-1}))$	Proportional odds (McCullagh, 1980), cumulative logit (Agresti, 2010).
Immediate threshold (IT)	$\varphi(-\alpha_{y-1}) + \varphi(\alpha_y)$	Explicit constraints (Chu and Keerthi, 2005), Fixed-margins (Shashua and Levin, 2003)
Least absolute deviation (LAD)	$\lvert y + \alpha_1 - \frac{3}{2} \rvert$	Least absolute error, least absolute residual, Sum of absolute deviations, ℓ_1 regression.
Least squares (LS)	$\left(y + \alpha_1 - \frac{3}{2}\right)^2$	Squared error, sum of squares, ℓ_2 regression.

The first subsection presents results for the absolute error, which is the most popular loss for ordinal regression. In the second subsection we provide consistency results for a surrogate of the squared loss. Finally, in the third subsection we show results for the 0-1 loss as, perhaps surprisingly, several commonly used surrogates turn out to be consistent with respect to this loss.

3.1 Absolute error surrogates

In this section we will assume that the loss function is the absolute error, i.e., $\ell(y, \alpha) = \left| y - \text{pred}(\alpha) \right|$ and we will focus on surrogates of this loss. For an arbitrary $\alpha \in \mathcal{S}$, the conditional risk for the absolute error can be reformulated using the development of the absolute error from Eq. (8):

$$\begin{aligned}
L(\alpha, p) &= \sum_{i=1}^{k} p_i \left(\sum_{j=1}^{i-1} [\![\alpha_j \geq 0]\!] + \sum_{j=i}^{k-1} [\![\alpha_j < 0]\!] \right) \\
&= \sum_{i=1}^{k} [\![\alpha_j \geq 0]\!] (1 - u_i(p)) + \sum_{j=1}^{k} [\![\alpha_j < 0]\!] u_i(p) \quad ,
\end{aligned}$$

where $u(p)$ is the vector of cumulative probabilities, i.e., $u_i(p) := \sum_{j=1}^{i} p_j$. Let $r = \text{pred}(\alpha)$. Then $\alpha_{r-1} < 0$ and $\alpha_r \geq 0$, from where the above can be simplified to

$$L(\alpha, p) = \sum_{i=1}^{r-1} u_i(p) + \sum_{i=r}^{k-1} (1 - u_i(p)) \quad . \tag{15}$$

Using this expression, we will now derive an explicit minimizer of the conditional risk. Note that because of the prediction function counts the number of nonzero coefficients, only the sign of this vector is of true interest.

Lemma 3 *For any $p \in \Delta^k$, let $\underline{\alpha}(p)$ be defined as*

$$\underline{\alpha}(p) = (2u_1(p) - 1, \ldots, 2u_{k-1}(p) - 1) \quad .$$

Then, $L(\cdot, p)$ achieves its minimum at $\underline{\alpha}(p)$, that is,

$$\underline{\alpha}(p) \in \arg\min L(\alpha, p) \quad .$$

Proof We will prove that for any $\alpha \in \mathcal{S}$ and any $p \in \Delta^k$, $L(\alpha, p) \geq L(\underline{\alpha}(p), p)$. We consider p and α fixed and we denote $r^* = \text{pred}(\underline{\alpha}(p))$ and $r = \text{pred}(\alpha)$. We distinguish three cases, $r < r^*$, $r > r^*$ and $r = r^*$.

- $r < r^*$. In this case, Eq. (15) implies that

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = -\sum_{i=r}^{r^*-1} u_i(p) + \sum_{i=r}^{r^*-1} (1 - u_i(p)) = -\sum_{i=r}^{r^*-1} 2u_i(p) - 1 \quad .$$

  Now, by the definition of prediction function, $2u_i(p) - 1 < 0$ for $i < r^*$, so we have

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = \sum_{i=r}^{r^*-1} \left|2u_i(p) - 1\right| \quad .$$

- $r > r^*$. Similarly, in this case Eq. (15) implies that

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = \sum_{i=r^*}^{r-1} u_i(p) - \sum_{i=r^*}^{r-1} (1 - u_i(p)) = \sum_{i=r^*}^{r-1} 2u_i(p) - 1 \quad .$$

  Since by definition of prediction function $2u_i(p) - 1 \geq 0$ for $i \geq r^*$, it is verified that

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = \sum_{i=r^*}^{r-1} \left|2u_i(p) - 1\right| \quad .$$

- $r = r^*$. In this case, Eq. (15) yields

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = 0 \quad .$$

Let I denote the set of indices for which α disagrees in sign with $\underline{\alpha}$, that is, $I = \{i : \alpha_i(2u_i(p) - 1) < 0\}$. Then, combining the three cases we have the following formula for the excess in conditional risk

$$L(\alpha, p) - L(\underline{\alpha}(p), p) = \sum_{i \in I} \left|2u_i(p) - 1\right| \quad , \tag{16}$$

which is always non-negative and hence $L^*(p) = L(\underline{\alpha}(p), p)$. ■

All threshold (AT). We will now consider the AT surrogate. We will prove that some properties known for binary classification are inherited by this loss function. More precisely, we will provide a characterization of consistency for convex φ in Theorem 5 and excess risk bounds in Theorem 6 that parallel those of Bartlett et al. (2003) for binary classification.

Through this section A will represent the conditional risk of the AT surrogate, which can be expressed as:

$$\begin{aligned} A(\alpha, p) &= \sum_{j=1}^{k} p_j \psi_{\text{AT}}(j, \alpha) = \sum_{j=1}^{k} p_j \left(\sum_{i=1}^{j-1} \varphi(-\alpha_i) + \sum_{i=j}^{k-1} \varphi(\alpha_i) \right) \\ &= \sum_{i=1}^{k-1} (1 - u_i(p))\varphi(-\alpha_i) + u_i(p)\varphi(\alpha_i) \quad , \end{aligned} \tag{17}$$

where as in the previous section $u_i(p) = \sum_{j=1}^{i} p_i$, $\alpha \in \mathcal{S}$ and $p \in \Delta^k$. This surrogate verifies a decomposable property that will be key to further analysis. The property that we are referring to is that the above conditional risk it can be expressed as the sum of $k-1$ binary classification conditional risks. For $\beta \in \mathbb{R}, q \in [0, 1]$, we define C as follows

$$C(\beta, q) = q\varphi(\beta) + (1 - q)\varphi(-\beta) \quad ,$$

where C can be seen as the conditional risk associated with the binary classification loss function φ. Using this notation, the conditional risk A can be expressed in terms of C as:

$$A(\alpha, p) = \sum_{i=1}^{k-1} C(\alpha_i, u_i(p)) \quad .$$

Our aim is to compute A^* in terms of the infimum of C, denoted $C^*(q) := \inf_\beta C(q, \beta)$. Since C is the conditional risk of a binary classification problem, this would yield a link between the optimal risk for the AT surrogate and the optimal risk for a binary classification surrogate. However, this is in general not possible because of the monotonicity constraints in $\mathcal{S}$: the infimum over $\mathcal{S}$ need not equal the infimum over the superset $\mathbb{R}^{k-1}$. We will now present a result that states sufficient conditions under which the infimum over $\mathcal{S}$ and over $\mathbb{R}^{k-1}$ do coincide. This implies that A^* can be estimated as the sum of $k-1$ different surrogate conditional risks, each one corresponding to a binary classification surrogate. A similar result was proven in the empirical approximation setting by Chu and Keerthi (2005, Lemma 1). In this work, the authors consider the hinge loss and show that any minimizer of this loss automatically verifies the monotonicity constraints in $\mathcal{S}$.

In the following lemma we give sufficient conditions on φ under which the monotonicity constraints can be ignored when computing A^*. This is an important step towards obtaining an explicit expression for A^*:

Lemma 4 *Let $\varphi : \mathbb{R} \to \mathbb{R}$ be a function such that $\varphi(\beta) - \varphi(-\beta)$ is a non-increasing function of $\beta \in \mathbb{R}$. Then for all $p \in \Delta^k$, it is verified that*

$$A^*(p) = \sum_{i=1}^{k-1} C^*(u_i(p)) \quad .$$

Proof Let $p \in \Delta^k$ be fixed and let $\alpha^* \in \arg\min_{\alpha \in \mathbb{R}^{k-1}} A(\alpha, p)$. If $\alpha^* \in \mathcal{S}$, then the result is immediate since

$$\sum_{i=1}^{k-1} C^*(u_i(p)) = A(\alpha^*, p) = \inf_{\alpha \in \mathcal{S}} A(\alpha, p) = A^*(p) \ .$$

Suppose now $\alpha^* \notin \mathcal{S}$. We will prove that in this case it is possible to find another vector $\tilde{\alpha} \in \mathcal{S}$ sith the same surrogate risk. By assumption there exists a i in the range $1 \leq i \leq k-2$ for which the monotonicity conditions in $\mathcal{S}$ are not verified. In this case it is verified that $\alpha_{i+1} < \alpha_i$. Since $(u_1(p), \ldots, u_{k-1}(p))$ is a non-decreasing sequence, for a fixed p it is possible to write $u_{i+1}(p) = u_i(p) + \varepsilon$, with $\varepsilon \geq 0$. Then it is true that

$$\begin{aligned} C(\alpha_i^*, u_{i+1}(p)) &= (1 - u_i(p) - \varepsilon)\varphi(-\alpha_i^*) + (u_i(p) + \varepsilon)\varphi(\alpha_i^*) \\ &= C(\alpha_i^*, u_i(p)) + \varepsilon(\varphi(\alpha_i^*) - \varphi(-\alpha_i^*)) \quad . \end{aligned}$$

By assumption $\varepsilon(\varphi(\alpha_i^*) - \varphi(-\alpha_i^*))$ is a non-increasing function of α_i^* and so $\alpha_{i+1}^* < \alpha_i^* \implies C(\alpha_i, u_{i+1}(p)) \leq C(\alpha_{i+1}, u_{i+1}(p))$. By the optimality of α_{i+1}^*, it must be $C(\alpha_i^*, u_{i+1}(p)) = C(\alpha_{i+1}^*, u_{i+1}(p))$. This implies that the vector in which α_{i+1}^* is replaced by α_i^* has the same conditional risk and hence suggest a procedure to construct a vector that satisfies the constraints in $\mathcal{S}$ and achieves the minimal risk in $\mathbb{R}^{k-1}$. More formally, we define $\tilde{\alpha} \in \mathcal{S}$ as:

$$\tilde{\alpha}_i = \begin{cases} \alpha_1^* \text{ if } i = 1 \\ \alpha_i^* \text{ if } \alpha_{i-1}^* \leq \alpha_i^* \\ \alpha_{i-1}^* \text{ if } \alpha_{i-1}^* > \alpha_i^* \end{cases} \quad .$$

Then by the above $C(\alpha_i^*, u_i(p)) = C(\tilde{\alpha}_i, u_i(p))$ for all i and so $A(\alpha^*, p) = A(\tilde{\alpha}, p)$. Now, since $\tilde{\alpha}$ is a non-decreasing vector by construction, $\tilde{\alpha} \in \mathcal{S}$ and we have the sequence of equalities

$$A(\alpha^*, p) = A(\tilde{\alpha}, p) = \sum_{i=1}^{k-1} C^*(u_i(p)) \quad ,$$

which completes the proof. ■

It is easy to verify that the condition on φ of this theorem is satisfied by all the binary losses that we consider: hinge loss, the squared hinge loss, the logistic loss, exponential loss

and the squared loss. With this result, if α_i^* is a minimizer of $C(u_i(p))$, then $(\alpha_1^*, \ldots, \alpha_{k-1}^*)$ will be a minimizer of $A(p)$. Hence, the optimal decision function for the aforementioned values of φ is simply the concatenation of known results for binary classification, which have been derived in Bartlett et al. (2003) for the hinge, squared hinge and Exponential loss and in (Zhang, 2004a) for the logistic loss. Using the results from binary classification we list the values of α^* and A^* in the case of AT for different values of φ:

- *Hinge AT*, : $\alpha_i^*(p) = \text{sign}(2u_i(p) - 1)$, $\quad A^*(p) = \sum_{i=1}^{k-1}\{1 - \big|2u_i(p) - 1\big|\}$.
- *Squared hinge AT*, : $\alpha_i^*(p) = (2u_i(p) - 1)$, $\quad A^*(p) = \sum_{i=1}^{k-1} 4u_i(p)(1 - u_i(p))$.
- *Logistic AT*: $\alpha_i^*(p) = \log\left(\frac{u_i(p)}{1-u_i(p)}\right)$, $A^*(p) = \sum_{i=1}^{k-1}\{-E(u_i(p)) - E(1 - u_i(p))\}$, where $E(t) = t\log(t)$.
- *Exponential AT*: $\alpha_i^*(p) = \frac{1}{2}\log\left(\frac{u_i(p)}{1-u_i(p)}\right)$, $\quad A^*(p) = \sum_{i=1}^{k-1} 2\sqrt{u_i(p)(1 - u_i(p))}$.
- *Squared AT*, $\alpha_i^*(p) = 2u_i(p) - 1$, $\quad A^*(p) = \sum_{i=1}^{k-1}(2 - 2u_i(p))^2$.

It is immediate to check that the models mentioned above are consistent since the decision functions coincides in sign with the minimizer of the risk defined in Lemma 3. Note that the sign of $\alpha_i^*(p)$ at $u_i(p) = \frac{1}{2}$ is irrelevant, since by Eq. (15) both signs have equal risk. We now provide a result that characterizes consistency for a convex φ:

Theorem 5 *Let $\varphi : \mathbb{R} \to \mathbb{R}$ be convex. Then the AT surrogate is consistent if and only if φ is differentiable at 0 and $\varphi'(0) < 0$.*

Proof We postpone the proof until Section 3.4, where this will follow as a particular case of Theorem 13. ■

We will now derive excess risk bounds for AT. These are inequalities that relate the excess conditional risk $L(\alpha) - L^*$, to the excess in surrogate conditional risk $A(\alpha) - A^*$. For this, we will make use of the γ-transform[3] of a binary loss function (Bartlett et al., 2003). For a convex function φ this is defined as

$$\gamma(\theta) = \varphi(0) - C^*\left(\frac{1+\theta}{2}\right) \quad . \tag{18}$$

We will now state the excess risk bound of the AT surrogate in terms of the γ-transform:

Theorem 6 (Excess risk bounds) *Let $\varphi : \mathbb{R} \to \mathbb{R}$ be a function that verifies the following conditions:*

- *φ is convex.*
- *φ is differentiable at 0 and $\varphi'(0) < 0$.*

3. Bartlett et al. (2003) define this as the ψ-transform. However, since we already use ψ to denote the surrogate loss functions we will use letter γ in this case.

- $\varphi(\beta) - \varphi(-\beta)$ *is a non-increasing function of* β.

Then for any $\alpha \in \mathcal{S}, p \in \Delta^k$*, the following excess risk bound is verified:*

$$\gamma\left(\frac{L(\alpha,p) - L^*(p)}{k-1}\right) \leq \frac{A(\alpha,p) - A^*(p)}{k-1} \quad . \tag{19}$$

Proof Let I denote the set of indices in which the sign of α does not coincide with $\underline{\alpha}$, that is, $I = \{i : \alpha_i(2u_i(p) - 1) < 0\}$. From Bartlett et al. (2003, Lemma 7), we know that if φ is convex and consistent (in the context of binary classification), then γ is convex and we can write

$$\begin{aligned}
\gamma\left(\frac{L(\alpha,p) - L^*(p)}{k-1}\right) &= \gamma\left(\frac{\sum_{i\in I} |2u_i(p) - 1|}{k-1}\right) && \text{(by Eq. (16))} \\
&\leq \frac{\sum_{i\in I} \gamma(|2u_i(p) - 1|)}{k-1} && \text{(by Jensen's inequality)} \\
&= \sum_{i\in I} \frac{\gamma(2u_i(p) - 1)}{k-1} && \text{(by symmetry of } \gamma) \\
&= \sum_{i\in I} \frac{\varphi(0) - C^*\left(u_i(p)\right)}{k-1} && \text{(by definition of } \gamma).
\end{aligned} \tag{20}$$

Let $q \in [0,1], \beta \in \mathbb{R}$. If we can further show that $\beta(2q-1) \leq 0$ implies $\varphi(0) \leq C(\beta, q)$, then

$$\begin{aligned}
\sum_{i\in I} \left(\varphi(0) - C^*(u_i(p))\right) &\leq \sum_{i\in I} \left(C(\alpha_i, u_i(p)) - C^*(u_i(p))\right) \\
&\leq \sum_{i=1}^{k-1} \left(C(\alpha_i, u_i(p)) - C^*(u_i(p))\right) \\
&= A(\alpha,p) - A^*(p) \quad \text{(by Lemma 4)}.
\end{aligned}$$

Combining this inequality with Eq. (20), we obtain the theorem. Therefore we only need to prove that $\beta(2q-1) \leq 0$ implies $\varphi(0) \leq C(\beta, q)$. Suppose $\beta(2q-1) \leq 0$. Then by Jensen's inequality

$$C(\beta, q) = q\varphi(\beta) + (1-q)\varphi(-\beta) \geq \varphi(q\beta - (1-q)\beta) = \varphi(\beta(2q-1)) \quad .$$

Now, by convexity of φ we have

$$\varphi(\beta(2q-1)) \geq \varphi(0) + \beta(2q-1)\varphi'(0) \geq \varphi(0) \quad ,$$

where the last inequality follows from the fact that $\varphi'(0) < 0$ and $\beta(2q-1) \leq 0$. This concludes the proof. ■

Note that we have given the excess risk bounds in terms of the conditional risk. These can also be expressed in terms of the full risk, as done for example by Bartlett et al. (2003);

Zhang (2004a). Within the conditions of the theorem, γ is convex and because of Jensen inequality, it is verified that

$$\gamma\left(\mathbb{E}_X\left[L(f(X), \eta(X)) - L^*(\eta(X))\right]\right) \leq \mathbb{E}_X\left[\gamma(L(f(X), \eta(X))\right] \quad .$$

This, together with Eq. (19) yields the following bound in terms of the full risk

$$\begin{aligned}
\gamma\left(\frac{\mathcal{L}(f) - \mathcal{L}}{k-1}\right) &\leq \mathbb{E}_X\left[\gamma\left(\frac{L(f(X), \eta(X)) - L^*(\eta(X))}{k-1}\right)\right] \\
&\leq \mathbb{E}_X\left[\frac{A(f(X), \eta(X)) - A^*(\eta(X))}{k-1}\right] \\
&= \frac{\mathcal{A}(f) - \mathcal{A}^*}{k-1}
\end{aligned}$$

Examples of excess risk bounds. We will now derive excess bounds for different instances of the AT loss function. The values of γ only depend on φ, so we refer the reader to Bartlett et al. (2003) on the estimation of γ for the hinge, squared hinge and Exponential loss and to (Zhang, 2004a) for the logistic loss. Here, we will merely apply the known form of γ to the aforementioned surrogates.

- *Hinge AT,* : $\gamma(\theta) = |\theta| \implies L(\alpha,p) - L^*(p) \leq A(\alpha,p) - A^*$.
- *Squared hinge AT,* : $\gamma(\theta) = \theta^2 \implies \left(\frac{L(\alpha,p) - L^*(p)}{k-1}\right)^2 \leq A(\alpha,p) - A^*$.
- *Logistic AT*: $\gamma(\theta) = \frac{\theta^2}{2} \implies \left(\frac{L(\alpha,p) - L^*(p)}{\sqrt{2}(k-1)}\right)^2 \leq A(\alpha,p) - A^*$.
- *Exponential AT*: $\gamma(\theta) = 1 - \sqrt{1-\theta^2} \implies$ $(k-1)(1 - \sqrt{1 - \frac{(L(\alpha,p) - L^*(p))^2}{k-1}}) \leq A(\alpha,p) - A^*$.
- *Squared AT*: $\gamma(\theta) = \theta^2 \implies \left(\frac{L(\alpha,p) - L^*(p)}{k-1}\right)^2 \leq A(\alpha,p) - A^*$.

For $k = 2$, these results generalize the known excess risk bounds for binary surrogates. For $k > 2$, the normalizing factor $\frac{1}{k-1}$ is not surprising, since the absolute error is bounded by $k-1$ while the 0-1 loss is bounded by 1. While similar excess risk bounds are known for multiclass classification (Zhang, 2004b; Ávila Pires et al., 2013), to the best of our knowledge this is the first time that such bounds have been developed for the AT surrogate ($k > 2$).

Cumulative link (CL). We now focus on the CL loss function defined in Eq. (21), which we restate here for convenience:

$$\psi_{\text{CL}}(y, \alpha) := \begin{cases} -\log(\sigma(\alpha_1)) & \text{if } y = 1 \\ -\log(\sigma(\alpha_y) - \sigma(\alpha_{y-1})) & \text{if } 1 < y < k \\ -\log(1 - \sigma(\alpha_{k-1})) & \text{if } y = k \quad . \end{cases} \tag{21}$$

The terms of this surrogate can be seen as the negative log-likelihood of a probabilistic model in which $\sigma(\alpha)$ model the cumulative probabilities:

$$\sigma(\alpha_i) = P(Y \leq i | X = x) = u_i(p) \quad , \tag{22}$$

and so the likelihood is maximized for $\sigma(\alpha_i^*) = u_i(p)$. Assuming that the inverse of the link function σ exists, this implies that the minimizer of the surrogate loss function (given by the negative log-likelihood) is given by $\alpha_i^*(p) = \sigma^{-1}(u_i(p))$. Plugging into the formula for the surrogate risk yields $A^*(p) = \sum_{i=1}^k p_i \log(p_i)$. This immediately leads to a characterization of consistency based on the link function σ:

Theorem 7 *Suppose σ is an invertible function. Then the CL surrogate is consistent if and only if the inverse link function verifies*

$$\left(\sigma^{-1}(t)\right)(2t-1) > 0 \text{ for } t \neq \frac{1}{2} \quad . \tag{23}$$

Proof ($\Longrightarrow$) Suppose CL is consistent but σ^{-1} does not verify Eq. (23), i.e., there exists a $\xi \neq 1/2$ such that $\sigma^{-1}(\xi)(2\xi - 1) \leq 0$. We consider a probability distribution P such that $u_1(p) = \xi$ for all $p \in \Delta^k$. In that case, by Eq. (22) $\alpha_1^*(p) = \sigma^{-1}(\xi)$ and so this has a sign opposite to the Bayes decision function $2\xi - 1$. By Eq. (16) this implies that $L(\alpha^*) - L^* \geq 2\xi - 1 > 0$. The last inequality implies that α^* does not reach the minimal risk, contradiction since CL is consistent by assumption.

($\Longleftarrow$) Let $0 < i < k$. For $u_i(p) \neq 1/2$, $\alpha_i^*(p) = \sigma^{-1}(u_i(p))$ by Eq. (22) agrees in sign with $2u_i(p) - 1$ and so by Lemma 3 has minimal risk. If $u_i(p) = 1/2$, then in light of Eq. (15) the risk is the same no matter the value of $\alpha_i^*(p)$. We have proven that $\alpha^*(p)$ has the same risk as a Bayes decision function, hence the CL model is consistent. This completes the proof. ■

The previous theorem captures the notion that the inverse of the link function should agree in sign with $2t-1$. When the link function is the sigmoid function, i.e., $\sigma(t) = 1/(1+e^{-t})$ this surrogate is convex and its inverse link function is given by the logit function, which verifies the assumptions of the theorem and hence is consistent. Its optimal decision function is given by

$$\alpha_i^*(p) = \log\left(\frac{u_i(p)}{1 - u_i(p)}\right) \quad ,$$

which coincides with the logistic AT surrogate. Despite the similarities between both surrogates, we have not been able to derive excess risk bounds for this surrogate since the separability properties of the AT are not met in this case. Furthermore, it is possible to construct a counter example that the γ-transform for the Logistic AT ($\gamma(\theta) = \theta^2/2$) loss does not yield a valid risk bound in this case. To see this, let $k = 3$ and p, α be as follows:

$$p = (1 - 2\varepsilon, 1.5\varepsilon, 0.5\varepsilon), \qquad \alpha = (-0.1, -0.05) \quad .$$

For these values we can compute the excess risk and excess surrogate risk as

$$L(\alpha, p) - L^* = \sum_{i=1}^{2}(2u_i(p) - 1) = 2 - 6\varepsilon$$

$$\mathcal{A}(\alpha, p) - \mathcal{A}^* = \sum_{i=1}^{3} p_i \psi_{\text{CL}}(i, \alpha) - \sum_{i=1}^{3} p_i \log(p_i)$$

If the risk bound is satisfied, then the residuals, defined as

$$\text{residuals} = \gamma\left(\frac{L(\alpha, p) - L^*}{k-1}\right) - \frac{\mathcal{A}(\alpha, p) - \mathcal{A}^*}{k-1}$$

must be always negative. However, as it can be seen in Figure 1, the residuals are increasing as ε goes to 0. Also, in the region $\varepsilon < 0.02$ the residuals become positive and hence the inequality does not hold.

We finish our treatment of the CL surrogate by stating the convexity of the logistic CL loss, which despite being a fundamental property of the loss, has not been proven before to the best of our knowledge.

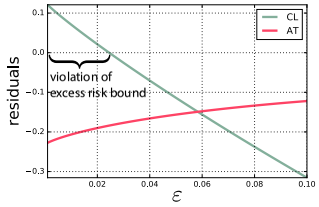

Figure 1: counterexample for the CL excess risk bound.

Lemma 8 *The logistic CL surrogate, $\alpha \mapsto \psi_{CL}(y, \alpha)$, is convex on $\mathcal{S}$ for every value of y.*

Proof $\psi_{\text{CL}}(1, \alpha)$ and $\psi_{\text{CL}}(k, \alpha)$ are convex because they are log-sum-exp functions. It is thus sufficient to prove that $\psi_{\text{CL}}(i, \cdot)$ is convex for $1 < i < k$. For convenience we will write this function as $f(a, b) = -\log\left(\frac{1}{1+\exp(a)} - \frac{1}{1+\exp(b)}\right)$, where $a > b$ is the domain of definition.

By factorizing the fraction inside f to a common denominator, f can equivalently be written as $-\log(\exp(a) - \exp(b)) + \log(1 + \exp(a)) + \log(1 + \exp(b))$. The last two terms are convex because they can be written as a log-sum-exp. The convexity of the first term, or equivalently the log-concavity of the function $f(a, b) = \exp(a) - \exp(b)$ can be settled by proving the positive-definiteness of the matrix $Q = \nabla f(a, b) \nabla f(a, b)^T - f(a, b) \nabla^2 f(a, b)$ for all (a, b) in the domain $\{b > a\}$ (Boyd and Vandenberghe, 2004). In our case,

$$Q = \begin{pmatrix} \exp(a+b) & -\exp(a+b) \\ -\exp(a+b) & \exp(a+b) \end{pmatrix} = \exp(a+b) \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \quad ,$$

which is a positive semidefinite matrix with eigenvalues $2\exp(a+b)$ and 0. This proves that Q is positive semidefinite and thus $\psi_{\text{CL}}(i, \cdot)$ is a convex function. ■

Least absolute deviation. We will now prove consistency of the least absolute deviation (LAD) surrogate. Consistency of this surrogate was already proven for the case $k = 3$

by Ramaswamy and Agarwal (2012). For completeness, we provide here an alternative proof for an arbitrary number of classes.

Theorem 9 *The least absolute deviation surrogate is consistent.*

Proof Recall that for $y \in \mathcal{Y}, \alpha \in \mathcal{S}$, the LAD surrogate is given by

$$\psi_{\text{LAD}}(y, \alpha) = \left| y + \alpha_1 - \frac{3}{2} \right| \quad .$$

The pointwise surrogate risk is then given by

$$A(\alpha, p) = \sum_{i=1}^{k} p_i \psi_{\text{LAD}}(y, \alpha) = \mathbb{E}_{Y \sim p} \left[\left| Y + \alpha_1 - \frac{3}{2} \right| \right] \quad ,$$

where $Y \sim p$ means that Y is distributed according to a multinomial distribution with parameter $p \in \Delta^k$. By the optimality conditions of the median, a value that minimizes this conditional risk is given by

$$\alpha_1^*(p) \in \text{Median}_{Y \sim p} \left(\frac{3}{2} - Y \right) \quad ,$$

where Med is the median, that is, $\alpha_1^*(p)$ is any value that verifies

$$P\left(\frac{3}{2} - Y \leq \alpha_1^*(p) \right) \geq \frac{1}{2} \text{ and } P\left(\frac{3}{2} - Y \geq \alpha_1^*(p) \right) \geq \frac{1}{2} \quad .$$

We will now prove that LAD is consistent by showing that $L(\alpha^*(p), p) = L(\underline{\alpha}(p), p)$, where $\underline{\alpha}$ is the Bayes decision function described in Lemma 3. Let $r^* = \text{pred}(\underline{\alpha}(p))$ and I denote the set $I = \{i : \alpha_i^*(p)(2u_i(p) - 1) < 0\}$. Suppose this set is non-empty and let $i \in I$. We distinguish the cases $\alpha_i^*(p) > 0$ and $\alpha_i^*(p) < 0$:

- $\alpha_i^*(p) < 0$. By Eq. (13), α_i^* and α_1^* are related by $\alpha_i^* = i - 1 + \alpha_1^*$. Then it is verified that

$$\begin{aligned} P\left(\frac{3}{2} - Y \geq \alpha_1^*(p) \right) &= P\left(\frac{3}{2} - Y \geq \alpha_i^* - i + 1 \right) = P\left(\frac{1}{2} + i - \alpha_i^* \geq Y \right) \\ &\geq P\left(\frac{1}{2} + i \geq Y \right) = u_i(p) \quad . \end{aligned}$$

  By assumption, $\alpha_i^*(p)(2u_i(p) - 1) < 0$, which implies $u_i(p) > 1/2$. Hence, by the above we have that $P\left(\frac{3}{2} - Y \geq \alpha_1^*(p) \right) > 1/2$. At the same time, by the definition of median, $P\left(\frac{3}{2} - Y \geq \alpha_1^*(p) \right) \leq 1/2$, contradiction.

- $\alpha_i^*(p) > 0$. Using the same reasoning as before, it is verified that

$$\begin{aligned} P\left(\frac{3}{2} - Y \leq \alpha_1^*(p) \right) &= P\left(\frac{3}{2} - Y \leq \alpha_i^* - i + 1 \right) = P\left(\frac{1}{2} + i - \alpha_i^* \leq Y \right) \\ &\geq P\left(\frac{1}{2} + i \leq Y \right) = 1 - u_i(p) \quad . \end{aligned}$$

  By assumption $u_i(p) < 1/2 \implies P\left(\frac{3}{2} - Y \leq \alpha_1^*(p) \right) > 1/2$. At the same time, by the definition of median, $P\left(\frac{3}{2} - Y \geq \alpha_1^*(p) \right) \leq 1/2$, contradiction.

Supposing I not empty has lead to contradictions in both cases, hence $I = \emptyset$. By Eq. (16), $L(\alpha^*(p), p) = L(\underline{\alpha}(p), p)$, which concludes the proof. ■

3.2 Squared error

We now consider the squared error, defined as

$$\ell(y, \alpha) = (y - \text{pred}(\alpha))^2 \quad ,$$

and its surrogate, the least squares loss,

$$\psi_{\text{LS}}(y, \beta) = \left(y + \alpha_1 - \frac{3}{2} \right)^2 \quad .$$

As for the case of the least absolute deviation, the only difference between the loss and its surrogate is the presence of the prediction function in the first.

We will now prove that the least squares surrogate is consistent with the squared error: we will first derive a value of α, denoted $\underline{\alpha}$ that reaches the Bayes optimal error and then show that the solution to the least squares surrogate agrees in sign with $\underline{\alpha}$ and so also reaches the Bayes optimal error.

Lemma 10 *Let $\underline{\alpha} \in \mathbb{R}^{k-1}$, be defined component-wise as*

$$\underline{\alpha}(p)_i = i - \left(\sum_{j=1}^{k} j p_j \right) + \frac{1}{2} \quad .$$

Then, $\underline{\alpha}$ is a Bayes predictor, that is, $\underline{\alpha} \in \arg\min_\alpha L(\alpha, p)$.

Proof Following our proof for the absolute error, we will show that $L(\alpha) - L(\underline{\alpha})$ is always non-negative, which implies that $\underline{\alpha}$ reaches the Bayes optimal error.

Let r and s be defined as $r = \text{pred}(\alpha)$, $s = \text{pred}(\underline{\alpha})$. Then we have the following sequence of equalities:

$$\begin{aligned} L(\alpha) - L(\underline{\alpha}) &= \sum_{i=1}^{k} p_i((i - r)^2 - (i - s))^2) \\ &= \sum_{i=1}^{k} p_i(-2ir + r^2 + 2is - s^2) \qquad \text{(developing the square)} \qquad (24) \\ &= r^2 - s^2 - 2(r - s) \sum_{i=1}^{k} i p_i \qquad (\text{using } \sum_{i=1}^{k} p_i = 1) \end{aligned}$$

We will now distinguish three cases: $r > s$, $r < s$ and $r = s$. For each of these cases we will show that $L(\alpha) - L(\underline{\alpha}) \geq 0$, which implies that $\underline{\alpha}$ has a smaller risk than any other α, and hence is a Bayes predictor.

- $s > r$. This implies that s is greater than 1 since $s > r \geq 1$. We can conclude from the definition of prediction function in Eq. (2) that the $(s-1)$-th coordinate of $\underline{\alpha}$ is strictly negative. By the definition of $\underline{\alpha}$ we have that $s - 1 - \sum_{i=1}^{k} ip_i + (1/2) < 0$ or equivalently $\sum_{i=1}^{k} ip_i > s - (1/2)$. Using this in Eq. (24) we have the following sequence of inequalities:

$$\begin{aligned} L(\alpha) - L(\underline{\alpha}) &= r^2 - s^2 - 2(r-s)\sum_{i=1}^{k} ip_i = r^2 - s^2 + \underbrace{(-2)(r-s)}_{\text{positive}}\sum_{i=1}^{k} ip_i \\ &\geq r^2 - s^2 + (-2)(r-s)(s - \frac{1}{2}) \qquad (\text{since } \sum_{i=1}^{k} ip_i \geq s - (1/2)) \\ &= \underbrace{r^2 + s^2 - 2rs}_{(r-s)^2} + r - s = \underbrace{(r-s)}_{<0}\underbrace{(r-s+1)}_{\leq 0} \\ &\geq 0 \end{aligned}$$

- $s < r$. We follow a similar argument but reversing the inequalities. The assumption in this case implies that s is smaller than k since $s < r \leq k$. We can conclude from the definition of prediction function in Eq. (2) that the s-th coordinate of $\underline{\alpha}$ is positive. By the definition of $\underline{\alpha}$ we have that $s - \sum_{i=1}^{k} ip_i + (1/2) \geq 0$ or equivalently $-\sum_{i=1}^{k} ip_i \geq -s - (1/2)$. Using this in Eq. (24) we have the following sequence of inequalities:

$$\begin{aligned} L(\alpha) - L(\underline{\alpha}) &= r^2 - s^2 - 2(r-s)\sum_{i=1}^{k} ip_i = r^2 - s^2 + \underbrace{2(r-s)}_{\text{positive}}(-\sum_{i=1}^{k} ip_i) \\ &\geq r^2 - s^2 + 2(r-s)(-s - \frac{1}{2}) \qquad (\text{since } -\sum_{i=1}^{k} ip_i \geq -s - (1/2)) \\ &= \underbrace{r^2 + s^2 - 2rs}_{(s-r)^2} + s - r = \underbrace{(s-r)}_{<0}\underbrace{(s-r+1)}_{\leq 0} \\ &\geq 0 \end{aligned}$$

- $s = r$. Since the excess risk only depends on r, s and not on the particular values of $\alpha, \underline{\alpha}$ (see Eq. (24)), the excess risk is the same in this case, i.e., $L(\alpha) - L(\underline{\alpha}) = 0$.

■

Theorem 11 *The least squares surrogate ψ_{LS} is consistent with respect to the squared error.*

Proof The proof follows closely that of the least absolute deviation (Theorem 9) replacing the median by the expected value. In this case, the pointwise error can be written as

$$A(\alpha, p) = \sum_{i=1}^{k} p_i \psi_{\text{LS}}(y, \alpha) = \mathbb{E}_{Y \sim p}\left(Y + \alpha_1 - \frac{3}{2}\right)^2 \quad ,$$

and by the optimality conditions of the expected value, we have that $\alpha_1^* = \mathbb{E}(\frac{3}{2} - Y | X = x) = \sum_{i=1} p_i(\frac{3}{2} - i)$. Hence, the value for a general α_i^* is given by $i + \alpha_1^*$ (Eq. 13), which can be written as

$$\alpha_i^* = i - \sum_{i=1}^{k} ip_i + \frac{1}{2} \quad .$$

This corresponds to the Bayes predictor of Lemma 10 and hence is consistent. ■

We will encounter another consistent loss function in the Experiments section, when we derive a variant of the AT loss function that is consistent with respect to the square error.

3.3 Surrogates of the 0-1 loss

Perhaps surprisingly, some popular models for ordinal regression turn out to be surrogates, not of the absolute error, but of the 0-1 loss. In this section we focus on the 0-1 loss and we provide a characterization of consistency for the immediate threshold loss function.

Immediate thresholds (IT). In this case, the conditional risk can be expressed as

$$A(\alpha, p) = \sum_{i=1}^{k} p_j \psi_{\text{IT}}(j, \alpha) = \sum_{i=1}^{k-1} p_i \varphi(-\alpha_i) + p_{i+1}\varphi(\alpha_i)$$

As pointed out by Chu and Keerthi (2005), and contrary to what happened for AT surrogate, the constraints can not be ignored in general when computing A^*. Results that rely on this property such as the excess error bound of Theorem 6 will not translate directly for the IT loss. However, we will still be able to characterize the functions φ that lead to a consistent surrogate, in a result analogous to Theorem 5 for the AT surrogate.

Theorem 12 *Let φ be convex. Then the IT surrogate is Fisher consistent with respect to the 0-1 loss if and only if φ is differentiable at 0 and $\varphi'(0) < 0$.*

Proof As for the AT surrogate, this can be seen as a particular case of Theorem 13 with ℓ the 0-1 loss. We will postpone the proof until Section 3.4. ■

3.4 Extension to other admissible loss functions

In this section we will show that the AT and IT surrogates can be seen as particular instances of a family of loss functions for which we will be able to provide a characterization of consistency.

The admissibility criterion that we require on the loss function is that this is of the form $\ell(i, \alpha) = g\left(\left|i - \text{pred}(\alpha)\right|\right)$, where g is a non-decreasing function. Intuitively, this condition implies that labels further away from the true label are penalized more than those closer by. This criterion is general enough to contain all losses considered before such as the absolute error, the squared error and (albeit in a degenerate sense) 0-1 loss. A very similar condition is the V-shape property of (Li and Lin, 2007). This property captures the notion that the loss should not decrease as the predicted value moves away from the true value

by imposing that ℓ verifies $\ell(y,\alpha) \leq \ell(y,\alpha')$ for $\left|y - \text{pred}(\alpha)\right| \leq \left|y - \text{pred}(\alpha')\right|$. The only difference between the two conditions is that our admissibility criterion adds a symmetric condition, i.e., ℓ verifies that the loss of predicting a when the true label is b is the same as the loss of predicting b when the true label is a, which is not necessarily true for V-shaped loss functions. We conjecture that the results in this section are valid for general V-shaped loss functions, although for simplicity we have only proven results for symmetric V-shaped loss functions. For the rest of this section, we will consider that ℓ is a loss function that verifies the admissibility criterion.

We define c_i by $c_0 = g(0)$ and $c_i = g(i) - g(i-1)$ for $0 < i \leq k$. With this notation it is easy to verify by induction that g can be written as a sum of c_i with the formula $g(i) = \sum_{j=1}^{i} c_j$ and that $c_i \geq 0$ by the admissibility property. Following the same development as in Eq. (8), any admissible loss function can be written as a sum of c_i as

$$\ell(y,\alpha) = g\left(\sum_{i=1}^{y-1} [\![\alpha_i \geq 0]\!] + \sum_{i=y}^{k-1} [\![\alpha_i < 0]\!]\right) = \sum_{i=1}^{y-1} c_{y-i} [\![\alpha_i \geq 0]\!] + \sum_{i=y}^{k-1} c_{i-y+1} [\![\alpha_i < 0]\!] \quad . \quad (25)$$

In light of this, it seems natural to define a surrogate for this general loss function by replacing the 0-1 loss with a surrogate as the hinge or logistic that we will denote by φ. This defines a new surrogate that we will denote *generalized all threshold (GAT)*:

$$\psi_{\text{GAT}}(y,\alpha) := \sum_{i=1}^{y-1} \varphi(-\alpha_i) c_{y-i} + \sum_{i=y}^{k-1} \varphi(\alpha_i) c_{i-y+1} \quad .$$

In the special case of the absolute error, c_i is identically equal to 1 and we recover AT loss of Eq. (10). Likewise, for the zero-one loss, c_i will be one for $i \in \{y-1, y\}$ and zero otherwise, recovering the IT loss of Eq. (12). We will now present the main result of this section, which has Theorems 5 and 12 as particular cases.

Theorem 13 *Let φ be convex. Then the GAT surrogate is consistent if and only if φ is differentiable at 0 and $\varphi'(0) < 0$.*

Before presenting the proof of this theorem, we will need some auxiliary results. Unlike for the absolute error, in this case we will not be able to derive a closed form of the optimal decision function. However, we will be able to derive a formula for the excess risk in terms of the functions $u, v : \Delta^k \to \mathbb{R}^{k-1}$, defined as

$$u_i(p) = \sum_{j=1}^{i} p_j c_{i-j+1} \quad v_i(p) = \sum_{j=i+1}^{k} p_j c_{j-i} \quad .$$

Note that we have overloaded the function u defined in Section 3.1. This is not a coincidence, as when ℓ is the absolute error both definitions coincide. Using this notation, the surrogate risk can be conveniently written as

$$\begin{aligned} A(\alpha,p) &= \sum_{i=1}^{k} p_i \psi_{\text{GAT}}(i,\alpha) = \sum_{i=1}^{k} p_i \left(\sum_{j=1}^{i-1} \varphi(-\alpha_j) c_{i-j} + \sum_{j=i}^{k-1} \varphi(\alpha_j) c_{j-i+1}\right) \\ &= \sum_{i=1}^{k-1} v_i(p)\varphi(-\alpha_i) + u_i(p)\varphi(\alpha_i) \quad , \end{aligned}$$

and we have the following formulas for the excess risk:

Lemma 14 *Let $p \in \Delta^k$, $\alpha \in \mathcal{S}$, $r = \text{pred}(\alpha)$ and r^* be the label predicted by any Bayes decision function at p. Then, it is verified that*

$$L(\alpha,p) - L^*(p) = \begin{cases} \sum_{i=r}^{r^*} (v_i(p) - u_i(p)) & \text{if } r < r^* \\ \sum_{i=r^*}^{r-1} (u_i(p) - v_i(p)) & \text{if } r > r^* \end{cases} \quad .$$

Proof The risk can be expressed in terms of u_i and v_i (where the dependence of p is implicit) as

$$\begin{aligned} L(\alpha) &= \sum_{i=1}^{k} p_i g(|r-i|) = \sum_{i=1}^{r-1} p_i g(r-i) + \sum_{i=r+1}^{k} p_i g(i-r) \\ &= \sum_{i=1}^{r-1} p_i \sum_{j=1}^{r-i} c_j + \sum_{i=r+1}^{k} p_i \sum_{j=1}^{i-r} c_j \\ &= \sum_{i=1}^{r-1} u_i + \sum_{i=r}^{k-1} v_i \quad , \end{aligned} \quad (26)$$

hence for $r < r^*$,

$$0 \leq L(\alpha) - L^* = \sum_{i=1}^{r-1} u_i + \sum_{i=r}^{k-1} v_i - \left(\sum_{i=1}^{r^*-1} u_i + \sum_{i=r^*}^{k-1} v_i\right) = \sum_{i=r}^{r^*-1} (v_i - u_i) \quad ,$$

and similarly for $r > r^*$

$$0 \leq L(\alpha) - L^* = \sum_{i=1}^{r-1} u_i + \sum_{i=r}^{k-1} v_i - \left(\sum_{i=1}^{r^*-1} u_i + \sum_{i=r^*}^{k-1} v_i\right) = \sum_{i=r^*}^{r-1} (u_i - v_i) \quad ,$$

■

Proof [Proof of Theorem 13] This proof loosely follows the steps by Bartlett et al. (2003, Theorem 6), with the difference that we must ensure that the optimal value of the surrogate risk lies within $\mathcal{S}$ and adapted to consider multiple classes. We denote by α^* the value in $\mathcal{S}$ that minimizes $A(\cdot)$, by r the prediction at α^* and by r^* the prediction of any Bayes decision function, where the dependence on p is implicit.

($\implies$) We first prove that consistency implies φ is differentiable at 0 and $\varphi'(0) < 0$. We do so by proving that the subdifferential at zero is reduced to a single vector. Since φ is convex, we can find subgradients $g_1 \geq g_2$ of φ at zero such that, for all $\beta \in \mathbb{R}$

$$\begin{aligned} \varphi(\beta) &\geq g_1 \beta + \varphi(0) \\ \varphi(\beta) &\geq g_2 \beta + \varphi(0) \quad . \end{aligned}$$

Then we have for all i

$$\begin{aligned} v_i\varphi(-\beta) + u_i\varphi(\beta) &\geq v_i(g_1\beta + \varphi(0)) + u_i(-g_2\beta + \varphi(0)) \\ &= (v_i g_1 - u_i g_2)\beta + (v_i + u_i)\varphi(0) \\ &= \beta\left(\frac{1}{2}(v_i + u_i)(g_1 - g_2) + \frac{1}{2}(v_i - u_i)(g_1 + g_2)\right) + (v_i + u_i)\varphi(0) \quad . \end{aligned} \tag{27}$$

For $0 < \varepsilon < 1/2$, we will consider the following vector of conditional probabilities

$$p = \left(0, \cdots, 0, \frac{1}{2} - \varepsilon, \frac{1}{2} + \varepsilon\right) \quad ,$$

from where u_i and v_i take the following simple form

$$u_i = \begin{cases} p_{k-1}c_1 & \text{if } i = k-1 \\ 0 & \text{otherwise} \end{cases}, \quad v_i = \begin{cases} p_k c_1 & \text{if } i = k-1 \\ p_{k-1}c_{k-i-1} + p_k c_{k-i} & \text{otherwise} \end{cases}$$

hence by Eq. (26) consistency implies $r = k$ and so we must have $\alpha^*_{k-1} < 0$.

Let now $\tilde{\alpha} \in \mathcal{S}$ be a vector that equals α^* in all except the last component, which is zero (i.e., $\tilde{\alpha}_{k-1} = 0$). We will now prove that if $g_1 > g_2$ then $A(\tilde{\alpha}, p) < A(\alpha^*, p)$ leading to a contradiction. For the particular choice of u_{k-1}, v_{k-1} above, equation (27) can be simplified to

$$v_{k-1}\varphi(-\beta) + u_{k-1}\varphi(\beta) \geq \beta\left[\frac{1}{2}(g_1 - g_2) + \varepsilon(g_1 + g_2)\right] + (v_{k-1} + u_{k-1})\varphi(0) \quad .$$

Since by assumption $g_1 > g_2$, it is always possible to choose ε small enough such that the quantity inside the square brackets is strictly positive. Special casing at $\beta = \alpha^*_{k-1}$ and using $\alpha^*_{k-1} < 0$ yields the following inequality:

$$v_{k-1}\varphi(-\alpha^*_{k-1}) + u_{k-1}\varphi(\alpha^*_{k-1}) \geq (v_{k-1} + u_{k-1})\varphi(0) \quad .$$

We then have the following sequence of inequalities:

$$\begin{aligned} A(\alpha^*, p) &= \sum_{i=1}^{k-1} v_i(p)\varphi(-\alpha^*_i) + u_i\varphi(\alpha^*_i) \\ &\geq \sum_{i=1}^{k-2} \left\{v_i(p)\varphi(-\alpha^*_i) + u_i\varphi(\alpha^*_i)\right\} + (v_{k-1} - u_{k-1})\alpha^*_{k-1} + (v_{k-1} + u_{k-1})\varphi(0) \\ &\qquad \text{(by last inequality)} \\ &> \sum_{i=1}^{k-2} \left\{v_i(p)\varphi(-\alpha^*_i) + u_i\varphi(\alpha^*_i)\right\} + v_{k-1}\varphi(0) + u_{k-1}\varphi(0) \\ &= A(\tilde{\alpha}, p) \quad , \end{aligned}$$

which results in $A(\alpha^*, p) > A(\tilde{\alpha}, p)$, contradiction since α^* is the value with lowest surrogate risk. This implies that if the GAT loss is consistent, then φ is differentiable at 0. To see that we must also have $\varphi'(0) < 0$, notice that from Eq. (27) we have

$$A_i(\beta) \geq (v_i - u_i)\varphi'(0)\beta + A_i(0) \quad .$$

But for any $v_i > u_i$ and $\beta < 0$, if $\varphi'(0) \geq 0$, then this expression is greater than $A_i(0)$. Hence, if GAT is consistent then $\varphi'(0) < 0$, which concludes one of the implications of the proof.

($\Longleftarrow$) We now prove that if φ is differentiable at 0 and $\varphi'(0) < 0$, then GAT is consistent.

The first order optimality conditions states that there exists $\lambda_i \geq 0$ such that the optimal value of $A(\alpha, p)$ subject to $\alpha \in \mathcal{S}$ is the minimizer of the following unconstrained function:

$$G(\alpha) = A(\alpha, p) + \sum_{i=1}^{k-1} \lambda_i(\alpha_i - \alpha_{i+1}) \quad .$$

We show that assuming GAT is not consistent (i.e., $L(\alpha^*) > L^*$) leads to a contradiction and hence GAT must be consistent.

We start by computing the partial derivative of G at zero:

$$\frac{\partial G}{\partial \alpha_i}\Big|_{\alpha_i = 0} = (u_i - v_i)\varphi'(0) - \lambda_{i-1} + \lambda_i \quad ,$$

were for convenience $\lambda_0 = 0$. Note that $\alpha^*_{r-1} < 0 \leq \alpha^*_r$ verifies by definition of prediction function. Hence, the inequality constraints are verified with strict inequality and by complementary slackness $\lambda_{r-1} = 0$. Suppose first $r < r^*$. Then, the addition of all partial derivatives between r and r^* yields

$$\sum_{i=r}^{r^*} \frac{\partial G}{\partial \alpha_i}\Big|_{\alpha_i = 0} = \left(\sum_{i=r}^{r^*} u_i - v_i\right)\varphi'(0) + \lambda_{r^*} \quad ,$$

which by Lemma 14 is strictly positive. Consider the convex real-valued function of $\alpha_i \to G(\alpha^*_1, \ldots, \alpha^*_{r-1}, \ldots, \alpha_i, \ldots)$, that is, the function $G(\alpha^*)$ restricted to $\alpha_i, i \geq r$. Since $\alpha^*_i \geq 0$ for all $i \geq r$ by the definition of prediction function, and knowing the subdifferential of a convex function is a monotonous, this implies that $\partial G/\partial \alpha_{i \geq r} \leq 0$ at $\alpha_i = 0$, contradiction.

Now we suppose $r > r^*$. Then, the addition of all partial derivatives between r^* and r yields

$$\sum_{i=r^*}^{r} \frac{\partial G}{\partial \alpha_i}\Big|_{\alpha_i = 0} = \left(\sum_{i=r^*}^{r} u_i - v_i\right)\varphi'(0) - \lambda_{r^*-1} \quad ,$$

which by Lemma 14 is strictly negative. As before, we consider the function the function $G(\alpha^*)$ restricted to $\alpha_i, i \geq r$. By the definition of prediction function, $\alpha^*_{i<r} < 0$ and so the fact that the subdifferential of a real-valued function is monotonous, we have that $\partial G/\partial \alpha_{i \geq r} \geq 0$ at $\alpha_i = 0$, contradiction. ■

4. Threshold-based decision functions and parametric consistency

In this section we revisit the assumption that the optimal decision function can be estimated independently at each point $x \in \mathcal{X}$. This is implicitly assumed on most consistency studies,

however in practice models often enforce inter-observational constraints (e.g. smoothness). In the case of ordinal regression it is often the case that the decision functions are of the form

$$f(x) = (\theta_1 - g(x), \theta_2 - g(x), \ldots, \theta_{k-1} - g(x)) \quad , \tag{28}$$

where $(\theta_1, \ldots, \theta_{k-1})$ is a non-decreasing vector (i.e., its components form a non-decreasing sequence) known as the *vector of thresholds* (hence the appearance of the name thresholds in many models) and g is a measurable function. We will call decision functions of this form *threshold-based* decision functions. All the examined models are of this form with the exception of the least absolute deviation are commonly constrained to this family of decision functions (Chu and Keerthi, 2005; Rennie and Srebro, 2005; Lin and Li, 2006; Shashua and Levin, 2003).

The main issue with such decision functions is that since the vector of thresholds is estimated from the data, it is no longer true that the optimal decision function can be estimated independently at each point. This implies that the pointwise characterization of Fisher consistency described in Lemma 2 does no longer hold when restricted to this family and hence the consistency proofs in previous sections no longer hold.

Let $\mathcal{F}$ be the set of functions of the form of Eq. (28). We will now apply the notion of $\mathcal{F}$-*consistency* or *parametric consistency* of (Shi et al., 2015) to the threshold-based setting. This is merely the notion of Fisher consistency where the decision functions are restricted to a family of interest:

Definition 15 *($\mathcal{F}$-**Consistency**) Given a surrogate loss function $\psi : \mathcal{Y} \times \mathcal{S} \to \mathbb{R}$, we will say that the surrogate loss function ψ is $\mathcal{F}$-consistent with respect to the loss $\ell : \mathcal{Y} \times \mathcal{S} \to \mathcal{Y}$ if for every probability distribution over $X \times Y$ it is verified that every minimizer of the ψ-risk reaches the optimal risk in $\mathcal{F}$, that is,*

$$f^* \in \arg\min_{f \in \mathcal{F}} \mathcal{A}(f) \implies \mathcal{L}(f^*) = \inf_{f \in \mathcal{F}} \mathcal{L}(f) \quad .$$

We will show that by imposing additional constraints on the probability distribution P we will be able to derive $\mathcal{F}$-consistency for particular surrogates. In the following theorem we give one sufficient condition for $\mathcal{F}$-consistency of the logistic all threshold and the logistic CL. This condition involves the odds-ratio, defined as

$$R_i(x) = \frac{u_i(\eta(x))}{1 - u_i(\eta(x))} \quad ,$$

where $\eta(x)$ is the vector of conditional probabilities defined in Section 1.2 and u_i is the vector of conditional probabilities.

Theorem 16 *If the quotient of successive R_i is independent of x for all $0 < i < k-1$, that is, if*

$$\frac{R_i(x)}{R_{i+1}(x)} = a_i \quad \forall x \in \mathcal{X} \quad ,$$

for some real number a_i, then the logistic all threshold and the logistic CL are $\mathcal{F}$-consistent.

Proof It will be sufficient to prove that under the constraints on P, the optimal decision function for the unconstrained problem belongs to $\mathcal{F}$. In Section 3.1 we derived the optimal decision function for the logistic all threshold and the logistic CL. Hence, we can write

$$\alpha_i^*(\eta(x)) - \alpha_{i+1}^*(\eta(x)) = \log\left(\frac{u_i(\eta(x))}{1 - u_i(\eta(x))}\right) - \log\left(\frac{u_{i+1}(\eta(x))}{1 - u_{i+1}(\eta(x))}\right) = \log\left(\frac{R_i(x)}{R_{i+1}(x)}\right) \quad .$$

It is clear that α is a threshold-based decision function of the form Eq. (28) if and only if $\alpha_i - \alpha_{i+1}$ does not depend on $x \in \mathcal{X}$. Given the above, we can guarantee that the optimal α belongs to $\mathcal{F}$ if the last term is independent of x. One can then easily recognize the quotient of odds-ratio of the theorem's conditions and conclude that $\alpha_i^*(\eta(x)) - \alpha_{i+1}^*(\eta(x))$ is independent of x. This concludes the proof. ■

This sufficient condition is admittedly a very stringent one on the probability distribution P. Unfortunately, a deeper understanding of $\mathcal{F}$-consistency, while an interesting future direction, is outside the scope of the current paper.

5. Experiments: A novel surrogate for the squared error

While the focus of this work is a theoretical investigation of consistency, we have also conducted experiments to study a novel surrogate suggested by the results of the last section. There, we constructed a surrogate that is consistent with any loss function that verifies an admissible criterion. In particular, Theorem 13 applied to the squared loss yields the following consistent surrogate:

$$\psi(y, \alpha) = \sum_{i=1}^{y-1} \varphi(-\alpha_i)(2(y-i) - 1) + \sum_{i=y}^{k-1} \varphi(\alpha_i)(2(i-y) + 1) \quad .$$

In principle, any binary loss function can be used for φ, although in the experiments we set it to the hinge loss function. To the best of our knowledge, this is a novel surrogate. We compare the cross-validation error of this surrogate on different datasets against the least squares surrogate (for which we proved consistency in §3.2) where $\beta \in \mathbb{R}$ and prediction is given by rounding to the closest integer. In both cases, we consider linear decision functions, i.e.

$$\alpha = (\theta_1 - \langle w, x\rangle, \ldots, \theta_{k-1} - \langle w, x\rangle) \quad \text{and} \quad \beta = \langle w, x\rangle \quad .$$

In each case, the optimal values of w, θ were found by minimizing the empirical surrogate risk. For the training sample $\{(x_1, y_1), \ldots, (x_n, y_n)\}$, $x_i \in \mathbb{R}^p$, it yielding the following optimization problems for GAT and least squares, respectively:

$$\arg\min_{\theta \in \mathcal{S}, w \in \mathbb{R}^p} \sum_{i=1}^{n} \left\{ \sum_{j=1}^{y_i - 1} \varphi(\langle w, x_i\rangle - \theta_j)(2(y-j) - 1) + \sum_{j=y_i}^{k-1} \varphi(\theta_j - \langle w, x_i\rangle)(2(j-y) + 1) \right\}$$

$$\arg\min_{w \in \mathbb{R}^p} \sum_{i=1}^{n} (y_i - \langle w, x_i\rangle)^2$$

The different datasets that we will consider are described in (Chu and Keerthi, 2005) and can be download from the authors website[4]. We display results for the 9 datasets of SET I using the version of the datasets with 5 bins, although similar results were observed when using the datasets with 10 bins. Given the small dimensionality of the datasets (between 6 and 60) and the comparatively high number of samples (between 185 and 4000), we did not consider the use of regularization.

Performance is computed as the squared error on left out data, averaged over 20 folds. We report this performance in Figure 2, where it can be seen that the GAT surrogate outperforms LS on 7 out of 9 datasets, although admittedly the difference is small and only statistically significant on 3 datasets. However, this shows that previous theoretical results can be used to generate consistent surrogates that are competitive in a practical scenario.

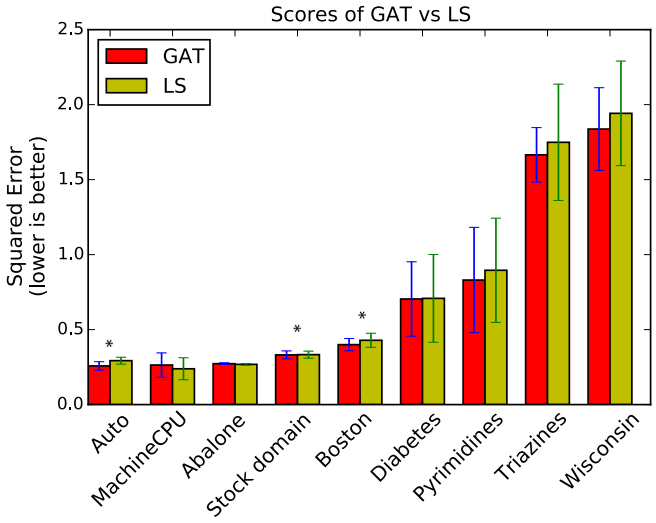

Figure 2: Scores of the generalized all threshold (GAT) and least squares (LS) surrogate on 6 different datasets. The scores are computed as the squared error between the prediction and the true labels on left out data, averaged over 20 cross-validation folds. On 7 out of 9 datasets all the GAT surrogate outperforms the least squares estimator, showing that this surrogate yields a highly competitive model. Datasets for which a Wilcoxon signed-rank test rejected the null hypothesis that the means are equal with p-value < 0.01 are highlighted by a $*$ symbol over the bars.

6. Conclusions

In this paper we have characterized the consistency for a rich family of surrogate loss functions used for ordinal regression. Our aim is to bridge the gap between the consistency properties known for classification and ranking and those known for ordinal regression.

We have first described a wide family of ordinal regression methods under the same framework. The surrogates of the absolute error that we have considered are the all threshold (AT), cumulative link (CL), and least absolute deviation (LAD), while the surrogate for the 0-1 loss is the immediate threshold (IT).

For all the surrogates considered, we have characterized its consistency. For AT and IT, consistency was characterized by the derivative of a real-valued convex function at zero (Theorems 5 and 12 respectively). For CL, consistency was characterized by a simple condition on its link function (Theorem 7) and for LAD we have extended the proof of Ramaswamy and Agarwal (2012) to an arbitrary number of classes (Theorem 5). Furthermore, we have proven that AT verifies a decomposability property and using this property we have provided excess risk bounds that generalize those of Bartlett et al. (2003) for binary classification(Theorem 6).

The derivation we have given when introducing IT and AT are identical except for the underlying loss function. This suggest that both can be seen as special cases of a more general family of surrogates. In Section 3.4 we have constructed such surrogate and characterized its consistency with respect to a general loss function that verifies an admissibility condition. Again, the characterization only relies on the derivative at zero of a convex real-valued function. We named this surrogate generalized all threshold (GAT).

In Section 4 we have turned back to examine one of the assumptions described in the introduction and that is common to the vast majority of consistency studies, i.e., that the optimal decision function can be estimated independently at every sample. However, in the setting of ordinal regression it is common for decision functions to have a particular structure known as threshold-based decision functions and which violates this assumption. Following (Shi et al., 2015), we are able to prove a restricted notion of consistency known as $\mathcal{F}$-consistency or parametric consistency on two surrogates by enforcing constraints on the probability distribution P. We believe this restricted notion of consistency to be important in practice and we look forward to see consistency studies extended to consider different types of decision functions, such as smooth functions, polynomial functions, etc.

Finally, in Section 5 we provide an empirical comparison for the GAT surrogate. The underlying loss function that we consider in this case is the squared error, in which case GAT yields a novel surrogate. We compare this surrogate against the least squares surrogate in terms of cross-validation error. Our results show that GAT outperforms least squares on 7 out of 9 datasets, showing the pertinence of such surrogate on real-world datasets.

A direction for future work would be to study the related notion of asymptotic consistency for ordinal regression loss functions, similar to the results that already exist for binary classification (Devroye et al., 1994; Steinwart, 2002).

Abstract

In this paper, we focus on parameters estimation of probabilistic models in discrete space. A naive calculation of the normalization constant of the probabilistic model on discrete space is often infeasible and statistical inference based on such probabilistic models has difficulty. In this paper, we propose a novel estimator for probabilistic models on discrete space, which is derived from an empirically localized homogeneous divergence. The idea of the empirical localization makes it possible to ignore an unobserved domain on sample space, and the homogeneous divergence is a discrepancy measure between two positive measures and has a weak coincidence axiom. The proposed estimator can be constructed without calculating the normalization constant and is asymptotically consistent and Fisher efficient. We investigate statistical properties of the proposed estimator and reveal a relationship between the empirically localized homogeneous divergence and a mixture of the α-divergence. The α-divergence is a non-homogeneous discrepancy measure that is frequently discussed in the context of information geometry. Using the relationship, we also propose an asymptotically consistent estimator of the normalization constant. Experiments showed that the proposed estimator comparably performs to the maximum likelihood estimator but with drastically lower computational cost.

Keywords: unnormalized model, homogeneous divergence, empirical localization, discrete model

1. Introduction

In the fields of machine learning and pattern recognition, probabilistic models on discrete space are useful for classification tasks or modeling discrete phenomena, so estimating parameters of probabilistic models on discrete space is a widely studied and important challenge. For example, the Boltzmann machine (with hidden variables) (Hinton and Sejnowski, 1986; Ackley et al., 1985; Amari et al., 1992) is a widely used probabilistic model to represent binary variables, and the restricted Boltzmann machine (RBM) is especially attracting increasing attention in the context of deep learning (Hinton, 2010; Hinton and Salakhutdinov, 2012). Training of probabilistic models on discrete space, i.e., estimation of parameters, is usually done by using the maximum likelihood estimation (MLE). An explicit expression of the MLE cannot generally be obtained, so the gradient-based optimization is usually used. A difficulty of the gradient-based optimization for such models comes from the calculation of the normalization constant. The calculation of the gradient requires calculation of the normalization constant in each step of the optimization and its computational cost sometimes increases exponentially. To tackle the problem of computational cost, various kinds of approximation methods have been proposed. One approach tries to approximate the probabilistic model (or expectation with the model) by using a tractable model or sampling techniques. The mean-field approximation is a popular method to approximate the model by assuming independence among variables (Opper and Saad, 2001). The contrastive divergence (Hinton, 2002) avoids the exponential order calculation using the Markov Chain Monte Carlo (MCMC) sampling: the method approximates the expectation using samples obtained by the MCMC that runs few steps from the empirical distribution with a transition matrix defined with a current model. Another approach is estimation based on an unnormalized model, which does not include the normalization constant and so is not necessarily a probability. In the literature of parameters estimation of probabilistic models for continuous variables, Hyvärinen (2005) used a score function which is a gradient of log-density with respect to the data vector rather than parameters. This approach makes it possible to estimate parameters without calculating the normalization term by focusing on the shape of the density function. Hyvärinen (2007) extended the method to discrete variables. This method uses information of a "neighbor" by contrasting its probability with that of a flipped variable. Gutmann and Hirayama (2012) extended the above framework and developed an approximated estimator on the basis of the Bregman divergence. Dawid et al. (2012) proposed a generalized local scoring rules on discrete sample spaces and theoretically discussed a class of scoring rules for appropriate estimation. Takenouchi (2015) focused on a specific class of models on discrete space and constructed an asymptotically consistent estimator using the Itakura-Saito distance.

In this paper, we propose a novel method of parameter estimation for probabilistic models on discrete space. The proposed estimator can be constructed without calculation of the normalization constant by utilizing the unnormalized model and has suitable statistical properties such as consistency and efficiency.[1] The proposed estimator is derived from minimization of a risk function defined by a combination of two ideas: the homogeneous divergence and an empirical localization. The conventional divergence measure that has a coincidence axiom ensures that the divergence is zero if and only if two positive measures are equal. On the other hand, the homogeneous divergence follows a weak coincidence axiom and is zero if and only if two positive measures have a proportional relationship. By virtue of the property, the homogeneous divergence that has the weak coincidence axiom can ignore the normalization constant, and the proposed estimator does not need to calculate the normalization constant. The empirical localization is a method of transformation of the unnormalized model and is an extension of the geometric mean of the model and the

1. A short version of this article was published as a conference paper (Takenouchi and Kanamori, 2015). In this paper, we show the possibility of generalization of the basic framework shown in (Takenouchi and Kanamori, 2015) and add some new theoretical results, including estimator for the normalization constant. Also we add experiments with various kinds of models and settings to assess the validity of the proposed method.

empirical distribution of a given dataset. By using the empirical localization, we can restrict the domain of the estimation problem to that of observed examples and omit calculations associated with the domain of unobserved examples. This restriction of the domain can drastically reduce computational cost. The derived risk function is convex for various kinds of models including the higher order Boltzmann machine and so is easy to optimize. Also, we investigate statistical properties of the proposed estimator and reveal that the proposed estimator has the same asymptotic efficiency as the MLE. The proposed risk function is closely related with the α-divergence (Amari and Nagaoka, 2000), which induces a Fisher efficient estimator for discrete probabilistic models. The α-divergence is not homogeneous divergence, and by utilizing the relationship, we also developed a feasible estimator of the normalization constant.

Basic settings are described in Section 2, and we introduce the homogeneous divergence and the idea of empirical localization of the unnormalized model in Section 3. We describe a novel estimator for probabilistic models on discrete spaces and investigate its statistical properties of the proposed estimator in Section 4. In Section 5, we discuss a characterization of the risk function of the proposed estimator with the α-divergence and construct a feasible estimator of the normalization constant. We numerically verify performance of the proposed estimator by using synthetic datasets in Section 6.

2. Settings

Let $\mathcal{X}$ be a discrete space such as $\{+1,-1\}^d$ or the set of natural numbers. The bracket $\langle f \rangle$ for a real-valued function f on $\mathcal{X}$ denotes the sum of $f(\boldsymbol{x})$ over $\mathcal{X}$ i.e., $\langle f \rangle = \sum_{\boldsymbol{x}\in\mathcal{X}} f(\boldsymbol{x})$. We define $\mathcal{M}$ and $\mathcal{P}$ as the set of all non-negative functions and that of all probability functions on $\mathcal{X}$,

$$\mathcal{M} = \{ f : \mathcal{X} \to \mathbb{R}_{\geq 0} \,|\, \langle f \rangle < \infty \}, \ \mathcal{P} = \{ f \in \mathcal{M} \,|\, \langle f \rangle = 1 \}$$

where $\mathbb{R}_{\geq 0}$ is the set of all non-negative real numbers.

In this paper, we focus on parameter estimation of a probabilistic model $\bar{q}_{\boldsymbol{\theta}}(\boldsymbol{x})$ on $\mathcal{X}$ that is written as

$$\bar{q}_{\boldsymbol{\theta}}(\boldsymbol{x}) = \frac{q_{\boldsymbol{\theta}}(\boldsymbol{x})}{Z_{\boldsymbol{\theta}}} \tag{1}$$

where $\boldsymbol{\theta}$ is an m-dimensional vector of parameters, $q_{\boldsymbol{\theta}}(\boldsymbol{x})$ is an unnormalized model in $\mathcal{M}$ and $Z_{\boldsymbol{\theta}} = \langle q_{\boldsymbol{\theta}} \rangle$ is the normalization constant. The equality $\langle q_{\boldsymbol{\theta}} \rangle = \sum_{\boldsymbol{x}\in\mathcal{X}} q_{\boldsymbol{\theta}}(\boldsymbol{x}) = 1$ does not necessarily hold for unnormalized models, and the normalization constant $Z_{\boldsymbol{\theta}}$ typically requires a high computational cost. We thus need a device to circumvent the computation of Z_θ in statistical inferences. Throughout the paper, we assume without loss of generality that the unnormalized model $q_{\boldsymbol{\theta}}(\boldsymbol{x})$ can be written as

$$q_{\boldsymbol{\theta}}(\boldsymbol{x}) = \exp(\psi_{\boldsymbol{\theta}}(\boldsymbol{x})), \tag{2}$$

where $\psi_{\boldsymbol{\theta}}(\boldsymbol{x})$ is a function on $\mathcal{X}$ with the parameter $\boldsymbol{\theta}$.

Remark 1 *By setting $\psi_{\boldsymbol{\theta}}(\boldsymbol{x})$ as $\psi_{\boldsymbol{\theta}}(\boldsymbol{x}) - \log Z_{\boldsymbol{\theta}}$, the normalized model* (1) *can be written as* (2).

Example 1 *The Bernoulli distribution on $\mathcal{X} = \{+1,-1\}$ is the simplest example of the probabilistic model* (1) *using the function $\psi_\theta(x) = \theta x$ for $x \in \mathcal{X}$ and $\theta \in \mathbb{R}$.*

Example 2 *For the parameter $\theta \in \mathbb{R}$, the function $\psi_\theta(x) = x\theta - \log x!$ leads to an unnormalized model for the Poisson distribution on $\mathcal{X} = \{0,1,2,\ldots\}$ with mean e^θ.*

Example 3 *Using a function $\psi_{\boldsymbol{\theta},k}(\boldsymbol{x}) = (x_1,\ldots,x_d,x_1x_2,\ldots,x_{d-1}x_d,x_1x_2x_3,\ldots)\boldsymbol{\theta}$ in which monomials of degree up to k appear, we can define a k-th order Boltzmann machine (Hinton and Sejnowski, 1986; Sejnowski, 1986).*

Example 4 *Let $\boldsymbol{x}_o \in \{+1,-1\}^{d_1}$ and $\boldsymbol{x}_h \in \{+1,-1\}^{d_2}$ be an observed vector and hidden vector, respectively, and $\boldsymbol{x} = \left(\boldsymbol{x}_o^T, \boldsymbol{x}_h^T\right) \in \{+1,-1\}^{d_1+d_2}$ where T indicates the transpose, be a concatenated vector. The Boltzmann machine with hidden variables is defined as $q_{h,\boldsymbol{\theta}}(\boldsymbol{x}_o) = \exp(\psi_{h,\boldsymbol{\theta}}(\boldsymbol{x}_o))$ where the function $\psi_{h,\boldsymbol{\theta}}(\boldsymbol{x}_o)$ is*

$$\psi_{h,\boldsymbol{\theta}}(\boldsymbol{x}_o) = \log \sum_{\boldsymbol{x}_h} \exp(\psi_{\boldsymbol{\theta},2}(\boldsymbol{x})) \tag{3}$$

and $\sum_{\boldsymbol{x}_h}$ denotes the summation with respect to the hidden variable $\boldsymbol{x}_h$.

Example 5 *Let $\boldsymbol{x}_o \in \{+1,-1\}^{d_1}$ and $\boldsymbol{x}_h \in \{+1,-1\}^{d_2}$ be the observed vector and hidden vector, respectively. The restricted Boltzmann machine is written as*

$$\begin{aligned} q_{\boldsymbol{\theta}}(\boldsymbol{x}_o) &= \sum_{\boldsymbol{x}_h} \exp\left(\boldsymbol{\theta}_o^T\boldsymbol{x}_o + \boldsymbol{\theta}_h^T\boldsymbol{x}_h + \boldsymbol{x}_h^T\boldsymbol{\theta}_{h,o}\boldsymbol{x}_o\right) \\ &= \exp\{\boldsymbol{\theta}_o^T\boldsymbol{x}_o\} \prod_{k=1}^{d_2} \left\{ e^{(\boldsymbol{\theta}_h+\boldsymbol{\theta}_{h,o}\boldsymbol{x}_o)_k} + e^{-(\boldsymbol{\theta}_h+\boldsymbol{\theta}_{h,o}\boldsymbol{x}_o)_k} \right\}, \end{aligned} \tag{4}$$

where $\boldsymbol{\theta}_o \in R^{d_1}, \boldsymbol{\theta}_h \in R^{d_2}$ are vectors of parameters, and $\boldsymbol{\theta}_{h,o} \in R^{d_2\times d_1}$ is a matrix of parameters. The index k in the above equation denotes the k-th element of the vector. Note that some parameters in the Boltzmann machine with hidden variables (3) *are restricted to* 0.

Suppose that a dataset $\mathcal{D} = \{\boldsymbol{x}_i\}_{i=1}^n$ generated from an underlying distribution $p(\boldsymbol{x})$ is observed. Let $\mathcal{Z}$ be a set of all patterns in the dataset $\mathcal{D}$. An empirical distribution $\tilde{p}(\boldsymbol{x})$ associated with the dataset $\mathcal{D}$ is defined as

$$\tilde{p}(\boldsymbol{x}) = \begin{cases} \frac{n_{\boldsymbol{x}}}{n} & \boldsymbol{x} \in \mathcal{Z}, \\ 0 & \text{otherwise}, \end{cases}$$

where $n_{\boldsymbol{x}}$ is the number of patterns $\boldsymbol{x}$ in the dataset $\mathcal{D}$. To estimate the parameter $\boldsymbol{\theta}$ of the probabilistic model $\bar{q}_{\boldsymbol{\theta}}$, the MLE defined by

$$\hat{\boldsymbol{\theta}}_{\mathrm{mle}} = \operatorname*{argmax}_{\boldsymbol{\theta}} L(\boldsymbol{\theta})$$

is frequently used, where

$$L(\boldsymbol{\theta}) = \sum_{i=1}^{n} \log \bar{q}_{\boldsymbol{\theta}}(\boldsymbol{x}_i)$$

is the log-likelihood of the parameter $\boldsymbol{\theta}$ using the normalized model $\bar{q}_{\boldsymbol{\theta}}$. The MLE is asymptotically consistent and efficient. However, the optimization of the log-likelihood function can be computationally demanding for normalized models on huge discrete sample spaces. Indeed, the gradient of $L(\boldsymbol{\theta})$ includes $\langle \tilde{p}\psi'_{\boldsymbol{\theta}} \rangle - \langle \bar{q}_{\boldsymbol{\theta}}\psi'_{\boldsymbol{\theta}} \rangle$, where $\psi'_{\boldsymbol{\theta}} = \frac{\partial \psi_{\boldsymbol{\theta}}}{\partial \boldsymbol{\theta}}$. While the first term $\langle \tilde{p}\psi'_{\boldsymbol{\theta}} \rangle$ is the empirical mean that is easily calculated, the second term $\langle \bar{q}_{\boldsymbol{\theta}}\psi'_{\boldsymbol{\theta}} \rangle$ requires 2^d times summation for $\mathcal{X} = \{+1, -1\}^d$. Therefore, the gradient-based optimization is computationally infeasible when d is large. To resolve this problem, we propose a novel estimator using ideas of a homogeneous divergence and an empirical localization in the following section.

3. Homogeneous Divergences for Statistical Inference

A divergence is an extension of the squared distance and is often used in statistical inference. The formal definition of the divergence $D(f, g)$ is a non-negative valued function on $\mathcal{M} \times \mathcal{M}$ or $\mathcal{P} \times \mathcal{P}$ such that $D(f, f) = 0$ holds for arbitrary f. Many popular divergences such as the Kullback-Leilber (KL) divergence defined on $\mathcal{P} \times \mathcal{P}$ enjoy the *coincidence axiom*, i.e., $D(f, g) = 0$ leads to $f = g$. The parameter in the statistical model $\bar{q}_{\boldsymbol{\theta}}$ is estimated by minimizing the divergence $D(\tilde{p}, \bar{q}_{\boldsymbol{\theta}})$ with respect to $\boldsymbol{\theta}$.

In statistical inference using unnormalized models, the coincidence axiom of the divergence is not suitable since the probability and the unnormalized model generally do not exactly match. Our purpose is to estimate the underlying distribution up to a constant factor using unnormalized models. Hence, a divergence that has the property of the weak coincidence axiom, i.e., $D(f, g) = 0$ if and only if $g = cf$ for some $c > 0$, is a good candidate. For a class of divergences having the weak coincidence axiom, we focus on homogeneous divergences that satisfy the equality $D(f, g) = D(f, cg)$ for any $f, g \in \mathcal{M}$ and any $c > 0$.

A representative of homogeneous divergences is the pseudo-spherical (PS) divergence (Good, 1971), or in other words, γ–divergence (Fujisawa and Eguchi, 2008), that is defined from the (reverse) Hölder inequality. For a positive constant γ and all non-negative functions f, g in $\mathcal{M}$, the Hölder inequality

$$\left\langle f^{1+\gamma} \right\rangle^{\frac{1}{1+\gamma}} \left\langle g^{1+\gamma} \right\rangle^{\frac{\gamma}{1+\gamma}} \geq \langle fg^{\gamma} \rangle \quad (\gamma > 0)$$

holds. Also for a negative constant $\gamma(\neq -1)$, the reverse Hölder inequality

$$\left\langle f^{1+\gamma} \right\rangle^{\frac{1}{1+\gamma}} \left\langle g^{1+\gamma} \right\rangle^{\frac{\gamma}{1+\gamma}} \leq \langle fg^{\gamma} \rangle \quad (\gamma < 0, \gamma \neq -1)$$

holds. The above inequalities become an equality if and only if f and g are linearly dependent. From the standard and reverse Hölder inequalities, the PS-divergence $D_\gamma(f, g)$ for $f, g \in \mathcal{M}$ is defined as

$$D_\gamma(f, g) = \mathrm{sgn}(\gamma) \left\{ \frac{1}{1+\gamma} \log \left\langle f^{1+\gamma} \right\rangle + \frac{\gamma}{1+\gamma} \log \left\langle g^{1+\gamma} \right\rangle - \log \langle fg^{\gamma} \rangle \right\} \quad (\gamma \neq 0, -1), \quad (5)$$

where the sign function $\mathrm{sgn}(\gamma)$ takes 1 for $\gamma > 0$ and -1 for $\gamma < 0$. The PS divergence is homogeneous, and the Hölder inequalities ensure the non-negativity and the weak coincidence axiom of the PS-divergence. A scaled PS-divergence converges to the extended KL-divergence defined on $\mathcal{M} \times \mathcal{M}$, as $\gamma \to 0$. Fujisawa and Eguchi (2008) used the PS-divergence with $\gamma > 0$ to obtain a robust estimator in parametric statistical inference.

The PS-divergence $D_\gamma(f, g)$ from the empirical distribution $f = \tilde{p}$ to the unnormalized model $g = q_{\boldsymbol{\theta}}$ is written as

$$D_\gamma(\tilde{p}, q_{\boldsymbol{\theta}}) = Const + \mathrm{sgn}(\gamma) \frac{\gamma}{1+\gamma} \log \sum_{\boldsymbol{x} \in \mathcal{X}} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1+\gamma} - \mathrm{sgn}(\gamma) \log \sum_{\boldsymbol{x} \in \mathcal{Z}} \frac{n_{\boldsymbol{x}}}{n} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{\gamma} \quad (6)$$

and computation of the second term is infeasible in our setup. To avoid such expensive computation, some approximation techniques have been proposed such as the MCMC. Here, we employ a new trick called "empirical localization." The empirical localization is a way to transform the model $q_{\boldsymbol{\theta}}$, and its idea is to localize the domain $\mathcal{X}$ of $q_{\boldsymbol{\theta}}$ to $\mathcal{Z}$ by considering an extension of the geometric mean with the empirical distribution $\tilde{p}$. The empirical localization of $q_{\boldsymbol{\theta}}$ with $\tilde{p}$ is defined by

$$\tilde{p}(\boldsymbol{x})^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha} = \begin{cases} \left(\frac{n_{\boldsymbol{x}}}{n}\right)^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha} & \boldsymbol{x} \in \mathcal{Z} \\ 0 & \text{otherwise,} \end{cases} \quad (7)$$

where α is a non-negative real number. The empirical localization forces the transformed function to be zero on a domain $\mathcal{X} \setminus \mathcal{Z}$ of unobserved points, satisfying $\tilde{p}(\boldsymbol{x}) = 0$. By using the localization trick, the total sum $\langle q_{\boldsymbol{\theta}}^{\gamma+1} \rangle$ is replaced with a quantity similar to the empirical mean,

$$\left\langle \tilde{p}^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle = \sum_{\boldsymbol{x} \in \mathcal{Z}} \left(\frac{n_{\boldsymbol{x}}}{n}\right)^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha}. \quad (8)$$

The above quantity is easy to compute unless the sample size is extremely large. If the sample size is large, a sub-sampling technique for obtaining an approximate of the empirical mean can be used. Note that the empirical localization (7) is not defined when the value of α is negative and the empirical distribution $\tilde{p}(\boldsymbol{x})$ is zero at some points. However, we can formally employ the trick of empirical localization (8) in such cases by ignoring a domain of unobserved points. Thus, in the following, we assume that α is a non-zero real number.

Remark 2 *The summation in* (8) *is defined on* $\mathcal{Z}$ *and is then computable even when* $\alpha < 0$. *Also the summation includes only* $\mathcal{Z}(\leq n)$ *terms, and its computational cost is* $\mathcal{O}(n)$.

In addition, for convenience of notations, we define an e-mixture model $r_{\alpha,\boldsymbol{\theta}}$ ($\tilde{r}_{\alpha,\boldsymbol{\theta}}$) of the unnormalized model (2) and p ($\tilde{p}$) with ratio $\alpha \in \mathbb{R}$, as follows (Amari and Nagaoka, 2000).

$$r_{\alpha,\boldsymbol{\theta}}(\boldsymbol{x}) = \frac{p(\boldsymbol{x})^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha}}{\left\langle p^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle}, \quad \tilde{r}_{\alpha,\boldsymbol{\theta}}(\boldsymbol{x}) = \frac{\tilde{p}(\boldsymbol{x})^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha}}{\left\langle \tilde{p}^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle}.$$

Note that $\tilde{r}_{\alpha,\boldsymbol{\theta}}$ is a normalized version of the empirical localization (7). If p or q takes zero, the parameter α is properly restricted.

Remark 3 *We observe that* $r_{0,\boldsymbol{\theta}}(\boldsymbol{x}) = \tilde{r}_{0,\boldsymbol{\theta}}(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}}(\boldsymbol{x})$, $r_{1,\boldsymbol{\theta}}(\boldsymbol{x}) = p(\boldsymbol{x})$, $\tilde{r}_{1,\boldsymbol{\theta}}(\boldsymbol{x}) = \tilde{p}(\boldsymbol{x})$. *Also, if* $p(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$, $r_{\alpha,\boldsymbol{\theta}_0}(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$ *holds for an arbitrary* α.

To use the trick of empirical localization, we define the *localized PS-divergence* $S_{\alpha,\alpha',\gamma}(p,q)$ for the probability distribution $p \in \mathcal{P}$ and the unnormalized model $q \in \mathcal{M}$ by considering the homogeneous divergence between $f = (p^\alpha q^{1-\alpha})^{\frac{1}{1+\gamma}}$ and $g = (p^{\alpha'} q^{1-\alpha'})^{\frac{1}{1+\gamma}}$ where α, α' are two distinct real numbers:

$$\begin{aligned} S_{\alpha,\alpha',\gamma}(p,q) &= D_\gamma((p^\alpha q^{1-\alpha})^{1/(1+\gamma)}, (p^{\alpha'} q^{1-\alpha'})^{1/(1+\gamma)}) \\ &= \mathrm{sgn}(\gamma) \left\{ \frac{1}{1+\gamma} \log \left\langle p^\alpha q^{1-\alpha} \right\rangle + \frac{\gamma}{1+\gamma} \log \langle p^{\alpha'} q^{1-\alpha'} \rangle - \log \left\langle p^{\bar{\alpha}} q^{1-\bar{\alpha}} \right\rangle \right\}, \end{aligned} \tag{9}$$

where $\bar{\alpha} = (\alpha + \gamma\alpha')/(1+\gamma)$. Note that the localized PS-divergence vanishes if and only if $p^\alpha q^{1-\alpha} \propto p^{\alpha'} q^{1-\alpha'}$, i.e., $q \propto p$. Substituting the empirical distribution $\tilde{p}$ into p, the total sum over $\mathcal{X}$ is replaced with a variant of the empirical mean (8) on $\mathcal{Z}$.

Since $S_{\alpha,\alpha',\gamma}(p,q) = S_{\alpha',\alpha,1/\gamma}(p,q)$ holds, we can assume $\alpha > \alpha'$. Also we observe that for $\gamma < -1$

$$S_{\alpha,\alpha',\gamma}(p,q) = \frac{\gamma}{1+\gamma} S_{\alpha, \frac{\alpha+\gamma\alpha'}{1+\gamma}, -1-\gamma}(p,q),$$

and for $-1 < \gamma < 0$

$$S_{\alpha,\alpha',\gamma}(p,q) = \frac{1}{1+\gamma} S_{\alpha', \frac{\alpha+\gamma\alpha'}{1+\gamma}, -\gamma}(p,q),$$

respectively. Hence, we can assume $\gamma > 0$ without loss of generality. In summary, the conditions of the real parameters α, α', γ in $S_{\alpha,\alpha',\gamma}$ are given by

$$0 < \gamma, \quad \alpha > \alpha', \ \alpha \neq 0, \ \alpha' \neq 0, \ \alpha + \gamma\alpha' \neq 0,$$

where the last condition implies $\bar{\alpha} \neq 0$.

Let us consider another aspect of the computational issue of the localized PS-divergence (9). For the probability distribution p and the unnormalized exponential model $q_{\boldsymbol{\theta}}$, we show that the localized PS-divergence $S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}})$ is convex in $\boldsymbol{\theta}$ when the parameters α, α' and γ are properly chosen.

Theorem 4 *Let* $p \in \mathcal{P}$ *be any probability distribution and* $q_{\boldsymbol{\theta}}$ *be the unnormalized exponential model* $q_{\boldsymbol{\theta}}(\boldsymbol{x}) = \exp\left(\boldsymbol{\theta}^T \boldsymbol{\phi}(\boldsymbol{x})\right)$, *where* $\boldsymbol{\phi}(\boldsymbol{x})$ *is a vector-valued function corresponding to the sufficient statistic in the (normalized) exponential model* $\bar{q}_{\boldsymbol{\theta}}$. *When* α, α' *and* γ *satisfy* $\bar{\alpha} = (\alpha + \gamma\alpha')/(1+\gamma) = 1$, *the localized PS-divergence* $S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}})$ *is convex in* $\boldsymbol{\theta}$. *Otherwise, there exist* p *and* $\boldsymbol{\phi}(\boldsymbol{x})$ *such that* $S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}})$ *is not convex in* $\boldsymbol{\theta}$.

The proof of Theorem 4 is found in Appendix A.

When the value of α is negative and the probability p vanishes at some points, the total sum $\left\langle p^\alpha q^{1-\alpha} \right\rangle$ is not formally defined. We can avoid such a situation by setting both α and $\alpha\prime$ to positive values and observe the following proposition indicating that the result in Theorem 4 holds even if both α and α' are assumed to be positive.

Proposition 5 *Even though* α *and* α' *in Theorem 4 are both restricted to positive numbers, we need* $\bar{\alpha} = 1$ *to guarantee the convexity of the localized PS-divergence* $S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}})$ *in* $\boldsymbol{\theta}$ *for any* p *and any* $\boldsymbol{\phi}(\boldsymbol{x})$.

The proof is found in Appendix B.

The localized PS-divergence with $\bar{\alpha} = 1$ characterized by Theorem 4 is denoted as $S_{\alpha,\alpha'}(p,q)$ where

$$S_{\alpha,\alpha'}(p,q) = \frac{1-\alpha'}{\alpha-\alpha'} \log \left\langle p^\alpha q^{1-\alpha} \right\rangle + \frac{\alpha-1}{\alpha-\alpha'} \log \langle p^{\alpha'} q^{1-\alpha'} \rangle. \tag{10}$$

for $\alpha > 1 > \alpha' \neq 0$. The parameter α' can be negative if the probability function p does not take zero on $\mathcal{X}$. Clearly, $S_{\alpha,\alpha'}(p,q)$ satisfies the homogeneity and the weak coincidence axiom as well as $S_{\alpha,\alpha',\gamma}(p,q)$.

The generalized Hölder's inequality admits an extension of the localized PS-divergence. For $f_1, \ldots, f_L \in \mathcal{M}$, the generalized Hölder's inequality

$$\left\langle \prod_{\ell=1}^L f_\ell^{\delta_\ell} \right\rangle \leq \prod_{\ell=1}^L \langle f_\ell \rangle^{\delta_\ell} \tag{11}$$

holds, where $\delta_1, \ldots, \delta_L$ satisfy $0 < \delta_\ell$ and $\sum_\ell \delta_\ell = 1$. The inequality becomes an equality if and only if all $f_1, \ldots, f_L$ are proportional to a non-negative function $g \in \mathcal{M}$. For the sake of completeness, the proof of the generalized Hölder's inequality is shown in Appendix C.

Substituting $p^{\alpha_\ell} q^{1-\alpha_\ell}$ into f_ℓ of the generalized Hölder's inequality, we obtain an extension of the localized PS-divergence defined as

$$S_{\boldsymbol{\alpha},\boldsymbol{\delta}}(p,q) = \sum_{\ell=1}^L \delta_\ell \log \left\langle p^{\alpha_\ell} q^{1-\alpha_\ell} \right\rangle - \log \left\langle p^{\bar{\alpha}} q^{1-\bar{\alpha}} \right\rangle \tag{12}$$

with $\bar{\alpha} = \sum_\ell \alpha_\ell \delta_\ell$. Theorem 4 can be extended for $S_{\boldsymbol{\alpha},\boldsymbol{\delta}}(p,q)$. We omit the proof since it is straightforward.

4. Estimation with Localized Pseudo-Spherical Divergences

Given the empirical distribution $\tilde{p}$ and the unnormalized model $q_{\boldsymbol{\theta}}$, we define a novel estimator $\hat{\boldsymbol{\theta}}$ with the localized PS-divergence $S_{\alpha,\alpha',\gamma}$ or $S_{\alpha,\alpha'}$:

$$\begin{aligned} \hat{\boldsymbol{\theta}} &= \operatorname*{argmin}_{\boldsymbol{\theta}} S_{\alpha,\alpha',\gamma}(\tilde{p}, q_{\boldsymbol{\theta}}) \\ &= \operatorname*{argmin}_{\boldsymbol{\theta}} \Big\{ \frac{1}{1+\gamma} \log \sum_{\boldsymbol{x} \in \mathcal{Z}} \left(\frac{n_{\boldsymbol{x}}}{n} \right)^\alpha q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha} + \frac{\gamma}{1+\gamma} \log \sum_{\boldsymbol{x} \in \mathcal{Z}} \left(\frac{n_{\boldsymbol{x}}}{n} \right)^{\alpha'} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha'} \\ &\qquad - \log \sum_{\boldsymbol{x} \in \mathcal{Z}} \left(\frac{n_{\boldsymbol{x}}}{n} \right)^{\bar{\alpha}} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\bar{\alpha}} \Big\}. \end{aligned} \tag{13}$$

Though the localized PS-divergence plugged-in the empirical distribution is not well-defined when $\alpha' < 0$ and $\tilde{p}(\boldsymbol{x}) = 0$, we can formally define the estimator by restricting the domain $\mathcal{X}$ to the observed set of examples $\mathcal{Z}$, even for such the case, as shown in Remark 2.

Proposition 6 *For the unnormalized model* (2), *the estimator* (13) *is Fisher consistent.*

Proof We observe

$$\frac{\partial}{\partial \boldsymbol{\theta}} S_{\alpha,\alpha',\gamma}(\bar{q}_{\boldsymbol{\theta}_0}, q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} = \left(\bar{\alpha} - \frac{\alpha+\gamma\alpha'}{1+\gamma}\right)\left\langle \bar{q}_{\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle = 0$$

implying the Fisher consistency of $\hat{\boldsymbol{\theta}}$. ■

Example 6 *For the Bernoulli distribution on $\mathcal{X}=\{+1,-1\}$, the estimator* (13) *is equivalent to the MLE, i.e., $\frac{1}{2}\log\frac{n_{+1}}{n_{-1}}$.*

Theorem 7 *Let $q_{\boldsymbol{\theta}}(\boldsymbol{x})$ be the unnormalized model* (2)*, and $\boldsymbol{\theta}_0$ be the true parameter of the underlying distribution $p(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$. Then, the asymptotic distribution of the estimator* (13) *is the normal distribution given as*

$$\sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \sim \mathcal{N}(\mathbf{0}, I(\boldsymbol{\theta}_0)^{-1}),$$

where $I(\boldsymbol{\theta}_0)$ is the Fisher information matrix of the normalized model $\bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$.

The proof is shown in Appendix D. The estimator defined from the general localized PS-divergence $S_{\boldsymbol{\alpha},\boldsymbol{\delta}}(\tilde{p}, q_{\boldsymbol{\theta}})$ defined by (12) has the same asymptotic property.

Remark 8 *The asymptotic distribution of* (13) *is equal to that of the MLE, and its variance does not depend on α, α', γ.*

Remark 9 *As shown in Remark 1, the normalized model* (1) *is a special case of the unnormalized model* (2) *and then Theorem 7 holds for the normalized model.*

5. Characterization of $S_{\alpha,\alpha'}$

Let us consider theoretical properties of the localized PS-divergence. In the following subsections, we discuss an influence of selection of α, α' and a characterization of $S_{\alpha,\alpha'}$ defined by (10).

5.1 Influence of Selection of α, α'

We investigate influence of selection of α, α' for the localized PS-divergence $S_{\alpha,\alpha'}$ with a view of the estimating equation. The estimator $\hat{\boldsymbol{\theta}}$ derived from $S_{\alpha,\alpha'}$ satisfies

$$\frac{\partial S_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}})}{\partial \boldsymbol{\theta}}\Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} \propto \left\langle \tilde{r}_{\alpha',\hat{\boldsymbol{\theta}}}\psi'_{\hat{\boldsymbol{\theta}}}\right\rangle - \left\langle \tilde{r}_{\alpha,\hat{\boldsymbol{\theta}}}\psi'_{\hat{\boldsymbol{\theta}}}\right\rangle = 0. \tag{14}$$

which is a moment matching with respect to two distributions $\tilde{r}_{\alpha,\boldsymbol{\theta}}$ and $\tilde{r}_{\alpha',\boldsymbol{\theta}}$ $(\alpha, \alpha' \neq 0, 1)$. On the other hand, the estimating equation of the MLE is written as

$$\frac{\partial L(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}}\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_{mle}} \propto \left\langle \tilde{p}\psi'_{\boldsymbol{\theta}_{mle}}\right\rangle - \left\langle \bar{q}_{\boldsymbol{\theta}_{mle}}\psi_{\boldsymbol{\theta}_{mle}}\right\rangle = \left\langle \tilde{r}_{1,\boldsymbol{\theta}_{mle}}\psi'_{\boldsymbol{\theta}_{mle}}\right\rangle - \left\langle \tilde{r}_{0,\boldsymbol{\theta}_{mle}}\psi'_{\boldsymbol{\theta}_{mle}}\right\rangle = 0, \tag{15}$$

which is a moment matching with respect to the empirical distribution $\tilde{p} = \tilde{r}_{1,\boldsymbol{\theta}_{mle}}$ and the normalized model $\bar{q}_{\boldsymbol{\theta}} = \tilde{r}_{0,\boldsymbol{\theta}_{mle}}$. While the localized PS-divergence $S_{\alpha,\alpha'}$ is not defined for $(\alpha, \alpha') = (0, 1)$, comparison of (14) with (15) implies that behavior the estimator $\hat{\boldsymbol{\theta}}$ is expected to be similar to that of the MLE in the limit of $\alpha \to 1$ and $\alpha' \to 0$.

5.2 Relationship with α-Divergence

The α-divergence between two positive measures $f, g \in \mathcal{M}$ is defined as

$$D_\alpha(f, g) = \frac{1}{\alpha(1-\alpha)}\left\langle \alpha f + (1-\alpha)g - f^\alpha g^{1-\alpha}\right\rangle.$$

Note that $D_\alpha(f, g) \geq 0$ and 0 if and only if $f = g$, and the α-divergence reduces to $\mathrm{KL}(f, g)$ and $\mathrm{KL}(g, f)$ in the limit of $\alpha \to 1$ and 0, respectively. See Amari and Nagaoka (2000) for details of the α-divergences.

Remark 10 *The estimator defined by minimizing α-divergence $D_\alpha(\tilde{p}, \bar{q}_{\boldsymbol{\theta}})$ between the empirical distribution $\tilde{p}$ and normalized model $\bar{q}$ satisfies*

$$\frac{\partial D_\alpha(\tilde{p}, \bar{q}_{\boldsymbol{\theta}})}{\partial \boldsymbol{\theta}} \propto \left\langle \tilde{p}^\alpha q_{\boldsymbol{\theta}}^{1-\alpha}\left(\psi'_{\boldsymbol{\theta}} - \left\langle \bar{q}_{\boldsymbol{\theta}}\psi'_{\boldsymbol{\theta}}\right\rangle\right)\right\rangle = 0,$$

which requires the computation of the normalizing constant. The same holds when unnormalized models are used. Hence, naive application of the α-divergences does not resolve the computational issue.

Here, we assume that $\alpha, \alpha' \neq 0, 1$ and consider a trick to cancel out the term $\langle g\rangle$ by mixing two α-divergences as follows.

$$\begin{aligned} D_{\alpha,\alpha'}(f, g) =& D_\alpha(f, g) + \left(\frac{-\alpha'}{\alpha}\right) D_{\alpha'}(f, g) \\ =& \left\langle \left(\frac{1}{1-\alpha} - \frac{\alpha'}{\alpha(1-\alpha')}\right) f - \frac{1}{\alpha(1-\alpha)} f^\alpha g^{1-\alpha} + \frac{1}{\alpha(1-\alpha')} f^{\alpha'} g^{1-\alpha'}\right\rangle. \end{aligned}$$

Note that $D_{\alpha,\alpha'}(f, g) \geq 0$ is divergence when $\alpha\alpha' < 0$ holds, i.e., $D_{\alpha,\alpha'}(f, g) \geq 0$ and $D_{\alpha,\alpha'}(f, g) = 0$ if and only if $f = g$. Without loss of generality, we assume that $\alpha' < 0 < \alpha \neq 1$ holds for the parameter of $D_{\alpha,\alpha'}$.

Firstly, let us consider the estimator obtained by the minimizer of $D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}})$,

$$\begin{aligned} \hat{\boldsymbol{\theta}} &= \operatorname*{argmin}_{\boldsymbol{\theta}} D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}) \\ &= \operatorname*{argmin}_{\boldsymbol{\theta}} \sum_{\boldsymbol{x}\in\mathcal{Z}} \frac{1}{\alpha}\left\{\frac{1}{1-\alpha'}\left(\frac{n_{\boldsymbol{x}}}{n}\right)^{\alpha'} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha'} - \frac{1}{1-\alpha}\left(\frac{n_{\boldsymbol{x}}}{n}\right)^{\alpha} q_{\boldsymbol{\theta}}(\boldsymbol{x})^{1-\alpha}\right\}. \end{aligned} \tag{16}$$

Note that the summation in (16) includes only $\mathcal{Z}(\leq n)$ terms. Let $\bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$ be the underlying distribution and $q_{\boldsymbol{\theta}}(\boldsymbol{x})$ be the unnormalized model (2). Then the above estimator is not Fisher consistent, i.e.,

$$\frac{\partial D_{\alpha,\alpha'}(\bar{q}_{\boldsymbol{\theta}_0}, q_{\boldsymbol{\theta}})}{\partial \boldsymbol{\theta}}\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} \propto \left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha'} q_{\boldsymbol{\theta}_0}^{1-\alpha'}\psi'_{\boldsymbol{\theta}_0} - \bar{q}_{\boldsymbol{\theta}_0}^{\alpha} q_{\boldsymbol{\theta}_0}^{1-\alpha}\psi'_{\boldsymbol{\theta}_0}\right\rangle = \left(\langle q_{\boldsymbol{\theta}_0}\rangle^{-\alpha'} - \langle q_{\boldsymbol{\theta}_0}\rangle^{-\alpha}\right)\left\langle q_{\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle \neq 0.$$

Hence, the estimator associated with $D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}})$ does not have suitable properties such as (asymptotic) unbiasedness and consistency, while computational cost is drastically reduced. Intuitively, this is because the divergence $D_{\alpha,\alpha'}$ satisfies the coincidence axiom, i.e., $D_{\alpha,\alpha'}(f, g) = 0$ leads to $f = g$.

The statistical consistency is recovered by employing a homogeneous divergence derived from $D_{\alpha,\alpha'}$. Let us consider the estimator defined by

$$(\hat{\boldsymbol{\theta}}, \hat{z}) = \operatorname*{argmin}_{\boldsymbol{\theta}, z>0} D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}/z), \tag{17}$$

where $\hat{z}$ is an estimator of the normalization term $Z_{\boldsymbol{\theta}} = \langle q_{\boldsymbol{\theta}} \rangle$.

Proposition 11 *Let $q_{\boldsymbol{\theta}}(\boldsymbol{x})$ be the unnormalized model* (2)*. Then, the minimum solution of*

$$\min_{\boldsymbol{\theta}} \min_{z>0} D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}/z)$$

with respect to $\boldsymbol{\theta}$ is equal to that of

$$\operatorname{sgn}(\alpha-1) S_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}),$$

where $S_{\alpha,\alpha'}$ is formally defined for (α, α') such that $\alpha' < 0 < \alpha \neq 1$.

Proof For a given $\boldsymbol{\theta}$, we observe that

$$\hat{z} = \operatorname*{argmin}_{z>0} D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}/z) = \left(\frac{\left\langle \tilde{p}^{\alpha'} q_{\boldsymbol{\theta}}^{1-\alpha'} \right\rangle}{\left\langle \tilde{p}^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle} \right)^{\frac{1}{\alpha-\alpha'}}. \tag{18}$$

Note that computation of (18) requires only sample order $\mathcal{O}(n)$ calculation. Then, we have

$$\begin{aligned} \min_{z>0} D_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}/z) &= \frac{\alpha-\alpha'}{\alpha(1-\alpha')(\alpha-1)} \left(\left\langle \tilde{p}^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle^{\frac{1-\alpha'}{\alpha-\alpha'}} \left\langle \tilde{p}^{\alpha'} q_{\boldsymbol{\theta}}^{1-\alpha'} \right\rangle^{\frac{\alpha-1}{\alpha-\alpha'}} - 1 \right) \\ &= \frac{\alpha-\alpha'}{\alpha(1-\alpha')(\alpha-1)} \left(e^{S_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}})} - 1 \right). \end{aligned} \tag{19}$$

for $\alpha' < 0 < \alpha \neq 1$. ■

If $\alpha' < 0$ and $1 < \alpha$ hold, the estimator using a homogeneous variant of $D_{\alpha,\alpha'}$ is equivalent to the estimator associated with the localized PS-divergence $S_{\alpha,\alpha'}$. For α and α' such that $\alpha' < 0 < \alpha < 1$, one can verify that $\operatorname{sgn}(\alpha-1) S_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}})$ is not convex in the parameter $\boldsymbol{\theta}$ of the unnormalized exponential model $q_{\boldsymbol{\theta}}(\boldsymbol{x}) = \exp\{\boldsymbol{\theta}^T \boldsymbol{\phi}(\boldsymbol{x})\}$, though $\operatorname{sgn}(\alpha-1) S_{\alpha,\alpha'}$ is still a homogeneous divergence. In any case, the mixture of α-divergences is expressed by $S_{\alpha,\alpha'}$.

From a viewpoint of the information geometry (Amari and Nagaoka, 2000), α-divergences induce the Fisher metric that is an information geometrical structure on statistical manifolds. In other word, the Hessian matrix of the α-divergences is nothing but the Fisher information matrix. This implies that the estimation based on the (mixture of) α-divergences is Fisher efficient and is an intuitive explanation of Theorem 7. The localized PS divergences, $S_{\alpha,\alpha',\gamma}$ and $S_{\alpha,\alpha'}$, and its extension $S_{\boldsymbol{\alpha},\boldsymbol{\delta}}$ in (12) can be interpreted as an extension of the α-divergences while keeping the Fisher efficiency.

We can estimate the normalization constant $Z_{\hat{\boldsymbol{\theta}}}$ by the optimal solution $\hat{z}$ of (18).

Theorem 12 *The asymptotic distribution of the estimator* (17) *is given as a degenerated multivariate normal distribution,*

$$\sqrt{n}\,(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0,\, \log \hat{z} - \log Z_{\boldsymbol{\theta}_0}) \;\sim\; N(\mathbf{0}, V),$$

where V is written as

$$V = \begin{pmatrix} I_{\boldsymbol{\theta}_0}^{-1} & I_{\boldsymbol{\theta}_0}^{-1} (\log Z_{\boldsymbol{\theta}_0})' \\ (\log Z_{\boldsymbol{\theta}_0})'^T I_{\boldsymbol{\theta}_0}^{-1} & (\log Z_{\boldsymbol{\theta}_0})'^T I_{\boldsymbol{\theta}_0}^{-1} (\log Z_{\boldsymbol{\theta}_0})' \end{pmatrix}.$$

Proof is shown in Appendix E.

6. Experiments

We especially focus on a setting of $\bar{\alpha} = 1$, i.e., convexity of the risk function with the unnormalized model $\exp(\boldsymbol{\theta}^T \boldsymbol{\phi}(\boldsymbol{x}))$ holds (Theorem 4), and examined the performance of the proposed estimator.

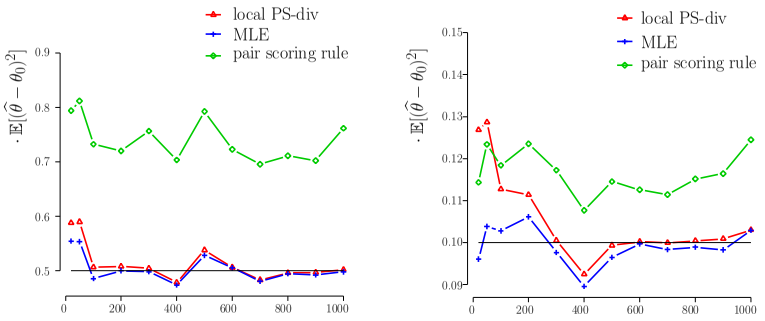
6.1 Fisher Efficiency

We investigate the Fisher efficiency of the estimator using the localized PS-divergence. In numerical experiments, training samples were generated from the Poisson distribution having the probability function

$$p_\theta(x) = \frac{e^{x\theta - e^\theta}}{x!}, \quad \theta \in \mathbb{R}$$

for $x = 0, 1, 2, \ldots$, where θ is the natural parameter. The usual parameter λ of the Poisson distribution is written as $\lambda = e^\theta$ that is equal to the expectation of x. Given the i.i.d. data $x_1, \ldots, x_n$, the MLE the parameter θ is given as $\log \bar{x}$ using the empirical mean $\bar{x} = \frac{1}{n}\sum_{i=1}^n x_i$.

We used the unnormalized model defined as



$$q_\theta(x) = \frac{e^{x\theta}}{x!}.$$

Theorem 4 ensures that the localized PS-divergence with $\bar{\alpha} = 1$ from the empirical distribution $\tilde{p}$ to the above unnormalized model, i.e., $S_{\alpha,\alpha'}(\tilde{p}, q_\theta)$, is convex in θ. In numerical experiments, the parameters of $S_{\alpha,\alpha'}$ was set to $\alpha = 1.1, \alpha' = 0.1$. In addition, the estimator using a pair scoring rule (Dawid et al., 2012),

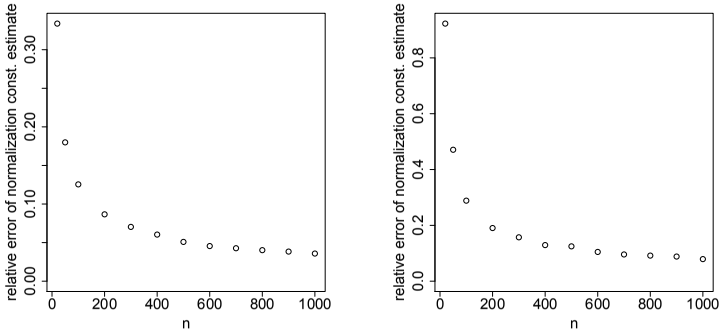
$$\hat{\theta}_\kappa = \frac{\sum_{x\geq 0} \tilde{p}(x+1)(x+1)^{1+\kappa}}{\sum_{x\geq 0} \tilde{p}(x)(x+1)^\kappa},$$

was compared to the MLE and proposed method. Note that the above estimator with $\kappa = 0$ is nothing but the MLE. The estimator with $\kappa = 1$ was used.

Numerical results are presented in Figure 1. The horizontal axis is the number of sample size n and the vertical axis is the averaged mean square errors of the estimated parameter from the true parameter θ_0 multiplied by n, i.e., $n \cdot \mathbb{E}[(\hat{\theta} - \theta_0)^2]$. Numerically, the

$\theta_0 = \log(2)$ $\theta_0 = \log(10)$

Figure 1: Mean square errors of the estimator using localized PS-divergence, MLE, and pair scoring rule are shown. Horizontal axis is the sample size and vertical axis is mean square errors multiplied by the sample size. Left panel: $\theta_0 = \log(2)$. Right panel: $\theta_0 = \log(10)$.



averaged mean square errors over 1000 repetitions were computed. The horizontal solid line denotes the Cramér-Rao bound. All the estimators are consistent, since the averaged mean square errors seems to be of the order $O(1/n)$. Numerically, we showed that the localized PS-divergence produces a Fisher efficient estimator, while the pair scoring rule does not achieve the Cramér-Rao bound.

When the variance of the data, i.e., e^{θ_0}, was large, the MSE of the proposed estimator for the small sample size became large. This result indicates that the regularization will be needed when a large-scale unnormalized model is used.

In addition to the parameter estimation, the normalization constant, $Z_\theta = e^{e^\theta}$, was also estimated using the equation (18). The results are presented in Fig. 2, which shows the averaged relative error of the estimator of the normalization constant, $|\hat{z} - Z_{\theta_0}|/Z_{\theta_0}$, over 1000 repetitions. Numerically, the convergence speed of the estimator (18) was approximately of the order $O(1/\sqrt{n})$.

6.2 Fully Visible Boltzmann Machine

In this subsection, we compared the proposed estimator with parameter settings $(\alpha, \alpha') = (1.01, 0.01), (1.01, -0.01), (2, -1)$, with the MLE and the ratio matching method (Hyvärinen, 2007). Note that the ratio matching method also does not require calculation of the normalization constant. In this experiment, we do not compare the proposed estimator with the pseudo-likelihood method and the contrastive divergence which also do not require the calculation of the normalization constant, because in (Hyvärinen, 2007), the ratio matching method has been numerically compared with the pseudo-likelihood method and the con-

$\theta_0 = \log(2)$ $\theta_0 = \log(10)$

Figure 2: Averaged relative errors of the estimator (18) for the normalization constant are shown. Horizontal axis is the sample size. Left panel: $\theta_0 = \log(2)$. Right panel: $\theta_0 = \log(10)$.

trastive divergence using the fully visible Boltzmann machine, and its result showed that all methods have almost equal performance. In addition, some theoretical properties of the pseudo-likelihood (and its extension, the composite likelihood) have been investigated in (Mardia et al., 2009; Kanamori, 2016), showing that the pseudo-likelihood is not Fisher efficient in general.

All methods were optimized with the *optim* function in R language (R Core Team, 2015). The dimension d of input was set to 10 and the synthetic dataset was randomly generated from the second order Boltzmann machine (Example 3) with a parameter $\boldsymbol{\theta}^* \sim \mathcal{N}(\mathbf{0}, I/d)$. We repeated comparison 50 times and observed averaged performance. Figure 3 (a) shows median of the root mean square errors (RMSEs) between $\boldsymbol{\theta}^*$ and $\hat{\boldsymbol{\theta}}$ of each method over 50 trials, against the number n of examples. We observe that the proposed estimator is comparable with the MLE as predicted by the Theorem 7, and the ratio matching is also comparable to the MLE under the setting. Figure 3 (b) shows a number of observed patterns in a dataset consists of n examples. Figure 3 (c) shows median of computational time of each method against n. The computational time of the MLE does not vary against n because the computational cost is dominated by the calculation of the normalization constant. Both the proposed estimator and the ratio matching method are significantly faster than the MLE.

We investigated performance of methods under an another situation, in which the true parameter distributes as $\boldsymbol{\theta}^* \sim \mathcal{N}(\mathbf{0}, I)$. Figure 4 (a) shows median of the root mean square errors (RMSEs) between $\boldsymbol{\theta}^*$ and $\hat{\boldsymbol{\theta}}$ of each method over 50 trials, against the number n of examples. We observe that the proposed estimator works well, but the MLE outperforms the proposed method contrary to the prediction of Theorem 7. This is because observed

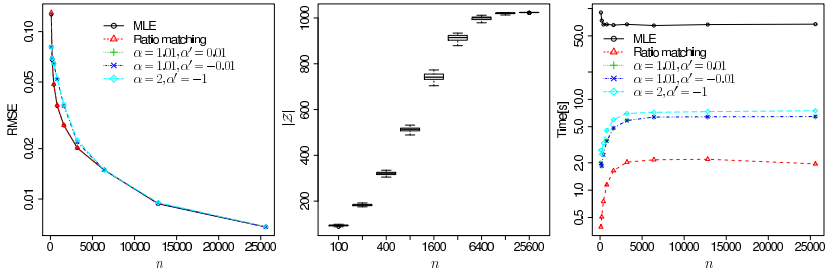


Figure 3: Results for datasets generated with a parameter $\boldsymbol{\theta}^* \sim \mathcal{N}(\mathbf{0}, I/d)$. (a) Median of RMSEs of each method against n, in log scale. (b) Box-whisker plot of number $|\mathcal{Z}|$ of unique patterns in the dataset $\mathcal{D}$ against n. (c) Median of computational time of each method against n, in log scale.

patterns were only a small portion of all possible patterns, as shown in Figure 4 (b). Even in such a case, the MLE can take all possible patterns ($2^{10} = 1024$) into account through the normalization term $Z_{\boldsymbol{\theta}}$ because the Taylor expansion of $\log Z_{\boldsymbol{\theta}}$ around $\boldsymbol{\theta} = \mathbf{0}$ which is approximated as

$$\log Z_{\boldsymbol{\theta}} \simeq d \log 2 + \frac{1}{2}||\boldsymbol{\theta}||^2$$

term behaves like a regularizer. On the other hand, the proposed method genuinely uses only the observed examples, and focuses on the restricted domain $\mathcal{Z}$ rather than the original domain $\mathcal{X}$, in which the asymptotic analysis would not be relevant in this case. Figure 4 (c) shows median of computational time of each method against n. Both the proposed estimator and the ratio matching method are significantly faster than the MLE. While the ratio matching method is faster than the proposed estimator, the RMSE of the proposed estimator is less than that of the ratio matching.

To overcome the degrade of performance of the proposed estimator caused by lack of example patterns, we consider a regularized version of the proposed estimator as,

$$\underset{\boldsymbol{\theta}}{\operatorname{argmin}} \left\{ S_{\alpha,\alpha'}(\tilde{p}, q_{\boldsymbol{\theta}}) + \frac{\lambda}{2n}||\boldsymbol{\theta}||^2 \right\}. \tag{20}$$

Note that we can employ the l_1 regularizer to obtain a sparse estimator, rather than the l_2 regularizer. Ravikumar et al. (2010) theoretically investigated conditions for correctly selecting edges of the Boltzmann machine using the l_1-regularized logistic regression.

We investigated performance of the regularized estimator with the same dataset ($\boldsymbol{\theta}^* \sim \mathcal{N}(0, I)$). Figure 5 shows median of RMSEs and computational time of the MLE, the ratio matching, and the regularized estimator ($\alpha = 1.01, \alpha' = 0.01, \lambda = 0, 10^{-2}, 10^{-4}$). The Figure shows that performance of the proposed estimator is improved by the regularization term $||\boldsymbol{\theta}||^2$, which can be interpreted as an approximation of the normalization constant $\log Z_{\boldsymbol{\theta}}$. Note that the computational time of the regularized estimator is drastically reduced

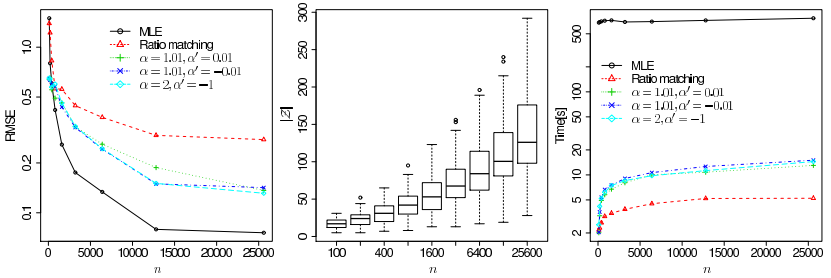

Figure 4: Results for datasets generated with a parameter $\boldsymbol{\theta}^* \sim \mathcal{N}(\mathbf{0}, I)$. (a) Median of RMSEs of each method against n, in log scale. (b) Box-whisker plot of number $|\mathcal{Z}|$ of unique patterns in the dataset $\mathcal{D}$ against n. (c) Median of computational time of each method against n, in log scale.

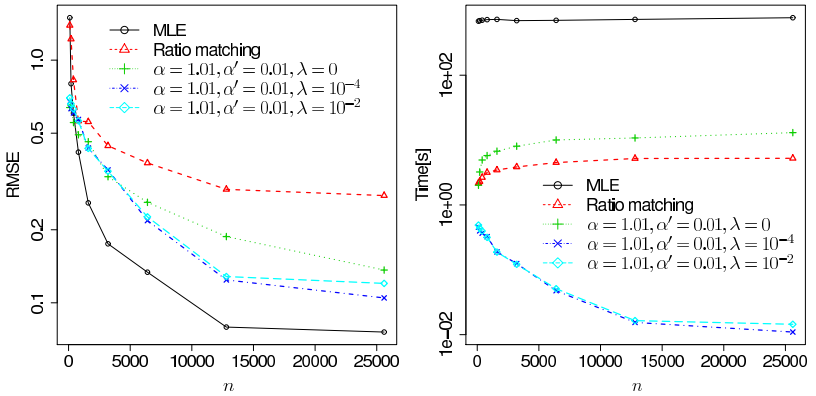

Figure 5: (a) Median of RMSE of the MLE, the ratio matching and the regularized estimator with $\alpha = 1.01, \alpha' = 0.01$, and $\lambda = 0, 10^{-2}, 10^{-4}$ against n, in log scale. (b) Median of computational time of each method against n, in log scale.

compared with that of estimator without regularization. This is because the cost function (20) becomes similar to a quadratic function and the condition number associated with the cost function is improved by the regularization, which influences required number of steps of the quasi-Newton method.

Also we investigated performance of the estimator (18) for the normalization constant $Z_{\boldsymbol{\theta}}$ and results for above two situations are shown in Figure 6. In the Figure 6, the averaged relative errors $|\hat{z} - Z_{\boldsymbol{\theta}_0}|/Z_{\boldsymbol{\theta}_0}$ of the proposed estimator ($(\alpha, \alpha') = (1.01, 0.01), (1.01, -0.01), (2, -1)$) are shown. We observe that the proposed estimator appropriately works.

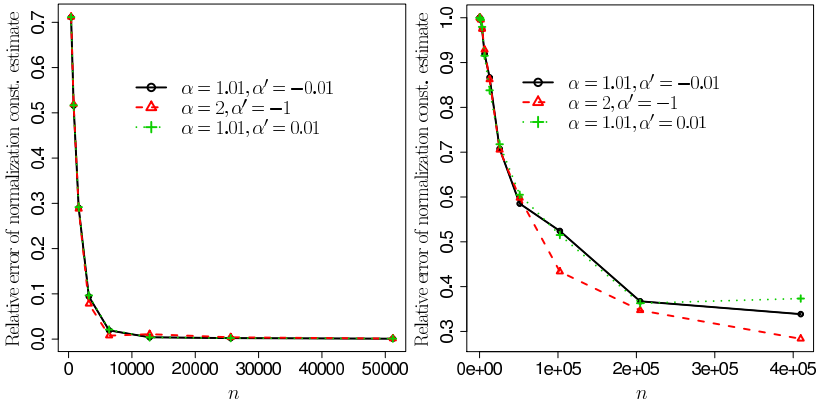

Figure 6: Median of relative errors of normalization constant estimates for two experiment scenarios: (a) $\boldsymbol{\theta}^* \sim \mathcal{N}(0, I/d)$. (b) $\boldsymbol{\theta}^* \sim \mathcal{N}(0, I)$.

6.3 Sample Complexity

We numerically investigated the sample complexity of the proposed estimator ($\alpha_1 = 1.01, \alpha' = 0.01$, without the regularization term), i.e., a number $N(\epsilon, \delta, d)$ of examples to attain

$$\Pr(\mathrm{KL}(\bar{q}_{\boldsymbol{\theta}_0}, \bar{q}_{\hat{\boldsymbol{\theta}}}) \geq \epsilon) < \delta$$

where ϵ and δ are arbitrary positive constants. For each dimension $d = 2, 3, \ldots, 21$, we generated a dataset containing $n = 50 \times 2^k (k = 1, \ldots, 9)$ examples from the fully visible Boltzmann machine and calculated the KL divergences $\mathrm{KL}(\bar{q}_{\boldsymbol{\theta}_0}, \bar{q}_{\hat{\boldsymbol{\theta}}})$. For two kinds of parameter settings, i.e., $\boldsymbol{\theta}_0 \sim \mathcal{N}(0, I/d)$ and $\boldsymbol{\theta}_0 \sim \mathcal{N}(0, I)$, we repeated these procedures 50 times and observed 50 values of KL divergence. Each panel in Figure 7 shows median of values of the KL divergence ($\delta = 0.5$) for each setting of the parameter, respectively. Both panels show that the proposed estimator requires approximately $2 \sim 3$ times as many examples examples against an increase of the dimensionality d at the same level ϵ of estimation error $\mathrm{KL}(\bar{q}_{\boldsymbol{\theta}_0}, \bar{q}_{\hat{\boldsymbol{\theta}}})$.

6.4 Boltzmann Machine with Hidden Variables

In this subsection, we applied the proposed estimator for the Boltzmann machine with hidden variables whose associated function is written as (3). The proposed estimator with parameter settings $(\alpha, \alpha') = (1.01, 0.01), (1.01, -0.01), (2, -1)$ was compared with the MLE. The dimension d_1 of observed variables was fixed to 10 and d_2 of hidden variables was set to 2, and the parameter $\boldsymbol{\theta}^*$ was generated as $\boldsymbol{\theta}^* \sim \mathcal{N}(\mathbf{0}, I)$ including parameters corresponding to hidden variables. Note that the Boltzmann machine with hidden variables is not identifiable and different values of the parameter do not necessarily generate different probability distributions, implying that estimators are influenced by local minimums. Then we

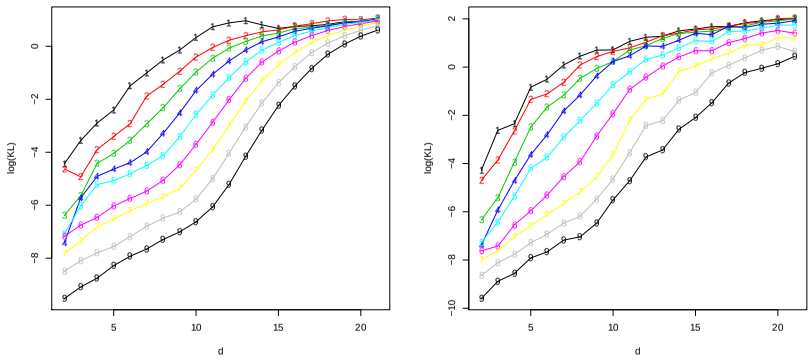

Figure 7: Median of KL divergences $\mathrm{KL}(\bar{q}_{\boldsymbol{\theta}_0}, \bar{q}_{\hat{\boldsymbol{\theta}}})$. Horizontal axis is dimension d, and vertical axis is median of KL divergences, in log-scale. Number k ($k = 1, \ldots, 9$) on a line corresponds to number $n = 50 \times 2^k$ of examples. (a) $\boldsymbol{\theta}_0 \sim \mathcal{N}(0, I/d)$. (b) $\boldsymbol{\theta}_0 \sim \mathcal{N}(0, I)$,

measured performance of each estimator by the averaged log-likelihood $\frac{1}{n}\sum_{i=1}^{n} \log \bar{q}_{\hat{\boldsymbol{\theta}}}(\boldsymbol{x}_i)$ rather than the RMSE of parameters. An initial value of the parameter was set by $\mathcal{N}(\mathbf{0}, I)$ and commonly used by all methods. We repeated the comparison 50 times and observed the averaged performance. Figure 8 (a) shows median of averaged log-likelihoods of each method for the training dataset over 50 trials, against the number n of example. We observe that the proposed estimator is comparable with the MLE when the number n of examples becomes large. Note that the averaged log-likelihood of MLE once decreases when n is small, and this is due to overfitting of the model. Figure 8 (b) shows median of averaged log-likelihoods of each method for test dataset consists of 10000 examples, over 50 trials. Figure 8 (c) shows median of computational time of each method against n, and we observe that the proposed estimator is significantly faster than the MLE.

In addition, we investigated performance of the regularized version (20) ($\alpha = 1.01, \alpha' = 0.01$ and $\lambda = 0, 10^{-2}, 10^{-4}$) and compared with the MLE. Figures 9 (a) and (b) show medians of averaged log-likelihoods of the MLE and the regularized estimator over 50 trials, for the training dataset and the test dataset, respectively. Figures imply that an appropriate regularization can improve performance of the estimator and also as the experiment in previous subsection, computational time of the regularized estimator is drastically reduced, in comparison with that of the estimator without regularization.

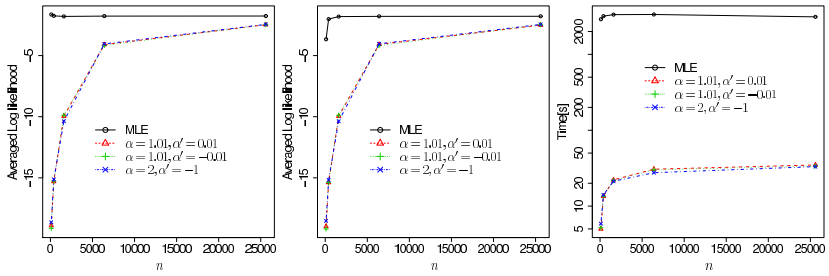

Figure 8: (a) Median of averaged log-likelihoods of each method against n. (b) Median of averaged log-likelihoods of each method calculated for test dataset against n. (c) Median of computational time of each method against n, in log scale.

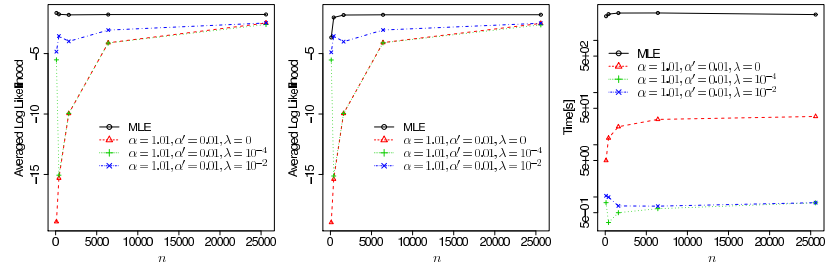

Figure 9: (a) Median of averaged log-likelihoods of the MLE and regularized estimator with $\lambda = 0, 10^{-2}, 10^{-4}$ against n. (b) Median of averaged log-likelihoods of each method calculated for test dataset against n. (c) Median of computational time of each method against n, in log scale.

7. Conclusions

We proposed a novel estimator for probabilistic models on discrete space, for which the normalization constant is infeasible to calculate. The proposed estimator is based on unnormalized models and an empirically localized PS-divergence having the homogeneous property and can be constructed without calculation of the normalization constant. We showed that homogeneous divergences with empirical localization allow the computation of the normalization constant to be avoided because of a weak coincidence axiom. The idea of empirical localization permits ignoring an unobserved domain on sample space, which can drastically reduce computational cost. We investigated statistical properties of the proposed estimator and revealed that the proposed estimator is asymptotically efficient and that its asymptotic distribution is equal to that of the maximum likelihood estimator (MLE). In addition, we showed a relationship between the empirically localized PS-divergence and a mixture of α-divergences. The Hessian matrix of the α-divergence is known to be equal

to the Fisher information matrix, which implies the Fisher efficiency of the proposed estimator. A difference between two divergences is that the mixture of α-divergence does not have homogeneous property. By utilizing this difference, we proposed an estimator for the normalization constant that requires only sample order $\mathcal{O}(n)$ calculation and is asymptotically consistent. We investigated the performance of the proposed estimator with various kinds of models on discrete sample space and showed that the proposed estimator performs comparably to the MLE, while required computational cost is drastically reduced.

A possible future direction for this work is application of the proposed framework for models on continuous space. While employment of the framework for continuous space is an interesting challenge, the empirical localization technique is difficult to apply to models on continuous space because of the power of the empirical distribution described by the delta function. Another direction is making the proposed estimator more robust. The PS-divergence used in this paper is well known to be robust against outlier noise (Kanamori and Fujisawa, 2015). The robustness of the PS-divergence can be controlled by the tuning parameter γ, which was fixed to a value ensuring convexity of the risk function in this paper. The robustification of the proposed estimator and its theoretical justification are important issues for data analysis application.

Appendix A. Proof of Theorem 4

Some calculation yields

$$\frac{\partial^2 \log \left\langle p^{\alpha} q_{\boldsymbol{\theta}}^{1-\alpha} \right\rangle}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^T} = (1-\alpha)^2 V_{r_{\alpha,\boldsymbol{\theta}}}[\boldsymbol{\phi}],$$

where $V_{r_{\alpha,\boldsymbol{\theta}}}[\boldsymbol{\phi}]$ is the covariance matrix of $\boldsymbol{\phi}(\boldsymbol{x})$ under the probability $r_{\alpha,\boldsymbol{\theta}}(\boldsymbol{x})$. Thus, the Hessian matrix of $S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}})$ is written as

$$\frac{\partial^2}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^T} S_{\alpha,\alpha',\gamma}(p, q_{\boldsymbol{\theta}}) = \frac{(1-\alpha)^2}{1+\gamma} V_{r_{\alpha,\boldsymbol{\theta}}}[\boldsymbol{\phi}] + \frac{\gamma(1-\alpha')^2}{1+\gamma} V_{r_{\alpha',\boldsymbol{\theta}}}[\boldsymbol{\phi}] - (1-\bar{\alpha})^2 V_{r_{\bar{\alpha},\boldsymbol{\theta}}}[\boldsymbol{\phi}].$$

The Hessian matrix is positive semidefinite if $\bar{\alpha} = 1$.

To prove the second part, we prove that there exists a distribution p, a model $q_{\boldsymbol{\theta}}$ and parameters α, α', γ such that the Hessian is not positive semidefinite, for a given $\bar{\alpha} \neq 1$. Suppose that $\mathcal{X} = \{+1, -1\}^d$ and the function $\boldsymbol{\phi}(\boldsymbol{x}) = (\phi_1(\boldsymbol{x}), \ldots, \phi_d(\boldsymbol{x})) \in \mathbb{R}^d$ is defined by $\phi_k(\boldsymbol{x}) = x_k$, $k = 1, \ldots, d$ for $\boldsymbol{x} = (x_1, \ldots, x_d) \in \mathcal{X}$. Let p be the uniform distribution on $\mathcal{X}$. The covariance matrix of $\boldsymbol{\phi}$ is the diagonal matrix given by

$$V_{r_{\alpha,\boldsymbol{\theta}}}[\boldsymbol{\phi}] = 4 \cdot \mathrm{diag}\left(\frac{1}{(e^{(1-\alpha)\theta_1} + e^{-(1-\alpha)\theta_1})^2}, \ldots, \frac{1}{(e^{(1-\alpha)\theta_d} + e^{-(1-\alpha)\theta_d})^2} \right).$$

Let δ be $\delta = 1/(1+\gamma)$, then $\delta \in (0,1)$ holds for $\gamma > 0$. We define

$$f(z;\theta) = \frac{(1-z)^2}{(e^{(1-z)\theta} + e^{-(1-z)\theta})^2}, \quad z, \theta \in \mathbb{R}.$$

Then, the i-th diagonal element of the Hessian matrix is expressed by

$$\Delta = \delta \cdot f(\alpha;\theta_i) + (1-\delta) \cdot f(\alpha';\theta_i) - f(\delta\alpha + (1-\delta)\alpha';\theta_i)$$

up to a positive constant. Our task is to find the parameter α, α', δ such that $\bar{\alpha} = \delta\alpha + (1-\delta)\alpha'$ and $\Delta < 0$ hold. The function f satisfies the following properties.

(a) $f(z;\theta) \geq 0$ and $f(z;\theta) = 0 \Leftrightarrow z = 1$.

(b) $f(1+\varepsilon;\theta) = f(1-\varepsilon;\theta) = f(1+\varepsilon;-\theta)$ for $\varepsilon \geq 0, \theta \in \mathbb{R}$.

(c) $\lim_{z\to\pm\infty} f(z;\theta) = 0$ holds for $\theta \neq 0$.

Let θ be a fixed non-zero real number. Since $\bar{\alpha} \neq 1$, $f(\bar{\alpha};\theta) > 0$ holds. Due to the properties (b) and (c), any sufficiently large $\varepsilon > 0$ satisfies $f(1-\varepsilon;\theta) = f(1+\varepsilon;\theta) < f(\bar{\alpha};\theta)$. Define $\alpha = 1+\varepsilon$ and $\alpha' = 1-\varepsilon$. By choosing $\delta \in (0,1)$ such that $\bar{\alpha} = \delta\alpha + (1-\delta)\alpha'$, we have $\Delta < 0$.

Appendix B. Proof of Proposition 5

Suppose that $\bar{\alpha} > 1$. Due to (a), (c) in Appendix A and the continuity of $f(z,\theta)$ at $z = 1$, there exists α and α' satisfying $1 < \alpha' < \bar{\alpha} < \alpha$ such that both $f(\alpha';\theta)$ and $f(\alpha;\theta)$ are less than $f(\bar{\alpha};\theta)$, where θ is a non-zero constant. Then, $\Delta < 0$ holds for $\delta \in (0,1)$ such that $\bar{\alpha} = \delta\alpha + (1-\delta)\alpha'$. We prove the case of $0 < \bar{\alpha} < 1$. For a sufficiently large θ, we have

$$\frac{f(0;\theta)}{f(\bar{\alpha};\theta)} = O\left(\frac{e^{-2\bar{\alpha}\theta}}{(1-\bar{\alpha})^2}\right) \to 0 \ (\theta \to \infty).$$

Hence, the continuity of f ensures that there exist a sufficiently large θ and a small positive α' such that $0 < \alpha' < \bar{\alpha}$ and $f(\alpha';\theta) < f(\bar{\alpha};\theta)$ hold. The property (c) in the Appendix A ensures that there exists a sufficiently large $\alpha > 1$ satisfying $f(\alpha;\theta) < f(\bar{\alpha};\theta)$. Again, $\Delta < 0$ holds for δ such that $\bar{\alpha} = \delta\alpha + (1-\delta)\alpha'$.

Appendix C. Generalized Hölder's inequality

This section includes the proof and the equality condition of the generalized Hölder's inequality. The inequality (11) of $L = 2$ is nothing but the standard Hölder's inequality. The inequality (11) of $L = 3$ is proved by using the standard one as follows:

$$\left\langle f_1^{\delta_1} f_2^{\delta_2} f_3^{\delta_3} \right\rangle = \left\langle (f_1^{\frac{\delta_1}{1-\delta_3}} f_2^{\frac{\delta_2}{1-\delta_3}})^{1-\delta_3} f_3^{\delta_3} \right\rangle \leq \left\langle f_1^{\frac{\delta_1}{1-\delta_3}} f_2^{\frac{\delta_2}{1-\delta_3}} \right\rangle^{1-\delta_3} \langle f_3 \rangle^{\delta_3} \leq \langle f_1 \rangle^{\delta_1} \langle f_2 \rangle^{\delta_2} \langle f_3 \rangle^{\delta_3},$$

where $\delta_1 + \delta_2 + \delta_3 = 1$ and $\delta_i > 0$ for $i = 1,2,3$ are assumed. The third inequality becomes equality if and only if f_1 and f_2 are linearly dependent, and the second inequality becomes

equality if and only if $f_1^{\frac{\delta_1}{1-\delta_3}} f_2^{\frac{\delta_2}{1-\delta_3}}$ and f_3 are linearly dependent. As a result, (11) of $L = 3$ becomes an equality if and only if there exists a function $g \in \mathcal{M}$ such that all f_1, f_2, f_3 are proportional to g. In the same way, we can prove the generalized Hölder's inequality of any natural number L.

Appendix D. Proof of Theorem 7

We show the asymptotic distribution of the estimator defined from the localized PS-divergence $S_{\alpha,\alpha',\gamma}$. Along the same line, one can prove the asymptotic property of the estimator defined from the general localized PS-divergence $S_{\boldsymbol{\alpha},\boldsymbol{\delta}}$.

Let us assume that the empirical distribution is written as

$$\tilde{p}(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x}) + \epsilon \cdot s(\boldsymbol{x}),$$

where ϵ is a small positive number and $s(\boldsymbol{x})$ satisfies $\langle s \rangle = 0$. Note that $r_{\alpha,\boldsymbol{\theta}_0}(\boldsymbol{x}) = \bar{q}_{\boldsymbol{\theta}_0}(\boldsymbol{x})$. By expanding an equilibrium condition of the estimator (13) around $\boldsymbol{\theta} = \boldsymbol{\theta}_0$, we obtain

$$\begin{aligned}
0 &= \frac{\partial}{\partial \boldsymbol{\theta}} S_{\alpha,\alpha',\gamma}(\tilde{p}, q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} \\
&= \frac{\partial}{\partial \boldsymbol{\theta}} S_{\alpha,\alpha',\gamma}(\tilde{p}, q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} + \frac{\partial^2}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^T} S_{\alpha,\alpha',\gamma}(\tilde{p}, q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) + \mathcal{O}(||\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0||^2) \\
&= \left\{ \frac{1-\alpha}{1+\gamma} \left\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \right\rangle + \frac{\gamma(1-\alpha')}{1+\gamma} \left\langle \tilde{r}_{\alpha',\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \right\rangle - (1-\bar{\alpha}) \left\langle \tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \right\rangle \right\} \\
&\quad + \left\{ \frac{(1-\alpha)^2}{1+\gamma} V_{\tilde{r}_{\alpha,\boldsymbol{\theta}_0}}[\psi'_{\boldsymbol{\theta}_0}] + \frac{\gamma(1-\alpha')^2}{1+\gamma} V_{\tilde{r}_{\alpha',\boldsymbol{\theta}_0}}[\psi'_{\boldsymbol{\theta}_0}] - (1-\bar{\alpha})^2 V_{\tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0}}[\psi'_{\boldsymbol{\theta}_0}] \right. \\
&\quad \left. + \frac{1-\alpha}{1+\gamma} \left\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0} \psi''_{\boldsymbol{\theta}_0} \right\rangle + \frac{\gamma(1-\alpha')}{1+\gamma} \left\langle \tilde{r}_{\alpha',\boldsymbol{\theta}_0} \psi''_{\boldsymbol{\theta}_0} \right\rangle - (1-\bar{\alpha}) \left\langle \tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0} \psi''_{\boldsymbol{\theta}_0} \right\rangle \right\} (\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) + \mathcal{O}(||\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0||^2),
\end{aligned}$$

where $\psi'_{\boldsymbol{\theta}_0}$ and $\psi''_{\boldsymbol{\theta}_0}$ are the gradient vector and the Hessian matrix of $\psi_{\boldsymbol{\theta}_0}(\boldsymbol{x})$ with respect to the parameter $\hat{\boldsymbol{\theta}}$. By the delta method (Van der Vaart, 1998), we observe that

$$\begin{aligned}
&(\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \rangle - \langle r_{\alpha,\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \rangle) \\
&= \alpha\epsilon \frac{\left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha-1} q_{\boldsymbol{\theta}_0}^{1-\alpha} \psi'_{\boldsymbol{\theta}_0} s \right\rangle \left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha} q_{\boldsymbol{\theta}_0}^{1-\alpha} \right\rangle - \left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha} q_{\boldsymbol{\theta}_0}^{1-\alpha} \psi'_{\boldsymbol{\theta}_0} \right\rangle \left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha-1} q_{\boldsymbol{\theta}_0}^{1-\alpha} s \right\rangle}{\left\langle \bar{q}_{\boldsymbol{\theta}_0}^{\alpha} q_{\boldsymbol{\theta}_0}^{1-\alpha} \right\rangle^2} + O(\epsilon^2) \\
&= \alpha\epsilon \left(\langle \psi'_{\boldsymbol{\theta}_0} s \rangle - \langle \bar{q}_{\boldsymbol{\theta}_0} \psi'_{\boldsymbol{\theta}_0} \rangle \langle s \rangle \right) + O(\epsilon^2) \\
&= \alpha\epsilon \langle \psi'_{\boldsymbol{\theta}_0} s \rangle + O(\epsilon^2).
\end{aligned}$$

Then we have

$$\begin{aligned}
&\frac{\partial}{\partial\boldsymbol{\theta}}S_{\alpha,\alpha',\gamma}(\tilde{p},q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} - \frac{\partial}{\partial\boldsymbol{\theta}}S_{\alpha,\alpha',\gamma}(p,q_{\boldsymbol{\theta}})\Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}\\
&= \frac{1-\alpha}{1+\gamma}\left(\left\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle - \left\langle r_{\alpha,\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right) + \frac{\gamma(1-\alpha')}{1+\gamma}\left(\left\langle \tilde{r}_{\alpha',\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle - \left\langle r_{\alpha',\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right)\\
&\quad - (1-\bar{\alpha})\left(\left\langle \tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle - \left\langle r_{\bar{\alpha},\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right)\\
&= \left\{\frac{1-\alpha}{1+\gamma}\left\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle + \frac{\gamma(1-\alpha')}{1+\gamma}\left\langle \tilde{r}_{\alpha',\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle - (1-\bar{\alpha})\left\langle \tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right\}\\
&\quad - \left\{1 - \frac{\alpha+\gamma\alpha'}{1+\gamma} - (1-\bar{\alpha})\right\}\left\langle \bar{q}_{\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\\
&= \left(\alpha\frac{1-\alpha}{1+\gamma} + \alpha'\frac{\gamma(1-\alpha')}{1+\gamma} - (1-\bar{\alpha})\bar{\alpha}\right)\left\langle \psi'_{\boldsymbol{\theta}_0}\epsilon s\right\rangle + O(\epsilon^2)\\
&= -\frac{\gamma}{(1+\gamma)^2}(\alpha-\alpha')^2\left\langle \psi'_{\boldsymbol{\theta}_0}(\tilde{p}-\bar{q}_{\boldsymbol{\theta}_0})\right\rangle + O(\epsilon^2).
\end{aligned}$$

From the central limit theorem,

$$\sqrt{n}\left\langle \psi'_{\boldsymbol{\theta}_0}(\tilde{p}-\bar{q}_{\boldsymbol{\theta}_0})\right\rangle = \frac{1}{\sqrt{n}}\sum_{i=1}^{n}\left(\psi'_{\boldsymbol{\theta}_0}(\boldsymbol{x}_i) - \left\langle \bar{q}_{\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right)$$

asymptotically follows the normal distribution with mean $\mathbf{0}$ and variance $V_{\bar{q}_{\boldsymbol{\theta}_0}}[\psi'_{\boldsymbol{\theta}_0}] = I_{\boldsymbol{\theta}_0}$. Also from the law of large numbers, we have

$$\begin{aligned}
&\frac{(1-\alpha)^2}{1+\gamma}V_{\tilde{r}_\alpha}[\psi'_{\boldsymbol{\theta}_0}] + \frac{\gamma(1-\alpha')^2}{1+\gamma}V_{\tilde{r}_{\alpha'}}[\psi'_{\boldsymbol{\theta}_0}] - (1-\bar{\alpha})^2 V_{\tilde{r}_{\bar{\alpha}}}[\psi'_{\boldsymbol{\theta}_0}] \to \frac{\gamma}{(1+\gamma)^2}(\alpha-\alpha')^2 I_{\boldsymbol{\theta}_0},\\
&\quad \frac{1-\alpha}{1+\gamma}\left\langle \tilde{r}_{\alpha,\boldsymbol{\theta}_0}\psi''_{\boldsymbol{\theta}_0}\right\rangle + \frac{\gamma(1-\alpha')}{1+\gamma}\left\langle \tilde{r}_{\alpha',\boldsymbol{\theta}_0}\psi''_{\boldsymbol{\theta}_0}\right\rangle - (1-\bar{\alpha})\left\langle \tilde{r}_{\bar{\alpha},\boldsymbol{\theta}_0}\psi''_{\boldsymbol{\theta}_0}\right\rangle\\
&\to \left(1 - \frac{\alpha+\gamma\alpha'}{1+\gamma} - (1-\bar{\alpha})\right)\left\langle \bar{q}_{\boldsymbol{\theta}_0}\psi''_{\boldsymbol{\theta}_0}\right\rangle = 0
\end{aligned}$$

in the limit of $n\to\infty$. Taking the probabilistic error in the law of large numbers into account, we obtain the equality

$$\sqrt{n}\left(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0\right) = I_{\boldsymbol{\theta}_0}^{-1}\left\{\frac{1}{\sqrt{n}}\sum_{i=1}^{n}\left(\psi'_{\boldsymbol{\theta}_0}(\boldsymbol{x}_i) - \left\langle \bar{q}_{\boldsymbol{\theta}_0}\psi'_{\boldsymbol{\theta}_0}\right\rangle\right)\right\} + o_p(1)$$

Consequently, the asymptotic distribution of the estimator is given as

$$\sqrt{n}\left(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0\right) \sim \mathcal{N}(\mathbf{0}, I_{\boldsymbol{\theta}_0}^{-1}).$$

Appendix E. Proof of Theorem 12

Let us consider the asymptotic property of $\hat{z}$. The logarithm of the estimator $\widehat{z}$ is expressed as

$$\log\widehat{z} = \frac{1}{\alpha-\alpha'}\log\left\langle \tilde{p}^{\alpha'}q_{\hat{\boldsymbol{\theta}}}^{1-\alpha'}\right\rangle - \frac{1}{\alpha-\alpha'}\log\left\langle \tilde{p}^{\alpha}q_{\hat{\boldsymbol{\theta}}}^{1-\alpha}\right\rangle.$$

In the same way as the calculation in Appendix D, we have

$$\log\left\langle p^{\alpha}q_{\hat{\theta}}^{1-\alpha}\right\rangle = (1-\alpha)\log Z_{\boldsymbol{\theta}_0} + (1-\alpha)(\log Z_{\boldsymbol{\theta}_0})'(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0) + o_p(\|\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0\|).$$

From the above equation, we have

$$\sqrt{n}(\log\hat{z} - \log Z_{\boldsymbol{\theta}_0}) = \sqrt{n}(\log Z_{\boldsymbol{\theta}_0})'^{T}(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0) + o_p(1).$$

Therefore, the asymptotic variance of of $\log(\hat{z})$ is given by

$$n\cdot V[\log(\hat{z})] \longrightarrow (\log Z_{\boldsymbol{\theta}_0})'^{T} I_{\boldsymbol{\theta}_0}^{-1}(\log Z_{\boldsymbol{\theta}_0})'.$$

We show the correlation between $\hat{\boldsymbol{\theta}}$ and $\log\hat{z}$. The asymptotic expansion above yields

$$n\cdot(\log\widehat{z} - (\log Z_{\boldsymbol{\theta}_0}))(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0) = (\sqrt{n}(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0))(\sqrt{n}(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0))^{T}(\log Z_{\boldsymbol{\theta}_0})' + o_p(1)$$

and we have

$$n\cdot\mathbb{E}[(\log\hat{z} - \log Z_{\boldsymbol{\theta}_0})(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0)] \longrightarrow I_{\boldsymbol{\theta}_0}^{-1}(\log Z_{\boldsymbol{\theta}_0})'.$$

Therefore, the asymptotic distribution of $\sqrt{n}(\hat{\boldsymbol{\theta}}-\boldsymbol{\theta}_0, \log\hat{z} - \log Z_{\boldsymbol{\theta}_0})$ is given as the multivariate normal distribution with mean zero and the following asymptotic variance

$$\begin{aligned}
n\cdot V[(\hat{\boldsymbol{\theta}}, \log\hat{z})] &\longrightarrow \begin{pmatrix} I_{\boldsymbol{\theta}_0}^{-1} & I_{\boldsymbol{\theta}_0}^{-1}(\log Z_{\boldsymbol{\theta}_0})'\\ (\log Z_{\boldsymbol{\theta}_0})'^{T}I_{\boldsymbol{\theta}_0}^{-1} & (\log Z_{\boldsymbol{\theta}_0})'^{T}I_{\boldsymbol{\theta}_0}^{-1}(\log Z_{\boldsymbol{\theta}_0})' \end{pmatrix}\\
&= \begin{pmatrix} E\\ (\log Z_{\boldsymbol{\theta}_0})'^{T}\end{pmatrix} I_{\boldsymbol{\theta}_0}^{-1}\begin{pmatrix} E & (\log Z_{\boldsymbol{\theta}_0})'\end{pmatrix},
\end{aligned}$$

where E is the identity matrix. Note that the distribution of the estimator $(\hat{\boldsymbol{\theta}}, \hat{z})$ is asymptotically degenerated.

Abstract

In this paper, we consider an infinite dimensional exponential family $\mathcal{P}$ of probability densities, which are parametrized by functions in a reproducing kernel Hilbert space $\mathcal{H}$, and show it to be quite rich in the sense that a broad class of densities on $\mathbb{R}^d$ can be approximated arbitrarily well in Kullback-Leibler (KL) divergence by elements in $\mathcal{P}$. Motivated by this approximation property, the paper addresses the question of estimating an unknown density p_0 through an element in $\mathcal{P}$. Standard techniques like maximum likelihood estimation (MLE) or pseudo MLE (based on the method of sieves), which are based on minimizing the KL divergence between p_0 and $\mathcal{P}$, do not yield practically useful estimators because of their inability to efficiently handle the log-partition function. We propose an estimator $\hat{p}_n$ based on minimizing the *Fisher divergence*, $J(p_0\|p)$ between p_0 and $p \in \mathcal{P}$, which involves solving a simple finite-dimensional linear system. When $p_0 \in \mathcal{P}$, we show that the proposed estimator is consistent, and provide a convergence rate of $n^{-\min\left\{\frac{2}{3}, \frac{2\beta+1}{2\beta+2}\right\}}$ in Fisher divergence under the smoothness assumption that $\log p_0 \in \mathcal{R}(C^\beta)$ for some $\beta \geq 0$, where C is a certain Hilbert-Schmidt operator on $\mathcal{H}$ and $\mathcal{R}(C^\beta)$ denotes the image of C^β. We also investigate the misspecified case of $p_0 \notin \mathcal{P}$ and show that $J(p_0\|\hat{p}_n) \to \inf_{p\in\mathcal{P}} J(p_0\|p)$ as $n \to \infty$, and provide a rate for this convergence under a similar smoothness condition as above. Through numerical simulations we demonstrate that the proposed estimator outperforms the non-parametric kernel density estimator, and that the advantage of the proposed estimator grows as d increases.

1. Introduction

Exponential families are among the most important classes of parametric models studied in statistics, and include many common distributions such as the normal, exponential, gamma, and Poisson. In its "natural form", the family generated by a probability density q_0 (defined over $\Omega \subseteq \mathbb{R}^d$) and *sufficient statistic*, $T : \Omega \to \mathbb{R}^m$ is defined as

$$\mathscr{P}_{\text{fin}} := \left\{ p_\theta(x) = q_0(x) e^{\theta^T T(x) - A(\theta)},\, x \in \Omega \,:\, \theta \in \Theta \subset \mathbb{R}^m \right\} \tag{1}$$

where $A(\theta) := \log \int_\Omega e^{\theta^T T(x)} q_0(x)\, dx$ is the cumulant generating function (also called the log-partition function), $\Theta \subset \{\theta \in \mathbb{R}^m : A(\theta) < \infty\}$ is the *natural parameter space* and θ is a finite-dimensional vector called the *natural parameter*. Exponential families have a number of properties that make them extremely useful for statistical analysis (see Brown, 1986 for more details).

In this paper, we consider an infinite dimensional generalization (Canu and Smola, 2005; Fukumizu, 2009) of (1),

$$\mathcal{P} = \left\{ p_f(x) = e^{f(x) - A(f)} q_0(x),\, x \in \Omega : f \in \mathcal{F} \right\},$$

where the function space $\mathcal{F}$ is defined as

$$\mathcal{F} = \left\{ f \in \mathcal{H} : e^{A(f)} < \infty \right\}, \text{ with } A(f) := \log \int_\Omega e^{f(x)} q_0(x)\, dx$$

being the cumulant generating function, and $(\mathcal{H}, \langle \cdot, \cdot \rangle_{\mathcal{H}})$ a reproducing kernel Hilbert space (RKHS) (Aronszajn, 1950) with k as its reproducing kernel. While various generalizations are possible for different choices of $\mathcal{F}$ (e.g., an Orlicz space as in Pistone and Sempi, 1995), the connection of $\mathcal{P}$ to the natural exponential family in (1) is particularly enlightening when $\mathcal{H}$ is an RKHS. This is due to the reproducing property of the kernel, $f(x) = \langle f, k(x, \cdot) \rangle_{\mathcal{H}}$, through which $k(x, \cdot)$ takes the role of the sufficient statistic. In fact, it can be shown (see Section 3 and Example 1 for more details) that every $\mathscr{P}_{\text{fin}}$ is generated by $\mathcal{P}$ induced by a finite dimensional RKHS $\mathcal{H}$, and therefore the family $\mathcal{P}$ with $\mathcal{H}$ being an infinite dimensional RKHS is a natural infinite dimensional generalization of $\mathscr{P}_{\text{fin}}$. Furthermore, this generalization is particularly interesting as in contrast to $\mathscr{P}_{\text{fin}}$, it can be shown that $\mathcal{P}$ is a rich class of densities (depending on the choice of k and therefore $\mathcal{H}$) that can approximate a broad class of probability densities arbitrarily well (see Propositions 1, 13 and Corollary 2). This generalization is not only of theoretical interest, but also has implications for statistical and machine learning applications. For example, in Bayesian non-parametric density estimation, the densities in $\mathcal{P}$ are chosen as prior distributions on a collection of probability densities (e.g., see van der Vaart and van Zanten, 2008). $\mathcal{P}$ has also found applications in nonparametric hypothesis testing (Gretton et al., 2012; Fukumizu et al., 2008) and dimensionality reduction (Fukumizu et al., 2004, 2009) through the mean and

covariance operators, which are obtained as the first and second Fréchet derivatives of $A(f)$ (see Fukumizu, 2009, Section 1.2.3). Recently, the infinite dimensional exponential family, $\mathcal{P}$ has been used to develop a gradient-free adaptive MCMC algorithm based on Hamiltonian Monte Carlo (Strathmann et al., 2015) and also has been used in the context of learning the structure of graphical models (Sun et al., 2015).

Motivated by the richness of the infinite dimensional generalization and its statistical applications, it is of interest to model densities by $\mathcal{P}$, and therefore the goal of this paper is to estimate unknown densities by elements in $\mathcal{P}$ when $\mathcal{H}$ is an infinite dimensional RKHS. Formally, given i.i.d. random samples $(X_a)_{a=1}^n$ drawn from an unknown density p_0, the goal is to estimate p_0 through $\mathcal{P}$. Throughout the paper, we refer to case of $p_0 \in \mathcal{P}$ as *well-specified*, in contrast to the *misspecified* case where $p_0 \notin \mathcal{P}$. The setting is useful because $\mathcal{P}$ is a rich class of densities that can approximate a broad class of probability densities arbitrarily well, hence it may be widely used in place of non-parametric density estimation methods (e.g., kernel density estimation (KDE)). In fact, through numerical simulations, we show in Section 6 that estimating p_0 through $\mathcal{P}$ performs better than KDE, and that the advantage of the proposed estimator grows with increasing dimensionality.

In the finite-dimensional case where $\theta \in \Theta \subset \mathbb{R}^m$, estimating p_θ through maximum likelihood (ML) leads to solving elegant likelihood equations (Brown, 1986, Chapter 5). However, in the infinite dimensional case (assuming $p_0 \in \mathcal{P}$), as in many non-parametric estimation methods, a straightforward extension of maximum likelihood estimation (MLE) suffers from the problem of ill-posedness (Fukumizu, 2009, Section 1.3.1). To address this problem, Fukumizu (2009) proposed a method of sieves involving pseudo-MLE by restricting the infinite dimensional manifold $\mathcal{P}$ to a series of finite-dimensional submanifolds, which enlarge as the sample size increases, i.e., $p_{\hat{f}^{(l)}}$ is the density estimator with

$$\hat{f}^{(l)} = \arg\max_{f \in \mathcal{F}^{(l)}} \frac{1}{n} \sum_{a=1}^{n} f(X_a) - A(f), \tag{2}$$

where $\mathcal{F}^{(l)} = \{f \in \mathcal{H}^{(l)} : e^{A(f)} < \infty\}$ and $(\mathcal{H}^{(l)})_{l=1}^{\infty}$ is a sequence of finite-dimensional subspaces of $\mathcal{H}$ such that $\mathcal{H}^{(l)} \subset \mathcal{H}^{(l+1)}$ for all $l \in \mathbb{N}$. While the consistency of $p_{\hat{f}^{(l)}}$ is proved in Kullback-Leibler (KL) divergence (Fukumizu, 2009, Theorem 6), the method suffers from many drawbacks that are both theoretical and computational in nature. On the theoretical front, the consistency in Fukumizu (2009, Theorem 6) is established by assuming a decay rate on the eigenvalues of the covariance operator (see (A-2) and the discussion in Section 1.4 of Fukumizu (2009) for details), which is usually difficult to check in practice. Moreover, it is not clear which classes of RKHS should be used to obtain a consistent estimator (Fukumizu, 2009, (A-1)) and the paper does not provide any discussion about the convergence rates. On the practical side, the estimator is not attractive as it can be quite difficult to construct the sequence $(\mathcal{H}^{(l)})_{l=1}^{\infty}$ that satisfies the assumptions in Fukumizu (2009, Theorem 6). In fact, the impracticality of the estimator, $\hat{f}^{(l)}$ is accentuated by the difficulty in efficiently handling $A(f)$ (though it can be approximated by numerical integration).

A related work was carried out by Barron and Sheu (1991)—also see references therein—where the goal is to estimate a density, p_0 by approximating its logarithm as an expansion in terms of basis functions, such as polynomials, splines or trigonometric series. Similar to

Fukumizu (2009), Barron and Sheu proposed the ML estimator $p_{\hat{f}_m}$, where

$$\hat{f}_m = \arg\max_{f \in \mathcal{F}_m} \frac{1}{n} \sum_{a=1}^{n} f(X_a) - A(f)$$

and $\mathcal{F}_m$ is the linear space of dimension m spanned by the chosen basis functions. Under the assumption that $\log p_0$ has square-integrable derivatives up to order r, they showed that $KL(p_0 \| p_{\hat{f}_m}) = O_{p_0}(n^{-2r/(2r+1)})$ with $m = n^{1/(2r+1)}$ for each of the approximating families, where $KL(p\|q) = \int p(x) \log(p(x)/q(x))\, dx$ is the KL divergence between p and q. Similar work was carried out by Gu and Qiu (1993), who assumed that $\log p_0$ lies in an RKHS, and proposed an estimator based on penalized MLE, with consistency and rates established in Jensen-Shannon divergence. Though these results are theoretically interesting, these estimators are obtained via a procedure similar to that in Fukumizu (2009), and therefore suffers from the practical drawbacks discussed above.

The discussion so far shows that the MLE approach to learning $p_0 \in \mathcal{P}$ results in estimators that are of limited practical interest. To alleviate this, one can treat the problem of estimating $p_0 \in \mathcal{P}$ in a completely non-parametric fashion by using KDE, which is well-studied (Tsybakov, 2009, Chapter 1) and easy to implement. This approach ignores the structure of $\mathcal{P}$, however, and is known to perform poorly for moderate to large d (Wasserman, 2006, Section 6.5) (see also Section 6 of this paper).

1.1 Score Matching and Fisher Divergence

To counter the disadvantages of KDE and pseudo/penalized-MLE, in this paper, we propose to use the *score matching method* introduced by Hyvärinen (2005, 2007). While MLE is based on minimizing the KL divergence, the score matching method involves minimizing the *Fisher divergence* (also called the Fisher information distance; see Definition 1.13 in Johnson (2004)) between two continuously differentiable densities, p and q on an open set $\Omega \subseteq \mathbb{R}^d$, given as

$$J(p\|q) = \frac{1}{2} \int_\Omega p(x) \left\| \nabla \log p(x) - \nabla \log q(x) \right\|_2^2 dx, \tag{3}$$

where $\nabla \log p(x) = (\partial_1 \log p(x), \ldots, \partial_d \log p(x))$ with $\partial_i \log p(x) := \frac{\partial}{\partial x_i} \log p(x)$. Fisher divergence is closely related to the KL divergence through de Bruijn's identity (Johnson, 2004, Appendix C) and it can be shown that $KL(p\|q) = \int_0^\infty J(p_t\|q_t)\, dt$, where $p_t = p * N(0, tI_d)$, $q_t = q * N(0, tI_d)$, $*$ denotes the convolution, and $N(0, tI_d)$ denotes a normal distribution on $\mathbb{R}^d$ with mean zero and diagonal covariance with $t > 0$ (see Proposition B.1 for a precise statement; also see Theorem 1 in Lyu, 2009). Moreover, convergence in Fisher divergence is a stronger form of convergence than that in KL, total variation and Hellinger distances (see Lemmas E.2 & E.3 in Johnson, 2004 and Corollary 5.1 in Ley and Swan, 2013).

To understand the advantages associated with the score matching method, let us consider the problem of density estimation where the data generating distribution (say p_0) belongs to $\mathscr{P}_{\text{fin}}$ in (1). In other words, given random samples $(X_a)_{a=1}^n$ drawn i.i.d. from $p_0 := p_{\theta_0}$, the goal is to estimate θ_0 as $\hat{\theta}_n$, and use $p_{\hat{\theta}_n}$ as an estimator of p_0. While the

MLE approach is well-studied and enjoys nice statistical properties in asymptopia (i.e., asymptotically unbiased, efficient, and normally distributed), the computation of $\hat{\theta}_n$ can be intractable in many situations as discussed above. In particular, this is the case for $p_\theta(x) = \frac{r_\theta(x)}{A(\theta)}$ where $r_\theta \geq 0$ for all $\theta \in \Theta$, $A(\theta) = \int_\Omega r_\theta(x)\,dx$, and the functional form of r is known (as a function of θ and x); yet we do not know how to easily compute A, which is often analytically intractable. In this setting (which is exactly the setting of this paper), assuming p_θ to be differentiable (w.r.t. x), and $\int_\Omega p_0(x)\|\nabla \log p_\theta(x)\|_2^2\,dx < \infty, \forall\, \theta \in \Theta$, $J(p_0\|p_\theta) =: J(\theta)$ in (3) reduces to

$$J(\theta) = \sum_{i=1}^{d} \int_\Omega p_0(x) \left(\frac{1}{2} \left(\partial_i \log p_\theta(x)\right)^2 + \partial_i^2 \log p_\theta(x) \right) dx + \frac{1}{2} \int_\Omega p_0(x) \left\|\nabla \log p_0(x)\right\|_2^2 dx, \tag{4}$$

through integration by parts (see Hyvärinen, 2005, Theorem 1), under appropriate regularity conditions on p_0 and p_θ for all $\theta \in \Theta$. Here $\partial_i^2 \log p_\theta(x) := \frac{\partial^2}{\partial x_i^2} \log p_\theta(x)$. The main advantage of the objective in (3) (and also (4)) is that when it is applied to the situation discussed above where $p_\theta(x) = \frac{r_\theta(x)}{A(\theta)}$, $J(\theta)$ is independent of $A(\theta)$, and an estimate of θ_0 can be obtained by simply minimizing the empirical counterpart of $J(\theta)$, given by

$$J_n(\theta) := \frac{1}{n} \sum_{a=1}^{n} \sum_{i=1}^{d} \left(\frac{1}{2} \left(\partial_i \log p_\theta(X_a)\right)^2 + \partial_i^2 \log p_\theta(X_a) \right) + \frac{1}{2} \int_\Omega p_0(x) \left\|\nabla \log p_0(x)\right\|_2^2 dx.$$

Since $J_n(\theta)$ is also independent of $A(\theta)$, $\hat{\theta}_n = \arg\min_{\theta\in\Theta} J_n(\theta)$ may be easily computable, unlike the MLE. We would like to highlight that while the score matching approach may have computational advantages over MLE, it only estimates p_θ up to the scaling factor $A(\theta)$, and therefore requires the approximation or computation of $A(\theta)$ through numerical integration to estimate p_θ. Note that this issue (of computing $A(\theta)$ through numerical integration) exists even with MLE, but not with KDE. In score matching, however, numerical integration is needed only once, while MLE would typically require a functional form of the log-partition function which is approximated through numerical integration at every step of an iterative optimization algorithm (for example, see (2)), thus leading to major computational savings. An important application that does not require the computation of $A(\theta)$ is in finding modes of the distribution, which has recently become very popular in image processing (Comaniciu and Meer, 2002), and has already been investigated in the score matching framework (Sasaki et al., 2014). Similarly, in sampling methods such as sequential Monte Carlo (Doucet et al., 2001), it is often the case that the evaluation of unnormalized densities is sufficient to calculate required importance weights.

1.2 Contributions

(i) We present an estimate of $p_0 \in \mathcal{P}$ in the well-specified case through the minimization of Fisher divergence, in Section 4. First, we show that estimating $p_0 := p_{f_0}$ using the score matching method reduces to estimating f_0 by solving a simple finite-dimensional linear system (Theorems 4 and 5). Hyvärinen (2007) obtained a similar result for $\mathscr{P}_{\text{fin}}$ where the estimator is obtained by solving a linear system, which in the case of Gaussian family

matches the MLE (Hyvärinen, 2005). The estimator obtained in the infinite dimensional case is not a simple extension of its finite-dimensional counterpart, however, as the former requires an appropriate regularizer (we use $\|\cdot\|_{\mathcal{H}}^2$) to make the problem well-posed. We would like to highlight that to the best of our knowledge, the proposed estimator is the first practically computable estimator of p_0 with consistency guarantees (see below).

(ii) In contrast to Hyvärinen (2007) where no guarantees on consistency or convergence rates are provided for the density estimator in $\mathscr{P}_{\text{fin}}$, we establish in Theorem 6 the consistency and rates of convergence for the proposed estimator of f_0, and use these to prove consistency and rates of convergence for the corresponding plug-in estimator of p_0 (Theorems 7 and B.2), even when $\mathcal{H}$ is infinite dimensional. Furthermore, while the estimator of f_0 (and therefore p_0) is obtained by minimizing the Fisher divergence, the resultant density estimator is also shown to be consistent in KL divergence (and therefore in Hellinger and total-variation distances) and we provide convergence rates in all these distances.

Formally, we show that the proposed estimator $\hat{f}_n$ is converges as

$$\|f_0 - \hat{f}_n\|_{\mathcal{H}} = O_{p_0}(n^{-\alpha}),\ KL(p_0\|p_{\hat{f}_n}) = O_{p_0}(n^{-2\alpha}) \text{ and } J(p_0\|p_{\hat{f}_n}) = O_{p_0}\left(n^{-\min\left\{\frac{2}{3}, \frac{2\beta+1}{2\beta+2}\right\}}\right)$$

if $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta > 0$, where $\mathcal{R}(A)$ denotes the range or image of an operator A, $\alpha = \min\{\frac{1}{4}, \frac{\beta}{2\beta+2}\}$, and $C := \sum_{i=1}^d \int_\Omega \partial_i k(x,\cdot) \otimes \partial_i k(x,\cdot)\, p_0(x)\,dx$ is a Hilbert-Schmidt operator on $\mathcal{H}$ (see Theorem 4) with k being the reproducing kernel and $\otimes$ denoting the tensor product. When $\mathcal{H}$ is a finite-dimensional RKHS, we show that the estimator enjoys parametric rates of convergence, i.e.,

$$\|f_0 - \hat{f}_n\|_{\mathcal{H}} = O_{p_0}(n^{-1/2}),\ KL(p_0\|p_{\hat{f}_n}) = O_{p_0}(n^{-1}) \text{ and } J(p_0\|p_{\hat{f}_n}) = O_{p_0}(n^{-1}).$$

Note that the convergence rates are obtained under a non-classical smoothness assumption on f_0, namely that it lies in the image of certain fractional power of C, which reduces to a more classical assumption if we choose k to be a Matérn kernel (see Section 2 for its definition), as it induces a Sobolev space. In Section 4.2, we discuss in detail the smoothness assumption on f_0 for the Gaussian (Example 2) and Matérn (Example 3) kernels. Another interesting point to observe is that unlike in the classical function estimation methods (e.g., kernel density estimation and regression), the rates presented above for the proposed estimator tend to saturate for $\beta > 1$ ($\beta > \frac{1}{2}$ w.r.t. J), with the best rate attained at $\beta = 1$ ($\beta = \frac{1}{2}$ w.r.t. J), which means the smoothness of f_0 is not fully captured by the estimator. Such a saturation behavior is well-studied in the inverse problem literature (Engl et al., 1996) where it has been attributed to the choice of regularizer. In Section 4.3, we discuss alternative regularization strategies using ideas from Bauer et al. (2007), which covers non-parametric least squares regression: we show that for appropriately chosen regularizers, the above mentioned rates hold for any $\beta > 0$, and do not saturate for the aforementioned ranges of β (see Theorem 9).

(iii) In Section 5, we study the problem of density estimation in the misspecified setting, i.e., $p_0 \notin \mathcal{P}$, which is not addressed in Hyvärinen (2007) and Fukumizu (2009). Using a more sophisticated analysis than in the well-specified case, we show in Theorem 12 that $J(p_0\|p_{\hat{f}_n}) \to \inf_{p\in\mathcal{P}} J(p_0\|p)$ as $n \to \infty$. Under an appropriate smoothness assumption

on $\log \frac{p_0}{q_0}$ (see the statement of Theorem 12 for details), we show that $J(p_0 \| p_{\hat{f}_n}) \to 0$ as $n \to \infty$ along with a rate for this convergence, even though $p_0 \notin \mathcal{P}$. However, unlike in the well-specified case, where the consistency is obtained not only in J but also in other distances, we obtain convergence only in J for the misspecified case. Note that while Barron and Sheu (1991) considered the estimation of p_0 in the misspecified setting, the results are restricted to the approximating families consisting of polynomials, splines, or trigonometric series. Our results are more general, as they hold for abstract RKHSs.

(iv) In Section 6, we present preliminary numerical results comparing the proposed estimator with KDE in estimating a Gaussian and mixture of Gaussians, with the goal of empirically evaluating performance as d gets large for a fixed sample size. In these two estimation problems, we show that the proposed estimator outperforms KDE, and the advantage grows as d increases. Inspired by this preliminary empirical investigation, our proposed estimator (or computationally efficient approximations) has been used by Strathmann et al. (2015) in a gradient-free adaptive MCMC sampler, and by Sun et al. (2015) for graphical model structure learning. These applications demonstrate the practicality and performance of the proposed estimator.

Finally, we would like to make clear that our principal goal is not to construct density estimators that improve uniformly upon KDE, but to provide a novel flexible modeling technique for approximating an unknown density by a rich parametric family of densities, with the parameter being infinite dimensional, in contrast to the classical approach of finite dimensional approximation.

Various notations and definitions that are used throughout the paper are collected in Section 2. The proofs of the results are provided in Section 8, along with some supplementary results in an appendix.

2. Definitions & Notation

We introduce the notation used throughout the paper. Define $[d] := \{1, \ldots, d\}$. For $a := (a_1, \ldots, a_d) \in \mathbb{R}^d$ and $b := (b_1, \ldots, b_d) \in \mathbb{R}^d$, $\|a\|_2 := \sqrt{\sum_{i=1}^d a_i^2}$ and $\langle a, b \rangle := \sum_{i=1}^d a_i b_i$. For $a, b > 0$, we write $a \lesssim b$ if $a \leq \gamma b$ for some positive universal constant γ. For a topological space $\mathcal{X}$, $C(\mathcal{X})$ (*resp.* $C_b(\mathcal{X})$) denotes the space of all continuous (*resp.* bounded continuous) functions on $\mathcal{X}$. For a locally compact Hausdorff space $\mathcal{X}$, $f \in C(\mathcal{X})$ is said to *vanish at infinity* if for every $\epsilon > 0$ the set $\{x : |f(x)| \geq \epsilon\}$ is compact. The class of all continuous f on $\mathcal{X}$ which vanish at infinity is denoted as $C_0(\mathcal{X})$. For open $\mathcal{X} \subset \mathbb{R}^d$, $C^1(\mathcal{X})$ denotes the space of continuously differentiable functions on $\mathcal{X}$. For $f \in C_b(\mathcal{X})$, $\|f\|_\infty := \sup_{x \in \mathcal{X}} |f(x)|$ denotes the supremum norm of f. $M_b(\mathcal{X})$ denotes the set of all finite Borel measures on $\mathcal{X}$. For $\mu \in M_b(\mathcal{X})$, $L^r(\mathcal{X}, \mu)$ denotes the Banach space of r-power ($r \geq 1$) μ-integrable functions. For $\mathcal{X} \subset \mathbb{R}^d$, we will use $L^r(\mathcal{X})$ for $L^r(\mathcal{X}, \mu)$ if μ is a Lebesgue measure on $\mathcal{X}$. For $f \in L^p(\mathcal{X}, \mu)$, $\|f\|_{L^r(\mathcal{X},\mu)} := \left(\int_{\mathcal{X}} |f|^r \, d\mu\right)^{1/r}$ denotes the L^r-norm of f for $1 \leq r < \infty$ and we denote it as $\|\cdot\|_{L^r(\mathcal{X})}$ if $\mathcal{X} \subset \mathbb{R}^d$ and μ is the Lebesgue measure. The convolution $f * g$ of two measurable functions f and g on $\mathbb{R}^d$ is defined as

$$(f * g)(x) := \int_{\mathbb{R}^d} f(y) g(x - y) \, dy,$$

provided the integral exists for all $x \in \mathbb{R}^d$. The Fourier transform of $f \in L^1(\mathbb{R}^d)$ is defined as

$$f^\wedge(y) = (2\pi)^{-d/2} \int_{\mathbb{R}^d} f(x) \, e^{-i\langle y, x \rangle} \, dx$$

where i denotes the imaginary unit $\sqrt{-1}$.

In the following, for the sake of completeness and simplicity, we present definitions restricted to Hilbert spaces. Let H_1 and H_2 be abstract Hilbert spaces. A map $S : H_1 \to H_2$ is called a *linear operator* if it satisfies $S(\alpha x) = \alpha S x$ and $S(x + x') = Sx + Sx'$ for all $\alpha \in \mathbb{R}$ and $x, x' \in H_1$, where $Sx := S(x)$. A linear operator S is said to be *bounded*, i.e., the image SB_{H_1} of B_{H_1} under S is bounded if and only if there exists a constant $c \in [0, \infty)$ such that for all $x \in H_1$ we have $\|Sx\|_{H_2} \leq c \|x\|_{H_1}$, where $B_{H_1} := \{x \in H_1 : \|x\|_{H_1} \leq 1\}$. In this case, the *operator norm* of S is defined as $\|S\| := \sup\{\|Sx\|_{H_2} : x \in B_{H_1}\}$. Define $\mathcal{L}(H_1, H_2)$ be the space of bounded linear operators from H_1 to H_2. $S \in \mathcal{L}(H_1, H_2)$ is said to be *compact* if $\overline{SB_{H_1}}$ is a compact subset in H_2. The *adjoint operator* $S^* : H_2 \to H_1$ of $S \in \mathcal{L}(H_1, H_2)$ is defined by $\langle x, S^* y \rangle_{H_1} = \langle Sx, y \rangle_{H_2}$, $x \in H_1, y \in H_2$. $S \in \mathcal{L}(H) := \mathcal{L}(H, H)$ is called *self-adjoint* if $S^* = S$ and is called *positive* if $\langle Sx, x \rangle_H \geq 0$ for all $x \in H$. $\alpha \in \mathbb{R}$ is called an *eigenvalue* of $S \in \mathcal{L}(H)$ if there exists an $x \neq 0$ such that $Sx = \alpha x$ and such an x is called the *eigenvector* of S and α. For compact, positive, self-adjoint $S \in \mathcal{L}(H)$, $S^r : H \to H$, $r \geq 0$ is called a *fractional power* of S and $S^{1/2}$ is the *square root* of S, which we write as $\sqrt{S} := S^{1/2}$. An operator $S \in \mathcal{L}(H_1, H_2)$ is *Hilbert-Schmidt* if $\|S\|_{HS} := (\sum_{j \in J} \|Se_j\|_{H_2}^2)^{1/2} < \infty$ where $(e_j)_{j \in J}$ is an arbitrary orthonormal basis of separable Hilbert space H_1. $S \in \mathcal{L}(H_1, H_2)$ is said to be of *trace class* if $\sum_{j \in J} \langle (S^* S)^{1/2} e_j, e_j \rangle_{H_1} < \infty$. For $x \in H_1$ and $y \in H_2$, $x \otimes y$ is an element of the tensor product space $H_1 \otimes H_2$ which can also be seen as an operator from H_2 to H_1 as $(x \otimes y) z = x \langle y, z \rangle_{H_2}$ for any $z \in H_2$. $\mathcal{R}(S)$ denotes the *range space (or image)* of S.

A real-valued symmetric function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is called a positive definite (pd) kernel if, for all $n \in \mathbb{N}$, $\alpha_1, \ldots, \alpha_n \in \mathbb{R}$ and all $x_1, \ldots, x_n \in \mathcal{X}$, we have $\sum_{i,j=1}^n \alpha_i \alpha_j k(x_i, x_j) \geq 0$. A function $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, $(x, y) \mapsto k(x, y)$ is a *reproducing kernel* of the Hilbert space $(\mathcal{H}_k, \langle \cdot, \cdot \rangle_{\mathcal{H}_k})$ of functions if and only if (i) $\forall\, y \in \mathcal{X}$, $k(y, \cdot) \in \mathcal{H}_k$ and (ii) $\forall\, y \in \mathcal{X}$, $\forall\, f \in \mathcal{H}_k$, $\langle f, k(y, \cdot) \rangle_{\mathcal{H}_k} = f(y)$ hold. If such a k exists, then $\mathcal{H}_k$ is called a *reproducing kernel Hilbert space*. Since $\langle k(x, \cdot), k(y, \cdot) \rangle_{\mathcal{H}_k} = k(x, y)$, $\forall\, x, y \in \mathcal{X}$, it is easy to show that every reproducing kernel (r.k.) k is symmetric and positive definite. Some examples of kernels that appear throughout the paper are: *Gaussian kernel*, $k(x, y) = \exp(-\sigma \|x - y\|_2^2)$, $x, y \in \mathbb{R}^d$, $\sigma > 0$ that induces the following *Gaussian RKHS*,

$$\mathcal{H}_k = \mathcal{H}_\sigma := \left\{ f \in L^2(\mathbb{R}^d) \cap C(\mathbb{R}^d) \, : \, \int |f^\wedge(\omega)|^2 e^{\|\omega\|_2^2 / 4\sigma} \, d\omega < \infty \right\},$$

the *inverse multiquadric kernel*, $k(x, y) = (1 + \|\frac{x - y}{c}\|_2^2)^{-\beta}$, $x, y \in \mathbb{R}^d$, $\beta > 0$, $c \in (0, \infty)$ and the *Matérn kernel*, $k(x, y) = \frac{2^{1-\beta}}{\Gamma(\beta)} \|x - y\|_2^{\beta - d/2} \mathfrak{K}_{d/2 - \beta}(\|x - y\|_2)$, $x, y \in \mathbb{R}^d$, $\beta > d/2$ that induces the Sobolev space, H_2^β,

$$\mathcal{H}_k = H_2^\beta := \left\{ f \in L^2(\mathbb{R}^d) \cap C(\mathbb{R}^d) \, : \, \int (1 + \|\omega\|_2^2)^\beta |f^\wedge(\omega)|^2 \, d\omega < \infty \right\},$$

where Γ is the Gamma function, and $\mathfrak{K}_v$ is the modified Bessel function of the third kind of order v (v controls the smoothness of k).

For any real-valued function f defined on open $\mathcal{X} \subset \mathbb{R}^d$, f is said to be m-times continuously differentiable if for $\alpha \in \mathbb{N}_0^d$ with $|\alpha| := \sum_{i=1}^d \alpha_i \leq m$, $\partial^\alpha f(x) = \partial_1^{\alpha_1} \dots \partial_d^{\alpha_d} f(x) = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_d^{\alpha_d}} f(x)$ exists. A kernel k is said to be m-times continuously differentiable if $\partial^{\alpha,\alpha} k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ exists and is continuous for all $\alpha \in \mathbb{N}_0^d$ with $|\alpha| \leq m$ where $\partial^{\alpha,\alpha} := \partial_1^{\alpha_1} \dots \partial_d^{\alpha_d} \partial_{1+d}^{\alpha_1} \dots \partial_{2d}^{\alpha_d}$. Corollary 4.36 in Steinwart and Christmann (2008) and Theorem 1 in Zhou (2008) state that if $\partial^{\alpha,\alpha} k$ exists and is continuous, then $\partial^\alpha k(x, \cdot) = \partial_1^{\alpha_1} \dots \partial_d^{\alpha_d} k(x, \cdot) = \frac{\partial^{|\alpha|}}{\partial x_1^{\alpha_1} \dots \partial x_d^{\alpha_d}} k((x_1, \dots, x_d), \cdot) \in \mathcal{H}_k$ with $x = (x_1, \dots, x_d)$ and for every $f \in \mathcal{H}_k$, we have $\partial^\alpha f(x) = \langle \partial^\alpha k(x, \cdot), f \rangle_{\mathcal{H}_k}$ and $\partial^{\alpha,\alpha} k(x, x') = \langle \partial^\alpha k(x, \cdot), \partial^\alpha k(x', \cdot) \rangle_{\mathcal{H}_k}$.

Given two probability densities, p and q on $\Omega \subset \mathbb{R}^d$, the Kullback-Leibler divergence (KL) and Hellinger distance (h) are defined as $KL(p\|q) = \int p(x) \log \frac{p(x)}{q(x)} dx$ and $h(p, q) = \|\sqrt{p} - \sqrt{q}\|_{L^2(\Omega)}$ respectively. We refer to $\|p - q\|_{L^1(\Omega)}$ as the total variation (TV) distance between p and q.

3. Approximation of Densities by $\mathcal{P}$

In this section, we first show that every finite dimensional exponential family, $\mathscr{P}_{\text{fin}}$ is generated by the family $\mathcal{P}$ induced by a finite dimensional RKHS, which naturally leads to the infinite dimensional generalization of $\mathscr{P}_{\text{fin}}$ when $\mathcal{H}$ is an infinite dimensional RKHS. Next, we investigate the approximation properties of $\mathcal{P}$ in Proposition 1 and Corollary 2 when $\mathcal{H}$ is an infinite dimensional RKHS.

Let us consider a r-parameter exponential family, $\mathscr{P}_{\text{fin}}$ with sufficient statistic $T(x) := (T_1(x), \dots, T_r(x))$ and construct a Hilbert space, $\mathcal{H} = \text{span}\{T_1(x), \dots, T_r(x)\}$. It is easy to verify that $\mathcal{P}$ induced by $\mathcal{H}$ is exactly the same as $\mathscr{P}_{\text{fin}}$ since any $f \in \mathcal{H}$ can be written as $f(x) = \sum_{i=1}^r \theta_i T_i(x)$ for some $(\theta_i)_{i=1}^r \subset \mathbb{R}$. In fact, by defining the inner product between $f = \sum_{i=1}^r \theta_i T_i$ and $g = \sum_{i=1}^r \gamma_i T_i$ as $\langle f, g \rangle_{\mathcal{H}} := \sum_{i=1}^r \theta_i \gamma_i$, it follows that $\mathcal{H}$ is an RKHS with the r.k. $k(x, y) = \langle T(x), T(y) \rangle_{\mathbb{R}^r}$ since $\langle f, k(x, \cdot) \rangle_{\mathcal{H}} = \sum_{i=1}^r \theta_i T_i(x) = f(x)$. Based on this equivalence between $\mathscr{P}_{\text{fin}}$ and $\mathcal{P}$ induced by a finite dimensional RKHS, it is therefore clear that $\mathcal{P}$ induced by a infinite dimensional RKHS is a strict generalization to $\mathscr{P}_{\text{fin}}$ with $k(\cdot, x)$ playing the role of a sufficient statistic.

Example 1 *The following are some popular examples of probability distributions that belong to $\mathscr{P}_{\text{fin}}$. Here we show the corresponding RKHSs $(\mathcal{H}, k)$ that generate these distributions. In some of these examples, we choose $q_0(x) = 1$ and ignore the fact that q_0 is a probability distribution as assumed in the definition of $\mathcal{P}$.*

Exponential: $\Omega = \mathbb{R}_{++} := \mathbb{R}_+ \backslash \{0\}$, $k(x, y) = xy$.

Normal: $\Omega = \mathbb{R}$, $k(x, y) = xy + x^2 y^2$.

Beta: $\Omega = (0, 1)$, $k(x, y) = \log x \log y + \log(1 - x) \log(1 - y)$.

Gamma: $\Omega = \mathbb{R}_{++}$, $k(x, y) = \log x \log y + xy$.

Inverse Gaussian: $\Omega = \mathbb{R}_{++}$, $k(x, y) = xy + \frac{1}{xy}$.

Poisson: $\Omega = \mathbb{N} \cup \{0\}$, $k(x, y) = xy$, $q_0(x) = (x!\, e)^{-1}$.

Binomial: $\Omega = \{0, \dots, m\}$, $k(x, y) = xy$, $q_0(x) = 2^{-m} \binom{m}{c}$.

While Example 1 shows that all popular probability distributions are contained in $\mathcal{P}$ for an appropriate choice of finite-dimensional $\mathcal{H}$, it is of interest to understand the richness of $\mathcal{P}$ (i.e., what class of distributions can be approximated arbitrarily well by $\mathcal{P}$?) when $\mathcal{H}$ is an infinite dimensional RKHS. This is addressed by the following result, which is proved in Section 8.1.

Proposition 1 *Define*

$$\mathcal{P}_0 := \left\{ \pi_f(x) = e^{f(x) - A(f)} q_0(x),\ x \in \Omega : f \in C_0(\Omega) \right\}$$

where $\Omega \subseteq \mathbb{R}^d$ is locally compact Hausdorff. Suppose $k(x, \cdot) \in C_0(\Omega)$, $\forall\, x \in \Omega$ and

$$\int \int k(x, y)\, d\mu(x)\, d\mu(y) > 0,\ \forall\, \mu \in M_b(\Omega) \backslash \{0\}. \tag{5}$$

Then $\mathcal{P}$ is dense in $\mathcal{P}_0$ w.r.t. Kullback-Leibler divergence, total variation (L^1 norm) and Hellinger distances. In addition, if $q_0 \in L^1(\Omega) \cap L^r(\Omega)$ for some $1 < r \leq \infty$, then $\mathcal{P}$ is also dense in $\mathcal{P}_0$ w.r.t. L^r norm.

A sufficient condition for $\Omega \subseteq \mathbb{R}^d$ to be locally compact Hausdorff is that it is either open or closed. Condition (5) is equivalent to k being c_0-universal (Sriperumbudur et al., 2011, p. 2396). If $k(x, y) = \psi(x - y)$, $x, y \in \Omega = \mathbb{R}^d$ where $\psi \in C_b(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$, then (5) can be shown to be equivalent to $\text{supp}(\psi^\wedge) = \mathbb{R}^d$ (Sriperumbudur et al., 2011, Proposition 5). Examples of kernels that satisfy the conditions in Proposition 1 include the Gaussian, Matérn and inverse multiquadrics. In fact, any compactly supported non-zero $\psi \in C_b(\mathbb{R}^d)$ satisfies the assumptions in Proposition 1 as $\text{supp}(\psi^\wedge) = \mathbb{R}^d$ (Sriperumbudur et al., 2010, Corollary 10). Though $\mathcal{P}_0$ is still a parametric family of densities indexed by a Banach space (here $C_0(\Omega)$), the following corollary (proved in Section 8.2) to Proposition 1 shows that a broad class of continuous densities are contained in $\mathcal{P}_0$ and therefore can be approximated arbitrarily well in L^r norm ($1 \leq r \leq \infty$), Hellinger distance, and KL divergence by $\mathcal{P}$.

Corollary 2 *Let $q_0 \in C(\Omega)$ be a probability density such that $q_0(x) > 0$ for all $x \in \Omega$, where $\Omega \subseteq \mathbb{R}^d$ is locally compact Hausdorff. Suppose there exists a constant ℓ such that for any $\epsilon > 0$, $\exists\, R > 0$ that satisfies $|\frac{p(x)}{q_0(x)} - \ell| \leq \epsilon$ for any x with $\|x\|_2 > R$. Define*

$$\mathcal{P}_c := \left\{ p \in C(\Omega) : \int_\Omega p(x)\, dx = 1, p(x) \geq 0,\ \forall\, x \in \Omega \text{ and } \frac{p}{q_0} - \ell \in C_0(\Omega) \right\}.$$

Suppose $k(x, \cdot) \in C_0(\Omega)$, $\forall\, x \in \Omega$ and (5) holds. Then $\mathcal{P}$ is dense in $\mathcal{P}_c$ w.r.t. KL divergence, TV and Hellinger distances. Moreover, if $q_0 \in L^1(\Omega) \cap L^r(\Omega)$ for some $1 < r \leq \infty$, then $\mathcal{P}$ is also dense in $\mathcal{P}_c$ w.r.t. L^r norm.

By choosing Ω to be compact and q_0 to be a uniform distribution on Ω, Corollary 2 reduces to an easily interpretable result that any continuous density p_0 on Ω can be approximated arbitrarily well by densities in $\mathcal{P}$ in KL, Hellinger and L^r ($1 \leq r \leq \infty$) distances.

Similar to the results so far, an approximation result for $\mathcal{P}$ can also be obtained w.r.t. Fisher divergence (see Proposition 13). Since this result is heavily based on the notions and results developed in Section 5, we defer its presentation until that section. Briefly, this result states that if $\mathcal{H}$ is sufficiently rich (i.e., dense in an appropriate class of functions), then any $p \in C^1(\Omega)$ with $J(p\|q_0) < \infty$ can be approximated arbitrarily well by elements in $\mathcal{P}$ w.r.t. Fisher divergence, where $q_0 \in C^1(\Omega)$.

4. Density Estimation in $\mathcal{P}$: Well-specified Case

In this section, we present our score matching estimator for an unknown density $p_0 := p_{f_0} \in \mathcal{P}$ (well-specified case) from i.i.d. random samples $(X_a)_{a=1}^n$ drawn from it. This involves choosing the minimizer of the (empirical) Fisher divergence between p_0 and $p_f \in \mathcal{P}$ as the estimator, $\hat{f}$ which we show in Theorem 5 to be obtained by solving a simple finite-dimensional linear system. In contrast, we would like to remind the reader that the MLE is infeasible in practice due to the difficulty in handling $A(f)$. The consistency and convergence rates of $\hat{f} \in \mathcal{F}$ and the plug-in estimator $p_{\hat{f}}$ are provided in Section 4.1 (see Theorems 6 and 7). Before we proceed, we list the assumptions on p_0, q_0 and $\mathcal{H}$ that we need in our analysis.

(A) Ω is a non-empty open subset of $\mathbb{R}^d$ with a piecewise smooth boundary $\partial\Omega := \overline{\Omega}\backslash\Omega$, where $\overline{\Omega}$ denotes the closure of Ω.

(B) p_0 is continuously extendible to $\overline{\Omega}$. k is twice continuously differentiable on $\Omega \times \Omega$ with continuous extension of $\partial^{\alpha,\alpha}k$ to $\overline{\Omega} \times \overline{\Omega}$ for $|\alpha| \leq 2$.

(C) $\partial_i\partial_{i+d}k(x,x)p_0(x) = 0$ for $x \in \partial\Omega$ and $\sqrt{\partial_i\partial_{i+d}k(x,x)}p_0(x) = o(\|x\|_2^{1-d})$ as $x \in \Omega$, $\|x\|_2 \to \infty$ for all $i \in [d]$.

(D) *(ε-Integrability)* For some $\varepsilon \geq 1$ and $\forall\, i \in [d]$, $\partial_i\partial_{i+d}k(x,x)$, $\sqrt{\partial_i^2\partial_{i+d}^2k(x,x)}$ and $\sqrt{\partial_i\partial_{i+d}k(x,x)}\partial_i \log q_0(x) \in L^\varepsilon(\Omega, p_0)$, where $q_0 \in C^1(\Omega)$.

Remark 3 (i) *Ω being a subset of $\mathbb{R}^d$ along with k being continuous ensures that $\mathcal{H}$ is separable (Steinwart and Christmann, 2008, Lemma 4.33). The twice differentiability of k ensures that every $f \in \mathcal{H}$ is twice continuously differentiable (Steinwart and Christmann, 2008, Corollary 4.36).* **(C)** *ensures that J in (3) is equivalent to the one in (4) through integration by parts on Ω (see Corollary 7.6.2 in Duistermaat and Kolk, 2004 for integration by parts on bounded subsets of $\mathbb{R}^d$ which can be extended to unbounded Ω through a truncation and limiting argument) for densities in $\mathcal{P}$. In particular,* **(C)** *ensures that $\int_\Omega \partial_i f(x)\partial_i p_0(x)\,dx = -\int_\Omega \partial_i^2 f(x)p_0(x)\,dx$ for all $f \in \mathcal{H}$ and $i \in [d]$, which will be critical to prove the representation in Theorem 4(ii), upon which rest of the results depend. The decay condition in* **(C)** *can be weakened to $\sqrt{\partial_i\partial_{i+d}k(x,x)}p_0(x) = o(\|x\|_2^{1-\overline{d}})$ as $x \in \Omega$, $\|x\|_2 \to \infty$ for all $i \in [d]$ if Ω is a (possibly unbounded) box where $\overline{d} = \#\{i \in [d] | (a_i, b_i)$ is unbounded$\}$.*

(ii) *When $\varepsilon = 1$, the first condition in* **(D)** *ensures that $J(p_0\|p_f) < \infty$ for any $p_f \in \mathcal{P}$. The other two conditions ensure the validity of the alternate representation for $J(p_0\|p_f)$ in (4) which will be useful in constructing estimators of p_0 (see Theorem 4). Examples of kernels that satisfy* **(D)** *are the Gaussian, Matérn (with $\beta > \max\{2, d/2\}$), and inverse multiquadric kernels, for which it is easy to show that there exists q_0 that satisfies* **(D)**.

(iii) (Identifiability) *The above list of assumptions do not include the identifiability condition that ensures $p_{f_1} = p_{f_2}$ if and only if $f_1 = f_2$. It is clear that if constant functions are included in $\mathcal{H}$, i.e., $1 \in \mathcal{H}$, then $p_f = p_{f+c}$ for any $c \in \mathbb{R}$. On the other hand, it can be shown that if $1 \notin \mathcal{H}$ and $\operatorname{supp}(q_0) = \Omega$, then $p_{f_1} = p_{f_2} \Leftrightarrow f_1 = f_2$. A sufficient condition for $1 \notin \mathcal{H}$ is $k \in C_0(\Omega \times \Omega)$. We do not explicitly impose the identifiability condition as a part of our blanket assumptions because the assumptions under which consistency and rates are obtained in Theorem 7 automatically ensure identifiability.*

Under these assumptions, the following result—proved in Section 8.3—shows that the problem of estimating p_0 through the minimization of Fisher divergence reduces to the problem of estimating f_0 through a weighted least squares minimization in $\mathcal{H}$ (see parts (i) and (ii)). This motivates the minimization of the regularized empirical weighted least squares (see part (iv)) to obtain an estimator $f_{\lambda,n}$ of f_0, which is then used to construct the plug-in estimate $p_{f_{\lambda,n}}$ of p_0.

Theorem 4 *Suppose* **(A)**–**(D)** *hold with $\varepsilon = 1$. Then $J(p_0\|p_f) < \infty$ for all $f \in \mathcal{F}$. In addition, the following hold.*

(i) For all $f \in \mathcal{F}$,

$$J(f) := J(p_0\|p_f) = \frac{1}{2}\langle f - f_0, C(f - f_0)\rangle_{\mathcal{H}}, \tag{6}$$

where $C : \mathcal{H} \to \mathcal{H}$, $C := \int_\Omega p_0(x)\sum_{i=1}^d \partial_i k(x,\cdot) \otimes \partial_i k(x,\cdot)\,dx$ is a trace-class positive operator with

$$Cf = \int_\Omega p_0(x)\sum_{i=1}^d \partial_i k(x,\cdot)\partial_i f(x)\,dx.$$

(ii) Alternatively,

$$J(f) = \frac{1}{2}\langle f, Cf\rangle_{\mathcal{H}} + \langle f, \xi\rangle_{\mathcal{H}} + J(p_0\|q_0)$$

where

$$\xi := \int_\Omega p_0(x)\sum_{i=1}^d \left(\partial_i k(x,\cdot)\partial_i \log q_0(x) + \partial_i^2 k(x,\cdot)\right)\,dx \in \mathcal{H}$$

and f_0 satisfies $Cf_0 = -\xi$.

(iii) For any $\lambda > 0$, a unique minimizer f_λ of $J_\lambda(f) := J(f) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2$ over $\mathcal{H}$ exists and is given by

$$f_\lambda = -(C + \lambda I)^{-1}\xi = (C + \lambda I)^{-1}Cf_0.$$

(iv) ***(Estimator of f_0)*** *Given samples $(X_a)_{a=1}^n$ drawn i.i.d. from p_0, for any $\lambda > 0$, the unique minimizer $f_{\lambda,n}$ of $\hat{J}_\lambda(f) := \hat{J}(f) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2$ over $\mathcal{H}$ exists and is given by*

$$f_{\lambda,n} = -(\hat{C} + \lambda I)^{-1}\hat{\xi},$$

where $\hat{J}(f) := \frac{1}{2}\langle f, \hat{C}f\rangle_{\mathcal{H}} + \langle f, \hat{\xi}\rangle_{\mathcal{H}} + J(p_0\|q_0)$, $\hat{C} := \frac{1}{n}\sum_{a=1}^{n}\sum_{i=1}^{d} \partial_i k(X_a,\cdot)\otimes\partial_i k(X_a,\cdot)$ *and*

$$\hat{\xi} := \frac{1}{n}\sum_{a=1}^{n}\sum_{i=1}^{d}\left(\partial_i k(X_a,\cdot)\partial_i \log q_0(X_a) + \partial_i^2 k(X_a,\cdot)\right).$$

An advantage of the alternate formulation of $J(f)$ in Theorem 4(ii) over (6) is that it provides a simple way to obtain an empirical estimate of $J(f)$—by replacing C and ξ by their empirical estimators, $\hat{C}$ and $\hat{\xi}$ respectively—from finite samples drawn i.i.d. from p_0, which is then used to obtain an estimator of f_0. Note that the empirical estimate of $J(f)$, i.e., $\hat{J}(f)$ depends only on $\hat{C}$ and $\hat{\xi}$ which in turn depend on the known quantities, k and q_0, and therefore $f_{\lambda,n}$ in Theorem 4(iv) should in principle be computable. In practice, however, it is not easy to compute the expression for $f_{\lambda,n} = -(\hat{C}+\lambda I)^{-1}\hat{\xi}$ as it involves solving an infinite dimensional linear system. In Theorem 5 (proved in Section 8.4), we provide an alternative expression for $f_{\lambda,n}$ as a solution of a simple finite-dimensional linear system (see (7) and (8)), using the general representer theorem (see Theorem A.2). It is interesting to note that while the solution to $J(f)$ in Theorem 4(ii) is obtained by solving a non-linear system, $Cf_0 = -\xi$ (the system is non-linear as C depends on p_0 which in turn depends on f_0), its estimator $f_{\lambda,n}$ proposed in Theorem 4, is obtained by solving a simple linear system. In addition, we would like to highlight the fact that the proposed estimator, $f_{\lambda,n}$ is precisely the Tikhonov regularized solution (which is well-studied in the theory of linear inverse problems) to the ill-posed linear system $\hat{C}f = -\hat{\xi}$. We further discuss the choice of regularizer in Section 4.3 using ideas from the inverse problem literature.

An important remark we would like to make about Theorem 4 is that though $J(f)$ in (6) is valid only for $f \in \mathcal{F}$, as it is obtained from $J(p_0\|p_f)$ where $p_0, p_f \in \mathcal{P}$, the expression $\langle f-f_0, C(f-f_0)\rangle_{\mathcal{H}}$ is valid for any $f \in \mathcal{H}$, as it is finite under the assumption that **(D)** holds with $\varepsilon = 1$. Therefore, in Theorem 4(iii, iv), f_λ and $f_{\lambda,n}$ are obtained by minimizing J_λ and $\hat{J}_\lambda$ over $\mathcal{H}$ instead of over $\mathcal{F}$, as the latter does not yield a nice expression (unlike f_λ and $f_{\lambda,n}$, respectively). However, there is no guarantee that $f_{\lambda,n} \in \mathcal{F}$, and so the density estimator $p_{f_{\lambda,n}}$ may not be valid. While this is not an issue when studying the convergence of $\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$ (see Theorem 6), the convergence of $p_{f_{\lambda,n}}$ to p_0 (in various distances) needs to be handled slightly differently depending on whether the kernel is bounded or not (see Theorems 7 and B.2). Note that when the kernel is bounded, we obtain $\mathcal{F} = \mathcal{H}$, which implies $p_{f_{\lambda,n}}$ is valid.

Theorem 5 (Computation of $f_{\lambda,n}$) *Let* $f_{\lambda,n} = \arg\inf_{f\in\mathcal{H}} \hat{J}_\lambda(f)$, *where* $\hat{J}_\lambda(f)$ *is defined in Theorem 4(iv) and* $\lambda > 0$. *Then*

$$f_{\lambda,n} = -\frac{\hat{\xi}}{\lambda} + \sum_{a=1}^{n}\sum_{i=1}^{d}\beta_{(a-1)d+i}\partial_i k(X_a,\cdot), \tag{7}$$

where $\hat{\xi}$ *is defined in Theorem 4(iv) and* $\boldsymbol{\beta} = (\beta_{(a-1)d+i})_{a,i}$ *is obtained by solving*

$$(\boldsymbol{G} + n\lambda I)\,\boldsymbol{\beta} = \frac{1}{\lambda}\boldsymbol{h} \tag{8}$$

with $(\boldsymbol{G})_{(a-1)d+i,(b-1)d+j} = \partial_i\partial_{j+d}k(X_a,X_b)$ *and*

$$(\boldsymbol{h})_{(a-1)d+i} = \langle\hat{\xi}, \partial_i k(X_a,\cdot)\rangle_{\mathcal{H}} = \frac{1}{n}\sum_{b=1}^{n}\sum_{j=1}^{d}\partial_i\partial_{j+d}^2 k(X_a,X_b) + \partial_i\partial_{j+d}k(X_a,X_b)\partial_j \log q_0(X_b).$$

We would like to highlight that though $f_{\lambda,n}$ requires solving a simple linear system in (8), it can still be computationally intensive when d and n are large as $\boldsymbol{G}$ is a $nd\times nd$ matrix. This is still a better scenario than that of MLE, however, since computationally efficient methods exist to solve large linear systems such as (8), whereas MLE can be intractable due to the difficulty in handling the log-partition function (though it can be approximated). On the other hand, MLE is statistically well-understood, with consistency and convergence rates established in general for the problem of density estimation (van de Geer, 2000) and in particular for the problem at hand (Fukumizu, 2009). In order to ensure that $f_{\lambda,n}$ and $p_{f_{\lambda,n}}$ are statistically useful, in the following section, we investigate their consistency and convergence rates under some smoothness conditions on f_0.

4.1 Consistency and Rate of Convergence

In this section, we prove the consistency of $f_{\lambda,n}$ (see Theorem 6(i)) and $p_{f_{\lambda,n}}$ (see Theorems 7 and B.2). Under the smoothness assumption that $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta > 0$, we present convergence rates for $f_{\lambda,n}$ and $p_{f_{\lambda,n}}$ in Theorems 6(ii), 7 and B.2. In reference to the following results, for simplicity we suppress the dependence of λ on n by defining $\lambda := \lambda_n$ where $(\lambda_n)_{n\in\mathbb{N}} \subset (0,\infty)$.

Theorem 6 (Consistency and convergence rates for $f_{\lambda,n}$) *Suppose* **(A)**–**(D)** *with* $\varepsilon = 2$ *hold.*

(i) If $f_0 \in \overline{\mathcal{R}(C)}$, *then* $\|f_{\lambda,n} - f_0\|_{\mathcal{H}} \xrightarrow{p_0} 0$ *as* $\lambda\to 0$, $\lambda\sqrt{n}\to\infty$ *and* $n\to\infty$.

(ii) If $f_0 \in \mathcal{R}(C^\beta)$ *for some* $\beta > 0$, *then for* $\lambda = n^{-\max\left\{\frac{1}{4},\frac{1}{2(\beta+1)}\right\}}$,

$$\|f_{\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}\left(n^{-\min\left\{\frac{1}{4},\frac{\beta}{2(\beta+1)}\right\}}\right) \text{ as } n\to\infty.$$

(iii) If $\|C^{-1}\| < \infty$, *then for* $\lambda = n^{-\frac{1}{2}}$, $\|f_{\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}(n^{-1/2})$ *as* $n\to\infty$.

Remark *(i)* While Theorem 6 (proved in Section 8.5) provides an asymptotic behavior for $\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$ under conditions that depend on p_0 (and are therefore not easy to check in practice), a non-asymptotic bound on $\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$ that holds for all $n \geq 1$ can be obtained under stronger assumptions through an application of Bernstein's inequality in separable Hilbert spaces. For the sake of simplicity, we provided asymptotic results which are obtained through an application of Chebyshev's inequality.

(ii) The proof of Theorem 6(i) involves decomposing $\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$ into an estimation error part, $\mathcal{E}(\lambda,n) := \|f_{\lambda,n} - f_\lambda\|_{\mathcal{H}}$, and an approximation error part, $\mathcal{A}_0(\lambda) := \|f_\lambda - f_0\|_{\mathcal{H}}$, where $f_\lambda = (C+\lambda I)^{-1}Cf_0$. While $\mathcal{E}(\lambda,n)\to 0$ as $\lambda\to 0$, $\lambda\sqrt{n}\to\infty$ and $n\to\infty$ without any assumptions on f_0 (see the proof in Section 8.5 for details), it is not reasonable to expect

$\mathcal{A}_0(\lambda) \to 0$ as $\lambda \to 0$ without assuming $f_0 \in \overline{\mathcal{R}(C)}$. This is because, if f_0 lies in the null space of C, then f_λ is zero irrespective of λ and therefore cannot approximate f_0.

(iii) The condition $f_0 \in \overline{\mathcal{R}(C)}$ is difficult to check in practice as it depends on p_0 (which in turn depends on f_0). However, since the null space of C is just constant functions if the kernel is bounded and $supp(q_0) = \Omega$ (see Lemma 14 in Section 8.6 for details), assuming $1 \notin \mathcal{H}$ yields that $\overline{\mathcal{R}(C)} = \mathcal{H}$ and therefore consistency can be attained under conditions that are easy to impose in practice. As mentioned in Remark 3(iii), the condition $1 \notin \mathcal{H}$ ensures identifiability and a sufficient condition for it to hold is $k \in C_0(\Omega \times \Omega)$, which is satisfied by Gaussian, Matérn and inverse multiquadric kernels.

(iv) It is well known that convergence rates are possible only if the quantity of interest (here f_0) satisfies some additional conditions. In function estimation, this additional condition is classically imposed by assuming f_0 to be sufficiently smooth, e.g., f_0 lies in a Sobolev space of certain smoothness. By contrast, the smoothness condition in Theorem 6(ii) is imposed in an indirect manner by assuming $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta > 0$—so that the results hold for abstract RKHSs and not just Sobolev spaces—which then provides a rate, with the best rate being $n^{-1/4}$ that is attained when $\beta \geq 1$. While such a condition has already been used in various works (Caponnetto and Vito, 2007; Smale and Zhou, 2007; Fukumizu et al., 2013) in the context of non-parametric least squares regression, we explore it in more detail in Proposition 8, and Examples 2 and 3. Note that this condition is common in the inverse problem theory (see Engl, Hanke, and Neubauer, 1996), and it naturally arises here through the connection of $f_{\lambda,n}$ being a Tikhonov regularized solution to the ill-posed linear system $\hat{C}f = -\hat{\xi}$. An interesting observation about the rate is that it does not improve with increasing β (for $\beta > 1$), in contrast to the classical results in function estimation (e.g., kernel density estimation and kernel regression) where the rate improves with increasing smoothness. This issue is discussed in detail in Section 4.3.

(v) Since $\|C^{-1}\| < \infty$ only if $\mathcal{H}$ is finite-dimensional, we recover the parametric rate of $n^{-1/2}$ in a finite-dimensional situation with an automatic choice for λ as $n^{-1/2}$.While Theorem 6 provides statistical guarantees for parameter convergence, the question of primary interest is the convergence of $p_{f_{\lambda,n}}$ to p_0. This is guaranteed by the following result, which is proved in Section 8.6.

Theorem 7 (Consistency and rates for $p_{f_{\lambda,n}}$) *Suppose* **(A)**–**(D)** *with* $\varepsilon = 2$ *hold and* $\|k\|_\infty := \sup_{x\in\Omega} k(x,x) < \infty$. *Assume* $\operatorname{supp}(q_0) = \Omega$. *Then the following hold:*

(i) For any $1 < r \leq \infty$ *with* $q_0 \in L^1(\Omega) \cap L^r(\Omega)$,

$$\|p_{f_{\lambda,n}} - p_0\|_{L^r(\Omega)} \to 0,\ h(p_{f_{\lambda,n}}, p_0) \to 0,\ KL(p_0 \| p_{f_{\lambda,n}}) \to 0 \ \text{ as } \lambda\sqrt{n} \to \infty,\ \lambda \to 0 \text{ and } n \to \infty.$$

In addition, if $f_0 \in \mathcal{R}(C^\beta)$ *for some* $\beta > 0$, *then for* $\lambda = n^{-\max\left\{\frac{1}{4}, \frac{1}{2(\beta+1)}\right\}}$,

$$\|p_{f_{\lambda,n}} - p_0\|_{L^r(\Omega)} = O_{p_0}(\theta_n),\ h(p_0, p_{f_{\lambda,n}}) = O_{p_0}(\theta_n),\ KL(p_0 \| p_{f_{\lambda,n}}) = O_{p_0}(\theta_n^2)$$

as $n \to \infty$ *where* $\theta_n := n^{-\min\left\{\frac{1}{4}, \frac{\beta}{2(\beta+1)}\right\}}$.

(ii) $J(p_0 \| p_{f_{\lambda,n}}) \to 0$ *as* $\lambda n \to \infty$, $\lambda \to 0$ *and* $n \to \infty$. *In addition, if* $f_0 \in \mathcal{R}(C^\beta)$ *for some* $\beta \geq 0$, *then for* $\lambda = n^{-\max\left\{\frac{1}{3}, \frac{1}{2(\beta+1)}\right\}}$,

$$J(p_0 \| p_{f_{\lambda,n}}) = O_{p_0}\left(n^{-\min\left\{\frac{2}{3}, \frac{2\beta+1}{2(\beta+1)}\right\}}\right) \ \text{ as } n \to \infty.$$

(iii) If $\|C^{-1}\| < \infty$, *then* $\theta_n = n^{-\frac{1}{2}}$ *and* $J(p_0 \| p_{f_{\lambda,n}}) = O_{p_0}(n^{-1})$ *with* $\lambda = n^{-\frac{1}{2}}$.

Remark *(i)* Comparing the results of Theorem 6(i) and Theorem 7(i) (for L^r, Hellinger and KL divergence), we would like to highlight that while the conditions on λ and n match in both the cases, the latter does not require $f_0 \in \overline{\mathcal{R}(C)}$ to ensure consistency. While $f_0 \in \overline{\mathcal{R}(C)}$ can be imposed in Theorem 7 to attain consistency, we replaced this condition with $supp(q_0) = \Omega$—a simple and easy condition to work with—which along with the boundedness of the kernel ensures that for any $f_0 \in \mathcal{H}$, there exists $\tilde{f}_0 \in \overline{\mathcal{R}(C)}$ such that $p_{\tilde{f}_0} = p_0$ (see Lemma 14).

(ii) In contrast to the results in L^r, Hellinger and KL divergence, consistency in J can be obtained with λ converging to zero at a rate faster than in these results. In addition, one can obtain rates in J with $\beta = 0$, i.e., no smoothness assumption on f_0, while no rates are possible in other distances (the latter might also be an artifact of the proof technique, as these results are obtained through an application of Theorem 6(ii) in Lemma A.1) which is due to the fact that the convergence in these other distances is based on the convergence of $\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$, which in turn involves convergence of $\mathcal{A}_0(\lambda) := \|f_\lambda - f_0\|_{\mathcal{H}}$ to zero while the convergence in J is controlled by $\mathcal{A}_{\frac{1}{2}}(\lambda) := \|\sqrt{C}(f_\lambda - f_0)\|_{\mathcal{H}}$ which can be shown to behave as $O(\sqrt{\lambda})$ as $\lambda \to 0$, without requiring any assumptions on f_0 (see Proposition A.3). Indeed, as a further consequence, the rate of convergence in J is faster than in other distances.

(iii) An interesting aspect in Theorem 7 is that $p_{f_{\lambda,n}}$ is consistent in various distances such as L^r, Hellinger and KL, despite being obtained by minimizing a different loss function, i.e., J. However, we will see in Section 5 that such nice results are difficult to obtain in the misspecified case, where consistency and rates are provided only in J.

While Theorem 7 addresses the case of bounded kernels, the case of unbounded kernels requires a technical modification. The reason for this modification, as alluded to in the discussion following Theorem 4, is due to the fact that $f_{\lambda,n}$ may not be in $\mathcal{F}$ when k is unbounded, and therefore the corresponding density estimator, $p_{f_{\lambda,n}}$ may not be well-defined. In order to keep the main ideas intact, we discuss the unbounded case in detail in Section B.2 in Appendix B.

4.2 Range Space Assumption

While Theorems 6 and 7 are satisfactory from the point of view of consistency, we believe the presented rates are possibly not minimax optimal since these rates are valid for any RKHS that satisfies the conditions **(A)**–**(D)** and does not capture the smoothness of k (and therefore the corresponding $\mathcal{H}$). In other words, the rates presented in Theorems 6 and 7 should depend on the decay rate of the eigenvalues of C which in turn effectively captures the smoothness of $\mathcal{H}$. However, we are not able to obtain such a result—see the remark following the proof of Theorem 6 for a discussion. While these rates do not reflect

the intrinsic smoothness of $\mathcal{H}$, they are obtained under the smoothness assumption, i.e., *range space condition* that $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta > 0$. This condition is quite different from the classical smoothness conditions that appear in non-parametric function estimation. While the range space assumption has been made in various earlier works (e.g., Caponnetto and Vito (2007); Smale and Zhou (2007); Fukumizu et al. (2013) in the context of non-parametric least square regression), in the following, we investigate the implicit smoothness assumptions that it makes on f_0 in our context. To this end, first it is easy to show (see the proof of Proposition B.3 in Section B.3) that

$$\mathcal{R}(C^\beta) = \left\{ \sum_{i\in I} c_i \phi_i \,:\, \sum_{i\in I} c_i^2 \alpha_i^{-2\beta} < \infty \right\}, \tag{9}$$

where $(\alpha_i)_{i\in I}$ are the positive eigenvalues of C, $(\phi_i)_{i\in I}$ are the corresponding eigenvectors that form an orthonormal basis for $\mathcal{R}(C)$, and I is an index set which is either finite (if $\mathcal{H}$ is finite-dimensional) or $I = \mathbb{N}$ with $\lim_{i\to\infty} \alpha_i = 0$ (if $\mathcal{H}$ is infinite dimensional). From (9) it is clear that larger the value of β, the faster is the decay of the Fourier coefficients $(c_i)_{i\in I}$, which in turn implies that the functions in $\mathcal{R}(C^\beta)$ are smoother. Using (9), an interpretation can be provided for $\mathcal{R}(C^\beta)$ ($\beta > 0$ and $\beta \notin \mathbb{N}$) as interpolation spaces (see Section A.5 for the definition of interpolation spaces) between $\mathcal{R}(C^{\lceil\beta\rceil})$ and $\mathcal{R}(C^{\lfloor\beta\rfloor})$ where $\mathcal{R}(C^0) := \mathcal{H}$ (see Proposition B.3 for details). While it is not completely straightforward to obtain a sufficient condition for $f_0 \in \mathcal{R}(C^\beta)$, $\beta \in \mathbb{N}$, the following result provides a necessary condition for $f_0 \in \mathcal{R}(C)$ (and therefore a necessary condition for $f_0 \in \mathcal{R}(C^\beta)$, $\forall\, \beta > 1$) for translation invariant kernels on $\Omega = \mathbb{R}^d$, whose proof is presented in Section 8.7.

Proposition 8 (Necessary condition) *Suppose $\psi, \phi \in C_b(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$ are positive definite functions on $\mathbb{R}^d$ with Fourier transforms $\psi^\wedge$ and $\phi^\wedge$ respectively. Let $\mathcal{H}$ and $\mathcal{G}$ be the RKHSs associated with $k(x,y) = \psi(x-y)$ and $l(x,y) = \phi(x-y), x, y \in \mathbb{R}^d$ respectively. For $1 \le r \le 2$, suppose the following hold:*

(i) $\int_{\mathbb{R}^d} \|\omega\|_2^2 \psi^\wedge(\omega)\, d\omega < \infty$; (ii) $\left\| \frac{\phi^\wedge}{\psi^\wedge} \right\|_\infty < \infty$; (iii) $\frac{\|\cdot\|_2^2 (\psi^\wedge)^2}{\phi^\wedge} \in L^{\frac{r}{2-r}}(\mathbb{R}^d)$; (iv) $q_0 \in L^r(\mathbb{R}^d)$.

Then $f_0 \in \mathcal{R}(C)$ implies $f_0 \in \mathcal{G} \subset \mathcal{H}$.

In the following, we apply the above result in two examples involving Gaussian and Matérn kernels to get insights into the range space assumption.

Example 2 (Gaussian kernel) *Let $\psi(x) = e^{-\sigma\|x\|^2}$ with $\mathcal{H}_\sigma$ as its corresponding RKHS (see Section 2 for its definition). By Proposition 8, it is easy to verify that $f_0 \in \mathcal{R}(C)$ implies $f_0 \in \mathcal{H}_\alpha \subset \mathcal{H}_\sigma$ for $\frac{\sigma}{2} < \alpha \le \sigma$. Since $\mathcal{H}_\beta \subset \mathcal{H}_\gamma$ for $\beta < \gamma$ (i.e., Gaussian RKHSs are nested), $f_0 \in \mathcal{R}(C)$ ensures that f_0 lies in $\mathcal{H}_{\frac{\sigma}{2}+\epsilon}$ for arbitrary small $\epsilon > 0$.*

Example 3 (Matérn kernel) *Let $\psi(x) = \frac{2^{1-s}}{\Gamma(s)} \|x\|_2^{s-\frac{d}{2}} \mathfrak{K}_{d/2-s}(\|x\|_2)$, $x \in \mathbb{R}^d$ with $H_2^s(\mathbb{R}^d)$ as its corresponding RKHS (see Section 2 for its definition) where $s > \frac{d}{2}$. By Proposition 8, we have that for $q_0 \in L^1(\mathbb{R}^d)$, if $f_0 \in \mathcal{R}(C)$, then $f_0 \in H_2^\alpha(\mathbb{R}^d) \subset H_2^s(\mathbb{R}^d)$ for $1 + \frac{d}{2} < s \le \alpha < 2s - 1 - \frac{d}{2}$. Since $H_2^\delta(\mathbb{R}^d) \subset H_2^\gamma(\mathbb{R}^d)$ for $\gamma < \delta$ (i.e., Sobolev spaces are nested), this means f_0 lies in $H_2^{2s-1-\frac{d}{2}-\epsilon}(\mathbb{R}^d)$ for arbitrarily small $\epsilon > 0$, i.e., f_0 has at least $2s - 1 - \lceil \frac{d}{2} \rceil$ weak-derivatives. By the minimax theory (Tsybakov, 2009, Chapter 2), it is well known that for any $\alpha > \delta \ge 0$,*

$$\inf_{\hat{f}_n} \sup_{f_0 \in H_2^\alpha(\mathbb{R}^d)} \|\hat{f}_n - f_0\|_{H_2^\delta(\mathbb{R}^d)} \asymp n^{-\frac{\alpha-\delta}{2(\alpha-\delta)+d}}, \tag{10}$$

where the infimum is taken over all possible estimators. Here $a_n \asymp b_n$ means that for any two sequences $a_n, b_n > 0$, a_n/b_n is bounded away from zero and infinity as $n \to \infty$. Suppose $f_0 \notin H_2^\alpha(\mathbb{R}^d)$ for $\alpha \ge 2s - 1 - \frac{d}{2}$, which means $f_0 \in H_2^{2s-1-\frac{d}{2}-\epsilon}(\mathbb{R}^d)$ for arbitrarily small $\epsilon > 0$. This implies that the rate of $n^{-1/4}$ obtained in Theorem 6 is minimax optimal if $\mathcal{H}$ is chosen to be $H_2^{1+d+\epsilon}(\mathbb{R}^d)$ (i.e., choose $\alpha = 2s - 1 - \frac{d}{2} - \epsilon$ and $\delta = s$ in (10) and solve for s by equating the exponent in the r.h.s. of (10) to $-\frac{1}{4}$). Similarly, it can be shown that if $q_0 \in L^2(\mathbb{R}^d)$, then the rate of $n^{-1/4}$ in Theorem 6 is minimax optimal if $\mathcal{H}$ is chosen to be $H_2^{1+\frac{d}{2}+\epsilon}(\mathbb{R}^d)$. This example also explains away the dimension independence of the rate provided by Theorem 6 by showing that the dimension effect is captured in the relative smoothness of f_0 w.r.t. $\mathcal{H}$.

While Example 3 provides some understanding about the minimax optimality of $f_{\lambda,n}$ under additional assumptions on f_0, the problem is not completely resolved. In the following section, however, we show that the rate in Theorem 6 is not optimal for $\beta > 1$, and that improved rates can be obtained by choosing the regularizer appropriately.

4.3 Choice of Regularizer

We understand from the characterization of $\mathcal{R}(C^\beta)$ in (9) that larger β values yield smoother functions in $\mathcal{H}$. However, the smoothness of $f_0 \in \mathcal{R}(C^\beta)$ for $\beta > 1$ is not captured in the rates in Theorem 6(ii), where the rate saturates at $\beta = 1$ providing the best possible rate of $n^{-1/4}$ (irrespective of the size of β). This is unsatisfactory on the part of the estimator, as it does not effectively capture the smoothness of f_0, i.e., the estimator is not adaptive to the smoothness of f_0. We remind the reader that the estimator $f_{\lambda,n}$ is obtained by minimizing the regularized empirical Fisher divergence (see Theorem 4(iv)) yielding $f_{\lambda,n} = -(\hat{C} + \lambda I)^{-1}\hat{\xi}$, which can be seen as a heuristic to solve the (non-linear) inverse problem $Cf_0 = -\xi$ (see Theorem 4(ii)) from finite samples, by replacing C and ξ with their empirical counterparts. This heuristic, which ensures that the finite sample inverse problem is well-posed, is popular in inverse problem literature under the name of Tikhonov regularization (Engl et al., 1996, Chapter 5). Note that Tikhonov regularization helps to make the ill-posed inverse problem a well-posed one by approximating α^{-1} by $(\alpha + \lambda)^{-1}$, $\lambda > 0$, where α^{-1} appears as the inverse of the eigenvalues of C while computing C^{-1}. In other words, if $\hat{C}$ is invertible, then an estimate of f_0 can be obtained as $\hat{f}_n = -\hat{C}^{-1}\hat{\xi}$, i.e., $\hat{f}_n = -\sum_{i\in I} \frac{\langle \hat{\xi}, \hat{\phi}_i \rangle_{\mathcal{H}}}{\hat{\alpha}_i} \hat{\phi}_i$, where $(\hat{\alpha}_i)_{i\in I}$ and $(\hat{\phi}_i)_{i\in I}$ are the eigenvalues and eigenvectors of $\hat{C}$ respectively. However, $\hat{C}$ being a rank n operator defined on $\mathcal{H}$ (which can be infinite dimensional) is not invertible and therefore the regularized estimator is constructed as $f_{\lambda,n} = -g_\lambda(\hat{C})\hat{\xi}$ where $g_\lambda(\hat{C})$ is defined through functional calculus (see Engl, Hanke, and

Neubauer, 1996, Section 2.3) as

$$g_\lambda(\hat{C}) = \sum_{i \in I} g_\lambda(\hat{\alpha}_i) \langle \cdot, \hat{\phi}_i \rangle_{\mathcal{H}} \hat{\phi}_i$$

with $g_\lambda : \mathbb{R}_+ \to \mathbb{R}$ and $g_\lambda(\alpha) := (\alpha + \lambda)^{-1}$. Since the Tikhonov regularization is well-known to saturate (as explained above)—see Engl et al. (1996, Sections 4.2 and 5.1) for details—, better approximations to α^{-1} have been used in the inverse problems literature to improve the rates by using g_λ other than $(\cdot + \lambda)^{-1}$ where $g_\lambda(\alpha) \to \alpha^{-1}$ as $\lambda \to 0$. In the statistical context, Rosasco et al. (2005) and Bauer et al. (2007) have used the ideas from Engl et al. (1996) in non-parametric regression for learning a square integrable function from finite samples through regularization in RKHS. In the following, we use these ideas to construct an alternate estimator for f_0 (and therefore for p_0) that appropriately captures the smoothness of f_0 by providing a better convergence rate when $\beta > 1$. To this end, we need the following assumption—quoted from Engl et al. (1996, Theorems 4.1–4.3 and Corollary 4.4) and Bauer et al. (2007, Definition 1)—that is standard in the theory of inverse problems.

(E) There exists finite positive constants A_g, B_g, C_g, η_0 and $(\gamma_\eta)_{\eta \in (0,\eta_0]}$ (all independent of $\lambda > 0$) such that $g_\lambda : [0, \chi] \to \mathbb{R}$ satisfies:

(a) $\sup_{\alpha \in \mathcal{D}} |\alpha g_\lambda(\alpha)| \leq A_g$, (b) $\sup_{\alpha \in \mathcal{D}} |g_\lambda(\alpha)| \leq \frac{B_g}{\lambda}$, (c) $\sup_{\alpha \in \mathcal{D}} |1 - \alpha g_\lambda(\alpha)| \leq C_g$ and (d) $\sup_{\alpha \in \mathcal{D}} |1 - \alpha g_\lambda(\alpha)| \alpha^\eta \leq \gamma_\eta \lambda^\eta$, $\forall\, \eta \in (0, \eta_0]$ where $\mathcal{D} := [0, \chi]$ and $\chi := d \sup_{x \in \Omega, i \in [d]} \partial_i \partial_{i+d} k(x, x) < \infty$.

The constant η_0 is called the *qualification* of g_λ which is what determines the point of saturation of g_λ. We show in Theorem 9 that if g_λ has a finite qualification, then the resultant estimator cannot fully exploit the smoothness of f_0 and therefore the rate of convergence will suffer for $\beta > \eta_0$. Given g_λ that satisfies **(E)**, we construct our estimator of f_0 as

$$f_{g,\lambda,n} = -g_\lambda(\hat{C})\hat{\xi}.$$

Note that the above estimator can be obtained by using the data dependent regularizer, $\frac{1}{2}\langle f, ((g_\lambda(\hat{C}))^{-1} - \hat{C}) f \rangle_{\mathcal{H}}$ in the minimization of $\hat{J}(f)$ defined in Theorem 4(iv), i.e.,

$$f_{g,\lambda,n} = \arg \inf_{f \in \mathcal{H}} \hat{J}(f) + \frac{1}{2}\langle f, ((g_\lambda(\hat{C}))^{-1} - \hat{C}) f \rangle_{\mathcal{H}}.$$

However, unlike $f_{\lambda,n}$ for which a simple form is available in Theorem 5 by solving a linear system, we are not able to obtain such a nice expression for $f_{g,\lambda,n}$. The following result (proved in Section 8.8) presents an analog of Theorems 6 and 7 for the new estimators, $f_{g,\lambda,n}$ and $p_{f_{g,\lambda,n}}$.

Theorem 9 (Consistency and convergence rates for $f_{g,\lambda,n}$ and $p_{f_{g,\lambda,n}}$) *Suppose* **(A)**–**(E)** *hold with* $\varepsilon = 2$.

(i) If $f_0 \in \mathcal{R}(C^\beta)$ *for some* $\beta > 0$, *then for any* $\lambda \geq n^{-1/2}$,

$$\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}(\theta_n),$$

where $\theta_n := n^{-\min\left\{\frac{\beta}{2(\beta+1)}, \frac{\eta_0}{2(\eta_0+1)}\right\}}$ *with* $\lambda = n^{-\max\left\{\frac{1}{2(\beta+1)}, \frac{1}{2(\eta_0+1)}\right\}}$. *In addition, if* $\|k\|_\infty < \infty$, *then for any* $1 < r \leq \infty$ *with* $q_0 \in L^1(\Omega) \cap L^r(\Omega)$,

$$\|p_{f_{g,\lambda,n}} - p_0\|_{L^r(\Omega)} = O_{p_0}(\theta_n),\ h(p_0, p_{f_{g,\lambda,n}}) = O_{p_0}(\theta_n) \ \text{ and } \ KL(p_0 \| p_{f_{g,\lambda,n}}) = O_{p_0}(\theta_n^2).$$

(ii) If $f_0 \in \mathcal{R}(C^\beta)$ *for some* $\beta \geq 0$, *then for any* $\lambda \geq n^{-1/2}$,

$$J(p_0 \| p_{f_{g,\lambda,n}}) = O_{p_0}\left(n^{-\frac{\min\{2\beta+1, 2\eta_0\}}{\min\{2\beta+2, 2\eta_0+1\}}}\right)$$

with $\lambda = n^{-\frac{1}{\min\{2\beta+2, 2\eta_0+1\}}}$.

(iii) If $\|C^{-1}\| < \infty$, *then for any* $\lambda \geq n^{-1/2}$,

$$\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}(\theta_n) \ \text{ and } \ J(p_0 \| p_{f_{g,\lambda,n}}) = O_{p_0}(\theta_n^2)$$

with $\theta_n = n^{-\frac{1}{2}}$ *and* $\lambda = n^{-\frac{1}{\min\{2, 2\eta_0\}}}$.

Theorem 9 shows that if g_λ has infinite qualification, then smoothness of f_0 is fully captured in the rates and as $\beta \to \infty$, we attain $O_{p_0}(n^{-1/2})$ rate for $\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}}$ in contrast to $n^{-1/4}$ (similar improved rates are also obtained for $p_{f_{g,\lambda,n}}$ in various distances) in Theorem 6. In the following example, we present two choices of g_λ that improve on Tikhonov regularization. We refer the reader to Rosasco et al. (2005, Section 3.1) for more examples of g_λ.

Example 4 (Choices of g_λ) *(i) Tikhonov regularization involves* $g_\lambda(\alpha) = (\alpha + \lambda)^{-1}$ *for which it is easy to verify that* $\eta_0 = 1$ *and therefore the rates saturate at* $\beta = 1$, *leading to the results in Theorems 6 and 7.*

(ii) Showalter's method and spectral cut-off use

$$g_\lambda(\alpha) = \frac{1 - e^{-\alpha/\lambda}}{\alpha} \ \text{ and } \ g_\lambda(\alpha) = \begin{cases} \frac{1}{\alpha}, & \alpha \geq \lambda \\ 0, & \alpha < \lambda \end{cases}$$

respectively for which it is easy to verify that $\eta_0 = +\infty$ *(see Engl, Hanke, and Neubauer, 1996, Examples 4.7 & 4.8 for details) and therefore improved rates are obtained for* $\beta > 1$ *in Theorem 9 compared to that of Tikhonov regularization.*

5. Density Estimation in $\mathcal{P}$: Misspecified Case

In this section, we analyze the misspecified case where $p_0 \notin \mathcal{P}$, which is a more reasonable case than the well-specified one, as in practice it is not easy to check whether $p_0 \in \mathcal{P}$. To this end, we consider the same estimator $p_{f_{\lambda,n}}$ as considered in the well-specified case where $f_{\lambda,n}$ is obtained from Theorem 5. The following result shows that $J(p_0 \| p_{f_{\lambda,n}}) \to \inf_{p \in \mathcal{P}} J(p_0 \| p)$ as $\lambda \to 0$, $\lambda n \to \infty$ and $n \to \infty$ under the assumption that there exists $f^* \in \mathcal{F}$ such that $J(p_0 \| p_{f^*}) = \inf_{p \in \mathcal{P}} J(p_0 \| p)$. We present the result for bounded kernels although it can be easily extended to unbounded kernels as in Theorem B.2. Also, the presented result for Tikhonov regularization extends easily to $p_{f_{g,\lambda,n}}$ using the ideas in the proof of Theorem 9. Note that unlike in the well-specified case where convergence in other distances can be shown even though the estimator is constructed from J, it is difficult to show such a result in the misspecified case.

Theorem 10 *Let p_0, $q_0 \in C^1(\Omega)$ be probability densities such that $J(p_0\|q_0) < \infty$ where Ω satisfies* **(A)**. *Assume that* **(B)**, **(C)** *and* **(D)** *with $\varepsilon = 2$ hold. Suppose $\|k\|_\infty < \infty$, $\operatorname{supp}(q_0) = \Omega$ and there exists $f^* \in \mathcal{F}$ such that*

$$J(p_0\|p_{f^*}) = \inf_{p\in\mathcal{P}} J(p_0\|p).$$

Then for an estimator $p_{f_{\lambda,n}}$ constructed from random samples $(X_a)_{a=1}^n$ drawn i.i.d. from p_0, where $f_{\lambda,n}$ is defined in (7)—also see Theorem 4(iv)—with $\lambda > 0$, we have

$$J(p_0\|p_{f_{\lambda,n}}) \to \inf_{p\in\mathcal{P}} J(p_0\|p) \;\text{ as } \lambda \to 0,\ \lambda n \to \infty \text{ and } n \to \infty.$$

In addition, if $f^* \in \mathcal{R}(C^\beta)$ for some $\beta \geq 0$, then

$$\sqrt{J(p_0\|p_{f_{\lambda,n}})} \leq \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} + O_{p_0}\left(n^{-\min\left\{\frac{1}{3},\frac{2\beta+1}{4(\beta+1)}\right\}}\right)$$

with $\lambda = n^{-\max\left\{\frac{1}{3},\frac{1}{2(\beta+1)}\right\}}$. If $\|C^{-1}\| < \infty$, then for $\lambda = n^{-\frac{1}{2}}$,

$$\sqrt{J(p_0\|p_{f_{\lambda,n}})} \leq \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} + O_{p_0}(n^{-1/2}).$$

with $\lambda = n^{-\frac{1}{2}}$.

While the above result is useful and interesting, the assumption about the existence of f^* is quite restrictive. This is because if p_0 (which is not in $\mathcal{P}$) belongs to a family $\mathcal{Q}$ where $\mathcal{P}$ is dense in $\mathcal{Q}$ w.r.t. J, then there is no $f \in \mathcal{H}$ that attains the infimum, i.e., f^* does not exist and therefore the proof technique employed in Theorem 10 will fail. In the following, we present a result (Theorem 12) that does not require the existence of f^* but attains the same result as in Theorem 10, but requiring a more complicated proof. Before we present Theorem 12, we need to introduce some notation.

To this end, let us return to the objective function under consideration,

$$J(p_0\|p_f) = \frac{1}{2}\int_\Omega p_0(x)\left\|\nabla \log\frac{p_0}{p_f}\right\|_2^2 dx = \frac{1}{2}\int_\Omega p_0(x)\sum_{i=1}^d (\partial_i f_\star - \partial_i f)^2\, dx,$$

where $f_\star = \log\frac{p_0}{q_0}$ and $p_0 \notin \mathcal{P}$. Define

$$\mathcal{W}_2(\Omega, p_0) := \left\{f \in C^1(\Omega) \,:\, \partial^\alpha f \in L^2(\Omega, p_0),\, \forall\, |\alpha| = 1\right\}.$$

This is a reasonable class of functions to consider as under the condition $J(p_0\|q_0) < \infty$, it is clear that $f_\star \in \mathcal{W}_2(\Omega, p_0)$. Endowed with a semi-norm,

$$\|f\|_{\mathcal{W}_2}^2 := \sum_{|\alpha|=1} \|\partial^\alpha f\|_{L^2(\Omega,p_0)}^2,$$

$\mathcal{W}_2(\Omega, p_0)$ is a vector space of functions, from which a normed space can be constructed as follows. Let us define $f, f' \in \mathcal{W}_2(\Omega, p_0)$ to be equivalent, i.e., $f \sim f'$, if $\|f - f'\|_{\mathcal{W}_2} = 0$.

In other words, $f \sim f'$ if and only if f and f' differ by a constant p_0-almost everywhere. Now define the quotient space $\mathcal{W}_2^\sim(\Omega, p_0) := \{[f]_\sim : f \in \mathcal{W}_2(\Omega, p_0)\}$ where $[f]_\sim := \{f' \in \mathcal{W}_2(\Omega, p_0) : f \sim f'\}$ denotes the equivalence class of f. Defining $\|[f]_\sim\|_{\mathcal{W}_2^\sim} := \|f\|_{\mathcal{W}_2}$, it is easy to verify that $\|\cdot\|_{\mathcal{W}_2^\sim}$ defines a norm on $\mathcal{W}_2^\sim(p_0)$. In addition, endowing the following bilinear form on $\mathcal{W}_2^\sim(\Omega, p_0)$

$$\langle [f]_\sim, [g]_\sim\rangle_{\mathcal{W}_2^\sim} := \int_\Omega p_0(x)\sum_{|\alpha|=1}(\partial^\alpha f)(x)(\partial^\alpha g)(x)\, dx$$

makes it a pre-Hilbert space. Let $W_2(\Omega, p_0)$ be the Hilbert space obtained by completion of $\mathcal{W}_2^\sim(\Omega, p_0)$. As shown in Proposition 11 below, under some assumptions, a continuous mapping $I_k : \mathcal{H} \to W_2(\Omega, p_0)$, $f \mapsto [f]_\sim$ can be defined, which is injective modulo constant functions. Since addition of a constant does not contribute to p_f, the space $W_2(\Omega, p_0)$ can be regarded as a parameter space extended from $\mathcal{H}$. In addition to I_k, Proposition 11 (proved in Section 8.10) describes the adjoint of I_k and relevant self-adjoint operators, which will be useful in analyzing $p_{f_{\lambda,n}}$ in Theorem 12.

Proposition 11 *Let $\operatorname{supp}(q_0) = \Omega$ where $\Omega \subset \mathbb{R}^d$ is non-empty and open. Suppose k satisfies* **(B)** *and $\partial_i\partial_{i+d}k(x,x) \in L^1(\Omega, p_0)$ for all $i \in [d]$. Then $I_k : \mathcal{H} \to W_2(\Omega, p_0)$, $f \mapsto [f]_\sim$ defines a continuous mapping with the null space $\mathcal{H} \cap \mathbb{R}$. The adjoint of I_k is $S_k : W_2(\Omega, p_0) \to \mathcal{H}$ whose restriction to $\mathcal{W}_2^\sim(\Omega, p_0)$ is given by*

$$S_k[h]_\sim(y) = \int_\Omega \sum_{i=1}^d \partial_i k(x,y)\partial_i h(x)\, p_0(x)\, dx, \qquad [h]_\sim \in \mathcal{W}_2^\sim(\Omega, p_0),\ y \in \Omega.$$

In addition, I_k and S_k are Hilbert-Schmidt and therefore compact. Also, $E_k := S_kI_k$ and $T_k := I_kS_k$ are compact, positive and self-adjoint operators on $\mathcal{H}$ and $W_2(\Omega, p_0)$ respectively where

$$E_k g(y) = \int_\Omega \sum_{i=1}^d \partial_i k(x,y)\partial_i g(x) p_0(x)\, dx, \qquad g \in \mathcal{H},\ y \in \Omega$$

and the restriction of T_k to $\mathcal{W}_2^\sim(\Omega, p_0)$ is given by

$$T_k[h]_\sim = \left[\int_\Omega \sum_{i=1}^d \partial_i k(x,\cdot)\partial_i h(x)\, p_0(x)\, dx\right]_\sim, \qquad [h]_\sim \in \mathcal{W}_2^\sim(\Omega, p_0).$$

Note that for $[h]_\sim \in \mathcal{W}_2^\sim(\Omega, p_0)$, the derivatives $\partial_i h$ do not depend on the choice of a representative element almost surely w.r.t. p_0, and thus the above integrals are well defined. Having constructed $W_2(\Omega, p_0)$, it is clear that $J(p_0\|p_f) = \frac{1}{2}\|[f_\star]_\sim - I_k f\|_{W_2}^2$, which means estimating p_0 is equivalent to estimating $f_\star \in W_2(\Omega, p_0)$ by $f \in \mathcal{F}$. With all these preparations, we are now ready to present a result (proved in Section 8.11) on consistency and convergence rate for $p_{f_{\lambda,n}}$ without assuming the existence of f^*.

Theorem 12 *Let p_0, $q_0 \in C^1(\Omega)$ be probability densities such that $J(p_0\|q_0) < \infty$. Assume that* **(A)**-**(D)** *hold with $\varepsilon = 2$ and $\chi := d\sup_{x\in\Omega, i\in[d]} \partial_i\partial_{i+d}k(x,x) < \infty$. Then the following*

hold.

(i) As $\lambda \to 0$, $\lambda n \to \infty$ *and* $n \to \infty$, $J(p_0\|p_{f_{\lambda,n}}) \to \inf_{p\in\mathcal{P}} J(p_0\|p)$.

(ii) Define $f_\star := \log \frac{p_0}{q_0}$. *If* $[f_\star]_\sim \in \overline{\mathcal{R}(T_k)}$, *then*

$$J(p_0\|p_{f_{\lambda,n}}) \to 0 \;\; as \;\; \lambda \to 0,\, \lambda n \to \infty \; and \; n \to \infty.$$

In addition, if $[f_\star]_\sim \in \mathcal{R}(T_k^\beta)$ *for some* $\beta > 0$, *then for* $\lambda = n^{-\max\left\{\frac{1}{3}, \frac{1}{2\beta+1}\right\}}$

$$J(p_0\|p_{f_{\lambda,n}}) = O_{p_0}\left(n^{-\min\left\{\frac{2}{3}, \frac{2\beta}{2\beta+1}\right\}}\right)$$

. (iii) If $\|E_k^{-1}\| < \infty$ *and* $\|T_k^{-1}\| < \infty$, *then* $J(p_0\|p_{f_{\lambda,n}}) = O_{p_0}\left(n^{-1}\right)$ *with* $\lambda = n^{-\frac{1}{2}}$.

Remark *(i)* The result in Theorem 12(ii) is particularly interesting as it shows that $[f_\star]_\sim \in W_2(\Omega, p_0)\backslash I_k(\mathcal{H})$ can be consistently estimated by $f_{\lambda,n} \in \mathcal{H}$, which in turn implies that certain $p_0 \notin \mathcal{P}$ can be consistently estimated by $p_{f_{\lambda,n}} \in \mathcal{P}$. In particular, if S_k is injective, then $I_k(\mathcal{H})$ is dense in $W_2(\Omega, p_0)$ w.r.t. $\|\cdot\|_{W_2}$, which implies $\inf_{p\in\mathcal{P}} J(p_0\|p) = 0$ though there does not exist $f^* \in \mathcal{H}$ for which $J(p_0\|p_{f^*}) = 0$. While Theorem 10 cannot handle this situation, (i) and (ii) in Theorem 12 coincide showing that $p_0 \notin \mathcal{P}$ can be consistently estimated by $p_{f_{\lambda,n}} \in \mathcal{P}$. While the question of when $I_k(\mathcal{H})$ is dense in $W_2(\Omega, p_0)$ is open, we refer the reader to Section B.4 for a related discussion.

(ii) Replicating the proof of Theorem 4.6 in Steinwart and Scovel (2012), it is easy to show that for all $0 < \gamma < 1$, $\mathcal{R}(T_k^{\gamma/2}) = [W_2(\Omega, p_0), I_k(\mathcal{H})]_{\gamma,2}$, where the r.h.s. is an interpolation space obtained through the real interpolation of $W_2(\Omega, p_0)$ and $I_k(\mathcal{H})$ (see Section A.5 for the notation and definition). Here $I_k(\mathcal{H})$ is endowed with the Hilbert space structure by $I_k(\mathcal{H}) \cong \mathcal{H}/\mathcal{H} \cap \mathbb{R}$. This interpolation space interpretation means that, for $\beta \geq \frac{1}{2}$, $\mathcal{R}(T_k^\beta) \subset \mathcal{H}$ modulo constant functions. It is nice to note that the rates in Theorem 12(ii) for $\beta \geq \frac{1}{2}$ match with the rates in Theorem 7 (i.e., the well-specified case) w.r.t. J for $0 \leq \beta \leq \frac{1}{2}$. We highlight the fact that $\beta = 0$ corresponds to $\mathcal{H}$ in Theorem 7 whereas $\beta = \frac{1}{2}$ corresponds to $\mathcal{H}$ in Theorem 12(ii) and therefore the range of comparison is for $\beta \geq \frac{1}{2}$ in Theorem 12(ii) versus $0 \leq \beta \leq \frac{1}{2}$ in Theorem 7. In contrast, Theorem 10 is very limited as it only provides a rate for the convergence of $J(p_0||p_{f_{\lambda,n}})$ to $\inf_{p\in\mathcal{P}} J(p_0||p)$ assuming that f^* is sufficiently smooth.

Based on the observation (i) in the above remark that $\inf_{p\in\mathcal{P}} J(p_0\|p) = 0$ if $I_k(\mathcal{H})$ is dense in $W_2(\Omega, p_0)$ w.r.t. $\|\cdot\|_{W_2}$, it is possible to obtain an approximation result for $\mathcal{P}$ (similar to those discussed in Section 3) w.r.t. Fisher divergence as shown below, whose proof is provided in Section 8.12.

Proposition 13 *Suppose* $\Omega \subset \mathbb{R}^d$ *is non-empty and open. Let* $q_0 \in C^1(\Omega)$ *be a probability density and*

$$\mathcal{P}_{\text{FD}} := \left\{p \in C^1(\Omega) : \int_\Omega p(x)\,dx = 1, p(x) \geq 0,\, \forall\, x \in \Omega \text{ and } J(p\|q_0) < \infty\right\}.$$

For any $p \in \mathcal{P}_{\text{FD}}$, *if* $I_k(\mathcal{H})$ *is dense in* $W_2(\Omega, p)$ *w.r.t.* $\|\cdot\|_{W_2}$, *then for every* $\epsilon > 0$, *there exists* $\tilde{p} \in \mathcal{P}$ *such that* $J(p\|\tilde{p}) \leq \epsilon$.

6. Numerical Simulations

We have proposed an estimator of p_0 that is obtained by minimizing the regularized empirical Fisher divergence and presented its consistency along with convergence rates. As discussed in Section 1, however one can simply ignore the structure of $\mathcal{P}$ and estimate p_0 in a completely non-parametric fashion, for example using the kernel density estimator (KDE). In fact, consistency and convergence rates of KDE are also well-studied (Tsybakov, 2009, Chapter 1) and the kernel density estimator is very simple to compute—requiring only $O(n)$ computations—compared to the proposed estimator, which is obtained by solving a linear system of size $nd \times nd$. This raises questions about the applicability of the proposed estimator in practice, though it is very well known that KDE performs poorly for moderate to large d (Wasserman, 2006, Section 6.5). In this section, we numerically demonstrate that the proposed score matching estimator performs significantly better than the KDE, and in particular, that the advantage with the proposed estimator grows as d gets large. Note further that the maximum likelihood approach of Barron and Sheu (1991) and Fukumizu (2009) does not yield estimators that are practically feasible, and therefore to the best of our knowledge, the proposed estimator is the only viable estimator for estimating densities through $\mathcal{P}$.

In the following, we consider two simple scenarios of estimating a multivariate normal and mixture of normals using the proposed estimator and demonstrate the superior performance of the proposed estimator over KDE. Inspired by this preliminary empirical investigation, recently, the proposed estimator has been explored in two concrete applications of gradient-free adaptive MCMC sampler (Strathmann et al., 2015) and graphical model structure learning (Sun et al., 2015) where the superiority of working with the infinite dimensional family is demonstrated. We would like to again highlight that the goal of this work is not to construct density estimators that improve upon KDE but to provide a novel modeling technique of approximating an unknown density by a rich parametric family of densities with the parameter being infinite dimensional in contrast to the classical approach of finite dimensional approximation.

We consider the problems of estimating a standard normal distribution on $\mathbb{R}^d$, $N(0, I_d)$ and mixture of Gaussians,

$$p_0(x) = \frac{1}{2}\phi_d(x; \alpha\mathbf{1}_n, I_d) + \frac{1}{2}\phi_d(x; \beta\mathbf{1}_n, I_d)$$

through the score matching approach and KDE, and compare their estimation accuracies. Here $\phi_d(x; \mu, \Sigma)$ is the p.d.f. of $N(\mu, \Sigma I_d)$. By choosing the kernel, $k(x, y) = \exp(-\frac{\|x-y\|_2^2}{2\sigma^2}) + r(x^T y + c)^2$, which is a Gaussian plus polynomial of degree 2, it is easy to verify that Gaussian distributions lie in $\mathcal{P}$, and therefore the first problem considers the well-specified case while the second problem deals with the misspecified case. In our simulations, we chose $r = 0.1$, $c = 0.5$, $\alpha = 4$ and $\beta = -4$. The base measure of the exponential family is $N(0, 10^2 I_d)$. The bandwidth parameter σ is chosen by cross-validation (CV) of the objective function $\hat{J}_\lambda$ (see Theorem 4(iv)) within the parameter set $\{0.1, 0.2, 0.4, 0.6, 0.8, 1, 1.2, 1.4, 1.6\} \times \sigma_*$, where σ_* is the median of pairwise distances of data, and the regularization parameter λ is set as $\lambda = 0.1 \times n^{-1/3}$ with sample size n. For KDE, the Gaussian kernel is used for the smoothing kernel, and the bandwidth parameter is chosen by CV from

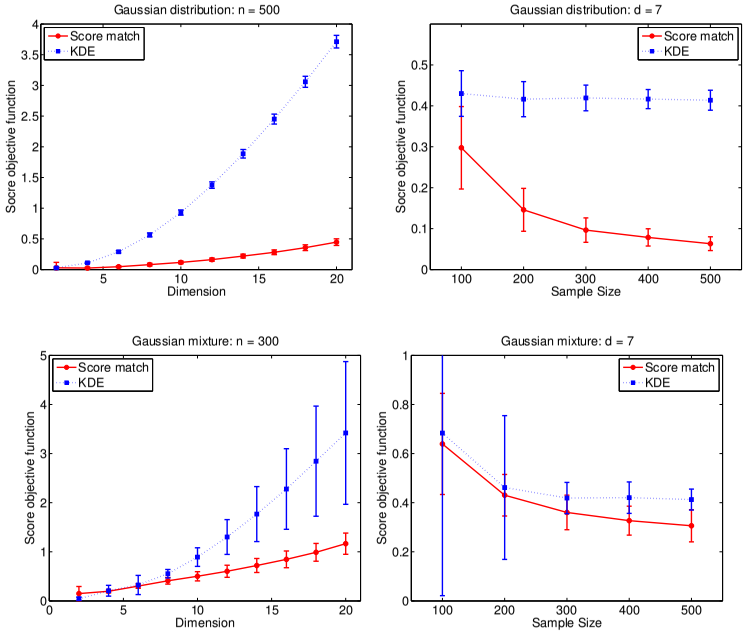

Figure 1: Experimental comparisons with the score objective function: proposed method and kernel density estimator

$\{0.02, 0.04, 0.06, 0.08, 0.1, 0.2, 0.4, 0.6, 0.8, 1.0\} \times \sigma_*$; where for both the methods, 5-fold CV is applied. Since it is difficult to accurately estimate the normalization constant in the proposed method, we use two methods to evaluate the accuracy of estimation. One is the objective function for the score matching method,

$$\tilde{J}(p) = \sum_{i=1}^{d} \int_{\Omega} \left(\frac{1}{2} \left| \partial_i \log p(x) \right|^2 + \partial_i^2 \log p(x) \right) p_0(x) dx,$$

and the other is correlation of the estimator with the true density function,

$$\mathrm{Cor}(p, p_0) := \frac{\mathbb{E}_R[p(X) p_0(X)]}{\sqrt{\mathbb{E}_R[p(X)^2] \mathbb{E}_R[p_0(X)^2]}},$$

where R is a probability distribution. For R, we use the empirical distribution based on 10000 random samples drawn i.i.d. from $p_0(x)$.

Figures 1 and 2 show the score objective function ($\tilde{J}(p)$) and the correlation ($\mathrm{Cor}(p, p_0)$) (along with their standard deviation as error bars) of the proposed estimator and KDE for the tasks of estimating a Gaussian and a mixture of Gaussians, for different sample sizes

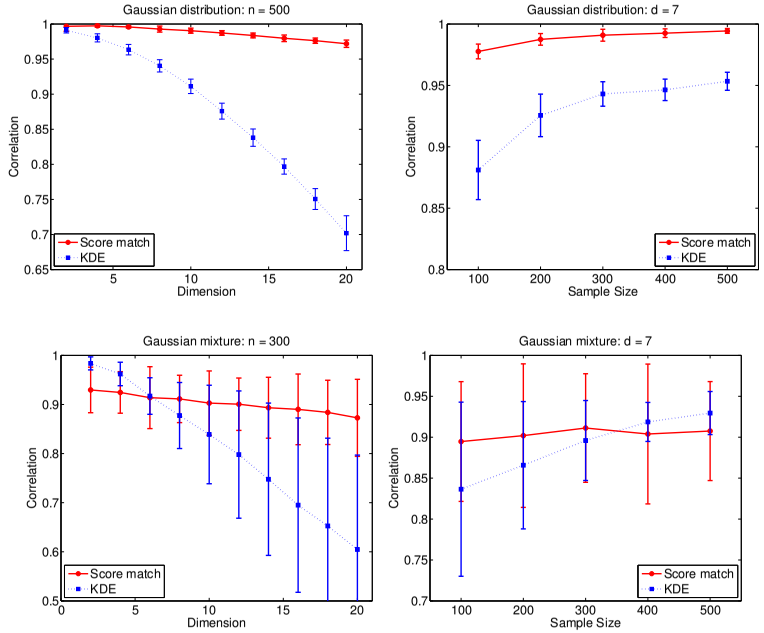

Figure 2: Experimental comparisons with the correlation: proposed method and kernel density estimator

(n) and dimensions (d). From the figures, we see that the proposed estimator outperforms (i.e., lower function values) KDE in all the cases except the low dimensional cases ($(n, d) = (500, 2)$ for the Gaussian, and $(n, d) = (300, 2), (300, 4)$ for the Gaussian mixture). In the case of the correlation measure, the score matching method yields better results (i.e., higher correlation) besides in the Gaussian mixture cases of $d = 2, 4, 6$ (Fig.2, lower-left) and some cases of $d = 7$ (lower-right). The proposed method shows an increased advantage over KDE as the dimensionality increases, thereby demonstrating the advantage of the proposed estimator for high dimensional data.

7. Summary & Discussion

We have considered an infinite dimensional generalization, $\mathcal{P}$, of the finite-dimensional exponential family, where the densities are indexed by functions in a reproducing kernel Hilbert space (RKHS), $\mathcal{H}$. We showed that $\mathcal{P}$ is a rich object that can approximate a large class of probability densities arbitrarily well in Kullback-Leibler divergence, and addressed the main question of estimating an unknown density, p_0 from finite samples drawn i.i.d. from it, in well-specified ($p_0 \in \mathcal{P}$) and misspecified ($p_0 \notin \mathcal{P}$) settings. We proposed a density

estimator based on minimizing the regularized version of the empirical Fisher divergence, which results in solving a simple finite-dimensional linear system. Our estimator provides a computationally efficient alternative to maximum likelihood based estimators, which suffer from the computational intractability of the log-partition function. The proposed estimator is also shown to empirically outperform the classical kernel density estimator, with advantage increasing as the dimension of the space increases. In addition to these computational and empirical results, we have established the consistency and convergence rates under certain smoothness assumptions (e.g., $\log p_0 \in \mathcal{R}(C^\beta)$) for both well-specified and misspecified scenarios.

Three important questions still remain open in this work which we intend to address in our future work. First, the assumption $\log p_0 \in \mathcal{R}(C^\beta)$ is not well understood. Though we presented a necessary condition for this assumption (with $\beta = 1$) to hold for bounded continuous translation invariant kernels on $\mathbb{R}^d$, obtaining a sufficient condition can throw light on the minimax optimality of the proposed estimator. Another alternative is to directly study the minimax optimality of the rates for $0 < \beta \leq 1$ (for $\beta > 1$, we showed that the above mentioned rates can be improved by an appropriate choice of the regularizer) by obtaining minimax lower bounds under the source condition $\log p_0 \in \mathcal{R}(C^\beta)$ and the eigenvalue decay rate of C, using the ideas in DeVore et al. (2004). Second, the proposed estimator depends on the regularization parameter, which in turn depends on the smoothness scale β. Since β is not known in practice, it is therefore of interest to construct estimators that are adaptive to unknown β. Third, since the proposed estimator is computationally expensive as it involves solving a linear system of size $nd \times nd$, it is important to study either alternate estimators or efficient implementations of the proposed estimator to improve the applicability of the method.

8. Proofs

We provide proofs of the results presented in Sections 3–5.

8.1 Proof of Proposition 1

Sriperumbudur et al. (2011, Proposition 5) showed that $\mathcal{H}$ is dense in $C_0(\Omega)$ w.r.t. uniform norm if and only if k satisfies (5). Therefore, the denseness in L^1, KL and Hellinger distances follow trivially from Lemma A.1. For L^r norm ($r > 1$), the denseness follows by using the bound $\|p_f - p_g\|_{L^r(\Omega)} \leq 2e^{2\|f-g\|_\infty} e^{2\|f\|_\infty} \|f - g\|_\infty \|q_0\|_{L^r(\Omega)}$ obtained from Lemma A.1(i) with $f \in C_0(\Omega)$ and $g \in \mathcal{H}$. ■

8.2 Proof of Corollary 2

For any $p \in \mathcal{P}_c$, define $p_\delta := \frac{p+\delta q_0}{1+\delta}$. Note that $p_\delta(x) > 0$ for all $x \in \Omega$ and $\|p - p_\delta\|_{L^r(\Omega)} = \frac{\delta \|p-q_0\|_{L^r(\Omega)}}{1+\delta}$, implying that $\lim_{\delta\to 0} \|p - p_\delta\|_{L^r(\Omega)} = 0$ for any $1 \leq r \leq \infty$. This means, for any $\epsilon > 0$, $\exists \delta_\epsilon > 0$ such that for any $0 < \theta < \delta_\epsilon$, we have $\|p - p_\theta\|_{L^r(\Omega)} \leq \epsilon$, where $p_\theta(x) > 0$ for all $x \in \Omega$.

Define $f := \log \frac{p_\theta}{q_0} - c_\theta$ where $c_\theta := \log \frac{\ell+\theta}{1+\theta}$. It is clear that $f \in C(\Omega)$ since $p, q \in C(\Omega)$. Fix any $\eta > 0$ and define

$$A := \{x : f(x) \geq \eta\} = \left\{ x : \frac{p(x)}{q_0(x)} - \ell \geq (\ell + \theta)\left(e^\eta - 1\right) \right\}.$$

Since $\frac{p}{q_0} - \ell \in C_0(\Omega)$, it is clear that A is compact and so $f \in C_0(\Omega)$. Also, it is easy to verify that $p_\theta = e^{f - A(f)} q_0$ which implies $p_\theta \in \mathcal{P}_0$, where $\mathcal{P}_0$ is defined in Proposition 1. This means, for any $\epsilon > 0$, there exists $p_g \in \mathcal{P}$ such that $\|p_\theta - p_g\|_{L^r(\Omega)} \leq \epsilon$ under the assumption that $q_0 \in L^1(\Omega) \cap L^r(\Omega)$. Therefore $\|p - p_g\|_{L^r(\Omega)} \leq 2\epsilon$ for any $1 \leq r \leq \infty$, which proves the denseness of $\mathcal{P}$ in $\mathcal{P}_c$ w.r.t. L^r norm for any $1 \leq r \leq \infty$. Since $h(p, q) \leq \sqrt{\|p - q\|_{L^1(\Omega)}}$ for any probability densities p, q, the denseness in Hellinger distance follows.

We now prove the denseness in KL divergence by noting that

$$\begin{aligned} KL(p\|p_\delta) = \int_{\{p>0\}} p \log \frac{p + p\delta}{p + q_0\delta}\, dx &\leq \int_{\{p>0\}} p \left(\frac{p + p\delta}{p + q_0\delta} - 1 \right) dx \\ &= \delta \int_{p>0} (p - q_0) \frac{p}{p + q_0\delta}\, dx \leq \delta \|p - q_0\|_{L^1(\Omega)} \leq 2\delta, \end{aligned}$$

which implies $\lim_{\delta\to 0} KL(p\|p_\delta) = 0$. This implies, for any $\epsilon > 0$, $\exists \delta_\epsilon > 0$ such that for any $0 < \theta < \delta_\epsilon$, $KL(p\|p_\theta) \leq \epsilon$. Arguing as above, we have $p_\theta \in \mathcal{P}_0$, i.e., there exists $f \in C_0(\Omega)$ such that $p_\theta = \frac{e^f q_0}{\int e^f q_0\, dx}$. Since $\mathcal{H}$ is dense in $C_0(\Omega)$, for any $f \in C_0(\Omega)$ and any $\epsilon > 0$, there exists $g \in \mathcal{H}$ such that $\|f - g\|_\infty \leq \epsilon$. For $p_g \in \mathcal{P}$, since $\int p \log \frac{p_\theta}{p_g}\, dx \leq \left\| \log \frac{p_\theta}{p_g} \right\|_\infty \leq 2\|f - g\|_\infty \leq 2\epsilon$, we have

$$KL(p\|p_g) = \int_\Omega p \log \frac{p}{p_g}\, dx = \int_\Omega p \log \frac{p}{p_\theta}\, dx + \int_\Omega p \log \frac{p_\theta}{p_g}\, dx \leq 3\epsilon$$

and the result follows. ■

8.3 Proof of Theorem 4

(i) By the reproducing property of $\mathcal{H}$, since $\partial_i f(x) = \langle f, \partial_i k(x, \cdot)\rangle_{\mathcal{H}}$ for all $i \in [d]$, it is easy to verify that

$$\begin{aligned} J(f) &= \frac{1}{2} \int_\Omega p_0(x) \sum_{i=1}^d \langle f - f_0, \partial_i k(x, \cdot)\rangle_{\mathcal{H}}^2\, dx \\ &= \frac{1}{2} \int_\Omega p_0(x) \sum_{i=1}^d \langle f - f_0, (\partial_i k(x, \cdot) \otimes \partial_i k(x, \cdot))\,(f - f_0)\rangle_{\mathcal{H}}\, dx \\ &= \frac{1}{2} \int_\Omega p_0(x) \langle f - f_0, C_x(f - f_0)\rangle_{\mathcal{H}}\, dx, \end{aligned} \tag{11}$$

where in the second line, we used $\langle a, b\rangle_H^2 = \langle a, b\rangle_H \langle a, b\rangle_H = \langle a, (b \otimes b)a\rangle_H$ for $a, b \in H$ with H being a Hilbert space and

$$C_x := \sum_{i=1}^d \partial_i k(x, \cdot) \otimes \partial_i k(x, \cdot). \tag{12}$$

Observe that for all $x \in \Omega$, C_x is a Hilbert-Schmidt operator as $\|C_x\|_{HS} \leq \sum_{i=1}^d \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^2 = \sum_{i=1}^d \partial_i \partial_{i+d} k(x,x) < \infty$ and $(f-f_0)\otimes(f-f_0)$ is also Hilbert-Schmidt as $\|(f-f_0)\otimes(f-f_0)\|_{HS} = \|f-f_0\|_{\mathcal{H}}^2 < \infty$. Therefore, (11) is equivalent to

$$J(f) = \frac{1}{2}\int_\Omega p_0(x)\,\langle (f-f_0)\otimes(f-f_0), C_x\rangle_{HS}\,dx.$$

Since the first condition in **(D)** implies $\int_\Omega \|C_x\|_{HS} p_0(x)\,dx < \infty$, C_x is p_0-integrable in the Bochner sense (see Diestel and Uhl, 1977, Definition 1 and Theorem 2), and therefore it follows from Diestel and Uhl (1977, Theorem 6) that

$$J(f) = \frac{1}{2}\left\langle (f-f_0)\otimes(f-f_0), \int_\Omega C_x\, p_0(x)\,dx\right\rangle_{HS},$$

where $C := \int_\Omega C_x\, p_0(x)\,dx$ is the Bochner integral of C_x, thereby yielding (6).

We now show that C is trace-class. Let $(e_l)_{l\in\mathbb{N}}$ be an orthonormal basis in $\mathcal{H}$ (a countable ONB exists as $\mathcal{H}$ is separable—see Remark 3(i)). Define $B := \sum_l \langle Ce_l, e_l\rangle_{\mathcal{H}}$ so that

$$B = \sum_l \int_\Omega \langle e_l, C_x e_l\rangle_{\mathcal{H}} p_0(x)\,dx = \sum_l \int_\Omega \sum_{i=1}^d \langle e_l, \partial_i k(x,\cdot)\rangle_{\mathcal{H}}^2 p_0(x)\,dx$$
$$\overset{(*)}{=} \int_\Omega \sum_{i\in[d],l} \langle e_l, \partial_i k(x,\cdot)\rangle_{\mathcal{H}}^2 p_0(x)\,dx \overset{(**)}{=} \int_\Omega \sum_{i=1}^d \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^2 p_0(x)\,dx < \infty,$$

which means C is trace-class and therefore compact. Here, we used monotone convergence theorem in $(*)$ and Parseval's identity in $(**)$. Note that C is positive since $\langle f, Cf\rangle_{\mathcal{H}} = \int_\Omega p_0(x)\,\|\nabla f\|_2^2\,dx \geq 0,\ \forall f \in \mathcal{H}$.

(ii) From (6), we have $J(f) = \frac{1}{2}\langle f, Cf\rangle_{\mathcal{H}} - \langle f, Cf_0\rangle_{\mathcal{H}} + \frac{1}{2}\langle f_0, Cf_0\rangle_{\mathcal{H}}$. Using $\partial_i f_0(x) = \partial_i \log p_0(x) - \partial_i \log q_0(x)$ for all $i \in [d]$, we obtain that for any $f \in \mathcal{H}$,

$$\begin{aligned}
\langle f, Cf_0\rangle_{\mathcal{H}} &= \int_\Omega p_0(x)\sum_{i=1}^d \partial_i f(x)\partial_i f_0(x)\,dx \\
&= \int_\Omega \sum_{i=1}^d \partial_i f(x)\partial_i p_0(x)\,dx - \int_\Omega p_0(x)\sum_{i=1}^d \partial_i f(x)\partial_i \log q_0(x)\,dx \\
&\overset{(b)}{=} -\int_\Omega p_0(x)\sum_{i=1}^d \partial_i^2 f(x)\,dx - \int_\Omega p_0(x)\sum_{i=1}^d \partial_i f(x)\partial_i \log q_0(x)\,dx \\
&= -\int_\Omega p_0(x)\left\langle f, \overbrace{\sum_{i=1}^d \partial_i^2 k(x,\cdot) + \partial_i k(x,\cdot)\partial_i \log q_0(x)}^{\xi_x}\right\rangle_{\mathcal{H}} dx \overset{(c)}{=} \langle f, -\xi\rangle_{\mathcal{H}}, \quad (13)
\end{aligned}$$

where (b) follows from integration by parts under **(C)** and the equality in (c) is valid as ξ_x is Bochner p_0-integrable under **(D)** with $\varepsilon = 1$. Therefore $Cf_0 = -\xi$. For the third term, $\langle f_0, Cf_0\rangle_{\mathcal{H}} = \int_\Omega p_0(x)\sum_{i=1}^d (\partial_i f_0(x))^2\,dx$ and the result follows.

(iii) Define $c_0 := J(p_0\|q_0)$. For any $\lambda > 0$, it is easy to verify that

$$J_\lambda(f) = \frac{1}{2}\|(C+\lambda I)^{1/2} f + (C+\lambda I)^{-1/2}\xi\|_{\mathcal{H}}^2 - \frac{1}{2}\langle \xi, (C+\lambda I)^{-1}\xi\rangle_{\mathcal{H}} + c_0.$$

Clearly, $J_\lambda(f)$ is minimized if and only if $(C+\lambda I)^{1/2} f = -(C+\lambda I)^{-1/2}\xi$ and therefore $f_\lambda = -(C+\lambda I)^{-1}\xi$ is the unique minimizer of $J_\lambda(f)$.

(iv) Since (iv) is similar to (iii) with C replaced by $\hat{C}$ and ξ replaced by $\hat{\xi}$, we obtain $f_{\lambda,n} = (\hat{C}+\lambda I)^{-1}\hat{\xi}$. ■

8.4 Proof of Theorem 5

We prove the result based on the general representer theorem (Theorem A.2). From Theorem 4(iv), we have

$$\begin{aligned}
f_{\lambda,n} &= \arg\inf_{f\in\mathcal{H}} \frac{1}{2}\langle f, \hat{C}f\rangle_{\mathcal{H}} + \langle f, \hat{\xi}\rangle_{\mathcal{H}} + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 \\
&= \arg\inf_{f\in\mathcal{H}} \frac{1}{2n}\sum_{a=1}^n\sum_{i=1}^d \langle f, \partial_i k(X_a,\cdot)\rangle_{\mathcal{H}}^2 + \langle f, \hat{\xi}\rangle_{\mathcal{H}} + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2 \\
&= \arg\inf_{f\in\mathcal{H}} V(\langle f,\phi_1\rangle_{\mathcal{H}}, \ldots, \langle f,\phi_{nd}\rangle_{\mathcal{H}}, \langle f,\phi_{nd+1}\rangle_{\mathcal{H}}) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2,
\end{aligned}$$

where $V(\theta_1,\ldots,\theta_{nd},\theta_{nd+1}) := \frac{1}{2n}\sum_{a=1}^n\sum_{i=1}^d \theta_{(a-1)d+i}^2 + \theta_{nd+1}$, $\phi_{(a-1)d+i} := \partial_i k(X_a,\cdot)$, $a \in [n]$, $i \in [d]$ and $\phi_{nd+1} := \hat{\xi}$. Therefore, it follows from Theorem A.2 that

$$f_{\lambda,n} = \delta\hat{\xi} + \sum_{a=1}^n\sum_{i=1}^d \beta_{(a-1)d+i}\phi_{(a-1)d+i} \quad (14)$$

where δ and $\boldsymbol{\beta}$ satisfy

$$\lambda\begin{pmatrix}\boldsymbol{\beta}\\ \delta\end{pmatrix} + \nabla V\left(\boldsymbol{K}\begin{pmatrix}\boldsymbol{\beta}\\ \delta\end{pmatrix}\right) = 0 \quad (15)$$

with $\boldsymbol{K} = \begin{pmatrix}\boldsymbol{G} & \boldsymbol{h}\\ \boldsymbol{h}^T & \|\hat{\xi}\|_{\mathcal{H}}^2\end{pmatrix}$. Since $\nabla V\begin{pmatrix}\boldsymbol{z}\\ t\end{pmatrix} = \begin{pmatrix}\frac{1}{n}\boldsymbol{z}\\ 1\end{pmatrix}$, (15) reduces to $\lambda\delta + 1 = 0$ and $\lambda\boldsymbol{\beta} + \frac{1}{n}\boldsymbol{G}\boldsymbol{\beta} + \frac{\delta}{n}\boldsymbol{h} = 0$ yielding $\delta = -\frac{1}{\lambda}$ and $(\frac{1}{n}\boldsymbol{G} + \lambda I)\boldsymbol{\beta} = \frac{1}{n\lambda}\boldsymbol{h}$. ■

Remark Instead of using the general representer theorem (Theorem A.2), it is possible to see that the standard representer theorem (Kimeldorf and Wahba, 1971; Schölkopf et al., 2001) gives a similar, but slightly different linear system, and the solutions are the same if $\boldsymbol{K}$ is non-singular. The general representer theorem yields that $\boldsymbol{\beta}$ and δ are solution to $\boldsymbol{F}\begin{pmatrix}\boldsymbol{\beta}\\ \delta\end{pmatrix} = \begin{pmatrix}\boldsymbol{0}\\ 1\end{pmatrix}$, where $\boldsymbol{F} = \begin{pmatrix}\frac{1}{n}\boldsymbol{G} + \lambda I & \frac{1}{n}\boldsymbol{h}\\ \boldsymbol{0}^T & \lambda\end{pmatrix}$. On the other hand, by using the standard representer theorem, it is easy to show that $f_{\lambda,n}$ has the form in (14) with δ and $\boldsymbol{\beta}$ being solution to $\boldsymbol{K}\boldsymbol{F}\begin{pmatrix}\boldsymbol{\beta}\\ \delta\end{pmatrix} = \boldsymbol{K}\begin{pmatrix}\boldsymbol{0}\\ 1\end{pmatrix}$. Clearly, both the solutions match if $\boldsymbol{K}$ is invertible while the latter has many solutions if $\boldsymbol{K}$ is not invertible.

8.5 Proof of Theorem 6

Consider

$$\begin{aligned} f_{\lambda,n} - f_\lambda &= -(\hat{C}+\lambda I)^{-1}\Big(\hat{\xi} + (\hat{C}+\lambda I) f_\lambda\Big) \overset{(*)}{=} -(\hat{C}+\lambda I)^{-1}\left(\hat{\xi} + \hat{C} f_\lambda + C(f_0 - f_\lambda)\right) \\ &= (\hat{C}+\lambda I)^{-1}(C-\hat{C})(f_\lambda - f_0) - (\hat{C}+\lambda I)^{-1}(\hat{\xi} + \hat{C} f_0) \\ &= (\hat{C}+\lambda I)^{-1}(C-\hat{C})(f_\lambda - f_0) - (\hat{C}+\lambda I)^{-1}(\hat{\xi} - \xi) + (\hat{C}+\lambda I)^{-1}(C-\hat{C}) f_0, \end{aligned}$$

where we used $\lambda f_\lambda = C(f_0 - f_\lambda)$ in $(*)$. Define $S_1 := \|(\hat{C}+\lambda I)^{-1}(C-\hat{C})(f_\lambda - f_0)\|_{\mathcal{H}}$, $S_2 := \|(\hat{C}+\lambda I)^{-1}(\hat{\xi}-\xi)\|_{\mathcal{H}}$ and $S_3 := \|(\hat{C}+\lambda I)^{-1}(C-\hat{C}) f_0\|_{\mathcal{H}}$ so that

$$\|f_{\lambda,n} - f_0\|_{\mathcal{H}} \le \|f_{\lambda,n} - f_\lambda\|_{\mathcal{H}} + \|f_\lambda - f_0\|_{\mathcal{H}} \le S_1 + S_2 + S_3 + \mathcal{A}_0(\lambda), \tag{16}$$

where $\mathcal{A}_0(\lambda) := \|f_\lambda - f_0\|_{\mathcal{H}}$. We now bound S_1, S_2 and S_3 using Proposition A.4. Note that $C = \int_\Omega C_x\, p_0(x)\, dx$ where C_x is defined in (12) is a positive, self-adjoint, trace-class operator and **(D)** (with $\varepsilon = 2$) implies that

$$\int_\Omega \|C_x\|_{HS}^2 p_0(x)\, dx \le \int_\Omega \left(\sum_{i=1}^d \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^2\right)^2 p_0(x)\, dx \le d \sum_{i=1}^d \int_\Omega \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^4\, p_0(x)\, dx < \infty.$$

Therefore, by Proposition A.4(i,iii),

$$S_1 \le \|(\hat{C}+\lambda I)^{-1}\| \|(C-\hat{C})(f_\lambda - f_0)\|_{\mathcal{H}} = O_{p_0}\left(\frac{\mathcal{A}_0(\lambda)}{\lambda\sqrt{n}}\right) \tag{17}$$

and

$$S_2 \le \|(\hat{C}+\lambda I)^{-1}\| \|\hat{\xi} - \xi\|_{\mathcal{H}} = O_{p_0}\left(\frac{1}{\lambda\sqrt{n}}\right), \tag{18}$$

where by using the technique in the proof of Proposition A.4(i), we show below that $\|\hat{\xi} - \xi\|_{\mathcal{H}} = O_{p_0}(n^{-1/2})$. Note that $\mathbb{E}_{p_0}\|\hat{\xi}-\xi\|_{\mathcal{H}}^2 = \frac{\int_\Omega \|\xi_x\|_{\mathcal{H}}^2 p_0(x)\, dx - \|\xi\|_{\mathcal{H}}^2}{n} \le \frac{\int_\Omega \|\xi_x\|_{\mathcal{H}}^2 p_0(x)\, dx}{n}$, where $\xi_x \in \mathcal{H}$ is defined in (13) and **(D)** (with $\varepsilon = 2$) implies that $\int_\Omega \|\xi_x\|_{\mathcal{H}}^2 p_0(x)\, dx < \infty$. Therefore $\|\hat{\xi} - \xi\|_{\mathcal{H}} = O_{p_0}(n^{-1/2})$ follows from an application of Chebyshev's inequality. Again using Proposition A.4(i,iii), we obtain that

$$S_3 \le \|(\hat{C}+\lambda I)^{-1}\| \|(C-\hat{C}) f_0\|_{\mathcal{H}} = O_{p_0}\left(\frac{1}{\lambda\sqrt{n}}\right). \tag{19}$$

Using the bounds in S_1, S_2 and S_3 in (16), we obtain

$$\|f_{\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}\left(\frac{1}{\lambda\sqrt{n}} + \frac{\mathcal{A}_0(\lambda)}{\lambda\sqrt{n}}\right) + \mathcal{A}_0(\lambda). \tag{20}$$

(i) By Proposition A.3(i), we have that $\mathcal{A}_0(\lambda) \to 0$ as $\lambda \to 0$ if $f_0 \in \overline{\mathcal{R}(C)}$. Therefore, it follows from (20) that $\|f_{\lambda,n} - f_0\|_{\mathcal{H}} \to 0$ as $\lambda \to 0$, $\lambda\sqrt{n} \to \infty$ and $n \to \infty$.

(ii) If $f_0 \in \mathcal{R}(C^\beta)$ for $\beta > 0$, it follows from Proposition A.3(ii) that

$$\mathcal{A}_0(\lambda) \le \max\{1, \|C\|^{\beta-1}\} \|C^{-\beta} f_0\|_{\mathcal{H}} \lambda^{\min\{1,\beta\}}$$

and therefore the result follows by choosing $\lambda = n^{-\max\left\{\frac{1}{4}, \frac{1}{2(\beta+1)}\right\}}$.

(iii) Note that

$$S_1 = \|(\hat{C}+\lambda I)^{-1}(C-\hat{C})(f_\lambda - f_0)\|_{\mathcal{H}} \le \|C(\hat{C}+\lambda I)^{-1}\| \|C^{-1}\| \|(C-\hat{C})(f_\lambda - f_0)\|_{\mathcal{H}},$$

$$S_2 = \|(\hat{C}+\lambda I)^{-1}(\hat{\xi}-\xi)\|_{\mathcal{H}} \le \|C(\hat{C}+\lambda I)^{-1}\| \|C^{-1}\| \|\hat{\xi} - \xi\|_{\mathcal{H}},$$

$$S_3 = \|(\hat{C}+\lambda I)^{-1}(C-\hat{C}) f_0\|_{\mathcal{H}} \le \|C(\hat{C}+\lambda I)^{-1}\| \|C^{-1}\| \|(C-\hat{C}) f_0\|_{\mathcal{H}}$$

and

$$\mathcal{A}_0(\lambda) = \|f_\lambda - f_0\|_{\mathcal{H}} \le \|C^{-1}\| \|C(f_\lambda - f_0)\|_{\mathcal{H}}.$$

It follows from Proposition A.4(v) that $\|C(\hat{C}+\lambda I)^{-1}\| \lesssim 1$ for $n \ge \frac{c}{\lambda^2}$ where c is a sufficiently large constant that depends on $\sum_{i=1}^d \int_\Omega (\partial_i \partial_{i+d} k(x,x))^2 p_0(x)\, dx$ but not on n and λ. Using the bounds on $\|(C-\hat{C})(f_\lambda - f_0)\|_{\mathcal{H}}$, $\|\hat{\xi} - \xi\|_{\mathcal{H}}$ and $\|(C-\hat{C}) f_0\|_{\mathcal{H}}$ from part (i) and the bound on $\|C(f_\lambda - f_0)\|_{\mathcal{H}}$ from Proposition A.3(ii), we therefore obtain

$$\|f_{\lambda,n} - f_0\|_{\mathcal{H}} \lesssim O_{p_0}\left(\frac{1}{\sqrt{n}}\right) + \lambda \tag{21}$$

as $n \to \infty$ and the result follows. ■

Remark Under slightly strong assumptions on the kernel, the bound on S_1 in (17) can be improved to obtain $S_1 = O_{p_0}(n^{-1/2})$ while the one on S_3 in (19) can be refined to obtain $S_3 = O_{p_0}\left(\sqrt{\frac{\mathcal{N}(\lambda)}{\lambda n}}\right)$ where $\mathcal{N}(\lambda) := Tr((C+\lambda I)^{-1} C)$ is the intrinsic dimension of $\mathcal{H}$. Using the fact that $\mathcal{N}(\lambda) \le \frac{1}{\lambda}$, it is easy to verify that the latter is an improved bound than the one in (19). In addition S_3 dominates S_1. However, if S_2 in (18) is not improved, then S_2 dominates S_3, thereby resulting in a bound that does not capture the smoothness of k (or the corresponding $\mathcal{H}$). Unfortunately, even with a refined analysis (not reported here), we are not able to improve the bound on S_2 wherein the difficulty lies with handling ξ.

8.6 Proof of Theorem 7

Before we prove the result, we present a lemma.

Lemma 14 *Suppose* $\sup_{x\in\Omega} k(x,x) < \infty$ *and* $\operatorname{supp}(q_0) = \Omega$. *Then* $\mathcal{F} = \mathcal{H}$ *and for any* $f_0 \in \mathcal{H}$ *there exists* $\tilde{f}_0 \in \overline{\mathcal{R}(C)}$ *such that* $p_{\tilde{f}_0} = p_0$.

Proof Since $\sup_{x\in\Omega} k(x,x) < \infty$, it implies that, for every $f \in \mathcal{H}$, $\int_\Omega e^{f(x)} q_0(x)\, dx < \infty$ and hence $\mathcal{F} = \mathcal{H}$. Also, under the assumptions on k and q_0, it is easy to verify that $\operatorname{supp}(p_0) = \Omega$, which implies

$$\mathcal{N}(C) = \left\{ f \in \mathcal{H} \,:\, \int_\Omega \|\nabla f\|_2^2\, p_0(x)\, dx = 0 \right\}$$

is either $\mathbb{R}$ or $\{0\}$, where $\mathcal{N}(C)$ denotes the null space of C. Let $\tilde{f}_0$ be the orthogonal projection of f_0 onto $\overline{\mathcal{R}(C)} = \mathcal{N}(C)^\perp$. Then $\tilde{f}_0 - f_0 \in \mathbb{R}$ and therefore $p_{\tilde{f}_0} = p_{f_0}$. ■

Proof of Theorem 7. From Theorem 4(iii), $f_\lambda = (C+\lambda I)^{-1}Cf_0 = (C+\lambda I)^{-1}C\tilde{f}_0$ where the second equality follows from the proof of Lemma 14. Now, carrying out the decomposition as in the proof of Theorem 6(i), we obtain $f_{\lambda,n} - f_\lambda = (\hat{C}+\lambda I)^{-1}(C-\hat{C})(f_\lambda - \tilde{f}_0) - (\hat{C}+\lambda I)^{-1}(\hat{\xi}-\xi) + (\hat{C}+\lambda I)^{-1}(C-\hat{C})\tilde{f}_0$ and therefore,

$$\|f_{\lambda,n} - \tilde{f}_0\|_{\mathcal{H}} \leq \|(\hat{C}+\lambda I)^{-1}\| \left(\|(C-\hat{C})(f_\lambda - \tilde{f}_0)\|_{\mathcal{H}} + \|\xi - \hat{\xi}\|_{\mathcal{H}} + \|(C-\hat{C})\tilde{f}_0\|_{\mathcal{H}} \right) + \tilde{\mathcal{A}}_0(\lambda),$$

where $\tilde{\mathcal{A}}_0(\lambda) = \|f_\lambda - \tilde{f}_0\|_{\mathcal{H}}$. The bounds on these quantities follow those in the proof of Theorem 6(i) verbatim and so the consistency result in Theorem 6(i) holds for $\|f_{\lambda,n} - \tilde{f}_0\|_{\mathcal{H}}$. By Lemma 14, since $p_{f_0} = p_{\tilde{f}_0}$, it is sufficient to consider the convergence of $p_{f_{\lambda,n}}$ to $p_{\tilde{f}_0}$. Therefore, the convergence (along with rates) in L^r (for any $1 \leq r \leq \infty$), Hellinger and KL distances follow from using the bound $\|f_{\lambda,n} - \tilde{f}_0\|_\infty \leq \sqrt{\|k\|_\infty}\|f_{\lambda,n} - \tilde{f}_0\|_{\mathcal{H}}$ (obtained through the reproducing property of k) in Lemma A.1 and invoking Theorem 6.

In the following, we obtain a bound on $J(p_0\|p_{f_{\lambda,n}}) = \frac{1}{2}\|\sqrt{C}(f_{\lambda,n} - f_0)\|^2_{\mathcal{H}}$. While one can trivially use the bound $\|\sqrt{C}(f_{\lambda,n} - f_0)\|^2_{\mathcal{H}} \leq \|\sqrt{C}\|^2\|f_{\lambda,n} - f_0\|^2_{\mathcal{H}}$ to obtain a rate on $J(p_0\|p_{f_{\lambda,n}})$ through the result in Theorem 6(ii), a better rate can be obtained by carefully bounding $\|\sqrt{C}(f_{\lambda,n} - f_0)\|^2_{\mathcal{H}}$ as shown below. Consider

$$\|\sqrt{C}(f_{\lambda,n} - f_0)\|_{\mathcal{H}} \leq \|\sqrt{C}(f_{\lambda,n} - f_\lambda)\|_{\mathcal{H}} + \tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda) + \mathcal{A}^\star_{\frac{1}{2}}(\lambda)$$

$$\leq \|\sqrt{C}(\hat{C}+\lambda I)^{-1}\| \left(\|(C-\hat{C})(f_\lambda - \tilde{f}_0)\|_{\mathcal{H}} + \|\xi - \hat{\xi}\|_{\mathcal{H}} + \|(C-\hat{C})\tilde{f}_0\|_{\mathcal{H}} \right) + \tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda) + \mathcal{A}^\star_{\frac{1}{2}}(\lambda),$$

where $\tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda) := \|\sqrt{C}(f_\lambda - \tilde{f}_0)\|_{\mathcal{H}}$ and $\mathcal{A}^\star_{\frac{1}{2}}(\lambda) := \|\sqrt{C}(\tilde{f}_0 - f_0)\|_{\mathcal{H}}$. It follows from Theorem 4(i) and Lemma 14 that $\mathcal{A}^\star_{\frac{1}{2}}(\lambda) = J(p_0\|p_{\tilde{f}_0}) = 0$. Also it follows from Proposition A.4(v) that $\|\sqrt{C}(\hat{C}+\lambda I)^{-1}\| \lesssim \frac{1}{\sqrt{\lambda}}$ for $n \geq \frac{c}{\lambda^2}$ where c is a large enough constant that does not depend on n and λ and depends only on $\sum_{i=1}^d \int \|\partial_i k(x,\cdot)\|^4_{\mathcal{H}} p_0(x)\,dx$. Using the bounds from the proof of Theorem 6(i) for the rest of the terms within parenthesis, we obtain

$$\|\sqrt{C}(f_{\lambda,n} - f_0)\|_{\mathcal{H}} \leq O_{p_0}\left(\frac{1}{\sqrt{\lambda n}}\right) + \tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda). \tag{22}$$

The consistency result therefore follows from Proposition A.3(i) by noting that $\tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda) \to 0$ as $\lambda \to 0$. If $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta \geq 0$, then Proposition A.3(ii) yields $\tilde{\mathcal{A}}_{\frac{1}{2}}(\lambda) \leq \max\{1, \|C\|^{\beta-\frac{1}{2}}\}\lambda^{\min\{1,\beta+\frac{1}{2}\}}\|C^{-\beta}f_0\|_{\mathcal{H}}$ which when used in (22) provides the desired rate with $\lambda = n^{-\max\{\frac{1}{3},\frac{1}{2(\beta+1)}\}}$. If $\|C^{-1}\| < \infty$, then the result follows by noting $\|\sqrt{C}(f_{\lambda,n} - f_0)\|_{\mathcal{H}} \leq \|\sqrt{C}\|\|f_{\lambda,n} - f_0\|_{\mathcal{H}}$ and invoking the bound in (21). ■

8.7 Proof of Proposition 8

Observation 1: By (Wendland, 2005, Theorem 10.12), we have

$$\mathcal{H} = \left\{ f \in L^2(\mathbb{R}^d) \cap C_b(\mathbb{R}^d) : \frac{f^\wedge}{\sqrt{\psi^\wedge}} \in L^2(\mathbb{R}^d) \right\},$$

where $f^\wedge$ is defined in L^2 sense. Since

$$\int_{\mathbb{R}^d} |f^\wedge(\omega)|\,d\omega \leq \left(\int_{\mathbb{R}^d} \frac{|f^\wedge(\omega)|^2}{\psi^\wedge(\omega)}\,d\omega \right)^{\frac{1}{2}} \left(\int_{\mathbb{R}^d} \psi^\wedge(\omega)\,d\omega \right)^{\frac{1}{2}} < \infty$$

where we used $\psi^\wedge \in L^1(\mathbb{R}^d)$ (see Wendland, 2005, Corollary 6.12), we have $f^\wedge \in L^1(\mathbb{R}^d)$. Hence Plancherel's theorem and continuity of f along with the inverse Fourier transform of $f^\wedge$ allow to recover any $f \in \mathcal{H}$ pointwise from its Fourier transform as

$$f(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{ix^T\omega} f^\wedge(\omega)\,d\omega,\ x \in \mathbb{R}^d. \tag{23}$$

Observation 2: Since $\psi^\wedge \in L^1(\mathbb{R}^d)$ and $\psi^\wedge \geq 0$, we have for all $j = 1, \ldots, d$,

$$\left(\int_{\mathbb{R}^d} |\omega_j| \psi^\wedge(\omega)\,d\omega \right)^2 = \left(\int_{\mathbb{R}^d} \psi^\wedge(\omega)\,d\omega \right)^2 \left(\int_{\mathbb{R}^d} |\omega_j| \frac{\psi^\wedge(\omega)}{\int_{\mathbb{R}^d} \psi^\wedge(\omega)\,d\omega}\,d\omega \right)^2$$
$$\overset{(*)}{\leq} \left(\int_{\mathbb{R}^d} \psi^\wedge(\omega)\,d\omega \right) \left(\int_{\mathbb{R}^d} |\omega_j|^2 \psi^\wedge(\omega)\,d\omega \right)$$
$$\leq \left(\int_{\mathbb{R}^d} \psi^\wedge(\omega)\,d\omega \right) \left(\int_{\mathbb{R}^d} \|\omega\|^2 \psi^\wedge(\omega)\,d\omega \right) \overset{(i)}{<} \infty,$$

where we used Jensen's inequality in $(*)$. This means $\omega_j \psi^\wedge(\omega) \in L^1(\mathbb{R}^d)$, $\forall\, j \in [d]$ which ensures the existence of its Fourier transform and so

$$\partial_j \psi(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} (i\omega_j)\psi^\wedge(\omega) e^{ix^T\omega}\,d\omega,\ x \in \mathbb{R}^d,\ \forall\, j \in [d]. \tag{24}$$

Observation 3: For $g \in \mathcal{H}$, we have for all $j \in [d]$,

$$\int_{\mathbb{R}^d} |\omega_j||g^\wedge(\omega)|\,d\omega \leq \left(\int_{\mathbb{R}^d} \frac{|g^\wedge(\omega)|^2}{\psi^\wedge(\omega)}\,d\omega \right)^{\frac{1}{2}} \left(\int_{\mathbb{R}^d} |\omega_j|^2 \psi^\wedge(\omega)\,d\omega \right)^{\frac{1}{2}}$$
$$\leq \left(\int_{\mathbb{R}^d} \frac{|g^\wedge(\omega)|^2}{\psi^\wedge(\omega)}\,d\omega \right)^{\frac{1}{2}} \left(\int_{\mathbb{R}^d} \|\omega\|^2 \psi^\wedge(\omega)\,d\omega \right)^{\frac{1}{2}} \overset{(i)}{<} \infty,$$

which implies $\omega_j g^\wedge(\omega) \in L^1(\mathbb{R}^d)$, $\forall\, j = 1, \ldots, d$. Therefore,

$$\partial_j g(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} (i\omega_j) g^\wedge(\omega) e^{ix^T\omega}\,d\omega,\ x \in \mathbb{R}^d,\ \forall\, j \in [d]. \tag{25}$$

Observation 4: For any $g \in \mathcal{G}$, we have

$$\int_{\mathbb{R}^d} \frac{|g^\wedge(\omega)|^2}{\psi^\wedge(\omega)}\,d\omega = \int_{\mathbb{R}^d} \frac{|g^\wedge(\omega)|^2}{\phi^\wedge(\omega)} \frac{\phi^\wedge(\omega)}{\psi^\wedge(\omega)}\,d\omega \leq \|g\|^2_{\mathcal{G}} \left\| \frac{\phi^\wedge}{\psi^\wedge} \right\|_\infty \overset{(ii)}{<} \infty,$$

which implies $g \in \mathcal{H}$, i.e., $\mathcal{G} \subset \mathcal{H}$.

We now use these observations to prove the result. Since $f_0 \in \mathcal{R}(C)$, there exists $g \in \mathcal{H}$ such that $f_0 = Cg$, which means

$$f_0(y) \;=\; \int_{\mathbb{R}^d} \sum_{j=1}^d \partial_j k(x,y)\,\partial_j\, p_0(x)\,dx$$

$$\overset{(24)}{=} \int_{\mathbb{R}^d} \sum_{j=1}^{d} \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{i(x-y)^T\omega} (i\omega_j)\psi^\wedge(\omega)\, d\omega\, \partial_j g(x)\, p_0(x)\, dx$$

$$\overset{(\dagger)}{=} \int_{\mathbb{R}^d} \sum_{j=1}^{d} \left(\frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{ix^T\omega} \partial_j g(x)\, p_0(x)\, dx \right) (i\omega_j)\psi^\wedge(\omega) e^{-iy^T\omega}\, d\omega$$

$$\overset{(25)}{=} \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} \sum_{j=1}^{d} \overline{(i(\cdot)_j g^\wedge * p_0^\wedge)(\omega)} (i\omega_j)\psi^\wedge(\omega) e^{-iy^T\omega}\, d\omega$$

which from (23) means $f_0^\wedge(\omega) = \sum_{j=1}^d \overline{(i(\cdot)_j g^\wedge * p_0^\wedge)(-\omega)}(-i\omega_j)\psi^\wedge(\omega)$ where we have invoked Fubini's theorem in (†) and $*$ represents the convolution. Define $\|\cdot\|_{L^r(\mathbb{R}^d)} := \|\cdot\|_r$ and $\theta := \frac{r}{r-1}$. Consider

$$\begin{aligned}
\|f_0\|_{\mathcal{G}}^2 &= \int_{\mathbb{R}^d} \frac{|f_0^\wedge(\omega)|^2}{\phi^\wedge(\omega)}\, d\omega = \int_{\mathbb{R}^d} \left| \sum_{j=1}^{d} \overline{(i(\cdot)_j g^\wedge * p_0^\wedge)(-\omega)}(i\omega_j) \right|^2 (\psi^\wedge)^2(\omega)(\phi^\wedge(\omega))^{-1}\, d\omega \\
&\le \int_{\mathbb{R}^d} \left(\sum_{j=1}^{d} \left| i(\cdot)_j g^\wedge * p_0^\wedge \right| (-\omega)|\omega_j| \right)^2 (\psi^\wedge)^2(\omega)(\phi^\wedge(\omega))^{-1}\, d\omega \\
&\le \int_{\mathbb{R}^d} \sum_{j=1}^{d} \left| i(\cdot)_j g^\wedge * p_0^\wedge \right|^2 (-\omega)\|\omega\|^2 (\psi^\wedge)^2(\omega)(\phi^\wedge(\omega))^{-1}\, d\omega \\
&\le \left\| \sum_{j=1}^{d} \left| i\omega_j g^\wedge(\omega) * p_0^\wedge(\omega) \right|^2 (\cdot) \right\|_{\frac{\theta}{2}} \left\| \|\cdot\|^2 (\psi^\wedge)^2(\cdot)(\phi^\wedge(\cdot))^{-1} \right\|_{\frac{r}{2-r}} \overset{(iii)}{<} \infty,
\end{aligned}$$

where in the following we show that $\sum_{j=1}^d |i\omega_j g^\wedge(\omega) * p_0^\wedge(\omega)|^2(\cdot) \in L^{\frac{\theta}{2}}(\mathbb{R}^d)$, i.e.,

$$\begin{aligned}
\left\| \sum_{j=1}^{d} \left| i\omega_j g^\wedge(\omega) * p_0^\wedge(\omega) \right|^2 (\cdot) \right\|_{\frac{\theta}{2}} &\le \sum_{j=1}^{d} \left\| \left| i\omega_j g^\wedge(\omega) * p_0^\wedge(\omega) \right|^2 (\cdot) \right\|_{\frac{\theta}{2}} = \sum_{j=1}^{d} \left\| i\omega_j g^\wedge(\omega) * p_0^\wedge(\omega) \right\|_\theta^2 \\
&\overset{(*)}{\le} \textstyle\sum_{j=1}^d \|i\omega_j g^\wedge(\omega)\|_1^2 \, \|p_0^\wedge\|_\theta^2 \overset{(**)}{\le} \|p_0\|_r^2 \sum_{j=1}^d \|i\omega_j g^\wedge(\omega)\|_1^2 \overset{(\ddagger)}{<} \infty,
\end{aligned}$$

where we have invoked generalized Young's inequality (Folland, 1999, Proposition 8.9) in $(*)$, Hausdorff-Young inequality (Folland, 1999, p. 253) in $(**)$, and observation 3 combined with (iv) in $(\ddagger)$. This shows that $f_0 \in \mathcal{R}(C) \Rightarrow f_0 \in \mathcal{G}$, i.e., $\mathcal{R}(C) \subset \mathcal{G}$. ■

8.8 Proof of Theorem 9

To prove Theorem 9, we need the following lemma (De Vito et al., 2012, Lemma 5), which is due to Andreas Maurer.

Lemma 15 *Suppose A and B are self-adjoint Hilbert-Schmidt operators on a separable Hilbert space H with spectrum contained in the interval $[a,b]$, and let $(\sigma_i)_{i\in I}$ and $(\tau_j)_{j\in J}$ be*

the eigenvalues of A and B, respectively. Given a function $r : [a,b] \to \mathbb{R}$, if there exists a finite constant L such that $|r(\sigma_i) - r(\tau_j)| \le L|\sigma_i - \tau_j|$, $\forall\, i \in I$, $j \in J$, then $\|r(A) - r(B)\|_{HS} \le L\|A - B\|_{HS}$.

Proof of Theorem 9. (i) The proof follows the ideas in the proof of Theorem 10 in Bauer et al. (2007), which is a more general result dealing with the smoothness condition, $f_0 \in \mathcal{R}(\Theta(C))$ where Θ is operator monotone. Recall that Θ is operator monotone on $[0,b]$ if for any pair of self-adjoint operators U, V with spectra in $[0,b]$ such that $U \le V$, we have $\Theta(U) \le \Theta(V)$, where "$\le$" is the partial ordering for self-adjoint operators on some Hilbert space H, which means for any $f \in H$, $\langle f, Uf\rangle_H \le \langle f, Vf\rangle_H$. In our case, we adapt the proof for $\Theta(C) = C^\beta$. Define $r_\lambda(\alpha) := g_\lambda(\alpha)\alpha - 1$. Since $f_0 \in \mathcal{R}(C^\beta)$, there exists $h \in \mathcal{H}$ such that $f_0 = C^\beta h$, which yields

$$\begin{aligned}
f_{g,\lambda,n} - f_0 &= -g_\lambda(\hat{C})\hat{\xi} - f_0 = -g_\lambda(\hat{C})(\hat{\xi} + \hat{C}f_0) + r_\lambda(\hat{C})C^\beta h \\
&= -g_\lambda(\hat{C})(\hat{\xi} - \xi) + g_\lambda(\hat{C})(C - \hat{C})f_0 + r_\lambda(\hat{C})\hat{C}^\beta h + r_\lambda(\hat{C})(C^\beta - \hat{C}^\beta)h. \quad (26)
\end{aligned}$$

so that

$$\begin{aligned}
\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} \le \underbrace{\|g_\lambda(\hat{C})(\hat{\xi} - \xi)\|_{\mathcal{H}}}_{(A)} + \underbrace{\|g_\lambda(\hat{C})(\hat{C} - C)f_0\|_{\mathcal{H}}}_{(B)} + \underbrace{\|r_\lambda(\hat{C})C^\beta h\|_{\mathcal{H}}}_{(C)} \\
+ \underbrace{\|r_\lambda(\hat{C})(C^\beta - \hat{C}^\beta)h\|_{\mathcal{H}}}_{(D)}.
\end{aligned}$$

We now bound (A)–(D). Since $(A) \le \|g_\lambda(\hat{C})\|\|\hat{\xi} - \xi\|_{\mathcal{H}}$, we have $(A) = O_{p_0}\left(\frac{1}{\lambda\sqrt{n}}\right)$ where we used (b) in **(E)** and the bound on $\|\hat{\xi} - \xi\|_{\mathcal{H}}$ from the proof of Theorem 6(i). Similarly, $(B) \le \|g_\lambda(\hat{C})\|\|(\hat{C} - C)f_0\|_{\mathcal{H}}$ implies $(B) = O_{p_0}\left(\frac{1}{\lambda\sqrt{n}}\right)$ where (b) in **(E)** and Proposition A.4(i) are invoked. Also, (d) in **(E)** implies that

$$(C) \le \|r_\lambda(\hat{C})\hat{C}^\beta\|\|h\|_{\mathcal{H}} \le \max\{\gamma_\beta, \gamma_{\eta_0}\}\lambda^{\min\{\beta,\eta_0\}}\|C^{-\beta}f_0\|_{\mathcal{H}}.$$

(D) can be bounded as

$$(D) \le \|r_\lambda(\hat{C})\|\|C^\beta - \hat{C}^\beta\|\|C^{-\beta}f_0\|_{\mathcal{H}}.$$

We now consider two cases:

$\underline{\beta \le 1}$: Since $\alpha \mapsto \alpha^\theta$ is operator monotone on $[0,\chi]$ for $0 \le \theta \le 1$, by Theorem 1 in Bauer et al. (2007), there exists a constant c_θ such that $\|\hat{C}^\theta - C^\theta\| \le c_\theta\|\hat{C} - C\|^\theta \le c_\theta\|\hat{C} - C\|_{HS}^\theta$. We now obtain a bound on $\|\hat{C} - C\|_{HS}$. To this end, consider

$$\begin{aligned}
\mathbb{E}\|\hat{C} - C\|_{HS}^2 &= \mathbb{E}\|\hat{C}\|_{HS}^2 - \|C\|_{HS}^2 \\
&\le \frac{1}{n}\int \left\| \sum_{i=1}^{d} \partial_i k(x,\cdot) \otimes \partial_i k(x,\cdot) \right\|_{HS}^2 p_0(x)\, dx \le \frac{d}{n} \sum_{i=1}^{d} \int \|\partial_i k(x,\cdot)\|^4 p_0(x)\, dx,
\end{aligned}$$

which by Chebyshev's inequality implies that

$$\|\hat{C} - C\|_{HS} = O_{p_0}(n^{-1/2})$$

and therefore $(D) = O_{p_0}(n^{-\beta/2})$. Since $\lambda \geq n^{-1/2}$, we have $(D) = O_{p_0}(\lambda^{\beta})$.

$\underline{\beta > 1}$: Since $\alpha \mapsto \alpha^{\theta}$ is Lipschitz on $[0, \chi]$ for $\theta \geq 1$, by Lemma 15, $\|C^{\beta} - \hat{C}^{\beta}\| \leq \|C^{\beta} - \hat{C}^{\beta}\|_{HS} \leq \beta\chi^{\beta-1}\|C - \hat{C}\|_{HS}$ and therefore $(C) = O_{p_0}(n^{-1/2})$.

Collecting all the above bounds, we obtain

$$\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} \leq O_{p_0}\left(\frac{1}{\lambda\sqrt{n}}\right) + O_{p_0}\left(\lambda^{\min\{\beta,\eta_0\}}\right)$$

and the result follows. The proofs of the claims involving L^r, h and KL follow exactly the same ideas as in the proof of Theorem 7 by using the above bound on $\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}}$ in Lemma A.1.

(ii) We now bound $J(p_0\|p_{f_{g,\lambda,n}}) = \|\sqrt{C}(f_{g,\lambda,n} - f_0)\|_{\mathcal{H}}^2$ as follows. Note that

$$\sqrt{C}(f_{g,\lambda,n} - f_0) = \underbrace{(\sqrt{C} - \sqrt{\hat{C}})(f_{g,\lambda,n} - f_0)}_{(I')} + \underbrace{\sqrt{\hat{C}}(f_{g,\lambda,n} - f_0)}_{(II')}.$$

We bound $\|(I')\|_{\mathcal{H}}$ as

$$\begin{aligned}\|(I')\|_{\mathcal{H}} \leq \|\sqrt{C} - \sqrt{\hat{C}}\|\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} &\leq c_{\frac{1}{2}}\sqrt{\|C - \hat{C}\|}_{HS}\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} \\ &= O_{p_0}\left(\frac{1}{\sqrt{\lambda n}}\right) + O_{p_0}\left(\lambda^{\min\{\beta,\eta_0\}+\frac{1}{2}}\right),\end{aligned}$$

where we used the fact that $\alpha \mapsto \sqrt{\alpha}$ is operator monotone along with $\lambda \geq n^{-1/2}$. Using (26), $\|(II')\|_{\mathcal{H}}$ can be bounded as

$$\begin{aligned}\|(II')\|_{\mathcal{H}} \leq \|\sqrt{\hat{C}}g_\lambda(\hat{C})\|\|\hat{\xi} + \hat{C}f_0\|_{\mathcal{H}} + \|\sqrt{\hat{C}}r_\lambda(\hat{C})\hat{C}^{\beta}\|\|C^{-\beta}f_0\|_{\mathcal{H}} \\ + \|\sqrt{\hat{C}}r_\lambda(\hat{C})\|\|C^{\beta} - \hat{C}^{\beta}\|\|C^{-\beta}f_0\|_{\mathcal{H}}\end{aligned}$$

where

$$\|\sqrt{\hat{C}}g_\lambda(\hat{C})\| \leq \sqrt{\frac{A_g B_g}{\lambda}}, \;\; \|\sqrt{\hat{C}}r_\lambda(\hat{C})\hat{C}^{\beta}\| \leq (\gamma_{\beta+\frac{1}{2}} \vee \gamma_{\eta_0})\lambda^{\min\{\beta+\frac{1}{2},\eta_0\}}$$

and

$$\|\sqrt{\hat{C}}r_\lambda(\hat{C})\| \leq (\gamma_{\frac{1}{2}} \vee \gamma_{\eta_0})\lambda^{\min\{\frac{1}{2},\eta_0\}}$$

with $\|\hat{C}f_0 + \hat{\xi}\|$ and $\|C^{\beta} - \hat{C}^{\beta}\|$ bounded as in part (i) above. Here $(a \vee b) := \max\{a, b\}$. Combining $\|(I')\|_{\mathcal{H}}$ and $\|(II')\|_{\mathcal{H}}$, we obtain the required result.

(iii) The proof follows the ideas in the proof of Theorems 6 and 7. Consider $f_{g,\lambda,n} - f_0 = -g_\lambda(\hat{C})(\hat{C}f_0 + \hat{\xi}) + r_\lambda(\hat{C})f_0$ so that

$$\begin{aligned}\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} &\leq \|C^{-1}\|\|Cg_\lambda(\hat{C})(\hat{C}f_0 + \hat{\xi})\|_{\mathcal{H}} + \|C^{-1}\|\|Cr_\lambda(\hat{C})f_0\|_{\mathcal{H}} \\ &\leq \|C^{-1}\|\|\hat{C}f_0 + \hat{\xi}\|_{\mathcal{H}}\left(\|\hat{C}g_\lambda(\hat{C})\| + \|\hat{C} - C\|\|g_\lambda(\hat{C})\|\right) \\ &\quad + \|C^{-1}\|\|f_0\|_{\mathcal{H}}\left(\|\hat{C}r_\lambda(\hat{C})\| + \|\hat{C} - C\|\|r_\lambda(\hat{C})\|\right).\end{aligned}$$

Therefore $\|f_{g,\lambda,n} - f_0\|_{\mathcal{H}} = O_{p_0}(n^{-1/2}) + O\left(\lambda^{\min\{1,\eta_0\}}\right)$ where we used the fact that $\lambda \geq n^{-1/2}$ and the result follows. ■

8.9 Proof of Theorem 10

Before we analyze $J(p_0\|p_{f_{\lambda,n}})$, we need a small calculation for notational convenience. For any probability densities $p, q \in C^1$, it is clear that $\sqrt{2J(p\|q)} = \|\|\nabla \log p - \nabla \log q\|_2\|_{L^2(p)}$. We generalize this by defining

$$\sqrt{2J(p\|q\|\mu)} := \|\|\nabla \log p - \nabla \log q\|_2\|_{L^2(\mu)}.$$

Clearly, if $\mu = p$, then $J(p\|q\|\mu)$ matches with $J(p\|q)$. Therefore, for probability densities $p, q, r \in C^1$,

$$\sqrt{J(p\|r\|p)} \leq \sqrt{J(p\|q\|p)} + \sqrt{J(q\|r\|p)}. \tag{27}$$

Based on (27), we have

$$\begin{aligned}\sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} &\leq \sqrt{J(p_0\|p_{f_{\lambda,n}}\|p_0)} \leq \sqrt{J(p_0\|p_{f^*}\|p_0)} + \sqrt{J(p_{f^*}\|p_{f_{\lambda,n}}\|p_0)} \\ &= \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p\|p_0)} + \sqrt{J(p_{f^*}\|p_{f_{\lambda,n}}\|p_0)} \\ &= \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} + \frac{1}{\sqrt{2}}\sqrt{\langle f_{\lambda,n} - f^*, C(f_{\lambda,n} - f^*)\rangle_{\mathcal{H}}} \\ &= \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} + \frac{1}{\sqrt{2}}\|\sqrt{C}(f_{\lambda,n} - f^*)\|_{\mathcal{H}} \\ &= \sqrt{\inf_{p\in\mathcal{P}} J(p_0\|p)} + \frac{1}{\sqrt{2}}\|\sqrt{C}(f_{\lambda,n} - f_\lambda)\|_{\mathcal{H}} + \frac{1}{\sqrt{2}}\mathcal{A}^*(\lambda),\end{aligned} \tag{28}$$

where $\mathcal{A}^*(\lambda) = \|\sqrt{C}(f_\lambda - f^*)\|_{\mathcal{H}}$. The result simply follows from the proof of Theorem 7, where we showed that $\|\sqrt{C}(f_{\lambda,n} - f_\lambda)\|_{\mathcal{H}} = O_{p_0}\left(\frac{1}{\sqrt{\lambda n}}\right)$ and $\mathcal{A}^*(\lambda) = O(\lambda^{\min\{1,\beta+\frac{1}{2}\}})$ if $f^* \in \mathcal{R}(C^{\beta})$ for $\beta \geq 0$ as $\lambda \to 0$, $n \to \infty$. When $\|C^{-1}\| < \infty$, we bound $\|\sqrt{C}(f_{\lambda,n} - f^*)\|_{\mathcal{H}}$ in (28) as $\|\sqrt{C}\|\|f_{\lambda,n} - f^*\|_{\mathcal{H}}$ where $\|f_{\lambda,n} - f^*\|_{\mathcal{H}}$ is in turn bounded as in (21). ■

8.10 Proof of Proposition 11

For $f \in \mathcal{H}$, we have

$$\|f\|_{\mathcal{W}_2}^2 = \int_\Omega \sum_{i=1}^d (\partial_i f)^2 p_0(x)\,dx \leq \|f\|_{\mathcal{H}}^2 \int_\Omega \sum_{i=1}^d \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^2 p_0(x)\,dx < \infty,$$

which means $f \in \mathcal{W}_2(\Omega, p_0)$ and therefore $[f]_\sim \in W_2(\Omega, p_0)$. Since $\|I_k f\|_{W_2} = \|[f]_\sim\|_{\mathcal{W}_2^\sim} = \|f\|_{\mathcal{W}_2} \leq c\|f\|_{\mathcal{H}} < \infty$ where c is some constant, it is clear that I_k is a continuous map from $\mathcal{H}$ to $W_2(\Omega, p_0)$. The adjoint $S_k : W_2(\Omega, p_0) \to \mathcal{H}$ of $I_k : \mathcal{H} \to W_2(\Omega, p_0)$ is defined by the relation $\langle S_k f, g\rangle_{\mathcal{H}} = \langle f, I_k g\rangle_{W_2}$, $f \in W_2(\Omega, p_0)$, $g \in \mathcal{H}$. If $f := [h]_\sim \in \mathcal{W}_2^\sim(\Omega, p_0)$, then

$$\langle [h]_\sim, I_k g\rangle_{W_2} = \langle [h]_\sim, [g]_\sim\rangle_{\mathcal{W}_2^\sim} = \sum_{|\alpha|=1} \int_\Omega (\partial^\alpha h)(x)(\partial^\alpha g)(x)\, p_0(x)\,dx.$$

For $y \in \Omega$ and $g = k(\cdot, y)$, this yields

$$S_k[h]_\sim(y) = \langle S_k[h]_\sim, k(\cdot,y)\rangle_{\mathcal{H}} = \langle [h]_\sim, I_k k(\cdot,y)\rangle_{W_2} = \int_\Omega \sum_{i=1}^d \partial_i k(x,y)\partial_i h(x) p_0(x)\,dx.$$

We now show that I_k is Hilbert-Schmidt. Since $\mathcal{H}$ is separable, let $(e_l)_{l\geq 1}$ be an ONB of $\mathcal{H}$. Then we have

$$\begin{aligned}\sum_l \|I_k e_l\|_{W_2}^2 = \sum_l \int_\Omega \sum_{i=1}^d (\partial_i e_l(x))^2 p_0(x)\,dx &= \int_\Omega \sum_{i=1}^d \sum_l \langle e_l, \partial_i k(x,\cdot)\rangle_{\mathcal{H}}^2 p_0(x)\,dx \\ &= \int_\Omega \sum_{i=1}^d \|\partial_i k(x,\cdot)\|_{\mathcal{H}}^2 p_0(x)\,dx < \infty,\end{aligned}$$

which proves that I_k is Hilbert-Schmidt (hence compact) and therefore S_k is also Hilbert-Schmidt and compact. The other assertions about $S_k I_k$ and $I_k S_k$ are straightforward. ■

8.11 Proof of Theorem 12

By slight abuse of notation, $f_\star$ is used to denote $[f_\star]_\sim$ in the proof for simplicity. For $f \in \mathcal{F}$, we have

$$J(p_0\|p_f) = \frac{1}{2}\|I_k f - f_\star\|_{W_2}^2 = \frac{1}{2}\langle E_k f, f\rangle_{\mathcal{H}} - \langle S_k f_\star, f\rangle_{\mathcal{H}} + \frac{1}{2}\|f_\star\|_{W_2}^2.$$

Since k satisfies **(C)** it is easy to verify that $\langle S_k f_\star, f\rangle_{\mathcal{H}} = \langle f, -\xi\rangle_{\mathcal{H}}$, $\forall\, f \in \mathcal{H}$ (see proof of Theorem 4(ii)). This implies $S_k f_\star = -\xi$ and

$$J(p_0\|p_f) = \frac{1}{2}\langle E_k f, f\rangle_{\mathcal{H}} + \langle f, \xi\rangle_{\mathcal{H}} + \frac{1}{2}\|f_\star\|_{W_2}^2, \tag{29}$$

where ξ is defined in Theorem 4(ii), and E_k is precisely the operator C defined in Theorem 4(ii). Following the proof of Theorem 4(ii), for $\lambda > 0$, it is easy to show that the unique minimizer of the regularized objective, $J(p_0\|p_f) + \frac{\lambda}{2}\|f\|_{\mathcal{H}}^2$ exists and is given by

$$f_\lambda = -(E_k + \lambda I)^{-1}\xi = (E_k + \lambda I)^{-1} S_k f_\star. \tag{30}$$

We would like to reiterate that (29) and (30) also match with their counterparts in Theorem 4 and therefore as in Theorem 4(iv), an estimator of $f_\star$ is given by $f_{\lambda,n} = -(\hat{E}_k + \lambda I)^{-1}\hat{\xi}$. In other words, this is the same as in Theorem 4(iv) since $\hat{E}_k = \hat{C}$, and can be solved by a simple linear system provided in Theorem 5. Here $\hat{E}_k$ is the empirical estimator of E_k. Now consider

$$\begin{aligned}\sqrt{2\,J(p_0\|p_{f_{\lambda,n}})} = \|I_k f_{\lambda,n} - f_\star\|_{W_2} &\leq \|I_k(f_{\lambda,n} - f_\lambda)\|_{W_2} + \|I_k f_\lambda - f_\star\|_{W_2} \\ &= \|\sqrt{E_k}(f_{\lambda,n} - f_\lambda)\|_{\mathcal{H}} + \mathcal{B}(\lambda),\end{aligned} \tag{31}$$

where $\mathcal{B}(\lambda) := \|I_k f_\lambda - f_\star\|_{W_2}$. The proof now proceeds using the following decomposition, equivalent to the one used in the proof of Theorem 6(i), i.e.,

$$f_{\lambda,n} - f_\lambda = -(\hat{E}_k + \lambda I)^{-1}\hat{\xi} - f_\lambda$$

$$\begin{aligned}&= -(\hat{E}_k + \lambda I)^{-1}(\hat{\xi} + \hat{E}_k f_\lambda + \lambda f_\lambda) \\ &\overset{(\dagger)}{=} -(\hat{E}_k + \lambda I)^{-1}(\hat{\xi} + \hat{E}_k f_\lambda + S_k f_\star - E_k f_\lambda - \hat{S}_k f_\star + \hat{S}_k f_\star),\end{aligned}$$

where we used (30) in (†). $\hat{S}_k f_\star$ is well-defined as it is the empirical version of the restriction of S_k to $\mathcal{W}_2^\sim(p_0)$. Since $S_k f_\star - E_k f_\lambda = S_k(f_\star - I_k f_\lambda)$ and $\hat{S}_k f_\star - \hat{E}_k f_\lambda = \hat{S}_k(f_\star - I_k f_\lambda)$, we have

$$f_{\lambda,n} - f_\lambda = -(\hat{E}_k + \lambda I)^{-1}(\hat{\xi} + \hat{S}_k f_\star) + (\hat{E}_k + \lambda I)^{-1}(\hat{S}_k - S_k)(f_\star - I_k f_\lambda)$$

and so

$$\|\sqrt{E_k}(f_{\lambda,n} - f_\lambda)\|_{\mathcal{H}} \leq \|\sqrt{E_k}(\hat{E}_k + \lambda I)^{-1}\| \left(\|\hat{\xi} + \hat{S}_k f_\star\|_{\mathcal{H}} + \|(\hat{S}_k - S_k)(f_\star - I_k f_\lambda)\|_{\mathcal{H}}\right). \tag{32}$$

It follows from Proposition A.4(v) that

$$\|\sqrt{E_k}(\hat{E}_k + \lambda I)^{-1}\| \lesssim \frac{1}{\sqrt{\lambda}} \tag{33}$$

for $n \geq \frac{c}{\lambda^2}$ where c is a sufficiently large constant that does not depend on n and λ. Following the proof of Proposition A.4(i), we have

$$\mathbb{E}\|\hat{\xi} + \hat{S}_k f_\star\|_{\mathcal{H}}^2 = \frac{n-1}{n}\|\xi + S_k f_\star\|_{\mathcal{H}}^2 + \frac{1}{n}\int_\Omega \left\|\sum_{i=1}^d \partial_i k(x,\cdot)\partial_i f_\star + \xi_x\right\|_{\mathcal{H}}^2 p_0(x)\,dx$$

wherein the first term is zero as $S_k f_\star + \xi = 0$ and since

$$\left\|\sum_{i=1}^d \partial_i k(x,\cdot)\partial_i f_\star + \xi_x\right\|_{\mathcal{H}}^2 \leq 2\|\xi_x\|_{\mathcal{H}}^2 + 2\chi\|\nabla f_\star\|_2^2,$$

the integral in the second term is finite because of **(D)** and $f^* \in W_2(\Omega, p_0)$. Therefore, an application of Chebyshev's inequality yields

$$\|\hat{\xi} + \hat{S}_k f_\star\|_{\mathcal{H}} = O_{p_0}(n^{-1/2}). \tag{34}$$

We now show that $\|(\hat{S}_k - S_k)(f_\star - I_k f_\lambda)\|_{\mathcal{H}} = O_{p_0}(\mathcal{B}(\lambda)n^{-1/2})$. To this end, define $g := f_\star - I_k f_\lambda$ and consider

$$\mathbb{E}_{p_0}\|\hat{S}_k g - S_k g\|_{\mathcal{H}}^2 = \frac{\int_\Omega \|\sum_{i=1}^d \partial_i k(x,\cdot)\partial_i g(x)\|_{\mathcal{H}}^2 p_0(x)\,dx - \|S_k g\|_{\mathcal{H}}^2}{n} \leq \frac{\chi}{n}\|g\|_{W_2}^2,$$

which therefore yields the claim through an application of Chebyshev's inequality. Using this along with (33) and (34) in (32), and using the resulting bound in (31) yields

$$\sqrt{2\,J(p_0\|p_{f_{\lambda,n}})} \leq O_{p_0}\left(\frac{1}{\sqrt{\lambda n}} + \frac{\mathcal{B}(\lambda)}{\sqrt{\lambda n}}\right) + \mathcal{B}(\lambda). \tag{35}$$

(i) We bound $\mathcal{B}(\lambda)$ as follows. First note that

$$\mathcal{B}(\lambda) = \|I_k(S_k I_k + \lambda I)^{-1} S_k f_\star - f_\star\|_{W_2} = \|(T_k + \lambda I)^{-1} T_k f_\star - f_\star\|_{W_2}$$

and so for any $h \in \mathcal{H}$, we have

$$\mathcal{B}(\lambda) = \|(T_k + \lambda I)^{-1} T_k f_\star - f_\star\|_{W_2} \leq \underbrace{\|((T_k + \lambda I)^{-1} T_k - I)(f_\star - I_k h)\|_{W_2}}_{(I)} + \underbrace{\|(T_k + \lambda I)^{-1} T_k I_k h - I_k h\|_{W_2}}_{(II)}. \quad (36)$$

Since T_k is a self-adjoint compact operator, there exists $(\alpha_l)_{l\in\mathbb{N}}$ and ONB $(\phi_l)_{l\in\mathbb{N}}$ of $\overline{\mathcal{R}(T_k)}$ so that $T_k = \sum_l \alpha_l \langle \phi_l, \cdot \rangle_{W_2} \phi_l$. Let $(\psi_j)_{j\in\mathbb{N}}$ be the orthonormal basis of $\mathcal{N}(T_k)$. Then we have

$$(I)^2 = \sum_l \left(\frac{\alpha_l}{\alpha_l + \lambda} - 1 \right)^2 \langle f_\star - I_k h, \phi_l \rangle_{W_2}^2 + \sum_j \langle f_\star - I_k h, \psi_j \rangle_{W_2}^2 \leq \sum_l \langle f_\star - I_k h, \phi_l \rangle_{W_2}^2 + \sum_j \langle f_\star - I_k h, \psi_j \rangle_{W_2}^2 = \|f_\star - I_k h\|_{W_2}^2. \quad (37)$$

From $(T_k + \lambda I)^{-1} T_k = I_k (E_k + \lambda I)^{-1} S_k$ and $S_k I_k h = E_k h$, we have

$$(II) = \|I_k (E_k + \lambda I)^{-1} E_k h - I_k h\|_{W_2} = \|\sqrt{E_k}(E_k + \lambda I)^{-1} E_k h - \sqrt{E_k} h\|_{\mathcal{H}} \leq \|h\|_{\mathcal{H}} \sqrt{\lambda}, \quad (38)$$

where the inequality follows from Proposition A.3(ii). Using (37) and (38) in (36), we obtain $\mathcal{B}(\lambda) \leq \|f_\star - I_k h\|_{W_2} + \|h\|_{\mathcal{H}} \sqrt{\lambda}$, using which in (35) yields

$$\sqrt{2\, J(p_0 \| p_{f_{\lambda,n}})} \leq \|f_\star - I_k h\|_{W_2} + O_{p_0}\left(\frac{1}{\sqrt{\lambda n}} \right) + \|h\|_{\mathcal{H}} \sqrt{\lambda}.$$

Since the above inequality holds for any $h \in \mathcal{H}$, we therefore have

$$\sqrt{2\, J(p_0 \| p_{f_{\lambda,n}})} \leq \inf_{h\in\mathcal{H}} \left(\|f_\star - I_k h\|_{W_2} + \sqrt{\lambda} \|h\|_{\mathcal{H}} \right) + O_{p_0}\left(\frac{1}{\sqrt{\lambda n}} \right) = K(f_\star, \sqrt{\lambda}, W_2(p_0), I_k(\mathcal{H})) + O_{p_0}\left(\frac{1}{\sqrt{\lambda n}} \right) \quad (39)$$

where the K-functional is defined in (A.6). Note that $I_k(\mathcal{H}) \cong \mathcal{H}/\mathcal{H} \cap \mathbb{R}$ is continuously embedded in $W(p_0)$. From (A.6), it is clear that the K-functional as a function of t is an infimum over a family of affine linear and increasing functions and therefore is concave, continuous and increasing w.r.t. t. This means, in (39), as $\lambda \to 0$,

$$K(f_\star, \sqrt{\lambda}, W_2(p_0), I_k(\mathcal{H})) \to \inf_{h\in\mathcal{H}} \|f_\star - I_k h\|_{W_2} = \sqrt{2 \inf_{p\in\mathcal{P}} J(p_0 \| p)}.$$

Since $J(p_0 \| p_{f_{\lambda,n}}) \geq \inf_{p\in\mathcal{P}} J(p_0 \| p)$, we have that $J(p_0 \| p_{f_{\lambda,n}}) \to \inf_{p\in\mathcal{P}} J(p_0 \| p)$ as $\lambda \to 0$, $\lambda n \to \infty$ and $n \to \infty$.

(ii) Recall $\mathcal{B}(\lambda)$ from (i). From Proposition A.3(i) it follows that $\mathcal{B}(\lambda) \to 0$ as $\lambda \to 0$ if $f_\star \in \overline{\mathcal{R}(T_k)}$. Therefore, (35) reduces to $\sqrt{2\, J(p_0 \| p_{f_{\lambda,n}})} \leq O_{p_0}\left(\frac{1}{\sqrt{\lambda n}} \right) + \mathcal{B}(\lambda)$ and the consistency result follows. If $f_\star \in \mathcal{R}(T_k^\beta)$ for some $\beta > 0$, then the rates follow from Proposition A.3 by noting that $\mathcal{B}(\lambda) \leq \max\{1, \|T_k\|^{\beta-1}\} \lambda^{\min\{1,\beta\}} \|T_k^{-\beta} f_\star\|_{W_2}$ and choosing $\lambda = n^{-\max\left\{\frac{1}{3}, \frac{1}{2\beta+1}\right\}}$.

(iii) This simply follows from an analysis similar to the one used in the proof of Theorem 6(iii). ■

8.12 Proof of Proposition 13

For any $p \in \mathcal{P}_{\text{FD}}$, define $f := \log \frac{p}{q_0}$, which implies that $[f]_\sim \in W_2(p)$. Since $I_k(\mathcal{H})$ is dense in $W_2(p)$, we have for any $\epsilon > 0$, there exists $g \in \mathcal{H}$ such that $\|[f]_\sim - I_k g\|_{W_2} \leq \sqrt{2\epsilon}$. For a given $g \in \mathcal{H}$, pick $p_g \in \mathcal{P}$. Therefore,

$$J(p \| p_g) = \frac{1}{2} \int_\Omega p(x) \|\nabla \log p - \nabla \log p_g\|_2^2 \, dx = \frac{1}{2} \|[f]_\sim - I_k g\|_{W_2}^2 \leq \epsilon$$

and the result follows. ■

Acknowledgments

We thank the action editor and two anonymous reviewers for their detailed comments that significantly improved the paper. Theorem A.2 and the proof are due to an anonymous reviewer. We also thank Dougal Sutherland for a careful reading of the paper which helped to fix minor errors. A part of the work was carried out while BKS was a Research Fellow in the Statistical Laboratory, Department of Pure Mathematics and Mathematical Statistics, University of Cambridge. BKS thanks Richard Nickl for many valuable comments and insightful discussions. KF is supported in part by MEXT Grant-in-Aid for Scientific Research on Innovative Areas 25120012.

A. Appendix: Technical Results

In this appendix, we present some technical results that are used in the proofs.

A.1 Bounds on Various Distances Between p_f and p_g

In the following result, claims (iii) and (iv) are quoted from Lemma 3.1 of van der Vaart and van Zanten (2008).

Lemma A.1 *Define $\mathcal{P}_\infty := \left\{ p_f = e^{f - A(f)} q_0 : f \in \ell^\infty(\Omega) \right\}$, where q_0 is a probability density on $\Omega \subseteq \mathbb{R}^d$ and $\ell^\infty(\Omega)$ is the space of bounded measurable functions on Ω. Then for any $p_f, p_g \in \mathcal{P}_\infty$, we have*

(i) $\|p_f - p_g\|_{L^r(\Omega)} \leq 2 e^{2\|f-g\|_\infty} e^{2\min\{\|f\|_\infty, \|g\|_\infty\}} \|f - g\|_\infty \|q_0\|_{L^r(\Omega)}$ *for any* $1 \leq r \leq \infty$;

(ii) $\|p_f - p_g\|_{L^1(\Omega)} \leq 2 e^{\|f-g\|_\infty} \|f - g\|_\infty$;

(iii) $KL(p_f\|p_g) \le c\,\|f-g\|_\infty^2 e^{\|f-g\|_\infty}\,(1+\|f-g\|_\infty)$ *where* c *is a universal constant;*

(iv) $h(p_f,p_g) \le e^{\|f-g\|_\infty/2}\|f-g\|_\infty$.

Proof *(i)* Define $B(f) := \int e^f q_0\,dx$. Consider

$$\begin{aligned}\|p_f-p_g\|_{L^r(\Omega)} &= \left\|\frac{e^f q_0}{B(f)}-\frac{e^g q_0}{B(g)}\right\|_{L^r(\Omega)} = \frac{\left\|e^f q_0 B(g)-e^g q_0 B(f)\right\|_{L^r(\Omega)}}{B(f)B(g)}\\ &= \frac{\left\|e^f q_0\,(B(g)-B(f))+\left(e^f-e^g\right)q_0 B(f)\right\|_{L^r(\Omega)}}{B(f)B(g)}\\ &\le \frac{\left\|e^f q_0\,(B(g)-B(f))\right\|_{L^r(\Omega)}}{B(f)B(g)}+\frac{\left\|\left(e^f-e^g\right)q_0 B(f)\right\|_{L^r(\Omega)}}{B(f)B(g)}\\ &\le \frac{|B(g)-B(f)|\,\|e^f q_0\|_{L^r(\Omega)}}{B(g)B(f)}+\frac{\left\|(e^f-e^g)q_0\right\|_{L^r(\Omega)}}{B(g)}. \end{aligned} \tag{A.1}$$

Observe that

$$|B(f)-B(g)| \le \int_\Omega |e^f-e^g|q_0\,dx = \int_\Omega e^g|e^{f-g}-1|q_0\,dx \le e^{\|f-g\|_\infty}\|f-g\|_\infty B(g)$$

since $|e^{u-v}-1| \le |u-v|e^{|u-v|}$ for any $u,v\in\mathbb{R}$. Similarly,

$$\left\|(e^f-e^g)q_0\right\|_{L^r(\Omega)} \le e^{\|f-g\|_\infty}\|f-g\|_\infty\|e^g q_0\|_{L^r(\Omega)}.$$

Using these above, we obtain

$$\|p_f-p_g\|_{L^r(\Omega)} \le e^{\|f-g\|_\infty}\|f-g\|_\infty\left(\frac{\|e^f q_0\|_{L^r(\Omega)}}{B(f)}+\frac{\|e^g q_0\|_{L^r(\Omega)}}{B(g)}\right). \tag{A.2}$$

Since $\|e^f q_0\|_{L^r(\Omega)} \le e^{\|f\|_\infty}\|q_0\|_{L^r(\Omega)}$ and $B(f)\ge e^{-\|f\|_\infty}$, from (A.2) we obtain

$$\begin{aligned}\|p_f-p_g\|_{L^r(\Omega)} &\le e^{\|f-g\|_\infty}\|f-g\|_\infty\|q_0\|_{L^r(\Omega)}\left(e^{2\|f\|_\infty}+e^{2\|g\|_\infty}\right).\\ &\le 2e^{\|f-g\|_\infty}\|f-g\|_\infty\|q_0\|_{L^r(\Omega)}e^{2\max\{\|f\|_\infty,\|g\|_\infty\}}\\ &\le 2e^{2\|f-g\|_\infty}\|f-g\|_\infty\|q_0\|_{L^r(\Omega)}e^{2\min\{\|f\|_\infty,\|g\|_\infty\}}\end{aligned}$$

where we used $\max\{a,b\}\le\min\{a,b\}+|a-b|$ for $a,b\ge 0$ in the last line above.
(ii) This simply follows from (A.2) by using $r=1$. ■

A.2 General Representer Theorem

The following is the general representer theorem for abstract Hilbert spaces.

Theorem A.2 (General representer theorem) *Let* H *be a real Hilbert space and let* $(\phi_i)_{i=1}^m \in H^m$. *Suppose* $J: H\to\mathbb{R}$ *be such that* $J(f) = V\left(\langle f,\phi_1\rangle_H,\ldots,\langle f,\phi_m\rangle_H\right)$, $f\in H$ *where* $V:\mathbb{R}^n\to\mathbb{R}$ *is a convex differentiable function. Define*

$$f_\lambda = \arg\inf_{f\in H} J(f)+\frac{\lambda}{2}\|f\|_H^2,$$

where $\lambda>0$. *Then there exists* $(\alpha_i)_{i=1}^m\in\mathbb{R}^m$ *such that* $f_\lambda=\sum_{i=1}^m\alpha_i\phi_i$ *where* $\boldsymbol{\alpha} := (\alpha_1,\ldots,\alpha_m)$ *satisfies the following (possibly nonlinear) equation*

$$\lambda\boldsymbol{\alpha}+\nabla V\left(\boldsymbol{K}\boldsymbol{\alpha}\right)=0,$$

with $\boldsymbol{K}$ *being a linear map on* $\mathbb{R}^m$ *and* $(\boldsymbol{K})_{i,j}=\langle\phi_i,\phi_j\rangle_H$, $i\in[m]$, $j\in[m]$.

Proof Define $A: H\to\mathbb{R}^m$, $f\mapsto(\langle f,\phi_i\rangle_H)_{i=1}^m$. Then $f_\lambda = \arg\inf_{f\in H} V(Af)+\frac{\lambda}{2}\|f\|_H^2$. Therefore, Fermat's rule yields

$$\begin{aligned}0=A^*\nabla V(Af_\lambda)+\lambda f_\lambda &\Leftrightarrow f_\lambda = A^*\left(-\frac{1}{\lambda}\nabla V(Af_\lambda)\right)\\ &\Leftrightarrow (\exists\,\boldsymbol{\alpha}\in\mathbb{R}^m)\quad f_\lambda=A^*\boldsymbol{\alpha},\ \boldsymbol{\alpha}=-\frac{1}{\lambda}\nabla V(Af_\lambda)\\ &\Leftrightarrow (\exists\,\boldsymbol{\alpha}\in\mathbb{R}^m)\quad f_\lambda=A^*\boldsymbol{\alpha},\ \boldsymbol{\alpha}=-\frac{1}{\lambda}\nabla V(AA^*\boldsymbol{\alpha}),\end{aligned}$$

where $A^*:\mathbb{R}^m\to H$ is the adjoint of A which can be obtained as follows. Note that

$$\langle Af,\boldsymbol{\alpha}\rangle = \sum_{i=1}^m\alpha_i\langle f,\phi_i\rangle_H = \left\langle f,\sum_{i=1}^m\alpha_i\phi_i\right\rangle_H \qquad (\forall\, f\in H)\ (\forall\,\boldsymbol{\alpha}\in\mathbb{R}^m)$$

and thus $A^*\boldsymbol{\alpha}=\sum_{i=1}^m\alpha_i\phi_i$. Therefore $AA^*\boldsymbol{\alpha}=\sum_{j=1}^m\alpha_j A\phi_j=\sum_{j=1}^m\alpha_j(\langle\phi_j,\phi_i\rangle_H)_{i=1}^m$, and so for every $i\in[m]$, $(AA^*\boldsymbol{\alpha})_i=\sum_{j=1}^m\langle\phi_j,\phi_i\rangle_H\alpha_j$ and hence $AA^*=\boldsymbol{K}$. ■

A.3 Bounds on Approximation Errors, $\mathcal{A}_0(\lambda)$ and $\mathcal{A}_{\frac{1}{2}}(\lambda)$

The following result is quite well-known in the linear inverse problem theory (Engl et al., 1996).

Proposition A.3 *Let* C *be a bounded, self-adjoint compact operator on a separable Hilbert space* H. *For* $\lambda>0$ *and* $f\in H$, *define* $f_\lambda := (C+\lambda I)^{-1}Cf$ *and* $\mathcal{A}_\theta(\lambda) := \|C^\theta(f_\lambda-f)\|_H$ *for* $\theta\ge 0$. *Then the following hold.*

(i) For any $\theta>0$, $\mathcal{A}_\theta(\lambda)\to 0$ *as* $\lambda\to 0$ *and if* $f\in\overline{\mathcal{R}(C)}$, *then* $\mathcal{A}_0(\lambda)\to 0$ *as* $\lambda\to 0$.

(ii) If $f\in\mathcal{R}(C^\beta)$ *for* $\beta\ge 0$ *and* $\beta+\theta>0$, *then*

$$\mathcal{A}_\theta(\lambda)\le\max\{1,\|C\|^{\beta+\theta-1}\}\lambda^{\min\{1,\beta+\theta\}}\|C^{-\beta}f\|_H.$$

Proof (i) Since C is bounded, compact, and self-adjoint, the Hilbert-Schmidt theorem (Reed and Simon, 1972, Theorems VI.16, VI.17) ensures that $C = \sum_l \alpha_l \phi_l \langle \phi_l, \cdot \rangle_H$, where $(\alpha_l)_{l\in\mathbb{N}}$ are the positive eigenvalues and $(\phi_l)_{l\in\mathbb{N}}$ are the corresponding unit eigenvectors that form an ONB for $\mathcal{R}(C)$. Let $\theta = 0$. Since $f \in \overline{\mathcal{R}(C)}$,

$$\mathcal{A}_0^2(\lambda) = \left\|(C+\lambda I)^{-1}Cf - f\right\|_H^2 = \left\|\sum_i \frac{\alpha_i}{\alpha_i+\lambda}\langle f,\phi_i\rangle_H \phi_i - \sum_i \langle f,\phi_i\rangle_H \phi_i\right\|_H^2$$
$$= \left\|\sum_i \frac{\lambda}{\alpha_i+\lambda}\langle f,\phi_i\rangle_H \phi_i\right\|_H^2 = \sum_i \left(\frac{\lambda}{\alpha_i+\lambda}\right)^2 \langle f,\phi_i\rangle_H^2 \to 0 \text{ as } \lambda \to 0$$

by the dominated convergence theorem. For any $\theta > 0$, we have

$$\mathcal{A}_\theta^2(\lambda) = \left\|C^\theta(C+\lambda I)^{-1}Cf - C^\theta f\right\|_H^2.$$

Let $f = f_R + f_N$ where $f_R \in \overline{\mathcal{R}(C^\theta)}$, $f_N \in \overline{\mathcal{R}(C^\theta)}^\perp$ if $0 < \theta \le 1$ and $f_R \in \overline{\mathcal{R}(C)}$, $f_N \in \overline{\mathcal{R}(C)}^\perp$ if $\theta \ge 1$. Then

$$\mathcal{A}_\theta^2(\lambda) = \left\|C^\theta(C+\lambda I)^{-1}Cf - C^\theta f\right\|_H^2 = \left\|C^\theta(C+\lambda I)^{-1}Cf_R - C^\theta f_R\right\|_H^2$$
$$= \left\|\sum_i \frac{\alpha_i^{1+\theta}}{\alpha_i+\lambda}\langle f_R,\phi_i\rangle_H \phi_i - \sum_i \alpha_i^\theta \langle f_R,\phi_i\rangle_H \phi_i\right\|_H^2$$
$$= \left\|\sum_i \frac{\lambda\alpha_i^\theta}{\alpha_i+\lambda}\langle f_R,\phi_i\rangle_H \phi_i\right\|_H^2 = \sum_i \left(\frac{\lambda\alpha_i^\theta}{\alpha_i+\lambda}\right)^2 \langle f_R,\phi_i\rangle_H^2 \to 0$$

as $\lambda \to 0$.

(ii) If $f \in \mathcal{R}(C^\beta)$, then there exists $g \in H$ such that $f = C^\beta g$. This yields

$$\mathcal{A}_\theta^2(\lambda) = \left\|C^\theta(C+\lambda I)^{-1}Cf - C^\theta f\right\|_H^2 = \left\|C^\theta(C+\lambda I)^{-1}C^{\beta+1}g - C^{\theta+\beta}g\right\|_H^2$$
$$= \left\|\sum_i \frac{\lambda\alpha_i^{\theta+\beta}}{\alpha_i+\lambda}\langle g,\phi_i\rangle_H \phi_i\right\|_H^2 = \sum_i \left(\frac{\lambda\alpha_i^{\theta+\beta}}{\alpha_i+\lambda}\right)^2 \langle g,\phi_i\rangle_H^2. \tag{A.3}$$

Suppose $0 < \beta + \theta < 1$. Then

$$\frac{\alpha_i^{\beta+\theta}\lambda}{\alpha_i+\lambda} = \left(\frac{\alpha_i}{\alpha_i+\lambda}\right)^{\beta+\theta}\left(\frac{\lambda}{\alpha_i+\lambda}\right)^{1-\theta-\beta}\lambda^{\beta+\theta} \le \lambda^{\beta+\theta}.$$

On the other hand, for $\beta + \theta \ge 1$, we have

$$\frac{\alpha_i^{\beta+\theta}\lambda}{\alpha_i+\lambda} = \left(\frac{\alpha_i}{\alpha_i+\lambda}\right)\alpha_i^{\beta+\theta-1}\lambda \le \|C\|^{\beta+\theta-1}\lambda.$$

Using the above in (A.3) yields the result. ■

A.4 Bound on the Norm of Certain Operators and Functions

The following result is used in many places throughout the paper. We would like to highlight that special cases of this result are known, e.g., see the proof of Theorem 4 in Caponnetto and Vito (2007) where concentration inequalities are obtained for the quantities in Proposition A.4 using Bernstein's inequality. Here, we provide asymptotic statements using Chebyshev's inequality.

Proposition A.4 *Let $\mathcal{X}$ be a topological space, H be a separable Hilbert space and $\mathcal{L}_2^+(H)$ be the space of positive, self-adjoint Hilbert-Schmidt operators on H. Define $R := \int_{\mathcal{X}} r(x)\, d\mathbb{P}(x)$ and $\hat{R} := \frac{1}{n}\sum_{a=1}^m r(X_a)$ where $\mathbb{P} \in M_+^1(\mathcal{X})$, $(X_a)_{a=1}^m \overset{i.i.d.}{\sim} \mathbb{P}$ and r is a $\mathcal{L}_2^+(H)$-valued measurable function on $\mathcal{X}$ satisfying $\int_{\mathcal{X}} \|r(x)\|_{HS}^2\, d\mathbb{P}(x) < \infty$. Define $g_\lambda := (R+\lambda I)^{-1}Rg$ for $g \in H$, $\lambda > 0$, and $\mathcal{A}_0(\lambda) := \|g_\lambda - g\|_H$. Let $\alpha \ge 0$ and $\theta > 0$. Then the following hold:*

(i) $\|(\hat{R}-R)(g_\lambda - g)\|_H = O_{\mathbb{P}}\left(\frac{\mathcal{A}_0(\lambda)}{\sqrt{m}}\right)$.

(ii) $\|R^\alpha(R+\lambda I)^{-\theta}\| \le \lambda^{\alpha-\theta}$.

(iii) $\|\hat{R}^\alpha(\hat{R}+\lambda I)^{-\theta}\| \le \lambda^{\alpha-\theta}$.

(iv) $\|(R+\lambda I)^{-\theta}(\hat{R}-R)\| = O_{\mathbb{P}}\left(\sqrt{\frac{1}{m\lambda^{2\theta}}}\right)$.

(v) $\|R^\alpha(\hat{R}+\lambda I)^{-1}\| \lesssim \lambda^{\alpha-1}$ *for* $m \ge \frac{c}{\lambda^2}$ *where is c is a sufficiently large constant that depends on $\int \|r(x)\|_{HS}^2\, d\mathbb{P}(x)$ but not on m and λ.*

Proof (i) Note that for any $f \in H$,

$$\mathbb{E}_{\mathbb{P}}\|(\hat{R}-R)f\|_H^2 = \mathbb{E}_{\mathbb{P}}\|\hat{R}f\|_H^2 + \|Rf\|_H^2 - 2\mathbb{E}_{\mathbb{P}}\langle \hat{R}f, Rf\rangle_H,$$

where $\mathbb{E}_{\mathbb{P}}\langle \hat{R}f, Rf\rangle_H = \frac{1}{n}\sum_{a=1}^n \mathbb{E}_{\mathbb{P}}\langle r(X_a)f, Rf\rangle_H = \frac{1}{n}\sum_{a=1}^n \mathbb{E}_{\mathbb{P}}\langle r(X_a), f\otimes Rf\rangle_{HS}$. Since $\int_{\mathcal{X}} \|r(x)\|_{HS}^2\, d\mathbb{P}(x) < \infty$, $r(x)$ is $\mathbb{P}$-integrable in the Bochner sense (see Diestel and Uhl, 1977, Definition 1 and Theorem 2), and therefore it follows from Diestel and Uhl (1977, Theorem 6) that $\mathbb{E}_{\mathbb{P}}\langle r(X_a), f\otimes Rf\rangle_{HS} = \langle \int_{\mathcal{X}} r(x)\, d\mathbb{P}(x), f\otimes Rf\rangle_{HS} = \|Rf\|_H^2$. Therefore,

$$\mathbb{E}_{\mathbb{P}}\|(\hat{R}-R)f\|_H^2 = \mathbb{E}_{\mathbb{P}}\|\hat{R}f\|_H^2 - \|Rf\|_H^2,$$

where

$$\mathbb{E}_{\mathbb{P}}\|\hat{R}f\|_H^2 = \mathbb{E}_{\mathbb{P}}\left\|\frac{1}{m}\sum_{a=1}^m r(X_a)f\right\|_H^2 = \frac{1}{m^2}\sum_{a,b=1}^m \mathbb{E}_{\mathbb{P}}\langle r(X_a)f, r(X_b)f\rangle_H.$$

Splitting the sum into two parts (one with $a = b$ and the other with $a \ne b$), it is easy to verify that $\mathbb{E}_{\mathbb{P}}\|\hat{R}f\|_H^2 = \frac{1}{m}\int_{\mathcal{X}} \|r(x)f\|_H^2\, d\mathbb{P}(x) + \frac{m-1}{m}\|Rf\|_H^2$, thereby yielding

$$\mathbb{E}_{\mathbb{P}}\|(\hat{R}-R)f\|_H^2 = \frac{1}{m}\left(\int_{\mathcal{X}} \|r(x)f\|_H^2\, d\mathbb{P}(x) - \|Rf\|_H^2\right) \le \frac{1}{m}\int_{\mathcal{X}} \|r(x)f\|_H^2\, d\mathbb{P}(x)$$
$$\le \frac{\|f\|_H^2}{m}\int_{\mathcal{X}} \|r(x)\|_H^2\, d\mathbb{P}(x).$$

Using $f = g_\lambda - g$, an application of Chebyshev's inequality yields the result.

(ii, iii) $\|R^\alpha(R+\lambda I)^{-\theta}\| = \sup_i \frac{\gamma_i^\alpha}{(\gamma_i+\lambda)^\theta} = \sup_i \left[\left(\frac{\gamma_i}{\gamma_i+\lambda}\right)^\alpha \frac{1}{(\gamma_i+\lambda)^{\theta-\alpha}}\right] \leq \sup_i \frac{1}{(\gamma_i+\lambda)^{\theta-\alpha}} \leq \lambda^{\alpha-\theta}$, where $(\gamma_i)_{i\in\mathbb{N}}$ are the eigenvalues of R. (iii) follows by replacing $(\gamma_i)_{i\in\mathbb{N}}$ with the eigenvalues of $\hat{R}$.

(iv) Since $\|(R+\lambda I)^{-\theta}(\hat{R}-R)\| \leq \|(R+\lambda I)^{-\theta}(\hat{R}-R)\|_{HS}$, consider $\mathbb{E}_{\mathbb{P}}\|(R+\lambda I)^{-\theta}(\hat{R}-R)\|_{HS}^2$, which using the technique in the proof of (i), can be shown to be bounded as

$$\mathbb{E}_{\mathbb{P}}\|(R+\lambda I)^{-\theta}(\hat{R}-R)\|_{HS}^2 \leq \frac{1}{m}\int_{\mathcal{X}} \|(R+\lambda I)^{-\theta} r(x)\|_{HS}^2 \, d\mathbb{P}(x). \tag{A.4}$$

Note that

$$\begin{aligned}\|(R+\lambda I)^{-\theta} r(x)\|_{HS}^2 &= \langle (R+\lambda I)^{-\theta} r(x), (R+\lambda I)^{-\theta} r(x)\rangle_{HS} \\ &= \|(R+\lambda I)^{-2\theta}\|\mathrm{Tr}\,(r(x)r(x)) = \|(R+\lambda I)^{-2\theta}\|\|r(x)\|_{HS}^2 \\ &\leq \lambda^{-2\theta}\|r(x)\|_{HS}^2, \end{aligned} \tag{A.5}$$

where the last inequality follows from (iii). Using (A.5) in (A.4), we obtain

$$\mathbb{E}_{\mathbb{P}}\|(R+\lambda I)^{-\theta}(\hat{R}-R)\|_{HS}^2 \leq \frac{1}{m\lambda^{2\theta}}\int_{\mathcal{X}} \|r(x)\|_{HS}^2 \, d\mathbb{P}(x).$$

The result therefore follows by an application of Chebyshev's inequality.

(v) We use the idea in Step 2.1 of the proof of Theorem 4 in Caponnetto and Vito (2007), where $R^\alpha(\hat{R}+\lambda I)^{-1}$ is written equivalently as follows: Note that $\hat{R}+\lambda I = (\hat{R}-R)+(R+\lambda I)$, which implies

$$(\hat{R}+\lambda I)^{-1} = \left((\hat{R}-R)+(R+\lambda I)\right)^{-1} = (R+\lambda I)^{-1}\left(I-(R-\hat{R})(R+\lambda I)^{-1}\right)^{-1}$$

and so $R^\alpha(\hat{R}+\lambda I)^{-1} = R^\alpha(R+\lambda I)^{-1}\left(I-(R-\hat{R})(R+\lambda I)^{-1}\right)^{-1}$. Using the Von Neumann series representation, we have

$$R^\alpha(\hat{R}+\lambda I)^{-1} = R^\alpha(R+\lambda I)^{-1}\sum_{j=0}^{\infty}\left((R-\hat{R})(R+\lambda I)^{-1}\right)^j$$

so that

$$\begin{aligned}\|R^\alpha(\hat{R}+\lambda I)^{-1}\| &\leq \|R^\alpha(R+\lambda I)^{-1}\|\sum_{j=0}^{\infty}\|(R-\hat{R})(R+\lambda I)^{-1}\|_{HS}^j \\ &\leq \lambda^{\alpha-1}\sum_{j=0}^{\infty}\|(R-\hat{R})(R+\lambda I)^{-1}\|_{HS}^j.\end{aligned}$$

From the proof of (iv), we have that for any $\delta > 0$, with probability at least $1-\delta$, $\|(R-\hat{R})(R+\lambda I)^{-1}\|_{HS} \leq \sqrt{\frac{\int_{\mathcal{X}}\|r(x)\|_{HS}^2 d\mathbb{P}(x)}{m\lambda^2\delta}}$. Suppose $m \geq \frac{\int_{\mathcal{X}}\|r(x)\|_{HS}^2 d\mathbb{P}(x)}{s^2\lambda^2\delta}$ where $s<1$. Then $\sum_{j=0}^{\infty}\|(R-\hat{R})(R+\lambda I)^{-1}\|_{HS}^j \leq \sum_{j=0}^{\infty} s^j = \frac{1}{1-s}$. This means for $m \geq \frac{c}{\lambda^2}$ where c is sufficiently large, we obtain $\|R^\alpha(\hat{R}+\lambda I)^{-1}\| \lesssim \lambda^{\alpha-1}$. ■

A.5 Interpolation Space

In this section, we briefly recall the definition of interpolation spaces of the real method. To this end, let E_0 and E_1 be two arbitrary Banach spaces that are continuously embedded in some topological (Hausdorff) vector space $\mathcal{E}$. Then, for $x \in E_0+E_1 := \{x_0+x_1 : x_0 \in E_0,\, x_1 \in E_1\}$ and $t>0$, the *K-functional* of the real interpolation method (see Bennett and Sharpley, 1988, Definition 1.1, p. 293) is defined by

$$K(x,t,E_0,E_1) := \inf\{\|x_0\|_{E_0} + t\|x_1\|_{E_1} \,:\, x_0 \in E_0,\, x_1 \in E_1,\, x = x_0+x_1\}.$$

Suppose E and F are two Banach spaces that satisfy $F \hookrightarrow E$ (i.e., $F \subset E$ and the inclusion operator $\mathrm{id} : F \to E$ is continuous), then the K-functional reduces to

$$K(x,t,E,F) = \inf_{y\in F}\|x-y\|_E + t\|y\|_F. \tag{A.6}$$

The K-functional can be used to define interpolation norms, for $0<\theta<1$, $1 \leq s \leq \infty$ and $x \in E_0+E_1$, as

$$\|x\|_{\theta,s} := \begin{cases} \left(\int \left(t^{-\theta}K(x,t)\right)^s t^{-1}\,dt\right)^{1/s}, & 1 \leq s < \infty \\ \sup_{t>0} t^{-\theta}K(x,t), & s=\infty. \end{cases}$$

Moreover, the corresponding interpolation spaces (Bennett and Sharpley, 1988, Definition 1.7, p. 299) are defined as

$$[E_0,E_1]_{\theta,s} := \{x \in E_0+E_1 \,:\, \|x\|_{\theta,s} < \infty\}.$$

B. Appendix: Miscellaneous Results

In this appendix, we present the proofs of some claims that we made in Sections 1, 4 and 5.

B.1 Relation between Fisher and Kullback-Leibler Divergences

The following result provides a relationship between Fisher and Kullback-Leibler divergences.

Proposition B.1 *Let p and q be probability densities defined on $\mathbb{R}^d$. Define $p_t := p * N(0,tI_d)$ and $q_t := q * N(0,tI_d)$ where $N(0,tI_d)$ denotes a normal distribution on $\mathbb{R}^d$ with mean zero and diagonal covariance with $t>0$. Suppose p_t and q_t satisfy*

$$\partial_i p_t(x)\log p_t(x) = o\left(\|x\|_2^\alpha\right),\ \partial_i p_t(x)\log q_t(x) = o\left(\|x\|_2^\alpha\right) \text{ and } \partial_i \log q_t(x) p_t(x) = o\left(\|x\|_2^\alpha\right)$$

as $\|x\|_2 \to \infty$ for all $i \in [d]$ where $\alpha = 1-d$. Then

$$KL(p\|q) = \int_0^\infty J(p_t\|q_t)\,dt, \tag{B.1}$$

where J is defined in (3).

Proof Under the conditions mentioned on p_t and q_t, it can be shown that

$$\frac{d}{dt}KL(p_t\|q_t) = -J(p_t\|q_t). \tag{B.2}$$

See Theorem 1 in Lyu (2009) for a proof. The above identity is a simple generalization of de Bruijn's identity that relates the Fisher information to the derivative of the Shannon entropy (see Cover and Thomas, 1991, Theorem 16.6.2). Integrating w.r.t. t on both sides of (B.2), we obtain $KL(p_t\|q_t)\Big|_{t=0}^{\infty} = -\int_0^\infty J(p_t\|q_t)\,dt$ which yields the equality in (B.1) as $KL(p_t\|q_t) \to 0$ as $t \to \infty$ and $KL(p_t\|q_t) \to KL(p\|q)$ as $t \to 0$. ■

B.2 Estimation of p_0: Unbounded k

To handle the case of unbounded k, in the following, we assume that there exists a positive constant M such that $\|f_0\|_{\mathcal{H}} \le M$, so that an estimator of f_0 can be constructed as

$$\breve{f}_{\lambda,n} = \arg\inf_{f\in\mathcal{H}} \hat{J}_\lambda(f) \;\text{ subject to }\; \|f\|_{\mathcal{H}} \le M, \tag{B.3}$$

where $\hat{J}_\lambda$ is defined in Theorem 4(iv). This modification yields a valid estimator $p_{\breve{f}_{\lambda,n}}$ as long as k satisfies $\int_\Omega e^{M\sqrt{k(x,x)}}q_0(x)\,dx < \infty$, since this implies $\breve{f}_{\lambda,n} \in \mathcal{F}$. The construction of $\breve{f}_{\lambda,n}$ requires the knowledge of M, however, which we assume is known *a priori*. Using the representer theorem in RKHS, it can be shown (see Section B.2.1) that

$$\breve{f}_{\lambda,n} = \breve{\delta}\hat{\xi} + \sum_{b=1}^{n}\sum_{j=1}^{d}\breve{\beta}_{(b-1)d+j}\partial_j k(X_b,\cdot)$$

where $\breve{\delta}$ and $\breve{\boldsymbol{\beta}}$ are obtained by solving the following quadratically constrained quadratic program (QCQP),

$$(\breve{\boldsymbol{\beta}},\breve{\delta}) =: \breve{\Theta} = \arg\min_{\Theta\in\mathbb{R}^{nd+1}} \frac{1}{2}\Theta^T\boldsymbol{H}\Theta + \Theta^T\Delta \;\text{ subject to }\; \Theta^T\boldsymbol{K}\Theta \le M^2,$$

with $\Delta := (\boldsymbol{h}, \|\hat{\xi}\|^2_{\mathcal{H}})$, $\Theta := (\boldsymbol{\beta},\delta)$ and $\boldsymbol{K}$, $\boldsymbol{H}$ being defined in the proof of Theorem 5 and the remark following it. The following result investigates the consistency and convergence rates for $p_{\breve{f}_{\lambda,n}}$.

Theorem B.2 (Consistency and rates for $p_{\breve{f}_{\lambda,n}}$) *Let $M \ge \|f_0\|_{\mathcal{H}}$ be a fixed constant, and $\breve{f}_{n,\lambda}$ be a clipped estimator given by (B.3). Suppose* **(A)**–**(D)** *with $\varepsilon = 2$ hold. Let $\operatorname{supp}(q_0) = \Omega$ and $\int_\Omega e^{M\sqrt{k(x,x)}}q_0(x)\,dx < \infty$. Define $\eta(x) = \sqrt{k(x,x)}e^{M\sqrt{k(x,x)}}$. Then, as $\lambda\sqrt{n} \to \infty$, $\lambda \to 0$ and $n \to \infty$,*

(i) $\|p_{\breve{f}_{\lambda,n}} - p_0\|_{L^1(\Omega)} \to 0$, $KL(p_0\|p_{\breve{f}_{\lambda,n}}) \to 0$ *if* $\eta \in L^1(\Omega, q_0)$;

(ii) for $1 < r \le \infty$, $\|p_{\breve{f}_{\lambda,n}} - p_0\|_{L^r(\Omega)} \to 0$ *if* $\eta q_0 \in L^1(\Omega)\cap L^r(\Omega)$ *and* $e^{M\sqrt{k(\cdot,\cdot)}}q_0 \in L^r(\Omega)$;

(iii) $h(p_{\breve{f}_{\lambda,n}}, p_0) \to 0$ *if* $\sqrt{k(\cdot,\cdot)}\eta \in L^1(\Omega, q_0)$;

(iv) $J(p_0\|p_{\breve{f}_{\lambda,n}}) \to 0$.

In addition, if $f_0 \in \mathcal{R}(C^\beta)$ for some $\beta > 0$, then $\|p_{\breve{f}_{\lambda,n}} - p_0\|_{L^r(\Omega)} = O_{p_0}(\theta_n)$, $h(p_0, p_{\breve{f}_{\lambda,n}}) = O_{p_0}(\theta_n)$, $KL(p_0\|p_{\breve{f}_{\lambda,n}}) = O_{p_0}(\theta_n)$ and $J(p_0\|p_{\breve{f}_{\lambda,n}}) = O_{p_0}(\theta_n^2)$ where $\theta_n := n^{-\min\left\{\frac{1}{4},\frac{\beta}{2(\beta+1)}\right\}}$ with $\lambda = n^{-\max\left\{\frac{1}{4},\frac{1}{2(\beta+1)}\right\}}$ assuming the respective conditions in (i)-(iii) above hold.

Proof For any $x \in \Omega$, since $|f_0(x)| \le \|f_0\|_{\mathcal{H}}\sqrt{k(x,x)} \le M\sqrt{k(x,x)}$ and $|\breve{f}_{\lambda,n}(x)| \le M\sqrt{k(x,x)}$, we have

$$\left|e^{\breve{f}_{\lambda,n}(x)} - e^{f_0(x)}\right| \le e^{M\sqrt{k(x,x)}}\left|\breve{f}_{\lambda,n}(x) - f_0(x)\right| \le \eta(x)\left\|\breve{f}_{\lambda,n} - f_0\right\|_{\mathcal{H}}, \tag{B.4}$$

where we used the fact that $|e^x - e^y| \le e^a|x-y|$ for $x, y \in [-a,a]$ and $\eta(x) := \sqrt{k(x,x)}e^{M\sqrt{k(x,x)}}$. In the following, we obtain bounds for $\left\|p_{\breve{f}_{\lambda,n}} - p_0\right\|_{L^r(\Omega)}$ for any $1 \le r \le \infty$, $h(p_{\breve{f}_{\lambda,n}}, p_0)$ and $KL(p_0\|p_{\breve{f}_{\lambda,n}})$ in terms of $\left\|\breve{f}_{\lambda,n} - f_0\right\|_{\mathcal{H}}$. Define $B(f) := \int_\Omega e^f q_0\,dx$. Since k satisfies $\int_\Omega e^{M\sqrt{k(x,x)}}q_0(x)\,dx < \infty$, then it is clear that $\breve{f}_{\lambda,n} \in \mathcal{F}$ as $B(\breve{f}_{\lambda,n}) < \infty$ since

$$\int_\Omega e^{\breve{f}_{\lambda,n}(x)}q_0(x)\,dx \le \int_\Omega e^{\|\breve{f}_{\lambda,n}\|_{\mathcal{H}}\sqrt{k(x,x)}}q_0(x)\,dx \le \int_\Omega e^{M\sqrt{k(x,x)}}q_0(x)\,dx < \infty.$$

Similarly, it is easy to verify that $B(f_0) < \infty$.

(i) Recalling (A.1), we have

$$\left\|p_{\breve{f}_{\lambda,n}} - p_0\right\|_{L^r(\Omega)} \le \frac{|B(\breve{f}_{\lambda,n}) - B(f_0)|\|e^{f_0}q_0\|_{L^r(\Omega)}}{B(\breve{f}_{\lambda,n})B(f_0)} + \frac{\|(e^{f_0} - e^{\breve{f}_{\lambda,n}})q_0\|_{L^r(\Omega)}}{B(\breve{f}_{\lambda,n})}.$$

If $r = 1$, we obtain

$$\left\|p_{\breve{f}_{\lambda,n}} - p_0\right\|_{L^1(\Omega)} \le \frac{|B(\breve{f}_{\lambda,n}) - B(f_0)|}{B(\breve{f}_{\lambda,n})} + \frac{\|(e^{f_0} - e^{\breve{f}_{\lambda,n}})q_0\|_{L^1(\Omega)}}{B(\breve{f}_{\lambda,n})}.$$

Using (B.4), we bound $|B(\breve{f}_{\lambda,n}) - B(f_0)|$ as

$$|B(\breve{f}_{\lambda,n}) - B(f_0)| \le \int_\Omega \left|e^{\breve{f}_{\lambda,n}(x)} - e^{f_0(x)}\right|q_0(x)\,dx \le \|\eta\|_{L^1(\Omega,q_0)}\left\|\breve{f}_{\lambda,n} - f_0\right\|_{\mathcal{H}}.$$

Also for any $f \in \mathcal{H}$ with $\|f\|_{\mathcal{H}} \le M$, we have $B(f) \ge \int_\Omega e^{-M\sqrt{k(x,x)}}q_0(x)\,dx =: \theta$, where $\theta > 0$. Again using (B.4), we have

$$\|(e^{f_0} - e^{\breve{f}_{\lambda,n}})q_0\|_{L^r(\Omega)} \le \|\eta q_0\|_{L^r(\Omega)}\|\breve{f}_{\lambda,n} - f_0\|_{\mathcal{H}}$$

and $\|e^{f_0}q_0\|_{L^r(\Omega)} \le \|e^{M\sqrt{k(x,x)}}q_0\|_{L^r(\Omega)}$. Therefore,

$$\left\|p_{\breve{f}_{\lambda,n}} - p_0\right\|_{L^r(\Omega)} \le \frac{\|\eta\|_{L^1(\Omega,q_0)}\|e^{M\sqrt{k(x,x)}}q_0\|_{L^r(\Omega)}\left\|\breve{f}_{\lambda,n} - f_0\right\|_{\mathcal{H}}}{\theta^2}$$

$$+\frac{\|\eta q_0\|_{L^r(\Omega)}\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}}{\theta}$$

and for $r=1$,

$$\left\|p_{\breve{f}_{\lambda,n}}-p_0\right\|_{L^1(\Omega)}\leq\frac{2\,\|\eta\|_{L^1(\Omega,q_0)}\left\|\breve{f}_{\lambda,n}-f_0\right\|_{\mathcal{H}}}{\theta}.$$

(ii) Also

$$\begin{aligned}KL(p_0\|p_{\breve{f}_{\lambda,n}})&=\int_\Omega p_0\log\frac{p_0}{p_{\breve{f}_{\lambda,n}}}\,dx=\int_\Omega\log\left(e^{f_0-\breve{f}_{\lambda,n}}\frac{B(\breve{f}_{\lambda,n})}{B(f_0)}\right)p_0(x)\,dx\\&=\int_\Omega\left(f_0-\breve{f}_{\lambda,n}+\log\frac{B(\breve{f}_{\lambda,n})}{B(f_0)}\right)p_0(x)\,dx\\&\leq\frac{|B(\breve{f}_{\lambda,n})-B(f_0)|}{B(f_0)}+\|\breve{f}_{\lambda,n}-f_0\|_{L^1(\Omega,p_0)}\leq\frac{2\,\|\eta q_0\|_{L^1(\Omega)}}{\theta}\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}.\end{aligned}$$

(iii) It is easy to verify that

$$\begin{aligned}h(p_{\breve{f}_{\lambda,n}},p_0)&=\left\|\frac{e^{\breve{f}_{\lambda,n}/2}}{\|e^{\breve{f}_{\lambda,n}/2}\|_{L^2(\Omega,q_0)}}-\frac{e^{f_0/2}}{\left\|e^{f_0/2}\right\|_{L^2(\Omega,q_0)}}\right\|_{L^2(\Omega,q_0)}\\&\leq\frac{2\|e^{\breve{f}_{\lambda,n}/2}-e^{f_0/2}\|_{L^2(\Omega,q_0)}}{\left\|e^{f_0/2}\right\|_{L^2(\Omega,q_0)}}\end{aligned}$$

where the above inequality is obtained by carrying out and simplifying the decomposition as in (A.1). Using (B.4), we therefore have

$$h(p_{\breve{f}_{\lambda,n}},p_0)\leq\sqrt{\frac{\int_\Omega k(x,x)e^{M\sqrt{k(x,x)}}q_0\,dx}{\theta}}\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}.$$

(iv) As $f_0,\,\breve{f}_{\lambda,n}\in\mathcal{F}$, by Theorem 4, we obtain $J(p_0\|p_{\breve{f}_{\lambda,n}})=\frac{1}{2}\|\sqrt{C}(\breve{f}_{\lambda,n}-f_0)\|_{\mathcal{H}}^2\leq\frac{1}{2}\|\sqrt{C}\|^2\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}^2$.

Note that we have bounded the various distances between $p_{\breve{f}_{\lambda,n}}$ and p_0 in terms of $\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}$. Since $\breve{f}_{\lambda,n}=f_{\lambda,n}$ with probability converging to 1, the assertions on consistency are proved by Theorem 6(i) in combination with Lemma 14—as we did not explicitly assume $f_0\in\overline{\mathcal{R}(C)}$—and the rates follow from Theorem 6(iii). ■

Remark The following observations can be made while comparing the scenarios of using bounded vs. unbounded kernels in the problem of estimating p_0 through Theorems 7 and B.2. First, the consistency results in L^r, Hellinger and KL distances are the same but for additional integrability conditions on k and q_0. The additional integrability conditions are not too difficult to hold in practice as they involve k and q_0 which can be chosen appropriately. However, the unbounded situation in Theorem B.2 requires the knowledge of M which is usually not known. On the other hand, the consistency result in J in Theorem B.2 is slightly weaker than in Theorem 7. This may be an artifact of our analysis as

we are not able to adapt the bounding technique used in the proof of Theorem 7 to bound $J(p_0\|p_{\breve{f}_{\lambda,n}})=\frac{1}{2}\|\sqrt{C}(\breve{f}_{\lambda,n}-f_0)\|_{\mathcal{H}}^2$ as it critically depends on the boundedness of k. Therefore, we used a trivial bound of $J(p_0\|p_{\breve{f}_{\lambda,n}})=\frac{1}{2}\|\sqrt{C}(\breve{f}_{\lambda,n}-f_0)\|_{\mathcal{H}}^2\leq\frac{1}{2}\|\sqrt{C}\|^2\|\breve{f}_{\lambda,n}-f_0\|_{\mathcal{H}}^2$, which yields the result through Theorem 6(i). Due to the same reason, we also obtain a slower rate of convergence in J. Second, the rate of convergence in KL is slower than in Theorem B.2, which again may be an artifact of our analysis. The convergence rate for KL in Theorem 7 is based on the application of Theorem 6(ii) in Lemma A.1, where the bound on KL in Lemma A.1 critically uses the boundedness to upper bound KL in terms of squared Hellinger distance.

B.2.1 Derivation of $\breve{f}_{\lambda,n}$

Any $f\in\mathcal{H}$ can be decomposed as $f=f_\parallel+f_\perp$ where

$$f_\parallel\in\operatorname{span}\left\{\hat{\xi},(\partial_j k(X_b,\cdot))_{b,j}\right\}=:\mathcal{H}_\parallel,$$

which is a closed subset of $\mathcal{H}$ and $f_\perp\in\mathcal{H}_\parallel^\perp:=\left\{g\in\mathcal{H}:\langle g,h\rangle_{\mathcal{H}}=0,\,\forall\,h\in\mathcal{H}_\parallel\right\}$ so that $\mathcal{H}=\mathcal{H}_\parallel\oplus\mathcal{H}_\parallel^\perp$. Since the objective function in (B.3) matches with the one in Theorem 5, using the above decomposition in (B.3), it is easy to verify that $\hat{J}$ depends only on $f_\parallel\in\mathcal{H}_\parallel$ so that (B.3) reduces to

$$(\breve{f}_{\lambda,n}^\parallel,\breve{f}_{\lambda,n}^\perp)=\arg\inf_{\substack{f_\parallel\in\mathcal{H}_\parallel,f_\perp\in\mathcal{H}^\perp\\\|f_\parallel\|_{\mathcal{H}}^2+\|f_\perp\|_{\mathcal{H}}^2\leq M^2}}\hat{J}_\lambda(f_\parallel)+\frac{\lambda}{2}\|f_\parallel\|_{\mathcal{H}}^2+\frac{\lambda}{2}\|f_\perp\|_{\mathcal{H}}^2\tag{B.5}$$

and $\breve{f}_{\lambda,n}=\breve{f}_{\lambda,n}^\parallel+\breve{f}_{\lambda,n}^\perp$. Since $f_\parallel$ is of the form in (14), using it in (B.5), it is easy to show that $\hat{J}_\lambda(f_\parallel)+\frac{\lambda}{2}\|f_\parallel\|_{\mathcal{H}}^2=\frac{1}{2}\Theta^T\boldsymbol{H}\Theta+\Theta^T\Delta$. Similarly, it can be shown that $\|f_\parallel\|_{\mathcal{H}}^2=\Theta^T\boldsymbol{K}\Theta$. Since $f_\perp$ appears in (B.5) only through $\|f_\perp\|_{\mathcal{H}}^2$, (B.5) reduces to

$$(\Theta_\parallel,c_\perp)=\arg\inf_{\substack{\Theta\in\mathbb{R}^{nd+1},c\geq0\\\Theta^T\boldsymbol{K}\Theta+c\leq M^2}}\frac{1}{2}\Theta^T\boldsymbol{H}\Theta+\Theta^T\Delta+\frac{\lambda}{2}c,\tag{B.6}$$

where $\breve{f}_{\lambda,n}^\parallel$ is constructed as in (14) using $\Theta_\parallel$ and $\breve{f}_{\lambda,n}^\perp$ is such that $\|\breve{f}_{\lambda,n}^\perp\|_{\mathcal{H}}^2=c_\perp$. The necessary and sufficient conditions for the optimality of $(\Theta_\parallel,c_\perp)$ is given by the following Karush-Kuhn-Tucker conditions,

$$\begin{aligned}(\boldsymbol{H}+2\tau\boldsymbol{K})\Theta_\parallel+\Delta=0,\ \frac{\lambda}{2}+\eta-\tau=0&\qquad\text{(Stationarity)}\\\Theta_\parallel^T\boldsymbol{K}\Theta_\parallel+c_\perp\leq M^2,\ c_\perp\geq0&\qquad\text{(Primal feasibility)}\\\eta\geq0,\ \tau\geq0&\qquad\text{(Dual feasibility)}\\\tau c_\perp=0,\ \eta(\Theta_\parallel^T\boldsymbol{K}\Theta_\parallel+c_\perp-M^2)=0&\qquad\text{(Complementary slackness)}\end{aligned}$$

Combining the dual feasibility and stationary conditions, we have $\eta=\tau-\frac{\lambda}{2}\geq0$, i.e., $\tau\geq\frac{\lambda}{2}$. Using this in the complementary slackness involving τ and $c_\perp$, it follows that $c_\perp=0$. Since $\|\breve{f}_{\lambda,n}^\perp\|^2=c_\perp$, we have $\breve{f}_{\lambda,n}^\perp=0$, i.e., $\breve{f}_{\lambda,n}$ is completely determined by $\breve{f}_{\lambda,n}^\parallel$. Therefore $\breve{f}_{\lambda,n}^\parallel$ is of the form in (14) and (B.6) reduces to a quadratically constrained quadratic program.

B.3 $\mathcal{R}(C^\beta)$ and Interpolation Spaces

Proposition B.3 presents an interpretation for $\mathcal{R}(C^\beta)$ ($\beta > 0$ and $\beta \notin \mathbb{N}$) as interpolation spaces between $\mathcal{R}(C^{\lceil\beta\rceil})$ and $\mathcal{R}(C^{\lfloor\beta\rfloor})$ where $\mathcal{R}(C^0) := \mathcal{H}$. An inspection of its proof shows that Proposition B.3 holds for any self-adjoint, bounded, compact operator defined on a separable Hilbert space.

Proposition B.3 *Suppose* **(B)** *and* **(D)** *hold with* $\varepsilon = 1$. *Then for all* $\beta > 0$ *and* $\beta \notin \mathbb{N}$

$$\mathcal{R}(C^\beta) = \left[\mathcal{R}(C^{\lfloor\beta\rfloor}), \mathcal{R}(C^{\lceil\beta\rceil})\right]_{\beta-\lfloor\beta\rfloor,2}$$

where $\mathcal{R}(C^0) := \mathcal{H}$, *and the spaces* $\mathcal{R}(C^\beta)$ *and* $\left[\mathcal{R}(C^{\lfloor\beta\rfloor}), \mathcal{R}(C^{\lceil\beta\rceil})\right]_{\beta-\lfloor\beta\rfloor,2}$ *have equivalent norms.*

To prove Proposition B.3, we need the following result which we quote from Steinwart and Scovel (2012, Lemma 6.3) (also see Tartar, 2007, Lemma 23.1) that interpolates L^2-spaces whose underlying measures are absolutely continuous with respect to a measure ν.

Lemma B.4 *Let* ν *be a measure on a measurable space* Θ *and* $w_0 : \Theta \to [0,\infty)$ *and* $w_1 : \Theta \to [0,\infty)$ *be measurable functions. For* $0 < \beta < 1$, *define* $w_\beta := w_0^{1-\beta} w_1^\beta$. *Then we have*

$$[L^2(w_0\, d\nu), L^2(w_1\, d\nu)]_{\beta,2} = L^2(w_\beta\, d\nu)$$

and the norms on these two spaces are equivalent. Moreover, this result still holds for weights $w_0 : \Theta \to (0,\infty)$ *and* $w_1 : \Theta \to [0,\infty]$, *if one uses the convention* $0 \cdot \infty := 0$ *in the definition of the weighted spaces.*

Proof of Proposition B.3. The proof is based on the ideas used in the proof of Theorem 4.6 in Steinwart and Scovel (2012). Recall that by the Hilbert-Schmidt theorem, C has the following representation,

$$C = \sum_{i\in I} \alpha_i \phi_i \langle \phi_i, \cdot\rangle_{\mathcal{H}}$$

where $(\alpha_i)_{i\in I}$ are the positive eigenvalues of C, $(\phi_i)_{i\in I}$ are the corresponding unit eigenvectors that form an ONB for $\mathcal{R}(C)$ and I is an index set which is either finite (if $\mathcal{H}$ is finite-dimensional) or $I = \mathbb{N}$ with $\lim_{i\to\infty} \alpha_i = 0$ (if $\mathcal{H}$ is infinite dimensional). Let $(\psi_i)_{i\in J}$ be an ONB for $\mathcal{N}(C)$ where J is some index set so that any $f \in \mathcal{H}$ can be written as

$$f = \sum_{i\in I} \langle f, \phi_i\rangle_{\mathcal{H}} \phi_i + \sum_{i\in J} \langle f, \psi_i\rangle_{\mathcal{H}} \psi_i =: \sum_{i\in I\cup J} a_i \theta_i$$

where $\theta_i := \phi_i$ if $i \in I$ and $\theta_i := \psi_i$ if $i \in J$ with $a_i := \langle f, \theta_i\rangle_{\mathcal{H}}$. Let $\beta > 0$. By definition, $g \in \mathcal{R}(C^\beta)$ is equivalent to $\exists h \in \mathcal{H}$ such that $g = C^\beta h$, i.e.,

$$g = \sum_{i\in I} \alpha_i^\beta \langle h, \phi_i\rangle_{\mathcal{H}} \phi_i =: \sum_{i\in I} b_i \alpha_i^\beta \phi_i$$

where $b_i := \langle h, \phi_i\rangle_{\mathcal{H}}$. Clearly $\sum_{i\in I} b_i^2 = \sum_{i\in I} \langle h, \phi_i\rangle_{\mathcal{H}}^2 \le \|h\|_{\mathcal{H}}^2 < \infty$, i.e., $(b_i) \in \ell_2(I)$. Therefore

$$\mathcal{R}(C^\beta) = \left\{ \sum_{i\in I} b_i \alpha_i^\beta \phi_i \,:\, (b_i) \in \ell_2(I) \right\} = \left\{ \sum_{i\in I} c_i \phi_i \,:\, (c_i) \in \ell_2(I, \alpha^{-2\beta}) \right\}$$

where $\alpha := (\alpha_i)_{i\in I}$. Let us equip this space with the bilinear form

$$\left\langle \sum_{i\in I} c_i\phi_i, \sum_{i\in I} d_i \phi_i \right\rangle_{\mathcal{R}(C^\beta)} := \langle (c_i), (d_i)\rangle_{\ell_2(I,\alpha^{-2\beta})}$$

so that it induces the norm

$$\left\| \sum_{i\in I} c_i \phi_i \right\|_{\mathcal{R}(C^\beta)} := \|(c_i)\|_{\ell_2(I,\alpha^{-2\beta})}\,.$$

It is easy to verify that $(\alpha_i^\beta \phi_i)_{i\in I}$ is an ONB of $\mathcal{R}(C^\beta)$. Also since $\mathcal{R}(C^{\beta_1}) \subset \mathcal{R}(C^{\beta_2})$ for $0 < \beta_2 < \beta_1 < \infty$ and $\mathrm{id} : \mathcal{R}(C^{\beta_1}) \to \mathcal{R}(C^{\beta_2})$ is continuous, i.e., for any $g \in \mathcal{R}(C^{\beta_1})$,

$$\begin{aligned}\|g\|_{\mathcal{R}(C^{\beta_2})} = \|(c_i)\|_{\ell_2(I,\alpha^{-2\beta_2})} = \sqrt{\sum_{i\in I} \frac{c_i^2}{\alpha_i^{2\beta_2}}} &\le \sup_{i\in I} |\alpha_i|^{\beta_1-\beta_2} \|(c_i)\|_{\ell_2(I,\alpha^{-2\beta_1})} \\ &= \|C\|^{\beta_1-\beta_2} \|g\|_{\mathcal{R}(C^{\beta_1})} < \infty\end{aligned}$$

and so $\mathcal{R}(C^{\beta_1}) \hookrightarrow \mathcal{R}(C^{\beta_2})$. Similarly, we can show that $\mathcal{R}(C) \hookrightarrow \mathcal{H}$. In the following, we first prove the result for $0 < \beta < 1$ and then for $\beta > 1$.

(a) $0 < \beta < 1$: For any $f \in \mathcal{H}$ and $g \in \mathcal{R}(C)$, we have

$$\|f-g\|_{\mathcal{H}}^2 = \left\| \sum_{i\in I\cup J} a_i\theta_i - \sum_{i\in I} c_i\phi_i \right\|_{\mathcal{H}}^2 = \left\| \sum_{i\in I\cup J} (a_i - c_i)\theta_i \right\|_{\mathcal{H}}^2 = \|(a_i-c_i)\|_{\ell_2(I\cup J)}^2$$

where we define $c_i := 0$ for $i \in J$. For $t > 0$, we find

$$\begin{aligned}K(f,t,\mathcal{H},\mathcal{R}(C)) &= \inf_{g\in\mathcal{R}(C)} \|f-g\|_{\mathcal{H}} + t\|g\|_{\mathcal{R}(C)} \\ &= \inf_{(c_i)\in\ell_2(I,\alpha^{-2})} \|(a_i-c_i)\|_{\ell_2(I\cup J)} + t\|(c_i)\|_{\ell_2(I,\alpha^{-2})} \\ &= K(a,t,\ell_2(I\cup J), \ell_2(I,\alpha^{-2}))\,.\end{aligned}$$

From this we immediately obtain the equivalence

$$f \in [\mathcal{H}, \mathcal{R}(C)]_{\beta,2} \iff (a_i) \in [\ell_2(I\cup J), \ell_2(I,\alpha^{-2})]_{\beta,2}$$

where $0 < \beta < 1$. Applying the second part of Lemma B.4 to the counting measure on $I \cup J$ yields

$$[\ell_2(I\cup J), \ell_2(I,\alpha^{-2})]_{\beta,2} = \ell_2(I, \alpha^{-2\beta}).$$

Since $\mathcal{R}(C^\beta)$ and $\ell_2(I, \alpha^{-2\beta})$ are isometrically isomorphic, we obtain $\mathcal{R}(C^\beta) = [\mathcal{H}, \mathcal{R}(C)]_{\beta,2}$.

(b) $\beta > 1$ and $\beta \notin \mathbb{N}$: Define $\gamma := \lfloor \beta \rfloor$. Let $f \in \mathcal{R}(C^\gamma)$ and $g \in \mathcal{R}(C^{\gamma+1})$, i.e., $\exists\, (c_i) \in \ell_2(I, \alpha^{-2\gamma})$ and $(d_i) \in \ell_2(I, \alpha^{-2\gamma-2})$ such that $f = \sum_{i\in I} c_i \phi_i$ and $g = \sum_{i\in I} d_i \phi_i$. Since

$$\|f - g\|^2_{\mathcal{R}(C^\gamma)} = \|(c_i - d_i)\|^2_{\ell_2(I,\alpha^{-2\gamma})},$$

for $t > 0$, we have

$$\begin{aligned} K(f, t, \mathcal{R}(C^\gamma), \mathcal{R}(C^{\gamma+1})) &= \inf_{g\in\mathcal{R}(C^{\gamma+1})} \|f - g\|_{\mathcal{R}(C^\gamma)} + t\|g\|_{\mathcal{R}(C^{\gamma+1})} \\ &= \inf_{(d_i)\in\ell_2(I,\alpha^{-2\gamma-2})} \|(c_i - d_i)\|_{\ell_2(I,\alpha^{-2\gamma})} + t\|(d_i)\|_{\ell_2(I,\alpha^{-2\gamma-2})} \\ &= K(c, t, \ell_2(I, \alpha^{-2\gamma}), \ell_2(I, \alpha^{-2\gamma-2})), \end{aligned}$$

from which we obtain the following equivalence

$$f \in [\mathcal{R}(C^\gamma), \mathcal{R}(C^{\gamma+1})]_{\beta-\gamma,2} \iff (c_i) \in [\ell_2(I, \alpha^{-2\gamma}), \ell_2(I, \alpha^{-2\gamma-2})]_{\beta-\gamma,2} \overset{(*)}{=} \ell_2(I, \alpha^{-2\beta}),$$

where $(*)$ follows from Lemma B.4 and the result is obtained by noting that $\ell_2(I, \alpha^{-2\beta})$ and $\mathcal{R}(C^\beta)$ are isometrically isomorphic. ■

B.4 Denseness of $I_k\mathcal{H}$ in $W_2(\mathbb{R}^d, p)$

In this section, we discuss the denseness of $I_k\mathcal{H}$ in $W_2(\mathbb{R}^d, p)$ for a given $p \in \mathcal{P}_{\text{FD}}$, where $\mathcal{P}_{\text{FD}}$ is defined in Theorem 13, which is equivalent to the injectivity of S_k (see Rudin, 1991, Theorem 4.12). To this end, in the following result we show that under certain conditions on a bounded continuous translation invariant kernel on $\mathbb{R}^d$, the restriction of S_k to $\mathcal{W}_2^\sim(\mathbb{R}^d, p)$ is injective when $d = 1$, while the result for any general $d > 1$ is open. However, even for $d = 1$, this does not guarantee the injectivity of S_k (which is defined on $W_2(\mathbb{R}^d, p)$). Therefore, the question of characterizing the injectivity of S_k (or equivalently the denseness of $I_k\mathcal{H}$ in $W_2(\mathbb{R}^d, p)$) is open.

Proposition B.5 *Suppose $k(x, y) = \psi(x - y)$, $x, y \in \mathbb{R}^d$ where $\psi \in C_b(\mathbb{R}^d) \cap L^1(\mathbb{R}^d)$, $\int \|\omega\|_2 \psi^\wedge(\omega)\, d\omega < \infty$ and $\operatorname{supp}(\psi^\wedge) = \mathbb{R}^d$. If $d = 1$, then the restriction of S_k to $\mathcal{W}_2^\sim(\mathbb{R}^d, p)$ is injective for any $p \in \mathcal{P}_{FD}$.*

Proof Fix any $p \in \mathcal{P}_{\text{FD}}$. We need to show that for $[f]_\sim \in \mathcal{W}_2^\sim(\mathbb{R}^d, p)$, $S_k[f]_\sim = 0$ implies $[f]_\sim = 0$. From Proposition 11, we have

$$\begin{aligned} S_k[f]_\sim &= \int_{\mathbb{R}^d} \sum_{j=1}^d \partial_j k(x, \cdot) \partial_j f(x)\, p(x)\, dx = \int_{\mathbb{R}^d} \sum_{j=1}^d \partial_j \psi(x - \cdot) \partial_j f(x)\, p(x)\, dx \\ &= \int_{\mathbb{R}^d} \sum_{j=1}^d \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} i\omega_j \psi^\wedge(\omega) e^{i\langle \omega, \cdot - x\rangle}\, d\omega\, \partial_j f(x)\, p(x)\, dx \\ &= \int_{\mathbb{R}^d} \sum_{j=1}^d \phi_j(\omega) \psi^\wedge(\omega) e^{i\langle \omega, \cdot\rangle}\, d\omega \end{aligned}$$

where

$$\phi_j(\omega) := \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} (i\omega_j) e^{-i\langle \omega, x\rangle} \partial_j f(x)\, p(x)\, dx.$$

$S_k f = 0$ implies $\sum_{j=1}^d \phi_j(\omega)\psi^\wedge(\omega) = 0$ for all $\omega \in \mathbb{R}^d$. Since $\operatorname{supp}(\psi^\wedge) = \mathbb{R}^d$, we have $\sum_{j=1}^d \phi_j(\omega) = 0$ a.e., i.e., for ω-a.e.,

$$0 = \sum_{j=1}^d \int_{\mathbb{R}^d} (i\omega_j) \partial_j f(x)\, p(x)\, e^{-i\langle \omega, x\rangle}\, dx = \sum_{j=1}^d (i\omega_j)(p\partial_j f)^\wedge(\omega).$$

For $d = 1$, this implies $(\partial_j f)p = 0$ a.e. and so $\|f\|_{W_2} = 0$. ■

Examples of kernels that satisfy the conditions in Proposition B.5 include the Gaussian, Matérn (with $\beta > 1$) and inverse multiquadrics on $\mathbb{R}$.

Abstract

In recent years it has become popular to study machine learning problems in a setting of ordinal distance information rather than numerical distance measurements. By ordinal distance information we refer to binary answers to distance comparisons such as $d(A, B) < d(C, D)$. For many problems in machine learning and statistics it is unclear how to solve them in such a scenario. Up to now, the main approach is to explicitly construct an ordinal embedding of the data points in the Euclidean space, an approach that has a number of drawbacks. In this paper, we propose algorithms for the problems of medoid estimation, outlier identification, classification, and clustering when given only ordinal data. They are based on estimating the lens depth function and the k-relative neighborhood graph on a data set. Our algorithms are simple, are much faster than an ordinal embedding approach and avoid some of its drawbacks, and can easily be parallelized.

Keywords: ordinal data, ordinal distance information, comparison-based algorithms, lens depth function, k-relative neighborhood graph, ordinal embedding, non-metric multi-dimensional scaling

1. Introduction

In a typical machine learning setting we are given a data set $\mathcal{D}$ of objects together with a dissimilarity function d (or a similarity function s) quantifying how "close" objects are to each other. The machine learning rationale is that objects that are close to each other tend to have the same class label, belong to the same clusters, and so on. However, in recent years a whole new branch of the machine learning literature has emerged that relaxes this scenario (e.g., Agarwal et al., 2007, Jamieson and Nowak, 2011, van der Maaten and Weinberger, 2012, Heikinheimo and Ukkonen, 2013, Kleindessner and von Luxburg, 2014, Terada and von Luxburg, 2014, Jain et al., 2016; see Section 5.1 for a discussion of related work). Instead of being able to evaluate the dissimilarity function d itself, we only get to see binary answers to some comparisons of dissimilarity values such as

$$d(A, B) \overset{?}{<} d(C, D), \tag{1}$$

where $A, B, C, D \in \mathcal{D}$. We refer to any collection of answers to such comparisons, some of them possibly being incorrect, as ordinal distance information or ordinal data.

Besides theoretical interest, there are several real-life motivations for studying machine learning tasks in a setting of ordinal distance information:

- Human-based computation / crowdsourcing: In complex tasks, such as estimating the value of a car shown in an image or clustering biographies of celebrities, it can be hard to come up with a meaningful dissimilarity function that can be evaluated automatically, while humans often have a good sense of which objects should be considered (dis-)similar. It is then natural to incorporate the human expertise into the machine learning process. As it is a general phenomenon that humans are significantly better at comparing stimuli than at identifying a single one (Stewart et al., 2005), it is widely believed and accepted that humans are also better and more reliable in assessing dissimilarity on a relative scale ("Movie A is more similar to movie B than movie C is to movie D") than on an absolute one ("The dissimilarity between A and B is 0.3 and the dissimilarity between C and D is 0.8"). For this reason, ordinal questions are often used whenever humans are involved in gathering distance information. In addition to obtaining more robust results, this also has the advantage that one does not need to align people's different assessment scales.

- There are situations where ordinal distance information is readily available, but the underlying dissimilarity function is completely in the dark. Schultz and Joachims (2003) provide the example of search-engine query logs: if a user clicks on two search results, say A and B, but not on a third result C, then A and B can be assumed to be semantically more similar than A and C, or B and C, are.

- There are several applications where actual dissimilarity values between objects can be collected, but it is clear to the practitioner that these values only reflect a rough picture and should be considered informative only on an ordinal scale level. In this case, feeding the numerical scores to a machine learning algorithm can offer the problem that the algorithm interprets them stronger than they are meant to be. For example, discarding the actual values of signal strength measurements but only keeping their order can help to reduce the influence of measurement errors and thus bring some benefit in sensor localization (Liu et al., 2004; Xiao et al., 2006).

A big part of the literature on ordinal data deals with the problem of ordinal embedding. Given a data set $\mathcal{D}$ together with ordinal relationships, the goal is to map the objects in $\mathcal{D}$ to points in a Euclidean space $\mathbb{R}^m$ such that the ordinal relationships are preserved, with respect to the Euclidean interpoint distances, as well as possible. Clearly, ordinal embedding is a way of transforming ordinal data back to a standard setting: once $\mathcal{D}$ is represented by points in $\mathbb{R}^m$, we can apply any machine learning algorithm for vector-valued data. However, such a two-step approach comes with a number of problems, among them the high running time of ordinal embedding algorithms and the necessity to choose a dimension m for the space of the embedding (to name just two—see Section 5.1.2 for a complete discussion). Our aim is to solve machine learning problems in a setting of ordinal distance information directly, without constructing an ordinal embedding as an intermediate step.

There exist several different approaches in which ordinal relationships can be evaluated (see Section 5.1.1 for more discussion and references). While comparisons of the form

$d(A,B) \overset{?}{<} d(C,D)$ as in (1) are the most general form, there are other forms that, depending on the application, are of higher relevance. In particular in scenarios of human-based computation and crowdsourcing it is popular to show three objects A, B, and C at a time and to ask for information on $d(A,B) \overset{?}{<} d(A,C)$, that is, compared to (1), object D equals object A ("Which of the bottom two images is more similar to the top one?"). Recently, Heikinheimo and Ukkonen (2013) proposed an algorithm for estimating a medoid of a data set $\mathcal{D}$ based on statements of the form

$$\textit{Object } A \textit{ is the outlier within the triple of objects } (A,B,C), \qquad (\boxplus)$$

where A, B, C are pairwise distinct objects in $\mathcal{D}$ and such a statement formally means that

$$\big(d(A,B) > d(B,C)\big) \;\wedge\; \big(d(A,C) > d(B,C)\big).$$

Statements of the kind $(\boxplus)$ can easily be collected via crowdsourcing too ("Which among the following three images is the odd one out?"). In this paper, we suggest and study a similar but subtly different kind of question. Given three objects, we ask which of the objects is "the most central" object in the sense that it is the best representative for the three objects. The answers then have the form

$$\textit{Object } A \textit{ is the most central object within the triple of objects } (A,B,C) \qquad (\star)$$

with the formal interpretation that

$$\big(d(A,B) < d(B,C)\big) \;\wedge\; \big(d(A,C) < d(B,C)\big).$$

An illustration of the meaning of a statement of the kind $(\star)$ is provided in Figure 1 (left) by an example of a triple of cars consisting of a sports car, a fire truck, and an off-road vehicle: the sports car and the fire truck are rather different, but the off-road vehicle is not so different from either of them and can most likely be taken for a representative of the three cars—the off-road vehicle is the most central object within the triple.

Considering machine learning problems when given only ordinal data, in many cases it is pretty unclear how to solve them other than by constructing an ordinal embedding. For example, how can we construct a classifier based solely on a collection of answers to distance comparisons of the form (1)? **The most important insight of this paper is that ordinal distance information in the form $(\star)$ (but not in other forms—in particular, not in the form $(\boxplus)$) can immediately be related to two very helpful tools: depth functions and relative neighborhood graphs.** In a nutshell, depth functions (see, e.g., Mosler, 2013) come from multivariate statistics and are a means to generalize the concept of a univariate median to multivariate distributions and to quantify "centrality" of points with respect to such a distribution. The relative neigborhood graph (RNG; Toussaint, 1980) and its generalization, the k-RNG, are examples of proximity graphs, which play a prominent role in computer vision. In a proximity graph two vertices are connected by an edge if and only if the two vertices are in some sense close to each other. It is known from the literature that both depth functions and relative neigborhood graphs can be used to solve various machine learning problems. Our contribution is

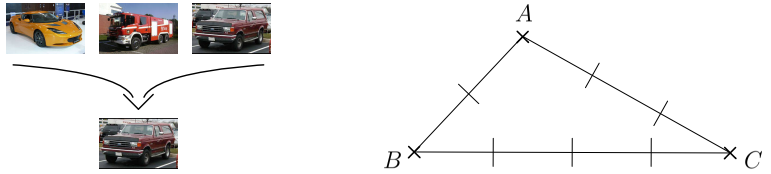

Figure 1: Illustration of the meaning of statement of the kind $(\star)$. Left: Within the three cars shown at the top, the off-road vehicle shown at the bottom a second time is the most central/best representative one. Right: A more formal approach: we have $d(A,B) < d(A,C) < d(B,C)$, and hence A is the most central data point within (A,B,C).

to establish that one particular depth function, the lens depth function (Liu and Modarres, 2011), as well as the k-RNG can be *computed* given the correct statements of the kind $(\star)$ for every triple of objects of $\mathcal{D}$, but nothing else. More importantly, the lens depth function and the k-RNG can be *estimated* when given not all but only some of possibly incorrect statements of the kind $(\star)$. This leads to algorithms solely based on ordinal data for four common machine learning problems, namely the problems of medoid estimation, outlier identification, classification, and clustering. Our algorithms are simple and can easily and highly efficiently be parallelized. We ran several experiments to compare our algorithms to competitors, in particular to the approach of first solving the ordinal embedding problem and then applying vector-based algorithms. We find that in situations with small sample size and small dimensions, the embedding approach tends to be superior to our algorithms in terms of error rates, while our algorithms are highly superior in terms of computing time (even without parallelization). The strength of our algorithms lies in the regime where the ordinal embedding algorithms break down due to computational complexity, but our algorithms still yield useful results. In any situation, our methods avoid some of the drawbacks inherent in an embedding approach.

The paper is organized as follows: We start with the setup including assumptions on the dissimilarity function d in Section 2. In Section 3 we formally define the lens depth function and the k-RNG and establish their relationships to ordinal data of the form $(\star)$. Furthermore, we motivate how we can make use of these relationships in order to solve the machine learning problems of medoid estimation, outlier identification, classification, and clustering when the only available information about a data set $\mathcal{D}$ is an arbitrary collection of statements of the kind $(\star)$. We formally state our proposed algorithms and discuss their running times, space requirements, and some implementation aspects in Section 4. Related work and further background are presented in Section 5. In Section 6 we present experiments on both artificial and real data. The paper concludes with a discussion and several directions to future work in Section 7.

2. Setup

Let $\mathcal{X}$ be an arbitrary set and $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a dissimilarity function on $\mathcal{X}$: a higher value of d means that two elements of $\mathcal{X}$ are more dissimilar to each other. The terms dissimilarity and distance are used synonymously. We assume d to satisfy the following properties for all $x, y \in \mathcal{X}$:

- $d(x, y) \geq 0$
- $d(x, y) = 0$ if and only if $x = y$
- $d(x, y) = d(y, x)$, that is d is symmetric.

With these properties, $(\mathcal{X}, d)$ is a semimetric space. Note that we do not require d to satisfy the triangle inequality, and hence $(\mathcal{X}, d)$ is not necessarily a metric space. In the following, we consider a finite subset $\mathcal{D} \subseteq \mathcal{X}$ and refer to $\mathcal{D}$ as a data set and to the elements of $\mathcal{D}$ as objects or data points.

We do not have access to d for evaluating dissimilarities between objects directly. Instead, we are only given an arbitrary collection $\mathcal{S}$ of statements

$$\textit{Object } A \textit{ is the most central object within the triple of objects } (A, B, C), \qquad (\star)$$

where (A, B, C) could be any triple of pairwise distinct objects in $\mathcal{D}$. At this point we do not make any assumptions on how $\mathcal{S}$ is related to the set of all statements, that is the set of statements of the kind $(\star)$ for all triples of objects (e.g., sampled uniformly at random). However, we need to make some assumptions if we want to provide a theoretical justification for our proposed algorithms (compare with Section 3.1 and Section 3.2.1). Statement $(\star)$ is equivalent to

$$\big(d(A, B) < d(B, C)\big) \;\wedge\; \big(d(A, C) < d(B, C)\big). \qquad (2)$$

Hence, the most central data point within a triple of data points is the data point opposite to the longest side in the triangle spanned by the three data points. An illustration of this can be seen in Figure 1 (right). Note that if we assume that there are no ties in the total order of all dissimilarities between objects, there is a unique most central object within every triple of objects. Also note that (2) is equivalent to

$$\big(d(A, B) + d(A, C)\big) < \big(d(B, A) + d(B, C)\big) \;\wedge\; \big(d(A, B) + d(A, C)\big) < \big(d(C, A) + d(C, B)\big),$$

and thus A is the medoid of $\{A, B, C\}$ (see Section 3.1 if you want to recall the definition of a medoid).

Statements might be repeatedly present in $\mathcal{S}$. More importantly, we allow $\mathcal{S}$ to be noisy due to errors in the measurement process and even inconsistent. Noisy means that $\mathcal{S}$ might comprise incorrect statements claiming that, for example, object A is the most central object within (A, B, C) although in fact object B is the most central one. Inconsistent means that we might have contradicting statements: one statement claims that object A is the most central object within (A, B, C), but another one claims that object B is. Noisy and inconsistent ordinal data is likely to be encountered in any real-world problem—think of a crowdsourcing setting, where different users will have different opinions from time to time.

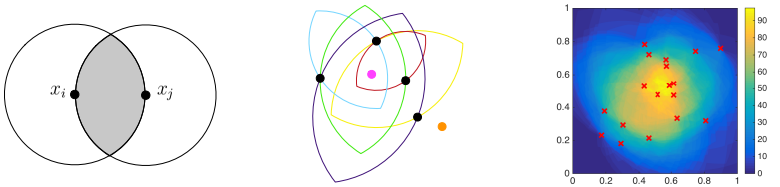

Figure 2: Left: Illustration of $Lens(x_i, x_j)$ in case of the Euclidean plane. The lens is shown in grey. Middle: The pink point at the center is contained in almost every lens spanned by any of two data points, while the orange one located at the bottom right edge of the point set is not contained in a single lens. Right: Heat map of the lens depth function for a data set of 18 points (in red) in the unit square of the Euclidean plane.

3. Lens Depth Function and k-Relative Neighborhood Graph and Motivation for our Algorithms

The most important geometric object in the following is the lens spanned by two points $x_i, x_j \in \mathcal{X}$. Consider a ball of radius $d(x_i, x_j)$ centered at x_i, and similarly a ball of the same radius centered at x_j. The lens spanned by x_i and x_j consists of all those points of $\mathcal{X}$ that are located in the intersection of these two balls. Formally,

$$\begin{aligned} Lens(x_i, x_j) &= \{x \in \mathcal{X} : d(x, x_i) < d(x_i, x_j)\} \cap \{x \in \mathcal{X} : d(x, x_j) < d(x_i, x_j)\} \\ &= \big\{x \in \mathcal{X} : \max\{d(x, x_i), d(x, x_j)\} < d(x_i, x_j)\big\}. \end{aligned}$$

An illustration of $Lens(x_i, x_j)$ in case of the Euclidean plane can be seen on the left side of Figure 2. The key insight for us are the following equivalences:

$$\begin{aligned} & x \in Lens(x_i, x_j) \Leftrightarrow \\ & d(x, x_i) < d(x_i, x_j) \text{ and } d(x, x_j) < d(x_i, x_j) \Leftrightarrow \\ & x \text{ is the most central point within } (x, x_i, x_j). \end{aligned} \qquad (3)$$

In particular, if we had knowledge of all ordinal relationships of type $(\star)$ for a data set $\mathcal{D} \subseteq \mathcal{X}$, we could check for any data point x_k and any two data points x_i, x_j whether x_k is contained in $Lens(x_i, x_j)$ or not.

3.1 Lens Depth Function

The lens depth function (Liu and Modarres, 2011) is an instance of a statistical depth function. These functions are a widely known tool in multivariate statistics. They have been designed to measure centrality with respect to point clouds or probability distributions. We will provide more information about statistical depth functions in general, including references, in Section 5.2. What makes the lens depth function special for us is that it does not rely on Euclidean structures or numeric distance values. This is in contrast to all other

depth functions from the literature. Given a data set $\mathcal{D} = \{x_1, \ldots, x_n\} \subseteq \mathcal{X}$, the lens depth function $LD(\,\cdot\,; \mathcal{D}) : \mathcal{X} \to \mathbb{N}_0$ is defined as

$$LD(x; \mathcal{D}) = \big|\, \{(x_i, x_j) : x_i, x_j \in \mathcal{D}, i < j, x \in Lens(x_i, x_j)\} \,\big|, \quad x \in \mathcal{X}.$$

To understand its meaning, consider a set of data points in the Euclidean plane. A point located at the "heart of the set" will lie in the lenses of many pairs of data points. Thus the lens depth function will attain a high value at this point, indicating its high centrality. In contrast, points at the boundary of the point cloud will lie in only a few lenses and will have a low lens depth value, indicating their low centrality. See the middle sketch of Figure 2 for an illustration. The right side of Figure 2 shows a heat map of the lens depth function for a data set consisting of 18 points in the Euclidean plane as an example.

Exploiting (3) we can see immediately how easily the lens depth function can be evaluated based on statements of the kind ($\star$). Given *all* statements of the kind ($\star$) for a data set $\mathcal{D} = \{x_1, \ldots, x_n\}$, that is one statement for every unordered triple (x_i, x_j, x_k) of pairwise distinct objects in $\mathcal{D}$, we can immediately *evaluate* $LD(x_t; \mathcal{D})$ for any $t \in \{1, \ldots, n\}$. It simply holds that

$$LD(x_t; \mathcal{D}) = \text{number of statements comprising } x_t \text{ as most central data point.} \tag{4}$$

We note that $LD(x_t; \mathcal{D})$ as given in (4) can be considered, up to a normalizing constant of $1/\binom{n-1}{2}$, as probability of the fixed data point x_t being the most central data point in a triple comprising x_t and two data points drawn uniformly at random without replacement from $\mathcal{D} \setminus \{x_t\}$. This insight gives us a handle for the realistic situation that we are not given all statements of the kind ($\star$), but only an arbitrary collection $\mathcal{S}$ of statements, some of them possibly being incorrect. Namely, we can still *estimate* $LD(x_t; \mathcal{D})$ by estimating the probability of the described event by its relative frequency:

$$LD(x_t; \mathcal{D}) \mathrel{\dot{\approx}} \frac{\text{number of statements in } \mathcal{S} \text{ that comprise } x_t \text{ as most central data point}}{\text{number of statements in } \mathcal{S} \text{ that comprise } x_t}. \tag{5}$$

This estimate will be reasonable whenever statements in $\mathcal{S}$ comprising x_t appear to be sampled approximately uniformly at random from the set of all statements that comprise x_t, the number of statements in $\mathcal{S}$ comprising x_t is large enough, and the proportion of incorrect statements is sufficiently small. Note that if we assume $\mathcal{S}$ to be sampled uniformly at random from the set of all statements, this will imply that for every $x_t \in \mathcal{D}$ statements in $\mathcal{S}$ comprising x_t are a uniform sample from the set of all statements that comprise x_t.

We now explain how we can use our insights to devise algorithms for the machine learning problems of medoid estimation, outlier identification, and classification when only given a collection of statements of the kind ($\star$) for a data set (the algorithms are formally stated in Section 4). The basic principle is that we replace the true lens depth function with its estimate according to (5) in the following existing approaches to these problems (see Section 5.2 for further information and references):

- **Medoid estimation (cf. Algorithm 1 in Section 4):** A medoid O_{MED} of a data set $\mathcal{D}$ is a most central object in the sense that it has minimal total distance to all other objects, that is it minimizes

$$D(O) = \sum_{O_i \in \mathcal{D}} d(O, O_i), \quad O \in \mathcal{D}. \tag{6}$$

  Since the lens depth function provides a measure of centrality too, even though in a different sense, a maximizer of the lens depth function (restricted to $\mathcal{D}$) is a natural candidate for an estimate of a medoid.

- **Outlier identification (cf. Algorithm 2 in Section 4):** An outlier in a data set $\mathcal{D}$ is "an observation . . . which appears to be inconsistent with the remainder of that set of data" (Barnett and Lewis, 1978, Chapter 1). Points with a low lens depth value are non-central points according to the lens depth function and thus are natural candidates for outliers. We will see in the experiments in Section 6.1.2 that this approach works well for data sets with a uni-modal structure, but can fail in multi-modal cases.

- **Classification (cf. Algorithm 3 in Section 4):** The simplest approach to classification based on the lens depth function is to assign a test point to that class in which it is a more central point: For each of the classes we could compute a separate lens depth function and evaluate a test point's corresponding depth value. The test point is then classified as belonging to the class that gives rise to the highest lens depth value. However, it has been found that such a *max-depth* approach has some severe limitations (compare with Section 5.2).

  To overcome these limitations, we use a feature-based approach. When dealing with a K-class classification problem, we consider the data-dependent feature map

$$x \mapsto (LD(x; Class_1), LD(x; Class_2), \ldots, LD(x; Class_K)) \in \mathbb{R}^K, \quad x \in \mathcal{X}, \tag{7}$$

  and then apply an out-of-the-box classification algorithm to the K-dimensional representation of the data set.

3.2 k-Relative Neighborhood Graph

We now use the lenses spanned by two data points in order to define the k-relative neighborhood graph (k-RNG). In our language, for a data set $\mathcal{D} = \{x_1, \ldots, x_n\} \subseteq \mathcal{X}$ and a parameter $k \in \mathbb{N}$ the k-RNG on $\mathcal{D}$ is the graph with vertex set $\mathcal{D}$ in which two distinct vertices x_i and x_j are connected by an undirected edge if and only if the lens spanned by these points contains fewer than k data points from $\mathcal{D}$:

$$x_i \sim x_j \;\Leftrightarrow\; |Lens(x_i, x_j) \cap \mathcal{D}| < k. \tag{8}$$

The rationale behind this definition is that two data points may be considered close to each other whenever the lens spanned by them contains only a few data points. The k-relative neighborhood graph is best known when $k = 1$. In this form it is simply called relative neighborhood graph (RNG) and has already been introduced in Toussaint (1980). The general k-RNG has been defined by Chang et al. (1992). Examples for a data set in

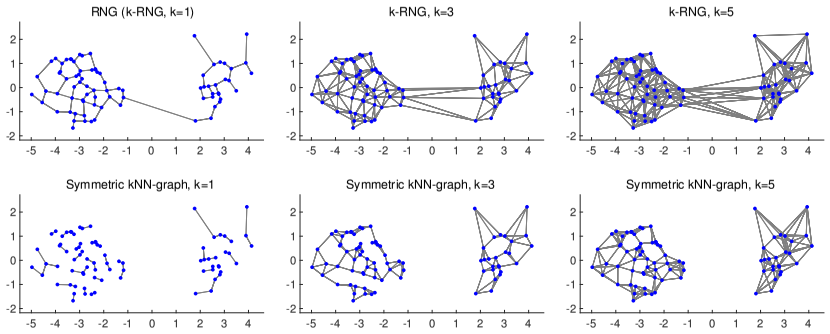

Figure 3: k-relative neighborhood graphs (1st row) and symmetric k-nearest neighbor graphs (2nd row) on 80 points from a mixture of two Gaussians. Note that as opposed to the k-NN graphs, the k-relative neighborhood graphs tend to have more connections between points from the different mixture components. In fact, a k-RNG is always connected (see Section 5.3). This might be desirable in some situations, but undesirable in others.

the Euclidean plane can be seen in Figure 3. For comparison, we also also show symmetric k-nearest neighbor graphs on the data set. The symmetric k-nearest neighbor graph or k-NN graph for short, also with parameter $k \in \mathbb{N}$, is more popular in machine learning. In that graph two vertices are connected by an undirected edge whenever one of them is among the k closest data points to the other one (with respect to the distance function d).

Given *all* statements of the kind $(\star)$ for a data set $\mathcal{D}$, it is straightforward to build the *true* k-RNG on $\mathcal{D}$ similarly to the exact evaluation of the lens depth function (4). Below, we will discuss how to build an *estimate* of the k-RNG on $\mathcal{D}$ when given only an arbitrary collection of statements, some of them possibly being incorrect, and a problem involved in Section 3.2.1. Before, let us explain how k-relative neighborhood graphs can be used for classification and clustering.

- **Classification (cf. Algorithm 4 in Section 4):** Given a set of labeled points and an additional test point that we would like to classify, we can construct the k-RNG on the union of the set of labeled points and the singleton of the test point and take a majority vote of the test point's neighbors in the graph. There is no need to construct the whole graph. We just have to find the test point's neighbors in the graph. Note that the basic principle is the same as for the well-known k-NN classifier (e.g., Shalev-Shwartz and Ben-David, 2014, Chapter 19), replacing the directed k-NN graph by the k-RNG.
- **Clustering (cf. Algorithm 5 in Section 4):** As we can do with the symmetric k-NN graph, it is straightforward to apply spectral clustering to the k-RNG on a data set $\mathcal{D}$ (see von Luxburg, 2007, for a comprehensive introduction to spectral clustering—that work suggests the symmetric k-NN graph as one of a few graphs that can be used). We propose

two versions: one is to simply work with an estimate of the ordinary unweighted k-RNG, the other one is to use an estimate of a k-RNG in which an edge between connected vertices x_i and x_j is weighted by

$$\exp\left(-\frac{1}{\sigma^2}\cdot\frac{|Lens(x_i,x_j)\cap\mathcal{D}|^2}{(|\mathcal{D}|-2)^2}\right) \tag{9}$$

for a scaling parameter $\sigma > 0$.

3.2.1 The Problem of Estimating the k-RNG from Noisy Ordinal Data

The key insight for estimating the k-RNG on a data set $\mathcal{D}$ from ordinal distance information of type $(\star)$ is similar to the one for estimating the lens depth function: the characterization (8) is equivalent to two distinct, fixed data points x_i and x_j being connected in the k-RNG if and only if the probability of a data point drawn uniformly at random from $\mathcal{D}\setminus\{x_i,x_j\}$ lying in $Lens(x_i,x_j)$ is smaller than $k/(|\mathcal{D}|-2)$. Given a collection $\mathcal{S}$ of statements of the kind $(\star)$, this probability can be estimated by

$$V(x_i,x_j)=\frac{N(x_i,x_j)}{D(x_i,x_j)}, \tag{10}$$

where

$$\begin{aligned} N(x_i,x_j) &= \text{number of statements in } \mathcal{S} \text{ comprising both } x_i \text{ and } x_j \text{ and} \\ &\qquad \text{another data point as most central data point,} \\ D(x_i,x_j) &= \text{number of statements in } \mathcal{S} \text{ comprising both } x_i \text{ and } x_j. \end{aligned} \tag{11}$$

Thus our strategy to estimate the k-RNG on $\mathcal{D}$ is the following: we connect two data points x_i and x_j with $i\neq j$ by an undirected edge if and only if

$$V(x_i,x_j) < \frac{k}{|\mathcal{D}|-2}. \tag{12}$$

If all statements in $\mathcal{S}$ are correct and, for every x_i and x_j with $i\neq j$, there are sufficiently many statements in $\mathcal{S}$ that comprise both x_i and x_j and these statements appear to be sampled approximately uniformly at random from the set of all statements that comprise x_i and x_j, we can expect our estimate of the k-RNG to be reasonable.

However, incorrect statements in $\mathcal{S}$ create a problem for our strategy. Usually, we are interested in a k-RNG for a small value of the parameter k, aiming at connecting only data points that are close to each other. Consequently, according to (12), in order that the data points x_i and x_j are connected in our estimate of the k-RNG, the estimated probability $V(x_i,x_j)$ has to be small. However, in case of erroneous ordinal data comprising sufficiently many incorrect statements, there will always be statements wrongly indicating that there are some data points in $Lens(x_i,x_j)$ that in fact are not, and thus $V(x_i,x_j)$ will always be somewhat large. Hence, many of the edges of the true k-RNG on $\mathcal{D}$ will not be present in our estimate.
To make this formal, consider the following simple noise model: Statements of the kind $(\star)$ are incorrect, independently of each other, with some fixed probability *errorprob*. In an

incorrect statement the two data points that are not most central appear to be most central with probability 1/2 each. In our experiments in Section 6.1, this noise model is referred to as Noise model I. Assume $\mathcal{S}$ to be sampled uniformly at random from all statements. Denote by $p = p(x_i, x_j)$ the probability that a data point drawn uniformly at random from $\mathcal{D} \setminus \{x_i, x_j\}$ lies in $Lens(x_i, x_j)$, that is $p = |Lens(x_i, x_j) \cap \mathcal{D}|/(|\mathcal{D}| - 2)$. Denote by $\tilde{p} = \tilde{p}(x_i, x_j)$ the probability that the following experiment yields a positive result: A data point is drawn uniformly at random from $\mathcal{D} \setminus \{x_i, x_j\}$. Independently, a Bernoulli trial with a probability of success equaling *errorprob* is performed. If the Bernoulli trial fails, the experiment yields a positive result if and only if the drawn data point falls into $Lens(x_i, x_j)$. If the Bernoulli trial succeeds, the experiment yields a positive result if and only if the data point does not fall into $Lens(x_i, x_j)$ and another Bernoulli trial, with a probability of success of one half and performed independently, succeeds. It is clear that under the considered model, $V(x_i, x_j)$ as given in (10) and (11) is an estimate of $\tilde{p}$ rather than of p. Assuming that *errorprob* is less than 2/3, we can relate $\tilde{p}$ and p via

$$\tilde{p} = p \cdot (1 - errorprob) + (1 - p) \cdot errorprob \cdot \frac{1}{2}, \tag{13}$$

or equivalently

$$p = \frac{\tilde{p} - \frac{1}{2} \cdot errorprob}{1 - \frac{3}{2} \cdot errorprob}. \tag{14}$$

The probability $\tilde{p}$ is obtained from p by applying an affine transformation and vice versa. It follows from (13) that our strategy yields an estimate of the k'-RNG with

$$k' = \frac{k - \frac{1}{2} \cdot errorprob \cdot (|\mathcal{D}| - 2)}{1 - \frac{3}{2} \cdot errorprob} \tag{15}$$

rather than of the intended k-RNG. In particular, we have $k' < k$ for $k < \frac{1}{3}(|\mathcal{D}| - 2)$ and $k' \leq 0$ for $k \leq \frac{1}{2} \cdot errorprob \cdot (|\mathcal{D}| - 2)$. This means that whenever $k < \frac{1}{3}(|\mathcal{D}| - 2)$, our strategy produces an estimate containing fewer edges than we would like to have, and whenever $k \leq \frac{1}{2} \cdot errorprob \cdot (|\mathcal{D}| - 2)$, it even produces an estimate of an empty graph, that is a graph without any edges at all.

These findings might seem worse than they actually are: using our estimated graph for classification or clustering, we do not care whether we work with the estimate of a k'-RNG instead of a k-RNG, but only whether our classification or clustering result is useful. However, we have to bear them in mind when choosing the parameter k in our algorithms: Using cross-validation for choosing k for Algorithm 4 (classification by means of a majority vote of neighbors in the graph), we may only use Leave-one-out cross-validation variants since we have to ensure roughly the same size of the training set during cross-validation and the training set in the ultimate classification task. Otherwise, a value of k that is optimal during cross-validation will not be optimal in the ultimate classification problem since k' depends on $|\mathcal{D}|$ as stated in (15). Applying Algorithm 5 (spectral clustering on the estimated k-RNG), we have to choose k so large that the constructed graph is connected. This is not only required by some versions of spectral clustering, but also indicates that the graph is indeed an estimate of a true k'-RNG with $k' \geq 1$ rather than of an empty graph.

If we know the value of *errorprob*, or have at least an estimate of it, we can correct for the bias of our strategy. In order to estimate the k-RNG on a data set $\mathcal{D}$ for the intended value of k, according to (14), two data points x_i and x_j with $i \neq j$ should be connected if and only if

$$\frac{V(x_i, x_j) - \frac{1}{2} \cdot errorprob}{1 - \frac{3}{2} \cdot errorprob} < \frac{k}{|\mathcal{D}| - 2}, \tag{16}$$

which equals (12) if $errorprob = 0$. Note that although the left-hand side of equation (16) is an unbiased estimator of $p(x_i, x_j)$ for every x_i and x_j with $i \neq j$ (assuming $\mathcal{S}$ to be sampled uniformly at random from all statements), due to the thresholding step in (16) our estimation strategy is still not an unbiased estimator of the intended k-RNG.

4. Algorithms for Medoid Estimation, Outlier Identification, Classification, and Clustering

In this section we formally state our algorithms for the problems of medoid estimation, outlier identification, classification, and clustering when the only available information about a data set $\mathcal{D}$ is a collection $\mathcal{S}$ of statements of the kind $(\star)$. Furthermore, we discuss running times, space requirements, and some implementation aspects.

4.1 Medoid Estimation

The following Algorithm 1 returns as output an estimate of a medoid of $\mathcal{D}$ as motivated in Section 3.1. The estimate is given by an object that maximizes the estimated lens depth function on $\mathcal{D}$. By setting the estimated lens depth value $LD(O)$ to zero for objects O that do not appear in any statement in $\mathcal{S}$, which means that we do not have any information about O, we ensure that such an object is never returned as output (unless there is no available information about $\mathcal{D}$ at all, i.e. $\mathcal{S} = \emptyset$).

Algorithm 1 Estimating a medoid

Input: a collection $\mathcal{S}$ of statements of the kind $(\star)$ for some data set $\mathcal{D}$

Output: an estimate of a medoid of $\mathcal{D}$

1: for every object O in $\mathcal{D}$ compute

$$LD(O) := \frac{\text{number of statements comprising } O \text{ as most central object}}{\text{number of statements comprising } O}$$

▷ if the denominator equals zero, set $LD(O) = 0$

2: **return** an object O for which $LD(O)$ is maximal

If we assume that every object in $\mathcal{D}$ can be identified by a unique index from $\{1, \ldots, |\mathcal{D}|\}$ and, given a statement in $\mathcal{S}$, the indices of the three objects involved can be accessed in constant time, then Algorithm 1 can be implemented with $\mathcal{O}(|\mathcal{D}| + |\mathcal{S}|)$ time and $\mathcal{O}(|\mathcal{D}|)$ space in addition to storing $\mathcal{S}$. This can be done by going through $\mathcal{S}$ only once and updating counters for the three objects found in a statement. If the objects in $\mathcal{D}$ are not indexed by

$1, \ldots, |\mathcal{D}|$, we can use minimal perfect hashing in order to first create such an indexing. This requires about $\mathcal{O}(|\mathcal{D}|)$ time and space (Hagerup and Tholey, 2001; Botelho et al., 2007), so the overall requirements remain unaffected by this additional step. An important feature of Algorithm 1 is that it can easily be parallelized by partitioning $\mathcal{S}$ into several subsets that may be processed independently. Since one usually may expect that $|\mathcal{S}| \gg |\mathcal{D}|$, such a parallelization has almost ideal speedup, that is doubling the number of processing elements leads to almost only half of the running time.

4.2 Outlier Identification

By means of the following Algorithm 2 we can identify outliers in $\mathcal{D}$ given as input only a collection $\mathcal{S}$ of statements of the kind $(\star)$. Outlier candidates are data points with low estimated lens depth values $LD(O)$. By setting $LD(O)$ to zero for objects O that do not appear in any statement we guarantee that such objects are identified as outliers.

Algorithm 2 Identifying outlier candididates

Input: a collection $\mathcal{S}$ of statements of the kind $(\star)$ for some data set $\mathcal{D}$

Output: a subset of $\mathcal{D}$ containing objects that are outlier candidates

1: for every object O in $\mathcal{D}$ compute

$$LD(O) := \frac{\text{number of statements comprising } O \text{ as most central object}}{\text{number of statements comprising } O}$$

▷ if the denominator equals zero, set $LD(O) = 0$

2: identify objects with exceptionally small values of $LD(O)$

3: **return** the set of identified objects

The only difference between Algorithm 2 and Algorithm 1 is that instead of returning the object with the highest value of $LD(O)$ as estimate of a medoid we return objects with exceptionally small values as outlier candidates. The running time of Algorithm 2 depends on the identification strategy in Step 2, but if one simply identifies c objects with smallest values ($1 \leq c \leq |\mathcal{D}|$), then Algorithm 2 can be implemented with $\mathcal{O}(|\mathcal{D}| + |\mathcal{S}|)$ time and $\mathcal{O}(|\mathcal{D}|)$ space in addition to storing $\mathcal{S}$ analogously to Algorithm 1. Here we make use of the fact that the selection of the c-th smallest value in an array of length $|\mathcal{D}|$ can be done in $\mathcal{O}(|\mathcal{D}|)$ time and space (Blum et al., 1973). Just as for Algorithm 1, the first step of Algorithm 2 can easily be parallelized.

4.3 Classification

We propose two different algorithms for dealing with K-class classification in a data set $\mathcal{D}$ consisting of a subset $\mathcal{L}$ of labeled objects and a subset $\mathcal{U}$ of unlabeled objects when given no more information than the class labels for the objects in $\mathcal{L}$ and a collection $\mathcal{S}$ of statements of the kind $(\star)$ for $\mathcal{D}$. Our goal is to predict a class label for every object in $\mathcal{U}$.

Our first proposed algorithm, Algorithm 3, is based on the lens depth function and has been motivated in Section 3.1. It consists of computing a feature embedding of $\mathcal{D}$ into

$[0,1]^K \subseteq \mathbb{R}^K$, in which each feature corresponds to the estimated lens depth value with respect to one class, and subsequently applying a classification algorithm that is suitable for K-class classification on $\mathbb{R}^K$ to this embedding.

Algorithm 3 K-class classification I

Input: a collection $\mathcal{S}$ of statements of the kind $(\star)$ for some data set $\mathcal{D}$ comprising a set $\mathcal{L}$ of labeled objects and a set $\mathcal{U}$ of unlabeled objects; a class label for every labeled object in $\mathcal{L}$ according to its membership in one of K classes (referred to as $Class_1, \ldots, Class_K$)
▷ note that we have $\mathcal{D} = \mathcal{L} \,\dot\cup\, \mathcal{U}$ and $\mathcal{L} = Class_1 \,\dot\cup\, Class_2 \,\dot\cup\, \ldots \,\dot\cup\, Class_K$

Output: an inferred class label for every unlabeled object in $\mathcal{U}$

1: for every object O in $\mathcal{D}$ and $i \in \{1, \ldots, K\}$ compute

$N_{C_i}(O) :=$ number of statements comprising O and two labeled objects from $Class_i$ with O as most central object

$D_{C_i}(O) :=$ number of statements comprising O and two labeled objects from $Class_i$

$$LD_{C_i}(O) := \frac{N_{C_i}(O)}{D_{C_i}(O)}$$

▷ if $D_{C_i}(O)$ equals zero, set $LD_{C_i}(O) = 0$

2: train an arbitrary classifier (suitable for K-class classification on $\mathbb{R}^K$) with training data

$$\{(LD_{C_1}(O_l), LD_{C_2}(O_l), \ldots, LD_{C_K}(O_l)) : O_l \in \mathcal{L}\} \subseteq \mathbb{R}^K$$

where the label of $(LD_{C_1}(O_l), LD_{C_2}(O_l), \ldots, LD_{C_K}(O_l))$ equals the label of O_l

3: **return** as inferred class label of every unlabeled object $O_u \in \mathcal{U}$ the label predicted by the classifier applied to $(LD_{C_1}(O_u), LD_{C_2}(O_u), \ldots, LD_{C_K}(O_u)) \in \mathbb{R}^K$

Assuming that the number of classes K is bounded by a constant, the first step of Algorithm 3 requires $\mathcal{O}(|\mathcal{D}| + |\mathcal{S}|)$ operations and $\mathcal{O}(|\mathcal{D}|)$ space in addition to storing $\mathcal{S}$. This is the same as for Algorithm 1 and Algorithm 2. As before, this step can easily and highly efficiently be parallelized (assuming that $|\mathcal{S}| \gg |\mathcal{D}|$). The time and space complexities of the remaining steps depend on the generic classifier that is used.

Our second proposed algorithm, Algorithm 4, is based on the k-RNG and has been motivated in Section 3.2. It is an instance-based learning method like the well-known k-NN classifier: There is no explicit training phase involved. An unlabeled object is readily classified by assigning the label that is most frequently encountered among the neighbors of the unlabeled object in the estimated k-RNG.
Assuming that the number of classes K is bounded by a constant, Algorithm 4 can be implemented with $\mathcal{O}(|\mathcal{D}|+|\mathcal{U}|\cdot|\mathcal{L}|+|\mathcal{S}|) = \mathcal{O}(|\mathcal{U}|\cdot|\mathcal{L}|+|\mathcal{S}|)$ time and $\mathcal{O}(|\mathcal{D}|+|\mathcal{U}|\cdot|\mathcal{L}|) = \mathcal{O}(|\mathcal{U}|\cdot|\mathcal{L}|)$ space in addition to storing $\mathcal{S}$. Here we have to assign to each labeled object a unique identifier in $\{1, \ldots, |\mathcal{L}|\}$ and to each unlabeled object a unique identifier in $\{1, \ldots, |\mathcal{U}|\}$ that can be looked up in constant time. This allows us to increment a value of $N(O_u, O_l)$ or $D(O_u, O_l)$ for $(O_u, O_l) \in \mathcal{U} \times \mathcal{L}$ stored in an array of size $|\mathcal{U}| \times |\mathcal{L}|$ within constant time. Once

Algorithm 4 K-class classification II

Input: a collection $\mathcal{S}$ of statements of the kind $(\star)$ for some data set $\mathcal{D}$ comprising a set $\mathcal{L}$ of labeled objects and a set $\mathcal{U}$ of unlabeled objects; a class label for every labeled object in $\mathcal{L}$ according to its membership in one of K classes (referred to as $Class_1, \ldots, Class_K$); an integer parameter k

▷ note that we have $\mathcal{D} = \mathcal{L} \,\dot\cup\, \mathcal{U}$ and $\mathcal{L} = Class_1 \,\dot\cup\, Class_2 \,\dot\cup\, \ldots \,\dot\cup\, Class_K$

Output: an inferred class label for every unlabeled object in $\mathcal{U}$

1: for every unlabeled object $O_u \in \mathcal{U}$ and every labeled object $O_l \in \mathcal{L}$ compute

$$\begin{aligned} N(O_u, O_l) &:= \text{number of statements comprising both } O_u \text{ and } O_l \text{ and another} \\ &\qquad \text{labeled object as most central object} \\ D(O_u, O_l) &:= \text{number of statements comprising both } O_u \text{ and } O_l \text{ and another} \\ &\qquad \text{labeled object} \\ V(O_u, O_l) &:= \frac{N(O_u, O_l)}{D(O_u, O_l)} \end{aligned}$$

▷ if $D(O_u, O_l)$ equals zero, set $V(O_u, O_l) = \infty$

2: **return** as inferred class label of every unlabeled object $O_u \in \mathcal{U}$ the majority vote (ties broken randomly) of the labels of those objects $O_l \in \mathcal{L}$ that satisfy

$$V(O_u, O_l) < \frac{k}{|\mathcal{L}| - 1}$$

the objects are indexed by $1, \ldots, |\mathcal{D}|$ (compare with Section 4.1), we can easily assign such identifiers in $\mathcal{O}(|\mathcal{D}|)$ time and space. Again, it is straightforward to parallelize Algorithm 4 by partitioning $\mathcal{S}$.

4.4 Clustering

Our proposed Algorithm 5 for clustering a data set $\mathcal{D}$ when only given a collection $\mathcal{S}$ of statements of the kind $(\star)$ as input consists of estimating the k-RNG on $\mathcal{D}$ and applying spectral clustering to the estimate. Note that some versions of spectral clustering require the underlying similarity graph not to contain isolated vertices. A true k-RNG never contains isolated vertices since a k-RNG is always connected (compare with Section 5.3), but if k is chosen too small, an estimated k-RNG might contain isolated vertices (compare with Section 3.2.1).

The first step of Algorithm 5 can be implemented with $\mathcal{O}(|\mathcal{D}|^2 + |\mathcal{S}|)$ time and $\mathcal{O}(|\mathcal{D}|^2)$ space in addition to storing $\mathcal{S}$. It can be parallelized in the same way as the corresponding parts of the previous algorithms. However, here we achieve almost ideal speedup only in case $|\mathcal{S}| \gg |\mathcal{D}|^2$. The second step can be implemented with $\mathcal{O}(|\mathcal{D}|^2)$ time and $\mathcal{O}(|\mathcal{D}|^2)$ space. The complexity of Step 3 is the one of spectral clustering after the construction of a similarity graph. Its costs are dominated by the complexity of eigenvector computations and are

Algorithm 5 Clustering

Input: a collection $\mathcal{S}$ of statements of the kind $(\star)$ for some data set $\mathcal{D} = \{O_1, \ldots, O_n\}$; an integer parameter k; number l of clusters to construct; a parameter $\sigma > 0$ in case of weighted version

Output: a hard clustering $C_1, \ldots, C_l \subseteq \mathcal{D}$ with $C_1 \,\dot\cup\, C_2 \,\dot\cup\, \ldots \,\dot\cup\, C_l = \mathcal{D}$

1: for every pair (O_i, O_j) of objects in $\mathcal{D}$ compute

$$\begin{aligned} N(O_i, O_j) &:= \text{number of statements comprising both } O_i \text{ and } O_j \\ &\qquad \text{and another object as most central object} \\ D(O_i, O_j) &:= \text{number of statements comprising both } O_i \text{ and } O_j \\ V(O_i, O_j) &:= \frac{N(O_i, O_j)}{D(O_i, O_j)} \end{aligned}$$

▷ if $D(O_i, O_j) = 0$, set $V(O_i, O_j) = \infty$ (in particular, $V(O_i, O_i) = \infty$ for $i = 1, \ldots, n$)

2: let $W = (w_{ij})_{i,j=1,\ldots,n}$ be a (n, n)-matrix and either set

$$W_{ij} = \begin{cases} 1 & \text{if } V(O_i, O_j) < k/(|\mathcal{D}| - 2) \\ 0 & \text{else} \end{cases} \qquad \triangleright \text{ unweighted version}$$

or

$$W_{ij} = \begin{cases} e^{-\frac{V(O_i, O_j)^2}{\sigma^2}} & \text{if } V(O_i, O_j) < k/(|\mathcal{D}| - 2) \\ 0 & \text{else} \end{cases} \qquad \triangleright \text{ weighted version}$$

3: apply spectral clustering to W with l as input parameter for the number of clusters

4: **return** clusters $C_1, \ldots, C_l$ according to the clusters produced in Step 3

commonly stated to be in general in $\mathcal{O}(n^3) = \mathcal{O}(|\mathcal{D}|^3)$ regarding time and $\mathcal{O}(n^2) = \mathcal{O}(|\mathcal{D}|^2)$ regarding space for an arbitrary number of clusters l, unless approximations are applied (Yan et al., 2009; Li et al., 2011). In many cases the estimate of the k-RNG constructed by Algorithm 5 might be sparse (compare with Section 5.3), and then the eigenvector computations can be done much more efficiently (Bai et al., 2000). However, in the worst case the overall running time of Algorithm 5 can be up to $\mathcal{O}(|\mathcal{D}|^3 + |\mathcal{S}|)$. The overall space requirements are $\mathcal{O}(|\mathcal{D}|^2)$ in addition to storing $\mathcal{S}$.

5. Related Work and Further Background

In this section we present related work and further background on ordinal data analysis, statistical depth functions, and the k-relative neighborhood graph. In a first reading, the reader may skip this part and go to the experimental Section 6 immediately.

5.1 Machine Learning in a Setting of Ordinal Distance Information

We have mentioned in Section 1 that ordinal data can be distinguished with respect to the kind of ordinal relationships that it consists of and that ordinal embedding is a general approach to machine learning in a setting of ordinal distance information. Here we discuss these two topics in more detail.

5.1.1 Different Types of Ordinal Data

The most general form of ordinal distance information consists of binary answers to some dissimilarity comparisons

$$d(A,B) \overset{?}{<} d(C,D), \tag{17}$$

where A, B, C, D could be any objects of some data set. In the machine learning literature, this very general type of ordinal data has been studied in Agarwal et al. (2007), Kleindessner and von Luxburg (2014), Terada and von Luxburg (2014), and Arias-Castro (2015).
The type most often studied in the literature is the one of similarity triplets (Jamieson and Nowak, 2011; Tamuz et al., 2011; van der Maaten and Weinberger, 2012; Wilber et al., 2014; Amid and Ukkonen, 2015; Heim et al., 2015; Amid et al., 2016; Jain et al., 2016; Haghiri et al., 2017). Similarity triplets are answers to dissimilarity comparisons of the restricted form

$$d(A,B) \overset{?}{<} d(A,C). \tag{18}$$

Compared to (17), A equals D and serves as an anchor point.
Another well-known type of ordinal data is the directed, but unweighted k-nearest neighbor graph on a data set (Shaw and Jebara, 2009; von Luxburg and Alamgir, 2013; Terada and von Luxburg, 2014; Hashimoto et al., 2015; Kleindessner and von Luxburg, 2015). This graph provides the ordinal dissimilarity relationships

$$d(V,N) < d(V,O)$$

for objects V, N, and O such that N is adjacent to V in the graph, but O is not.

Ordinal distance information in the form ($\star$), which we consider in this work, is similar to statements of the form (compare with Section 1)

$$\textit{Object } A \textit{ is the outlier within the triple of objects } (A,B,C). \tag{$\boxplus$}$$

This type of ordinal data has been studied by Heikinheimo and Ukkonen (2013) and also by Ukkonen et al. (2015). Heikinheimo and Ukkonen (2013) proposed an algorithm for estimating a medoid of a data set based on statements of the kind ($\boxplus$). Their approach is closely related to ours (compare with Algorithm 1): For every fixed data point, they estimate the probability that the data point is the outlier within a triple of three data points containing the fixed data point and two data points chosen uniformly at random from the remaining ones. Then they take the data point with minimal estimated probability as an

estimate of a medoid. However, the conceptual problem with their approach is that the function that it is based on,

$$F(x;P) = 1 - \mathit{Probability}(x \text{ is the outlier within the triple of points } (x,X,Y)), \tag{19}$$

is *not* a valid statistical depth function. It does not satisfy one of the most crucial properties of statistical depth functions, namely maximality at the center for symmetric distributions (see Section 5.2). As a consequence, their approach always fails to return a true medoid for certain data sets, even though given access to the correct statements of the kind ($\boxplus$) for all triples of data points. As we will see in the experiments in Section 6.1.1, Algorithm 1 consistently achieves better results in recovering a true medoid of a data set compared to the method by Heikinheimo and Ukkonen when both methods are given the same number of statements, either of the kind ($\star$) or of the kind ($\boxplus$), as input.
As Heikinheimo and Ukkonen remark, one can adapt their method to the problem of outlier identification by considering data points with high estimated probabilities as outlier candidates—in the same way as Algorithm 2 is related to Algorithm 1. In the experiments in Section 6.1.2 we will compare Algorithm 2 to such an approach.

Dealing with ordinal distance information comes with a critical drawback compared to a standard setting of cardinal distance information. While for a data set comprising n objects there are in total "only" $\Theta(n^2)$ distances between objects, there are $\Theta(n^4)$ different distance comparisons of the form (17). If one only allows for comparisons of the form (18), that is one considers similarity triplets, there are still $\Theta(n^3)$ different comparisons. This is also the order of magnitude for the number of all statements of the kind ($\star$) or ($\boxplus$). Unless n is rather small, in practice it is prohibitive to collect all statements or answers to all different distance comparisons. The hope is that much fewer statements or answers already contain the bulk of usable information due to high redundancy in the ordinal data. This gives rise to distinguishing between a batch setting and an active setting in the study of algorithms for ordinal distance information: while in a batch setting we are given the ordinal data a priori, in an active setting we are allowed to query ordinal relationships, trying to do it in such a way as to exploit redundancy (Jamieson and Nowak, 2011; Tamuz et al., 2011). Our Algorithms 1 to 5 are designed for the general batch setting. We leave it for future work to devise algorithms for the considered problems in an active setting (see Section 7).

5.1.2 Ordinal Embedding

One important and general approach to machine learning in a setting of ordinal distance information is to construct an ordinal embedding of the data set, that is to map data points to points in a Euclidean space $\mathbb{R}^m$ such that the embedding (with respect to the Euclidean interpoint distances) preserves the given ordinal data as well as possible. After doing so, one can simply apply any algorithm designed for vector-valued data to the embedding for solving the task at hand. This approach is justified by theoretical results showing that for a sufficiently large number of given ordinal relationships and data sets that can be perfectly embedded (this means that all available ordinal relationships are preserved) the embedding is uniquely determined up to similarity transformations as the size of the data set goes to

infinity (Kleindessner and von Luxburg, 2014; Arias-Castro, 2015).

The problem of ordinal embedding dates back to the development of ordinal multidimensional scaling in the 1960s (also known as non-metric multidimensional scaling; Shepard, 1962a,b, and Kruskal, 1964a,b, also see the monograph Borg and Groenen, 2005). More recently, it has been studied in the machine learning community resulting in a number of algorithms (Agarwal et al., 2007; Shaw and Jebara, 2009; Tamuz et al., 2011; van der Maaten and Weinberger, 2012; Terada and von Luxburg, 2014; Amid and Ukkonen, 2015; Heim et al., 2015; Amid et al., 2016; Jain et al., 2016). For none of these algorithms theoretical bounds for their complexity are available in the literature, but it is widely known that they are utterly slow and not appropriate when dealing with large data sets and/or many ordinal relationships (this is confirmed by our experiments in Section 6.1.1). Furthermore, these algorithms either solve a non-convex optimization problem or a relaxed version of such one, in both cases involving the risk of finding only a suboptimal solution. Often, their outcome depends on a random initialization of the ordinal embedding. Moreover, the choice of the dimension of the space of the embedding can be crucial and highly influences the running time of the algorithms, as does the amount of noise in the available ordinal data. All these are strong arguments for aiming to solve machine learning problems in a setting of ordinal distance information directly, that is without constructing an ordinal embedding as an intermediate step, and thus for our proposed Algorithms 1 to 5.

5.2 Statistical Depth Functions and Lens Depth Function

Statistical depth functions (see, e.g., Serfling, 2006, Cascos, 2009, Mosler, 2013, or the introduction of the dissertation of Van Bever, 2013, for basic reviews) have been developed to generalize the concept of the univariate median to multivariate distributions. To this end, a depth function is supposed to measure the centrality of all points $x \in \mathbb{R}^m$ with respect to a probability distribution, in the sense that the depth value at x is high if x resides in the "middle" of the distribution and that it is lower the more distant from the mass of the distribution x is located.
The first statistical depth function has been proposed by Tukey (1974). Given a probability distribution P on $\mathbb{R}^m$, the seminal halfspace depth function HD maps every point $x \in \mathbb{R}^m$ to the smallest probability of a closed halfspace containing x, that is

$$HD(x;P) = \inf_{u \in S^{m-1}} P(\{y \in \mathbb{R}^m : u^T(y-x) \geq 0\}),$$

where $S^{m-1} = \{u \in \mathbb{R}^m : u^T u = 1\}$ denotes the unit sphere in $\mathbb{R}^m$. The intuition behind this definition is simplest to understand in case of an absolutely continuous distribution P: in this case $HD(x;P) \leq 1/2$, $x \in \mathbb{R}^m$, and in order for a point x to be considered central with respect to P it should hold that any hyperplane passing through x splits $\mathbb{R}^m$ into two halfspaces of almost equal probability $1/2$. Hence, points x are considered more central the higher their halfspace depth value $HD(x;P)$ is, and any point maximizing $HD(\,\cdot\,;P)$ is called a Tukey median. Figure 4 shows examples of the halfspace depth function for two absolutely continuous distributions on $\mathbb{R}^2$. Note that a depth function can resemble the density function of the underlying distribution only in case of a unimodal distribution—as

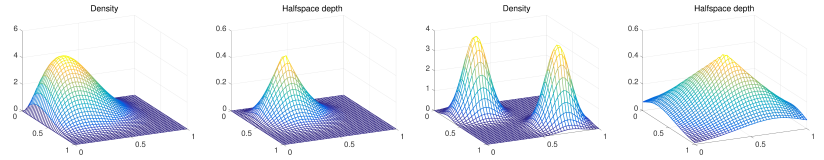

Figure 4: Illustration of the halfspace depth function. Mesh plot of the density and the halfspace depth function of a product of two $Beta(2,4)$-distributions (1st & 2nd plot) and a mixture of two Gaussians (3rd & 4th plot), respectively.

a measure of global centrality depth functions are intended to be unimodal. We will take this up again in Section 6.1.2 and Section 7.
For a univariate and continuous distribution any ordinary median is also a Tukey median. In addition, the halfspace depth function HD satisfies a number of desirable properties:

1. Affine invariance: HD considered as a function in both x and P is invariant under affine transformations.

2. Maximality at the center: for a (halfspace) symmetric distribution the center of symmetry is a Tukey median.

3. Monotonicity with respect to the deepest point: if there is a unique Tukey median μ, $HD(x;P)$ decreases as x moves away along a ray from μ.

4. Vanishing at infinity: $HD(x;P) \to 0$ as $\|x\| \to \infty$.

Even though there is not a unique definition of a statistical depth function, these or closely related properties are typically requested for a function to qualify as depth function. Beside Tukey's halfspace depth, prominent examples of depth functions are simplicial depth (Liu, 1988, 1990), majority depth, projection depth, or Mahalanobis depth (Liu, 1992; Zuo and Serfling, 2000). To the best of our knowledge, the lens depth function (Liu and Modarres, 2011) is the only statistical depth function from the literature that can be evaluated given only ordinal distance information about a data set in an arbitrary semimetric space. Note that the function F defined in (19), which the approach by Heikinheimo and Ukkonen (2013) is based on, is provably not a statistical depth function. It does not satisfy the property of maximality at the center for symmetric distributions. Indeed, as Heikinheimo and Ukkonen observe, in case of a symmetric bimodal distribution in one dimension with the two modes sufficiently far apart, the center of symmetry is in fact a minimizer of F.

We provide some references related to our Algorithms 2 and 3: The idea of considering data points with a small depth value as outliers has been thoroughly studied in the setting of a contamination model in Chen et al. (2009) and Dang and Serfling (2010). In particular, they deal with the question of determining what a *small* depth value is.
The simple max-depth approach to binary classification outlined in Section 3.1 has already been proposed by Liu (1990), using simplicial depth instead of the lens depth function.

It has been theoretically studied in Ghosh and Chaudhuri (2005). Ghosh and Chaudhuri were able to prove that the max-depth approach is consistent, that is it asymptotically achieves Bayes risk, for equally probable and elliptically symmetric classes that only differ in location when using one of several depth functions and dealing with general K-class problems. Working not too well when these assumptions are not satisfied, the max-depth approach has been refined by Li et al. (2012) by allowing for more general classifiers on the DD-plot, thus overcoming some of its original limitations. The DD-plot (depth vs. depth plot; introduced by Liu et al., 1999) is the image of the data under the feature map $x \mapsto (DF(x; Class_1), DF(x; Class_2)) \in \mathbb{R}^2$, where DF denotes the depth function under consideration. Interestingly, Li et al. again only consider the 2-class case and propose a one-vs-one approach for the general case, which is different from our strategy of simply considering

$$x \mapsto (DF(x; Class_1), DF(x; Class_2), \ldots, DF(x; Class_K)) \in \mathbb{R}^K$$

as feature map and subsequently performing classification on $\mathbb{R}^K$.

We conclude this section with some comments about the lens depth function. An early version of the lens depth function has already been mentioned, but not seriously studied, by Lawrence (1996, Section 2.3) and by Bartoszynski et al. (1997). The main reference for the lens depth function is Liu and Modarres (2011), where the lens depth function has been defined and systematically investigated. However, after reading the proofs in detail, we found that there is still an important gap. Liu and Modarres (2011) claim that the lens depth function satisfies the property of maximality at the center for centrally symmetric distributions on $\mathbb{R}^m$ (Theorem 6 in their paper). However, there is an error in their proof. It is *not* true that, conditioning on X_1, the probability of X_2 falling into a region such that $t \in Lens(X_1, X_2)$ holds decreases as $t \in \mathbb{R}^m$ moves away from the center for *all* values of X_1, and hence the monotonicity of the integral is not guaranteed. The same mistake appears in Elmore et al. (2006) and in Section 2.5 of Yang (2014) when showing the property for the spherical depth function and the β-skeleton depth function, respectively. So it has not yet been established that the lens depth function satisfies this essential property of statistical depth functions. We were not able to fix the proof, but we still believe that the statement is correct. At least, unlike for the function F defined in (19), we have not been able to construct any example of a symmetric distribution for which the lens depth function does not attain its maximum at the center.

5.3 k-Relative Neighborhood Graph

The k-RNG belongs to the class of proximity graphs: two vertices are connected if they are in some sense close to each other (see Jaromczyk and Toussaint, 1992, for a basic survey or Bose et al., 2012, for a more recent paper). Beside the k-RNG, Gabriel graphs (Gabriel and Sokal, 1969) and k-NN graphs are prominent examples of proximity graphs.

The 1-RNG, which is simply known as RNG, has been used in a wide range of applications (see Toussaint, 2014, for a review and detailed references). Most interesting for us are its use in classification and clustering as related to our Algorithms 4 and 5, respectively:

Instance-based classification based on the RNG neighborhood, that is inferring a point's label by taking a majority vote of the point's neighbors in the RNG, has been empirically shown to be competitive with the k-NN classifier in Sánchez et al. (1997a) and Toussaint and Berzan (2012). Instance-based classification based on the RNG neighborhood has also been used for prototype selection for the 1-NN classifier (Toussaint et al., 1984; Sánchez et al., 1997b). The RNG has been used for spectral clustering in Correa and Lindstrom (2012) with a strategy of assigning locally adapted edge weights. Our experiments in Section 6.1.4 show that such a strategy is dispensable and that using the k-RNG weighted as in (9), or also unweighted, yields reasonable results as well.

We have mentioned in Section 3.2 and Section 4.4 that a true k-RNG (not an estimated one) is always connected. This follows from the fact that the RNG on a data set $\mathcal{D}$ contains the minimal spanning tree on $\mathcal{D}$ as a subgraph. By minimal spanning tree we mean the minimal spanning tree of the complete graph on $\mathcal{D}$ in which an edge is weighted with the distance between two points. A proof of this property for data points in the Euclidean plane, which readily generalizes to data sets in arbitrary semimetric spaces, can be found in Toussaint (1980). The RNG is guaranteed to be sparse for data sets in the 2-dimensional or 3-dimensional Euclidean space, but it can be dense in higher-dimensional spaces or if d is induced by the 1-norm or the maximum norm (Jaromczyk and Toussaint, 1992). There is a large literature on the question how to efficiently compute a k-RNG on a data set, mainly for data sets in $\mathbb{R}^2$ or $\mathbb{R}^3$ (see the references in Toussaint, 2014), and how to *approximate* the RNG by a graph that is easier to compute (Andrade and de Figueiredo, 2001). We are not aware of any work that deals with *estimating* the k-RNG as we do in this paper.

6. Experiments

We performed several experiments for examining the performance of our proposed Algorithms 1 to 5 and compared them to ordinal embedding approaches. In case of Algorithm 1 and Algorithm 2 we also made a comparison with the methods proposed by Heikinheimo and Ukkonen (2013) explained in Section 5.1.1. Recall that an ordinal embedding approach consists of first constructing an ordinal embedding of a data set $\mathcal{D}$ based on the given ordinal distance information and then solving the problem on the embedding by applying a standard algorithm. For example, in the case of medoid estimation a medoid of an ordinal embedding is computed and the corresponding object is returned as an estimate of a medoid of $\mathcal{D}$. For constructing an ordinal embedding we tried several algorithms: the GNMDS (generalized non-metric multidimensional scaling) algorithm by Agarwal et al. (2007), the SOE (soft ordinal embedding) algorithm by Terada and von Luxburg (2014), and the STE (stochastic triplet embedding) and t-STE (t-distributed stochastic triplet embedding) algorithms by van der Maaten and Weinberger (2012). The GNMDS algorithm and the SOE algorithm can take answers to arbitrary dissimilarity comparisons of the form (17) as input, while the STE and t-STE algorithms are designed only for similarity triplets, that is answers to comparisons (18). The ordinal data that we gave to the embedding algorithms were all the similarity triplets obtained via (2) from a collection of statements of the kind ($\star$) that we provided as input to one of our algorithms. We used the Matlab implementations of GNMDS, STE, and t-STE provided by van der Maaten and Weinberger (2012) and the

R implementation of SOE provided by Terada and von Luxburg (2014). We set all parameters except the dimension m of the space of the embedding to the provided default parameters (for all algorithms the default dimension is two). Note that all algorithms try to iteratively minimize an objective function that measures the amount of violated ordinal relationships, and in doing so their results depend on a random initialization of the ordinal embedding.

We start with presenting experiments on artificial data in Section 6.1. In Section 6.2 we deal with real data consisting of 60 images of cars and ordinal distance information of the kind ($\star$) that we have collected via crowdsourcing in an online survey.

6.1 Artificial Data

In the following, except the plots in Figures 8 and 9, where outliers have to be identified by visual inspection, and one plot in Figure 5, which provides a visualization of available statements per data point, all plots of this section show results averaged over running the experiments for 100 times.

We primarily study the performance of the considered methods with respect to the number of provided input statements, but also with respect to the amount of noise in the provided ordinal data. We consider two different noise models: Noise model I (with parameter $0 \leq errorprob \leq 1$) equals the one described in Section 3.2.1, that is a statement of the kind ($\star$) is incorrect, independently of other statements, with some fixed error probability $errorprob$. In an incorrect statement the two data points that are not most central appear to be most central with probability 1/2 each. In Noise model II (with parameter $noiseparam \geq 0$) we distort the dissimilarity values $d(A, B)$, which then induces a distortion of statements. Concretely, we add Gaussian noise with mean zero and standard deviation $noiseparam \cdot SD$, where SD denotes the standard deviation of all true dissimilarity values $d(A, B)$, $A \neq B \in \mathcal{D}$, independently to each dissimilarity value $d(A, B)$. For choosing input statements we essentially consider two sampling strategies: The first one, referred to as uniform sampling, is to choose input statements uniformly at random without replacement from the set of all statements, that is the set of statements for all triples of data points, which were generated according to the noise model under consideration. When applying this sampling strategy and studying performance as a function of the number of input statements, the rightmost measurement in a plot corresponds to the case that all statements are provided as input. In the experiment presented in Figure 7 the provided statements are chosen uniformly at random with replacement from the set of all statements, but there the set of all statements is so large that in fact this does not make any difference. In these plots the rightmost measurement corresponds to a number of input statements of less than one permil of the number of all statements. In order to illustrate our claim that our algorithms require statements to be sampled only approximately uniformly with respect to a fixed data point (Algorithms 1 to 3), or a fixed pair of data points (Algorithms 4 and 5), we also consider a second sampling strategy, referred to as Sampling II. When sampling according to this strategy, we partition the data set into ten groups. For each group we form a set consisting of all statements, generated according to the noise model under consideration, that comprise at least one data point from the corresponding group. We then sample with replacement by selecting one of the ten sets according to probabilities $i^2 / \sum_{j=1}^{10} j^2$, $i = 1, \ldots, 10$, and choosing a statement from the selected set uniformly at random.
When comparing Algorithm 1 or Algorithm 2 to the corresponding methods by Heikinheimo and Ukkonen (2013) in Sections 6.1.1 and 6.1.2, their methods are given a collection of statements of the kind ($\boxplus$) as input that contains as many statements as the input to our algorithm and is created in a completely analogous way.

6.1.1 Medoid Estimation

We measure performance of a method for medoid estimation by the relative error in the objective D (given in (6)), which is given by

$$\text{relative error} = \frac{D(\text{estimated medoid}) - D(\text{true medoid})}{D(\text{true medoid})}. \tag{20}$$

Figure 5 shows in the first two rows the relative error of Algorithm 1, the method by Heikinheimo and Ukkonen (2013), and the embedding approach, using the various embedding algorithms, as a function of the number of provided input statements and as a function of $errorprob$ (Noise model I) for 100 points from a 2-dimensional Gaussian $N_2(0, I_2)$ and d being the Euclidean metric. Obviously, the embedding approach outperforms Algorithm 1 and the method by Heikinheimo and Ukkonen when dealing only with correct statements, that is $errorprob = 0$, and embedding into the true dimension (1st row, 1st plot). However, it is not superior over Algorithm 1 anymore when $errorprob = 0.3$ and the dimension of the embedding is chosen as five (2nd row, 1st plot). Algorithm 1 consistently outperforms the method by Heikinheimo and Ukkonen. All methods show a similar behavior with respect to $errorprob$ (2nd row, 2nd & 3rd plot). Interestingly, the strongest incline in the error does not occur until the transition from $errorprob = 0.6$ to $errorprob = 0.7$. The bottom row of Figure 5 also shows the relative error of the various methods as a function of the number of provided input statements, but here input statements were sampled according to the strategy Sampling II. Compared to the strategy of sampling statements uniformly at random without replacement from the set of all statements, Algorithm 1 performs slightly worse, but we consider the difference to be negligible. The last plot of the bottom row shows the difference in the two sampling strategies: while in the uniform case, for all data points there is almost the same number of input statements comprising the data point, when sampling according to Sampling II there are data points for which this number is twice as large as for others (the plot is based on a total of 4500 input statements corresponding to the third measurement in the first and second plot of the bottom row).
The biggest advantage of Algorithm 1 (in fact of *all* our proposed algorithms) compared to an ordinal embedding approach becomes obvious from the plots in the third and fourth row of Figure 5, which show the running times of the experiments shown in the plots in the two top rows: For a fixed size $|\mathcal{D}|$ of the data set, like the running times of our proposed algorithms and the method by Heikinheimo and Ukkonen, the running time of the embedding approach with any of the considered embedding algorithms also grows linearly with the number $|\mathcal{S}|$ of input statements (indicated by the orange curves). However, in practice Algorithm 1 and the method by Heikinheimo and Ukkonen are vastly superior in

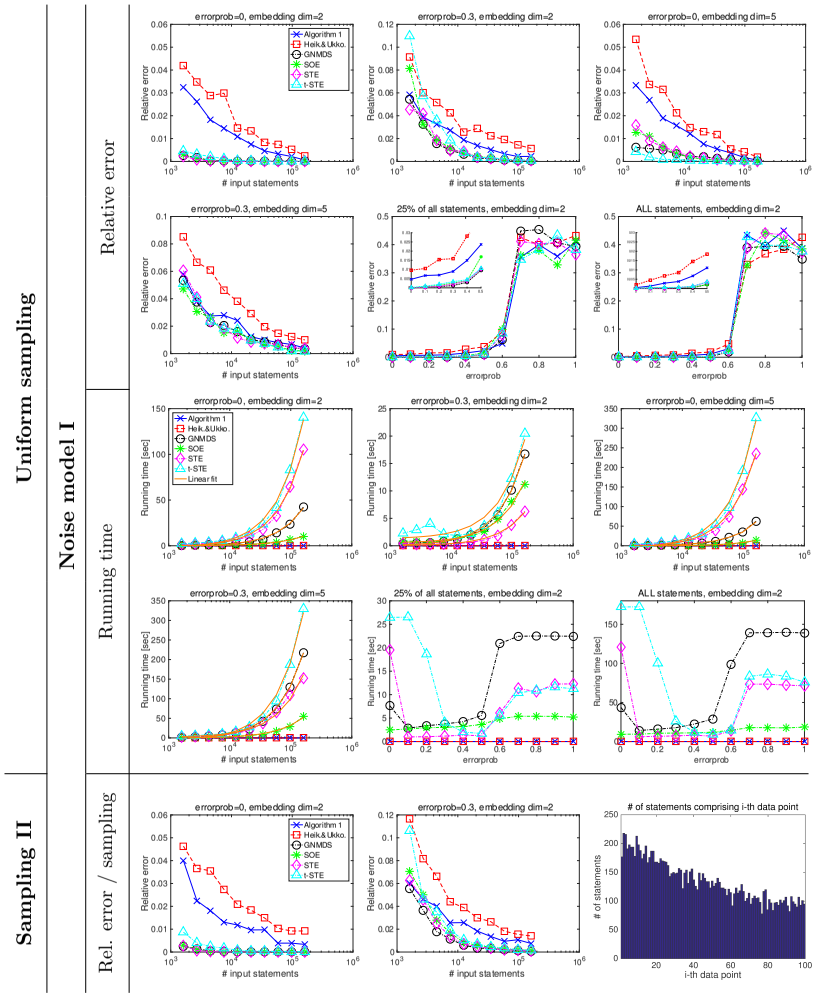

Figure 5: Medoid estimation — 100 points from a 2-dim Gaussian $N_2(0, I_2)$ with Euclidean metric. Relative error (20) and running time as a function of the number of provided statements of the kind ($\star$) or of the kind ($\boxplus$) and as a function of *errorprob* for Algorithm 1, for the method by Heikinheimo and Ukkonen, and for the embedding approach using the various embedding methods.

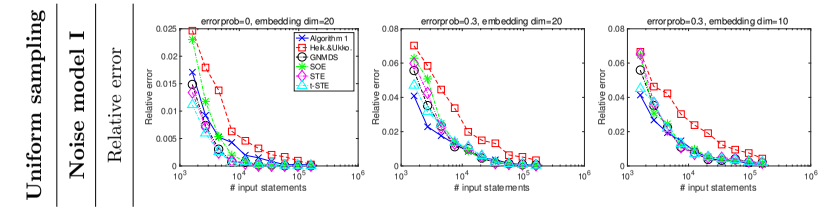

Figure 6: Medoid estimation — 100 points from a 20-dim Gaussian $N_{20}(0, I_{20})$ with Euclidean metric. Relative error (20) as a function of the number of provided statements of the kind ($\star$) or of the kind ($\boxplus$) for Algorithm 1, for the method by Heikinheimo and Ukkonen, and for the embedding approach using the various embedding methods.

terms of running time compared to the embedding approach, even without making use of their potential of simple and highly efficient parallelization. For example, when all statements are provided as input, *errorprob* $= 0$, and the embedding dimension is chosen as two, the running time of the embedding approach is between 10 seconds (when using the SOE algorithm) and 141 seconds (when using the t-STE algorithm), while Algorithm 1 or the method by Heikinheimo and Ukkonen only run for 0.01 seconds (3rd row, 1st plot). Note that the running times of Algorithm 1 and the method by Heikinheimo and Ukkonen are independent of *errorprob* and, of course, of the choice of a dimension of the space of the embedding. The running times of the embedding algorithms tend to increase with the embedding dimension (e.g., differences between the first and the third plot in the third row). The running time of the SOE algorithm also increases with *errorprob* (4th row, 2nd & 3rd plot). For the GNMDS algorithm this holds for *errorprob* ≥ 0.1. The running times of the STE and t-STE algorithms vary non-monotonically with *errorprob*. All experiments shown in Figure 5 were performed in MATLAB R2015a on a MacBook Pro with 2.6 GHz Intel Core i7 and 8 GB 1600 MHz DDR3. Within MATLAB we invoked R 3.2.2 for computing the SOE embedding. In order to make a fair comparison we did not use MEX files in the implementation of Algorithm 1 or the method by Heikinheimo and Ukkonen.

Figure 6 shows almost the same experiments as Figure 5, but this time dealing with 100 points from a 20-dimensional Gaussian $N_{20}(0, I_{20})$. The distance function d again equals the Euclidean metric. In this high-dimensional case the embedding approach cannot be considered superior anymore. In fact, when *errorprob* $= 0.3$ and the number of input statements is small, Algorithm 1 performs best (2nd plot). We omit to show plots of the relative error as a function of *errorprob* since they look very similar to the ones in Figure 5. Time measurements show that the differences in running times between the embedding approach and Algorithm 1 or the method by Heikinheimo and Ukkonen are even more severe compared to Figure 5, as to be expected because of the high embedding dimensions (plots omitted).

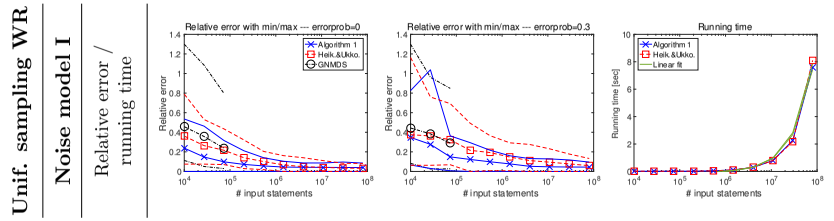

Figure 7: Medoid estimation — 8638 vertices in a collaboration network with shortest-path-distance. 1st & 2nd plot: Relative error (20) as a function of the number of provided statements of the kind ($\star$) or of the kind ($\boxplus$) for Algorithm 1, for the method by Heikinheimo and Ukkonen, and for the embedding approach using GNMDS (for the first three measurements). Average over 100 runs together with the minimum and the maximum of the 100 runs. 3rd plot: The corresponding running times with fitted linear functions.

Finally, we applied Algorithm 1 and the method by Heikinheimo and Ukkonen to a large network with the dissimilarity function d equaling the shortest-path-distance. In this context, a medoid is usually referred to as a "most central point with respect to the closeness centrality measure" (Freeman, 1978). Our data set consists of 8638 vertices, which form the largest connected component of a collaboration network with 9877 vertices that represent authors of papers submitted to arXiv in the High Energy Physics - Theory category and with two vertices being connected if the authors co-authored at least one paper (Leskovec et al., 2007). Comparing against the embedding methods as in the previous experiments on this large data set would have taken months (considering various numbers of input statements and averaging over 100 runs), so we only compared against GNMDS (embedding dimension chosen to equal two) for a small number of input statements. The first and the second plot of Figure 7 show the relative error of Algorithm 1 and the method by Heikinheimo and Ukkonen as a function of the number of provided statements of the kind ($\star$) or of the kind ($\boxplus$). The number of provided statements varies between 10^4 and $8 \cdot 10^7$. The latter is less than one permil of the number of all statements, which is $\binom{8638}{3} \approx 10^{11}$. This number is so large that the set of all statements does by no means fit into the main memory of a single machine. The plots also show the relative error of the embedding approach using the GNMDS algorithm for 10000, 27144, and 73680 input statements. As in the previous experiments, the shown error is the average over 100 runs of the experiment, but here the data set is fixed and the only sort of randomness comes from the input statements (and the random initialization of the ordinal embedding in case of GNMDS). In addition to the average error the plots show the minimum and maximum error of the 100 runs for illustrating the variance in the methods. In both the cases of $errorprob = 0$ (1st plot) and $errorprob = 0.3$ (2nd plot), when the number of input statements is small, Algorithm 1 outperforms the method by Heikinheimo and Ukkonen. Both methods outperform the embedding approach, which might have difficulties due to the data set being non-Euclidean or might struggle with a too small embedding dimension. For comparison, a strategy of

choosing a data point uniformly at random as medoid estimate incurs a relative error of 0.47 in expectation. Even when given only 10000 input statements, when $errorprob = 0$, the error of Algorithm 1 is only about one half of this. The variance seems to be similar for both Algorithm 1 and the method by Heikinheimo and Ukkonen and seems to be significantly larger for the embedding approach. As expected, it decreases as the number of input statements increases. In case of $errorprob = 0$, we also applied GNMDS to the data set providing 10857670 statements as input (corresponding to the eighth measurement in the plots): averaging over 10 runs we obtained an average relative error of 0.28 (which is more than six times larger than the error of Algorithm 1 or the method by Heikinheimo and Ukkonen), where computation took 2.84 hours on average. The third plot of Figure 7 shows the running times of Algorithm 1 and the method by Heikinheimo and Ukkonen as a function of the number of input statements. Both methods have the same running time, which is linear in the number of input statements. The plot does not show the running times of GNMDS at the first three measurements. These were 110, 860, and 879 seconds in case of $errorprob = 0$ and 92, 848, and 898 seconds in case of $errorprob = 0.3$.

6.1.2 Outlier Identification

We started with testing Algorithm 2 and the corresponding method by Heikinheimo and Ukkonen (2013) by applying them to two visualizable data sets containing some obvious outliers. Both of the Figures 8 and 9 show a scatterplot of the points of a data set $\mathcal{D}$ in the Euclidean plane with the "regular" points in black and the outliers in color. For assessing the performance of the two considered methods we plotted the sorted values of $LD(O)$, $O \in \mathcal{D}$, as needed for Algorithm 2 as well as the sorted values of estimated probabilities of being an outlier within a triple of objects as needed for the method by Heikinheimo and Ukkonen (compare with Section 5.1.1). Both methods were provided with the same number of statements as input, either of the kind ($\star$) or of the kind ($\boxplus$). Both Figure 8 and Figure 9 provide several such plots, varying with this number of input statements as well as with the error probability $errorprob$ (we generated statements according to Noise model I). In all the plots, values belonging to outliers have the same color as the corresponding outlier in the scatterplot. The methods are successful if these colored values appear at the very end of the sorted values, either at the lower end for Algorithm 2 or at the upper end for the method by Heikinheimo and Ukkonen, and there is a (preferably large) gap between the colored values and the remaining ones since then it is easy to correctly identify the outliers. There are inlay plots showing the bottom or top ten values for more precise inspection. Note that there is no averaging involved in creating these plots and they may change with every run of the experiment since they depend on the random data set, the random choice of statements that are provided as input, and the random occurrence of incorrect statements.

In Figure 8 the data set consists of 100 points that were drawn from a 2-dimensional Gaussian $N_2(0, I_2)$ and three outliers added by hand. The dissimilarity function d equals the Euclidean metric. We can see that for both methods the values corresponding to the outliers appear at the right place when given all correct statements as input (top row). However, when given only 25 percent of all statements and $errorprob = 0.3$, for Algorithm 2 the estimated lens depth value of the pink outlier ranks only sixth smallest, and thus this outlier

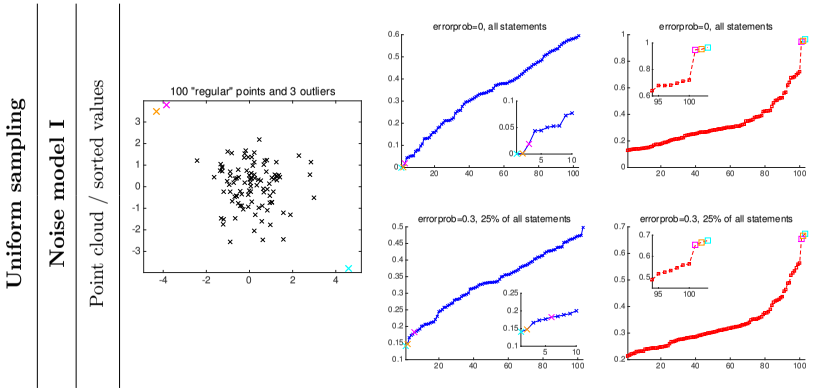

Figure 8: Outlier identification — 100 points from a 2-dim Gaussian $N_2(0, I_2)$ and three outliers added by hand with Euclidean metric. Data set and sorted values of $LD(O)$ as needed for Algorithm 2 (left; in blue) and of estimated probabilities as needed for the method by Heikinheimo and Ukkonen (right; in red).

might not be identified (bottom left). Furthermore, even in the previous situation it might not be possible to correctly infer the number of outliers based on the plot corresponding to Algorithm 2 due to the lack of a clear gap, whereas in both situations this can easily be done for the method by Heikinheimo and Ukkonen. We made similar observations for smaller numbers of provided input statements and other values of *errorprob* too (plots omitted).

In Figure 9 the data set consists of 200 points from a Two-moons data set and four outliers added by hand. Again, d equals the Euclidean metric. Both methods correctly identify the three outliers located quite far apart from the bulk of the data points, and the gap between their values and values belonging to the "regular" data points is large enough to be easily spotted. However, both methods fail to identify the outlier located in-between the two moons (yellow point). The estimated lens depth values or probabilities indicate that this outlier might be the unique medoid—which is indeed the case. For Algorithm 2 this has to be expected and stresses the inherent property of the lens depth function, and statistical depth functions in general, of globally measuring centrality. In doing so, it ignores multimodal aspects of the data (compare with Section 5.2 and Section 7) and cannot be used for identifying outliers that are globally seen at the heart of a data set. At least for the data set of Figure 9 this also holds for the function F defined in (19), which the method by Heikinheimo and Ukkonen is based on. However, for the function F this behavior is not systematic as the example of a symmetric bimodal distribution in one dimension as mentioned in Section 5.2 shows.

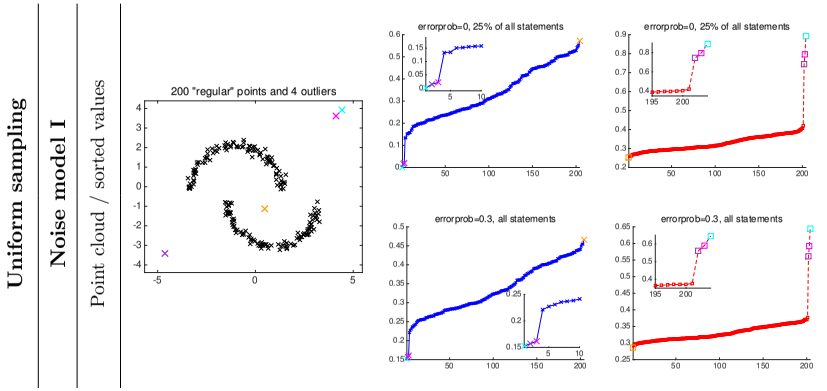

Figure 9: Outlier identification — 200 points from a Two-moons data set and four outliers added by hand with Euclidean metric. Data set and sorted values of $LD(O)$ as needed for Algorithm 2 (left; in blue) and of estimated probabilities as needed for the method by Heikinheimo and Ukkonen (right; in red).

In the last experiment of this section we study Algorithm 2 and the method by Heikinheimo and Ukkonen by using them for outlier identification in a data set consisting of USPS digits. The data set consists of 500 digits chosen uniformly at random from digits 6 and ten outlier digits chosen uniformly at random from the remaining digits. The dissimilarity function d equals the Euclidean metric. We assess the performance of Algorithm 2 and the method by Heikinheimo and Ukkonen by counting how many of the ten outliers are among the ten digits ranked lowest or highest according to the values of $LD(O)$ and estimated probabilities, respectively. Figure 10 shows these numbers as a function of the number of provided input statements in case of uniform sampling and statements generated according to Noise model I (1st row) and in case of Sampling II and statements generated according to Noise model II (2nd row), for $errorprob = 0$ / $noiseparam = 1$ (1st plot), $errorprob = 0.1$ / $noiseparam = 1.5$ (2nd plot), and $errorprob = 0.3$ / $noiseparam = 2$ (3rd plot). We can see that the method by Heikinheimo and Ukkonen performs slightly better in the setting of the first row and that the performance of both methods is essentially the same in the setting of the second row. Most often, the methods can identify three to five outliers, which we consider to be not bad, but not good either. Choosing another digit than 6 for defining the bulk of "regular" points leads to similar results (plots omitted).

To sum up the insights from the experiments shown in Figures 8 to 10, we may conclude that both methods are capable of identifying outliers located lonely and far apart from the bulk of a data set, but should be used with some care in general. The method by Heikinheimo and Ukkonen seems to be superior—which is not very surprising since statements of the

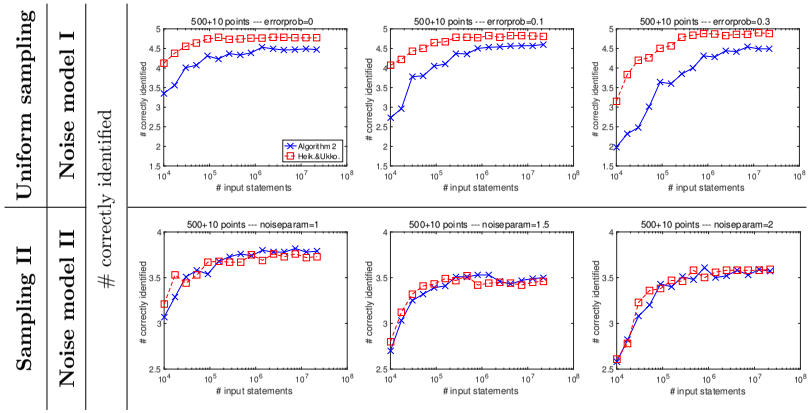

Figure 10: Outlier identification — 500 points from the subset of USPS digits 6 and ten outlier digits with Euclidean metric. Number of correctly ranked outliers as a function of the number of provided statements of the kind ($\star$) or of the kind ($\boxplus$) for Algorithm 2 and for the method by Heikinheimo and Ukkonen.

kind ($\boxplus$) readily inform about outliers within triples of data points. It produces larger and thus easier to spot gaps than Algorithm 2, but is less understood theoretically.

6.1.3 Classification

We compared Algorithms 3 and 4 to an ordinal embedding approach that consists of embedding a data set $\mathcal{D}$ comprising a set $\mathcal{L}$ of labeled data points and a set $\mathcal{U}$ of unlabeled data points into $\mathbb{R}^m$ using the given ordinal distance information and applying a classification algorithm to the embedding. Note that this approach is semi-supervised since it makes use of answers to dissimilarity comparisons involving data points of $\mathcal{U}$ for constructing the embedding of $\mathcal{D}$. Algorithm 3, in contrast, only uses ordinal distance information involving data points of $\mathcal{L}$ for approximately evaluating the feature map (7) on $\mathcal{L}$ and hence is a supervised technique as long as the classifier on top is. Algorithm 4 is a supervised instance-based learning method. Algorithm 3 as well as the embedding approach require an ordinary classifier on top, that is a classifier appropriate for real-valued feature vectors. For simplicity, in the experiments presented here we either used the k-NN classifier or the SVM (support vector machine) algorithm with the standard linear kernel (e.g., Cristianini and Shawe-Taylor, 2000). Both these classification algorithms require to set parameters, which we did by means of 10-fold cross-validation: the parameter k for the k-NN classifier was chosen from the range $1, 3, 5, 7, 11, 15, 23$ and the regularization parameter for the SVM algorithm was chosen from $0.01, 0.05, 0.1, 0.5, 1, 5, 10, 50, 100, 500, 1000$. The ordinal embedding algorithms produce embeddings on an arbitrary scale. Before applying the classification algorithms, we rescaled an ordinal embedding to have diameter 2. The feature embedding

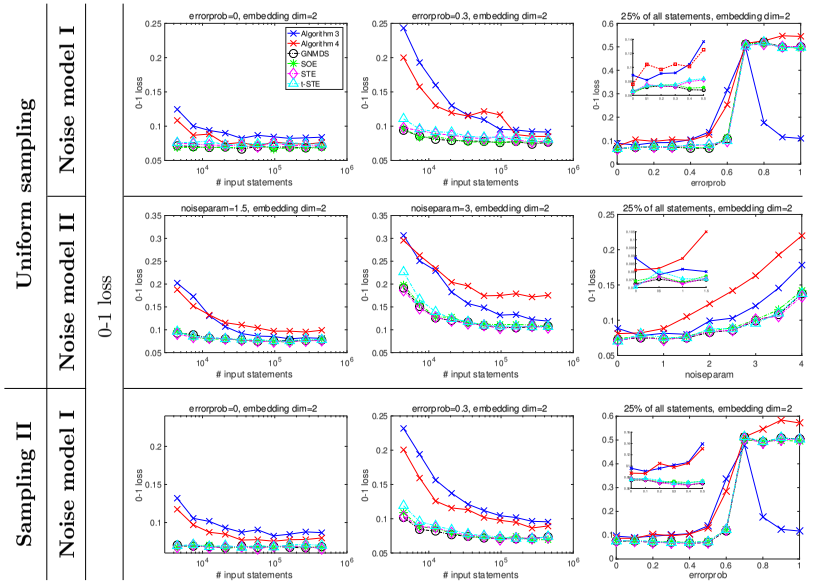

Figure 11: Classification — 100 labeled and 40 unlabeled points from a mixture of two equally probable 2-dim Gaussians $N_2(0, I_2)$ and $N_2((3, 0)^T, I_2)$ with Euclidean metric. SVM algorithm with linear kernel on top of Algorithm 3 as well as on the embedding approach. 0-1 loss (21) as a function of the number of provided statements of the kind ($\star$) and as a function of *errorprob* / *noiseparam* for Algorithm 3, for Algorithm 4, and for the embedding approach using the various embedding methods.

constructed by Algorithm 3 always resides in $[0, 1]^K$ for a K-class classification problem and no rescaling was done here. Algorithm 4 requires to set the parameter k describing which k-RNG it is based on, but this is more subtle: As we have seen in Section 3.2.1, when input statements are incorrect with some error probability $errorprob > 0$ (Noise model I), then our estimation strategy does not estimate the k-RNG anymore, but rather a k'-RNG with $k' = k'(k, errorprob, |\mathcal{D}|)$ depending on the size of the data set as given in (15). We thus have to choose the range of possible values for the parameter k in Algorithm 4 depending on $|\mathcal{D}|$. Furthermore, we cannot use 10-fold cross-validation for choosing the best value within this range since, roughly speaking, this would lead to choosing the best parameter for a data set of size of only 90 percent of $|\mathcal{D}|$. Instead, we used a non-exhaustive variant of leave-one-out cross-validation: we randomly selected a single training point as validation set and repeated this procedure for 20 times, and finally chose the parameter that showed the best performance on average.

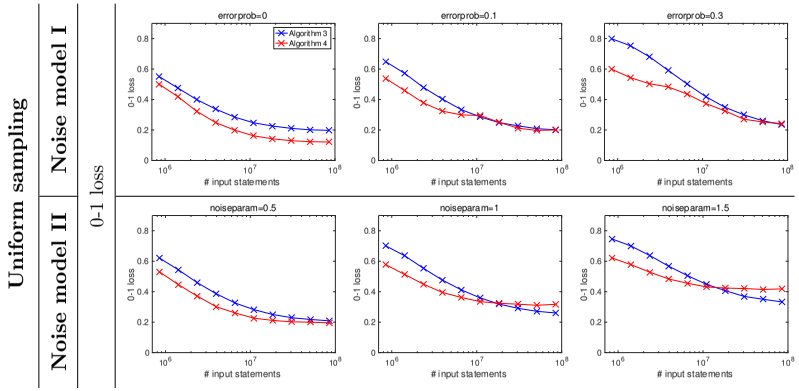

Figure 12: Classification — 300 labeled and 500 unlabeled USPS digits with Euclidean metric. k-NN classifier on top of Algorithm 3. 0-1 loss (21) as a function of the number of provided statements of the kind ($\star$) for Algorithm 3 and for Algorithm 4.

We measure performance of Algorithms 3 and 4 and the embedding approach by considering their incurred 0-1 loss given by

$$\text{0-1 loss} = \frac{1}{|\mathcal{U}|} \cdot \sum_{O \in \mathcal{U}} \mathbb{1}\{\text{predicted label}(O) \neq \text{true label}(O)\}. \tag{21}$$

Figure 11 shows the results for a data set consisting of 100 labeled and 40 unlabeled points from a mixture of two equally probable 2-dimensional Gaussians $N_2(0, I_2)$ and $N_2((3,0)^T, I_2)$ and d being the Euclidean metric. True class labels of the points correspond to which Gaussian they come from. On top of Algorithm 3 as well as on the embedding methods we used the SVM algorithm with the linear kernel. The parameter k for Algorithm 4 was chosen from the range $1, 2, 3, 5, 7, 15, 25, 45, 70$. The dimension of the space of the ordinal embedding was chosen to equal the true dimension two, but we observed similar results when we chose it as five instead (plots omitted). The embedding approach outperforms both Algorithm 3 and Algorithm 4, but their results appear to be acceptable too. Interestingly, other than for Algorithm 4 and the embedding approach, the 0-1 loss incurred by Algorithm 3 studied as a function of *errorprob* (1st & 3rd row, 3rd plot) increases only up to *errorprob* $= 0.7$ and then drops again, finally yielding almost the same result for *errorprob* $= 1$ as for *errorprob* $= 0$. In hindsight, this is not surprising: If *errorprob* $= 1$, and thus every statement is incorrect, and the two possibilities of an incorrect statement are equally likely, as it is the case under Noise model I, then Algorithm 3 approximately evaluates the feature map

$$x \mapsto \left(\frac{1}{2} - \frac{1}{2}LD(x; Class_1), \frac{1}{2} - \frac{1}{2}LD(x; Class_2), \ldots, \frac{1}{2} - \frac{1}{2}LD(x; Class_K)\right) \in \mathbb{R}^K.$$

This feature map coincides with the original one given in (7) up to a similarity transformation and hence gives rise to the same classification results.

In Figure 12 we study the performance of Algorithms 3 and 4 when used for classifying USPS digits. We deal with 800 digits chosen uniformly at random from the set of all USPS digits and randomly split into 300 labeled and 500 unlabeled data points. The dissimilarity function d equals the Euclidean metric. We chose input statements uniformly at random without replacement from the set of all statements, which we generated according to Noise model I (1st row) or Noise model II (2nd row). On top of Algorithm 3 we used the k-NN classifier. The parameter k for Algorithm 4 was chosen from $1, 2, 3, 5, 7, 15, 25, 45, 70, 100, 150, 230, 350$. For small values of *errorprob* or *noiseparam* we consider the results of our proposed algorithms to be satisfactory and useful. Note that in this 10-class classification problem a strategy of random guessing would yield a 0-1 loss of about 0.9. Not surprisingly, we obtained slightly better results when the ratio between labeled and unlabeled data points was chosen as 400/400 instead of 300/500 and slightly worse results when it was chosen as 200/600 (plots omitted).

6.1.4 Clustering

We compared Algorithm 5, both in its weighted and in its unweighted version, to an embedding approach in which we applied spectral clustering to a symmetric k-NN graph on an ordinal embedding of a data set $\mathcal{D}$. We put Gaussian weights $\exp(-\|u_i - u_j\|^2/\sigma^2)$, where u_i and u_j are connected points of the embedding and $\sigma > 0$ is a scaling parameter, on the edges of this k-NN graph. Again, we rescaled an ordinal embedding to have diameter 2. Both in Algorithm 5 and in the ordinal embedding approach we used the normalized version of spectral clustering as stated in von Luxburg (2007) and invented by Shi and Malik (2000). For assessing the quality of a clustering we measure its purity with respect to a ground truth partitioning of the data set $\mathcal{D}$ (e.g., Manning et al., 2008, Chapter 16): if $\mathcal{D}$ consists of L different classes $C_1, \ldots, C_L$ that we would like to recover and the clustering $\mathcal{C}$ comprises K different clusters $U_1, \ldots, U_K$, then the purity of $\mathcal{C}$ is given by

$$\text{purity}(\mathcal{C}) = \text{purity}(\mathcal{C}; \mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{k=1}^{K} \max_{l=1,..,L} |U_k \cap C_l|. \tag{22}$$

We always have $K/|\mathcal{D}| \leq \text{purity}(\mathcal{C}) \leq 1$, and a high value indicates a good clustering. In the experiments presented in this section, we always provided Algorithm 5 and the embedding approach with the correct number L of clusters as input.

Figure 13 shows the purity of the clusterings produced by Algorithm 5 and the embedding approach when applied to a data set consisting of 100 points from a uniform distribution on two equally sized moons in $\mathbb{R}^2$. The two moons correspond to a ground truth partitioning into two classes. The dissimilarity function d equals the Euclidean metric. The curves shown here are the results obtained by a particular choice of input parameters k and σ: within a reasonably large range of parameter configurations this choice of parameters yielded the best performance on average with respect to the number of input statements. We study the sensitivity of Algorithm 5 with respect to the parameters in another experiment (shown

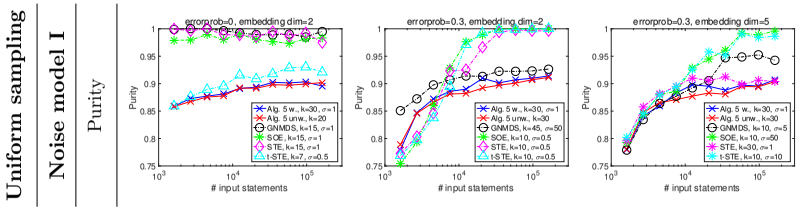

Figure 13: Clustering — 100 points from a uniform distribution on two equally sized moons in $\mathbb{R}^2$ with Euclidean metric. Purity (22) as a function of the number of provided statements of the kind ($\star$) for Algorithm 5 in its weighted and unweighted version and for the embedding approach using the various embedding methods.

in Figure 14). The embedding approach clearly outperforms Algorithm 5 if *errorprob* $= 0$ (1st plot), where three of the considered embedding algorithms achieve significantly higher purity values over the whole range of the number of input statements. However, given the numerous advantages common to all our proposed algorithms compared to an ordinal embedding approach, we consider the performance of Algorithm 5 to be acceptable. For comparison, a random clustering in which data points are randomly assigned to one of two clusters independently of each other with probability one half has an average purity of 0.54. If *errorprob* $= 0.3$, the embedding approach is superior to Algorithm 5 only if the number of input statements is large. Interestingly, there is almost no difference in the performance of the weighted and the unweighted version of Algorithm 5.

The experiment shown in Figure 14 deals with a data set $\mathcal{D}$ consisting of 600 digits chosen uniformly at random from the set of all USPS digits and d being the Euclidean metric. We assume a ground truth partitioning of $\mathcal{D}$ into ten classes according to the digits' values. For various parameter configurations the plots show the purity of the clusterings produced by the weighted (in blue) and unweighted (in red) version of Algorithm 5 as a function of the number of input statements. The plots also show the purity of the clusterings obtained when applying spectral clustering to the true weighted (in light blue) and unweighted (in bronze) k-RNG on $\mathcal{D}$. Note that these two curves only vary with the number of input statements because of random effects in the K-means step of spectral clustering. Although it might look odd at a first glance that the purity achieved by Algorithm 5 is not monotonic with respect to the number of input statements, we can see that the purity is always between 0.67 and 0.7 for a wide range of values of k and σ when *errorprob* $= 0$ (1st row; 2nd row, 1st plot). For comparison, a random clustering in which data points are randomly assigned to one of ten clusters independently of each other with probability one-tenth has an average purity of 0.19. A clustering obtained by applying spectral clustering to a symmetric k-NN graph with Gaussian edge weights $\exp(-d(x_i, x_j)^2/\sigma^2)$ on $\mathcal{D}$ (the true data set—not an ordinal embedding) has an average purity of not higher than 0.75, even for a good choice of k and σ. When *errorprob* $= 0.3$, Algorithm 5 completely fails for small values of k (2nd row, 2nd plot) as has to be expected because of our findings in Section 3.2.1. For k sufficiently large

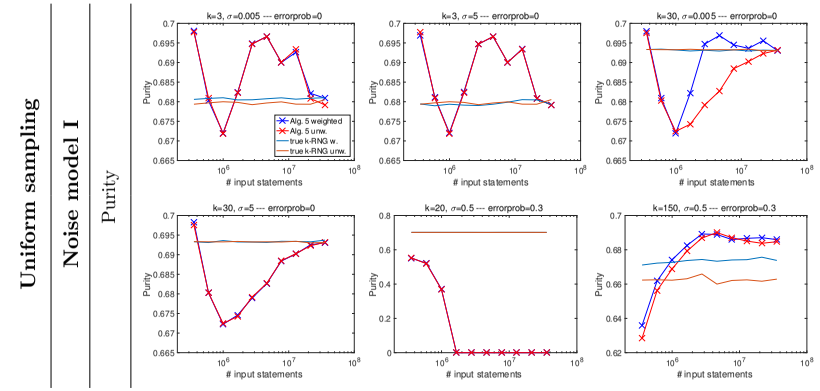

Figure 14: Clustering — 600 USPS digits with Euclidean metric. Purity (22) as a function of the number of provided statements of the kind ($\star$) for Algorithm 5 in its weighted and unweighted version. The light blue curve and the bronze curve show the purity of the clusterings obtained by applying spectral clustering to the true weighted and unweighted k-RNG on the data set.

it finally yields the same purity values as when *errorprob* $= 0$ (2nd row, 3rd plot). In fact, this is true already for $k = 100$ and a wide range of values of σ (plots omitted). Again, both in the case of *errorprob* $= 0$ and in the case of *errorprob* $= 0.3$, there is almost no difference in the performance of the weighted and the unweighted version of Algorithm 5.

6.2 Real Data

We set up an online survey for collecting ordinal distance information of the kind ($\star$) for 60 images of cars, shown in Figure 15. All images were found on Wikimedia Commons (`https://commons.wikimedia.org`) and have been explicitly released into the public domain by their authors. We refer to the set of these images as the car data set. We instructed participants of the survey to determine the most central object within a triple of three shown images according to how they perceive dissimilarity between *cars*. We explicitly stated that they should not judge differences between the *pictures*, like perspective, lighting conditions, or background. Every participant was shown triples of cars in random order (more precisely, triples shown to a participant were drawn uniformly at random without replacement from the set of all possible triples). Also the order of cars within a triple, that is whether a car's image appeared to the left, in the middle, or to the right, was random. One complete round of the survey consisted of 50 shown triples, but we encouraged participants to contribute more than one round, possibly at a later time. There was no possibility of skipping triples, that is even if a participant had no idea which car might be the most central one in a triple, he/she had to make a choice—or quit the current round of the survey. Within the first ten triples every participant was shown a test case triple (shown

Figure 15: Car data set. We collected ordinal distance information of the kind ($\star$) for this data set via an online survey. The framed triple in the first row was used as a test case: T_All and T_All_reduced comprise only statements provided by participants that chose the off-road vehicle as the most central car in this triple. The pictures were found on Wikimedia Commons and have been explicitly released into the public domain by their authors.

within a frame in Figure 15), consisting of an off-road vehicle, a sports car, and a fire truck. We believe the off-road vehicle to be the obvious most central car in this triple and used this test case for checking whether a participant might have got the task of choosing a most central object correctly. The survey was online for about two months and the link to the survey was distributed among colleagues and friends. We took no account of rounds of the survey that were quitted before 30 triples (of the fifty per round) were shown. In doing so, we ended up with 146 rounds (some of them not fully completed) and a total of 7097 statements. It is hard to guess how many different people contributed to these 146 rounds, but assuming an average of three to four rounds per person, which seems to be reasonable according to personal feedback, their number should be around 40. In only 7 out of the 146 rounds the off-road vehicle was not chosen as most central car in the test case triple. We refer to the collection of the total of 7097 statements as the collection All and to its subcollection comprising 6757 statements gathered in the 139 rounds in which the off-road vehicle was chosen as most central car in the test case triple as the collection T_All. From All and T_All we derived two more collections of statements of the kind ($\star$) for the car data set as follows: All_reduced is obtained from All by replacing all statements dealing with the same triple of cars by just one statement about this triple, with the most central car being that car that is most often the most central car in the statements to be replaced. T_All_reduced is derived from T_All analogously. The characteristic values of the collections All, All_reduced, T_All, and T_All_reduced are summarized in Table 1. All survey data and these four collections can be downloaded along with the car data set from `http://www.tml.cs.uni-tuebingen.de/team/luxburg/code_and_data`.

	All	All_reduced	T_All	T_All_reduced
Number of statements	7097	6338	6757	6056
Number of statements in percent of number of triples [$\binom{60}{3} = 34220$]	20.74	18.52	19.75	17.70
Average number of statements in which a car appears	354.85	316.90	337.85	302.80
Minimum number of statements in which a car appears	307	286	292	269
Maximum number of statements in which a car appears	503	347	478	333
Median response time per shown triple (in seconds)	4.02		4.15	

Table 1: Characteristic values of All, All_reduced, T_All, and T_All_reduced. Note that All and T_All contain repeatedly present and contradicting statements.

We applied Algorithms 1 to 5 to the car data set and the statements in All, All_reduced, T_All, or T_All_reduced. In doing so, we assumed a partitioning of the car data set into four subclasses: ordinary cars, sports cars, off-road/sport utility vehicles, and outliers. We considered the fire truck, the motortruck, the tractor, and the antique car as outliers. Looking at Figure 15, there should be no doubts about the other classes.

6.2.1 Medoid Estimation

We applied Algorithm 1 to the car data set as well as to the three classes of ordinary cars, sports cars, and off-road/sport utility vehicles in order to estimate a medoid within these subclasses with the statements in All, All_reduced, T_All, or T_All_reduced. The estimated medoids obtained when working with All or T_All coincide and are shown in Figure 16. The estimated medoids obtained when working with All_reduced or T_All_reduced differ from these only for the whole car data set and the subclass of off-road/sport utility vehicles. Note that for estimating a medoid of a subset of a data set we consider only statements dealing with three objects of the subset. For example, when estimating a medoid of the subclass of sports cars based on the statements in All, we effectively work with 89 out of the 7097 statements in All.

It is interesting to study an ordinal embedding of the car data set. Figure 18 shows an ordinal embedding in the two-dimensional plane that we computed with the SOE algorithm based on the statements in T_All. We cannot only see a grouping of the cars according to the subclasses (compare with Section 6.2.4) and the outer positioning of the outliers (compare with in Section 6.2.2), but also that our medoid estimates are located quite at the center of the corresponding subclasses (with the exception of the subclass of off-road/sport utility vehicles). This confirms the plausibility of our estimates. Note that we observe slightly different embeddings depending on the random initialization in the SOE algorithm.

Figure 16: The estimated medoids for the car data set and the subclasses of ordinary cars, sports cars, and off-road/sport utility vehicles when working with the statements in All or T_All.

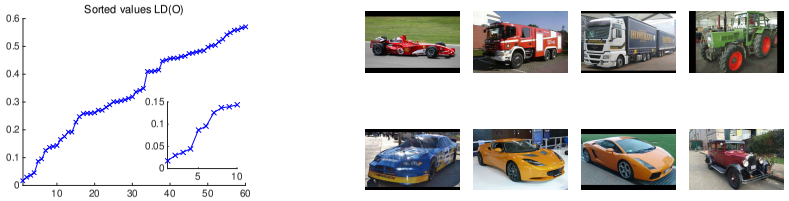

Figure 17: The sorted values $LD(O)$ (O in car data set) as well as the eight cars with smallest values (increasingly ordered) when working with the statements in T_All.

Also, it is not useful to compare the medoid estimates of Algorithm 1 with estimates based on an ordinal embedding since the latter change with every run of the embedding algorithm.

6.2.2 Outlier Identification

We applied Algorithm 2 to the car data set and the statements in All, All_reduced, T_All, and T_All_reduced, respectively. For all of the four collections of statements we obtained very similar results. Figure 17 shows a plot of the sorted values $LD(O)$ (for O being an element of the car data set) as well as the eight cars with smallest values when working with T_All. Looking at the plot it might be reasonable to assume that there are at least four outliers. Indeed, the Formula One car, the fire truck, the motortruck, and the tractor, which appear rather odd in the car data set, are ranked lowest. Also the other cars shown in Figure 17 are quite out of character for the car data set. In the ordinal embedding shown in Figure 18 all these cars are located far outside. These findings support our claim that Algorithm 2 can be used for outlier identification when given only ordinal distance information of the kind ($\star$).

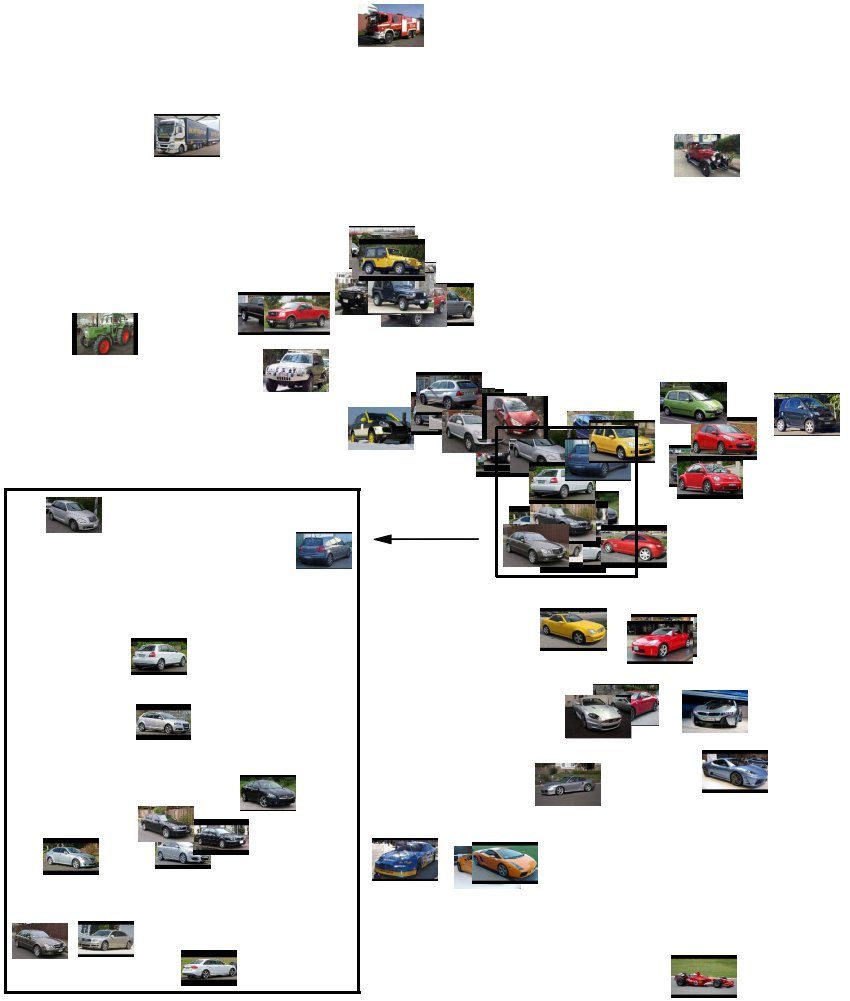

Figure 18: An ordinal embedding of the car data set based on the statements in T_All. A larger version is available on `http://www.tml.cs.uni-tuebingen.de/team/luxburg/code_and_data`.

	All	All_reduced	T_All	T_All_reduced
Number of statements	5624	5121	5349	4886
Number of statements in percent of number of triples $[\binom{56}{3} = 27720]$	20.29	18.47	19.30	17.63

Table 2: Number of statements after removing the fire truck, the motortruck, the tractor, and the antique car from the car data set. Note that All and T_All contain repeatedly present and contradicting statements.

6.2.3 Classification

For setting up a classification problem on the car data set we removed the four outliers (the fire truck, the motortruck, the tractor, and the antique car) and assigned a label to the remaining cars according to which of the three classes of ordinary cars, sports cars, or off-road/sport utility vehicles they belong to. By removing from the collections All, All_reduced, T_All, and T_All_reduced all statements that comprise one or more outliers, we obtained collections of statements of the kind ($\star$) for these 56 labeled cars. A bit sloppy, from now on till the end of Section 6.2, by All, All_reduced, T_All, and T_All_reduced we mean these newly created, reduced collections. Their sizes are given in Table 2.

We randomly selected 16 cars that we used as test points, that is we ignored their labels and predicted them by applying Algorithms 3 and 4 and an embedding approach based on the label information of the remaining 40 labeled cars and the ordinal distance information in All, All_reduced, T_All, or T_All_reduced. In Table 3 we report the average 0-1 loss (see equation (21) for its definition) and its standard deviation, where the average is over hundred random selections of test points, for the considered methods and various classification algorithms on top of Algorithm 3 or the embedding approach. We chose the dimension of the space of the embedding as two. As classifiers on top we used both the k-NN classifier and the SVM algorithm, the latter with the linear as well as with the Gaussian kernel. Since we are dealing with a 3-class classification problem, we combined the SVM algorithm with a one-vs-all strategy. We chose the parameter k for the k-NN classifier and the regularization parameter for the SVM algorithm by means of 10-fold cross-validation from $1, 3, 5, 7, 11, 15$ and $0.01, 0.05, 0.1, 0.5, 1, 5, 10, 50, 100, 500, 1000$, respectively. When using the SVM algorithm with the Gaussian kernel, we chose the kernel bandwidth σ by means of 10-fold cross-validation from $0.01, 0.05, 0.1, 0.5, 1, 5$. The parameter k for Algorithm 4 was chosen from $1, 2, 3, 5, 7, 10, 15$ by means of a non-exhaustive variant of leave-one-out cross-validation as explained in Section 6.1.3. Clearly, the ordinal embedding approach outperforms Algorithms 3 and 4. However, one should judge the performance of our algorithms with regards to their great simplicity compared to the embedding approach. In doing so, we consider the 0-1 loss incurred by Algorithms 3 or 4 to be acceptable. As one might expect, working with T_All or T_All_reduced leads to a slightly lower misclassification rate than working with All or All_reduced.

	All	All_reduced	T_All	T_All_reduced

Table 3: Average 0-1 loss (± standard deviation) when predicting labels for a randomly chosen subset of 16 cars (average over 100 choices).

6.2.4 Clustering

Like in the previous Section 6.2.3 we removed the four outliers from the car data set. We then used Algorithm 5 and an ordinal embedding approach for clustering the remaining 56 cars into three clusters, aiming to recover the cars' grouping into classes of ordinary cars, sports cars, and off-road/sport utility vehicles. In the embedding approach we applied spectral clustering to a symmetric k-NN graph with Gaussian edge weights on an ordinal embedding of the data set as we did in Section 6.1.4. Table 4 shows the average purity (see equation (22) for its definition) of the clusterings produced by the considered methods with respect to our assumed ground truth partitioning. The average is over 100 runs of the experiment. Note that clusterings produced by Algorithm 5 and obtained in different runs only differ due to random effects in the K-means step of spectral clustering, while the clusterings produced by the ordinal embedding approach also differ because of the random initialization in the embedding methods. For this reason, standard deviations of the purity values achieved by the embedding approach are much larger than those of the purity values achieved by Algorithm 5 (which are on the order machine epsilon) and are shown in Table 4 too. All methods perform nearly equally well, with the unweighted version of Algorithm 5 slightly inferior compared to the other methods when their parameters are chosen optimally. At least for Algorithm 5 working with the statements in T_All or T_All_reduced yields

	All	All_reduced	T_All	T_All_reduced
Alg. 5 w., $k = 5$, $\sigma = 0.5$	0.82	0.82	0.86	0.88

Table 4: Average purity ($\pm$ standard deviation) of clusterings produced by the various methods when clustering the 56 cars from the classes of ordinary cars, sports cars, and off-road/sport utility vehicles into three clusters (average over 100 runs).

better results than working with the statements in All or All_reduced, but this does not seem to be the case for the ordinal embedding approach.

7. Discussion, Future Work, and Open Problems

In this paper, we have proposed algorithms for the problems of medoid estimation, outlier identification, classification, and clustering when given only ordinal distance information. We argue that information of the form ($\star$) is particularly useful as it can be related to the lens depth function, which is an instance of a statistical depth function, and k-relative neighborhood graphs. Our algorithms solve the problems by direct approaches instead of constructing an ordinal embedding of a data set as an intermediate step. Thus they avoid

some of the problems inherent in such an embedding approach (discussed in Section 5.1.2). In particular, the running time of our algorithms is lower by several orders of magnitude. In a number of experiments on small data sets we have demonstrated that our algorithms are competitive with or at least not much worse than an embedding approach in terms of the quality of the produced solution. We also performed some experiments on medium-sized data sets, for which there was already no hope to compute an ordinal embedding in somewhat reasonable time, but still our algorithms yielded useful results. Our algorithms are appealingly simple and can easily and highly efficiently be parallelized. Hence, we believe that they are a useful alternative to the generic ordinal embedding approach and applicable in situations in which embedding algorithms are not.

Our work inspires several follow-up questions, we focus on two of them:

- **A more local point of view:** The problems studied in this paper are global problems in the sense that they look at a data set as a whole. In contrast, local problems like density estimation or nearest neighbor search look at single data points and their neighborhoods with respect to the dissimilarity function d, thus spotting only fragments of the data set. The tools used in this paper, the lens depth function and the k-RNG, are global in their nature too. Indeed, as we have seen in Section 6.1.2, the lens depth function cannot detect outliers sitting in-between several modes of a data set since such outliers are globally seen at the heart of the data.

  It is interesting to consider local problems in a setting of ordinal distance information. A concept that becomes attractive then is that of local depth functions: Agostinelli and Romanazzi (2008, 2011) introduced a notion of localized simplicial depth, which can easily be transferred to the lens depth function and is then given by

  $$LD_{\text{local}}(x; \tau, P) = Probability(x \in Lens(X, Y) \wedge d(X, Y) \leq \tau), \tag{23}$$

  where X and Y are independent random variables distributed according to a probability distribution P and $\tau > 0$ is a parameter. Agostinelli and Romanazzi have shown (theoretically for one-dimensional and empirically for multidimensional Euclidean data) that for τ tending to zero their local version of simplicial depth is closely related to the density function of the underlying distribution and that maximizing the local simplicial depth function provides reasonable estimates of the distribution's modes. We believe that such a connection also holds for the local lens depth function (23)—note that in one dimension the lens depth function coincides with the simplicial depth function. Unfortunately, unlike for the ordinary lens depth function, the local lens depth function cannot be evaluated with respect to an empirical distribution of a data set $\mathcal{D}$ given only ordinal distance information of the kind ($\star$) about $\mathcal{D}$. Even if we replace the event "$d(X, Y) \leq \tau$" by the event "$d(X, Y)$ is among the smallest τ distances between data points in $\mathcal{D}$", it is not clear at all how to evaluate or estimate (23). One solution would be to allow for additional ordinal distance information of the general kind (17), that is answers to comparisons $d(X, Y) < d(\widetilde{X}, \widetilde{Y})$, like Ukkonen et al. (2015) do in their paper, but this seems to be a rather unattractive way out. We have tried several heuristics for approximately evaluating the general comparison (17) given only statements of the kind ($\star$), like

  $$Probability(x \in Lens(X, Y) \mid y \in Lens(X, Y)) \approx f(d(x, y))$$

for a monotonically decreasing function $f : \mathbb{R}_0^+ \to [0,1]$, which would be useful since we can easily estimate the probability on the left side. However, none of them was promising. They all suffer from the same problem, namely that the number of data points in $Lens(X,Y)$ can be small for two completely different reasons: either $d(X,Y)$ is small, or $d(X,Y)$ is large, but $Lens(X,Y)$ is located in an area of low probability. Unfortunately, there is no obvious way for distinguishing between these two reasons.

This raises the question whether density estimation or solving any other local problem is possible at all given only ordinal distance information of the kind $(\star)$, and indeed the answer is negative for intrinsically one-dimensional data sets: Consider data points $x_1, \ldots, x_n$ on the real line and assume d to be the Euclidean metric. Then the ordinal distance information given by all statements of the kind $(\star)$ only depends on the order of the data points: given any three data points, the center is always given by the data point sitting in the middle, and any order-preserving transformation of the data points will give rise to exactly the same ordinal distance information. For this reason it is impossible to estimate any local property of an underlying distribution, and ordinal distance information of the kind $(\star)$ comes along with a substantial loss in effective information compared to similarity triplets, that is answers to (18): while, under some assumptions on the data points, all similarity triplets asymptotically uniquely determine the actual positions of the points on the real line up to a similarity transformation (Proposition 10 in Kleindessner and von Luxburg, 2014), all statements of the kind $(\star)$ only determine the ranking of the data points up to inversion. However, such a loss in information does not seem to occur when dealing with data sets of higher intrinsic dimensionality: If we start with data points from $\mathbb{R}^m$ for $m \geq 2$ (again equipped with the Euclidean metric) that are reasonably scattered, collect all statements of the kind $(\star)$, and provide them as input to an ordinal embedding algorithm, then the algorithm is able to almost perfectly recover the configuration of the data points up to a similarity transformation. An example of this happening can be seen in Figure 19 for a set of 100 points in $\mathbb{R}^2$: the blue points are the data points that we start with and the red ones are the recovered data points after a Procrustes analysis, that is aligning the points of the ordinal embedding with the original ones via a similarity transformation. We have observed this phenomenon for a broad variety of point configurations in Euclidean spaces $\mathbb{R}^m$ of arbitrary dimensions $m \geq 2$ and want to state it as a conjecture. We formulate the conjecture similarly to the theorems in Kleindessner and von Luxburg (2014) and Arias-Castro (2015), which state the asymptotic uniqueness property for ordinal data consisting of answers to general dissimilarity comparisons (17) and for similarity triplets, that is answers to comparisons (18).

Conjecture: *Let B_1 and B_2 be two closed and bounded balls in $\mathbb{R}^m$, $m \geq 2$, with arbitrary centers and radii. Let $(x_n)_{n\in\mathbb{N}}$ be a sequence of points $x_n \in B_1$ such that $\{x_n : n \in \mathbb{N}\}$ is dense in B_1. For $n \in \mathbb{N}$, let $X_n = \{x_1, \ldots, x_n\}$ and let $Y_n = \{y_1^n, \ldots, y_n^n\} \subseteq B_2$ be an ordinal embedding of X_n that preserves all statements of the kind $(\star)$ (but not necessarily any other ordinal relationships). Then there exists a sequence $(S_n)_{n\in\mathbb{N}}$ of similarity transformations $S_n : \mathbb{R}^m \to \mathbb{R}^m$ such that*

$$\max_{i=1,\ldots,n} \|S_n(y_i^n) - x_i\| \to 0 \quad as \quad n \to 0.$$

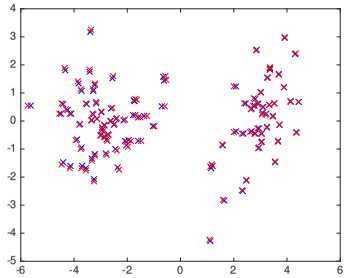

Figure 19: An example illustrating the conjecture of this section. Given all statements of the kind $(\star)$ for the set of blue points, an algorithm for ordinal embedding is able to almost perfectly recover the point configuration up to a similarity transformation (red points—after a Procrustes analysis).

Hence, there is hope: if our conjecture holds, when dealing with a Euclidean data set of known intrinsic dimension, which is greater than one, then all statements of the kind $(\star)$ asymptotically contain all cardinal distance information up to rescaling. At least for such a data set we may hope that, in principle, we are able to solve any local problem that we can solve in a standard machine learning setting of cardinal distance information also in a setting of ordinal distance information of the type $(\star)$. However, it remains an open problem how to solve a local problem in practice except for an embedding approach.

- **Active learning:** Algorithms 1 to 5 can deal with arbitrary collections of statements of the kind $(\star)$ that are gathered *before* the application of the algorithm and are provided as input all at once. However, in many scenarios one might have the chance to actively query statements for intentionally chosen triples of objects. In such a scenario an algorithm for a machine learning task should interact with the process of querying statements and adaptively choose triples of objects for which statements are to be queried in such a way that the task at hand is solved as fast, accurately, cheaply, ... as possible. For the problems of medoid estimation or outlier identification it is easy to adapt Algorithm 1 and Algorithm 2 in order to derive adaptive versions: starting with rough estimates of values $LD(O)$ for every object O in the data set, one could immediately rule out some objects with very small (or high) estimated values and continue improving only estimates of the values of the remaining objects by querying further statements only for them. This strategy has been suggested by Heikinheimo and Ukkonen (2013) for their method for medoid estimation. Studying the questions whether such a strategy comes with any guarantees, whether there might be better alternatives (of course, this depends on what one wants to achieve), or whether similar approaches apply to Algorithms 3 to 5 is left for future work.

Two further follow-up questions are: I. If one is free to choose the particular type of ordinal data that one is working with, for example in a crowdsourcing scenario, then which type is

most appropriate for which problems (in terms that it is both informative for the problem at hand and can easily be provided by the crowd)? II. How can we fix the error in the proof of Theorem 6 in Liu and Modarres (2011) (see Section 5.2)?

Abstract

We consider the problem of inferring node labels in a partially labeled graph where each node in the graph has multiple label *types* and each label type has a large number of possible labels. Our primary example, and the focus of this paper, is the joint inference of label types such as hometown, current city, and employers for people connected by a social network; by predicting these user profile fields, the network can provide a better experience to its users. Existing approaches such as Label Propagation (Zhu et al., 2003) fail to consider interactions between the label types. Our proposed method, called EdgeExplain, explicitly models these interactions, while still allowing scalable inference under a distributed message-passing architecture. On a large subset of the Facebook social network, collected in a previous study (Chakrabarti et al., 2014), EdgeExplain outperforms label propagation for several label types, with lifts of up to 120% for recall@1 and 60% for recall@3.

Keywords: label inference, graphs, social networks, variational methods, label propagation

1. Introduction

The most common classification setting assumes the presence of independent and identically distributed training examples, and attempts prediction on independent test instances drawn from the same distribution. However, the case of dependent examples has drawn much interest as well. This is particularly the case for networks where the nodes comprise the training/testing instances, and the edges between them imply dependence.

Consider the problem of inferring the labels of nodes in a network. For example, given a network of sports-related blogs connected by hyperlinks, we may want to know which blogs discuss baseball, or football, or hockey. The training data consists of known labels for a subset of blogs. The goal is to infer the labels of the remaining blogs. While the content of the blogs can be useful, the hyperlinks between blogs are clearly informative: we expect blogs to link primarily to other blogs discussing the same sport. This is a network label inference problem with only one label type (sport) and only a few labels (baseball, football, and hockey). The question we ask is: *how can we infer missing labels of multiple types, where each label type can be high-dimensional and the different types can be correlated?*

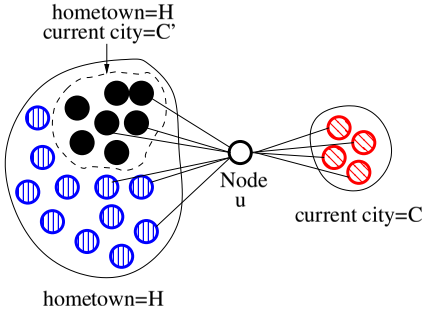

Figure 1: *An example graph of u and her friends:* The hometown friends of u coincidentally contain a subset with current city C'. This swamps the group from u's actual current city C, causing label propagation to infer C' for u. However, our proposed model (called EdgeExplain) correctly explains all friendships by setting the hometown to be H and current city to be C.

The concrete problem considered in this paper is that of inferring multiple fields such as the hometowns, current cities, and employers of users of a social network, where users often only partially fill in their profile, if at all. Here, each user is associated with one label of each *type* (such as hometown, employer, etc.), and the set of possible labels for each type is very high-dimensional. Inference of such label types is important for many ranking and relevance applications. By predicting the profile fields, the social network can make better friend recommendations or show more relevant content. Consequently, accurate predictions can greatly improve the user experience. We show that this inference problem cannot be split up into separate problems, one for each label type, without loss of accuracy. Knowledge of one label type influences inferences regarding the other types. Thus, this *joint inference* problem presents interesting opportunities for modeling and optimization.

A standard method of label inference is label propagation (Zhu and Ghahramani, 2002; Zhu et al., 2003), which tries to set the label probabilities of nodes so that friends have similar probabilities. This is based on the idea of homophily, that is, the more two nodes have in common, the more likely they are to connect (McPherson et al., 2001). However, label propagation assumes only a single category of relationships. It therefore fails to address the complexity of edge formation in networks, where nodes have different reasons to link to each other. As an example, consider the snapshot of a social network in Figure 1, where we want to predict the hometown and current city of node u, given what we know about u and u's neighbors. Here, the labels of node u are completely unknown, but her friends' labels are completely known. Label propagation would treat each label independently and infer the hometown of u to be the most common hometown among her friends, the current city to be the most common current city among friends, and so on. Hence, if the bulk of friends

of u are from her hometown H, then inferences for current city will be dominated by the most common current city among her hometown friends (say, C') and not friends from her actual current city C; indeed, the same will happen for all other label types as well.

Our proposed method, named EdgeExplain, approaches the problem from a different viewpoint, using the following intuition: Two people form an edge in a social network because they share the same label for one or more label types (e.g., both went to the same college). Using this intuition, we can go beyond standard label propagation in the following way: instead of taking the graph as given, and modeling labels as items that propagate over this graph, we consider the labels as factors that can *explain* the observed graph structure. For example, the inferences for u made by label propagation leave u's edges from C completely unexplained. Our proposed method rectifies this, by trying to infer node labels such that for each edge $u \sim v$, we can explain the existence of the edge in terms of a shared label — u and v are friends from the same hometown, or college, or the like. While we are primarily interested in inferring labels, we note that the inferred reason for each edge can be useful by itself. For example, if a new node u joins a network and forms and edge with v, and we can infer that the reason is a shared college, we can recommend other college friends of v as possible new edges for u.

We note that a seemingly simple alternative solution—cluster the graph and then propagate the most common labels within a cluster—is in fact quite problematic. The clustering must also be complex enough to allow many overlapping clusters. This is an active area of research (Xie et al., 2013), but it still entails a significant computational burden. In addition, any clustering based solely on the graph structure ignores labels already available from user profiles, which clearly carry crucial information. A clustering method that tries to use these labels must deal with incomplete and missing labels, significantly increasing its complexity. Instead, our method will be able to operate only on dyads, without having to infer the higher-level clusters themselves. Social network cluster sizes must display wide variation (e.g., the cluster for users living in New York city versus those in small rural areas), and it is unclear if current network community detection algorithms offer good performance across the entire range of community sizes (Leskovec et al., 2010). Hence, we believe that clustering does not readily lend itself to a solution for our problem.

This paper tackles the following five questions.

How can "explaining links" be codified in a model? We propose a probabilistic model, called EdgeExplain, for the social network given the labels of all nodes in the network. The model has two key properties. First, the presence or absence of a link is conditionally independent of all other nodes and edges given the labels of the two endpoints of the link. This enables distributed computation for inference, which is useful for large networks. Second, labels corresponding to all the label types are jointly considered in the model.

How can inference be performed efficiently on large networks? The model likelihood function is non-convex, and only local optima can be found. However, we present several approaches for this problem. The first uses alternating maximization on a relaxation of the objective, such that each iteration solves a convex problem. The second is a variational approach that operates directly on the model objective. We show via simulations the presence of two regimes: while the alternating minimization works best when there is significant missing data, the variational approach works better in the presence of copious and correct information, i.e., when the labels of most neighbors of a node are known with relatively high certainty. This leads to our final hybrid method that combines the two approaches.

How do the model parameters affect accuracy vis-a-vis label propagation? We present an analysis of EdgeExplain that specifies the conditions under which label propagation will be particularly inaccurate. The quality of predictions of label propagation for a user u is shown to depend on three factors: (a) the degree to which any one label type is the preferred "reason" for forming friendships as compared to the other label types, (b) the degree to which any one label dominates among all labels of a particular type, and (c) the number of friends of a user u.

How well does it work in practice? Our iterative methods for inferring labels can be easily implemented in large-scale message-passing architectures. We empirically demonstrate their scalability on a large subset of the Facebook social network (Chakrabarti et al., 2014) and a 5 million node sample of the Google+ network (Gong et al., 2012), using publicly available user profiles and friendships. On Facebook, EdgeExplain significantly outperforms label propagation for several label types, with lifts of up to 120% for recall@1 and 60% for recall@3. On the Google+ sample, which exhibits extreme sparsity of labels, all algorithms are roughly equal. We also present empirical results on a movie network, where EdgeExplain outperforms label propagation as well as other competing methods (Zheleva and Getoor, 2009; Yin et al., 2010; Gong et al., 2014). The accuracy and scalability of EdgeExplain clearly demonstrate its usefulness for label inference on large networks.

How do variational methods compare with relaxation labeling? A subtheme of our paper is the comparison, via simulations as well as empirical evaluation on real-world data, of variational and relaxation labeling techniques. When both are designed to use only per-node parameters (which are well-suited for message-passing architectures), we find that relaxation labeling works better for our problem. This is in spite of the fact that our variational updates are exact, and only the standard approximation of the joint distribution with a product of per-node marginals is made.

The paper is organized as follows. We survey related work in Section 2, and then present our proposed EdgeExplain model in Section 3. For parameter inference, we present two methods: a gradient ascent approach on a relaxed version of the problem (Section 4) and a variational approach for optimizing the original problem objective (Section 5). We then present a detailed analysis of our model in Section 6, focusing on the conditions under which label propagation would fail. Simulations on synthetic data sets (Section 7) confirm our analysis, and also help us identify the conditions under which the two inference mechanisms work best. Empirical evidence demonstrating the effectiveness of EdgeExplain is presented in Section 8. Generalizations of the model are discussed in Section 9. We conclude in Section 10.

2. Related Work

The problem of inferring labels of nodes in a network has been studied extensively in the literature on graph-based semi-supervised learning, statistical relational learning, and latent models for networks. In this section, we highlight the prior work in these fields, and then review recent works that specifically focus on the problem of attribute inference in social networks.

Semi-supervised learning. Our work falls under the paradigm of graph-based semi-supervised learning (Zhu, 2008), where the goal is to estimate a function over the nodes of the graph that satisfies two properties: (1) the function is close (or equal) to the observed labels, and (2) the function is smooth (similar) at adjacent nodes. In their seminal paper, Zhu and Ghahramani (2002) proposed an algorithm called Label Propagation, where the values at the nodes are relaxed to be real-valued, and inference is performed by averaging the values at neighboring nodes. Their follow-up paper (Zhu et al., 2003) formulated Label Propagation as inference in Gaussian random fields, stating additional interpretations as random walks on the graph and electric networks. The Gaussian random field formulation can be viewed as a special case of the regularization framework proposed by Zhou et al. (2003) that allows a tradeoff between edge smoothness and label fitting. This framework was analyzed by Belkin et al. (2004), proving generalization bounds and stability properties. Belkin et al. (2006) placed the problem in the context of reproducing kernel Hilbert spaces to provide further theoretical basis for the algorithms and obtain an out-of-sample extension. Consequently, they can handle both the inductive and transductive settings. Finally, Baluja et al. (2008) and Talukdar and Crammer (2009) introduced abandonment probability into the random walk, which can be viewed as having a special "dummy" label. This formulation addresses a challenge present in some graphs, where the random walk becomes uninformative once it visits a high-degree node. None of these approaches consider interactions between multiple label types, and hence fail to capture the edge formation process in graphs considered here. Although we do assume that observed labels are fixed, our approach could be generalized to handle soft constraints on node labels. Finally, while we do not address the inductive setting, the graphs we consider tend to change slowly, hence we can leverage the standard approach of initializing the iteration with the results of the previous run.

Often, the algorithms for graph-based semi-supervised learning can be expressed as an update rule that scales linearly with the number of nodes and edges of the graph. However, the update and space complexity are also linear in the number of distinct label values; this number can be very large in some applications (e.g., Deng et al., 2009; Shi et al., 2009). To address this challenge, Talukdar and Cohen (2014) use count-min sketch, a randomized data structure that allows them to reduce the time and space complexity to be logarithmic in the number of distinct labels. We face a similar challenge in our work, because the number of distinct values in each field is very large. However, instead of using count-min sketches, we have found it effective to compute a sparse projection of the distribution onto the probability simplex in each update (Kyrillidis et al., 2013).

Statistical relational learning. Our work is also related to the field of statistical relational learning. Here, the goal is to classify an entity such as a web page or a patent into a fixed number of labels (classes). Each entity is typically associated with attributes such as text, and we observe the links between entities. Chakrabarti et al. (1998) noted that it is ineffective to build a classifier based on the attributes of the node and its neighbors directly. Instead, they proposed a naive Bayes classifier that considers only the neighbors' labels (in addition to the local attributes). In order to propagate information through the network, they use an approximation of belief propagation. Lu and Getoor (2003) extended this work with a structured logistic regression model built separately on the local content and the links, using maximum a posteriori probability (MAP) for inference. Macskassy and Provost (2007) show that these approaches can be placed in a single framework, with

different choices of (a) a local classifier that uses a node's attributes alone, (b) a relational classifier that uses the labels at adjacent nodes, and (c) a collective inference procedure that propagates the information through the network. They provide an extensive empirical evaluation of the various combinations of these choices and observe that the best combination, weighted-vote relational neighbor classifier (Macskassy and Provost, 2003) with relaxation labeling (Rosenfeld et al., 1976; Hummel and Zucker, 1983), tends to perform as well as label propagation, which we outperform. We note that these algorithms typically focus on a single label type, whereas we explicitly model the interactions among multiple types. Although there has been some work on understanding how to combine and weigh different edge types for best prediction performance (Macskassy, 2007), the edge types (analogous to our reason for an edge) were given up front; we recover them automatically.

There is also extensive work on probabilistic relational models. Relational Bayesian Networks (RBNs; Koller and Pfeffer, 1998; Friedman et al., 1999) provide representation of organizational structure while maintaining a coherent probabilistic representation of uncertainty. Unfortunately, due to their directed nature, RBNs cannot efficiently represent homophily. Relational Markov Networks (Taskar et al., 2002) and Relational Dependency Networks (Neville and Jensen, 2007) do not impose acyclicity, and could be conceptually applied to the problem considered in this paper. Yet, we cannot use these general formalisms directly, because learning the models with high-cardinality labels would require large amounts of labeled data. Instead, it is our explicit modeling assumptions regarding multiple label types that yield gains in accuracy.

Latent models. Graph structure has been modeled using latent classes (Nowicki and Snijders, 2001; Kemp et al., 2006; Xu et al., 2006; Airoldi et al., 2008) and latent variables (Hoff et al., 2002; Miller et al., 2009; Palla et al., 2012), with an emphasis on link prediction. Nowicki and Snijders (2001) describe a stochastic blockmodel (SBM), where each node belongs to one of a fixed number of clusters, and edge generation is governed entirely by the clusters of the adjacent nodes. Kemp et al. (2006) and Xu et al. (2006) extend this work to an unknown number of clusters using the Chinese restaurant process (Pitman, 2006), while Airoldi et al. (2008) propose a mixed membership stochastic blockmodel (MMSB), where the node class membership varies from one dyad to another. The use of latent variables was initially explored in (Hoff et al., 2002), who consider generative process of edges based on the embedding of the adjacent nodes. The Latent Feature Infinite Relational Model (Miller et al., 2009) uses an infinite number of binary features controlled by an Infinite buffet process (Griffiths and Ghahramani, 2005); the Infinite Latent Attribute Model (Palla et al., 2012) then allows each feature to be partitioned into disjoint subgroups. Similarly to these approaches, in our work, each node is associated with (a finite number of) attributes. However, unlike the literature on latent models, where the latent features can be arbitrary combinations of user attributes and are unlikely to represent the concrete label types we wish to predict, our goal is to make predictions about the label types directly, using the observations made at a subset of the nodes. Several of these models may also not easily scale to large networks.

There is also a growing body of work on simultaneously explaining the connections between documents as well as their word distributions (Nallapati et al., 2008; Chang and Blei, 2010; Ho et al., 2012). Nallapati et al. (2008) propose two models that combine Latent Dirichlet allocation (LDA; Blei et al., 2003) and Mixed membership stochastic blockmodel

(MMSB; Airoldi et al., 2008), where topic proportions generate both word topics and the cluster assignments for linking. Chang and Blei (2010) also combine LDA and linking, but use the entire vector of word topic assignments for linking, thus allowing their model to better infer words from links and vice versa. Finally, Ho et al. (2012) use a hierarchy of topics specified as a nested Chinese restaurant process (Blei et al., 2010), where the link between two nodes is given by the deepest level they share. Although we do not consider the problem of modeling text data, our model permits us to incorporate node attributes, and we show empirical results for an instance where group memberships are used as additional node features. The number of distinct label values in our application is very large (on the order of millions), and we suspect that the latent variables would have to have a large dimension to explain the edges in our graph well.

Attribute inference in social networks. Several of the aforementioned techniques have recently been applied specifically to the problem of inferring node attributes in social networks. Zheleva and Getoor (2009) study the privacy implications of methods that can predict a user's private profile from the public profiles of others in the social network. They compare several algorithms for profile inference, and find that two methods work well when no extra side-information is available. One is collective classification based on the labels of neighboring nodes, where their specific implementation is essentially identical to Label Propagation. The second method (called LINK) predicts a node's labels based on a feature vector consisting of the node-IDs of its neighboring nodes. Thus, a graph with N nodes has N features, which is clearly difficult to scale.

Dong et al. (2014) consider inference of gender (2 categories) and age (4 categories) using a social network. They consider three sets of factors: (a) connections between the attribute values of a node and the node's network characteristics (such as its degree), (b) connections between attributes of node pairs connected by a link, and (c) factors for attributes of social triads. This is a comprehensive model, and is one of the few that considers triadic factors. However, the model requires several parameters for each possible value of the (gender, age-category) attribute vector. This is feasible only when the set of attribute values is extremely restricted (only 8 possibilities in their setting). Our primary problem setting has five attributes, with millions of possible values for each attribute; scaling the method to this setting appears to be extremely difficult.

Yin et al. (2010) propose attribute inference on a combined "Social Attribute Network (SAN)," where both people and attribute values are represented by nodes, and links connect people to their friends as well as to their attribute values (whenever these are known). For nodes with no attribute links, they predict the most likely attributes using a random walk on the SAN. Gong et al. (2014) extend this idea by adapting a variety of traditional link-prediction algorithms to the SAN. They find that two methods work well for attribute prediction on the Google+ SAN. The first performs random walks with restarts (RWR-SAN). The second method uses the number of "common neighbors" (CN-SAN) as a predictor. Specifically, the affinity of user u towards attribute a is measured by the number of neighbors of u who are connected to a in the SAN, and each unlabeled user picks the attribute for which she has the highest affinity. This process is iterated until convergence. Note that this method can be interpreted as a variant of Label Propagation where each unlabeled node is assigned the most common attributes among her friends (in contrast to vanilla Label Propagation where nodes have distributions over attributes).

Thus, recent works confirm the findings of earlier comparative studies (Macskassy and Provost, 2007) that Label Propagation (LP) achieves the best prediction accuracy. We shall show that our method (EdgeExplain) is as accurate as LP on the Google+ data set; LP is equivalent to CN-SAN, which was one of the two best methods for this data set (Gong et al., 2014). However, the Google+ data set suffers from extreme sparsity. On the Facebook data set, EdgeExplain achieves significantly higher accuracy as compared to LP. We also compare EdgeExplain against LP and all the feasible methods mentioned above (LINK, CN-SAN, and RWR-SAN) on a SAN derived from IMDB movie data, and show that EdgeExplain outperforms all of them.

3. Proposed Model

In this section we first build intuition about our model using a running example. Suppose we want to infer the *labels* (e.g., "Palo Alto High School" and "Stanford University") corresponding to several *label types* (e.g., high school and college) for a large collection of users. The available data consist of labels publicly declared by some users, and the (public) social network among users, as defined by their friendship network. While the desired set of label types may depend on the application, here we focus on five label types: hometown, high school, college, current city, and employer.

Our solution exploits three properties of these label types:

(P1) They represent the primary situations where two people can meet and become friends, for example, because they went to the same high school or college.

(P2) These situations are (mostly) mutually exclusive. While there may be occasional friendships sharing, say, hometown and high-school, we make the simplifying assumption that most edges can be explained by only one label type.

(P3) Sharing the same label is a *necessary* but not *sufficient* condition. For example, "We are friends from Chicago" typically implies that the indicated individuals were, at some point in time, co-located in a small area within Chicago (say, lived in the same building, met in the same cafe), but hardly implies that two randomly chosen individuals from Chicago are likely to be friends.

(P1) is a direct result of our application; our desired label types were targeted at friendship formation. Combined with **(P2)**, our five label types can be considered a set of mutually exclusive and exhaustive "reasons" for friendship; while this is not strictly true for high school and hometown, empirical evidence suggests that it is a good approximation (shown later in Section 8) and we defer a discussion on this point to Section 9. However, as **(P3)** shows, we cannot simply cast the labels as features whose mere presence or absence significantly affects the probability of friendship; instead, a more careful analysis is needed.

Formally, we are given a graph, $\mathcal{G} = (V, E)$ and a set of label types $\mathcal{T} = \{t_1, \ldots, t_{|\mathcal{T}|}\}$. For each label type t, let $L(t)$ denote the (high-dimensional) set of labels for that label type. Each node in the graph is associated with binary variables $S_{ut\ell}$, where $S_{ut\ell} = 1$ if node $u \in V$ has label ℓ for label type t. Let $\boldsymbol{S}_V$ and $\boldsymbol{S}_H$ represent the sets of visible and hidden variables, respectively. We want to infer the correct values of $\boldsymbol{S}_H$, given $\boldsymbol{S}_V$ and $\mathcal{G}$.

A popular method for label inference is *label propagation* (Zhu and Ghahramani, 2002; Zhu et al., 2003). For a single label type, this approach represents the labeling by a set of indicator variables $S_{u\ell}$, where $S_{u\ell} = 1$ if node u is labeled as ℓ and 0 otherwise. Zhu et al. (2003) relax the labeling to real-valued variables $f_{u\ell}$ over all nodes u and labels ℓ that are clamped to one (or zero) for nodes known to possess that label (or not). They then define a quadratic energy function that assigns lower energy states to configurations where f at adjacent nodes are similar:

$$E(\boldsymbol{f}) = \frac{1}{2}\sum_{u\sim v} w_{uv} \sum_{\ell} (f_{u\ell} - f_{v\ell})^2. \tag{1}$$

Here, $u \sim v$ means that u and v are linked by an edge, and w_{uv} is a non-negative weight on the edge $u \sim v$. The minimum of Eq. 1 is found by solving the fixed point equations

$$f_{u\ell} = \frac{1}{d_u}\sum_{u\sim v} w_{uv} f_{v\ell},$$

where $d_u = \sum_{u\sim v} w_{uv}$. This procedure encourages $f_{u\ell}$ of nodes connected to clamped nodes to be close to the clamped value and propagates the labels outwards to the rest of the graph. Multiple label types can be handled similarly by minimizing Eq. 1 independently for each type.

While this formulation makes full use of **(P1)** and has the advantage of simplicity, it completely ignores **(P2)**. Intuitively, label propagation assumes that friends tend to be similar in *all* respects (i.e., all label types), whereas what **(P2)** suggests is that each friendship tends to have a single *reason*: an edge $u \sim v$ exists because u and v share the same high school *or* college *or* current city, etc. This highly non-linear function is not easily expressed as a quadratic or similar variant.

Instead, we propose a different probabilistic model, which we call EdgeExplain. As described above, let $\mathcal{G}$ denote the graph, and $\boldsymbol{S}_V$ and $\boldsymbol{S}_H$ represent the sets of visible and hidden variables respectively; the variable $S_{ut\ell}$ is known (visible) if user u has publicly declared the label ℓ for type t, and unknown (hidden) otherwise. We define EdgeExplain as follows:

$$P(\boldsymbol{S}_V, \boldsymbol{S}_H \mid \mathcal{G}) = \frac{1}{Z}\prod_{u\sim v} \underset{t\in\mathcal{T}}{\text{softmax}}(r(u,v,t)) \tag{2}$$

$$r(u,v,t) = \sum_{\ell\in L(t)} S_{ut\ell} S_{vt\ell} \tag{3}$$

$$\underset{t\in\mathcal{T}}{\text{softmax}}(r(u,v,t)) = \sigma\left(\alpha \sum_{t\in\mathcal{T}} r(u,v,t) + c\right), \tag{4}$$

where Z is a normalization constant. Here, $r(u,v,t)$ indicates whether a shared label type t is the *reason* underlying the edge $u \sim v$ (Eq. 3). The $\text{softmax}(r_1, \ldots, r_{|\mathcal{T}|})$ function should have three properties: (a) it should be monotonically non-decreasing in each argument, (b) it should achieve a value close to its maximum as long as any one of its parameters is "high", and also (c) it should be differentiable, for ease of analysis. In Eq. 4, we use the sigmoid function to implement this: $\sigma(x) = 1/(1+e^{-x})$. This monotonically increases from

0 to 1, and achieves values greater than $1-\epsilon$ once x is greater than an ϵ-dependent threshold. In addition, the sigmoid enables fine control of the degree of "explanation" required for each edge (discussed below) and allows for easy extensions to more complex label types and extra features (Section 9), all of which make it our preferred choice for the softmax.

In a nutshell, our modeling assumption can be stated as follows: *It is better to explain as many friendships as possible, rather than to explain a few friendships really well.* Eq. 2 is maximized if the softmax function achieves a high value for each edge $u \sim v$, i.e., if each edge is "explained." This is achieved if the sum $\sum_{t\in\mathcal{T}} r(u,v,t)$ is relatively high, which in turn is satisfied if the product $S_{ut\ell}S_{vt\ell}$ is 1 for even one label ℓ — in other words, when there exists any label ℓ that both u and v share. The parameter α controls the degree of explanation needed for each edge; a small α forces the learning algorithm to be very sure that u and v share one or more label types, while with a large α, a single matching label type is enough. Empirical results shown later in Section 8 prove that large α values perform better (we use $\alpha = 10$ in our evaluation), suggesting that even a single matching label type is enough to explain the edge. The parameter c in Eq. 4 can be thought of as the probability of matching on an unknown label type, distinct from the five we consider. Higher values of c can be used to model uncertainty that the available label types form an *exhaustive* set of reasons for friendships. For our running example in the social network setting, we set $c = 0$ to reflect our belief that the five label types we consider represent the primary reasons for friendship formation (property **(P1)**).

Further intuition can be gained by considering a node u whose labels are completely unknown, but whose friends' labels are completely known (see Figure 1). As we discussed earlier in Section 1, label propagation would infer the hometown of u to be the most common hometown among her friends (i.e., H), the current city to be the most common current city among friends (i.e., C'), and so on. However, such an inference leaves u's friendships from C completely unexplained. Our proposed method rectifies this; Eq. 2 will be maximized by correctly inferring H and C as u's hometown and current city respectively, since H is enough to explain all friendships with the hometown friends, and the marginal extra benefit obtained from explaining these same friendships a little better by using C' as u's current city is outweighed by the significant benefits obtained from explaining all the friendships from C by setting u's current city to be C.

To summarize, Eq. 3 encapsulates property **(P1)** by trying to have matching labels between friends; Eq. 4 models property **(P2)** by enabling any one label type to explain each friendship; and the form of the probability distribution (Eq. 2) uses only existing edges $u \sim v$ and not all node pairs, and thus is not affected when, say, two nodes with Chicago as their current city are not friends, which reflects the idea that matching label types are necessary but not sufficient **(P3)**.

4. Inference via relaxation labeling

We present two methods for inference under EdgeExplain. The first considers a relaxation of the model that yields an objective which can be optimized via projected gradient descent, and this is discussed in the current section. The second method is optimizes a variational lower bound on the likelihood of EdgeExplain, and this is discussed later in Section 5. A

priori, there is little reason to choose one or the other, and we discuss their relative merits via simulations and evaluation on real data (Sections 7 and 8).

The probabilistic description of EdgeExplain in Eqs. 2-4 can be restated as an optimization problem in the variables $S_{ut\ell} \in \{0,1\}$. In the spirit of (Zhu et al., 2003), we propose a relaxation in terms of a real-valued function $\boldsymbol{f}$, with $f_{ut\ell} \in [0,1]$ representing the probability that $S_{ut\ell} = 1$, i.e., the probability that user u has label ℓ for label type t. This yields the following optimization:

$$\underset{\boldsymbol{f}}{\text{Maximize}} \sum_{u \sim v} \log\Big(\underset{t \in \mathcal{T}}{\text{softmax}}(r(u,v,t))\Big) \tag{5}$$

$$\text{where } r(u,v,t) = \sum_{\ell \in L(t)} f_{ut\ell} f_{vt\ell} \tag{6}$$

$$\sum_{\ell \in L(t)} f_{ut\ell} = 1 \quad \forall t \in \mathcal{T} \tag{7}$$

$$f_{ut\ell} \geq 0 \tag{8}$$

where softmax$(\cdot)$ is defined as in Eq. 4, and the equation for $r(\cdot)$ is analogous to Eq. 3 but measures the total probability that u and v have the same label for a given label type t.

The problem is not convex in $\boldsymbol{f}$, but is convex in $\boldsymbol{f}_u = \{f_{ut\ell} | t \in \mathcal{T}, \ell \in L(t)\}$ if the distributions $\boldsymbol{f}_v$ are held fixed for all nodes $v \neq u$. Hence, we propose an iterative algorithm to infer $\boldsymbol{f}$. Given $\boldsymbol{f}_v$ for all $v \neq u$, finding the optimal $\boldsymbol{f}_u$ corresponds to solving the following problem:

$$\underset{\boldsymbol{f}_u}{\text{Maximize}}\ g(\boldsymbol{f}_u) = \sum_{v \in \Gamma(u)} \log\Big(\underset{t \in \mathcal{T}}{\text{softmax}}(r(u,v,t))\Big),$$

where the summation is only over the set $\Gamma(u)$ of the friends of u, and we again restrict $\boldsymbol{f}_u$ to be a set of $|\mathcal{T}|$ probability distributions, one for each label type. We note that $g(\cdot)$ is convex and Lipschitz continuous with constant $L = \alpha \cdot |\Gamma(u)|$, where $|\Gamma(u)|$ is the number of friends of u.

This is a constrained maximization problem with no closed form solution for $\boldsymbol{f}_u$. To solve it, we use projected gradient ascent. This is an iterative method where in each iteration, we take a step in the direction of the gradient, and then project it back to the probability simplex $\Delta = \Big\{f_{ut\ell} \mid f_{ut\ell} \geq 0, \sum_{\ell \in L(t)} f_{ut\ell} = 1 \,\forall t \in \mathcal{T}\Big\}$. Specifically, let ∇g represent the gradient of g, with components given by:

$$\frac{\partial g(\boldsymbol{f}_u)}{\partial f_{ut\ell}} = \sum_{v \in \Gamma(u)} \alpha f_{vt\ell} \cdot \sigma\Big(-\alpha \sum_{t \in \mathcal{T}} \sum_{\ell \in L(t)} f_{ut\ell} f_{vt\ell} - c\Big).$$

Let $\boldsymbol{f}_u^{(k-1)} = \big\{f_{ut\ell}^{(k-1)} | t \in \mathcal{T}, \ell \in L(t)\big\}$ be the estimated probability distributions for each of the $\mathcal{T}$ label types at the end of iteration $k-1$, and let $q_{ut\ell}^{(k)}$ represent the (possibly improper) ending point of the k-th gradient step:

$$\boldsymbol{q}_u^{(k)} = \boldsymbol{f}_u^{(k-1)} + c_k \nabla g,$$

where c_k is a step-size parameter that we could set to a constant $c_k = 1/L$. The point $\boldsymbol{q}_u^{(k)}$ is now projected to the closest point in Δ:

$$\boldsymbol{f}_u^{(k)} = \underset{\boldsymbol{q}' \in \Delta}{\arg\min} \|\boldsymbol{q}_u^{(k)} - \boldsymbol{q}'\|_2.$$

This can be easily achieved in expected linear time over the size of the label set $\sum_t L(t)$ (Duchi et al., 2008). If only sparse distributions can be stored for each label type (say, only the top k labels for each type), the optimal k-sparse projections can be obtained simply by setting to 0 all but the top k labels for each label type, and then projecting on to the simplex (Kyrillidis et al., 2013).

This algorithm converges to a fixed point, and the function values converge to the optimal at a $1/k$ rate (Beck and Teboulle, 2009):

$$g^* - g^{(k)} \leq \frac{L\|\boldsymbol{f}_u^{(0)} - \boldsymbol{f}_u^*\|^2}{2k} \leq \frac{L|\mathcal{T}|}{k},$$

where $\boldsymbol{f}_u^*$ represents the optimal set of probability distributions, and g^* is the optimal function value. An important consequence of the algorithm is that computation of $\boldsymbol{f}_u$ only requires information from $\boldsymbol{f}_v$ for the neighbors v of u. Thus, it is a "local" algorithm that can be easily implemented in distributed message-passing architectures, such as Giraph (Giraph; Ching, 2013).

5. Variational inference

The relaxation labeling approach discussed above is intuitive, but its objective function is neither a bound nor a formal approximation of the likelihood of EdgeExplain. We now present a variational inference procedure where the inferred label probabilities do maximize a lower bound of the likelihood.

From Eqs. 2-4, we have:

$$\begin{aligned} P(S_V, S_H \mid \mathcal{G}) &= \frac{1}{Z} \prod_{u \sim v} \sigma\Big(\alpha \sum_{t \in \mathcal{T}} \sum_{\ell \in L(t)} S_{ut\ell} S_{vt\ell} + c\Big) \\ &= \frac{1}{Z} \prod_{u \sim v} \frac{1}{1 + \exp(-\alpha \sum_{t \in \mathcal{T}} \sum_{\ell \in L(t)} S_{ut\ell} S_{vt\ell} - c)}. \end{aligned}$$

Given a fixed assignment to the visible variables S_V and any distribution $Q(S_H)$ over the hidden variables, we have the inequality:

$$\ln P(S_V \mid \mathcal{G}) \geq -\sum_{S_H} Q(S_H) \ln \frac{Q(S_H)}{P(S_H, S_V \mid \mathcal{G})}. \tag{9}$$

We shall choose a fully factorized distribution for $Q(S_H)$:

$$Q(S_H) = \prod_u \prod_{t \in \mathcal{T}} \prod_{\ell \in L(t)} \mu_{ut\ell}^{S_{ut\ell}},$$

where $\mu_{ut\cdot}$ represents a multinomial distribution over all labels $\ell \in L(t)$ for label type t for user u; for notational convenience, we set $\mu_{ut\ell}$ to 0 or 1 if the user's labels are known. Such factored distributions are common in variational inference. They also have the same number of parameters as the relaxation labeling approach, allowing a fair comparison between the two. With this choice of distribution $Q(\cdot)$, the variational lower bound (Eq. 9) can be written as

$$\begin{aligned}\ln P(S_V \mid \mathcal{G}) \geq & -\sum_{ut\ell} \mu_{ut\ell} \ln \mu_{ut\ell} \\ & -\sum_{u\sim v} \left\langle \ln\left(1+\exp\left(-\alpha \sum_{t\ell} S_{ut\ell} S_{vt\ell} - c\right)\right)\right\rangle_{Q(S_H)} \\ & -\ln Z,\end{aligned} \tag{10}$$

where $\langle\cdot\rangle_Q$ represents expectation with respect to $Q(\cdot)$, and ℓ is summed over $L(t)$. We want to set the variational parameters $\boldsymbol{\mu} = \{\mu_{ut\ell}\ \forall u, t, \ell \in L(t)\}$ to maximize this lower bound.

Define $\eta_{uvt} = \sum_{\ell \in L(t)} \mu_{ut\ell}\mu_{vt\ell}$. Let $\mathbf{w} \in \{0,1\}^{|\mathcal{T}|}$ represent a binary vector of length $|\mathcal{T}|$, with w_t being the t^{th} component and $|\mathbf{w}|$ the number of "ones".

Theorem 1 *Consider one node u and one label type t. Given the parameters $\boldsymbol{\mu} \setminus \{\mu_{ut\cdot}\}$, the distribution $\mu^*_{ut\ell}$ that maximizes the lower bound of Eq. 10 is given by:*

$$\mu^*_{ut\ell} \propto \exp\left\{\sum_{\{v|u\sim v\}} \mu_{vt\ell} \sum_{\mathbf{w}} \phi_{uvt}(\mathbf{w})\right\}$$

$$\phi_{uvt}(\mathbf{w}) = \ln\left(1+e^{-(\alpha|\mathbf{w}|+c)}\right)(-1)^{w_t} \prod_{t'\neq t} \kappa(w_{t'}, \eta_{uvt'})$$

$$\kappa(w_{t'}, \eta_{uvt'}) = \eta_{uvt'}^{w_{t'}}(1-\eta_{uvt'})^{1-w_{t'}}.$$

Proposition 1 $\sum_{\mathbf{w}} \phi_{uvt}(\mathbf{w}) \geq 0$.

Both proofs are deferred to Appendix A.

It follows that the probability of node u having label ℓ for type t under the variational approximation is given by a (normalized, exponentiated) weighted linear combination of the neighboring node labels. For intuition, consider the case of large α. Then, the sum $\sum_{\mathbf{w}} \phi_{uvt}(\mathbf{w})$ is dominated by the case of $\mathbf{w}^{(-t)} = \mathbf{0}$, the all-zero vector:

$$\sum_{\mathbf{w}} \phi_{uvt}(\mathbf{w}) \approx \ln\left(\frac{1+e^{-c}}{1+e^{-\alpha-c}}\right) \prod_{t'\neq t}(1-\eta_{uvt'}).$$

Thus, the highest-probability label of type t for u is the most the common label among friends of u, *unless* the edge $u \sim v$ is already explained by some other label type t', i.e., if $\eta_{uvt'} \approx 1$. Hence, the probabilities $\mu^*_{ut\ell}$ attempt to explain as many friendship edges as possible, which is precisely the expected behavior for large α. Our variational inference method iteratively updates the parameter vector $\boldsymbol{\mu}$ by repeatedly applying Thm. 1.

6. Analysis

We now present a theoretical analysis of EdgeExplain, and its relationship with Label Propagation (LP). Even if node labels for different label types are dependent (as in EdgeExplain) rather than independent (as in LP), the labels inferred by LP could still be correct. We will find the conditions under which LP-based inference yields incorrect results, and hence inference tailored to EdgeExplain can outperform LP.

Simplified model. We will make several simplifications to EdgeExplain to focus on its main aspects. First, we will consider the "hard-threshold" variant of the problem, where even one shared attribute between two friends is enough to explain their friendship; this corresponds to setting $\alpha \to \infty$ in Eq. 4. Such a choice is also justified empirically, as will be shown in Section 8. Second, we will consider the case of one node (the "ego") whose attributes are all unknown, surrounded by N friends whose attributes are all known. This can be thought of as the fundamental inference problem template, with the actual problem using a softer version of this template that associates probabilities with the labels of friends. Finally, Eqs. 2–4 only specify a discriminative model, but we will need a generative model for our analysis. Hence, we devise a simple probabilistic model for generating node labels (represented by the binary variables $\boldsymbol{S}$) that is consistent with properties **(P1)**-**(P3)** outlined in Section 3.

Specifically, consider an "ego network" $\mathcal{G}_u$ consisting of a central node u surrounded by N friends $v_1, \ldots, v_N$. Let $Y_u = \{Y_u(t_1), \ldots, Y_u(t_{|\mathcal{T}|})\}$ denote the labels of u for each of the $|\mathcal{T}|$ label types; these are precisely the labels that are turned "on" in the binary indicator variables $\boldsymbol{S}$ restricted to u. Similarly, let Y_i represent the vector of labels for node v_i. Let $\pi(Y_u, Y_{v_1}, \ldots, Y_{v_N})$ denote the probability of observing these labels. Since $\mathcal{G}_u$ is a tree rooted at u, the labels of the friends are conditionally independent given the labels of the ego: $\pi(Y_u, Y_{v_1}, \ldots, Y_{v_N}) = \pi(Y_u) \cdot \prod \pi(Y_i \mid Y_u)$. Thus, we can generate node labels in the following manner. First, the ego u selects her labels first according to the prior $\pi(Y_u)$. Then, conditioned on Y_u, the labels Y_i for friends v_i are drawn independently of each other. In order to satisfy **(P1)**, this second step must itself be split into two stages. In the first stage, each friend v_i selects a "reason" for her friendship with u by selecting the label type Z_i that v_i shares with u. This shared label type is drawn according to a multinomial distribution q: $q(Z_i = t) = q_t$. Thus, $Y_i(Z_i) = Y_u(Z_i)$ with probability 1. Then, in the second stage, the remaining labels of v_i are set via the distribution $\pi(Y_i \mid Y_i(Z_i))$. Under this setting of Y_u and Y_i, there is a shared label for each edge, and the model π is the most general one that satisfies **(P1)** and the independence assumptions encoded in $\mathcal{G}_u$, and is symmetric across all friends.

This leads to the following simplified problem statement:

Given the network $\mathcal{G}_u$ and the labels Y_i of all friends v_i, predict the labels Y_u of the ego.

Relation to set-cover. At first sight, this appears to be a variant of the well-known set-cover problem where, for each node, we must pick sets of friends sharing some attribute such that the union of these sets covers all the friendships. However, note that we can pick only one set for each label type, since the ego can have only one label for each type Thus, the computational complexity is $O\left(\prod_{t\in\mathcal{T}} |\mathcal{L}_t|\right)$, and since we consider only a limited

number of label types ($|\mathcal{T}| = 5$), the complexity is polynomial. The set-cover problem, on the other hand, can consider any number of sets, and is an NP-hard problem.

Failure conditions for Label Propagation. The correct labels Y_u for the ego offer (one of) the best solutions for EdgeExplain, since each friendship is explained by at least one shared label. LP fails if the ego has a label ℓ of type t (i.e., $Y_u(t) = \ell$), but a different label $\ell' \neq \ell$ of the same type t is shared by more friends; we will call this the event *"LP fails via* (t, ℓ, ℓ')*."* Thus, $P(\text{LP fails}) \geq \max_{t,\ell,\ell'} P(\text{LP fails via } (t, \ell, \ell'))$, and we will develop lower bounds for the latter quantity.

Let us denote by $p_{t,t'}(\ell)$ the probability of friend v_i having the correct label ℓ for label type t given that it shares some other label type t' with the ego u; as discussed earlier, this probability is assumed to be the same for all friends:

$$p_{t,t'}(\ell) \triangleq \pi(Y_i(t) = \ell \mid Y_u \text{ and } \{Z_i = t' \neq t\}).$$

Analogously, let $p_{t,t'}(\ell')$ denote the probability of friend v_i having an incorrect label ℓ'. Furthermore, let $\Delta_{t,\ell,\ell'}$ denote the expected difference of $p_{t,t'}(\ell')$ and $p_{t,t'}(\ell)$ w.r.t. q:

$$\Delta_{t,\ell,\ell'} \triangleq \sum_{t' \neq t} q_{t'} \left(p_{t,t'}(\ell') - p_{t,t'}(\ell) \right) - q_t. \tag{11}$$

Theorem 2 *If $\Delta_{t,\ell,\ell'} > 0$, then for any small ϵ such that $0 < \epsilon < \Delta_{t,\ell,\ell'}$, we have:*

$$P(\textit{LP fails via } (t, \ell, \ell')) \geq \sum_{\{Y_u | Y_u(t) = \ell\}} \pi(Y_u) \cdot \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right).$$

The proof is deferred to Appendix A.

Thus, LP is likely to fail when $\Delta_{t,\ell,\ell'}$ is large. This happens when the following two conditions hold: (a) label ℓ is somewhat less likely than ℓ' in the entire population (so that $p_{t,t'}(\ell') - p_{t,t'}(\ell) > 0$), and (b) friendships based on a shared label for label type t are rare (i.e., q_t is small and consequently $q_{t'}$ can be large). Intuitively, under these conditions, the ego can have label ℓ for a rarely shared label type t (say, employer), but enough friends can have a different label ℓ' simply due to its prevalence in the population. It becomes likely that the number of friends with label ℓ' is more than those with ℓ, leading to an erroneous inference by LP. This is precisely the situation illustrated in Figure 1 earlier.

Optimum conditions for EdgeExplain. We shall now derive the conditions which imply the greatest possibility of error by LP. Consider a system with only two label types t and t' (call this TwoLabels). Thus, $q_{t'} = 1 - q_t$. Since LP's probability of failure is monotonically increasing in $p_{t,t'}(\ell')$ (via Eqs. 11 and Thm. 2), the worst case for LP is when all the mass is concentrated in a single alternate label ℓ'. Then without any loss of generality, we can let label type t take only two values ℓ and ℓ', with $p_{t,t'}(\ell') = 1 - p_{t,t'}(\ell)$. We will assume that the labels for the ego and her friends follow the same marginal distribution, so

$$\pi(Y_u(t) = k \mid Y_u(t')) = \pi(Y_i(t) = k \mid Y_u(t') \text{ and } \{Z_i = t'\}) \triangleq p_{t,t'}(k) \qquad \text{for } k \in \{\ell, \ell'\}.$$

Theorem 3 *The lower bound in Theorem 2 under* TwoLabels *is maximized for*

$$\Delta_{t,\ell,\ell'} = O\left(\sqrt{\frac{\log N}{N}}\right), \qquad p_{t,t'}(\ell) = \frac{1 - 2q_t - \epsilon}{2(1 - q_t)} - O\left(\sqrt{\frac{\log N}{N}}\right), \qquad q_t < 0.5.$$

Corollary 4 *For a given N, the optimum conditions for* EdgeExplain *vis-a-vis LP under* TwoLabels *are obtained for $p_{t,t'}(\ell) + q_t - p_{t,t'}(\ell) \cdot q_t \approx const.$*

Both proofs are deferred to Appendix A.

Theorem 3 demonstrates the link between the probability $p_{t,t'}(\ell)$ of a person having label ℓ and the probability q_t of forming a friendship based on a shared label of type t. If $p_{t,t'}(\ell)$ is too large, then it becomes very unlikely that another label ℓ' can be shared by more friends than ℓ. Conversely, if $p_{t,t'}(\ell)$ is too small, the ego will rarely have label ℓ, so there will be fewer situations where LP fails. Setting $p_{t,t'}(\ell) \approx (1 - 2q_t)/(2(1 - q_t))$ achieves the optimal balance between these two. Alternatively, for small $p_{t,t'}(\ell)$ and q_t, the optimum linearly trades off $p_{t,t'}(\ell)$ and q_t (Corollary 4).

A second point of interest is the effect of the number of friends N: the optimal $p_{t,t'}(\ell)$ increases with increasing N. This can be explained by noting that as N increases, any difference in the expected popularities of ℓ' and ℓ becomes more likely to be reflected in their observed frequencies, and hence even a small expected difference $\Delta_{t,\ell,\ell'}$ is sufficient to create a situation where LP fails. However, when N is small, the effect of randomness is greater, and hence a smaller $p_{t,t'}(\ell)$ is needed to ensure that ℓ' is observed more often among the friends than ℓ.

7. Simulations

We seek answers to three questions from our simulation runs: (a) how can we simulate networks according to EdgeExplain, (b) how well do the various inference algorithms (relaxation labeling and variational) perform on such networks, and (c) how does the accuracy of label propagation vary with model parameters?

7.1 Simulating EdgeExplain

This closely follows the TwoLabels setting described in Section 6, i.e., we use two label types t and t'. Generating the simulation graph consists of three stages: (a) label generation, (b) edge generation, and (c) hiding labels.

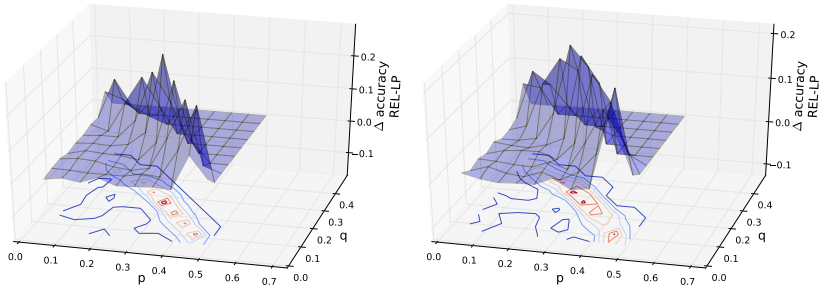
Label generation: We generate small *neighborhoods* consisting of one node (the "ego") and her friends (the "alters", whose number N is a parameter of the simulation), as follows. First, the ego u selects her labels Y_u from a predefined joint distribution $\pi(Y_u)$ over all labels of all label types. Next, the ego selects, for each friend $v_1, \ldots, v_N$, the label type Z_i that explains their friendship; Z_i is picked from a distribution q over the set of label types. Clearly, this sets the corresponding label $Y_i(Z_i) = Y_u(Z_i)$. Conditioned on this, the labels of v_i for the other label type are given by $p_{t,t'}(\ell) \triangleq \pi(Y_i(t) \mid Y_u \text{ and } Z_i = t' \neq t) = \pi(Y_i(t) \mid Y_i(t') = Y_u(t'), Z_i = t' \neq t)$. We set $p_{t,t'}(\ell) = \pi(Y_i(t) = \ell)$.

Edge generation: To make the model more realistic, we introduce inter-friend links in addition to the links between the ego u and all her friends. For each pair of friends sharing at least one label type, a link is added between them with an inter-friend link probability p_{if}.

Hiding labels: Next, we hide some labels to create the actual train/test instances. All labels of the ego u are hidden. In addition, for each of the N friends, with probability p_h, all labels are hidden. This creates an ego network where some nodes have full information and others have no information. The goal is to infer the hidden labels of u from the network structure and the known labels of some friends.

Parameter choices: In order to create the simplest instance where parameter tradeoffs can be investigated, the labels and their probabilities are set as follows. We allow two possible labels for t, with marginal probabilities p and $1-p$ respectively. We allow three possible labels for t', with marginal probabilities fixed at 0.3, 0.3, and 0.4. Since there are only two label types, the distribution $q(Z_i)$ over label types can be represented via just one number q, with $q_t = q$ and $q_{t'} = 1-q$. Thus, each train/test instance can be indexed by the 4-tuple (p, q, p_{if}, p_h).

We set $N = 1,000$ and run 50 repetitions for each simulation setting. For each simulation, we check if the right label for label type t was inferred, since this is the label type whose label probabilities are varied via the parameter p. The average fraction of correct inferences over all simulations gives the accuracy of the inference technique. The parameter range is restricted to $q < 0.5$ in accordance with Thm. 3; for $q > 0.5$, label type t is shared most often with friends, so none of the inference algorithms face any difficulty. We also keep $p < 0.5$, since the case of $p > 0.5$ is symmetric (we do not differentiate between the two labels for type t).



We note two points. First, the only test instance is the ego node u; friends with hidden labels are not considered in the test set since they might have other friends not present in the ego network of u. Second, while we could extend the graph generation process by adding friends of friends of u, the primary driver of inference accuracy is the information available among friends of u. Thus, the ego network with hidden node labels is the basic structure on which the accuracy of inference can be tested.

7.2 Comparison of inference algorithms

We will compare the accuracies of the three inference methods seen so far: relaxation labeling (REL), variational inference (VAR), and label propagation (LP).

Comparison against LP. Figure 2 shows the difference in accuracy between REL and LP as the parameters p, q, and p_h change, with $p_{if} = 0.3$ (the plots are almost identical with $p_{if} = 0$ and $p_{if} = 0.5$). We can make the following observations:

- REL is always at least as accurate as LP, and often much more accurate. Thus, under EdgeExplain, REL dominates LP.
- The parameter settings for which REL outperforms LP the most lie almost on a line in the pq-plane. This corresponds to $p + q \approx$ const., which agrees with Corollary 4.
- The results are unaffected by the probability of hiding labels and the probability of having links between friends. Hence, the difference between EdgeExplain inference

(a) $p_h = 0.0$ (b) $p_h = 0.5$

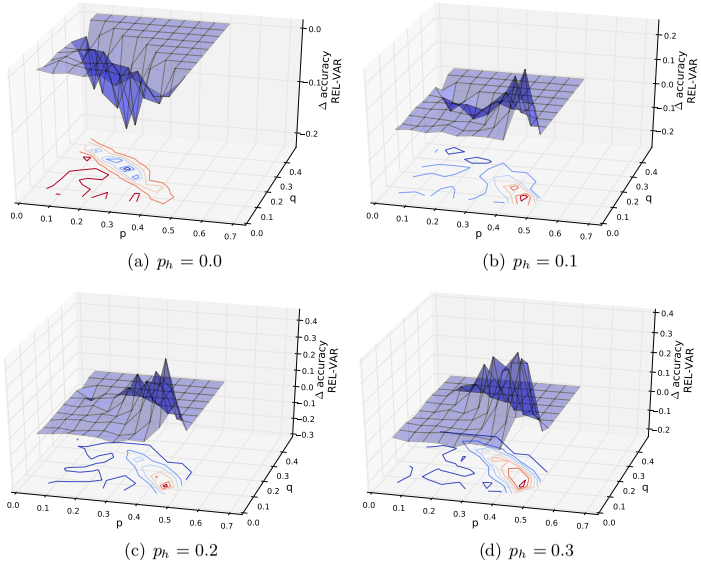


Figure 2: REL *outperforms* LP*:* The REL inference method under EdgeExplain outperforms LP irrespective of the fraction of friends whose labels are hidden. The greatest difference is when $p + q \approx$ const., agreeing with Corollary 4.

and label propagation is primarily a function of the relative probabilities of the various labels (the p) and the chances of various label types being used for forming friendships (the q); again, this is what we saw in Section 6.

Comparison of REL and VAR. Figure 3 compares REL against VAR. We observe the following:

- Although both are algorithms for inference under EdgeExplain, they perform better under different parameter regimes. When the labels of all friends are known perfectly ($p_h = 0$), VAR performs better than REL. However, as p_h increases, information in the neighborhood of the ego becomes more uncertain, and REL performs better for high p_h. The transition point is around $p_h \approx 0.1$, i.e., when 90% of friend labels are known.
- The greatest difference is in the same region of the pq-plane where REL outperformed LP the most.
- With p_h fixed, the greatest *magnitude* of difference occurs for larger values of p.
- Indeed, for large p_h, VAR performs worse than even LP for large p and small q (Figure 4).

The underlying reason is the form of the variational update (Thm. 1), in particular, in the exponentiation which serves to magnify even minor differences in its argument. When p_h is high, there are more errors in labels assigned to friends with missing information. This leads to incorrect estimation of the chances that two nodes share a label (the parameter η_{uvt} in Theorem 1). This error gets compounded by the exponentiation, causing a quick convergence to erroneous locally-optimum labels in VAR.

(a) $p_h = 0.0$ (b) $p_h = 0.1$

(c) $p_h = 0.2$ (d) $p_h = 0.3$

Figure 3: REL *versus* VAR*:* REL is better when more friends hide their labels ($p_h \geq 0.1$). However, when labels of all friends are known ($p_h = 0$), VAR is better.

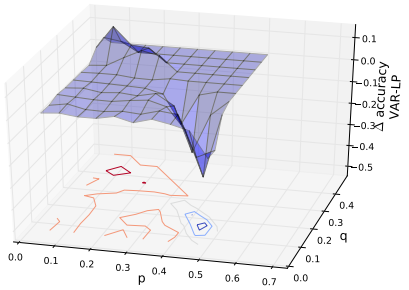
The problem is even more acute when p is high and q is low: the low q means that label type t is rarely shared among friends, while high p means that both possible labels of type t are common (recall that $p < 0.5$, so a high p corresponds to $p \approx 0.5$). This implies greater chances of mistakes in calculating η_{uvt} in the initial iterations, which is exacerbated by the exponentiation.

However, the positive side of exponentiation is that when friend labels are not noisy (as when $p_h = 0$), VAR converges quickly to the correct labels, while REL may get stuck in local minima during its gradient ascent. This explains why VAR is better for low p_h.

7.3 A hybrid inference algorithm

The previous discussion suggests the following hybrid inference procedure: in any iteration, for any node u, update its label probabilities via VAR if we are quite confident about the labels of most of the friends of u, otherwise use REL for the update. In effect, this tries to use VAR and REL precisely where they worked best in the previous simulations.

Thus, HYBRID counts the fraction of friends of u whose labels are "nearly certain" (for each label type, at least one label has probability greater than θ_1, normalized by the



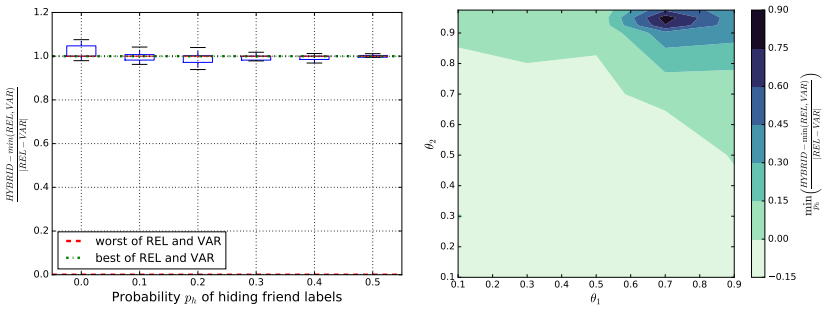


Figure 4: VAR *versus* LP *for one parameter setting:* With $p_h = 0.3$ and $p_{if} = 0.3$, VAR is better than LP for low p , and worse for high p.

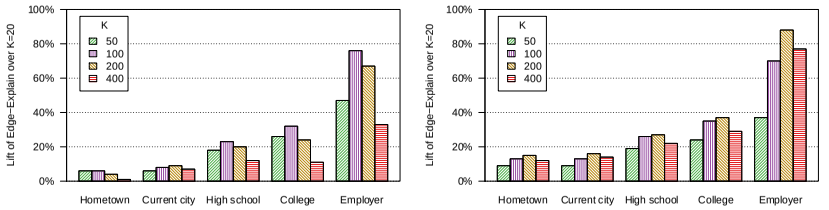
number of labels in the neighborhood) and applies the variational update (VAR) if this fraction is more than θ_2, otherwise the relaxation labeling update (REL) is used.

Figure 5 compares the accuracy of HYBRID to REL and VAR. Plot (a) shows, for $(\theta_1 = 0.7, \theta_2 = 0.95)$, the lift in accuracy of HYBRID against the others; a lift of 0 corresponds to accuracy equivalent to the worst of the two, while a lift of 1 corresponds to the best of the two. We see that HYBRID is in fact as good as the best of them for all p_h (recall that VAR was better for small p_h, and REL elsewhere). The results are very similar when the probability p_{if} of inter-friend edges is varied. Plot (b) shows a contour plot of the worst-case lift (i.e., the minimum lift among all p_h) over the (θ_1, θ_2) range. While the best setting is $(\theta_1 = 0.7, \theta_2 = 0.95)$, we note that performance is quite robust even without picking the precise maximum.

(a) Lift of HYBRID (b) Lift as a function of (θ_1, θ_2)

Figure 5: HYBRID *performs as well as the best of* REL *and* VAR*:* (a) The lift of HYBRID (with $\theta_1 = 0.7$ and $\theta_2 = 0.95$) over the minimum of REL and VAR is plotted against p_h (restricted to parameter settings where REL and VAR differ in accuracy by at least 0.01); a lift of 0 corresponds to no improvement over the worst of the two, while 1 corresponds to the performance of the better of the two. HYBRID is seen to provide better performance than REL or VAR over the entire range of p_h. (b) The minimum lift over all p_h is plotted for various (θ_1, θ_2) settings, with $\theta_1 = 0.7$, $\theta_2 = 0.95$ performing the best.

8. Empirical evaluation



Previously, we provided intuition and examples supporting the claim that EdgeExplain is better suited to inference of our desired label types than label propagation. In this section, we demonstrate this via empirical evidence on two large social network data sets from Facebook and Google+, and a movie network.

8.1 Evaluation on the Facebook network

We performed a study on a previously collected subgraph of the Facebook social network (Chakrabarti et al., 2014). [1] This data set consists of a large number of users and their friendship edges, as well as the hometown, current city, high school, college, and employer for each user, whenever these fields are available and have their visibility set to public. The dimensionality of our five label types range from almost $900K$ to over $6.3M$. We describe below in Implementation Details our process for generating the edges. This forms our base data set.

Evaluation Methodology. The set of users is randomly split into five parts and the accuracy is measured via 5-fold cross-validation, with the known profile information from four folds being used to predict labels for all types for users in the fifth fold. Results over the

1. We worked on a snapshot of data, and there was no interaction with users or their experience on the site.

(a) Recall at 1 (b) Recall at 3

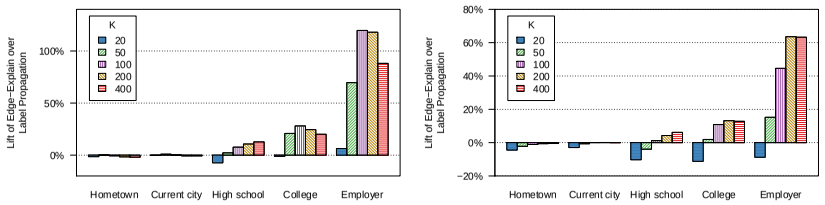


Figure 6: *Recall of* EdgeExplain *for graphs built with different number of friends K:* The plot shows lift in recall with respect to a fixed baseline of EdgeExplain with $K = 20$. Increasing K increases recall up to a point, but then the extra friends introduce noise which hurts accuracy.

various folds are identical to three decimal places. All differences are therefore significant and we do not show variances as they are too small to be noticeable.

For each evaluation, we run inference on the training set and compute a ranking of labels for each label type for each user. This ranking is provided by the label probabilities computed by each label inference method. We then measure recall at the top-1 and top-3 positions, i.e., we measure the fraction of (user, label type) pairs in the test set where the predicted top-ranked label (or any of the top-3 labels) match the actual user-provided label. For reasons of confidentiality, we only present the *lift* in recall values with respect to a clearly specified baseline.

Implementation Details. We implemented EdgeExplain in Giraph (Ching, 2013) which is an iterative graph processing system based on the Bulk Synchronous Processing model (Malewicz et al., 2010; Valiant, 1990). The entire set of nodes is split among 200 machines, and in each iteration, every node u sends the probability distributions ($f_{ut\ell}$ for REL, $\mu_{ut\ell}$ for VAR) to all friends of u. To limit the communication overhead, we implemented two features: (a) for each user u and label type t, the label distribution for each (user, type) pair was clipped to retain only the top 8 entries optimally (Kyrillidis et al., 2013), and (b) the friendship graph is sparsified so as to retain, for each user u, the top K friends whose ages are closest to that of u. This choice of friends is guided by the intuition that friends of similar age are most likely to share certain label types such as high school and college. We find that clipping the distributions makes little difference to accuracy while significantly improving running time. However, the value of K matters significantly, and we detail these effects next.

Accuracy of EdgeExplain. We first show how recall varies as a function of the number of friends K. In the following, EdgeExplain with REL inference is used unless noted otherwise; comparisons with VAR are shown later. Figure 6 shows recall versus K, with recall at $K = 20$ being the baseline. We observe that recall increases up to a certain K and then decreases. The optimal value is $K = 100$ for recall at 1, and $K = 200$ for recall at 3. This demonstrates both the importance and the limits of scalability: increasing the

(a) Recall at 1 (b) Recall at 3

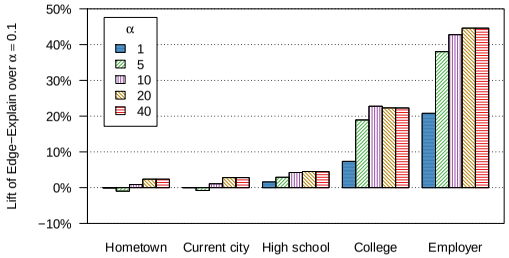
Figure 7: *Lift of* EdgeExplain *over label propagation:* Increasing the number of friends K benefits EdgeExplain much more than label propagation for high school, college, and especially employer.

number of friends enables better inference but beyond a point, more friends increase noise. Thus, $K \approx 100$ friends appear to be enough for inference under EdgeExplain.

Figure 6 also shows an increasing trend from hometown to employer in the degree of improvement obtained over the $K = 20$ baseline. This is because (a) the baseline itself is best for hometown and worst for employer, but also because (b) Facebook users appear to have many more friends from label types other than from their current employer. The effect of this latter observation is that if we only have a small K, it is very likely that the few friends from the same current employer are not included in that limited set of friends (which we empirically verified). As K increases and such same-employer edges become available, EdgeExplain can easily learn the reason for these edges (hence the dramatic increase in recall), but label propagation will likely be confused by the overall distribution of different employers among all friends and therefore does not benefit equally from adding more friends, as we show next.

Comparison with Label Propagation. Figure 7 shows the lift in recall achieved by EdgeExplain over label propagation as we increase K for both. We observe similar performance of both methods for hometown and current city, but increasing improvements for high school, college, and employer. This again points to the first two label types being easier to infer, while the latter three are more difficult. With fewer employer-based friendships, the prototypical example of Figure 1 would also occur frequently, with label propagation likely picking common employers of (say) hometown friends instead of the less common friendships based on the actual employer. By attempting to explain each friendship, EdgeExplain is able to infer the employer even under such difficult circumstances. This ability to perform well even for under-represented label types makes EdgeExplain particularly attractive.

Effect of α. Figure 8 shows that the lift in recall at 1 for various values of the parameter α, with respect to $\alpha = 0.1$. Performance generally improves with increasing α. Results for recall at 3 are qualitatively similar, though the effect is more muted. We find that $\alpha \in [10, 40]$ offer the best results, and EdgeExplain is robust to the specific choice of α within this range. Recall that with large α, a single matching label is enough to explain an edge,



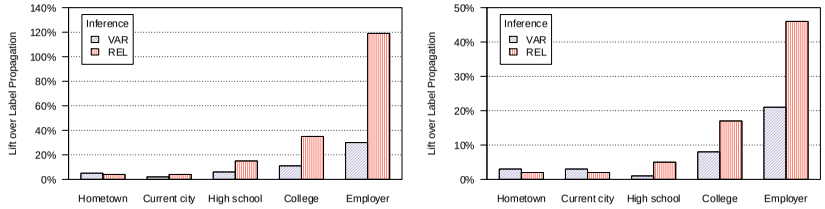


Figure 8: *Effect of α:* Lift in recall at 1 is plotted for different values of α, with respect to $\alpha = 0.1$. The best results are for $\alpha \in [10, 40]$.

(a) Recall at 1 (b) Recall at 3

Figure 9: *Comparison of* VAR *and* REL*:* The lift of each inference method over label propagation propagation is plotted for $K = 100$. REL is seen to outperform VAR, and both are better than LP.

while with small α, multiple matching labels may be needed. Thus, the outperformance of large α provides empirical validation of property **(P2)** (on our network).

Variational inference versus Relaxation Labeling. Our two main methods for inference under EdgeExplain are REL and VAR. Recall that while both use per-node parameters, they attempt to optimize Eqs. 2–4 in different ways. REL relaxes the problem by replacing the hidden variables $S_{ut\ell}$ by their "probabilities" $f_{ut\ell}$, but the relaxed objective is not formally related to the probabilistic model. On the other hand, VAR formally optimizes a lower-bound on the model log-likelihood, but the lower bound may not be very tight (we note, however, that this is the standard variational assumption when per-node parameters are needed).

Figure 9 compares the two inference methods. The lift in recall of each method over LP is shown, with $K = 100$. While both outperform LP, REL is more accurate than VAR. This agrees with our simulation results, where VAR outperformed REL only in a narrow parameter regime, where the labels of most friends of a given node are known with

Table 1: *Lift in recall from using group memberships:* Inclusion of group membership barely improves recall@3, even though it is an orthogonal feature with wide coverage. Thus, information about label types is already encoded in the network structure, and careful modeling via EdgeExplain is sufficient to extract it.

Label Type	Recall at 1	Recall at 3
Hometown	−0.1%	0.7%
Current city	0.4%	1.0%
High school	0.1%	0.8%
College	−0.6%	1.0%
Employer	−2.8%	1.2%

high confidence. Such instances are unlikely in social networks, contributing to the relative weakness of VAR.

Given the better performance of REL on this data set, the following results in this section use REL.

Inclusion of extra features. EdgeExplain easily generalizes to broader settings with multiple user features, such as group memberships, topics of interest, keywords, or pages liked by the user. As an example, consider group memberships of users. Intuitively, if most members of a group come from the same college, then it is likely a college-friends group, and this can aid inference for group members whose college is unknown. This can be easily handled by creating a special node for each group, and creating "friendship" edges between the group node and its members. EdgeExplain will infer labels for the group node as well, and will explain its "friendships" via the college label. This, in turn, will influence college inference for group members with unknown college labels. Group memberships are extensive and provide information that is orthogonal to friendships; hence, *a priori*, one would expect the addition of group membership features to have significant impact on label inference.

Table 1 shows the lift in recall for EdgeExplain when group memberships are used in addition to $K = 100$ friends. While the addition of group memberships increases the size of the graph by $\approx 25\%$, the observed benefits for recall are minor: a maximum lift of only 1.2% for employer inference, and indeed reduced recall at 1 for several label types. Note that the lift in recall would have appeared very significant had we compared it to label propagation with $K = 100$; however, this gain largely disappears when the friendships are considered in the framework of EdgeExplain. Thus, it is not merely the scalability of EdgeExplain, but also the careful modeling of properties **(P1)-(P3)** that makes group membership redundant.

Given the *a priori* expectations of the impact of group memberships, this surprising result suggests that information regarding our label types are already encoded in the structure of the social network and hence the orthogonal information from the group memberships actually turns out to be redundant.

The limits of resolution. Our model theoretically should be able to handle any number of label types, but empirically this may not hold true for our network. How many friends

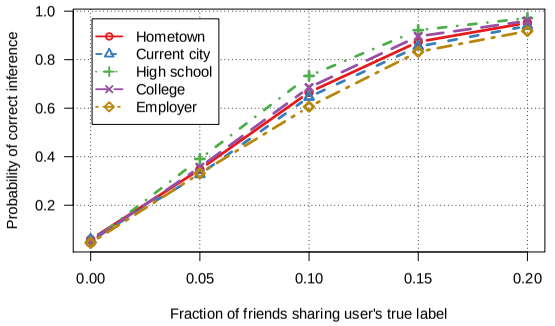

Figure 10: *Probability of correctly inferring (in the top-3) the value of a given label type t for a user, given the fraction of friends with known label for t who actually share the user's label for t:* All label types are broadly similar, with a fraction of 0.1 usually being sufficient for inference. For fraction > 0.2, the plot flattens out.

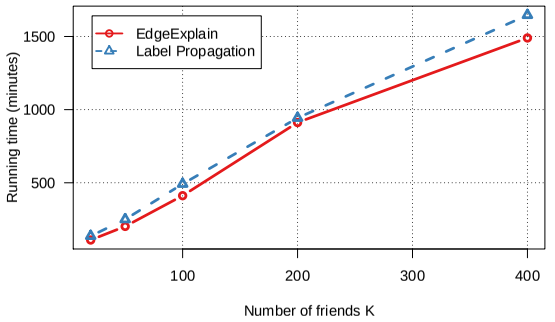

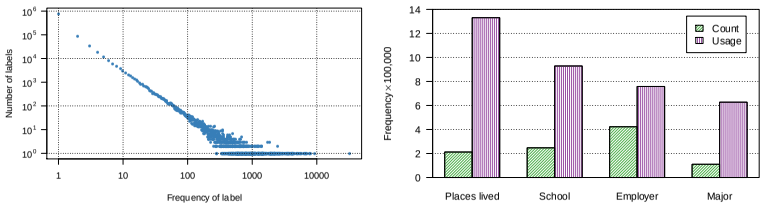

Figure 11: Running time increases linearly with K.

sharing a certain label type (say, the same college) does a user need to have in order to correctly infer the value of that label type? To answer this, we select, for each user, the set of friends whose label for the given label type t is known, and we compute the fraction that actually shared the user's label for t. Figure 10 shows the probability that EdgeExplain correctly infers the user's label as a function of this fraction (i.e., the correct label is among the top 3 predictions). All label types are similar, though high school is somewhat easier and employer harder; having $10 - 15\%$ of friends sharing a user's label is sufficient to infer the label in our graph. Note that certain label types are more likely to be publicly declared than others, and this explains differences in recall observed earlier.

(a) Label usage frequency distribution (b) Number of labels and label usage for each type

Figure 12: Descriptive statistics for Google+.

Running time. Figure 11 shows the wall-clock time as a function of K. The running time should depend linearly on the graph size, which grows almost linearly with K; as expected, the plot is linear, with deviations due to garbage collection stoppages in Java.

8.2 Evaluation on the Google+ network

We also conducted empirical evaluation on data collected from the Google+ social network (Gong et al., 2012). The data set consists of several snapshots of the network, of which we picked the oldest snapshot for our evaluation. This snapshot contains $4,693,129$ users connected by $47,130,325$ links. In addition, the data lists four attributes of each user (if the user has provided this information publicly): their employer, school, major, and the places where they have lived. There are $991,545$ labels, and $4,443,631$ (user, label) pairs in the data set. Gong et al. (2012) compared several methods for attribute inference on this data set, and found that a close variant of Label Propagation (which they called CN-SAN) has the highest precision. Hence, we only compare against Label Propagation.

We first note the extreme sparsity of the data set. There are only 10 friends per person on average, and only 1 label per person. In fact, only $909,669$ people have any labels associated with them at all (i.e., only 19% of the total). The number of people who declared all four of their label types is only $123,023$, or 2.6% of all people. Figure 12 shows some descriptive statistics regarding the labels. The distribution of labels among users (plot (a)) demonstrates a power-law: a few labels are extremely common, while the vast majority occur only once. Plot (b) shows the number of labels, and the usage, for each label type. While the most commonly used labels refer to "places lived," the "employer" label type has the most distinct labels. In other words, information about employers is particularly sparse, as in the Facebook data set.

Figure 13 shows the accuracy of each inference algorithm on all four label types. We see that there is practically no difference between the algorithms. This is due to the sparsity of the data; with so little information, there is hardly enough information among friends for EdgeExplain to differentiate itself from unrestricted homophily, and the most common label among friends is often the only reasonable choice for REL, VAR, or HYBRID (and of course for LP).

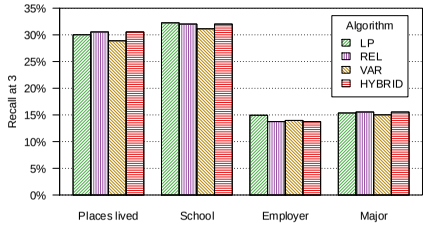

Figure 13: *Recall on the Google+ data set:* All algorithms perform similarly, primarily because the data set is too sparsely labeled.

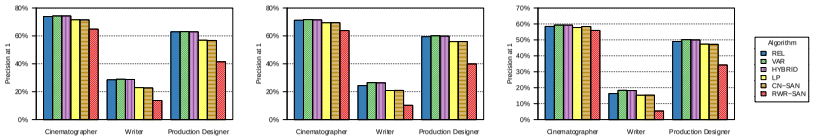
8.3 Evaluation on a Movie Network



We have so far compared EdgeExplain to Label Propagation (LP), which has been shown to be among the best predictors of node attributes in previous work (see Section 2). We have shown that EdgeExplain works as well as LP on the sparse Google+ data set, and significantly outperforms it on the Facebook data set. Now, we will perform a broader comparison of EdgeExplain against LP as well as other competing methods on a movie network.

We construct the network as follows. Each node is an English-language movie, and has three label types: the writer, the cinematographer, and the production designer.[2] These three figures represent critical behind-the-scenes roles that support the movie's director.[3] We only keep movies with a single label for each label type (i.e., no "joint writers" etc.), so as to simplify testing of prediction accuracy. There are $23,921$ such movies. Two movies are connected by an edge if they have the same writer, or cinematographer, or production designer (they could share several of these label types); note that connecting nodes to their "nearest-neighbors" is a standard technique for converting feature-based data sets into networks, and has been used for LP as well (Zhou et al., 2003). There are $100,098$ such movie pairs that share cinematographers, $20,560$ pairs sharing writers, and $84,328$ pairs sharing production designers. There are $189,828$ edges overall. Thus, by construction, the network structure reflects shared labels, satisfying the basic assumption upon which all label inference methods rest.

We shall compare all inference methods for EdgeExplain (i.e., REL, VAR, and HYBRID) against LP. In addition, we test three algorithms that have been recommended by prior work:

- LINK (Zheleva and Getoor, 2009), where each node is represented by a feature vector encoding the IDs of its neighboring nodes, and a standard classifier is used to predict labels from the feature vector. Given the size of the feature vector ($23,921$ binary

2. The data is available at `ftp://ftp.fu-berlin.de/pub/misc/movies/database/`.
3. We have also experimented with other label types such as director and composer. All results are qualitatively similar and exhibit the same trends.

(a) 5% unlabeled nodes (b) 20% unlabeled nodes (c) 50% unlabeled nodes

Figure 14: Precision@1 for various label inference methods on the movie network.

features) and the size of the output labels (39, 317 labels in total), we choose Naive Bayes as the classifier.

- CN-SAN (Gong et al., 2014), which assigns to each unlabeled node the most popular label of each label type among the node's neighbors, and iterates this process until convergence.

- RWR-SAN (Yin et al., 2010; Gong et al., 2014), which picks labels for each label type based on random walks with restarts on a combined graph that includes movie-movie and movie-label edges. We use a restart probability of 0.15.

Figure 14 shows the precision@1 for different fractions of the network being labeled. All methods achieve higher accuracy for cinematographer and production designer, but lower accuracy for writer. This is because less than 11% of the edges have a shared-writer as the reason for that edge.

All EdgeExplain inference procedures (REL, VAR, and HYBRID) are better than the competing methods for all label types. All EdgeExplain methods are similar for predicting cinematographers and production designers. However, for writer prediction, VAR is better than REL by about 7% on average. This is because edges are formed primarily due to shared cinematographers and production-designers, and these are reasonably easy to infer (for instance, even LP works well for these). Thus, the fraction of "near-certain friends" (i.e., friendships for which the underlying reason is accurately estimated; see Algorithm 1) is high enough that VAR becomes more accurate than REL at predicting writers, as shown earlier in our simulation studies (Figure 5(b)). Note that for the Facebook data set, REL was much better than VAR. This shows the usefulness of HYBRID in tracking the best-performing variant of EdgeExplain.

The differences between the EdgeExplain variants are much less than that between EdgeExplain and the second-best method, which is LP. The greatest difference is again for writer prediction, where HYBRID is always $20-25\%$ better than LP. This mirrors our observations on the Facebook network where the greatest difference between EdgeExplain and LP was in predicting a person's employer; again, friendships formed due to a shared employer are relatively rare.

We again note the fact that LP is the best among the baseline methods. This agrees with previous work by Macskassy and Provost (2007) which showed the high prediction accuracy of LP. Observe that CN-SAN performs about as well as LP; this is expected, since CN-SAN is just LP with a hard label assignment in each iteration. Finally, we note that

LINK performed poorly and is omitted from the plots. We believe this is because both the number of nodes and the number of labels are too large. LINK might be a better option for predicting label types with fewer possible labels such as gender and political affiliation, as in (Zheleva and Getoor, 2009).

9. Generalizations

We now discuss some aspects and generalizations of EdgeExplain that demonstrate its wide applicability.

Related label types. Property **(P2)** assumes that the reasons for friendship formation are mutually exclusive, but this need not be strictly true. For example, some high school friends could be a subset of hometown friends.[4] Let us again consider Figure 1, but with current city replaced by high school. Suppose that the solid-black nodes represent actual high school friends, and we are trying to infer u's high school. If the small cluster on the right did not exist, then Eq. 2 would be maximized by picking the most common high school among u's friends (i.e., the solid-black nodes), even if they are already explained by a shared hometown; thus, EdgeExplain would pick the correct high school. On the other hand, if some friendships would remain unexplained without a shared high school (e.g., the small cluster in Figure 1), then it is not obvious whether we should prefer a high school that explains these edges or a high school that represents a large segment of hometown friends. The parameter α modulates this trade-off, with a higher value of α emphasizing the explanation of all edges as against the explanation of several edges a little better. The choice of α must depend on the characteristics of the social network; for the Facebook network, the best empirical results are achieved for large α (shown in Section 8.1), suggesting that many of our label types are indeed mutually exclusive.

Incorporating edge features. There are several situations where edge-specific features could be useful. First, we may want to give more importance to certain kinds of edges, such as the group-membership edges mentioned above. Second, some features could be important for one label type but not another: e.g., the age difference between friends could be useful for inferring high school but not employer. All these situations can be easily handled by modifying Eq. 3 to include an edge-specific and label type-specific weight. The corresponding modifications to the inference method are trivial.

Nodes with multiple labels. Our original formulation of EdgeExplain (Eqs. 2–4) assumes that each node has a single label for each label type, i.e., for any user u and label type t, only one of the indicator variables $S_{ut\ell}$ is 1. The accuracy of EdgeExplain on real-world data sets shows that this is at least a reasonable approximation. However, if handling multiple labels is critical, two generalizations of EdgeExplain are possible.

First, we can allow $S_{ut\ell}$ to be 1 for multiple labels ℓ of label type t. This leads to a modified relaxation labeling formulation, where the inferred label scores $f_{ut\ell}$ need not sum

4. The relationship between high school and hometown is in fact more complicated. The high school could be within driving distance of the hometown, but not in it; and sometimes even this does not hold.

to 1. Specifically, we choose the label scores as follows:

$$\begin{aligned}
&\underset{\boldsymbol{f}}{\text{Maximize}} \sum_{u\sim v} \log\Big(\underset{t\in\mathcal{T}}{\text{softmax}}(r(u,v,t))\Big) - \gamma \cdot \sum_u \sum_{t\in\mathcal{T}} \left(\sum_\ell f_{ut\ell} - 1\right)_+ \\
&\text{where } r(u,v,t) = \sum_{\ell\in L(t)} f_{ut\ell} f_{vt\ell} \\
&\qquad f_{ut\ell} \geq 0 \\
&\qquad f_{ut\ell} \leq 1
\end{aligned}$$

Thus, the inferred label scores $f_{ut\ell}$ need to sum to 1, but a hinge loss penalty $(\sum_\ell f_{ut\ell} - 1)_+$ is applied whenever it is greater than 1 (x_+ denotes $\max(x, 0)$). Increasing the penalty parameter γ enforces the constraint more strictly, and as $\gamma \to \infty$, we regain our original relaxation labeling formulation (Eqs. 5-8).

The second approach is to modify EdgeExplain, by again allowing $S_{ut\ell}$ to be 1 for multiple labels ℓ, but using a normalization when computing the degree to which a label type "explains" an edge. More precisely, we replace $r(u,v,t) = \sum_\ell S_{ut\ell} S_{vt\ell}$ (Eq. 3) by a probabilistic version:

$$P\left(r(u,v,t) > 0 \mid S_{ut.}, S_{vt.}\right) = \sum_\ell \left(\frac{S_{ut\ell}}{\sum_{\ell'} S_{ut\ell'}} \cdot \frac{S_{vt\ell}}{\sum_{\ell'} S_{vt\ell'}}\right) \tag{12}$$

In addition, we shall let the indicator random variables $S_{ut\ell}$ be drawn independently from Bernoulli distributions: $P(S_{ut\ell} = 1 \mid \mathcal{S}^-) = f_{ut\ell}$, where $\mathcal{S}^-$ represents all indicators except $S_{ut\ell}$. Then, by marginalizing our $S_{ut.}$ and $S_{vt.}$ in Eq. 12, we can express the marginal probability $P(r(u,v,t) > 0)$ in terms of the parameters $\boldsymbol{f}$. In effect, we solve the following optimization problem:

$$\begin{aligned}
&\underset{\boldsymbol{f}}{\text{Maximize}} \sum_{u\sim v} \log\Big(\underset{t\in\mathcal{T}}{\text{softmax}}\left(P(r(u,v,t) > 0)\right)\Big) \\
&\text{where } P\left(r(u,v,t) > 0\right) = \sum_{\ell\in L(t)} E_{S_{ut.}|f_{ut.}}\left[\frac{S_{ut\ell}}{\sum_{\ell'} S_{ut\ell'}}\right] \cdot E_{S_{vt.}|f_{vt.}}\left[\frac{S_{vt\ell}}{\sum_{\ell'} S_{vt\ell'}}\right] \\
&\qquad f_{ut\ell} \geq 0 \\
&\qquad f_{ut\ell} \leq 1
\end{aligned}$$

The first approach has the advantage of being a simple extension to our existing relaxation labeling approach, which already works well. However, it might require careful tuning for the extra parameter γ. The second approach directly incorporates the desired quantities $\boldsymbol{f}$ as model parameters, so it does not require an extra relaxation step. However, it must make a strong independence assumption. We leave a detailed comparison of these approaches for future work.

10. Conclusions

We proposed the problem of jointly inferring multiple correlated label types in a large network and described the problems with existing single-label models. We noted that one particular failure mode of existing methods in our problem setting is that edges are often created for a reason associated with a particular label type (e.g., in a social network, two users may link because they went to the same high school, but they did not go to the same college). We identified three network properties that model this phenomenon: edges are created for a reason **(P1)**, they are generally created only for one reason **(P2)**, and sharing the same value for a label type is necessary but not sufficient for having an edge between two nodes **(P3)**.

We introduced EdgeExplain, which carefully models these properties. We presented two inference methods for EdgeExplain: a relaxation-labeling method and a variational approach, both of which lead to fast iterative inference that is equivalent in running time to basic label propagation. Our empirical evaluation on a large subset of the Facebook graph amply demonstrates the benefits of EdgeExplain, with significant improvements across a set of different label types. Our further analysis validates many of the properties and intuitions we had about modeling networks, primarily that one can achieve significant improvements if one considers and models the *reason* an edge exists. Whether one is interested in inferring one or multiple label types, modeling these explanations will have significant impact on the accuracy of the final predictions.

Appendix A. Proofs

Proof [Theorem 1] Note that $\sum_{t\ell} S_{ut\ell} S_{vt\ell}$ is the number of matching label types between u and v, and hence is an integer between 0 and $|\mathcal{T}|$. Thus,

$$\left\langle \ln\left(1 + e^{-\left(\alpha \sum_{t\ell} S_{ut\ell} S_{vt\ell} + c\right)}\right)\right\rangle = \sum_{k=0}^{|\mathcal{T}|} \ln\left(1 + e^{-(\alpha k + c)}\right) \left\langle I\left\{\sum_{t\ell} S_{ut\ell} S_{vt\ell} = k\right\}\right\rangle.$$

Now, $\sum_{t\ell} S_{ut\ell} S_{vt\ell}$ equals k iff exactly k label types out of $|\mathcal{T}|$ are shared, i.e., there exists a binary vector $\mathbf{w} \in \{0,1\}^{|\mathcal{T}|}$ of length $|\mathcal{T}|$ such that exactly k bits are "one" ($|\mathbf{w}| = k$), and

$$\sum_\ell S_{ut\ell} S_{vt\ell} = \begin{cases} 1 & \text{if } w_t = 1 \\ 0 & \text{otherwise.} \end{cases}$$

Thus,

$$I\left\{\sum_{t\ell} S_{ut\ell} S_{vt\ell} = k\right\} = \sum_{\{\mathbf{w}\,:\,|\mathbf{w}|=k\}} \prod_t M_t^{w_t} (1 - M_t)^{1 - w_t},$$

where $M_t = I\left\{\sum_\ell S_{ut\ell} S_{vt\ell} = 1\right\}$ indicates a shared label type t (the subscripts u and v are dropped for clarity). Thus,

$$\left\langle I\left\{\sum_{t\ell} S_{ut\ell} S_{vt\ell} = k\right\}\right\rangle_Q = \sum_{\{\mathbf{w}\,:\,|\mathbf{w}|=k\}} \prod_t \left\langle M_t^{w_t} (1 - M_t)^{1 - w_t}\right\rangle_Q,$$

using the linearity of expectation and the independence of label types in the factorized distribution Q. Now, the expectation $\langle M_t \rangle_Q$ is just the probability of sharing a label of type t, so $\langle M_t \rangle_Q = \sum_\ell \mu_{ut\ell} \mu_{vt\ell} = \eta_{uvt}$. Then,

$$\kappa(w_t, \eta_{uvt}) \triangleq \left\langle M_t^{w_t} (1 - M_t)^{1 - w_t}\right\rangle_Q = \eta_{uvt}^{w_t} (1 - \eta_{uvt})^{1 - w_t}.$$

We want to find the optimal $\boldsymbol{\mu}$ that maximizes the lower bound of Eq. 10, under the constraint that $\sum_\ell \mu_{ut\ell} = 1$ for all label types t and users u. Combining all the above equations, we want to

$$\begin{aligned}\underset{\boldsymbol{\mu}}{\text{maximize}} \; & -\sum_{ut\ell} \mu_{ut\ell} \ln \mu_{ut\ell} \\ & -\sum_{u\sim v} \sum_{\mathbf{w}} \ln\left(1+e^{-(\alpha|\mathbf{w}|+c)}\right) \prod_t \kappa(w_t, \eta_{uvt}) \\ & -\sum_{ut} \lambda_{ut} \left(\sum_\ell \mu_{ut\ell} - 1\right),\end{aligned}$$

where λ_{ut} are the Lagrange multipliers. Setting the derivatives with respect to $\boldsymbol{\mu}_u$ to zero and holding $\boldsymbol{\mu}_v$ fixed for $v \neq u$, we find:

$$\begin{aligned}\mu^*_{ut\ell} &\propto \exp\left\{\sum_{\{v|u\sim v\}} \mu_{vt\ell} \sum_{\mathbf{w}} \phi(\mathbf{w})\right\} \\ \phi(\mathbf{w}) &= \ln\left(1+e^{-(\alpha|\mathbf{w}|+c)}\right)(-1)^{w_t} \prod_{t'\neq t} \kappa(w_{t'}, \eta_{uvt'}).\end{aligned}$$

Normalizing this expression over all $\ell' \in L(t)$ gives the exact value of $\mu_{ut\ell}$. In practice, only the top few labels for label type t need to be considered. ■

Proof [Proposition 1] Let $\mathbf{w}^{(-t)} \in \{0,1\}^{|\mathcal{T}|-1}$ represent the binary vector $\mathbf{w}$ restricted to all but the t^{th} component. Denoting $\prod_{t'\neq t} \kappa(w_{t'}, \eta_{uvt'})$ by $\chi(\mathbf{w}^{(-t)})$,

$$\begin{aligned}\sum_{\mathbf{w}} \phi_{uv}(\mathbf{w}) &= \sum_{\mathbf{w}} \chi(\mathbf{w}^{(-t)})(-1)^{w_t} \ln\left(1+e^{-(\alpha|\mathbf{w}|+c)}\right) \\ &= \sum_{\mathbf{w}^{(-t)}} \chi(\mathbf{w}^{(-t)}) \ln\left(\frac{1+e^{-\alpha|\mathbf{w}^{(-t)}|-c}}{1+e^{-\alpha(|\mathbf{w}^{(-t)}|+1)-c}}\right) \\ &\geq 0,\end{aligned}$$

where the first equality follows by grouping the two $\mathbf{w}$ terms with the same $\mathbf{w}^{(-t)}$ and summing the contributions for $w_t = 0$ and 1. The inequality holds because the numerator inside the logarithm is greater than the denominator, and $\chi \geq 0$. ■

Proof [Theorem 2] Let $\mathcal{U}$ represent the event that the ego has already selected her labels Y_u, and has chosen label ℓ for label type t. Define the random variable X_i as $+1$ if the friend v_i has label ℓ' for type t, -1 if it is ℓ, and 0 otherwise: $X_i = I_{Y_i(t)=\ell'} - I_{Y_i(t)=\ell}$. Then, LP fails via (t,ℓ,ℓ') if $\sum_i X_i > 0$. We bound the probability of the latter quantity by noting that it is the sum of independent random variables X_i, so a Hoeffding bound applies:

$$P\left(\sum X_i \geq E\left[\sum X_i\right] - Nx \,\middle|\, \mathcal{U}\right) \geq 1 - \exp\{-0.5Nx^2\} \quad (\text{for } x \geq 0). \tag{13}$$

Then, $E[X_i \mid \mathcal{U}]$ is easily seen to be:

$$\frac{E\left[\sum X_i \mid \mathcal{U}\right]}{N} = E[X_i \mid \mathcal{U}] = \sum_{t'\neq t} q_{t'}\left(p_{t,t'}(\ell') - p_{t,t'}(\ell)\right) - q_t = \Delta_{t,\ell,\ell'}.$$

Thus, $\Delta_{t,\ell,\ell'}$ is the expected difference in the rates of occurrences of ℓ' and ℓ; note that it depends on both how frequent the labels ℓ and ℓ' are, and the ego's preferences for choosing friends sharing each label type. Setting $x = E\left[\sum X_i \mid \mathcal{U}\right]/N - \epsilon = \Delta_{t,\ell,\ell'} - \epsilon$ for some small $\epsilon > 0$ in Eq. 13, we find:

$$P\left(\sum X_i > 0 \,\middle|\, \mathcal{U}\right) \geq 1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}.$$

Hence,

$$\begin{aligned}P(\text{LP fails via } (t,\ell,\ell')) &\geq P\left(\sum X_i > 0\right) \\ &= \sum_{\{Y_u|Y_u(t)=\ell\}} \pi(Y_u) \cdot P\left(\sum X_i > 0 \,\middle|\, Y_u \text{ where } Y_u(t) = \ell\right) \\ &= \sum_{\{Y_u|Y_u(t)=\ell\}} \pi(Y_u) \cdot P\left(\sum X_i > 0 \,\middle|\, \mathcal{U}\right) \\ &\geq \sum_{\{Y_u|Y_u(t)=\ell\}} \pi(Y_u) \cdot \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right). \end{aligned} \tag{14}$$

■

Proof [Theorem 3] Restating Eq. 14, we find:

$$\begin{aligned}P(\text{LP fails via } (t,\ell,\ell')) &\geq \sum_{\{Y_u|Y_u(t)=\ell\}} \pi(Y_u) \cdot \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right) \\ &= \sum \pi(Y_u(t')) \cdot \pi(Y_u(t) = \ell \mid Y_u(t')) \cdot \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right) \\ &= \sum \pi(Y_u(t')) \cdot p_{t,t'}(\ell) \cdot \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right).\end{aligned}$$

To optimize the lower bound, we set the derivative of the RHS with respect to $p_{t,t'}(\ell)$ to 0. Noting that under TwoLabels, $p_{t,t'}(\ell') = 1 - p_{t,t'}(\ell)$, $q_{t'} = 1 - q_t$, and $\Delta_{t,\ell,\ell'} = q_{t'}(1 - 2p_{t,t'}(\ell)) - q_t = (1-q_t)(1-2p_{t,t'}(\ell)) - q_t$, we find:

$$\begin{aligned}0 &= \left(1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\}\right) \\ &\quad - 2Np_{t,t'}(\ell) \cdot \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\} \cdot (\Delta_{t,\ell,\ell'} - \epsilon) \cdot (1-q_t) \\ &= 1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\} \cdot \left(1 + 2Np_{t,t'}(\ell)(1-q_t)\left((1-q_t)(1-2p_{t,t'}(\ell)) - q_t - \epsilon\right)\right) \\ &= 1 - \exp\{-0.5N(\Delta_{t,\ell,\ell'} - \epsilon)^2\} \times \\ &\qquad \left(1 + \underbrace{2(1-q_t)(1-2q_t-\epsilon)}_{c_1} Np_{t,t'}(\ell) - \underbrace{4(1-q_t)^2}_{c_2} Np_{t,t'}(\ell)^2\right) \\ &= 1 - \exp\{-0.5N \cdot \underbrace{\left((1-2q_t-\epsilon) - 2(1-q_t)p_{t,t'}(\ell)\right)^2}_{c_3}\} \cdot \left(1 + c_1 Np_{t,t'}(\ell) - c_2 Np_{t,t'}(\ell)^2\right).\end{aligned} \tag{15}$$

For large N, this can be satisfied only if $c_3 \approx 0$. Hence, let us express $p_{t,t'}(\ell)$ as $p_{t,t'}(\ell) = (1 - 2q_t - \epsilon)/(2(1 - q_t)) - p' \triangleq \kappa - p'$ for some small p', where $p' > 0$ to ensure that $\Delta_{t,\ell,\ell'} - \epsilon > 0$. Using this in Eq. 15, we find:

$$\begin{aligned}\exp\{2N(1-q_t)^2 p'^2\} &= 1 + c_1 N(\kappa - p') - c_2 N(\kappa - p')^2 \\ &= 1 + N\kappa(c_1 - c_2\kappa) + Np'(2c_2\kappa - c_1) - Np'^2 c_2 \\ &\leq 1 + N\kappa(c_1 - c_2\kappa) + N|(2c_2\kappa - c_1)| \\ \Rightarrow p' &= O\left(\sqrt{\frac{\log N}{N}}\right).\end{aligned}$$

Hence, $\Delta_{t,\ell,\ell'} = (1 - 2q_t) - 2(1 - q_t)p_{t,t'}(\ell) = (1 - 2q_t) - 2(1 - q_t)(\kappa - p') = O\left(\sqrt{\frac{\log N}{N}}\right)$. The requirement that $q_t < 0.5$ is necessitated by $p_{t,t'}(\ell) > 0$. ■

Proof [Corollary 4] When N is fixed, Theorem 3 suggests requiring

$$\begin{aligned}\Delta_{t,\ell,\ell'} &\approx \text{const.} \\ \Rightarrow (1 - q_t)(1 - 2p_{t,t'}(\ell)) - q_t &\approx \text{const.} \\ \Rightarrow 1 - 2\left(p_{t,t'}(\ell) + q_t - p_{t,t'}(\ell) \cdot q_t\right) &\approx \text{const.}\end{aligned}$$

which proves the claim. ■

Abstract

Community detection is a fundamental statistical problem in network data analysis. In this paper, we present a polynomial time two-stage method that provably achieves optimal statistical performance in misclassification proportion for stochastic block model under weak regularity conditions. Our two-stage procedure consists of a refinement stage motivated by penalized local maximum likelihood estimation. This stage can take a wide range of weakly consistent community detection procedures as its initializer, to which it applies and outputs a community assignment that achieves optimal misclassification proportion with high probability. The theoretical property is confirmed by simulated examples.

Keywords: Clustering, Community detection, Minimax rates, Network analysis, Spectral clustering.

1. Introduction

Network data analysis (Wasserman, 1994; Goldenberg et al., 2010) has become an important topic in statistics. In fields such as physics, computer science, social science and biology, one observes a network among a large number of subjects of interest such as particles, computers, people, etc. The observed network can be modeled as an instance of a random graph and the goal is to infer structures of the underlying generating process. A structure of particular interest is *community*: there is a partition of the graph nodes in some suitable sense so that each node belongs to a community. Starting with the proposal of a series of methodologies (Girvan and Newman, 2002; Newman and Leicht, 2007; Handcock et al., 2007; Karrer and Newman, 2011), we have seen a large literature devoted to algorithmic solutions to uncovering community structure. Great advances have also been made in recent years on the theoretical understanding of the problem in terms of statistical consistency and thresholds for detection and exact recoveries. See, for instance, Bickel and Chen (2009); Decelle et al. (2011); Zhao et al. (2012); Mossel et al. (2012, 2013b); Massoulié (2014); Abbe et al. (2014); Mossel et al. (2014); Hajek et al. (2014), among others. The major goal of the present paper is to propose a computationally feasible algorithm for community detection in stochastic block models with adaptive minimax optimal performance.

To describe network data with community structure, we focus on the stochastic block model (SBM) proposed by Holland et al. (1983). Let $A \in \{0,1\}^{n\times n}$ be the symmetric adjacency matrix of an undirected random graph generated according to an SBM with k communities. The diagonal entries of A are all zeros and each $A_{uv} = A_{vu}$ for $u > v$ is an independent Bernoulli random variable with mean $P_{uv} = B_{\sigma(u)\sigma(v)}$ for some symmetric connectivity matrix $B \in [0,1]^{k\times k}$ and some label function $\sigma : [n] \to [k]$. Here and after, for any positive integer m, $[m] = \{1,\dots,m\}$. In other word, if the u^{th} node and the v^{th} node belong to the i^{th} and the j^{th} community respectively, then $\sigma(u) = i$, $\sigma(v) = j$ and there is an edge connecting u and v with probability B_{ij}. We define a and b through $\min_i B_{ii} = a/n$ and $\max_{i\neq j} B_{ij} = b/n$. Community detection then refers to the problem of estimating the label function σ subject to a permutation of the community labels $\{1,\dots,k\}$. A natural loss function for such an estimation problem is the proportion of wrong labels (subject to a permutation of the label set $[k]$), which we refer to as misclassification proportion from here on.

Literature review The field of community detection in SBMs has been growing fast. Results on fundamental limits and various algorithms for achieving them have been obtained in the literature. We first review the most relevant results prior to our work.

1. *Detection.* In ground breaking works by Mossel et al. (2012, 2013b) and Massoulié (2014), the authors established sharp threshold for the regimes in which it is possible and impossible to achieve a misclassification proportion strictly less than $\frac{1}{2}$ (so that it is better than random guess) when $k = 2$ and both communities are of the same size. This solved the conjecture in Decelle et al. (2011) that was only justified in physics rigor. The necessary and sufficient condition for doing better than random guess is $(a-b)^2 > 2(a+b)$.

2. *Weak consistency.* In the current context, weak consistency means recovering all but a vanishing proportion of the community labels. As was shown in Mossel et al. (2014), the necessary and sufficient condition for achieving weak consistency is $(\sqrt{a}-\sqrt{b})^2 \to \infty$ in the equal-sized two community setting. Conditions of weak consistency in general SBMs were obtained and discussed in Zhang and Zhou (2015); Yun and Proutiere (2014a); Abbe and Sandon (2015a).

3. *Strong consistency.* Abbe et al. (2014); Mossel et al. (2014) established the necessary and sufficient condition for ensuring zero misclassification proportion (usually referred to as "strong consistency") with high probability when $k = 2$ and community sizes are equal. The result was later generalized to general SBMs with possibly unequal community sizes by Abbe and Sandon (2015a) using the notion of Chernoff-Hellinger (CH) divergence.

4. *Minimax optimal rates.* The foregoing three categories of results mainly focused on sharp conditions of achieving detection, weak consistency and strong consistency, respectively. Arguably, what is of more interest to statisticians is the optimal rates of misclassification proportion. When $(\sqrt{a}-\sqrt{b})^2/(k\log k) \to \infty$, it was derived by Zhang and Zhou (2015) that the optimal rate of misclassification proportion takes the

form of

$$\exp\left(-(1+o(1))\frac{nI^*}{k}\right), \tag{1}$$

for a k-community SBM with equal community sizes, where I^* is the Rényi divergence of order $\frac{1}{2}$ between Bern $\left(\frac{a}{n}\right)$ and Bern $\left(\frac{b}{n}\right)$ (Rényi, 1961). See Theorem 1 below for a more general and precise statement of the result. A special case of this result for symmetric SBMs with $k = 2$ was obtained in Yun and Proutiere (2014a).

5. *Algorithms.* Various algorithms have been proposed in the literature to achieve detection, weak consistency and strong consistency. A popular approach is spectral clustering. Its application on network data dates back to Hagen and Kahng (1992); McSherry (2001). Its performance on SBMs has been investigated by Coja-Oghlan (2010); Rohe et al. (2011); Sussman et al. (2012); Fishkind et al. (2013); Qin and Rohe (2013); Joseph and Yu (2013); Lei and Rinaldo (2014); Vu (2014); Chin et al. (2015); Jin (2015); Le et al. (2015), among others. Various ways for refining spectral clustering have been proposed, such as those in Amini et al. (2013); Abbe et al. (2014); Mossel et al. (2014); Lei and Zhu (2014); Yun and Proutiere (2014a); Chin et al. (2015), which lead to strong consistency or convergence rates that are exponential in signal-to-noise ratio, while Mossel et al. (2013a) studied the problem of minimizing a non-vanishing misclassification proportion. However, in the regime of weak consistency, with the exception of Yun and Proutiere (2014a) for equal-sized two community case, these refinement methods cannot attain the optimal misclassification proportion.

   Another important line of research is devoted to the investigation of likelihood-based methods, which was initiated by Bickel and Chen (2009) and later extended to more general settings by Zhao et al. (2012); Choi et al. (2012). To tackle the intractability of optimizing the likelihood function, an EM algorithm using pseudo-likelihood was proposed by Amini et al. (2013). Another way to overcome the intractability of the maximum likelihood estimator (MLE) is by convex relaxation. Various semi-definite relaxations were studied by Cai and Li (2014); Chen and Xu (2014); Amini and Levina (2014), and the sharp threshold for strong consistency can indeed be achieved by semi-definite programming (Hajek et al., 2014, 2015).

Main contribution The current paper proposes a computationally feasible algorithm that provably achieves the optimal misclassification proportion established in Zhang and Zhou (2015) adaptively under weak regularity conditions. It covers the cases of both finite and diverging number of communities and both equal and unequal community sizes, and it achieves both weak and strong consistency in the respective regimes. In addition, the algorithm is guaranteed to compute in polynomial time even when the number of communities diverges with the number of nodes. Since the error bound of the algorithm matches the optimal misclassification proportion (1) in Zhang and Zhou (2015) under weak conditions, it achieves various existing detection boundaries in the literature. For instance, for any fixed number of communities, the procedure is weakly consistent under the necessary and sufficient condition of Mossel et al. (2012, 2013b), and strongly consistent under the necessary and sufficient condition of Abbe et al. (2014); Mossel et al. (2014). Moreover, it could match the optimal misclassification proportion in Zhang and Zhou (2015) even

when k diverges. It is remarkable that the same algorithm can lead to optimal performance in both strong and weak consistency regiems, while most papers in the literature require different algorithms in the two regimes.

The core of the algorithm is a refinement scheme for community detection motivated by penalized MLE, an idea that was previously explored in Amini et al. (2013); Abbe et al. (2014); Mossel et al. (2014); Lei and Zhu (2014); Yun and Proutiere (2014a); Chin et al. (2015). As long as there exists an initial estimator that satisfies a certain weak consistency condition, the refinement scheme is able to obtain an improved estimator that achieves the optimal misclassification proportion with high probability. The key to achieve this goal is to optimize the *local* penalized likelihood function for each node separately. This local optimization step is completely data-driven and has a closed form solution, and hence can be computed very efficiently. The additional penalty term is indispensable as it plays a key role in ensuring the optimal performance when the community sizes are unequal and when the within community and/or between community edge probabilities are unequal.

To obtain a qualified initial estimator, we show that both spectral clustering and its normalized variant could satisfy the desired condition needed for subsequent refinement, though the refinement scheme works for any other method satisfying a certain weak consistency condition. Note that spectral clustering can be considered as a *global* method, and hence our two-stage algorithm runs in a "*from global to local*" fashion. In essence, with high probability, the global stage pinpoints a local neighborhood in which we shall search for solution to each local penalized maximum likelihood problem, and the subsequent local stage finds the desired solution.

Notable results after initial posting of this manuscript After the initial posting of this manuscript on arXiv (arXiv:1505.03772), there have appeared a number of papers with notable and related results. Below, we highlight them with brief discussions:

1. *Detection.* The algorithm proposed in this paper achieves optimal misclassification proportion in the weak and the strong consistency regimes. In the detection regime, optimal misclassification proportion and its statistical-computational gap have been studied in Deshpande et al. (2015); Mossel and Xu (2015); Abbe and Sandon (2015b).

2. *Strong and weak consistency.* Two algorithms were proposed in Abbe and Sandon (2015c) for community detection in general SBMs. One for the strong consistency regime, and the other for weak consistency and detection. The one for strong consistency was shown to achieve the goal all the way to the CH divergence threshold, which is tighter than the strong consistency result in the present paper for asymmetric SBMs. However, the convergence rate for the other algorithm is sub-optimal in the weak consistency regime even for symmetric SBMs. See also the discussion below for the further improvement in Yun and Proutiere (2015).

3. *Weighted/labeled SBMs.* Jog and Loh (2015) extends the results in Zhang and Zhou (2015) to networks with weighted/labeled edges using Rényi divergence of order $\frac{1}{2}$. A more recent paper Yun and Proutiere (2015) studied optimal misclassification proportion for weighted/labeled SBMs. The proposed algorithm in Yun and Proutiere (2015) is able to achieve the CH limit (Abbe and Sandon, 2015a) in the strong consistency regime. It also attains optimal misclassification proportion in the weak consistency

regime with respect to a potentially smaller class than the ones used in our paper. However, their stronger results also require a relatively stronger set of conditions. For example, they require $k = O(1)$. Moreover, for equal-sized two community binary SBMs, with a and b defined at the beginning of this section, Yun and Proutiere (2015) requires $a \asymp b$ and $a - b \asymp b$. In comparison, we do not require the latter for any result in this manuscript. We can even drop the former if we are willing to accept any $1 - \epsilon$ relaxation of the tight constant of the exponent in our error rates. See, for instance, Theorem 12.

4. *Degree-corrected block models.* The paper Gao et al. (2016) studied degree-corrected block models by deriving the minimax rates for misclassification proportion and proposing an adaptive algorithm.

In summary, progress has been made along several different directions after initial posting of the present manuscript. However, none of the aforementioned results dominates those we are to present in the rest of the paper.

Organization and notation The rest of the paper is organized as follows. Section 2 formally sets up the community detection problem and presents the two-stage algorithm. The theoretical guarantees for the proposed method are given in Section 3, followed by numerical results demonstrating its competitive performance on simulated datasets in Section 4. A discussion on the results in the current paper and possible directions for future investigation is included in Section 5. Section 6 presents the proofs of main results with some technical details deferred to the appendix.

We close this section by introducing some notation. For a matrix $M = (M_{ij})$, we denote its Frobenius norm by $\|M\|_{\mathrm{F}} = \sqrt{\sum_{ij} M_{ij}^2}$ and its operator norm by $\|M\|_{\mathrm{op}} = \max_l \lambda_l(M)$, where $\lambda_l(M)$ is its l^{th} singular value. We use M_{i*} to denote its i^{th} row. The norm $\|\cdot\|$ is the usual Euclidean norm for vectors. For a set S, $|S|$ denotes its cardinality. The notation $\mathbb{P}$ and $\mathbb{E}$ are generic probability and expectation operators whose distribution is determined from the context. For two positive sequences $\{x_n\}$ and $\{y_n\}$, $x_n \asymp y_n$ means $x_n/C \le y_n \le C x_n$ for some constant $C \ge 1$ independent of n, while $x_n = o(y_n)$ means $x_n/y_n \to 0$ as $n \to \infty$. Throughout the paper, unless otherwise noticed, we use C, c and their variants to denote absolute constants, whose values may change from line to line.

2. Problem formulation and methodology

In this section, we give a precise formulation of the community detection problem and present a new method for it. The method consists of two stages: initialization and refinement. We shall first introduce the second stage, which is the main algorithm of the paper. It clusters the network data by performing a node-wise penalized neighbor voting based on some initial community assignment. Then, we will discuss several candidates for the initialization step including a new greedy algorithm for clustering the leading eigenvectors of the adjacency matrix or of the graph Laplacian that is tailored specifically for stochastic block models. Theoretical guarantees for the algorithms introduced in the current section will be presented in Section 3.

2.1 Community detection in stochastic block model

Recall that a stochastic block model is completely characterized by a symmetric connectivity matrix $B \in [0,1]^{k\times k}$ and a label vector $\sigma \in [k]^n$. One widely studied parameter space of SBM is

$$\Theta_0(n,k,a,b,\beta) = \Big\{ (B,\sigma) : \sigma : [n] \to [k], |\{u \in [n] : \sigma(u) = i\}| \in \left[\frac{n}{\beta k} - 1, \frac{\beta n}{k} + 1\right], \ \forall i \in [k], \\ B = (B_{ij}) \in [0,1]^{k\times k}, B_{ii} = \frac{a}{n} \text{ for all } i \text{ and } B_{ij} = \frac{b}{n} \text{ for all } i \neq j \Big\} \quad (2)$$

where $\beta \ge 1$ is an absolute constant. This parameter space $\Theta_0(n,k,a,b,\beta)$ contains all SBMs in which the within community connection probabilities are all equal to $\frac{a}{n}$ and the between community connection probabilities are all equal to $\frac{b}{n}$. In the special case of $\beta = 1$, all communities are of nearly equal sizes.

Assuming equal within and equal between connection probabilities can be restrictive. Thus, we also introduce the following larger parameter space

$$\Theta(n,k,a,b,\lambda,\beta;\alpha) = \Big\{ (B,\sigma) : \sigma : [n] \to [k], |\{u \in [n] : \sigma(u) = i\}| \in \left[\frac{n}{\beta k} - 1, \frac{\beta n}{k} + 1\right], \ \forall i \in [k], \\ B = B^T = (B_{ij}) \in [0,1]^{k\times k}, \frac{b}{\alpha n} \le \frac{1}{k(k-1)} \sum_{i\neq j} B_{ij} \le \max_{i\neq j} B_{ij} = \frac{b}{n}, \\ \frac{a}{n} = \min_i B_{ii} \le \max_i B_{ii} \le \frac{\alpha a}{n}, \\ \lambda_k(P) \ge \lambda \text{ with } P = (P_{uv}) = (B_{\sigma(u),\sigma(v)}) \Big\}. \quad (3)$$

Throughout the paper, we treat $\beta \ge 1$ and $\alpha \ge 1$ as absolute constants, while k, a, b and λ should be viewed as functions of the number of nodes n which can vary as n grows. Moreover, we assume $0 < \frac{b}{n} < \frac{a}{n} \le 1 - \epsilon$ throughout the paper for some numeric constant $\epsilon \in (0,1)$. Thus, the parameter space $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ requires that the within community connection probabilities are bounded from below by $\frac{a}{n}$ and the connection probabilities between any two communities are bounded from above by $\frac{b}{n}$. In addition, it requires that the sizes of different communities are comparable. In order to guarantee that $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ is a larger parameter space than $\Theta_0(n,k,a,b,\beta)$, we always require λ to be positive and sufficiently small such that

$$\Theta_0(n,k,a,b,\beta) \subset \Theta(n,k,a,b,\lambda,\beta;\alpha). \quad (4)$$

According to Proposition 24 in the appendix, a sufficient condition for (4) is $\lambda \le \frac{a-b}{2\beta k}$. We assume (4) throughout the rest of the paper.

The labels on the n nodes induce a community structure $[n] = \cup_{i=1}^k \mathcal{C}_i$, where $\mathcal{C}_i = \{u \in [n] : \sigma(u) = i\}$ is the i^{th} community with size $n_i = |\mathcal{C}_i|$. Our goal is to reconstruct this partition, or equivalently, to estimate the label of each node modulo any permutation of label symbols. Therefore, a natural error measure is the misclassification proportion defined as

$$\ell(\widehat{\sigma}, \sigma) = \min_{\pi \in S_k} \frac{1}{n} \sum_{u \in [n]} \mathbf{1}_{\{\widehat{\sigma}(u) \neq \pi(\sigma(u))\}}, \quad (5)$$

where S_k stands for the symmetric group on $[k]$ consisting of all permutations of $[k]$.

2.2 Main algorithm

We now present the main method of the paper – a refinement algorithm for community detection in stochastic block model motivated by penalized local maximum likelihood estimation.

To motivate our proposal, for any SBM in the parameter space $\Theta_0(n,k,a,b,1)$ with equal community size, the MLE for σ (Cai and Li, 2014; Chen and Xu, 2014; Zhang and Zhou, 2015) is

$$\widehat{\sigma} = \underset{\sigma:[n]\to[k]}{\operatorname{argmax}} \sum_{u<v} A_{uv}\mathbf{1}_{\{\sigma(u)=\sigma(v)\}}, \tag{6}$$

which is a combinatorial optimization problem and hence is computationally intractable. However, node-wise optimization of (6) has a simple closed form solution. Suppose the values of $\{\sigma(u)\}_{u=2}^n$ are known and we want to estimate $\sigma(1)$. Then, (6) reduces to

$$\widehat{\sigma}(1) = \underset{i\in[k]}{\operatorname{argmax}} \sum_{\{v\neq 1:\sigma(v)=i\}} A_{1v}. \tag{7}$$

For each $i\in[k]$, the quantity $\sum_{\{v\neq1:\sigma(v)=i\}} A_{1v}$ is the number of neighbors that the first node has in the i^{th} community. Therefore, the most likely label for the first node is the one it has the most connections with when all communities are of equal sizes. In practice, we do not know any label in advance. However, we may estimate the labels of all but the first node by first applying a community detection algorithm σ^0 on the subnetwork excluding the first node and its associated edges, the adjacency matrix of which is denoted by A_{-1} since it is the $(n-1)\times(n-1)$ submatrix of A with its first row and first column removed. Once we estimate the remaining labels, we can apply (7) to estimate $\sigma(1)$ but with $\{\sigma(v)\}_{v=2}^n$ replaced with the estimated labels.

For any $u\in[n]$, let A_{-u} denote the $(n-1)\times(n-1)$ submatrix of A with its u^{th} row and u^{th} column removed. Given any community detection algorithm σ^0 which is able to cluster any graph on $n-1$ nodes into k categories, we present the precise description of our refinement scheme in Algorithm 1.

The algorithm works in two consecutive steps. The first step carries out the foregoing heuristics on a node by node basis. For each fixed node u, we first leave the node out and apply the available community detection algorithm σ^0 on the remaining $n-1$ nodes and the edges among them (as summarized in the matrix $A_{-u}\in\{0,1\}^{(n-1)\times(n-1)}$) to obtain an initial community assignment vector σ_u^0. For convenience, we make σ_u^0 an n-vector by fixing $\sigma_u^0(u)=0$, though applying σ^0 on A_{-u} does not give any community assignment for u. We then assign the label of the u^{th} node according to (10), which is essentially (7) with σ replaced with σ_u^0 except for the additional penalty term. The additional penalty term is added to ensure the optimal performance even when both the diagonal and the off-diagonal entries of the connectivity matrix B are allowed to take different values and the community sizes are not necessarily equal. To determine the penalty parameter ρ_u in an adaptive way as spelled out in (11) – (12), we first estimate the connectivity matrix B based on A_{-u} in (8) – (9). After we obtain the community assignment for u, we organize the assignment for all n vertices into an n-vector $\widehat{\sigma}_u$. We call this step "penalized neighbor voting" since the first term on the RHS of (10) counts the number of neighbors of u in each (estimated) community while the second term is a penalty term proportional to the size of each (estimated) community.

Algorithm 1: A refinement scheme for community detection

Input: Adjacency matrix $A\in\{0,1\}^{n\times n}$,
number of communities k,
initial community detection method σ^0.

Output: Community assignment $\widehat{\sigma}$.

Penalized neighbor voting:

for $u=1$ **to** n **do**

Apply σ^0 on A_{-u} to obtain $\sigma_u^0(v)$ for all $v\neq u$ and let $\sigma_u^0(u)=0$;

Define $\widetilde{\mathcal{C}}_i^u=\{v:\sigma_u^0(v)=i\}$ for all $i\in[k]$; let $\widetilde{\mathcal{E}}_i^u$ be the set of edges within $\widetilde{\mathcal{C}}_i^u$, and $\widetilde{\mathcal{E}}_{ij}^u$ the set of edges between $\widetilde{\mathcal{C}}_i^u$ and $\widetilde{\mathcal{C}}_j^u$ when $i\neq j$;

Define

$$\widehat{B}_{ii}^u=\frac{|\widetilde{\mathcal{E}}_i^u|}{\frac{1}{2}|\widetilde{\mathcal{C}}_i^u|(|\widetilde{\mathcal{C}}_i^u|-1)},\quad \widehat{B}_{ij}^u=\frac{|\widetilde{\mathcal{E}}_{ij}^u|}{|\widetilde{\mathcal{C}}_i^u||\widetilde{\mathcal{C}}_j^u|},\quad \forall i\neq j\in[k], \tag{8}$$

and let

$$\widehat{a}_u=n\min_{i\in[k]}\widehat{B}_{ii}^u \quad\text{and}\quad \widehat{b}_u=n\max_{i\neq j\in[k]}\widehat{B}_{ij}^u. \tag{9}$$

Define $\widehat{\sigma}_u:[n]\to[k]$ by setting $\widehat{\sigma}_u(v)=\sigma_u^0(v)$ for all $v\neq u$ and

$$\widehat{\sigma}_u(u)=\underset{l\in[k]}{\operatorname{argmax}}\sum_{\sigma_u^0(v)=l}A_{uv}-\rho_u\sum_{v\in[n]}\mathbf{1}_{\{\sigma_u^0(v)=l\}} \tag{10}$$

where for

$$t_u=\frac{1}{2}\log\frac{\widehat{a}_u(1-\widehat{b}_u/n)}{\widehat{b}_u(1-\widehat{a}_u/n)}, \tag{11}$$

we define

$$\rho_u=-\frac{1}{2t_u}\log\left(\frac{\frac{\widehat{a}_u}{n}e^{-t_u}+1-\frac{\widehat{a}_u}{n}}{\frac{\widehat{b}_u}{n}e^{t_u}+1-\frac{\widehat{b}_u}{n}}\right), \tag{12}$$

end

Consensus:

Define $\widehat{\sigma}(1)=\widehat{\sigma}_1(1)$. For $u=2,\ldots,n$, define

$$\widehat{\sigma}(u)=\underset{l\in[k]}{\operatorname{argmax}}\left|\{v:\widehat{\sigma}_1(v)=l\}\cap\{v:\widehat{\sigma}_u(v)=\widehat{\sigma}_u(u)\}\right|. \tag{13}$$

Once we complete the above procedure for each of the n nodes, we obtain n vectors $\widehat{\sigma}_u \in [k]^n$, $u = 1, \ldots, n$, and turn to the second step of the algorithm. The basic idea behind the second step is to obtain a unified community assignment by assembling $\{\widehat{\sigma}_u(u) : u \in [n]\}$ and the immediate hurdle is that each $\widehat{\sigma}_u$ is only determined up to a permutation of the community labels. Thus, the second step aims to align these different permutations by (13) before we assemble the $\widehat{\sigma}_u(u)$'s. We call this step "consensus" since we are essentially looking for a consensus on the community labels for n possibly different community assignments, under the assumption that all of them are close to the ground truth up to some permutation.

2.3 Initialization via spectral methods

In this section, we present algorithms that can be used as initializers in Algorithm 1. Note that for any model in (3), the matrix P has rank at most k and $\mathbb{E}A_{uv} = P_{uv}$ for all $u \neq v$. We may first reduce the dimension of the data and then apply some clustering algorithm. Such an approach is usually referred to as spectral clustering (von Luxburg, 2007). The application of spectral clustering on network data goes back to Hagen and Kahng (1992); McSherry (2001), and its performance under the stochastic block model has been investigated by Coja-Oghlan (2010); Rohe et al. (2011); Sussman et al. (2012); Fishkind et al. (2013); Qin and Rohe (2013); Joseph and Yu (2013); Lei and Rinaldo (2014); Vu (2014); Chin et al. (2015); Jin (2015); Le et al. (2015), among others. Technically speaking, spectral clustering refers to the general method of clustering eigenvectors of some data matrix. For random graphs, two commonly used methods are unnormalized spectral clustering (USC) and normalized spectral clustering (NSC). The former refers to clustering the eigenvectors of the adjacency matrix A itself and the latter refers to clustering the eigenvectors of the associated graph Laplacian $L(A)$. To formally define the graph Laplacian, we introduce the notation $d_u = \sum_{v\in[n]} A_{uv}$ for the degree of the u^{th} node. The graph Laplacian operator $L : A \mapsto L(A)$ is defined by $L(A) = ([L(A)]_{uv})$ where $[L(A)]_{uv} = d_u^{-1/2} d_v^{-1/2} A_{uv}$. Although there have been debates and studies on which one works better (see, for example, von Luxburg et al. (2008); Sarkar and Bickel (2013)), for our purpose, both of them can lead to sufficiently decent initial estimators.

The performances of USC and NSC depend critically on the bounds $\|A - P\|_{\text{op}}$ and $\|L(A) - L(P)\|_{\text{op}}$, respectively. However, as pointed out by Chin et al. (2015); Le et al. (2015), the matrices A and $L(A)$ are not good estimators of P and $L(P)$ under the operator norm when the graph is sparse in the sense that $\max_{u,v\in[n]} P_{uv} = o(\log n/n)$. Thus, it is necessary to regularize A and $L(A)$ in order to achieve better performances for USC and NSC. The adjacency matrix A can be regularized by trimming those nodes with high degrees. Define the trimming operator $T_\tau : A \mapsto T_\tau(A)$ by replacing the u^{th} row and the u^{th} column of A with 0 whenever $d_u \geq \tau$, and so $T_\tau(A)$ and A are of the same dimensions. It is argued in Chin et al. (2015) that by removing those high-degree nodes, $T_\tau(A)$ has better convergence properties. Regularization method for graph Laplacian goes back to Amini et al. (2013) and its theoretical properties have been studied by Joseph and Yu (2013); Le et al. (2015). In particular, Amini et al. (2013) proposed to use $L(A_\tau)$ for NSC where $A_\tau = A + \frac{\tau}{n}\mathbf{1}\mathbf{1}^T$ and $\mathbf{1} = (1, 1, ..., 1)^T \in \mathbb{R}^n$. From now on, we use USC(τ) and NSC(τ) to denote unnormalized spectral clustering and normalized spectral clustering with

regularization parameter τ, respectively. Note that the unregularized USC is USC(∞) and the unregularized NSC is NSC(0).

Another important issue in spectral clustering lies in the subsequent clustering method used to cluster the eigenvectors. A popular choice is k-means clustering. However, finding the global solution to the k-means problem is NP-hard (Aloise et al., 2009; Mahajan et al., 2009). Kumar et al. (2004) proposed a polynomial time algorithm for achieving $(1 + \epsilon)$ approximation to the k-means problem for any fixed k, which was utilized in Lei and Rinaldo (2014) to establish consistency for spectral clustering under stochastic block models with a fixed number of communities. However, a closer look at the complexity bound suggests that the smallest possible ϵ is proportional to k. Thus, applying the algorithm and the associated bound in Kumar et al. (2004) directly in our settings can lead to inferior error bounds when $k \to \infty$ as $n \to \infty$. To address this issue for stochastic block models, we propose a greedy clustering method in Algorithm 2. The method is inspired by the fact that the clustering centers in stochastic block models are well separated from each other on the population level. It is straightforward to check that the complexity of Algorithm 2 is polynomial in n.

Algorithm 2: A greedy method for clustering

Input: Data matrix $\widehat{U} \in \mathbb{R}^{n\times k}$, either the leading eigenvectors of $T_\tau(A)$ or that of $L(A_\tau)$,
number of communities k,
critical radius $r = \mu\sqrt{\frac{k}{n}}$ with some constant $\mu > 0$.

Output: Community assignment $\widehat{\sigma}$.

Set $S = [n]$;
for $i = 1$ **to** k **do**
  Let $t_i = \arg\max_{u\in S} \left|\left\{v \in S : \left\|\widehat{U}_{v*} - \widehat{U}_{u*}\right\| < r\right\}\right|$;
  Set $\widehat{\mathcal{C}}_i = \left\{v \in S : \left\|\widehat{U}_{v*} - \widehat{U}_{t_i*}\right\| < r\right\}$;
  Label $\widehat{\sigma}(u) = i$ for all $u \in \widehat{\mathcal{C}}_i$;
  Update $S \leftarrow S\backslash\widehat{\mathcal{C}}_i$.
end
If $S \neq \varnothing$, then for any $u \in S$, set $\widehat{\sigma}(u) = \text{argmin}_{i\in[k]} \frac{1}{|\widehat{\mathcal{C}}_i|}\sum_{v\in\widehat{\mathcal{C}}_i} \left\|\widehat{U}_{u*} - \widehat{U}_{v*}\right\|$.

Last but not least, we would like to emphasize that one needs not limit the initialization algorithm to the spectral methods introduced in this section. As Theorem 4 below shows, Algorithm 1 works for any initialization method that satisfies a weak consistency condition.

3. Theoretical properties

Before stating the theoretical properties of the proposed method, we first review the minimax rate in Zhang and Zhou (2015), which serves as the optimality benchmark. The

minimax risk is governed by the following critical quantity,

$$I^* = -2\log\left(\sqrt{\frac{a}{n}}\sqrt{\frac{b}{n}} + \sqrt{1-\frac{a}{n}}\sqrt{1-\frac{b}{n}}\right), \tag{14}$$

which is the Rényi divergence of order $\frac{1}{2}$ between Bern $\left(\frac{a}{n}\right)$ and Bern $\left(\frac{b}{n}\right)$, i.e., Bernoulli distributions with success probabilities $\frac{a}{n}$ and $\frac{b}{n}$ respectively. Recall that $0 < \frac{b}{n} < \frac{a}{n} \le 1-\epsilon$ is assumed throughout the paper. It can be shown that $I^* \asymp \frac{(a-b)^2}{na}$. Moreover, when $\frac{a}{n} = o(1)$,

$$\begin{aligned} I^* &= (1+o(1))\frac{(\sqrt{a}-\sqrt{b})^2}{n} = (1+o(1))\left[\left(\sqrt{\frac{a}{n}}-\sqrt{\frac{b}{n}}\right)^2 + \left(\sqrt{1-\frac{a}{n}}-\sqrt{1-\frac{b}{n}}\right)^2\right] \\ &= (2+o(1))H^2\left(\text{Bern}\left(\tfrac{a}{n}\right), \text{Bern}\left(\tfrac{b}{n}\right)\right), \end{aligned}$$

where $H^2(P,Q) = \frac{1}{2}\int(\sqrt{\mathrm{d}P} - \sqrt{\mathrm{d}Q})^2$ is the squared Hellinger distance between two distributions P and Q. The minimax rate for the parameter spaces (2) and (3) under the loss function (5) is given in the following theorem.

Theorem 1 (Zhang and Zhou (2015)) *When $\frac{(a-b)^2}{ak\log k} \to \infty$, we have*

$$\inf_{\widehat{\sigma}} \sup_{(B,\sigma)\in\Theta} \mathbb{E}_{B,\sigma}\ell(\widehat{\sigma},\sigma) = \begin{cases} \exp\left(-(1+\eta)\frac{nI^*}{2}\right), & k=2; \\ \exp\left(-(1+\eta)\frac{nI^*}{\beta k}\right), & k \ge 3, \end{cases}$$

for both $\Theta = \Theta_0(n,k,a,b,\beta)$ and $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$ with any $\lambda \le \frac{a-b}{2\beta k}$ and any $\beta \in [1,\sqrt{5/3})$, where $\eta = \eta_n \to 0$ is some sequence tending to 0 as $n \to \infty$.

Remark 2 *The assumption $\beta \in [1,\sqrt{5/3})$ is needed in Zhang and Zhou (2015) for some technical reason. Here, the parameter β enters the minimax rates when $k \ge 3$ since the worst case is essentially when one has two communities of size $\frac{n}{\beta k}$, while for $k = 2$, the worst case is essentially two communities of size $\frac{n}{2}$. For all other results in this paper, we allow β to be an arbitrary constant no less than* 1.

Remark 3 *The rate in Theorem 1 is optimal in a minimax sense. It is optimal for the worse-case instances in $\Theta_0(n,k,a,b,1)$. More general instance-optimal fundamental limits are referred to Abbe and Sandon (2015a). Details discussion will be given in Section 5.*

To this end, let us show that the two-stage algorithm proposed in Section 2 achieves the optimal misclassification proportion. The essence of the two-stage algorithm lies in the refinement scheme described in Algorithm 1. As long as any initialization step satisfies a certain weak consistency criterion, the refinement step directly leads to a solution with optimal misclassification proportion. To be specific, the initialization step needs to satisfy the following condition.

Condition 1 *There exist constants $C_0, \delta > 0$ and a positive sequence $\gamma = \gamma_n$ such that*

$$\inf_{(B,\sigma)\in\Theta} \min_{u\in[n]} \mathbb{P}_{B,\sigma}\left\{\ell(\sigma,\sigma_u^0) \le \gamma\right\} \ge 1 - C_0 n^{-(1+\delta)}, \tag{15}$$

for some parameter space Θ.

Under Condition 1, we have the following upper bounds regarding the performance of the proposed refinement scheme.

Theorem 4 *Suppose as $n \to \infty$, $\frac{(a-b)^2}{ak\log k} \to \infty$, $a \asymp b$ and Condition 1 is satisfied for*

$$\gamma = o\left(\frac{1}{k\log k}\right) \tag{16}$$

and $\Theta = \Theta_0(n,k,a,b,\beta)$. Then there is a sequence $\eta \to 0$ such that

$$\begin{aligned} \sup_{(B,\sigma)\in\Theta} \mathbb{P}_{B,\sigma}\left\{\ell(\sigma,\widehat{\sigma}) \ge \exp\left(-(1-\eta)\frac{nI^*}{2}\right)\right\} \to 0, \qquad &\text{if } k = 2, \\ \sup_{(B,\sigma)\in\Theta} \mathbb{P}_{B,\sigma}\left\{\ell(\sigma,\widehat{\sigma}) \ge \exp\left(-(1-\eta)\frac{nI^*}{\beta k}\right)\right\} \to 0, \qquad &\text{if } k \ge 3, \end{aligned} \tag{17}$$

where I^* is defined as in (14).

If in addition Condition 1 is satisfied for γ satisfying both (16) *and*

$$\gamma = o\left(\frac{a-b}{ak}\right) \tag{18}$$

and $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$, then the conclusion in (17) *continues to hold for $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$.*

Theorem 4 assumes $a \asymp b$. The case when $a \asymp b$ may not hold is considered in Section 5. Compared with Theorem 1, the upper bounds (17) achieved by Algorithm 1 is minimax optimal. The condition (16) for the parameter space $\Theta_0(n,k,a,b,\beta)$ is very mild. When $k = O(1)$, it reduces to $\gamma = o(1)$ and simply means that the initialization should be weakly consistent. For $k \to \infty$, it implies that the misclassification proportion within each community converges to zero. Note that if the initialization step gives wrong labels to all nodes in one particular community, then the misclassification proportion is at least $1/k$. The condition (16) rules out this situation. For the parameter space $\Theta(n,k,a,b,\lambda,\beta;\alpha)$, an extra condition (18) is required. This is because estimating the connectivity matrix B in $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ is harder than in $\Theta_0(n,k,a,b,\beta)$. If we do not pursue adaptive estimation, (18) is not needed.

Remark 5 *Theorem 4 is an adaptive result without assuming the knowledge of a and b. When these two parameters are known, we can directly use a and b in (11) of Algorithm 1. By scrutinizing the proof of Theorem 4, the conditions (16) and (18) can be weakened to $\gamma = o(k^{-1})$ in this case.*

Given the results of Theorem 4, it remains to check the initialization step via spectral clustering satisfies Condition 1. For matrix $P = (P_{uv}) = (B_{\sigma(u)\sigma(v)})$ with (B, σ) belonging to either $\Theta_0(n, k, a, b, \beta)$ or $\Theta(n, k, a, b, \lambda, \beta; \alpha)$, we use λ_k to denote $\lambda_k(P)$. Define the average degree by

$$\bar{d} = \frac{1}{n} \sum_{u \in [n]} d_u. \tag{19}$$

Theorem 6 *Assume $e \le a \le C_1 b$ for some constant $C_1 > 0$ and*

$$\frac{ka}{\lambda_k^2} \le c, \tag{20}$$

for some sufficiently small $c \in (0, 1)$. Consider USC(τ) with a sufficiently small constant $\mu > 0$ in Algorithm 2 and $\tau = C_2 \bar{d}$ for some sufficiently large constant $C_2 > 0$. For any constant $C' > 0$, there exists some $C > 0$ only depending on C', C_1, C_2 and μ such that

$$\ell(\widehat{\sigma}, \sigma) \le C \frac{a}{\lambda_k^2},$$

with probability at least $1 - n^{-C'}$. If k is fixed, the same conclusion holds without assuming $a \le C_1 b$.

Remark 7 *Theorem 6 improves the error bound for spectral clustering in Lei and Rinaldo (2014). While Lei and Rinaldo (2014) requires the assumption $a > C \log n$, our result also holds for $a = o(\log n)$. A result close to ours is that by Chin et al. (2015), but their clustering step is different from Algorithm 2. Moreover, the conclusion of Theorem 6 holds with probability $1 - n^{-C'}$ for an arbitrary large C', which is critical because the initialization step needs to satisfy Condition 1 for the subsequent refinement step to work. On the other hand, the bound in Chin et al. (2015) is stated with probability $1 - o(1)$.*

Remark 8 *For the parameter space $\Theta_0(n, k, a, b, \beta)$, we have $\lambda_k \ge \frac{a-b}{\beta k}$. Then, Theorem 6 implies that consistency is achieved when $\frac{(a-b)^2}{a} \to \infty$ in the case $k = O(1)$, and when $\frac{(a-b)^2}{ak^3} > C$ for some sufficiently large $C > 0$ in the case $k \to \infty$.*

When $k = O(1)$, Theorem 4 and Theorem 6 jointly imply the following result.

Corollary 9 *Consider Algorithm 1 initialized by σ^0 with USC(τ) for $\tau = C\bar{d}$, where C is a sufficiently large constant. Suppose as $n \to \infty$, $k = O(1)$, $\frac{(a-b)^2}{a} \to \infty$ and $a \asymp b$. Then, there exists a sequence $\eta \to 0$ such that*

$$\sup_{(B,\sigma) \in \Theta} \mathbb{P}_{B,\sigma} \left\{ \ell(\sigma, \widehat{\sigma}) \ge \exp\left(-(1 - \eta) \frac{nI^*}{2} \right) \right\} \to 0, \qquad \text{if } k = 2,$$

$$\sup_{(B,\sigma) \in \Theta} \mathbb{P}_{B,\sigma} \left\{ \ell(\sigma, \widehat{\sigma}) \ge \exp\left(-(1 - \eta) \frac{nI^*}{\beta k} \right) \right\} \to 0, \qquad \text{if } k \ge 3,$$

where the parameter space is $\Theta = \Theta_0(n, k, a, b, \beta)$.

Compared with Theorem 1, the proposed procedure achieves the minimax rate under the condition $\frac{(a-b)^2}{a} \to \infty$ and $a \asymp b$. When $k = O(1)$, the condition $\frac{(a-b)^2}{a} \to \infty$ is necessary and sufficient for weak consistency in view of Theorem 1. More general results including the case of $k \to \infty$ are stated and discussed in Section 5.

The following theorem characterizes the misclassification rate of normalized spectral clustering.

Theorem 10 *Assume $e \le a \le C_1 b$ for some constant $C_1 > 0$ and*

$$\frac{ka \log a}{\lambda_k^2} \le c, \tag{21}$$

for some sufficiently small $c \in (0, 1)$. Consider NSC(τ) with a sufficiently small constant $\mu > 0$ in Algorithm 2 and $\tau = C_2 \bar{d}$ for some sufficiently large constant $C_2 > 0$. Then, for any constant $C' > 0$, there exists some $C > 0$ only depending on C', C_1, C_2 and μ such that

$$\ell(\widehat{\sigma}, \sigma) \le C \frac{a \log a}{\lambda_k^2},$$

with probability at least $1 - n^{-C'}$. If k is fixed, the same conclusion holds without assuming $a \le C_1 b$.

Remark 11 *A slightly different regularization of normalized spectral clustering is studied by Qin and Rohe (2013) only for the dense regime, while Theorem 10 holds under both dense and sparse regimes. Moreover, our result also improves that of Le et al. (2015) due to our tighter bound on $\|L(A_\tau) - L(P_\tau)\|_{\text{op}}$ in Lemma 22 below. We conjecture that the $\log a$ factor in both the assumption and the bound of Theorem 10 can be removed.*

Note that Theorem 6 and Theorem 10 are stated in terms of the quantity λ_k. We may specialize the results into the parameter spaces defined in (2) and (3). By Proposition 24, $\lambda_k \ge \frac{a-b}{2\beta k}$ for $\Theta_0(n, k, a, b, \beta)$ and $\lambda_k \ge \lambda$ for $\Theta(n, k, a, b, \lambda, \beta; \alpha)$. The implications of Theorem 6 and Theorem 10 and their use as initialization in for Algorithm 1 are discussed in full details in Section 5.

4. Numerical results

In this section we present the performance of the proposed algorithm on simulated datasets. The experiments cover three different scenarios: (1) dense network with communities of equal sizes; (2) dense network with communities of unequal sizes; and (3) sparse network. Recall the definition of $\bar{d}$ in (19). For each setting, we report results of Algorithm 1 initialized with four different approaches: USC(∞), USC($2\bar{d}$), NSC(0) and NSC($\bar{d}$), the description of which can all be found in Section 2.3. For all these spectral clustering methods, Algorithm 2 was used to cluster the leading eigenvectors. The constant μ in the critical radius definition was set to be 0.5 in all the results reported here. For each setting, the results are based on 100 independent draws from the underlying stochastic block model.

To achieve faster running time, we also ran a simplified version of Algorithm 1. Instead of obtaining n different initializers $\{\sigma_u\}_{u \in [n]}$ to refine each node separately, the simplified

algorithm refines all the nodes with a single initialization on the whole network. Thus, the running time can be reduced roughly by a factor of n. Simulation results below suggest that the simplified version achieves similar performances to that of Algorithm 1 in all the settings we have considered. For the precise description of the simplified algorithm, we refer readers to Algorithm 3 in the appendix.

Balanced case In this setting, we generate networks with 2500 nodes and 10 communities, each of which consists of 250 nodes, and we set $B_{ii} = 0.48$ for all i and $B_{ij} = 0.32$ for all $i \neq j$. Figure 1 shows the boxplots of the number of misclassified nodes. The first four boxplots correspond to the four different spectral clustering methods, in the order of USC(∞), USC($2\bar{d}$), NSC(0) and NSC($\bar{d}$). The middle four correspond to the results achieved by applying the simplified refinement scheme with these four initialization methods, and the last four show the results of Algorithm 1 with these four initialization methods. Regardless of the initialization method, Algorithm 1 or its simplified version reduces the number of misclassified nodes from around 30 to around 5.

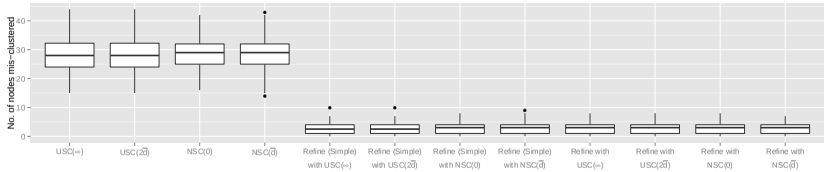

Figure 1: Boxplots of number of misclassified nodes: Balanced case. *Simple* indicates that the simplified version of Algorithm 1 is used instead.

Imbalanced case In this setting, we generate networks with 2000 nodes and 4 communities, the sizes of which are $200, 400, 600$ and 800, respectively. The connectivity matrix is

$$B = \begin{pmatrix} 0.50 & 0.29 & 0.35 & 0.25 \\ 0.29 & 0.45 & 0.25 & 0.30 \\ 0.35 & 0.25 & 0.50 & 0.35 \\ 0.25 & 0.30 & 0.35 & 0.45 \end{pmatrix}.$$

Hence, the within-community edge probability is no smaller than 0.45 while the between-community edge probability is no greater than 0.35, and the underlying SBM is inhomogeneous. Figure 2 shows the boxplots of the number of misclassified nodes obtained by different initialization methods and their refinements, and the boxplots are presented in the same order as those in Figure 1. Similarly, we can see refinement significantly reduces the error.

Sparse case In this setting we consider a much sparser stochastic block model than the previous two cases. In particular, each simulated network has 4000 nodes, divided into 10 communities all of size 400. We set all $B_{ii} = 0.032$ and all $B_{ij} = 0.005$ when

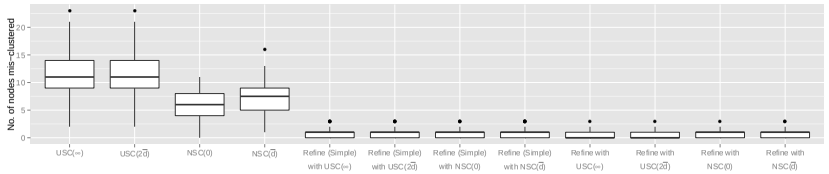

Figure 2: Boxplots of number of misclassified nodes: imbalanced case. *Simple* indicates that the simplified version of Algorithm 1 is used instead.

$i \neq j$. The average degree of each node in the network is around 30. Figure 3 shows the boxplots of the number of misclassified nodes obtained by different initialization methods and their refinements, and the boxplots are presented in the same order as those in Figure 1. Compared with either USC or NSC initialization, refinement reduces the number of misclassified nodes by 50%.

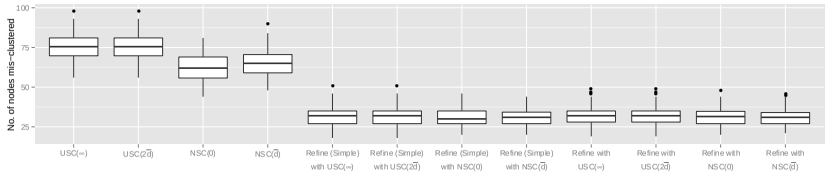

Figure 3: Boxplots of number of misclassified nodes: Sparse case. *Simple* indicates that the simplified version of Algorithm 1 is used instead.

Summary In all three simulation settings, for all four initialization approaches considered, the refinement scheme in Algorithm 1 (and its simplified version) was able to significantly reduce the number of misclassified nodes, which is in agreement with the theoretical properties presented in Section 3.

5. Discussion

In this section, we discuss a few important issues related to the methodology and the theory we have presented in the previous sections.

5.1 Error bounds when $a \asymp b$ may not hold

In Section 3, we established upper bounds on misclassification proportion under the assumption of $a \asymp b$. The following theorem shows that slightly weaker upper bounds can be obtained even when $a \asymp b$ does not hold. To state the result, recall that we assume throughout the paper $\frac{a}{n} \leq 1 - \epsilon$ for some numeric constant $\epsilon \in (0, 1)$.

Theorem 12 *Suppose as $n \to \infty$, $\frac{(a-b)^2}{ak\log k} \to \infty$ and Condition 1 is satisfied for γ satisfying* (16) *and $\Theta = \Theta_0(n,k,a,b,\beta)$. Then for some positive constants c_ϵ and C_ϵ that depend only on ϵ, for any sufficiently small constant $\epsilon_0 \in (0, c_\epsilon)$, if we replace the definition of t_u's in* (11) *with*

$$t_u = \left(\frac{1}{2}\log\frac{\widehat{a}_u(1-\widehat{b}_u/n)}{\widehat{b}_u(1-\widehat{a}_u/n)}\right) \wedge \log\frac{1}{\epsilon_0/2}, \tag{22}$$

then we have

$$\begin{aligned} \sup_{(B,\sigma)\in\Theta} \mathbb{P}_{B,\sigma}\left\{\ell(\sigma,\widehat{\sigma}) \geq \exp\left(-(1-C_\epsilon\epsilon_0)\frac{nI^*}{2}\right)\right\} \to 0, \qquad &\text{if } k = 2, \\ \sup_{(B,\sigma)\in\Theta} \mathbb{P}_{B,\sigma}\left\{\ell(\sigma,\widehat{\sigma}) \geq \exp\left(-(1-C_\epsilon\epsilon_0)\frac{nI^*}{\beta k}\right)\right\} \to 0, \qquad &\text{if } k \geq 3, \end{aligned} \tag{23}$$

where I^* is defined as in (14). *In particular, we can set $C_\epsilon = \frac{10}{3}\frac{2-\epsilon}{\frac{\epsilon}{2}\log\frac{2}{\epsilon}}$ and $c_\epsilon = \min(\frac{1}{10C_\epsilon}, \frac{\epsilon}{2-\epsilon})$.*

If in addition Condition 1 is satisfied for γ satisfying both (16) *and* (18) *and $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$, then the same conclusion holds for $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$.*

Compared with the conclusion (17) in Theorem 4, the vanish sequence η in the exponent of the upper bound is replaced by $C_\epsilon\epsilon_0$, which is guaranteed to be smaller than $\min(0.1, \frac{2}{\log(2/\epsilon)})$ and can be driven to be arbitrarily small by decreasing ϵ_0. To achieve this, the t_u's used in defining the penalty parameters in the penalized neighbor voting step need to be truncated at the value $\log\frac{1}{\epsilon_0/2}$.

5.2 Implications of the results

We now discuss some implications of the results in Theorems 4 – 12.

When using USC as initialization for Algorithm 1, we obtain the following results by combining Theorem 4, Theorem 6 and Theorem 12. Recall that $\bar{d}$ is the average degree of nodes in A defined in (19).

Theorem 13 *Consider Algorithm 1 initialized by σ^0 with USC(τ) with $\tau = C\bar{d}$ for some sufficiently large constant $C > 0$. If as $n \to \infty$, $a \asymp b$ and*

$$\frac{(a-b)^2}{ak^3\log k} \to \infty, \tag{24}$$

then there is a sequence $\eta \to 0$ such that (17) *holds with $\Theta = \Theta_0(n,k,a,b,\beta)$. If as $n \to \infty$, $a \asymp b$ and*

$$\frac{\lambda^2}{ak(\log k + a/(a-b))} \to \infty, \tag{25}$$

then (17) *holds for $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$. If for either parameter space, $a \asymp b$ may not hold but k is fixed and* (24) *or* (25) *holds respectively, then* (23) *holds as long as t_u is replaced by (22) in Algorithm 1.*

Compared with Theorem 1, the minimax optimal performance is achieved under mild conditions. Take $\Theta = \Theta_0(n,k,a,b,\beta)$ for example. For any fixed k, the minimax optimal misclassification proportion is achieved with high probability only under the additional condition of $a \asymp b$. In addition, weak consistency is achieved for fixed k as long as $\frac{(a-b)^2}{a} \to \infty$, regardless of the behavior of $\frac{a}{b}$. This condition is indeed necessary and sufficient for weak consistency. See, for instance, Mossel et al. (2012, 2013b); Yun and Proutiere (2014b); Zhang and Zhou (2015). To achieve strong consistency for fixed k, it suffices to ensure $\ell(\sigma,\widehat{\sigma}) < \frac{1}{n}$ and Theorem 13 implies that it is sufficient to have

$$\liminf_{n\to\infty}\frac{nI^*}{2\log n} > 1, \quad \text{when } k = 2; \quad \liminf_{n\to\infty}\frac{nI^*}{\beta k\log n} > 1, \quad \text{when } k \geq 3, \tag{26}$$

regardless of the behavior of $\frac{a}{b}$. On the other hand, Theorem 1 shows that it is impossible to achieve strong consistency if

$$\limsup_{n\to\infty}\frac{nI^*}{2\log n} < 1, \quad \text{when } k = 2; \quad \limsup_{n\to\infty}\frac{nI^*}{\beta k\log n} < 1, \quad \text{when } k \geq 3. \tag{27}$$

When $\frac{a}{n} = o(1)$, $nI^* = (1+o(1))(\sqrt{a}-\sqrt{b})^2$ and so one can replace nI^* in (26) – (27) with $(\sqrt{a}-\sqrt{b})^2$. In the literature, Abbe et al. (2014) and Mossel et al. (2014) obtained comparable strong consistency results via efficient algorithms for the special case of two communities of equal sizes, i.e., $k = 2$ and $\beta = 1$. Abbe and Sandon (2015a) investigated the case of fixed k and $\beta \geq 1$. Their results give necessary and sufficient conditions for each instance of model parameters. In comparison, our result characterizes minimax optimality through worst case analysis and is less general than those of Abbe and Sandon (2015a). On the other hand, compared with Abbe and Sandon (2015a), we allow any fixed k and any $\beta \geq 1$ without assuming $a \asymp b \asymp \log n$. In the weak consistency regime, in terms of misclassification proportion, for the special case of $k = 2$ and $\beta = 1$, Yun and Proutiere (2014a) achieved the optimal rate for $\Theta_0(n,2,a,b,1)$ when $a \asymp b \asymp a - b$, while the error bounds in other papers are typically off by a constant multiplier on the exponent. In comparison, Theorem 13 provides optimal results (17) and near optimal results (23) for a much broader class of models under much weaker conditions. Last but not least, our algorithm can provably achieve strong consistency and minimax optimal performance even for growing k, which to our limited knowledge, is the first in the literature.

The performance of Algorithm 1 initialized by NSC can be summarized as the following theorem by combining Theorem 4, Theorem 10 and Theorem 12. In this case, the sufficient condition for achieving minimax optimal performance is slightly stronger than when USC is used for initialization.

Theorem 14 *Consider Algorithm 1 initialized by σ^0 with NSC(τ) with $\tau = C\bar{d}$ for some sufficiently large constant $C > 0$. If as $n \to \infty$, $a \asymp b$ and*

$$\frac{(a-b)^2}{ak^3\log k\log a} \to \infty, \tag{28}$$

then there is a sequence $\eta \to 0$ such that (17) *holds with $\Theta = \Theta_0(n,k,a,b,\beta)$. If as $n \to \infty$, $a \asymp b$ and*

$$\frac{\lambda^2}{ak\log a(\log k + a/(a-b))} \to \infty, \tag{29}$$

then (17) *holds for* $\Theta = \Theta(n, k, a, b, \lambda, \beta; \alpha)$. *If for either parameter space,* $a \asymp b$ *may not hold but* k *is fixed and* (28) *or* (29) *holds respectively, then* (23) *holds as long as* t_u *is replaced by (22) in Algorithm 1.*

Last but not least, we would like to point out that when the key parameters a and b are known, we can obtain the desired performance guarantee under weaker conditions as summarized in the following theorem.

Theorem 15 (The case of known a, b**)** *Suppose* a, b *are known. Consider Algorithm 1 initialized by* σ^0 *with USC(*τ*) with* $\tau = Ca$ *for some sufficiently large constant* $C > 0$ *and* $\widehat{a}_u = a$, $\widehat{b}_u = b$ *in* (9) *for all* $u \in [n]$. *If as* $n \to \infty$, $a \asymp b$ *and*

$$\frac{(a-b)^2}{ak^3} \to \infty, \tag{30}$$

then there is a sequence $\eta \to 0$ *such that* (17) *holds with* $\Theta = \Theta_0(n, k, a, b, \beta)$. *If as* $n \to \infty$, $a \asymp b$ *and*

$$\frac{\lambda^2}{ak} \to \infty, \tag{31}$$

then (17) *holds with* $\Theta = \Theta(n, k, a, b, \lambda, \beta; \alpha)$. *If for either parameter space without assuming* $a \asymp b$, (30) *or* (31) *holds respectively, then* (23) *holds if in addition* t_u *is replaced by* (22).

If instead NSC(τ*) is used for initialization with* $\tau = Ca$ *for some sufficiently large constant* $C > 0$, *then the above conclusions hold if we replace* (30) *with* $\frac{(a-b)^2}{ak^3 \log a} \to \infty$ *and* (31) *with* $\frac{\lambda^2}{ak \log a} \to \infty$, *respectively.*

6. Proofs of main results

The main result of the paper, Theorem 4, is proved in Section 6.1. Theorem 6 and Theorem 10 are proved in Section 6.2 and Section 6.3 respectively. The proofs of the remaining results, together with some auxiliary lemmas, are given in the appendix.

6.1 Proof of Theorem 4

We first state a lemma that guarantees the accuracy of parameter estimation in Algorithm 1.

Lemma 16 *Let* $\Theta = \Theta(n, k, a, b, \lambda, \beta; \alpha)$. *Suppose as* $n \to \infty$, $\frac{(a-b)^2}{ak} \to \infty$ *and Condition 1 holds with* γ *satisfying* (16) *and* (18). *Then there is a sequence* $\eta \to 0$ *as* $n \to \infty$ *and a constant* $C > 0$ *such that*

$$\min_{u \in [n]} \inf_{(B,\sigma) \in \Theta} \mathbb{P}\left\{ \min_{\pi \in S_k} \max_{i,j \in [k]} |\widehat{B}^u_{ij} - B_{\pi(i)\pi(j)}| \le \eta \left(\frac{a-b}{n} \right) \right\} \ge 1 - Cn^{-(1+\delta)}. \tag{32}$$

For $\Theta = \Theta_0(n, k, a, b, \beta)$, *the conclusion* (32) *continues to hold even when the assumption* (18) *is dropped.*

Proof 1° Let $\Theta = \Theta(n, k, a, b, \lambda, \beta; \alpha)$. For any community assignments σ_1 and σ_2, define

$$\ell_0(\sigma_1, \sigma_2) = \frac{1}{n} \sum_{u=1}^{n} \mathbf{1}_{\{\sigma_1(u) \neq \sigma_2(u)\}}. \tag{33}$$

Fix any $(B, \sigma) \in \Theta$ and $u \in [n]$. Define event

$$E_u = \left\{ \ell_0(\pi_u(\sigma), \sigma^0_u) \le \gamma \right\}. \tag{34}$$

To simplify notation, assume that $\pi_u = \mathrm{Id}$ is the identity permutation.

Fix any $i \in [k]$. On E_u,

$$n_i \ge |\widetilde{\mathcal{C}}^u_i \cap \mathcal{C}_i| \ge n_i - \gamma_1 n, \ |\widetilde{\mathcal{C}}^u_i \cap \mathcal{C}^c_i| \le \gamma_2 n, \quad \text{where } \gamma_1, \gamma_2 \ge 0 \text{ and } \gamma_1 + \gamma_2 \le \gamma. \tag{35}$$

Let $\mathcal{C}'_i$ be any deterministic subset of $[n]$ such that (35) holds with $\widetilde{\mathcal{C}}^u_i$ replaced by $\mathcal{C}'_i$. By definition, there are at most

$$\sum_{l=0}^{\gamma n} \binom{n_i}{l} \sum_{m=0}^{\gamma n} \binom{n-n_i}{m} \le (\gamma n + 1)^2 \left(\frac{en_i}{\gamma n} \right)^{\gamma n} \left(\frac{en}{\gamma n} \right)^{\gamma n} \le \exp\left\{ 2\log(\gamma n + 1) + 2\gamma n \log \frac{e}{\gamma} \right\}$$
$$\le \exp\left\{ C_1 \gamma n \log \frac{1}{\gamma} \right\}$$

different subsets with this property where $C_1 > 0$ is an absolute constant. Let $\mathcal{E}'_i$ be the edges within $\mathcal{C}'_i$. Then $|\mathcal{E}'_i|$ consists of independent Bernoulli random variables, where at least $(1-\beta\gamma k)^2$ proportion of them follow the $\mathrm{Bern}(B_{ii})$ distribution, at most $(\beta\gamma k)^2$ proportion that are stochastically smaller than $\mathrm{Bern}(\frac{\alpha a}{n})$ and stochastically larger than $\mathrm{Bern}(\frac{a}{n})$, and at most $2\beta\gamma k$ proportion are stochastically smaller than $\mathrm{Bern}(\frac{b}{n})$. Therefore, we obtain that

$$(1-\beta\gamma k)^2 B_{ii} + (\beta\gamma k)^2 \frac{a}{n} \le \mathbb{E}\left[\frac{|\mathcal{E}'_i|}{\frac{1}{2}|\mathcal{C}'_i|(|\mathcal{C}'_i|-1)} \right] \le \max_{t \in [0, \beta\gamma k]} \left\{ (1-t)^2 B_{ii} + t^2 \frac{\alpha a}{n} + 2t \frac{b}{n} \right\}. \tag{36}$$

Note that the LHS is $(1 - (2 + o(1))\beta\gamma k) B_{ii}$. On the other hand, under condition (18), the RHS is attained at $t = 0$ and equals B_{ii} exactly. Thus, we conclude that

$$\left| \mathbb{E}\left[\frac{|\mathcal{E}'_i|}{\frac{1}{2}|\mathcal{C}'_i|(|\mathcal{C}'_i|-1)} \right] - B_{ii} \right| \le C\beta\gamma k \frac{\alpha a}{n} = \eta' \left(\frac{a-b}{n} \right) \tag{37}$$

for some $\eta' \to 0$ that depends only on a, k, α, β and γ, where the last inequality is due to (18).

On the other hand, by Bernstein's inequality, for any $t > 0$,

$$\mathbb{P}\left\{ \left| |\mathcal{E}'_i| - \mathbb{E}|\mathcal{E}'_i| \right| > t \right\} \le 2\exp\left\{ -\frac{t^2}{2(\frac{1}{2}(n_i + \gamma n)^2 \frac{\alpha a}{n} + \frac{2}{3}t)} \right\}.$$

Let

$$t^2 = (n_i+\gamma n)^2\frac{\alpha a}{n}(C_1\gamma n\log\gamma^{-1}+(3+\delta)\log n)\vee(2C_1\gamma n\log\gamma^{-1}+2(3+\delta)\log n)^2$$
$$\lesssim \left(\frac{n}{k}\sqrt{a\gamma\log\gamma^{-1}}+\gamma n\log\gamma^{-1}\right)^2,$$

where we the second inequality holds since $\frac{\log x}{x}$ is monotone decreasing as x increases and so $\gamma\log\gamma^{-1}\geq\frac{1}{n}\log n$ for any $\gamma\geq\frac{1}{n}$, which is the case of most interest since $\gamma<\frac{1}{n}$ leads to $\gamma=0$ and so the initialization is already perfect. Even when $\gamma=0$, we can still continue to the following arguments by replacing every γ with $\frac{1}{n}$ and all the steps continue to hold. Thus, we obtain that for positive constant $C_{\alpha,\beta,\delta}$ that depends only on α,β and δ,

$$\mathbb{P}\left\{\left||\mathcal{E}_i'|-\mathbb{E}|\mathcal{E}_i'|\right|>C_{\alpha,\beta,\delta}\left(\frac{n}{k}\sqrt{a\gamma\log\gamma^{-1}}+\gamma n\log\gamma^{-1}\right)\right\}\leq\exp\left\{-C_1\gamma n\log\gamma^{-1}\right\}n^{-(3+\delta)}. \tag{38}$$

Thus, with probability at least $1-\exp\left\{-C_1\gamma n\log\gamma^{-1}\right\}n^{-(3+\delta)}$,

$$\left|\frac{|\mathcal{E}_i'|}{\frac{1}{2}|\mathcal{C}_i'|(|\mathcal{C}_i'|-1)}-\mathbb{E}\frac{|\mathcal{E}_i'|}{\frac{1}{2}|\mathcal{C}_i'|(|\mathcal{C}_i'|-1)}\right|\leq C_{\alpha,\beta,\delta}\left(\frac{k}{n}\sqrt{a\gamma\log\gamma^{-1}}+\frac{k^2\gamma\log\gamma^{-1}}{n}\right)=\eta'\left(\frac{a-b}{n}\right), \tag{39}$$

where $\eta'\to0$ depends only on a,k,α,β,γ and δ. Here, the last inequality holds since

$$k\sqrt{a\gamma\log\gamma^{-1}}=\sqrt{ak}\sqrt{k\gamma\log\gamma^{-1}},$$

where $\sqrt{ak}\ll a-b$ since $\frac{(a-b)^2}{ak}\to\infty$ and $k\gamma\log\gamma^{-1}=O(1)$, and

$$k^2\gamma\log\gamma^{-1}=k\gamma\log\gamma^{-1}\cdot k\lesssim k\ll\frac{(a-b)^2}{a}\lesssim a-b.$$

We combine (37) and (39) and apply the union bound to obtain that for a sequence $\eta\to0$ that depends only on a,k,α,β,γ and δ, with probability at least $1-n^{-(3+\delta)}$

$$\left|\frac{|\widetilde{\mathcal{E}}_i^u|}{\frac{1}{2}|\widetilde{\mathcal{C}}_i^u|(|\widetilde{\mathcal{C}}_i^u|-1)}-B_{ii}\right|\leq\eta\left(\frac{a-b}{n}\right). \tag{40}$$

The proof for B_{ij} estimation is analogous and hence is omitted. A final union bound on $i,j\in[k]$ leads to the desired claim since all the constants and vanishing sequences in the above analysis depend only on $a,b,k,\alpha,\beta,\gamma$ and δ, but not on u, B or σ.

2° If $\Theta=\Theta_0(n,k,a,b,\beta)$, then condition (18) on γ is no longer needed. This is because (36) can be replaced by

$$\min_{t\in[0,\beta\gamma k]}\left\{(1-t)^2\frac{a}{n}+2t(1-t)\frac{b}{n}+t^2\frac{b}{n}\right\}$$
$$\leq\mathbb{E}\left[\frac{|\mathcal{E}_i'|}{\frac{1}{2}|\mathcal{C}_i'|(|\mathcal{C}_i'|-1)}\right]\leq\max_{t\in[0,\beta\gamma k]}\left\{(1-t)^2\frac{a}{n}+t^2\frac{a}{n}+2t(1-t)\frac{b}{n}\right\},$$

where the LHS equals $\frac{a}{n}-(1-\beta\gamma k(1+o(1)))\frac{a-b}{n}=\frac{a}{n}+o(\frac{a-b}{n})$ and the RHS equals $\frac{a}{n}$. Thus, no additional condition is needed to guarantee (37) in the foregoing arguments. This completes the proof. ■

The next two lemmas establish the desired error bound for the node-wise refinement.

Lemma 17 *Let Θ_0 be defined as in (2) and $k\geq2$. Suppose as $n\to\infty$, $\frac{(a-b)^2}{ak}\to\infty$ and $a\asymp b$. If there exists two sequences $\gamma=o(1/k)$ and $\eta=o(1)$, constants $C,\delta>0$ and permutations $\{\pi_u\}_{u=1}^n\subset S_k$ such that*

$$\inf_{(B,\sigma)\in\Theta_0}\min_{u\in[n]}\mathbb{P}\left\{\ell_0(\pi_u(\sigma),\sigma_u^0)\leq\gamma,\ |\widehat{a}_u-a|\leq\eta(a-b),\ |\widehat{b}_u-b|\leq\eta(a-b)\right\}\geq1-Cn^{-(1+\delta)}. \tag{41}$$

Then for $\widehat{\sigma}_u(u)$ defined as in (10) with $\rho=\rho_u$ in (12), there is a sequence $\eta'=o(1)$ such that for $k=2$,

$$\sup_{(B,\sigma)\in\Theta_0}\max_{u\in[n]}\mathbb{P}\left\{\widehat{\sigma}_u(u)\neq\pi_u(\sigma(u))\right\}\leq(k-1)\exp\left\{-(1-\eta')\frac{nI^*}{2}\right\}+Cn^{-(1+\delta)},$$

and for $k\geq3$,

$$\sup_{(B,\sigma)\in\Theta_0}\max_{u\in[n]}\mathbb{P}\left\{\widehat{\sigma}_u(u)\neq\pi_u(\sigma(u))\right\}\leq(k-1)\exp\left\{-(1-\eta')\frac{nI^*}{\beta k}\right\}+Cn^{-(1+\delta)}.$$

Proof In what follows, let E_u denote the event in (41). For the sake of brevity, we let $p=a/n$, $q=b/n$, $\widehat{p}_u=\widehat{a}_u/n$ and $\widehat{q}_u=\widehat{b}_u/n$. Moreover, let $\sigma_u=\pi_u(\sigma)$, $n_i=|\{v:\sigma_u(v)=i\}|$, $m_i=|\{v:\sigma_u^0(v)=i\}|$ and $m_i'=|\{v:\sigma_u^0(v)=\sigma_u(v)=i\}|$. Without loss of generality, let $\sigma_u(u)=1$.

Then we have

$$\mathbb{P}\left\{\widehat{\sigma}_u(u)\neq1\text{ and }E_u\right\}\leq\sum_{l\neq1}\mathbb{P}\left\{E_u\text{ and }\sum_{\sigma_u(v)=l}A_{uv}-\sum_{\sigma_u(v)=1}A_{uv}\geq\rho_u(m_l-m_1)\right\}=\sum_{l\neq1}p_l. \tag{42}$$

Now we bound each p_l. By the independence structure and Chernoff bound, we have

$$\begin{aligned}p_l &\leq \mathbb{E}\Big\{\exp\left(-t_u\rho_u(m_l-m_1)\right)(qe^{t_u}+1-q)^{m_l'}(pe^{t_u}+1-p)^{m_l-m_l'}\\ &\qquad(pe^{-t_u}+1-p)^{m_1'}(qe^{-t_u}+1-q)^{m_1-m_1'}\mathbf{1}_{\{E_u\}}\Big\} &(43)\\ &\leq \mathbb{E}\left\{\exp\left(-t_u\rho_u(m_l-m_1)\right)(qe^{t_u}+1-q)^{m_l}(pe^{-t_u}+1-p)^{m_1}\mathbf{1}_{\{E_u\}}\right\} &(44)\\ &\quad\times\mathbb{E}\left\{\left(\frac{pe^{t_u}+1-p}{qe^{t_u}+1-q}\right)^{m_l-m_l'}\left(\frac{qe^{-t_u}+1-q}{pe^{-t_u}+1-p}\right)^{m_1-m_1'}\mathbf{1}_{\{E_u\}}\right\}. &(45)\end{aligned}$$

We are going to give bounds for the terms in (44) and (45) respectively. Before doing that, we need some preparatory inequalities. Define t^* through the equation

$$e^{t^*}=\sqrt{\frac{p(1-q)}{q(1-p)}}.$$

Then, on the event E_u,

$$e^{t_u - t^*} + e^{t^* - t_u} \le \exp(C_1 \eta), \tag{46}$$

for some constant $C_1 > 0$. Moreover,

$$|e^{t_u} - 1| \vee |e^{-t_u} - 1| \le C_2 \frac{p-q}{p} = C_2 \frac{a-b}{a}, \tag{47}$$

for some constant $C_2 > 0$. Therefore, for the term in (44), on the event E_u,

$$\begin{aligned} & \exp\left(-t_u \rho_u (m_l - m_1)\right) \left(qe^{t_u} + 1 - q\right)^{m_l} \left(pe^{-t_u} + 1 - p\right)^{m_1} \\ = \; & \exp\left(-t_u \rho_u (m_l - m_1)\right) \left(qe^{t_u} + 1 - q\right)^{(m_l - m_1)/2} \left(pe^{-t_u} + 1 - p\right)^{(m_1 - m_l)/2} \qquad (48) \\ & \times \left(qe^{t_u} + 1 - q\right)^{(m_1 + m_l)/2} \left(pe^{-t_u} + 1 - p\right)^{(m_1 + m_l)/2}. \qquad (49) \end{aligned}$$

By (46), the term in (49) is upper bounded by

$$\begin{aligned} & \left(pq + (1-p)(1-q) + \sqrt{pq}\sqrt{(1-p)(1-q)}(e^{t_u - t^*} + e^{t^* - t_u})\right)^{\frac{m_1 + m_l}{2}} \\ & \le \exp\left(-(1+o(1))\frac{m_1 + m_l}{2} I^*\right) \le \exp\left(-(1+o(1))\frac{n_1 + n_l}{2} I^*\right). \end{aligned}$$

By (47), the term in (48) is upper bounded by

$$\begin{aligned} & \exp\left(-t_u \rho_u (m_l - m_1)\right) \left(qe^{t_u} + 1 - q\right)^{(m_l - m_1)/2} \left(pe^{-t_u} + 1 - p\right)^{(m_1 - m_l)/2} \\ = \; & \exp\left(\frac{m_1 - m_l}{2}\left(\log \frac{pe^{-t_u} + 1 - p}{qe^{t_u} + 1 - q} - \log \frac{\widehat{p}_u e^{-t_u} + 1 - \widehat{p}_u}{\widehat{q}_u e^{t_u} + 1 - \widehat{q}_u}\right)\right) \\ \le \; & \exp\left(\frac{|m_1 - m_l|}{2}\left(|e^{-t_u} - 1||\widehat{p}_u - p| + |e^{t_u} - 1||\widehat{q}_u - q|\right)\right) \\ \le \; & \exp\left(o\left(\frac{n}{k}\frac{(p-q)^2}{p}\right)\right) \\ = \; & \exp\left(o(1)\frac{n_1 + n_l}{2} I^*\right). \end{aligned}$$

Therefore, we can upper bound (44) as

$$\mathbb{E}\left\{e^{-t_u \rho_u (m_l - m_1)} (qe^{t_u} + 1 - q)^{m_l} (pe^{-t_u} + 1 - p)^{m_1} \mathbf{1}_{\{E_u\}}\right\} \le \exp\left(-(1+o(1))\frac{n_1 + n_l}{2} I^*\right). \tag{50}$$

Now we provide an upper bound for (45). By (47), on E_u,

$$\frac{pe^{t_u} + 1 - p}{qe^{t_u} + 1 - q} = 1 + \frac{(p-q)(e^{t_u} - 1)}{qe^{t_u} + 1 - q} \le 1 + O\left(\frac{(p-q)^2}{p}\right) \le \exp\left(O\left(\frac{(p-q)^2}{p}\right)\right),$$

and

$$\frac{qe^{-t_u} + 1 - q}{pe^{-t_u} + 1 - p} = 1 + \frac{(p-q)(1 - e^{-t_u})}{pe^{-t_u} + 1 - p} \le 1 + O\left(\frac{(p-q)^2}{p}\right) \le \exp\left(O\left(\frac{(p-q)^2}{p}\right)\right).$$

Therefore,

$$\mathbb{E}\left\{\left(\frac{pe^{t_u} + 1 - p}{qe^{t_u} + 1 - q}\right)^{m_l - m_l'} \left(\frac{qe^{-t_u} + 1 - q}{pe^{-t_u} + 1 - p}\right)^{m_1 - m_1'} \mathbf{1}_{\{E_u\}}\right\} \le \exp\left(o(1)\frac{n_1 + n_l}{2} I^*\right). \tag{51}$$

By combining (50) and (51), we have

$$p_l \le \exp\left(-(1+o(1))\frac{n_1 + n_l}{2} I^*\right). \tag{52}$$

Using (42), this implies

$$\mathbb{P}\left\{\widehat{\sigma}_u(u) \ne 1 \text{ and } E_u\right\} \le (k-1)\exp\left(-(1+o(1))\min_{l \ne 1}\left(\frac{n_1 + n_l}{2}\right) I^*\right),$$

and so

$$\mathbb{P}\left\{\widehat{\sigma}_u(u) \ne 1\right\} \le (k-1)\exp\left(-(1+o(1))\min_{l \ne 1}\left(\frac{n_1 + n_l}{2}\right) I^*\right) + Cn^{-(1+\delta)}.$$

When $k = 2$, $\min_{l \ne 1}\left(\frac{n_1 + n_l}{2}\right) = \frac{n}{2}$, and when $k \ge 3$, $\min_{l \ne 1}\left(\frac{n_1 + n_l}{2}\right) \ge \frac{n}{\beta k}$. Thus, the proof is complete. ■

Lemma 18 *Let Θ be defined as in (3) and $k \ge 2$. Suppose as $n \to \infty$, $\frac{(a-b)^2}{ak} \to \infty$ and $a \asymp b$. If there exists two sequences $\gamma = o\left(\frac{a-b}{ak}\right)$ and $\eta = o(1)$, constants $C, \delta > 0$ and permutations $\{\pi_u\}_{u=1}^n \subset S_k$ such that (41) holds. Then for $\widehat{\sigma}_u(u)$ defined as in (10) with $\rho = \rho_u$ in (12), the conclusions of Lemma 17 continue to hold.*

Proof The proof is similar to that of Lemma 17 and we use the same notation as there. First, we give a bound for p_l defined in (42). Let $X_j \sim \text{Bern}(q)$, $Y_j \sim \text{Bern}(p)$ and $Z_j \sim \text{Bern}(\alpha p)$, $j \ge 1$, be mutually independent. Then, a stochastic order argument gives

$$\begin{aligned} p_l \; \le \; & \mathbb{E}\left[\mathbb{P}\left\{\sum_{j=1}^{m_l'} X_j + \sum_{j=1}^{m_l - m_l'} Z_j - \sum_{j=1}^{m_1'} Y_j \ge \rho(m_l - m_1) \text{ and } E_u \middle| A_{-u}\right\}\right] \\ \le \; & \mathbb{E}\left\{\exp\left(-t_u \rho_u (m_l - m_1)\right)\left(qe^{t_u} + 1 - q\right)^{m_l}\left(pe^{-t_u} + 1 - p\right)^{m_1} \mathbf{1}_{\{E_u\}}\right\} \qquad (53) \\ & \times \mathbb{E}\left\{\left(\frac{1}{qe^{t_u} + 1 - q}\right)^{m_l - m_l'} \left(\frac{1}{pe^{-t_u} + 1 - p}\right)^{m_1 - m_1'} \right. \qquad (54) \\ & \left. (\alpha p e^{t_u} + 1 - \alpha p)^{m_l - m_l'} \mathbf{1}_{\{E_u\}}\right\}. \end{aligned}$$

Note that the term in (53) is the same as that in (44), and thus it can be upper bounded by (50) as before. To bound for (54), observe that by (47),

$$\frac{1}{qe^{t_u} + 1 - q} \le \exp\left(q|e^{t_u} - 1|\right) \le \exp\left(O(p-q)\right),$$

$$\frac{1}{pe^{-t_u}+1-p} \le \exp\left(Cp|e^{-t_u}-1|\right) \le \exp\left(O(p-q)\right)$$

and

$$\alpha p e^{t_u} + 1 - \alpha p \le \exp\left(\alpha p|e^{t_u}-1|\right) \le \exp\left(O(p-q)\right).$$

Thus, under the assumption $\gamma = o\left(\frac{p-q}{kp}\right)$, the term (54) is bounded by $\exp\left(o(1)\frac{n_1+n_l}{2}I^*\right)$. The remaining proof is the same as that of Lemma 17. ■

Finally, we need a lemma to justify the consensus step in Algorithm 1.

Lemma 19 *For any community assignments σ and σ': $[n] \to [k]$, such that for some constant $C \ge 1$*

$$\min_{l\in[k]} |\{u : \sigma(u) = l\}|, \min_{l\in[k]} |\{u : \sigma'(u) = l\}| \ge \frac{n}{Ck}, \quad \text{and} \quad \min_{\pi\in S_k} \ell_0(\sigma, \pi(\sigma')) < \frac{1}{Ck}.$$

Define map $\xi : [k] \to [k]$ as

$$\xi(i) = \operatorname*{argmax}_l \left|\{u : \sigma(u) = l\} \cap \{u : \sigma'(u) = i\}\right|, \quad \forall i \in [k]. \tag{55}$$

Then $\xi \in S_k$ and $\ell_0(\sigma, \xi(\sigma')) = \min_{\pi\in S_k} \ell_0(\sigma, \pi(\sigma'))$.

Proof By the definition in (55), we obtain

$$\xi = \operatorname*{argmin}_{\xi':[k]\to[k]} \ell_0(\sigma, \xi'(\sigma')), \quad \text{and} \quad \ell_0(\sigma, \xi(\sigma')) \le \min_{\pi\in S_k} \ell_0(\sigma, \pi(\sigma')) < \frac{1}{Ck}.$$

Thus, what remains to be shown is that $\xi \in S_k$, i.e., $\xi(l_1) \ne \xi(l_2)$ for any $l_1 \ne l_2$. To this end, note that if for some $l_1 \ne l_2$, $\xi(l_1) = \xi(l_2)$, then there would exist some $l_0 \in [k]$ such that for any $l \in [k]$, $\xi(l) \ne l_0$, and so

$$\ell_0(\sigma, \xi(\sigma')) \ge \frac{1}{n} \sum_{u:\sigma(u)=l_0} \mathbf{1}_{\{\sigma(u)\ne\xi(\sigma'(u))\}} = \frac{|\{u : \sigma(u) = l_0\}|}{n} \ge \frac{1}{Ck}.$$

This is in contradiction to the second last display, and hence $\xi \in S_k$. This completes the proof. ■

Proof [Proof of Theorem 4] Let $\Theta = \Theta(n, k, a, b, \lambda, \beta; \alpha)$, and fix any $(B, \sigma) \in \Theta$. For any $u \in [n]$, by Condition 1 and the fact that σ_u^0 and $\widehat{\sigma}_u$ differ only at the community assignment of u, for $\gamma' = \gamma + 1/n$, there exists some $\pi_u \in S_k$ such that

$$\mathbb{P}\left\{\ell_0(\sigma, \pi_u^{-1}(\widehat{\sigma}_u)) \le \gamma_n'\right\} \ge 1 - C_0 n^{-(1+\delta)}. \tag{56}$$

Without loss of generality, we assume $\pi_1 = \mathrm{Id}$ is the identity map. Now for any fixed $u \in \{2, \ldots, n\}$, define map $\xi_u : [k] \to [k]$ as in (55) with σ and σ' replaced by $\widehat{\sigma}_1$ and $\widehat{\sigma}_u$. Then by definition

$$\widehat{\sigma}(u) = \xi_u(\widehat{\sigma}_u(u)). \tag{57}$$

In addition, (56) implies with probability at least $1 - Cn^{-(1+\delta)}$, we have

$$\ell_0(\sigma, \widehat{\sigma}_1) \le \gamma' \quad \text{and} \quad \ell_0(\sigma, \pi_u^{-1}(\widehat{\sigma}_u)) \le \gamma'.$$

So the triangle inequality implies $\ell_0(\widehat{\sigma}_1, \pi_u^{-1}(\widehat{\sigma}_u)) \le 2\gamma'$ and hence the condition of Lemma 19 is satisfied. Thus, Lemma 19 implies

$$\mathbb{P}\left\{\xi_u = \pi_u^{-1}\right\} \ge 1 - Cn^{-(1+\delta)}. \tag{58}$$

When $k \ge 3$, Lemma 16, (16) and (18) imply that the condition of Lemma 18 is satisfied, which in turn implies that for a sequence $\eta' = o(1)$,

$$\begin{aligned}
\mathbb{P}\{\widehat{\sigma}(u) \ne \sigma(u)\} &= \mathbb{P}\{\xi_u(\widehat{\sigma}_u(u)) \ne \sigma(u)\} \\
&\le \mathbb{P}\left\{\xi_u(\widehat{\sigma}_u(u)) \ne \sigma(u), \xi_u = \pi_u^{-1}\right\} + \mathbb{P}\left\{\xi_u \ne \pi_u^{-1}\right\} \\
&\le \mathbb{P}\{\widehat{\sigma}_u(u) \ne \pi_u(\sigma(u))\} + \mathbb{P}\left\{\xi_u \ne \pi_u^{-1}\right\} \\
&\le Cn^{-(1+\delta)} + (k-1)\exp\left\{-(1-\eta')\frac{nI^*}{\beta k}\right\}.
\end{aligned}$$

Set

$$\eta = \eta' + \beta\sqrt{\frac{k}{nI^*}} = o(1) \tag{59}$$

where the last inequality holds since $\frac{nI^*}{k} \asymp \frac{(a-b)^2}{ak} \to \infty$. Thus, Markov's inequality leads to

$$\begin{aligned}
&\mathbb{P}\left\{\ell_0(\sigma, \widehat{\sigma}) > (k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}\right\} \\
&\quad\le \frac{1}{(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}} \frac{1}{n}\sum_{u=1}^n \mathbb{P}\{\widehat{\sigma}(u) \ne \sigma(u)\} \\
&\quad\le \exp\left\{-(\eta-\eta')\frac{nI^*}{\beta k}\right\} + \frac{Cn^{-(1+\delta)}}{(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}} \\
&\quad\le \exp\left\{-\sqrt{\frac{nI^*}{k}}\right\} + \frac{Cn^{-(1+\delta)}}{(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}}.
\end{aligned}$$

If $(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\} \ge n^{-(1+\delta/2)}$, then

$$\mathbb{P}\left\{\ell_0(\sigma, \widehat{\sigma}) > (k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}\right\} \le \exp\left\{-\sqrt{\frac{nI^*}{k}}\right\} + Cn^{-\delta/2} = o(1).$$

If $(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\} < n^{-(1+\delta/2)}$, then

$$\begin{aligned}
\mathbb{P}\left\{\ell_0(\sigma, \widehat{\sigma}) > (k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\}\right\} &= \mathbb{P}\{\ell_0(\sigma, \widehat{\sigma}) > 0\} \le \sum_{u=1}^n \mathbb{P}\{\widehat{\sigma}(u) \ne \sigma(u)\} \\
&\le n(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\} + Cn^{-\delta} \le Cn^{-\delta/2} = o(1).
\end{aligned}$$

Here, the second last inequality holds since $\eta > \eta'$ and so $(k-1)\exp\{-(1-\eta')nI^*/(\beta k)\} < (k-1)\exp\{-(1-\eta)nI^*/(\beta k)\} < n^{-(1+\delta/2)}$. We complete the proof for the case of $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ and $k \geq 3$ by noting that $(k-1)\exp\left\{-(1-\eta)\frac{nI^*}{\beta k}\right\} = \exp\left\{-(1-\eta'')\frac{nI^*}{\beta k}\right\}$ for another sequence $\eta'' = o(1)$ under the assumption $\frac{(a-b)^2}{ak\log k} \to \infty$ and no constant or sequence in the foregoing arguments involves B, σ or u. When $\Theta = \Theta(n,k,a,b,\lambda,\beta;\alpha)$ and $k = 2$, the foregoing arguments continue to hold with β and k replaced with 1 and 2 respectively.

When $\Theta = \Theta_0(n,k,a,b,\beta)$, we can run the foregoing arguments with Lemma 18 replaced by Lemma 17 to reach the conclusion in (17), which does not require condition (18). This completes the proof. ■

6.2 Proof of Theorem 6

The following lemma is critical to establish the result of Theorem 6. Its proof is given in the appendix. Let us introduce the notation $O(k_1,k_2) = \{V \in \mathbb{R}^{k_1\times k_2} : V^TV = I_{k_2}\}$ for $k_1 \geq k_2$.

Lemma 20 *Consider a symmetric adjacency matrix $A \in \{0,1\}^{n\times n}$ and a symmetric matrix $P \in [0,1]^{n\times n}$ satisfying $A_{uu} = 0$ for all $u \in [n]$ and $A_{uv} \sim Bernoulli(P_{uv})$ independently for all $u > v$. For any $C' > 0$, there exists some $C > 0$ such that*

$$\|T_\tau(A) - P\|_{\mathrm{op}} \leq C\sqrt{np_{\max}+1},$$

with probability at least $1-n^{-C'}$ uniformly over $\tau \in [C_1(np_{\max}+1), C_2(np_{\max}+1)]$ for some sufficiently large constants C_1, C_2, where $p_{\max} = \max_{u\geq v} P_{uv}$.

Lemma 21 *For $P = (P_{uv}) = (B_{\sigma(u)\sigma(v)})$, we have SVD $P = U\Lambda U^T$, where*

$$U = Z\Delta^{-1}W,$$

with $\Delta = diag(\sqrt{n_1}, ..., \sqrt{n_k})$, $Z \in \{0,1\}^{n\times k}$ is a matrix with exactly one nonzero entry in each row at $(i,\sigma(i))$ taking value 1 and $W \in O(k,k)$.

Proof Note that

$$P = ZBZ^T = Z\Delta^{-1}\Delta B\Delta(Z\Delta^{-1})^T,$$

and observe that $Z\Delta^{-1} \in O(n,k)$. Apply SVD to the matrix $\Delta B\Delta^T = W\Lambda W^T$ for some $W \in O(k,k)$, and then we have $P = U\Lambda U^T$ with $U = Z\Delta^{-1}W \in O(k,k)$. ■

Proof [Proof of Theorem 6] Under the current assumption, $\mathbb{E}\tau \in [C_1'a, C_2'a]$ for some large C_1' and C_2'. Using Bernstein's inequality, we have $\tau \in [C_1a, C_2a]$ for some large C_1 and C_2 with probability at least $1-e^{-C'n}$. When (20) holds, by Lemma 20, we deduce that the k^{th} eigenvalue of $T_\tau(A)$ is lower bounded by $c_1\lambda_k$ with probability at least $1-n^{-C'}$ for some small constant $c_1 \in (0,1)$. By Davis–Kahan's sin-theta theorem (Davis and Kahan, 1970),

we have $\|\widehat{U} - UW_1\|_{\mathrm{F}} \leq C\frac{\sqrt{k}}{\lambda_k}\|T_\tau(A) - P\|_{\mathrm{op}}$ for some $W_1 \in O(k,k)$ and some constant $C > 0$. Applying Lemma 21, we have

$$\|\widehat{U} - V\|_{\mathrm{F}} \leq C\frac{\sqrt{k}}{\lambda_k}\|T_\tau(A) - P\|_{\mathrm{op}}, \tag{60}$$

where $V = Z\Delta^{-1}W_2 \in O(n,k)$ for some $W_2 \in O(k,k)$. Combining (60), Lemma 20 and the conclusion $\tau \in [C_1a, C_2a]$, we have

$$\|\widehat{U} - V\|_{\mathrm{F}} \leq \frac{C\sqrt{k}\sqrt{a}}{\lambda_k}, \tag{61}$$

with probability at least $1-n^{-C'}$. The definition of V implies that

$$\|V_{u*} - V_{v*}\| = \sqrt{\frac{1}{n_u}+\frac{1}{n_v}}\mathbf{1}_{\{\sigma(u)\neq\sigma(v)\}}. \tag{62}$$

In other words, define $Q = \Delta^{-1}W_2 \in \mathbb{R}^{k\times k}$ and we have $V_{u*} = Q_{\sigma(u)*}$ for each $u \in [n]$. Hence, for $\sigma(u) \neq \sigma(v)$, $\left\|Q_{\sigma(u)*} - Q_{\sigma(v)*}\right\| = \|V_{u*} - V_{v*}\| \geq \sqrt{\frac{2k}{\beta n}}$. Recall the definition $r = \mu\sqrt{\frac{k}{n}}$ in Algorithm 2. Define the sets

$$T_i = \left\{u \in \sigma^{-1}(i) : \left\|\widehat{U}_{u*} - Q_{i*}\right\| < \frac{r}{2}\right\}, \quad i \in [k].$$

By definition, $T_i \cap T_j = \varnothing$ when $i \neq j$, and we also have

$$\cup_{i\in[k]} T_i = \left\{u \in [n] : \left\|\widehat{U}_{u*} - V_{u*}\right\| < \frac{r}{2}\right\}. \tag{63}$$

Therefore,

$$\left|\left(\cup_{i\in[k]}T_i\right)^c\right|\frac{r^2}{4} \leq \sum_{u\in[n]}\left\|\widehat{U}_{u*} - V_{u*}\right\|^2 \leq \frac{C^2ka}{\lambda_k^2},$$

where the last inequality is by (61). After rearrangement, we have

$$\left|\left(\cup_{i\in[k]}T_i\right)^c\right| \leq \frac{4C^2na}{\mu^2\lambda_k^2}. \tag{64}$$

In other words, most nodes are close to the centers and are in the set (63). Note that the sets $\{T_i\}_{i\in[k]}$ are disjoint. Suppose there is some $i \in [k]$ such that $|T_i| < |\sigma^{-1}(i)| - \left|\left(\cup_{i\in[k]}T_i\right)^c\right|$, we have $\left|\cup_{i\in[k]}T_i\right| = \sum_{i\in[k]}|T_i| < n - \left|\left(\cup_{i\in[k]}T_i\right)^c\right| = \left|\cup_{i\in[k]}T_i\right|$, which is impossible. Thus, the cardinality of T_i for each $i \in [k]$ is lower bounded as

$$|T_i| \geq |\sigma^{-1}(i)| - \left|\left(\cup_{i\in[k]}T_i\right)^c\right| \geq \frac{n}{\beta k} - \frac{4C^2na}{\mu^2\lambda_k^2} > \frac{n}{2\beta k}, \tag{65}$$

where the last inequality above is by the assumption (20). Intuitively speaking, except for a negligible proportion, most data points in $\{\widehat{U}_{u*}\}_{u\in[n]}$ are very close to the population

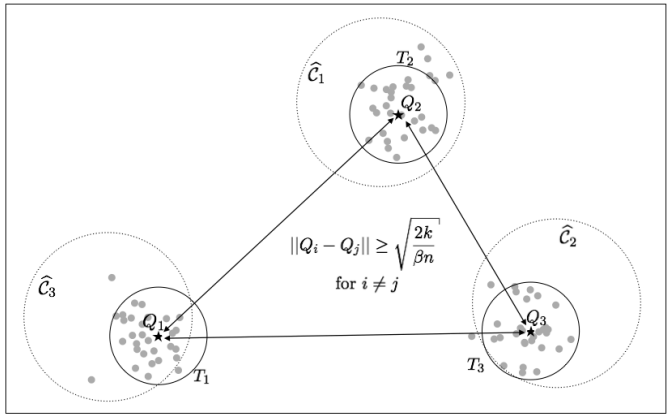

Figure 4: The schematic plot for the proof of Theorem 6. The balls $\{T_i\}_{i\in[k]}$ are centered at $\{Q_i\}_{i\in[k]}$, and the centers are at least $\sqrt{\frac{2k}{\beta n}}$ away from each other. The balls $\{\widehat{\mathcal{C}}_i\}_{i\in[k]}$ intersect with large proportions of $\{T_i\}_{i\in[k]}$, and their subscripts do not need to match due to some permutation.

centers $\{Q_{i*}\}_{i\in[k]}$. Since the centers are at least $\sqrt{\frac{2k}{\beta n}}$ away from each other and $\{T_i\}_{i\in[k]}$ and $\{\widehat{C}_i\}_{i\in[k]}$ are both defined through the critical radius $r = \mu\sqrt{\frac{k}{n}}$ for a small μ, each $\widehat{C}_i$ should intersect with only one T_i (see Figure 4). We claim that there exists some permutation π of the set $[k]$, such that for $\widehat{C}_i$ defined in Algorithm 2,

$$\widehat{\mathcal{C}}_i \cap T_{\pi(i)} \neq \varnothing \quad \text{and} \quad |\widehat{\mathcal{C}}_i| \geq |T_{\pi(i)}| \quad \text{for each } i \in [k]. \tag{66}$$

In what follows, we first establish the result of Theorem 6 by assuming (66). The proof of (66) will be given in the end. Note that for any $i \neq j$, $T_{\pi(i)} \cap \widehat{\mathcal{C}}_j = \varnothing$, which is deduced from the fact that $\widehat{\mathcal{C}}_j \cap T_{\pi(j)} \neq \varnothing$ and the definition of $\widehat{\mathcal{C}}_j$. Therefore, $T_{\pi(i)} \subset \widehat{\mathcal{C}}_j^c$ for all $j \neq i$. Combining with the fact that $T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c \subset \widehat{\mathcal{C}}_i^c$, we get $T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c \subset (\cup_{i\in[k]}\widehat{\mathcal{C}}_i)^c$. Therefore,

$$\cup_{i\in[k]} \left(T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c\right) \subset \left(\cup_{i\in[k]}\widehat{\mathcal{C}}_i\right)^c. \tag{67}$$

Since $T_i \cap T_j = \varnothing$ for $i \neq j$, we deduce from (67) that

$$\sum_{i\in[k]} \left|T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c\right| \leq \left|\left(\cup_{i\in[k]}\widehat{\mathcal{C}}_i\right)^c\right|. \tag{68}$$

By definition, $\widehat{\mathcal{C}}_i \cap \widehat{\mathcal{C}}_j = \varnothing$ for $i \neq j$, we deduce from (66) that

$$\left|\left(\cup_{i\in[k]}\widehat{\mathcal{C}}_i\right)^c\right| = n - \sum_{i\in[k]} |\widehat{\mathcal{C}}_i| \leq n - \sum_{i\in[k]} |T_i| = \left|\left(\cup_{i\in[k]}T_i\right)^c\right|. \tag{69}$$

Combining (68), (69) and (64), we have

$$\sum_{i\in[k]} \left|T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c\right| \leq \frac{4C^2na}{\mu^2\lambda_k^2}. \tag{70}$$

Since for any $u \in \cup_{i\in[k]}(\widehat{\mathcal{C}}_i \cap T_{\pi(i)})$, we have $\widehat{\sigma}(u) = i$ when $\sigma(u) = \pi(i)$, the mis-classification rate is bounded as

$$\begin{aligned}
\ell_0(\widehat{\sigma}, \pi^{-1}(\sigma)) &\leq \frac{1}{n}\left|\left(\cup_{i\in[k]}(\widehat{\mathcal{C}}_i \cap T_{\pi(i)})\right)^c\right| \\
&\leq \frac{1}{n}\left(\left|\left(\cup_{i\in[k]}(\widehat{\mathcal{C}}_i \cap T_{\pi(i)})\right)^c \cap \left(\cup_{i\in[k]}T_i\right)\right| + \left|\left(\cup_{i\in[k]}T_i\right)^c\right|\right) \\
&\leq \frac{1}{n}\left(\sum_{i\in[k]}\left|T_{\pi(i)} \cap \widehat{\mathcal{C}}_i^c\right| + \left|\left(\cup_{i\in[k]}T_i\right)^c\right|\right) \\
&\leq \frac{8C^2a}{\mu^2\lambda_k^2},
\end{aligned}$$

where the last inequality is from (70) and (64). This proves the desired conclusion.

Finally, we are going to establish the claim (66) to close the proof. We use mathematical induction. For $i = 1$, it is clear that $|\widehat{\mathcal{C}}_1| \geq \max_{i\in[k]}|T_i|$ holds by the definition of $\widehat{\mathcal{C}}_1$. Suppose $\widehat{\mathcal{C}}_1 \cap T_i = \varnothing$ for all $i \in [k]$, and then we must have

$$\left|\left(\cup_{i\in[k]}T_i\right)^c\right| \geq |\widehat{\mathcal{C}}_1| \geq \max_{i\in[k]}|T_i| \geq \frac{n}{2\beta k},$$

where the last inequality is by (65). This contradicts (64) under the assumption (20). Therefore, there must be a $\pi(1)$ such that $\widehat{\mathcal{C}}_1 \cap T_{\pi(1)} \neq \varnothing$ and $|\widehat{\mathcal{C}}_1| \geq |T_{\pi(1)}|$. Moreover,

$$\begin{aligned}
|\widehat{\mathcal{C}}_1^c \cap T_{\pi(1)}| &= |T_{\pi(1)}| - |T_{\pi(1)} \cap \widehat{\mathcal{C}}_1| \\
&\leq |\widehat{\mathcal{C}}_1| - |T_{\pi(1)} \cap \widehat{\mathcal{C}}_1| \\
&= |\widehat{\mathcal{C}}_1 \cap T_{\pi(1)}^c| \\
&\leq \left|\left(\cup_{i\in[k]}T_i\right)^c\right|,
\end{aligned}$$

where the last inequality is because $T_{\pi(1)}$ is the only set in $\{T_i\}_{i\in[k]}$ that intersects $\widehat{\mathcal{C}}_1$ by the definitions. By (64), we get

$$|\widehat{\mathcal{C}}_i^c \cap T_{\pi(i)}| \leq \frac{4C^2na}{\mu^2\lambda_k^2}, \tag{71}$$

for $i = 1$.

Now suppose (66) and (71) are true for $i = 1, ..., l-1$. Because of the sizes of $\{\widehat{\mathcal{C}}_i\}_{i\in[l-1]}$ and the fact that $\{T_i\}_{i\in[k]}$ are mutually exclusive, we have

$$\left(\cup_{i=1}^{l-1}\widehat{\mathcal{C}}_i\right) \cap \left(\cup_{i\in[k]\setminus\cup_{i=1}^{l-1}\{\pi(i)\}}T_i\right) = \varnothing.$$

Therefore, for the set S in the current step, $\cup_{i\in[k]\setminus\cup_{i=1}^{l-1}\{\pi(i)\}}T_i \subset S$. By the definition of $\widehat{\mathcal{C}}_l$, we have $|\widehat{\mathcal{C}}_l| \geq \max_{i\in[k]\setminus\cup_{i=1}^{l-1}\{\pi(i)\}}|T_i| \geq \frac{n}{2\beta k}$. Suppose $\widehat{\mathcal{C}}_l \cap T_{\pi(i)} \neq \varnothing$ for some $i = 1, ..., l-1$. Then, this $T_{\pi(i)}$ is the only set in $\{T_i\}_{i\in[k]}$ that intersects $\widehat{\mathcal{C}}_l$ by their definitions. This implies that

$$|\widehat{\mathcal{C}}_l| \leq |\widehat{\mathcal{C}}_l \cap T_{\pi(i)}| + \left|\left(\cup_{i\in[k]}T_i\right)^c\right|.$$

Since $\widehat{\mathcal{C}}_l \cap \widehat{\mathcal{C}}_{\pi(i)} = \varnothing$, $|\widehat{\mathcal{C}}_l \cap T_{\pi(i)}| \leq |\widehat{\mathcal{C}}_i^c \cap T_{\pi(i)}|$ is bounded by (71). Together with (64), we have

$$|\widehat{\mathcal{C}}_l| \leq \frac{8C^2na}{\mu^2\lambda_k^2},$$

which contradicts $|\widehat{\mathcal{C}}_l| \geq \frac{n}{2\beta k}$ under the assumption (20). Therefore, we must have $\widehat{\mathcal{C}}_l \cap T_{\pi(i)} = \varnothing$ for all $i = 1, ..., l-1$. Now suppose $\widehat{\mathcal{C}}_l \cap T_{\pi(i)} = \varnothing$ for all $i \in [k]$, we must have

$$\left|\left(\cup_{i\in[k]}T_i\right)^c\right| \geq |\widehat{\mathcal{C}}_l| \geq \frac{n}{2\beta k},$$

which contradicts (64). Hence, $\widehat{\mathcal{C}}_l \cap T_{\pi(l)} \neq \varnothing$ for some $\pi(l) \in [k]\setminus\cup_{i=1}^{l-1}\{\pi(i)\}$, and (66) is established for $i = l$. Moreover, (71) can also be established for $i = l$ by the same argument that is used to prove (71) for $i = 1$. The proof is complete. ■

6.3 Proof of Theorem 10

Define $P_\tau = P + \frac{\tau}{n}\mathbf{1}\mathbf{1}^T$. The proof of the following lemma is given in the appendix.

Lemma 22 *Consider a symmetric adjacency matrix $A \in \{0,1\}^{n\times n}$ and a symmetric matrix $P \in [0,1]^{n\times n}$ satisfying $A_{uu} = 0$ for all $u \in [n]$ and $A_{uv} \sim Bernoulli(P_{uv})$ independently for all $u > v$. For any $C' > 0$, there exists some $C > 0$ such that*

$$\|L(A_\tau) - L(P_\tau)\|_{\text{op}} \leq C\sqrt{\frac{\log(e(np_{\max}+1))}{np_{\max}+1}},$$

with probability at least $1-n^{-C'}$ uniformly over $\tau \in [C_1(np_{\max}+1), C_2(np_{\max}+1)]$ for some sufficiently large constants C_1, C_2, where $p_{\max} = \max_{u\geq v}P_{uv}$.

Lemma 23 *Consider $P = (P_{uv}) = (B_{\sigma(u)\sigma(v)})$. Let the SVD of the matrix $L(P_\tau)$ be $L(P_\tau) = U\Sigma U^T$, with $U \in O(n,k)$ and $\Sigma = diag(\sigma_1, ..., \sigma_k)$. For $V = UW$ with any $W \in O(r,r)$, we have $\|V_{u*} - V_{v*}\| = \sqrt{\frac{1}{n_u}+\frac{1}{n_v}}$ when $\sigma(u) \neq \sigma(v)$ and $V_{u*} = V_{v*}$ when $\sigma(u) = \sigma(v)$. Moreover, $\sigma_k \geq \frac{\lambda_k}{2\tau}$ as long as $\tau \geq np_{\max}$.*

Proof The first part is Lemma 1 in Joseph and Yu (2013). Define $\bar{d}_v = \sum_{u\in[n]}P_{uv}$ and $\bar{D}_\tau = \text{diag}(\bar{d}_1+\tau, ..., \bar{d}_n+\tau)$. Then, we have $L(P_\tau) = \bar{D}_\tau^{-1/2}P_\tau\bar{D}_\tau^{-1/2}$. Note that P_τ has an SBM structure so that it has rank at most k, and the k^{th} eigenvalue of P_τ is lower bounded by λ_k. Thus, we have

$$\sigma_k \geq \frac{\lambda_k}{\max_{u\in[n]}\bar{d}_u + \tau}.$$

Observe that $\max_{u\in[n]}\bar{d}_u \leq np_{\max} \leq \tau$, and the proof is complete. ■

Proof [Proof of Theorem 10] As is shown in the proof of Theorem 6, $\tau \in [C_1a, C_2a]$ for some large C_1, C_2 with probability at least $1-e^{-C'n}$. By Davis–Kahan's sin-theta theorem (Davis and Kahan, 1970), we have $\|\widehat{U} - UW\|_{\text{F}} \leq C_1\frac{\sqrt{k}}{\sigma_k}\|L(A_\tau) - L(P_\tau)\|_{\text{op}}$ for some $W \in O(r,r)$ and some constant $C_1 > 0$. Let $V = UW$ and apply Lemma 22 and Lemma 23, we have

$$\|\widehat{U} - V\|_{\text{F}} \leq \frac{C\sqrt{k}\sqrt{a\log a}}{\lambda_k}, \tag{72}$$

with probability at least $1-n^{-C'}$. Note that by Lemma 23, V satisfies (62). Replace (61) by (72), and follow the remaining proof of Theorem 6, the proof is complete. ■

Appendix A. A simplified version of Algorithm 1

We give in Algorithm 3 the precise description of the simplified version of Algorithm 1 that we have used in Section 4.

A.1 Additional simulation results

We report some additional simulation results comparing the performances of Algorithm 1 and Algorithm 3. In particular, we consider networks with 400 nodes and 2 communities with four different sets of community sizes, within and between community connection probabilities and initialization methods, and the simulation results are reported in Figure 5 on page 34. From Figure 5 on page 34 we can see the performances of both algorithms remain similar across all these different settings.

Appendix B. Proofs of Theorem 12

Proof [Proof of Theorem 12] Let us consider $\Theta = \Theta_0(n,k,a,b,\beta)$ and the case of $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ is similar except that the condition (18) is needed to establish the counterpart of Lemma 18. The proof essentially follows the same steps as those in the proof of Theorem 4. First, we note that Lemma 16 continues to hold since it does not need the assumption of a/b being bounded. Thus, the first job is to establish the counterpart of Lemma 17 with η' replaced with $C_\epsilon\frac{2\epsilon_0}{3}$. As before, let $p = a/n$ and $q = b/n$.

To this end, we first proceed in the same way to obtain (42) – (52). Without loss of generality, let us consider the case where $t^* > \log\frac{2}{\epsilon_0}$ and $t_u = \log\frac{2}{\epsilon_0}$ since otherwise we can essentially repeat the proof of Theorem 4. Note that this implies $\frac{a}{b} > (\frac{2}{\epsilon_0})^2$. In this case, with the new t_u in (22), we have on the event E_u,

$$(qe^{t_u}+1-q)(pe^{-t_u}+1-p) = e^{-I'}$$

Algorithm 3: A simplified refinement scheme for community detection

Input: Adjacency matrix $A \in \{0,1\}^{n\times n}$,
number of communities k,
initial community detection method σ^0.

Output: Community assignment $\widehat{\sigma}$.

Initialization:

Apply σ^0 on A to obtain $\sigma^0(u)$ for all $u \in [n]$;

Define $\widetilde{\mathcal{C}}_i = \{v : \sigma^0(v) = i\}$ for all $i \in [k]$; let $\widetilde{\mathcal{E}}_i$ be the set of edges within $\widetilde{\mathcal{C}}_i$, and $\widetilde{\mathcal{E}}_{ij}$ the set of edges between $\widetilde{\mathcal{C}}_i$ and $\widetilde{\mathcal{C}}_j$ when $i \neq j$;

Define

$$\widehat{B}_{ii} = \frac{|\widetilde{\mathcal{E}}_i|}{\frac{1}{2}|\widetilde{\mathcal{C}}_i|(|\widetilde{\mathcal{C}}_i|-1)}, \quad \widehat{B}_{ij} = \frac{|\widetilde{\mathcal{E}}_{ij}|}{|\widetilde{\mathcal{C}}_i||\widetilde{\mathcal{C}}_j|}, \quad \forall i \neq j \in [k],$$

and let

$$\widehat{a} = n \min_{i\in[k]} \widehat{B}_{ii} \quad \text{and} \quad \widehat{b} = n \max_{i\neq j\in[k]} \widehat{B}_{ij}.$$

Penalized neighbor voting:

For

$$t = \frac{1}{2}\log\frac{\widehat{a}(1-\widehat{b}/n)}{\widehat{b}(1-\widehat{a}/n)},$$

define

$$\rho = -\frac{1}{2t}\log\left(\frac{\frac{\widehat{a}}{n}e^{-t}+1-\frac{\widehat{a}}{n}}{\frac{\widehat{b}}{n}e^{t}+1-\frac{\widehat{b}}{n}}\right),$$

For each $u \in [n]$, set

$$\widehat{\sigma}(u) = \operatorname*{argmax}_{l\in[k]} \sum_{\sigma^0(v)=l} A_{uv} - \rho \sum_{v\in[n]} \mathbf{1}_{\{\sigma^0(v)=l\}}.$$

where

$$\begin{aligned} I' &= -\log\left((1-p)(1-q)+pq+\left(e^{t_u-t^*}+e^{t^*-t_u}\right)\sqrt{(1-p)(1-q)pq}\right) \\ &\geq \left(1-C_\epsilon\frac{3\epsilon_0}{5}\right)I^*. \end{aligned} \tag{73}$$

To see this, we first note that for any $x, y \in (0,1)$ and sufficient small constant $c_0 > 0$, if $y \geq x \geq (1-c_0)y$ and $\frac{y-x}{1-y} \leq 1$, then

$$-\log(1-x) = -\log(1-y) - \log\left(1+\frac{y-x}{1-y}\right) \geq -\log(1-y) - 2\frac{y-x}{1-y} \geq -\left(1-C'_y c_0\right)\log(1-y),$$

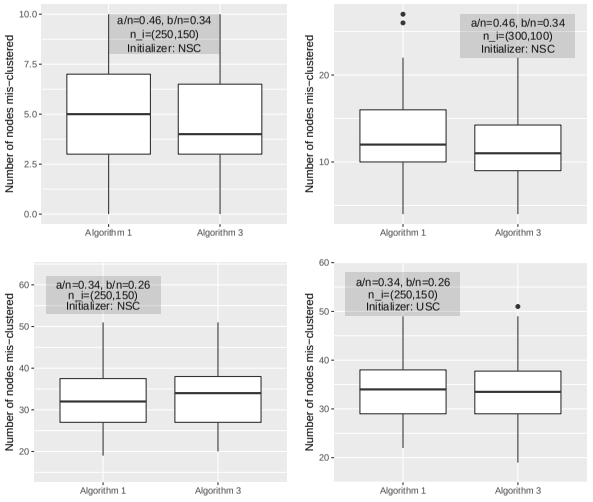

Figure 5: Comparison of Algorithm 1 and its simplified version (Algorithm 3) under various parameters for two-community networks. The parameters are displayed inside each boxplot. Here n_i gives the community sizes and B matrix satisfies $B_{ii} = a/n, \forall i = 1,2$ and $B_{ij} = b/n, \forall i \neq j$. Each pair of boxplots are based on 100 runs.

where $C'_y = \frac{2y}{-(1-y)\log(1-y)}$. When $\frac{a}{b} > (\frac{2}{\epsilon_0})^2$ and $t_u = \log\frac{2}{\epsilon_0}$, we have $I' = -\log(1-x)$ for

$$x = p+q-2pq-(e^{t_u-t^*}+e^{t^*-t_u})\sqrt{(1-p)(1-q)pq} \geq p-2pq-qe^{t_u}-pe^{-t_u} \geq p(1-\epsilon_0-\frac{\epsilon_0^2}{2}),$$

while $I^* = -\log(1-y)$ for

$$y = p+q-2pq-2\sqrt{(1-p)(1-q)pq} \leq p+q \leq p(1+(\frac{\epsilon_0}{2})^2).$$

Thus, for any $\epsilon_0 \in (0, c_\epsilon)$, $1-\frac{\epsilon}{2} \geq y \geq x \geq (1-2\epsilon_0)y$ and $\frac{y-x}{1-y} \leq 1$, and we apply the inequality in the third last display to obtain (73).

Thus, the term in (49) is upper bounded by

$$\exp\left(-\left(1-C_\epsilon\frac{3\epsilon_0}{5}\right)\frac{n_1+n_l}{2}I^*\right).$$

On the other hand, since $|e^{-t_u}-1| \leq 1$, $|e^{t_u}-1|$ is bounded and $\frac{p-q}{p} \asymp 1$, the term in (48) continues to be bounded by

$$\exp\left(-o(1)\frac{n_1+n_l}{2}I^*\right).$$

Moreover, by the same argument as in Lemma 17, (51) continues to hold. Thus, we can replace (52) as

$$p_l \le \exp\left(-\big(1-C_\epsilon\frac{2\epsilon_0}{3}\big)\frac{n_1+n_l}{2}I^*\right),$$

and so when $k\ge 3$,

$$\mathbb{P}\left\{\widehat{\sigma}_u(u)\neq\pi_u(\sigma(u))\right\}\le(k-1)\exp\left\{-\left(1-C_\epsilon\frac{2\epsilon_0}{3}\right)\frac{nI^*}{\beta k}\right\}+Cn^{-(1+\delta)} \tag{74}$$

and when $k=2$, we can replace β by 1 in the last display.

When $k\ge 3$, given the last display and (58), we have

$$\begin{aligned}\mathbb{P}\left\{\widehat{\sigma}(u)\neq\sigma(u)\right\}&=\mathbb{P}\left\{\xi_u(\widehat{\sigma}_u(u))\neq\sigma(u)\right\}\\&\le\mathbb{P}\left\{\xi_u(\widehat{\sigma}_u(u))\neq\sigma(u),\,\xi_u=\pi_u^{-1}\right\}+\mathbb{P}\left\{\xi_u\neq\pi_u^{-1}\right\}\\&\le\mathbb{P}\left\{\widehat{\sigma}_u(u)\neq\pi_u(\sigma(u))\right\}+\mathbb{P}\left\{\xi_u\neq\pi_u^{-1}\right\}\\&\le Cn^{-(1+\delta)}+(k-1)\exp\left\{-\left(1-C_\epsilon\frac{2\epsilon_0}{3}\right)\frac{nI^*}{\beta k}\right\}.\end{aligned} \tag{75}$$

Thus, the assumption that $\frac{(a-b)^2}{ak\log k}\to\infty$ and Markov's inequality leads to

$$\begin{aligned}&\mathbb{P}\left\{\ell_0(\sigma,\widehat{\sigma})>\exp\left\{-(1-C_\epsilon\epsilon_0)\frac{nI^*}{\beta k}\right\}\right\}\\&\quad\le\mathbb{P}\left\{\ell_0(\sigma,\widehat{\sigma})>(k-1)\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}\right\}\\&\quad\le\frac{1}{(k-1)\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}}\frac{1}{n}\sum_{u=1}^n\mathbb{P}\left\{\widehat{\sigma}(u)\neq\sigma(u)\right\}\\&\quad\le\exp\left\{-\frac{C_\epsilon\epsilon_0}{6}\frac{nI^*}{\beta k}\right\}+\frac{Cn^{-(1+\delta)}}{(k-1)\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}}.\end{aligned} \tag{76}$$

If $(k-1)\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}\ge n^{-(1+\delta/2)}$, then

$$\mathbb{P}\left\{\ell_0(\sigma,\widehat{\sigma})>\exp\left\{-(1-C_\epsilon\epsilon_0)\frac{nI^*}{\beta k}\right\}\right\}\le\exp\left\{-\frac{C_\epsilon\epsilon_0}{6}\frac{nI^*}{\beta k}\right\}+Cn^{-\delta/2}=o(1). \tag{77}$$

If $(k-1)\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}< n^{-(1+\delta/2)}$, then

$$\begin{aligned}\mathbb{P}\left\{\ell_0(\sigma,\widehat{\sigma})>\exp\left\{-(1-C_\epsilon\epsilon_0)\frac{nI^*}{\beta k}\right\}\right\}&\le\mathbb{P}\left\{\ell_0(\sigma,\widehat{\sigma})>0\right\}\le\sum_{u=1}^n\mathbb{P}\left\{\widehat{\sigma}(u)\neq\sigma(u)\right\}\\&\le n(k-1)\exp\left\{-(1-C_\epsilon\frac{2\epsilon_0}{3})\frac{nI^*}{\beta k}\right\}+Cn^{-\delta}\le Cn^{-\delta/2}=o(1).\end{aligned} \tag{78}$$

Here, the second last inequality holds since $(k-1)\exp\left\{-(1-C_\epsilon\frac{2\epsilon_0}{3})\frac{nI^*}{\beta k}\right\}<\exp\left\{-(1-C_\epsilon\frac{5\epsilon_0}{6})\frac{nI^*}{\beta k}\right\}<n^{-(1+\delta/2)}$. We complete the proof for the case of $k\ge 3$ by noting that no constant or sequence in the foregoing arguments involves B,σ or u. When $k=2$, we run the foregoing arguments with β replaced by 1 to obtain the desired claim. ■

Appendix C. Proofs of Theorems 13, 14 and 15

Proposition 24 *For SBM in the space $\Theta_0(n,k,a,b,\beta)$ satisfying $n\ge 2\beta k$, we have $\lambda_k\ge\frac{a-b}{\beta k}$.*

Proof Since the eigenvalues of P are invariant with respect to permutation of the community labels, we consider the case where $\sigma(u)=i$ for $u\in\left\{\sum_{j=1}^{i-1}n_j-1,\sum_{j=1}^i n_j\right\}$ without loss of generality, where $\sum_{j=1}^0 n_j=0$. Let us use the notation $\mathbf{1}_d\in\mathbb{R}^d$ and $\mathbf{0}_d\in\mathbb{R}^d$ to denote the vectors with all entries being 1 and 0 respectively. Then, it is easy to check that

$$P-\frac{b}{n}\mathbf{1}_n\mathbf{1}_n^T=\frac{a-b}{n}\sum_{i=1}^k v_iv_i^T,$$

where $v_1=(\mathbf{1}_{n_1}^T,\mathbf{0}_{n_2}^T,...,\mathbf{0}_{n_k}^T)^T$, $v_1=(\mathbf{0}_{n_1}^T,\mathbf{1}_{n_2}^T,\mathbf{0}_{n_3}^T,...,\mathbf{0}_{n_k}^T)^T$,..., $v_k=(\mathbf{0}_{n_1}^T,...,\mathbf{0}_{n_{k-1}}^T,\mathbf{1}_{n_k}^T)^T$. Note that $\{v_i\}_{i=1}^k$ are orthogonal to each other, and therefore

$$\lambda_k\left(\sum_{i=1}^k v_iv_i^T\right)\ge\min_{i\in[k]}n_i\ge\frac{n}{\beta k}-1\ge\frac{n}{2\beta k}.$$

By Weyl's inequality (Theorem 4.3.1 of Horn and Johnson (2012)),

$$\lambda_k(P)\ge\frac{a-b}{n}\lambda_k\left(\sum_{i=1}^k v_iv_i^T\right)+\lambda_n\left(\frac{b}{n}\mathbf{1}_n\mathbf{1}_n^T\right)\ge\frac{a-b}{2\beta k}.$$

This completes the proof. ■

Proof [Proof of Theorem 13] Let us first consider $\Theta_0(n,k,a,b,\beta)$. By Theorem 6 and Proposition 24, the misclassification proportion is bounded by $C\frac{k^2a}{(a-b)^2}$ under the condition $\frac{k^3a}{(a-b)^2}\le c$ for some small c. Thus, Condition 1 holds when $\frac{k^3a}{(a-b)^2}=o(1)$, which leads to the desired conclusion in view of Theorem 4 and Theorem 12. The proof of the space $\Theta(n,k,a,b,\lambda,\beta;\alpha)$ follows the same argument. ■

Proof [Proof of Theorem 14] The proof is the same as that of Theorem 13. ■

Proof [Proof of Theorem 15] When the parameters a and b are known, we can use $\tau=Ca$ for some sufficiently large $C>0$ for both USC(τ) and NSC(τ). Then, the results of Theorem 6 and Theorem 10 hold without assuming $a\le C_1b$ or fixed k. Moreover, $\widehat{a}_u$ and $\widehat{b}_u$ in

(11) and (22) can be replaced by a and b. Then, the conditions (16) and (18) in Theorem 4 and Theorem 12 can be weakened as $\gamma = o(k^{-1})$ because the we do not need to establish Lemma 16 anymore. Combining Theorem 4, Theorem 6, Theorem 10 and Theorem 12, we obtain the desired results. ■

Appendix D. Proofs of Lemma 20 and Lemma 22

The following lemma is Corollary A.1.10 in Alon and Spencer (2004).

Lemma 25 *For independent Bernoulli random variables $X_u \sim Bern(p_u)$ and $p = \frac{1}{n}\sum_{u\in[n]} p_u$, we have*

$$\mathbb{P}\left(\sum_{u\in[n]}(X_u - p_u) \geq t\right) \leq \exp\left(t - (pn+t)\log\left(1+\frac{t}{pn}\right)\right),$$

for any $t \geq 0$.

The following result is Lemma 3.5 in Chin et al. (2015).

Lemma 26 *Consider any adjacency matrix $A \in \{0,1\}^{n\times n}$ for an undirected graph. Suppose $\max_{u\in[n]}\sum_{v\in[n]} A_{uv} \leq \gamma$ and for any $S, T \subset [n]$, one of the following statements holds with some constant $C > 0$:*

1. $\frac{e(S,T)}{|S||T|\frac{\gamma}{n}} \leq C$,
2. $e(S,T)\log\left(\frac{e(S,T)}{|S||T|\frac{\gamma}{n}}\right) \leq C|T|\log\frac{n}{|T|}$,

where $e(S,T)$ is the number of edges connecting S and T. Then, $\sum_{(u,v)\in H} x_u A_{uv} y_v \leq C'\sqrt{\gamma}$ uniformly over all unit vectors x, y, where $H = \{(u,v) : |x_u y_v| \geq \sqrt{\gamma}/n\}$ and $C' > 0$ is some constant.

The following lemma is critical for proving both theorems.

Lemma 27 *For any $\tau > C(1 + np_{\max})$ with some sufficiently large $C > 0$, we have*

$$|\{u \in [n] : d_u \geq \tau\}| \leq \frac{n}{\tau}$$

with probability at least $1 - e^{-C'n}$ for some constant $C' > 0$.

Proof Let us consider any fixed subset of nodes $S \subset [n]$ such that it has degree at least τ and $|S| = l$ for some $l \in [n]$. Let $e(S)$ be the number of edges in the subgraph S and $e(S, S^c)$ be the number of edges connecting S and S^c. By the requirement on S, either $e(S) \geq C_1 l\tau$ or $e(S, S^c) \geq C_1 l\tau$ for some universal constant $C_1 > 0$. We are going to show that both $\mathbb{P}(e(S) \geq C_1 l\tau)$ and $\mathbb{P}(e(S, S^c) \geq C_1 l\tau)$ are small. Note that $\mathbb{E}e(S) \leq C_2 l^2 p_{\max}$

and $\mathbb{E}e(S, S^c) \leq C_2 lnp_{\max}$ for some universal $C_2 > 0$. Then, when $\tau > C(np_{\max} + 1)$ for some sufficiently large $C > 0$, Lemma 25 implies

$$\mathbb{P}(e(S) \geq C_1 l\tau) \leq \exp\left(-\frac{1}{4}C_1 l\tau\log\left(1+\frac{C_1\tau}{2C_2 lp_{\max}}\right)\right),$$

and

$$\mathbb{P}(e(S, S^c) \geq C_1 l\tau) \leq \exp\left(-\frac{1}{4}C_1 l\tau\log\left(1+\frac{C_1\tau}{2C_2 np_{\max}}\right)\right).$$

Applying union bound, the probability that the number of nodes with degree at least τ is greater than ξn is

$$\begin{aligned}
& \mathbb{P}\Big(|\{u \in [n] : d_u \geq \tau\}| > \xi n\Big) \\
\leq & \sum_{l>\xi n}\mathbb{P}\Big(|\{u \in [n] : d_u \geq \tau\}| = l\Big) \\
\leq & \sum_{l>\xi n}\sum_{|S|=l}\left(\mathbb{P}(e(S) \geq C_1 l\tau) + \mathbb{P}(e(S, S^c) \geq C_1 l\tau)\right) \\
\leq & \sum_{l>\xi n}\exp\left(l\log\frac{en}{l}\right)\left(\exp\left(-\frac{1}{4}C_1 l\tau\log\left(1+\frac{C_1\tau}{2C_2 lp_{\max}}\right)\right)\right. \\
& \left.+\exp\left(-\frac{1}{4}C_1 l\tau\log\left(1+\frac{C_1\tau}{2C_2 np_{\max}}\right)\right)\right) \\
\leq & \sum_{l>\xi n} 2\exp\left(l\log\frac{en}{l} - \frac{1}{4}C_1 l\tau\log\left(1+\frac{C_1\tau}{2C_2 np_{\max}}\right)\right) \\
\leq & \exp(-C'n),
\end{aligned}$$

where the last inequality is by choosing $\xi = \tau^{-1}$. Therefore, with probability at least $1 - e^{-C'n}$, the number of nodes with degree at least τ is bounded by $\tau^{-1}n$. ■

Lemma 28 *Given $\tau > 0$, define the subset $J = \{u \in [n] : d_u \leq \tau\}$. Then for any $C' > 0$, there is some $C > 0$ such that*

$$\|A_{JJ} - P_{JJ}\|_{\text{op}} \leq C\left(\sqrt{np_{\max}} + \sqrt{\tau} + \frac{np_{\max}}{\sqrt{\tau} + \sqrt{np_{\max}}}\right),$$

with probability at least $1 - n^{-C'}$.

Proof The idea of the proof follows the argument in Friedman et al. (1989); Feige and Ofek (2005). By definition,

$$\|A_{JJ} - P_{JJ}\|_{\text{op}} = \sup_{x,y\in S^{n-1}}\sum_{(u,v)\in J\times J} x_u(A_{uv} - P_{uv})y_v.$$

Define $L = \{(u,v) : |x_u y_v| \le (\sqrt{\tau} + \sqrt{p_{\max} n})/n\}$ and $H = \{(u,v) : |x_u y_v| \ge (\sqrt{\tau} + \sqrt{p_{\max} n})/n\}$, then we have

$$\|A_{JJ} - P_{JJ}\|_{\mathrm{op}} \le \sup_{x,y \in S^{n-1}} \sum_{(u,v) \in L \cap J \times J} x_u (A_{uv} - P_{uv}) y_v + \sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u (A_{uv} - P_{uv}) y_v.$$

A discretization argument in Chin et al. (2015) implies that

$$\begin{aligned} \sup_{x,y \in S^{n-1}} \sum_{(u,v) \in L \cap J \times J} x_u (A_{uv} - P_{uv}) y_v \lesssim & \max_{x,y \in \mathcal{N}} \max_{S \subset [n]} \sum_{(u,v) \in L \cap S \times S} x_u (A_{uv} - \mathbb{E} A_{uv}) y_v \\ & + \max_{x,y \in \mathcal{N}} \max_{S \subset [n]} \sum_{(u,v) \in L \cap S \times S} x_u (\mathbb{E} A_{uv} - P_{uv}) y_v, \end{aligned}$$

where $\mathcal{N} \subset S^{n-1}$ and $|\mathcal{N}| \le 5^n$. Then, Bernstein's inequality and union bound imply that $\max_{x,y \in \mathcal{N}} \max_{S \subset [n]} \sum_{(u,v) \in L \cap S \times S} x_u (A_{uv} - \mathbb{E} A_{uv}) y_v \le C(\sqrt{\tau} + \sqrt{n p_{\max}})$ with probability at least $1 - e^{-C' n}$. We also have $\max_{x,y \in \mathcal{N}} \max_{S \subset [n]} \sum_{(u,v) \in L \cap S \times S} x_u (\mathbb{E} A_{uv} - P_{uv}) y_v \le \|\mathbb{E} A - P\|_{\mathrm{op}} \le 1$. This completes the first part.

To bound the second part $\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u (A_{uv} - P_{uv}) y_v$, we are going to bound $\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u A_{uv} y_v$ and $\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u P_{uv} y_v$ separately. By the definition of H,

$$\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u P_{uv} y_v = \sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} \frac{x_u^2 y_v^2}{|x_u y_v|} P_{uv} \le \frac{n p_{\max}}{\sqrt{\tau} + \sqrt{p_{\max} n}}.$$

To bound $\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u A_{uv} y_v$, it is sufficient to check the conditions of Lemma 26 for the graph A_{JJ}. By definition, its degree is bounded by τ. Following the argument of Lei and Rinaldo (2014), the two conditions of Lemma 26 hold with $\gamma = \tau + n p_{\max}$ with probability at least $1 - n^{-C'}$. Thus, $\sup_{x,y \in S^{n-1}} \sum_{(u,v) \in H \cap J \times J} x_u A_{uv} y_v \le C(\sqrt{\tau} + \sqrt{n p_{\max}})$ with probability at least $1 - n^{-C'}$. Hence, the proof is complete. ■

Proof [Proof of Lemma 20] By triangle inequality,

$$\|T_\tau(A) - P\|_{\mathrm{op}} \le \|T_\tau(A) - T_\tau(P)\|_{\mathrm{op}} + \|T_\tau(P) - P\|_{\mathrm{op}},$$

where $T_\tau(P)$ is the matrix obtained by zeroing out the u^{th} row and column of P with $d_u \ge \tau$. Let $J = \{u \in [n] : d_u \le \tau\}$, and then $\|T_\tau(A) - T_\tau(P)\|_{\mathrm{op}} = \|A_{JJ} - P_{JJ}\|_{\mathrm{op}}$, whose bound has been established in Lemma 28. By Lemma 27, $|J^c| \le n/\tau$ with high probability. This implies $\|T_\tau(P) - P\|_{\mathrm{op}} \le \|T_\tau(P) - P\|_{\mathrm{F}} \le \sqrt{2n|J^c| p_{\max}^2} \le \frac{\sqrt{2} n p_{\max}}{\sqrt{\tau}}$. Taking $\tau \in [C_1(1 + n p_{\max}), C_2(1 + n p_{\max})]$, the proof is complete. ■

Now let us prove Lemma 22. The following lemma, which controls the degree, is Lemma 7.1 in Le et al. (2015).

Lemma 29 *For any $C' > 0$, there exists some $C > 0$ such that with probability at least $1 - n^{-C'}$, there exists a subset $J \subset [n]$ satisfying $n - |J| \le \frac{n}{2e(np_{\max}+1)}$ and*

$$|d_v - \mathbb{E} d_v| \le C\sqrt{(np_{\max} + 1)\log(e(np_{\max} + 1))}, \quad \text{for all } v \in J,$$

where $d_v = \sum_{u \in [n]} A_{uv}$.

Using this lemma, together with Lemma 27 and Lemma 28, we are able to prove the following result, which improves the bound in Theorem 7.2 of Le et al. (2015).

Lemma 30 *For any $C' > 0$, there exists some $C > 0$ such that with probability at least $1 - n^{-C'}$, there exists a subset $J \subset [n]$ satisfying $n - |J| \le n/d$ and*

$$\|(L(A_\tau) - L(P_\tau))_{J \times J}\|_{\mathrm{op}} \le C\left(\frac{\sqrt{d \log d}(d + \tau)}{\tau^2} + \frac{\sqrt{d}}{\tau}\right),$$

where $d = e(np_{\max} + 1)$.

Proof Let us use the notation $d_v = \sum_{u \in [n]} A_{uv}$ in the proof. Define the set $J_1 = \{v \in [n] : d_v \le C_1 d\}$ for some sufficiently large constant $C_1 > 0$. Using Lemma 27 and Lemma 28, with probability at least $1 - n^{-C'}$, we have

$$n - |J_1| \le \frac{n}{2d}, \tag{79}$$

and

$$\|(A - P)_{J_1 J_1}\|_{\mathrm{op}} \le C\sqrt{d}. \tag{80}$$

Let J_2 be the subset in Lemma 29, and then with probability at least $1 - n^{-C'}$, J_2 satisfies

$$n - |J_2| \le \frac{n}{2d}, \tag{81}$$

and

$$|d_v - \mathbb{E} d_v| \le C\sqrt{d \log d}, \quad \text{for all } v \in J_2. \tag{82}$$

Define $J = J_1 \cap J_2$. By (79) and (81), we have

$$n - |J| = |(J_1 \cap J_2)^c| \le |J_1^c| + |J_2^c| = n - |J_1| + n - |J_2| \le \frac{n}{d}, \tag{83}$$

and

$$\|(A - P)_{JJ}\|_{\mathrm{op}} \le \|(A - P)_{J_1 J_1}\|_{\mathrm{op}} \le C\sqrt{d}. \tag{84}$$

Moreover, (82) implies

$$\max_{v \in J} |d_v - \mathbb{E} d_v| \le C\sqrt{d \log d}.$$

Define $\bar{d}_v = \sum_{u \in [n]} P_{uv}$. Then,

$$\max_{v \in J} |d_v - \bar{d}_v| \le \max_{v \in J} |d_v - \mathbb{E} d_v| + 1 \le C\sqrt{d \log d}. \tag{85}$$

Define $D_\tau = \mathrm{diag}(d_1+\tau, ..., d_n+\tau)$ and $\bar{D}_\tau = \mathrm{diag}(\bar{d}_1+\tau, ..., \bar{d}_n+\tau)$. We introduce the notation

$$R = (A_\tau)_{JJ}, \quad B = (D_\tau)_{JJ}^{-1/2}, \quad \bar{R} = (P_\tau)_{JJ}, \quad \bar{B} = (\bar{D}_\tau)_{JJ}^{-1/2}.$$

Using (85), we have

$$\|B - \bar{B}\|_{\mathrm{op}} \le \max_{v\in[n]} \left| \frac{1}{\sqrt{d_v+\tau}} - \frac{1}{\sqrt{\bar{d}_v+\tau}} \right| \le C\frac{\sqrt{d\log d}}{\tau^{3/2}},$$

for some constant $C > 0$. The definitions of B and $\bar{B}$ implies $\|B\|_{\mathrm{op}} \vee \|\bar{B}\|_{\mathrm{op}} \le \frac{1}{\sqrt{\tau}}$. We rewrite the bound (84) as $\|R-\bar{R}\|_{\mathrm{op}} \le C\sqrt{d}$. Since all entries of $\mathbb{E}A_\tau$ is bounded by $(\tau+d)/n$, we have $\|\bar{R}\|_{\mathrm{op}} \le \|\mathbb{E}A_\tau\|_{\mathrm{op}} \le d+\tau$. Therefore, $\|R\|_{\mathrm{op}} \le \|\bar{R}\|_{\mathrm{op}} + \|R-\bar{R}\|_{\mathrm{op}} \le C(d+\tau)$. Finally,

$$\begin{aligned} & \|(L(A_\tau) - L(P_\tau))_{J\times J}\|_{\mathrm{op}} \\ \le\ & \|B\|_{\mathrm{op}}\|R\|_{\mathrm{op}}\|B-\bar{B}\|_{\mathrm{op}} + \|B\|_{\mathrm{op}}\|R-\bar{R}\|_{\mathrm{op}}\|\bar{B}\|_{\mathrm{op}} + \|B-\bar{B}\|_{\mathrm{op}}\|\bar{R}\|_{\mathrm{op}}\|\bar{B}\|_{\mathrm{op}} \\ \le\ & C\left(\frac{\sqrt{d\log d}(d+\tau)}{\tau^2} + \frac{\sqrt{d}}{\tau}\right). \end{aligned}$$

The proof is complete. ■

Proof [Proof of Lemma 22] Recall that $d = np_{\max}+1$. Following the proof of Theorem 8.4 in Le et al. (2015), it can be shown that with probability at least $1-n^{-C'}$, for any $J \subset [n]$ such that $n - |J| \le n/d$,

$$\|L(A_\tau) - L(P_\tau)\|_{\mathrm{op}} \le \|(L(A_\tau) - L(P_\tau))_{JJ}\|_{\mathrm{op}} + C\left(\frac{1}{\sqrt{d}} + \sqrt{\frac{\log d}{\tau}}\right),$$

where the first term on the right side of the inequality above is bounded in Lemma 30 by choosing an appropriate J. Hence, with probability at least $1-2n^{-C'}$,

$$\|L(A_\tau) - L(P_\tau)\|_{\mathrm{op}} \le C\left(\frac{\sqrt{d\log d}(d+\tau)}{\tau^2} + \frac{\sqrt{d}}{\tau}\right) + C\left(\frac{1}{\sqrt{d}} + \sqrt{\frac{\log d}{\tau}}\right).$$

Choosing $\tau \in [C_1(1+np_{\max}), C_2(1+np_{\max})]$, the proof is complete. ■

Editor: Network Analysis Special Issue

Abstract

Our work in this paper is inspired by a statistical observation that is both elementary and broadly relevant to network analysis in practice—that the uncertainty in approximating some true graph $G = (V, E)$ by some estimated graph $\hat{G} = (V, \hat{E})$ manifests as errors in our knowledge of the presence/absence of edges between vertex pairs, which must necessarily propagate to any estimates of network summaries $\eta(G)$ we seek. Motivated by the common practice of using plug-in estimates $\eta(\hat{G})$ as proxies for $\eta(G)$, our focus is on the problem of characterizing the distribution of the discrepancy $D = \eta(\hat{G}) - \eta(G)$, in the case where $\eta(\cdot)$ is a subgraph count. Specifically, we study the fundamental case where the statistic of interest is $|E|$, the number of edges in G. Our primary contribution in this paper is to show that in the empirically relevant setting of large graphs with low-rate measurement errors, the distribution of $D_E = |\hat{E}| - |E|$ is well-characterized by a Skellam distribution, when the errors are independent or weakly dependent. Under an assumption of independent errors, we are able to further show conditions under which this characterization is strictly better than that of an appropriate normal distribution. These results derive from our formulation of a general result, quantifying the accuracy with which the difference of two sums of dependent Bernoulli random variables may be approximated by the difference of two independent Poisson random variables, i.e., by a Skellam distribution. This general result is developed through the use of Stein's method, and may be of some general interest. We finish with a discussion of possible extension of our work to subgraph counts $\eta(G)$ of higher order.

Keywords: Limit distribution, network analysis, Skellam distribution, Stein's method.

1. Introduction

The analysis of network data is widespread across the scientific disciplines. Technological and infrastructure, social, biological, and information networks are a few of the major network classes in which such analyses have been employed. However, despite the already substantial body of work in network analysis generally (e.g., see Jackson, 2010; Kolaczyk, 2009; Newman, 2010), with contributions from a variety of different fields of study, much work still remains to more fully develop the theory and methods of statistical analysis of network data, particularly for certain classes of problems of a fairly fundamental nature. Here in this paper we pose and address a version of one such fundamental problem, that regarding the propagation of error through the process of network construction and summary.

In applied network analysis, a common *modus operandi* is to (i) gather basic measurements relevant to the interactions among elements in a system of interest, (ii) construct a graph-based representation of that system, with nodes serving as elements and links indicating interactions between pairs of elements, and (iii) summarize the structure of the resulting graph using a variety of numerical and visual tools. See Kolaczyk (2009, Chs 3 & 4) for background and several case studies illustrating this process. Key here is the point that the process of network analysis usually rests upon some collection of measurements of a more basic nature. For example, online social networks (e.g., Facebook) are based on the extraction and merging of lists of 'friends' from millions of individual accounts (Hansen et al., 2010, Ch 11.8). Similarly, biological networks (e.g., of gene regulatory relationships) are often based on notions of association (e.g., correlation, partial correlation, etc.) among experimental measurements of gene activity levels (Fogelberg and Palade, 2009). Finally, maps of the logical Internet traditionally have been synthesized from the results of surveys in which paths along which information flows are learned through a large set of packet probes (e.g., Cheswick et al., 2000).

Importantly, while it is widely recognized that there is measurement error associated with these and other common types of network constructions, most applied network analyses in practice effectively proceed as if there were in fact no error. There are at least two possible reasons for this current state of affairs: (1) there is comparatively little in the way of formal probabilistic analyses characterizing the propagation of such error and of statistical methods accounting for such propagation, and (2) in many settings (arguably due at least in part to (1)), much attention is given at the stages of measurement and network construction to trying to keep the rate of error 'low' in declaring the presence and absence of links between nodes.

Here we offer a formal treatment of the problem of propagation of error. We provide a general framework within which it is possible to characterize the manner in which errors made in assigning links between nodes accumulate in the reporting of certain functions of the network as a whole. Our treatment is probabilistic, wherein our goal is to understand the nature of the distribution induced on the graph functions by that of the errors in the graph construction. We anticipate that this contribution will provide part of a critical foundation upon which, in turn, it should be possible to develop a statistical treatment, e.g., the construction of appropriate confidence intervals for graph-based quantities of interest.

More formally, we consider a setting wherein an underlying (undirected) network-graph G possesses a network characteristic $\eta(G)$ of interest. While there are many types of functions $\eta(\cdot)$ used in practice to characterize networks (e.g., centralities, path-based metrics, output from methods of community detection, etc.) we restrict our attention here to the canonical problem of subgraph counting. That is, we are interested in the class of functions η of the form

$$\eta_H(G) = \frac{1}{|Iso(H)|} \sum_{H' \subseteq K_{n_v}, H' \cong H} 1\{H' \subseteq G\} \ , \tag{1}$$

where $n_v = |V(G)|$ is the number of vertices in G, K_{n_v} is the complete graph on n_v vertices, H is a graph of interest (i.e., copies of which we desire to count), and $H \subseteq G$ indicates that H is a subgraph of G (i.e., $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$). The value $|Iso(H)|$ is a normalization

factor for the number of isomorphisms of H. We will concentrate primarily on the fundamental case where $\eta(G) = |E|$, i.e., the number of edges in G.

If $\hat{G}$ is a network-graph resulting from an attempt to construct G from some collection of basic measurements, then the common practice of reporting the analogous characteristics of $\hat{G}$ is equivalent to the use of $\eta\left(\hat{G}\right)$, i.e., effectively a plug in estimator. Let the discrepancy between these two quantities be defined as $D = \eta\left(\hat{G}\right) - \eta\left(G\right)$, which in the case of counting edges reduces to $D_E = |\hat{E}| - |E|$. Our goal is to make precise probabilistic statements about the behavior of D under certain conditions.

Importantly, in the case where η is defined as a subgraph count, as in (1), D may be expressed as the difference of (i) the number of times the subgraph H arises somewhere in $\hat{G}$ but does *not* in fact exist in the same manner in G, and (ii) vice versa. Hence, D may be understood in this context to be the difference in total number of Type I and Type II errors, respectively. Intuitively, in the cases where a sufficiently low rate of error occurs on a large graph G, each of these two sums should have a Poisson-like behavior. This observation suggests that the propagation of low-rate measurement error to subgraph counts should behave, under appropriate conditions, like the difference of two Poisson random variables, i.e., a so-called Skellam distribution (Skellam, 1946).

Our contribution in this paper is to provide an initial set of results on the accuracy with which the Skellam distribution may be used in approximating the distribution of D, under the setting where the graph G is large and the rate of error is low. We consider the cases of both sparse and dense networks. The primary technical device used here is Stein's method (e.g, Barbour and Chen, 2005). Specifically, we present a Stein operator for the Skellam probability distribution and, in a manner consistent with the Stein methodology, we derive several bounds on the discrepancy between the distribution of the difference of two arbitrary sums of binary random variables to an appropriately parameterized Skellam distribution. The latter in turn is then used to establish in particular the rate of weak convergence of D_E to an appropriate Skellam random variable, under either independent or weakly dependent measurement errors.

As remarked above, there appears to be little in the way of a formal and general treatment of the error propagation problem we consider here. However, there are, of course, several areas in which the probabilistic or statistical treatment of uncertainty enters prominently in network analysis. The closest area to what we present here is the extensive literature on distributions of subgraph counts in random graphs. See Janson et al. (2011), for example, for comprehensive coverage. Importantly, there the graph G is assumed to emerge according to a (classical) random graph and uncertainty typically is large enough that normal limit theorems are the norm (although Poisson limit theorems also have been established). In contrast, in our setting we assume that G is a fixed, true underlying graph, and then study the implications of observing a 'noisy' version $\hat{G}$ of that graph, under various assumptions on the nature of the noise, which involves two specific types of error (i.e., Type I and II errors), the contributions of which are informed in part by the topology of G itself. An area related to this work in random graphs is the work in statistical models for networks, such as exponential random graph models (ERGMs). See Lusher et al. (2012) for a recent treatment. Here, while these models are inherently statistical in nature, the randomness due to generation of the graph G and due to observation of G—resulting in what we call $\hat{G}$—usually are combined into a single realization from the underlying distribution. And while subgraph counts do play a key role in traditional ERGMs, they typically enter as covariates in these (auto)regressive models. In a somewhat different direction, uncertainty in network construction due to sampling has also been

studied in some depth. See, for example, Kolaczyk (2009, Ch 5) or Ahmed et al. (2014) for surveys of this area. However, in this setting, the uncertainty arises only from sampling—the subset of vertices and edges obtained through sampling are typically assumed to be observed without error. Finally, we note that there just recently have started to emerge in the statistics literature formal treatments of the same type of graph observation error model that we propose here. There the emphasis is on producing estimators of network model parameters and/or classifiers (e.g., Priebe et al., 2015), for example, rather than on the type of basic network summary statistics that are the focus here.

The organization of this paper is as follows. In Section 2 we provide necessary background. In Section 3 we then provide a general set of results useful for our general problem. Specifically, we establish a bound for the Kolmogorov-Smirnov distance between the distribution of the difference of two arbitrary sums of binary random variables from a certain Skellam. This work is based on the application of Stein's method to the Skellam distribution, a first of its kind to the best of our knowledge, and the results therefore are of some independent interest as well. In Section 4 we then illustrate the way in which these general results may be used to understand the propagation of error in networks for counting edges. In doing so, several other general results are established. Some implications of these results on the problem of counting subgraphs of higher order are noted in Section 5, along with other related discussion. Proofs of our key results may be found in the appendices.

2. Background

In this section, we provide essential notation and background for our forthcoming general results.

2.1 Notation and Assumptions

By $G = (V, E)$ we will mean an undirected graph, with vertex set V of cardinality $|V|$ and edge set E of cardinality $|E|$. Vertex pairs in the complement of E, i.e., in E^c, will be referred to as non-edges. Much of the results that follow will be stated as a function of the number of vertices which, for notational convenience, we denote $n_v = |V|$. Let $\mu = \mu(G) = 2|E|/n_v$ correspond to the average degree of a vertex in G. We assume the vertex set V is known but that the edge set E is unknown. However, we assume there is information by which to construct an approximation to E or, more formally, by which to infer E, as a set $\hat{E}$, yielding an inferred graph $\hat{G} = (V, \hat{E})$.

While there are many ways in practice by which the set $\hat{E}$ is obtained, one principled way of viewing the task is as one of performing $\binom{n_v}{2}$ hypothesis tests, using the data underlying the graph construction process as input, one for each of the vertex pairs $\{i, j\}$ in the graph G. In some contexts, $\hat{G}$ is literally obtained through hypothesis testing procedures; for instance, in constructing some gene regulatory networks from microarray expression data. See Kolaczyk (2009, Ch 7), for example. Formally, in such cases we can think of $\hat{G}$ as resulting from a collection of testing problems

$$H_0 : \{i, j\} \notin E \text{ versus } H_1 : \{i, j\} \in E \ ,$$

for $\{i, j\} \in V^{(2)}$, where

$$V^{(2)} = \{\{i, j\} : i, j \in V; i < j\} \ .$$

These tests amount to a collection of $\binom{n_v}{2}$ binary random variables $\left\{Y_{ij} : \{i,j\} \in V^{(2)}\right\}$, where

$$Y_{ij} = \begin{cases} 1 & \text{if } H_0 \text{ is rejected} \\ 0 & \text{if } H_0 \text{ is not rejected.} \end{cases}$$

Note that the random variables Y_{ij} need not be independent and, in fact, in many contexts will most likely be dependent. Gene regulatory networks inferred by correlating gene expression values at each vertex i with that of all other vertices $j \in V \setminus \{i\}$ and maps of the logical Internet obtained through merging paths learned by sending traffic probes between many sources and destinations are just two examples where dependency can be expected.

Whether obtained informally or formally, we can define the inferred edge set $\hat{E}$ as

$$\hat{E} = \left\{\{i,j\} \in V^{(2)} : Y_{ij} = 1\right\} \ .$$

It is useful to think of the collection of random variables $\left\{Y_{ij} : \{i,j\} \in V^{(2)}\right\}$ as being associated with two types of errors. That is, we express the marginal distributions of the Y_{ij} in the form

$$Y_{ij} \sim \begin{cases} \text{Bernoulli}\left(\alpha_{ij}\right), \text{if } \{i,j\} \in E^c, \\ \text{Bernoulli}\left(1-\beta_{ij}\right), \text{if } \{i,j\} \in E, \end{cases} \tag{2}$$

where $E^c = V^{(2)} \setminus E$. Again pursuing the example of network construction based on hypothesis testing, α_{ij} can be interpreted as the probability of Type-I error for the test on vertex pair $\{i,j\} \in E^c$, while β_{ij} is interpreted as the probability of Type-II error for the test on vertex pair $\{i,j\} \in E$. For example, α_{ij} might be the probability of incorrectly inferring a regulatory relationship between two genes i and j, based on thresholding the empirical correlation between their expression values, as quantified through deep sequencing measurements over a series of experiments. Similarly, β_{ij} might be the probability of missing a logical link in the Internet topology between two routers i and j, due to artifacts in measurement technologies (e.g., traceroute).

Our interest in this paper is in characterizing the manner in which the uncertainty in the Y_{ij} propagates to subgraph counts on $\hat{G}$. More specifically, we seek to characterize the distribution of the difference

$$D = \frac{1}{|Iso(H)|} \sum_{H' \subseteq K_{n_v}, H' \cong H} \left[1\{H' \subseteq \hat{G}\} - 1\{H' \subseteq G\}\right] \ , \tag{3}$$

for a given choice of subgraph H. Naturally, this distribution will depend in no small part on context. Here we focus on a general formulation of the problem in which we make the following three assumptions.

(A1) *Large Graphs:* $n_v \to \infty$.

(A2) *Edge Unbiasedness:* $\sum_{\{i,j\} \in E^c} \alpha_{ij} = \sum_{\{i,j\} \in E} \beta_{ij} \ (\equiv \lambda)$.

(A3) *Low Error Rate:* $\lambda = \Theta\left(\mu\right)$.

Assumption (A1) reflects both the fact that the study of large graphs is a hallmark of modern applied work in complex networks and, accordingly, our desire to make statements that are asymptotic in n_v.

Our use of assumption (A2) reflects the understanding that a 'good' approximation $\hat{G}$ to the graph G should at the very least have roughly the right number of edges. The difference of the two sums defined in (A2) is in fact the expectation of the statistic D in (3) for the case where the subgraph being counted is just a single edge, i.e., it is the expected discrepancy between the number of observed edges $|\hat{E}|$ and the actual number of edges $|E|$. So (A2) states that this particular choice of D has expectation zero. Alternatively, (A2) may be interpreted as saying that the total numbers of Type I and Type II errors should be equal to a common value λ.

Finally, we capture the notion of a 'low' rate of error in $\hat{G}$ through assumption (A3). Specifically, we assume that the number of Type I or Type II errors in edge status that we expect throughout the network is roughly on par with the average number of edges incident to any given vertex in the network. This condition can be re-expressed in a useful manner with respect to n_v if, as is common in the literature, we distinguish between sparse and dense graphs. By the term *sparse* we will mean a graph for which $|E| = \Theta\left(n_v \log n_v\right)$, and by *dense*, $|E| = \Theta\left(n_v^2\right)$. Hence, assumption (A3) reduces to $\lambda = \Theta\left(\log n_v\right)$ in the case of sparse graphs, and to $\lambda = \Theta(n_v)$, in the case of dense graphs.

In addition, for convenience, we add to the core assumptions (A1)-(A3) a fourth assumption, upon which we will call periodically throughout the paper when desiring to simplify some of our expressions.

(A4) *Homogeneity:* $\alpha_{ij} \equiv \alpha$ and $\beta_{ij} \equiv \beta$, for $\alpha, \beta \in (0,1)$.

In other words, we assume that the probability of making a Type I or II error (as the case may be) does not depend upon the specific (non)edge in question.

Lastly, for completeness, we recall the definition of the Skellam distribution. A random variable W defined on the integers is said to have a Skellam distribution, with parameters $\lambda_1, \lambda_2 > 0$, i.e., $W \sim \text{Skellam}\left(\lambda_1, \lambda_2\right)$, if

$$\mathbb{P}\left(W = k\right) = e^{-(\lambda_1+\lambda_2)} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k\left(2\sqrt{\lambda_1\lambda_2}\right) \text{ for } k \in \mathbb{Z}, \tag{4}$$

where $I_k\left(2\sqrt{\lambda_1\lambda_2}\right)$ is the modified Bessel function of the first kind with index k and argument $2\sqrt{\lambda_1\lambda_2}$. The Skellam distribution may be constructed by defining W through the difference of two independent Poisson random variables, with means λ_1 and λ_2, respectively. The mean and variance of this distribution are given by $\mathbb{E}[W] = \lambda_1 - \lambda_2$ and $\text{Var}(W) = \lambda_1 + \lambda_2$. The distribution of W is in general asymmetric, with symmetry holding if and only if $\lambda_1 = \lambda_2$.

The main results we provide in this paper are in the form of bounds on the extent to which the distribution of random variables like the discrepancy D in (3) may be well-approximated by an appropriate Skellam distribution. For this purpose, we adopt the Kolmogorov-Smirnov distance to quantify the distance between distributions of two random variables, say, X_1 and X_2, i.e.,

$$ds_{KS}(X_1, X_2) \equiv \sup_{x \in \mathbb{R}} \left|\mathbb{P}\left(X_1 \leq x\right) - \mathbb{P}\left(X_2 \leq x\right)\right| .$$

2.2 Counting Edges

Generic subgraph counts, and the corresponding noise in obtaining them, can be quite varied in real applications. Accordingly, most of our specific results pertain to the fundamental case of counting

edges. That is, where the choice of subgraph H is simply a single edge, and therefore the function $\eta(G)$ in (1) is just the total number of edges in G, i.e., $\eta(G) = |E|$. We will consider two scenarios for this case, wherein the random variables Y_{ij} are independent or weakly dependent.

In the case where the edge noise is independent, the discrepancy

$$\begin{aligned} D_E &= |\hat{E}| - |E| \\ &= \sum_{\{i,j\} \in E^c} Y_{ij} - \sum_{\{i,j\} \in E} (1 - Y_{ij}) \end{aligned}$$

has expectation $\mathbb{E}[D_E] = \alpha|E^c| - \beta|E| = \lambda - \lambda = 0$ and variance $\sigma^2 = \alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|$, and its behavior can be established using existing methods from the literature (i.e., essentially, Chen-Stein methods). However, we include it as an important base case, comparing results obtainable by our methods to those obtainable by more traditional techniques, in Section 4.1.

Alternatively, suppose that the variables Y_{ij} are *dependent*. The random variable D_E again has expectation zero, although its variance—and hence its asymptotic behavior—will differ from the independent case, in a manner dictated by the nature of the underlying dependency in the noise. It often can be expected in practice that the error associated with construction of the empirical graph $\hat{G}$ will involve dependency across (non)edges. For example, relations in gene regulatory networks are often declared based on sufficiently strong levels of association between gene-specific measurements (e.g., measures of gene expression). The comparison of the measurements for each gene with those of all of the others necessarily induces potential dependencies among the random variables Y_{ij}. However, a precise characterization of such dependency is typically problem-specific and, more often than not, nontrivial in nature. In Section 4.2 we will assume general dependency conditions in the spirit of traditional monotone coupling arguments, which will allow for further analysis and interpretation.

3. General Results on Approximation by Skellam

Recall the general form of our statistic of interest D in (3), as the difference of two sums of binary random variables. Under appropriate conditions it seems reasonable to expect that the distribution of D be well-approximated by a Skellam distribution. And for the simplest case, in which we are counting edges under independent noise, it is possible to show that this is in fact the case, through manipulation of existing results for approximating sums by Poisson distributions. Without independence, however, it is necessary to approach the problem directly, by explicitly using the Skellam distribution. In this section, we therefore provide the results of such an approach. This is a completely general treatment—devoid of the motivating context of counting subgraphs—and therefore also likely of some independent interest. In Section 4 we return to the problem of counting subgraphs under low-rate error and illustrate the use of the results presented here in this section through application to the case of counting edges.

Our approach in this section is through Stein's method. This choice is reminiscent, naturally, of the Chen-Stein treatment for Poisson approximations. However, the task is technically more involved at several points, as it requires handling a Stein function that is defined through a second-order difference, rather than the first-order difference encountered in the Poisson problem. Moreover, the kernel of the Skellam distribution includes a modified Bessel function of the first kind, which emerges in ways necessitating a somewhat delicate treatment.

3.1 A Stein Bound for the Skellam Distribution

Let U be a random variable defined as

$$U = \sum_{k=1}^{n} L_k - \sum_{k=1}^{m} M_k \ , \tag{5}$$

where $\{\{L_k\}_{k=1}^n, \{M_k\}_{k=1}^m\}$ is a collection of two sets of indicator random variables with $\mathbb{E}[L_k] = p_k$ for $k = 1, \ldots, n$ and $\mathbb{E}[M_k] = q_k$ for $k = 1, \ldots, m$. In the case of our subgraph counting problem, $U = D$, where D is defined in (3), although for the remainder of this current section U is defined generally.

Recall the definition of a Skellam random variable W in (4). We desire a bound on

$$d_{KS}(U, W) := \sup_{x \in \mathbb{R}} |\mathbb{P}(U \leq x) - \mathbb{P}(W \leq x)| \ , \tag{6}$$

quantifying how close the distribution of U is to that of W. In pursuing the standard paradigm for Stein's method, we first determine an operator $\mathcal{A}[f(k)]$ such that

$$\mathbb{E}\mathcal{A}[f(W)] = 0 \quad \text{if and only if} \quad W \sim \text{Skellam}(\lambda_1, \lambda_2)$$

for any bounded function $f : \mathbb{Z} \mapsto \mathbb{R}$. This operator need not be unique, but the theory only requires one. This is accomplished through the following result, the proof of which uses several properties of the modified Bessel function of the first kind, as detailed in the appendix, in Section A.1.

Theorem 1 *A Stein operator $\mathcal{A}$ for the Skellam (λ_1, λ_2) distribution is*

$$\mathcal{A}[f(k)] = \lambda_1 f(k+1) - k f(k) - \lambda_2 f(k-1) .$$

With this operator in hand, and again following the usual paradigm under Stein's method, we set

$$\mathcal{A}[f(k)] = g(k)$$

for a class of test functions $g(k)$, and allow that to implicitly define the function f. The choice of the test functions g is guided by the choice of the metric used to measure the distance between U and W. Since the metric we choose to measure the distance between U and W is given by $d_{KS}(U, W)$ in (6), we choose the test function $g := g_x$ given by

$$g_x(k) = 1\{k \leq x\} - \mathbb{P}(W \leq x) \tag{7}$$

for any $x \in \mathbb{R}$.

At this point it is common to exhibit a solution f defined by our choice of g. Instead, we forestall that step until later in this section, choosing rather to state a general result that will allow us to more quickly gain insight into the nature of the bounds we are able to obtain. Our result employs a minor variant of the notion of coupling that is common to the literature on Chen-Stein approximations.

Theorem 2 *Let U be as in (5) and let $\mathcal{L}(U)$ denote the law of U. Let*

$$\mathcal{L}\left(U_k^{(L)} + 1\right) = \mathcal{L}(U | L_k = 1) \quad \text{for} \quad k = 1, \ldots, n$$

and

$$\mathcal{L}\left(U_k^{(M)} - 1\right) = \mathcal{L}\left(U | M_k = 1\right), \quad \text{for} \quad k = 1 \ldots, m$$

be a collection of random variables all defined on a common probability space. If $\lambda_1 = \sum_{k=1}^n p_k$ *and* $\lambda_2 = \sum_{k=1}^m q_k$*, and* $W \sim Skellam(\lambda_1, \lambda_2)$*, then*

$$d_{KS}(U, W) \leq ||\Delta f|| \left\{ \sum_{k=1}^n p_k \mathbb{E}\left|U - U_k^{(L)}\right| + \sum_{k=1}^m q_k \mathbb{E}\left|U - U_k^{(M)}\right| \right\} \quad , \tag{8}$$

where

$$||\Delta f|| = \sup_{x \in \mathbb{R}} \sup_{j \in \mathbb{Z}} \left| f_x\left(j+1\right) - f_x\left(j\right) \right|$$

and f_x *is a solution to* $\mathcal{A}\left[f_x(k)\right] = g_x(k)$ *for* $k \in \mathbb{Z}$*.*

The proof of this result relies on elementary considerations of the equation $\mathcal{A}[f_x(k)] = g_x(k)$ and may be found in the appendix in Section A.2. The extent to which it allows one to obtain error estimates of practical interest in a particular setting will depend on the extent to which both the main expression within brackets in (8) and the preceding constant $||\Delta f||$ can be further controlled. While control of the former is problem dependent, control of the latter is not, and may be dealt with separately, as we do next. Afterwards, in Section 4, we illustrate the control of the bracketed expression in (8), in the context of the problem of counting edges introduced in Section 2.2.

3.2 Controlling the Constant Term

Controlling $||\Delta f||$ in (8) first requires understanding the solution $f_x(k)$. We provide a family of closed-form expressions for this solution in the following.

Theorem 3 *Let* g_k *be defined as in equation (7). If* f_x *is a bounded solution to the difference equation*

$$\lambda_1 f_x\left(k+1\right) - k f_x\left(k\right) - \lambda_2 f_x\left(k-1\right) = g_x\left(k\right)$$

for $k \in \mathbb{Z}$*, then* f_x *is given by*

$$f_x\left(m\right) = \begin{cases} (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m\left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f\left(c\right) \right. \\ \left. + \frac{e^{\lambda_1+\lambda_2}}{\sqrt{\lambda_1\lambda_2}} \sum_{n=c}^{m-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \mathbb{P}\left(W \leq \min\left\{n, x\right\}\right) \mathbb{P}\left(W > \max\left\{n, x\right\}\right) \right] & \text{if } m > c \\ (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m\left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f\left(c\right) \right. \\ \left. - \frac{e^{\lambda_1+\lambda_2}}{\sqrt{\lambda_1\lambda_2}} \sum_{n=m}^{c-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \mathbb{P}\left(W \leq \min\left\{n, x\right\}\right) \mathbb{P}\left(W > \max\left\{n, x\right\}\right) \right] & \text{if } m < c. \end{cases}$$

for any initial condition $(c, f_x\left(c\right))$ *with* $c \in \mathbb{Z}$ *and* $f_x\left(c\right) \in \mathbb{R}$*. Here* I_m *is used as short-hand for* $I_m(2\sqrt{\lambda_1\lambda_2})$*.*

The proof of this theorem is similar to that of solving a second order linear differential equation. An integrating factor is found, integration is performed with a boundary condition at $-\infty$, and then a second integration is performed with the initial condition. Details are provided in the appendix in Section A.3.

Leveraging our insight into f_x to control $||\Delta f||$ means producing a bound on the absolute differences $|\Delta f_x(j)| = |f_x(j+1) - f_x(j)|$ independent of $x \in \mathbb{R}$ and $j \in \mathbb{Z}$. Consider first the special case where λ_1 and λ_2 are equal, for which we are able to offer the following result.

Theorem 4 *Suppose that* $\lambda_1 = \lambda_2 \equiv \lambda$*, so that* $\mathbb{E}[U] = 0$ *and* W *is a Skellam*(λ, λ) *distribution, symmetric about zero. Assume* $\lambda \geq 1$*. Then*

$$||\Delta f|| \leq \frac{160}{2\lambda}.$$

The proof of this theorem is highly technical in nature, and relies on a concentration inequality for the Skellam(λ, λ) distribution (Balachandran et al., 2013b) with several other technical arguments. A sketch of the proof may be found in the appendix in Section A.4, while a detailed presentation is available in the online appendix.

Note that the bound in Theorem 4 is essentially the analogue of the classical result for Poisson approximation, in which, for sufficiently large λ, the term $1/\lambda$ is the standard factor. In both cases, therefore, the corresponding term $||\Delta f||$ is bounded by the inverse of the expected total number of counts, where here that is $\mathbb{E}[T_1 + T_2] = 2\lambda$.

The above result is of immediate relevance to the problem of counting edges, given assumption (A2), whether under the assumption that the edge noise is independent or dependent. We will make use of this result in the next section. For applications involving higher-order subgraphs, we can expect to need an extension of Theorem 4 to the general case of $\lambda_1 \neq \lambda_2$. For arbitrary $\lambda_1, \lambda_2 > 0$, we are unable to produce a satisfactory bound. However, supported by preliminary numerical work, we have the following conjecture.

Conjecture 5 *In general, for* λ_1 *and* λ_2 *sufficiently close and large,*

$$||\Delta f|| \leq \frac{C}{\lambda_1 + \lambda_2},$$

for some constant $C > 0$ *independent of* λ_1, λ_2*.*

4. Application of General Results to Counting Edges

We now illustrate the use of our general results for the problem of characterizing the propagation of low-rate measurement error to subgraph counts in large graphs, for the specific case of counting edges.

4.1 Edge Counts Under Independent Edge Noise

Recall the problem wherein the function of interest (1) counts the number of edges in G, i.e., $\eta(G) = |E|$, and the variables Y_{ij} in (2) are independent. In light of Theorems 2 and 4, we have the following result characterizing the behavior of the discrepancy D in (3), which here is simply $D_E = |\hat{E}| - |E|$.

Theorem 6 *Under assumptions (A1)-(A4) and independence among errors in declaring (non)edge status (i.e., among the* Y_{ij}*),*

$$d_{KS}\left(\, D_E \,,\, Skellam(\lambda, \lambda)\,\right) \leq O\left(n_v^{-1}\right) \quad , \tag{9}$$

for both sparse and dense graphs G*.*

Proof of this result may be found in the appendix, in Section A.5. The theorem establishes a rate at which—in large networks, whether sparse or dense, with independent and homogeneous low-rate errors—the distribution of the discrepancy D_E tends to that of an appropriate Skellam distribution, i.e., symmetric and centered on zero, with variance 2λ. The same rate may be established using more standard arguments from Chen-Stein theory, the proof of which we also include in the appendix, for completeness. These latter arguments, of course, only hold in the case of independence assumed here, and do not extend generally to the case of dependence in the edge noise.

To put the rate established in the above theorem in better context, it is interesting to compare to the case where a normal distribution is used instead to approximate that of the discrepancy D_E. The following theorem, proof of which also may be found in Section A.5, provides both upper and lower bounds.

Theorem 7 *Let $\sigma^2 = Var(D_E)$. Under the same conditions as Theorem 6 , in the case of sparse graphs*

$$\Omega\left(\log^{-1} n_v\right) \leq d_{KS}\left(\, D_E/\sigma \,,\, N(0,1)\,\right)\right) \leq O\left(\log^{-1/2} n_v\right) \quad , \tag{10}$$

while in the case of dense graphs,

$$\Omega\left(n_v^{-1}\right) \leq d_{KS}\left(\, D_E/\sigma \,,\, N(0,1)\,\right)\right) \leq O\left(n_v^{-1/2}\right) \quad , \tag{11}$$

where $N(0,1)$ refers to a standard normal random variable.

These two theorems together indicate that in this context a Skellam approximation is clearly superior to a normal for sparse graphs, and they suggest that it can be better as well for dense graphs. These statements are supported by the results of a small simulation study, shown in Figure 1. There we compared the two approximations as n_v ranges from 100 to 1000 to 10,000, for error rates λ defined to be constant, logarithmic, square root, or linear functions of n_v. For the sparse and dense cases, we let $|E|$ equal $n_v \log n_v$ and $n_v(n_v-1)/4$, respectively. Looking at the sparse case, for when $\lambda = \log n_v$, the Skellam approximation clearly dominates the normal. However, interestingly, this dominance continues even when the error rate is set equal to $n_v^{1/2}$. Only once the error rate is n_v do we see the normal approximation begin to overtake the Skellam approximation. Note that by this stage, $\beta = O(1)$, and so essentially there is no 'signal' standing out from the 'noise'. Similarly, looking at the dense case, we see that the Skellam approximation is better than the normal approximation at all error rates, including, in particular, when the error rate equals n_v, the case addressed by the above two theorems.

In summary, in the independent case, the Skellam distribution dominates the normal as an approximation when there can be expected to be a clear graph 'signal' standing out against the 'noise' induced by underlying low-rate measurement errors.

4.2 Edge Counts Under Dependent Edge Noise

Again, as just above, consider the context wherein counting edges is of interest, so that $\eta(G) = |E|$ and our goal is to characterize the accuracy with which $D_E = |\hat{E}| - |E|$ is approximated by a Skellam(λ, λ) random variable. Now, however, we assume that the error associated with construction of the empirical graph $\hat{G}$ will involve dependency across (non)edges. That is, the random variables Y_{ij} are now dependent. A precise characterization of such dependency is typically problem-specific and, more often than not, nontrivial in nature. Here, for the purposes of illustration, we instead provide certain results of a general nature, working from the bound (8) of Theorem 2.

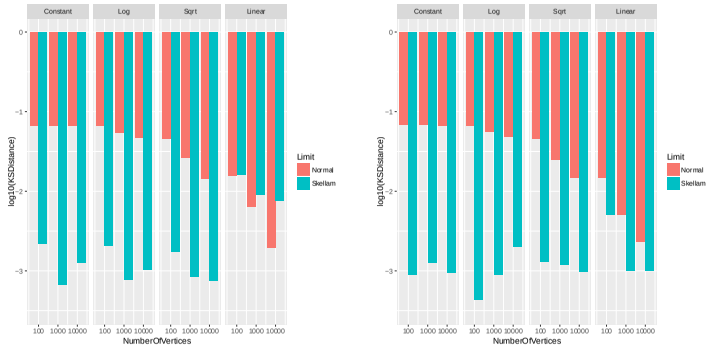

Figure 1: (Log)Kolmogorov-Smirnov distance between Skellam and standard normal approximations to the distribution of discrepancy D_E in edge counts under independent errors. *Left:* Sparse case. *Right:* Dense case.

Of the two terms in (8), the first term $||\Delta f||$ is again known to behave as $O(\lambda^{-1})$, by Theorem 4. On the other hand, control of the second term, in brackets, requires some care. For example, naive inter-change of absolute values and summations with expectation yields that

$$p_k \mathbb{E}\left|U - U_k^{(L)}\right| \leq p_k^2 + \sum_{k \neq j} p_k p_j + E[L_k L_j] + \sum_{\ell=1}^{m} p_k q_\ell + E[L_k M_\ell] \quad ,$$

and similarly for $q_k \mathbb{E}\left|U - U_k^{(M)}\right|$. Unfortunately, it is straightforward to show that for the dependent error version of the problem considered in the previous subsection (i.e., involving independent and homogeneous low-rate errors on large-spare networks) the bound we obtain for $d_{KS}\left(\, D_E \,,\, \text{Skellam}(\lambda,\lambda)\,\right)$ will be no better than $O(\lambda)$—regardless of the nature of the dependency among the Y_{ij}.

One possible approach to a more subtle handling of these terms is motivated by considerations of hypothesis testing. Suppose that the L_k correspond to indicators of Type I error for n tests under their corresponding null hypotheses, and the M_k, to indicators of Type II error for m tests under their corresponding alternative hypotheses. Furthermore, suppose that the corresponding test statistics are all defined on the same scale and compared to the same threshold. Moreover, for simplicity, we assume these statistics all have non-negative values and that their distribution under the null sits to the left of that under the alternative, so that more extreme positive values tend to support the alternative. In this setting, if we know, for example, that $L_1 = 1$, we know that at least one rejection of a null hypothesis has occurred, indicating that the threshold sits to the left of the right-most extreme of the empirical null distribution. Accordingly, we are inclined to expect that there may be other such rejections of the null, i.e., other Type I errors. At the same time, we would expect fewer Type II errors, i.e., fewer M that equal 1. Conversely, if we see a Type II error, say $M_1 = 1$, it can be argued that we would be inclined to expect more Type II errors and, at

the same time, fewer Type I errors. These arguments are heuristic, of course, although intuitively appealing. From a practical perspective, their validity would need to be examined within specific applied contexts. However, that work lies beyond the scope of the present manuscript.

Together these high-level arguments suggest that a reasonable generic model for these errors is one in which there is positive correlation *within* the L's and M's, respectively, but negative correlation *between*. The conditions of the following theorem capture this notion, which in turn allow us to produce a sensible bound, improving on that of Theorem 8.

Theorem 8 *Let $\tilde{L}_j^{L_k}$ and $\tilde{M}_\ell^{L_k}$ be random variables distributed as L_j and M_ℓ respectively, conditional on $L_k = 1$. Similarly, let $\tilde{L}_j^{M_k}$ and $\tilde{M}_\ell^{M_k}$ be distributed as L_j and M_ℓ, conditional on $M_k = 1$. Suppose that*

i. $\tilde{L}_j^{L_k} \geq L_j$ and $\tilde{M}_\ell^{L_k} \leq M_\ell$, for $j \neq k$ and $\ell = 1, \ldots, m$, while

ii. $\tilde{L}_j^{M_k} \leq L_j$ and $\tilde{M}_\ell^{M_k} \geq M_\ell$, $j = 1 \ldots, n$ and $\ell \neq k$.

Then

$$d_{KS}(U, W) \leq ||\Delta f|| \left\{ Var(U) - (\lambda_1 + \lambda_2) \right\} \quad , \tag{12}$$

where $W \sim$ Skellam(λ_1, λ_2), with λ_1, λ_2 defined as in Theorem 2.

The proof of this theorem is given in the appendix, in Section A.6. We note that for a collection of binary random variables to satisfy conditions (i) and (ii) in the above theorem, it is sufficient, for example, to generate a vector of positively associated random variables $(L_1, \ldots, L_n, 1 - M_1, \ldots, 1 - M_m)$. The L's and the M's will then be positively associated within, but negatively associated between, which in turn implies the conditions (i.e., analogous to positive and negative relatedness, respectively). See Barbour and Chen (2005, p. 78), for example, for a brief summary of these latter notions and their relationships.

With this theorem, the following then holds for large networks with dependent and homogeneous errors, when the dependency is of the nature just defined.

Corollary 9 *Suppose that the collections of edge indicator random variables $\{Y_{ij}\}_{\{i,j\} \in E^c}$ and $\{Y_{ij}\}_{\{i,j\} \in E}$ satisfy conditions (i) and (ii) of Theorem 8 , playing the roles of the L's and M's, respectively. Then under assumptions (A1)-(A2),*

$$d_{KS}\left(D_E \,,\, \text{Skellam}(\lambda, \lambda) \right) = O\left(\frac{Var(D_E) - 2\lambda}{2\lambda} \right) \quad .$$

This result can be compared to that of Theorem 6 , where the edge noise was independent and the error in approximating by a Skellam decayed like n_v^{-1}. By way of contrast, Corollary 9 tells us that in order to achieve a decay in approximation error like $O(f(n_v))$, we must have $\text{Var}(D_E) = 2\lambda\,(1 + O(f(n_v)))$.

More generally, the quality of the approximation of D_E by a Skellam will be influenced by the nature of the dependency in the errors, as the latter manifests itself through the overall variance $\text{Var}(D_E)$. The nature of that dependency is highly problem-specific, and a detailed investigation of possible cases is well beyond the scope of the present paper, although we provide some initial insight later as it arises in the context of counting higher-order subgraphs, through Theorem 10 in Section 5.

However, nontrivial insight also can be gained into the influence of the level of dependency on accuracy through numerical work under the following simple model.

For a vector of binary random variables $(L_1, \ldots, L_n, 1 - M_1, \ldots, 1 - M_m)$, let $S = D + m$, where $D = \sum_{i=1}^n L_i - \sum_{i=1}^m M_i$. We equip S with a distribution of the form

$$\mathbb{P}(S = k) \propto \binom{n+m}{k}^{\nu - 1} \mathbb{P}(U + V = k) \quad , \tag{13}$$

for ν a real number, where U and V are binomial, with parameters (n, p) and (m, q), respectively. This distribution is a rescaling of that of the sum of two independent binomials, in a spirit analogous to the Conway-Maxwell binomial (COMB) distribution introduced recently by Kadane (2014). The COMB distribution is a simple extension of the binomial distribution that introduces dependency among the corresponding Bernoulli random variables. Our proposed distribution for S in (13) involves two binomial random variables, for which the corresponding Bernoulli random variables are dependent both within and between the two. Accordingly, we call this a COMB2 distribution.

Now impose assumption (A2) on this model. Since the assumption implies that $\mathbb{E}[D] = 0$, it follows that necessarily we must have $\mathbb{E}[S] = m$. Furthermore, the limiting Skellam distribution in Corollary 9 will be symmetric under this assumption. Symmetry can be imposed here on the distribution of S, and hence D, by taking $n = m$ and $q = 1 - p$. Therefore, we let $|E| = \binom{n_v}{2}/2 = n_v(n_v - 1)/4$ and $\alpha = 1 - \beta$. Note that this choice of $|E|$ means that our numerical work pertains to the case of dense graphs. (We are unable to exhibit a sparse variant of the COMB2 model with the necessary characteristics above.)

Note that when $\nu = 1$, the binary random variables $(L_1, \ldots, L_n, 1 - M_1, \ldots, 1 - M_m)$ are independent. On the other hand, proceeding along lines of reasoning similar to those in Kadane (2014), it can be argued that the COMB2 distribution, with the parameter constraints just described, renders the $(L_1, \ldots, L_n, 1 - M_1, \ldots, 1 - M_m)$ positively associated when $\nu < 1$, with the mass being transferred increasingly to the endpoints of the support of the distribution of D as $\nu \to -\infty$. As a result, per the discussion immediately following Theorem 8, the particular COMB2 distribution we have defined can be used to simulate network edge data in a way that satisfies the conditions of Corollary 9.

In Figure 2 are shown the results of numerical work calculating the Kolmogorov-Smirnov distance between the Skellam and standard normal approximations to the distribution of the discrepancy D_E in edge counts under the COMB2 distribution, for $\nu = 0, 0.5$, and 1.0. The noise levels used here are the same as used earlier in producing Figure 1. We see that the accuracy of the Skellam distribution decays slightly with increasing dependency in the errors, and with increasing noise levels.

5. Discussion

The propagation of uncertainty in network analysis is a topic that currently lags the field in development. Despite almost 15 years of work in the modern 'network science' era, on a vast array of topics, from researchers in many different disciplines, there remains a sizable gap in our understanding of how 'low level' errors (i.e., at the level of declaration of edge / non-edge status between vertex pairs) propagate to 'high level' summaries (e.g., subgraph counts, centralities, etc.). As a result, in most practical work, network summary statistics are cited without any indication of likely error.

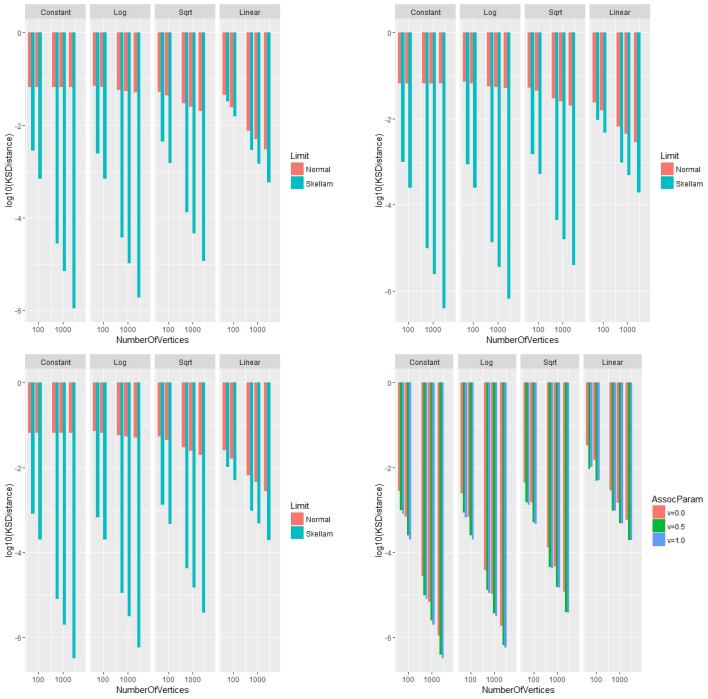

Figure 2: (Log)Kolmogorov-Smirnov distances to the distribution of the discrepancy D_E in edge counts under the COMB2 distribution, with $\nu = 0$ (top left), $\nu = 0.5$ (top right), and $\nu = 1.0$ (bottom left), for the Skellam and standard normal approximations. Also shown is a comparison of Skellam approximations as a function of ν (bottom right).

Our contributions in this paper are aimed at helping to begin laying a foundation for work in this area, with a focus on establishing an initial understanding of the distributional behavior of certain simple network summary statistics. Our choice to work with subgraph counts is both natural and motivated by convenience, whereas our emphasis on the specific case of large networks with low-rate measurement error is intended to capture a sizable fraction of what arguably is encountered in practice.

Ultimately, however, this initial work leaves us still well short of natural practical endpoints in applied statistics and machine learning for network science—for example, even to be able to do hypothesis testing or construct confidence intervals for graph-based parameters of interest (i.e., for $\eta(G)$). To close this gap is well beyond the scope of this paper. Indeed, we anticipate that it

will require the contributions of many papers in this emerging topic area, from researchers across a combination of probability, statistics and machine learning, and domain areas. Accordingly, we devote the remainder of this paper to a brief discussion of what we view as key challenges in terms of applied probability, statistical and machine learning methodology, and practical applications.

5.1 Challenges in Applied Probability

From the perspective of applied probability—including random graph theory—our problem formulation appears to be new. Our formulation is reminiscent of the type of 'signal plus noise' model commonly used in nonparametric function estimation and digital signal processing. Notably, in our formulation the true underlying graph G is fixed. This necessitates a different treatment than, say, traditional analysis of subgraph counts in classical Erdős-Rényi random graphs (e.g., Janson et al., 2011, Chs 3 & 6). In the special case where an Erdős-Rényi model is assumed, as well as assuming independence among the measurement errors, and the analysis is done without conditioning on G, then the problem could be viewed as involving a classical random graph wherein the (marginal) probability of an edge is a function not only of an initial edge frequency but also the Type I and Type II error rates. In general, however, either when G is fixed, as assumed in this paper, or from some other class of random graph models (e.g., various models with heterogeneous degree distributions), or when the measurement errors are dependent, the problem is more involved. By conditioning on G, our formulation allows us to focus our analysis firstly on a high-level notion of Type I and II errors among (non)edges, and then secondly on the manner in which the structure of the underlying graph G may interact with those errors.

We view our work in part as laying a key initial piece of the foundation on an important new class of problems in applied probability. However, we have provided a detailed analysis only for the most fundamental of subgraph count statistics, i.e., the number of edges in a network. Our initial work on extension to counts for subgraphs of higher order suggests that the problem becomes increasingly nontrivial. Specifically, the interaction of noise level, graph topology, and choice of subgraph would appear to need to be studied with care.

The following general theorem should be useful in exploring further in this direction.

Theorem 10 *Let H be a given subgraph of interest. Re-express the difference D in subgraph counts defined in equation (3) as*

$$D_H = \sum_{H' \notin \mathcal{C}_H} L_{H'} - \sum_{H' \in \mathcal{C}_H} M_{H'} \ ,$$

for $\mathcal{C}_H = \{H' \subseteq K_{n_v} : H' \cong H, H' \subseteq G\}$, where $L_{H'}$ and $M_{H'}$ are indicator variables of Type I and Type II error, respectively, for a subgraph H'. Under the assumption of independent edge noise,

$$d_{KS}(D_H, W) \leq ||\Delta f|| \{Var(D_H) - (\lambda_1 + \lambda_2)\} \ , \tag{14}$$

where $W \sim$ Skellam(λ_1, λ_2), with $\lambda_1 = \sum_{H' \notin \mathcal{C}_H} p_{H'}$ and $\lambda_2 = \sum_{H' \in \mathcal{C}_H} q_{H'}$, for $p_{H'} = \mathbb{E}[L_{H'}]$ and $q_{H'} = \mathbb{E}[M_{H'}]$.

This result follows directly from application of Theorem 8 and the comment immediately following that theorem. In particular, each of the indicator random variables $L_{H'}$ and $1 - M_{H'}$ may be expressed as a product of $n_{v(H)}$ choose two binary random variables, where $n_{v(H)}$ is the order of the subgraph H. Since these products are non-decreasing functions of their arguments, and their

arguments are independent, it follows that the collection of random variables defined by the union of the $L_{H'}$ and the $1 - M_{H'}$ are positively associated (e.g., Esary et al., 1967).

Application of this theorem to specific choices of subgraphs H requires calculation or bounding of the two key elements within brackets in (14), i.e., $\text{Var}(D_H)$ and $\lambda_1 + \lambda_2$, as well as control of the constant $||\Delta f||$. For the case of independent edge noise (which, nevertheless, yields *dependent* indicator variables $L_{H'}$ and $M_{H'}$), there is some hope that the former two quantities may be bounded through straightforward calculations, at least for low-order subgraphs. As for the latter quantity, under Conjecture 5 this term is controlled by a term of order $(\lambda_1 + \lambda_2)^{-1}$, but this conjecture, while supported by numerical work, remains to be proven.

By way of illustration, consider the problem of counting two-stars on the one-dimensional toroidal lattice of degree $2r$, $r \geq 1$. That is, the graph G is composed of a ring, with each vertex connected to its r nearest neighbors in each direction. The subgraph H is simply a chain of length two, i.e., a subgraph on three vertices $\{i, j, k\}$ with edges $\{i, j\}$ and $\{i, k\}$. In this case, the total number of two-stars is $\eta(G) = n_v \binom{2r}{2}$. Under homogeneous Type I and Type II error rates α and β, the parameters λ_1 and λ_2 in Theorem 10 take the values

$$\lambda_1 = 2rn_v \left(n_v - 2r - 1\right) \alpha \left(1 - \beta\right) + n_v \binom{n_v - 2r - 1}{2} \alpha^2$$

and

$$\lambda_2 = n_v \binom{2r}{2} \left[1 - (1 - \beta)^2\right] \ .$$

Here the two terms defining λ_1 derive from counting the number of vertex triples in G that possess only one edge or no edges among them, respectively. Under assumptions (A1) - (A4), and supposing that G is sparse, λ_1 and λ_2, are both $O(\log^2 n_v)$, so that neither of the sums in D_H dominates the other. However, λ_1 is in general not equal to λ_2, and so Conjecture 5 is pertinent here. At the same time, calculation of the variance in (14) is decidedly more involved, as it requires evaluation of the covariances $\text{Cov}\left(L_{H'}, L_{H''}\right)$, $\text{Cov}\left(M_{H'}, M_{H''}\right)$, and $\text{Cov}\left(L_{H'}, M_{H''}\right)$ over all pairs of vertex-triples, corresponding to putative subgraphs H' and H''. Under independent edge noise, the calculations simplify to some extent, in that these covariances are non-zero only in the case where the relevant pair of vertex triples is defined in terms of a total of only either three or four unique vertices. (When five or six unique vertices define the two triples, the indicators L and/or M are functions of two independent sets of edge indicators Y_{ij}.) Nevertheless, there still remain several subcases to enumerate for each of the three forms of covariance above in order to complete the calculation, rendering the exercise arguably feasible but tedious. Ultimately, however, since the denominator in (14) is $O\left(\log^2 n_v\right)$ under Conjecture 5, we see that under this particular noise level, with this particular graph topology, the convergence to Skellam is unlikely to be fast. Numerical experiments confirm this expectation.

This small illustration is sufficient to illustrate the point we assert above, i.e., that the interaction of noise level, graph topology, and choice of subgraph are likely to be nontrivial in the class of problems introduced here in this paper, and will likely require substantial and careful study in applied probability. Of course, looking even more broadly, by restricting our attention to subgraph counts we have only considered a portion of the full universe of network summary statistics. Clearly there are other classes of summaries of interest to be explored, and which can be expected to potentially display different behavior. Summaries relying on shortest path behavior (e.g., the diameter of a graph, between centrality of nodes, etc.) are a natural example.

5.2 Challenges in Statistics and Machine Learning Methodology

From the perspective of statistics and machine learning, the work in this paper is largely a necessary means to an end. In the context of network-based propagation of error, a central goal of interest in these fields would be, for example, to develop methods of hypothesis testing or confidence interval construction for graph-based parameters of interest (i.e., for $\eta(G)$) based on an observed graph $\hat{G}$. Alternatively, one might wish to use such network summaries (or perhaps even the networks themselves) as input into a regression or classifier. Here, again, much work remains to be done.

For parameter estimation and testing in the spirit of classical statistics (e.g., Statistics 101), it is typical to first understand the probability distribution underlying a quantity of interest. That is the goal of this manuscript and, for an important subclass of problems in this space, our results offer some initial insight. But knowledge of this distribution does not necessarily yield a tool for statistical inference. For example, to apply the Skellam results here in practice would require knowledge of the Type I and II error rates. If that knowledge is lacking (as generally is the case), then they must be estimated. How best to perform such estimation will presumably depend on context. To the best of our knowledge, this question has not been explored broadly in the literature. See Section 5.3 for additional comments in this direction.

In our work here, we have purposely taken an agnostic stance on the nature of G. However, it can be expected that additional leverage on the propagation of error problem—and, in particular, related problems of statistical inference—can be gained by incorporating additional model structure into the problem. For example, within the statistics and machine learning literatures, arguably the canonical methodology for producing an estimate $\hat{G}$ of a graph G from data is the neighborhood selection approach of Meinshausen and Bühlmann (2006) and the many derivatives thereof. In this approach, we assume we have available n independent and identically distributed observations of a n_v-dimensional random vector $\mathbf{X}$ that follows a multivariate normal distribution, with mean 0 and covariance matrix Σ. The graph G in this setting is taken to be the so-called concentration graph, defined so as to have an edge between a given vertex pair i and j if and only if the i, j-th entry of the concentration matrix Σ^{-1} is non-zero. Since it is typical to have $n \ll n_v$ in practice, methods of inference for this problem generally make use of complexity-penalized optimization. The original proposal in Meinshausen and Bühlmann (2006) makes use of ℓ_1-penalized regression. In what appears to be a first, the combination of Gaussian graphical models and hypothesis testing for network structure has been explored by Neykov et al. (2016) in recent work. There they characterize the complexity of what they call combinatorial inference problems through the use of minimax lower bounds. Algorithms are provided for tests that achieve those lower bounds.

Examples of other related work in this space include methodology for predicting network topology or attributes with models that explicitly include a component for network noise (e.g., Jiang et al., 2011; Jiang and Kolaczyk, 2012), the 'denoising' of noisy networks (e.g., Chatterjee, 2015), and the adaptation of methods for vertex classification using networks observed with errors Priebe et al. (2015). Also related is recent work by Cai et al. (2017) on the detection of ring lattice structure in the presence of random connections (i.e., small worlds). While there are undoubtedly other examples in this space that we have not cited here, it is nevertheless the case that we are currently still only at the start of methodological development of this type.

Finally, we note that network summary statistics have also long been used in practice as input to regressions and classifiers. A canonical example in the field of marketing is Hill et al. (2006), where the focus is on the identification of early adopters through the use of consumer networks,

with neighborhood summaries (e.g., proportion of neighbors adopting a product) being used as predictors. Similar use has been made in the social sciences. For example, Hahm et al. (2012) use vertex centrality measures from a friendship network as input in an effort to predict adolescents at risk of binge drinking. In these and other cases, it is certainly conceivable that the network summary measures are observed with error. In that case, incorporation of ideas like errors-in-variables regression might be appropriate (Fuller, 2009). Characterization of distributional properties for network summary measures, as in this paper, can be an important step towards understanding an appropriate error model for the predictors.

5.3 Challenges for Practical Applications

When all is said and done, probabilistic and statistical / machine learning development in the area of network-based propagation of error will only have significant practical impact when paired with an appropriate degree of context-specific understanding of the nature and magnitude of errors that arise in network construction. Certainly in most applied settings it is widely recognized by practitioners that there is measurement error associated with common types of network constructions. And in many settings the general issue has received nontrivial attention, such as, for example, in the context of protein-protein interaction networks (e.g., Hart et al., 2006) or social networks (e.g, Almquist, 2012).

In order to interface in a productive manner with theoretical and methodological development, such as offered in this paper, it will be important to be able to quantify the noise levels in applications. The difficulty of this task, of course, can vary greatly by context, as well as can the magnitude of the noise. In the case of protein-protein interaction networks, for example, it is understood that Type I and Type II error rates associated with traditional affinity binding experiments can be alarmingly high. Hart et al. (2006) summarized the fairly substantial literature on quantifying these rates, finding that values of $\alpha \approx 0.35$ and $\beta \approx 0.40$ were not atypical. In this case, such rates derive largely from experimental evidence. Alternatively, Balachandran et al. (2013a) employ empirical null principles (Efron, 2012) for correlation-based inference of a small gene regulatory network in yeast to estimate error rates $\alpha \approx 0.004$ and $\beta \approx 0.009$. But these later should be taken with a grain of salt. Cosgrove et al. (2010) show that such nominal estimates of error rates can be decidedly off from actual error rates when the underlying model assumptions are violated in ways that can often be expected in practice (e.g., due to experimental batch effects).

Finally, it is important to note that in some areas of network science the notion of 'ground truth'—in the sense of what constitutes a true (non)edge—can be a slippery concept. For example, there continues to be much discussion and debate in computational neuroscience as to what functional (or, alternatively, effective) connectivity represents, as inferred from data (e.g., from neuroimaging measurements), in contrast to anatomical (or, alternatively, physical or structural) connectivity. See, for instance, the review by Friston (2011). Such concerns further complicate the task of defining and quantifying appropriately the notions of Types I and II errors used in this paper.

Acknowledgments

We thank Kostas Spiliopoulos and Tasso Kaper for helpful discussions. This work was supported in part by AFOSR award 12RSL042 and NSF grant CNS-0905565.

Appendix A.

A.1 Proof of Theorem 1

Proof We begin with the operator,

$$\mathcal{A}[f(k)] = \lambda_1 f(k+1) - k f(k) - \lambda_2 f(k-1)$$

with the intent of showing that the random variable $W \sim \text{Skellam}(\lambda_1, \lambda_2)$ if and only if $\mathbb{E}\mathcal{A}[f(W)] = 0$ for any bounded function $f : \mathbb{Z} \mapsto \mathbb{R}$.

We begin with the necessity direction and the computation of

$$\begin{aligned}\mathbb{E}\mathcal{A}[f(W)] &= \mathbb{E}[\lambda_1 f(W+1) - W f(W) - \lambda_2 f(W-1)] \\ &\propto \sum_{k=-\infty}^{\infty} [\lambda_1 f(k+1) - k f(k) - \lambda_2 f(k-1)] \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k\end{aligned}$$

where $\propto$ is to be read as "proportional to," and as shorthand, we write I_k for $I_k(2\sqrt{\lambda_1\lambda_2})$. By standard properties of I_k (e.g., Abramowitz and Stegun, 1972) we have that

$$I_{k-1} - I_{k+1} = \frac{k}{\sqrt{\lambda_1\lambda_2}} I_k$$

or, in other words,

$$\sqrt{\lambda_1\lambda_2}\frac{I_{k-1}}{I_k} - \sqrt{\lambda_1\lambda_2}\frac{I_{k+1}}{I_k} = k. \tag{15}$$

This means that

$$\begin{aligned}\mathbb{E}\mathcal{A}[f(W)\,1\{W \le n\}] &\propto \sum_{k=-\infty}^{n} \left[\sqrt{\frac{\lambda_1}{\lambda_2}} f(k+1) - \frac{I_{k-1}}{I_k} f(k) + \right. \\ &\qquad \left. \frac{I_{k+1}}{I_k} f(k) - \sqrt{\frac{\lambda_2}{\lambda_1}} f(k-1)\right] \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k \\ &= \sum_{k=-\infty}^{n} \left[\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k+1} I_k f(k+1) - \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k} I_{k-1} f(k)\right] \\ &\qquad + \sum_{k=-\infty}^{n} \left[\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k} I_{k+1} f(k) - \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k-1} I_k f(k-1)\right] \\ &= \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n+1} I_n f(n+1) + \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n} I_{n+1} f(n).\end{aligned}$$

Now, since f is bounded,

$$\lim_{n\to\infty} \left\{ \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n+1} I_n f(n+1) + \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n} I_{n+1} f(n) \right\} = 0$$

so that by monotone convergence,

$$\begin{aligned}\mathbb{E}\left[\mathcal{A}\left[f(W)\right]\right] &= \lim_{n\to\infty} \mathbb{E}\mathcal{A}\left[f\left(W\right)1\left\{W\leq n\right\}\right] \\ &= \lim_{n\to\infty}\left\{\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n+1} I_n f\left(n+1\right)+\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n} I_{n+1} f\left(n\right)\right\} \\ &= 0\end{aligned}$$

which proves the claim.

To prove sufficiency, we begin with $\mathbb{E}\mathcal{A}\left[f\left(W\right)\right]=0$ and suppose that $f_k\left(j\right)=1\left\{j=k\right\}$ for some $j\in\mathbb{Z}$ in which case

$$\lambda_1 p\left(k-1\right)-kp\left(k\right)-\lambda_2 p\left(k+1\right)=0$$

where $p\left(k\right)=\mathbb{P}\left(W=k\right)$. An *ansatz* of

$$S\left(k\right)=\left(\sqrt{\tfrac{\lambda_1}{\lambda_2}}\right)^k I_k\left(2\sqrt{\lambda_1\lambda_2}\right) \quad \text{and} \quad T\left(k\right)=\left(\sqrt{\tfrac{\lambda_1}{\lambda_2}}\right)^k K_k\left(2\sqrt{\lambda_1\lambda_2}\right)$$

shows that S and T form two linearly independent solutions to this second order linear difference equation, where $I_k(x)$ and $K_k(x)$ are the modified Bessel functions of the first and second kinds. Thus, we know that the general solution is given by,

$$p\left(k\right)=C_1 S\left(k\right)+C_2 T\left(k\right)$$

for some constants $C_1, C_2\in\mathbb{R}$.

Now, to determine the constants C_1 and C_2 we appeal to the fact that $\sum_{k=-\infty}^{\infty} p\left(k\right)=1$. Since $I_k, K_k>0$ for all $k\in\mathbb{Z}$ and $\sum_{k=-\infty}^{\infty} K_k=\infty$ it must be that $C_2=0$. Now, consider the generating function

$$e^{\frac{z}{2}(t+1/t)}=\sum_{k=-\infty}^{\infty} t^k I_k\left(z\right)$$

which means that

$$\begin{aligned}C_1 &= \frac{1}{\sum_{k=-\infty}^{\infty}\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k\left(2\sqrt{\lambda_1\lambda_2}\right)} \\ &= \frac{1}{e^{\sqrt{\lambda_1\lambda_2}\left(\sqrt{\frac{\lambda_1}{\lambda_2}}+\sqrt{\frac{\lambda_2}{\lambda_1}}\right)}} \\ &= e^{-(\lambda_1+\lambda_2)}\end{aligned}$$

so that

$$p\left(k\right)=e^{-(\lambda_1+\lambda_2)}\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k\left(2\sqrt{\lambda_1\lambda_2}\right)$$

so that $W\sim\text{Skellam}\left(\lambda_1,\lambda_2\right)$. ■

A.2 Proof of Theorem 2

Proof Given that f_x is a solution to $\mathcal{A}[f_x(k)]=g_x(k)$, we have

$$\lambda_1 f_x(k+1)-kf_x(k)-\lambda_2 f_x(k-1)=1(k\leq x)-\mathbb{P}\left[W\leq x\right].$$

Substituting $k=U$ and taking expected values, we obtain,

$$\left|\mathbb{P}\left[U\leq x\right]-\mathbb{P}\left[W\leq x\right]\right|=\left|\mathbb{E}\left[\lambda_1 f_x(U+1)-Uf_x(U)-\lambda_2 f_x(U-1)\right]\right| \quad . \tag{16}$$

Next, recall from (5) that $U=\sum_{k=1}^n L_k-\sum_{k=1}^m M_k$. Since $\lambda_1=\sum_{k=1}^n p_k$ and $\lambda_2=\sum_{k=1}^m q_k$, we have after conditioning on L_k and M_k,

$$\begin{aligned}&\left|\mathbb{E}\left[\lambda_1 f_x(U+1)-Uf_x(U)-\lambda_2 f_x(U-1)\right]\right| \\ &= \left|\sum_{k=1}^n \mathbb{E}\left[p_k f_x(U+1)-L_k f_x(U)\right]+\sum_{k=1}^m \mathbb{E}\left[M_k f_x(U)-q_k f_x(U-1)\right]\right| \\ &= \left|\sum_{k=1}^n p_k\left(\mathbb{E}\left[f_x(U+1)\right]-\mathbb{E}\left[f_x(U)|L_k=1\right]\right)+\sum_{k=1}^m q_k\left(\mathbb{E}\left[f_x(U)|M_k=1\right]-\mathbb{E}\left[f_x(U-1)\right]\right)\right| \\ &= \left|\sum_{k=1}^n p_k\left(\mathbb{E}\left[f_x(U+1)-f_x\left(U_k^{(L)}+1\right)\right]\right)+\sum_{k=1}^m q_k\left(\mathbb{E}\left[f_x\left(U_k^{(M)}-1\right)-f_x(U-1)\right]\right)\right| \\ &\leq \sum_{k=1}^n p_k||\Delta f||\mathbb{E}\left|U-U_k^{(L)}\right|+\sum_{k=1}^m q_k||\Delta f||\mathbb{E}\left|U-U_k^{(M)}\right| \\ &= ||\Delta f||\left[\sum_{k=1}^n p_k\mathbb{E}\left|U-U_k^{(L)}\right|+\sum_{k=1}^m q_k\mathbb{E}\left|U-U_k^{(M)}\right|\right].\end{aligned}$$

Combining this with (16) yields the result. ■

A.3 Proof of Theorem 3

Proof First, consider the solution to

$$\lambda_1 f\left(k+1\right)-kf\left(k\right)-\lambda_2 f\left(k-1\right)=g\left(k\right), \tag{17}$$

for some bounded function $g:\mathbb{Z}\mapsto\mathbb{R}$, with the boundary condition

$$\lim_{k\to-\infty}\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k f\left(k\right)=0. \tag{18}$$

We use (15) to substitute for k in (17). Then, multiplying both sides of (17) by $\left(\sqrt{\lambda_1/\lambda_2}\right)^k I_k$, we obtain,

$$\begin{aligned}
&\lambda_1\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k f(k+1) - \lambda_1\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k-1} I_{k-1} f(k) \\
&+ \lambda_2\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k+1} I_{k+1} f(k) - \lambda_2\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k} I_k f(k-1) \\
&= \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k)
\end{aligned}$$

which is the same as,

$$\begin{aligned}
&\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k+1} I_k f(k+1) - \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k} I_{k-1} f(k) \\
&+ \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k} I_{k+1} f(k) - \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{k-1} I_k f(k-1) \\
&= \frac{1}{\sqrt{\lambda_1\lambda_2}}\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k).
\end{aligned}$$

Notice that we have grouped terms together so that summing over k yields a telescoping sum. So, summing over $k \in \{-\infty, \ldots, n\}$ and using the boundary condition (18),

$$\left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n+1} I_n f(n+1) + \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^{n} I_{n+1} f(n) = \frac{1}{\sqrt{\lambda_1\lambda_2}} \sum_{k=-\infty}^{n} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k).$$

Now, multiplying both sides by $(-1)^{n+1}/(I_n I_{n+1})$ and summing over $n \in \{c, c+1, \ldots, m\}$ for $m > c$ and over $n \in \{m, m+1, \ldots, c-1\}$, for some initial condition $c \in \mathbb{Z}$ and $f(c) \in \mathbb{R}$, we obtain

$$f(m) = \begin{cases} (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m \left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f(c) \right. \\ \left. + \frac{1}{\sqrt{\lambda_1\lambda_2}} \sum_{n=c}^{m-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \sum_{k=-\infty}^{n} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k)\right] & \text{if } m > c \\ (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m \left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f(c) \right. \\ \left. - \frac{1}{\sqrt{\lambda_1\lambda_2}} \sum_{n=m}^{c-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \sum_{k=-\infty}^{n} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k)\right] & \text{if } m < c. \end{cases}$$

Note that if

$$g(k) = g_x(k) = 1\{k \le x\} - \mathbb{P}(W \le x)$$

then

$$\sum_{k=-\infty}^{n} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k) = \begin{cases} e^{\lambda_1+\lambda_2}\mathbb{P}(W \le n)\,\mathbb{P}(W > x) & \text{if } n \le x \\ e^{\lambda_1+\lambda_2}\mathbb{P}(W \le x)\,\mathbb{P}(W > n) & \text{if } n \ge x \end{cases}$$

since, for example if $n \le x$

$$\begin{aligned}
\sum_{k=-\infty}^{n} \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^k I_k g(k) &= e^{\lambda_1+\lambda_2} \sum_{k=-\infty}^{n} \mathbb{P}(W=k)\, g(k) \\
&= e^{\lambda_1+\lambda_2} \sum_{k=-\infty}^{n} \mathbb{P}(W=k)\,[1\{k \le x\} - \mathbb{P}(W \le x)] \\
&= e^{\lambda_1+\lambda_2}\,[\mathbb{P}(W \le \min\{n,x\}) - \mathbb{P}(W \le x)\,\mathbb{P}(W \le n)] \\
&= e^{\lambda_1+\lambda_2}\mathbb{P}(W \le n)\,[1 - \mathbb{P}(W \le x)] \\
&= e^{\lambda_1+\lambda_2}\mathbb{P}(W \le n)\,\mathbb{P}(W > x).
\end{aligned}$$

The case that $n \ge x$ is similar. This means that

$$f_x(m) = \begin{cases} (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m \left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f(c) \right. \\ \left. + \frac{e^{\lambda_1+\lambda_2}}{\sqrt{\lambda_1\lambda_2}} \sum_{n=c}^{m-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \mathbb{P}(W \le \min\{n,x\})\,\mathbb{P}(W > \max\{n,x\})\right] & \text{if } m > c \\ (-1)^m \left(\sqrt{\frac{\lambda_2}{\lambda_1}}\right)^m I_m \left[(-1)^c \left(\sqrt{\frac{\lambda_1}{\lambda_2}}\right)^c \frac{1}{I_c} f(c) \right. \\ \left. - \frac{e^{\lambda_1+\lambda_2}}{\sqrt{\lambda_1\lambda_2}} \sum_{n=m}^{c-1} \frac{(-1)^{n+1}}{I_n I_{n+1}} \mathbb{P}(W \le \min\{n,x\})\,\mathbb{P}(W > \max\{n,x\})\right] & \text{if } m < c. \end{cases}$$

■

A.4 Proof of Theorem 4

Our proof of Theorem 4 is highly involved, from an analysis perspective, but the overall program can be stated in a relatively succinct manner. Accordingly, we sketch here the overall program behind our proof and refer the interested reader to the online appendix for a detailed account.

Proof Recall that we are trying to obtain a bound on $|\Delta f_x(j)| = |f_x(j+1) - f_x(j)|$ independent of $x \in \mathbb{R}$ and $j \in \mathbb{Z}$. From Theorem 3, we have the solution to the Stein equation, however to use it to bound $|\Delta f_x(j)|$, we need to simplify it further. For ease of notation, we simply refer to f instead of f_x and g instead of g_x.

First, note that we have the freedom to choose the initial condition $(c, f(c))$. Making the choice that $c = \lambda_2 - \lambda_1$, and hence that $c = 0$ under the assumption that $\lambda_1 = \lambda_2$, we are able to simplify our expression for f in Theorem 3 to read, in the case that $m > 0$, as

$$\begin{aligned}
f(m+1) = (-1)^{m+1} I_{m+1} \Bigg[&\frac{1}{I_0} f(0) \\
&- \frac{e^{2\lambda}}{\lambda} \frac{1}{I_0 I_1} \mathbb{P}(W \le \min\{0,x\})\,\mathbb{P}(W > \max\{0,x\}) \\
&- \frac{e^{2\lambda}}{\lambda} \sum_{n=0}^{m-1} \frac{(-1)^{n+1}}{I_{n+1} I_{n+2}} \mathbb{P}(W \le \min\{n+1,x\})\,\mathbb{P}(W > \max\{n+1,x\}) \Bigg]
\end{aligned}$$

and, in the case that if $m < 0$, as

$$f(m-1) = (-1)^{m-1} I_{m-1} \left[\frac{1}{I_0} f(0) - \frac{e^{2\lambda}}{\lambda} \frac{1}{I_0 I_1} \mathbb{P}(W \leq \min\{-1, x\}) \mathbb{P}(W > \max\{-1, x\}) + \frac{e^{2\lambda}}{\lambda} \sum_{n=m}^{-1} \frac{(-1)^{n+1}}{I_{n-1} I_n} \mathbb{P}(W \leq \min\{n-1, x\}) \mathbb{P}(W > \max\{n-1, x\}) \right].$$

Finally, for the case $m = 0$, we have

$$\begin{aligned} f(0) &= \frac{e^{2\lambda}}{2\lambda} \frac{1}{I_0 + I_1} [\mathbb{P}(W \leq \min\{0, x\}) \mathbb{P}(W > \max\{0, x\}) \\ &\quad + \mathbb{P}(W \leq \min\{-1, x\}) \mathbb{P}(W > \max\{-1, x\})]. \end{aligned}$$

Next, through manipulation of the arguments in the sums defining the above expressions for f, exploiting properties of the modified Bessel functions I_k, and applying the triangle inequality, we are able to produce bounds on the differences $|f(m+1) - f(m)|$ of the form

$$\begin{aligned} |f(m+1) - f(m)| &\leq \frac{\mathbb{P}(W \leq x)}{\lambda} \left\{ \left| \sum_{n=1,3,\ldots}^{m-1} \frac{I_{m+1}}{I_{n+2}} - \frac{I_m}{I_{n-1}} \right| \right. \\ &\quad + \sum_{n=1,3,\ldots}^{m-1} H(n) \left| \frac{I_{m+1} I_n}{I_{n+1} I_{n+2}} - \frac{I_m}{I_{n+1}} - \frac{I_{m+1}}{I_{n+1}} + \frac{I_m}{I_{n-1}} \right| \Bigg\} \\ &\quad + \left| I_m \frac{1}{I_0} f(0) + I_{m+1} \left\{ \frac{1}{I_0} f(0) \right. \right. \\ &\quad \left. \left. - \frac{e^{2\lambda}}{\lambda} \frac{1}{I_0 I_1} \mathbb{P}(W \leq \min\{0, x\}) \mathbb{P}(W > \max\{0, x\}) \right\} \right| , \end{aligned} \tag{19}$$

if m is even, and

$$\begin{aligned} |f(m+1) - f(m)| &\leq \frac{\mathbb{P}(W \leq x)}{\lambda} \left\{ \left| \sum_{n=1,3,\ldots}^{m-1} \frac{I_{m+1}}{I_{n+2}} - \frac{I_m}{I_{n-1}} \right| \right. \\ &\quad + \sum_{n=1,3,\ldots}^{m-1} H(n) \left| \frac{I_{m+1} I_n}{I_{n+1} I_{n+2}} - \frac{I_m}{I_{n+1}} - \frac{I_{m+1}}{I_{n+1}} + \frac{I_m}{I_{n-1}} \right| \\ &\quad + |H(m+1) - H(m)| \Bigg\} \\ &\quad + \left| I_m \frac{1}{I_0} f(0) + I_{m+1} \left\{ \frac{1}{I_0} f(0) \right. \right. \\ &\quad \left. \left. - \frac{e^{2\lambda}}{\lambda} \frac{1}{I_0 I_1} \mathbb{P}(W \leq \min\{0, x\}) \mathbb{P}(W > \max\{0, x\}) \right\} \right| , \end{aligned} \tag{20}$$

if m is odd. Here $H(n) = \mathbb{P}(W > n) / \mathbb{P}(W = n)$ is the inverse of the hazard function of the Skellam distribution (and is not to be confused with our use of H in the main body of the paper as a subgraph of the graph G).

Note that (19) is defined by three key terms, while (20) has the same three, augmented by the addition of a fourth, i.e., $|H(m+1) - H(m)|$. Through a series of arguments (the result for each of which is presented as a separate proposition in the online appendix), we are able to control each of these terms as follows. First, we show that

$$\sup_{m \in \mathbb{N}^+} \left| \sum_{n=1,3,\ldots}^{m-1} \frac{I_{m+1}}{I_{n+2}} - \frac{I_m}{I_{n-1}} \right| \leq 5 \ .$$

Next we show that

$$\sum_{n=1,3,\ldots}^{m-1} H(n) \left| \frac{I_{m+1} I_n}{I_{n+1} I_{n+2}} - \frac{I_m}{I_{n+1}} - \frac{I_{m+1}}{I_{n+1}} + \frac{I_m}{I_{n-1}} \right| \leq 73 \ ,$$

for $\lambda \geq 1$. And furthermore, we show that

$$\begin{aligned} &\left| I_m \frac{1}{I_0} f(0) + I_{m+1} \left\{ \frac{1}{I_0} f(0) - \frac{e^{2\lambda}}{\lambda} \frac{1}{I_0 I_1} \mathbb{P}(W \leq \min\{0, x\}) \mathbb{P}(W > \max\{0, x\}) \right\} \right| \\ \leq \ &\frac{\mathbb{P}(W \leq x)}{\lambda} \ . \end{aligned}$$

Finally, it is clear that

$$\begin{aligned} &H(m) - H(m+1) \\ = \ &\frac{\mathbb{P}(W > m)}{\mathbb{P}(W = m)} - \frac{\mathbb{P}(W > m+1)}{\mathbb{P}(W = m+1)} \\ = \ &\frac{1}{\mathbb{P}(W = m)} [\mathbb{P}(W > m) - \mathbb{P}(W > m+1)] \\ = \ &\frac{\mathbb{P}(W = m+1)}{\mathbb{P}(W = m)} \\ \leq \ &1 \end{aligned}$$

and, at the same time $H(m) - H(m+1) \geq 0$ so, we have that we may bound the magnitude of this final term by 1.

As a result of all of the above, we may conclude that

$$|f(m+1) - f(m)| \leq \frac{80}{\lambda}$$

for $m > 0$. Or, equivalently, we may express the right-hand side above as $160/2\lambda$.

The argument for the case of $m < 0$ involves similar reasoning, as described in the online appendix. ■

A.5 Proof of Theorems 6 and 7

A.5.1 PROOF OF THEOREM 6

Proof The terms $\mathbb{E}\left|U - U_k^{(L)}\right|$ and $\mathbb{E}\left|U - U_k^{(M)}\right|$ in (8) measure the dependence of U on the events $L_k = 1$ and $M_k = 1$, respectively. In the context of the empirical graph $\hat{G}$, the random variables L are equal to Y_{ij}, for $\{i,j\} \in E^c$, while the random variables M are equal to Y_{ij}, for $\{i,j\} \in E$. With the Y_{ij} assumed independent, $U_k^{(L)}$ and $U_k^{(M)}$ are independent of their respective events, and so we obtain

$$d_{KS}(U,W) \leq ||\Delta f|| \left[\sum_{k=1}^{n} p_k^2 + \sum_{k=1}^{m} q_k^2\right] \ . \tag{21}$$

Accordingly, and drawing on definitions and the result of Theorem 4,

$$\begin{aligned} d_{KS}\left(D_E, \text{Skellam}(\lambda,\lambda)\right) \leq \frac{1}{\lambda}\left[\sum_{(i,j)\in E^c} \alpha^2 + \sum_{(i,j)\in E} \beta^2\right] &= \frac{|E^c|\alpha^2 + |E|\beta^2}{|E^c|\alpha} \\ &= \frac{|E^c|\alpha^2 + |E|\left(\frac{|E^c|}{|E|}\right)^2\alpha^2}{|E^c|\alpha} \\ &= \alpha + \frac{|E^c|}{|E|}\alpha \\ &= \alpha + \frac{\binom{n_v}{2} - |E|}{|E|}\alpha \\ &= \frac{\binom{n_v}{2}}{|E|}\alpha \ . \end{aligned}$$

Noting that $\alpha = \lambda/|E^c|$, and recalling that $|E^c| = \Theta\left(n_v^2\right)$ under both sparse and dense graphs G, the last quantity above is seen to behave like $\lambda/|E|$ which, under assumption (A3) and our definition of sparse and dense in Section 2 , reduces to $O\left(n_v^{-1}\right)$. So the bound in (9) is established.

Note that the right-hand side of (21) is analogous to the classical form of the bound for individual sums of independent indicator random variables (e.g., Barbour and Chen, 2005). As remarked in the main text, for this particular case of independent Y_{ij}, those more classical techniques could also be used to produce the result of Theorem 6. Specifically, Let $T_1, T_2, \tilde{T}_1$, and $\tilde{T}_2$ be independent random variables supported on the integers. Denote by $d_{TV}(X_1, X_2)$ the total-variation distance between two random variables X_1 and X_2. Then

$$\begin{aligned} d_{KS}\left(T_1 - T_2, \tilde{T}_1 - \tilde{T}_2\right) &\leq d_{TV}\left(T_1 - T_2, \tilde{T}_1 - \tilde{T}_2\right) \\ &\leq d_{TV}\left((T_1, T_2), (\tilde{T}_1, \tilde{T}_2)\right) \\ &\leq d_{TV}\left(T_1, \tilde{T}_1\right) + d_{TV}\left(T_2, \tilde{T}_2\right) \ , \end{aligned}$$

where the first inequality exploits the fact that total-variation distance provides an upper bound on Kolmogorov-Smirnov distance, and the second and third inequalities follow from Lemmas 3.6.3

and 3.6.2 of Durrett (2010), respectively. Now define

$$T_1 = \sum_{\{i,j\}\in E^c} Y_{ij} \quad \text{and} \quad T_2 = \sum_{\{i,j\}\in E} (1 - Y_{ij}) \ ,$$

and let $\tilde{T}_1$ and $\tilde{T}_2$ be independent Poisson random variables with common mean λ. Setting $\lambda = |E^c|\alpha = |E|\beta$, and applying to each of $d_{TV}\left(T_1, \tilde{T}_1\right)$ and $d_{TV}\left(T_2, \tilde{T}_2\right)$ the standard Stein bounds for Poisson approximation to sums of independent indicators (e.g., Barbour and Chen, 2005, Eqn 2.6), we again obtain that

$$d_{KS}\left(D_E, \text{Skellam}(\lambda,\lambda)\right) \leq \frac{1}{\lambda}\left[\sum_{(i,j)\in E^c} \alpha^2 + \sum_{(i,j)\in E} \beta^2\right] = \frac{|E^c|\alpha^2 + |E|\beta^2}{|E^c|\alpha} \ ,$$

and the rest follows. ■

A.5.2 PROOF OF THEOREM 7

To establish the bounds in (10) and (11), we use the following result from Stein's method for the normal distribution (e.g., Barbour and Chen, 2005).

Theorem 11 *Let $\xi_1, \ldots, \xi_n$ be independent random variables which have zero means and finite variances $\mathbb{E}\left[\xi_i^2\right] = \sigma_i^2$, $1 \leq i \leq n$, and satisfy $\sum_{i=1}^n \sigma_i^2 = 1$. If $F_n(x)$ is the cumulative distribution function of $\sum_{i=1}^n \xi_i$, then, for every $\epsilon > 0$,*

$$\frac{1 - e^{-\frac{\epsilon^2}{4}}}{40}\sum_{i=1}^{n} \mathbb{E}\left[\xi_i^2 I_{\{|\xi_i|>\epsilon\}}\right] - \sum_{i=1}^{n}\sigma_i^4 \leq \sup_{x\in\mathbb{R}}|F_n(x) - \Phi(x)| \leq 7\sum_{i=1}^{n}\mathbb{E}\left[|\xi_i|^3\right].$$

Proof of Theorem 7 We apply Theorem 11, with $\xi_i = X_i/\sigma$ where X_i is a term in one of the sums of D_E, to establish each of our upper and lower bounds in turn.

Upper Bounds in (10) and (11): First, note that since

$$\sum_{i=1}^{n}\mathbb{E}\left[|\xi_i|^3\right] = \frac{\sum_{i=1}^n \mathbb{E}\left[|X_i|^3\right]}{\sigma^3} \ ,$$

and

$$\mathbb{E}\left[|X_i|^3\right] = \alpha(1-\alpha)\left[(1-\alpha)^2 + \alpha^2\right] \quad \text{or} \quad \beta(1-\beta)\left[(1-\beta)^2 + \beta^2\right] \ ,$$

with n understood to be either $|E^c|$ or $|E|$, it follows that

$$\begin{aligned} \sum_{i=1}^{n}\mathbb{E}\left[|\xi_i|^3\right] &= \frac{\alpha(1-\alpha)\left[(1-\alpha)^2+\alpha^2\right]|E^c| + \beta(1-\beta)\left[(1-\beta)^2+\beta^2\right]|E|}{\left(\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|\right)^{\frac{3}{2}}} \\ &\leq \max\{(1-\alpha)^2+\alpha^2, (1-\beta)^2+\beta^2\}\frac{\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|}{\left(\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|\right)^{\frac{3}{2}}} \\ &= \frac{\max\{(1-\alpha)^2+\alpha^2, (1-\beta)^2+\beta^2\}}{\left(\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|\right)^{\frac{1}{2}}} \\ &= \frac{\max\{(1-\alpha)^2+\alpha^2, (1-\beta)^2+\beta^2\}}{\sqrt{2-(\alpha+\beta)}} \cdot \frac{1}{\sqrt{\alpha|E^c|}} \ , \end{aligned}$$

where in the last equality we have used the fact that $\beta = (|E^c|/|E|)\,\alpha$ follows from (A2). Finally, note that

$$(1-\alpha)^2 + \alpha^2 = 1 - 2\alpha + 2\alpha^2 = 1 - 2\alpha(1-\alpha) \leq 1$$

and the same holds for $(1-\beta)^2 + \beta^2$, since $0 \leq \alpha, \beta \leq 1$, so that

$$\sum_{i=1}^{n} \mathbb{E}\left[|\xi_i|^3\right] \leq \frac{1}{\sqrt{2-(\alpha+\beta)}} \cdot \frac{1}{\sqrt{\alpha|E^c|}} \ .$$

This immediately implies, after another application of $\beta = (|E^c|/|E|)\alpha$,

$$\sup_{x\in\mathbb{R}} |F_n(x) - \Phi(x)| \leq \frac{7}{\sqrt{2-(\alpha+\frac{|E^c|}{|E|}\alpha)}} \cdot \frac{1}{\sqrt{\alpha|E^c|}} \ .$$

Using $\alpha = \lambda/|E^c|$, and invoking the assumption of low-rate measurement error in (A3) and the definitions of sparse and dense graphs in Section 2, the upper bounds in (10) and (11) follow.

Lower bound in (10) and (11): First, note that since $\xi_i = X_i/\sigma$, $\sigma_i^2 = \alpha(1-\alpha)/\sigma^2$ or $\sigma_i^2 = \beta(1-\beta)/\sigma^2$. Thus,

$$\begin{aligned}
\sum_{i=1}^{n} \sigma_i^4 &= \frac{(\alpha(1-\alpha))^2|E^c| + (\beta(1-\beta))^2|E|}{(\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|)^2} \\
&= \frac{(\alpha(1-\alpha))^2|E^c| + \left(\frac{|E^c|}{|E|}\alpha(1-\beta)\right)^2|E|}{(2-(\alpha+\beta))^2(\alpha|E^c|)^2} \\
&= \frac{1}{|E^c|} \cdot \frac{1}{(2-(\alpha+\beta))^2} \cdot \left[(1-\alpha)^2 + \frac{|E^c|}{|E|}(1-\beta)^2\right] \\
&= \frac{1}{(2-(\alpha+\beta))^2}\left[\frac{(1-\alpha)^2}{|E^c|} + \frac{(1-\beta)^2}{|E|}\right]
\end{aligned} \ ,$$

where in the second equality, we have used $\beta = (|E^c|/|E|)\alpha$.

Next, choose $\epsilon = 1/(2\sigma)$. Note that this is the midpoint of the intervals

$$\left(\frac{\alpha}{\sigma}, \frac{1-\alpha}{\sigma}\right), \quad \text{and} \quad \left(\frac{\beta}{\sigma}, \frac{1-\beta}{\sigma}\right)$$

if $\alpha, \beta < 1/2$ and of the intervals

$$\left(\frac{1-\alpha}{\sigma}, \frac{\alpha}{\sigma}\right), \quad \text{and} \quad \left(\frac{1-\beta}{\sigma}, \frac{\beta}{\sigma}\right) \ .$$

if $\alpha, \beta \geq 1/2$. In either case, these are the endpoints of the interval formed by the values of $|\xi_i| = |X_i|/\sigma$.

Due to the symmetry in these intervals about $\frac{1}{2}$ we may, without loss of generality, assume $\alpha, \beta < 1/2$. In doing so, and using $\beta = (|E^c|/|E|)\alpha$,

$$\begin{aligned}
&\frac{1-e^{-\frac{\epsilon^2}{4}}}{40} \sum_{i=1}^{n} \mathbb{E}\left[\xi_i^2 I_{\{|\xi_i|>\epsilon\}}\right] \\
&= \frac{1-e^{-\frac{\epsilon^2}{4}}}{40} \cdot \frac{(1-\alpha)^2\alpha|E^c| + (1-\beta)^2\beta|E|}{\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|} \\
&= \frac{1-e^{-\frac{\epsilon^2}{4}}}{40} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{2-(\alpha+\beta)} \\
&= e^{-\frac{\epsilon^2}{4}} \frac{e^{\frac{\epsilon^2}{4}}-1}{40} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{2-(\alpha+\beta)} \\
&\geq e^{-\frac{\epsilon^2}{4}} \frac{\epsilon^2}{160} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{2-(\alpha+\beta)} \\
&= e^{-\frac{\epsilon^2}{4}} \frac{1}{640} \cdot \frac{1}{\alpha(1-\alpha)|E^c| + \beta(1-\beta)|E|} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{2-(\alpha+\beta)} \\
&= e^{-\frac{\epsilon^2}{4}} \frac{1}{640} \cdot \frac{1}{\alpha|E^c|} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{(2-(\alpha+\beta))^2} \ .
\end{aligned}$$

Combining the two sets of expressions above, the lower bound becomes

$$\begin{aligned}
&\frac{1-e^{-\frac{\epsilon^2}{4}}}{40} \sum_{i=1}^{n} \mathbb{E}\left[\xi_i^2 I_{\{|\xi_i|>\epsilon\}}\right] - \sum_{i=1}^{n} \sigma_i^4 \\
\geq\ & e^{-\frac{\epsilon^2}{4}} \frac{1}{640} \cdot \frac{1}{\alpha|E^c|} \cdot \frac{(1-\alpha)^2 + (1-\beta)^2}{(2-(\alpha+\beta))^2} - \frac{1}{(2-(\alpha+\beta))^2}\left[\frac{(1-\alpha)^2}{|E^c|} + \frac{(1-\beta)^2}{|E|}\right] \\
=\ & \frac{1}{(2-(\alpha+\beta))^2}\left[(1-\alpha)^2\left(\frac{\exp\left(-\frac{1}{16}\cdot\frac{1}{\alpha|E^c|}\cdot\frac{1}{2-(\alpha+\beta)}\right)}{640} \cdot \frac{1}{\alpha|E^c|} - \frac{1}{|E^c|}\right)\right. \\
&\left. +(1-\beta)^2\left(\frac{\exp\left(-\frac{1}{16}\cdot\frac{1}{\alpha|E^c|}\cdot\frac{1}{2-(\alpha+\beta)}\right)}{640} \cdot \frac{1}{\alpha|E^c|} - \frac{1}{|E|}\right)\right] \ . \qquad (22)
\end{aligned}$$

But for sufficiently large n_v, the exponential term in (22) behaves like $\exp[-1/(16\lambda)] \approx 1 - (1/16\lambda)$. Substituting accordingly and simplifying to ignore the various terms tending to a constant in large n_v, the expression in (22) can be seen to behave asymptotically like

$$\frac{1}{4}\left[\left(\frac{1}{640\lambda} - \frac{1}{|E^c|}\right) + \left(\frac{1}{640\lambda} - \frac{1}{|E|}\right)\right] \ .$$

Again, by the assumption of low-rate measurement error in (A3) and the definitions of sparse and dense graphs given in Section 2, appropriate substitution of the values for λ, $|E|$, and $|E^c|$ yield the lower bounds in (10) and (11). This completes the proof of Theorem 7. ■

A.6 Proof of Theorem 8

Proof The proof follows by rewriting each of the two sums bracketed in (8), and then aggregating terms. Under condition (i) of the theorem,

$$\begin{aligned}\left|U - U_k^{(L)}\right| &= \left|L_k + \sum_{j\neq k} L_j - \sum_{\ell} M_\ell - \left(\sum_{j\neq k} \tilde{L}_j^{L_k} - \sum_{\ell} \tilde{M}_\ell^{L_k}\right)\right| \\ &= \sum_{j\neq k} \tilde{L}_j^{L_k} - \sum_{\ell} \tilde{M}_\ell^{L_k} - \left(\sum_{j\neq k} L_j - \sum_{\ell} M_\ell\right) - L_k \\ &= U_k^{(L)} - U \ .\end{aligned}$$

Similarly, under condition (ii) of the theorem, $\left|U - U_k^{(M)}\right| = U - U_k^{(M)}$.

In the absence of having to deal directly with the absolute values, we find that

$$\sum_{k=1}^{n} p_k E\left|U - U_k^{(L)}\right| = \sum_{k=1}^{n}\sum_{k\neq j} E\left[L_k L_j\right] - \sum_{k,\ell} E\left[L_k M_\ell\right] - E\left[U\right]\lambda_1$$

and

$$\sum_{k=1}^{m} q_k E\left|U - U_k^{(M)}\right| = \sum_{k=1}^{m}\sum_{\ell\neq k} E\left[M_k M_\ell\right] - \sum_{k,\ell} E\left[L_k M_\ell\right] + E\left[U\right]\lambda_2 \ .$$

As a result, the bracketed term in (8) takes the form

$$\begin{aligned}&\sum_{k=1}^{n} p_k E\left|U - U_k^{(L)}\right| + \sum_{k=1}^{m} q_k E\left|U - U_k^{(M)}\right| \\ =\ & \sum_{k=1}^{n}\sum_{k\neq j} E\left[L_k L_j\right] + \sum_{k=1}^{m}\sum_{\ell\neq k} E\left[M_k M_\ell\right] - 2\sum_{k,\ell} E\left[L_k M_\ell\right] - \left(E\left[U\right]\right)^2 \\ =\ & E\left[U^2\right] - \left(E\left[U\right]\right)^2 - \sum_{k=1}^{n} E\left[L_k^2\right] - \sum_{\ell=1}^{m} E\left[M_\ell^2\right] \\ =\ & \mathrm{Var}(U) - \sum_{k=1}^{n} E\left[L_k\right] - \sum_{\ell=1}^{m} E\left[M_\ell\right] \\ =\ & \mathrm{Var}(U) - (\lambda_1 + \lambda_2) \\ =\ & \mathrm{Var}(U) - \mathrm{Var}(W) \ .\end{aligned}$$

Abstract

We introduce a novel approach for estimating Latent Dirichlet Allocation (LDA) parameters from collapsed Gibbs samples (CGS), by leveraging the full conditional distributions over the latent variable assignments to efficiently average over multiple samples, for little more computational cost than drawing a single additional collapsed Gibbs sample. Our approach can be understood as adapting the soft clustering methodology of Collapsed Variational Bayes (CVB0) to CGS parameter estimation, in order to get the best of both techniques. Our estimators can straightforwardly be applied to the output of any existing implementation of CGS, including modern accelerated variants. We perform extensive empirical comparisons of our estimators with those of standard collapsed inference algorithms on real-world data for both unsupervised LDA and Prior-LDA, a supervised variant of LDA for multi-label classification. Our results show a consistent advantage of our approach over traditional CGS under all experimental conditions, and over CVB0 inference in the majority of conditions. More broadly, our results highlight the importance of averaging over multiple samples in LDA parameter estimation, and the use of efficient computational techniques to do so.

1. Introduction

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a probabilistic model which organizes and summarizes large corpora of text documents by automatically discovering the semantic themes, or *topics*, hidden within the data. Since the model was introduced by Blei et al. (2003), LDA and its extensions have been successfully applied to many other data types and application domains, including bioinformatics (Zheng et al., 2006), computer vision (Cao and Fei-Fei, 2007), and social network analysis (Zhang et al., 2007), in addition to text mining and analytics (AlSumait et al., 2008). It has also been the subject of numerous adaptations and improvements, for example to deal with supervised learning tasks (Blei and McAuliffe, 2007; Ramage et al., 2009; Zhu et al., 2009), time and memory efficiency issues (Newman et al., 2007; Porteous et al., 2008; Yao et al., 2009) and large or streaming data settings (Gohr et al., 2009; Hoffman et al., 2010b; Rubin et al., 2012; Foulds et al., 2013).

When training an LDA model on a collection of documents, two sets of parameters are primarily estimated: the *distributions over word types* ϕ for topics, and the *distributions over topics* θ for documents. After more than a decade of research on LDA training algorithms, the Collapsed Gibbs Sampler (CGS) (Griffiths and Steyvers, 2004) remains a popular choice for topic model estimation, and is arguably the de facto industry standard technique for commercial and industrial applications. Its success is due in part to its simplicity, along with the availability of efficient implementations (McCallum, 2002a; Smola and Narayanamurthy, 2010) leveraging sparsity (Yao et al., 2009; Li et al., 2014) and parallel architectures (Newman et al., 2007). It exhibits much faster convergence than the naive uncollapsed Gibbs sampler of Pritchard et al. (2000), as well as the partially collapsed Gibbs sampling scheme (Asuncion, 2011). The CGS algorithm marginalizes out parameters ϕ and θ, necessitating a procedure to recover them from samples of the model's latent variables $\mathbf{z}$. Griffiths and Steyvers (2004) proposed such a procedure, which, while very successful, has not been revisited in the last decade to our knowledge. Our goal is to improve upon this procedure.

In this paper, we propose a new method for estimating topic model parameters ϕ and θ from collapsed Gibbs samples. Our approach approximates the posterior mean of the parameters, which leads to increased stability and statistical efficiency relative to the standard estimator. Crucially, our approach leverages the *distributional information given by the form of the Gibbs update equation* to implicitly average over multiple Markov chain Monte Carlo (MCMC) samples, with little more computational cost than that which is required to compute a single sample. As such, our work is focused on the realistic practical scenario where we can afford a moderate burn-in period, but cannot afford to compute and average over enough post burn-in MCMC samples to accurately estimate the parameters' posterior mean. In our experiments, this requires several orders of magnitude further sampling iterations beyond burn-in.

Our use of the full conditional distribution of each topic assignment is reminiscent of the CVB0 algorithm for collapsed variational inference (Asuncion et al., 2009). The update equations of CVB0 bear resemblance to those of CGS, except that they involve deterministic updates of dense probability distributions, while CGS draws sparse samples from similar distributions, with corresponding trade-offs in execution time and convergence behavior, as we study in Section 5.5. Our approach can be understood as adapting this dense *soft clustering* methodology of the CVB0 algorithm to CGS parameter estimation, leveraging

	training phase	parameter recovery	update rule	inference algorithm	memory per token
CVB0	dense	dense	deterministic	variational Bayes	$O(K)$
CGS	sparse	sparse	random	MCMC	$O(1)$
CGS_p	sparse	dense	random	MCMC	$O(1)$

Table 1: Properties of CVB0, CGS, and our proposed CGS_p method.

the corresponding uncertainty information, as in CVB0, but within a Markov chain Monte Carlo framework, in order to draw on the benefits of both techniques. Our approach does not incur the memory overhead of CVB0, relative to CGS. The properties of CVB0, CGS, and our proposed estimators are summarized in Table 1.

It is important to note that we do not modify the CGS algorithm, and thus do not affect its runtime or memory requirements. Rather, we modify the *procedure for recovering parameter estimates from collapsed Gibbs samples*. After running the standard CGS algorithm (or a modern accelerated approximate implementation) for a sufficient number of iterations, we obtain the standard document-topic and topic-word count matrices. At this point, instead of using the standard CGS parameter estimation equations to calculate θ and ϕ, we employ our proposed estimators. As a result, our estimators can be plugged in to the output of any CGS-based inference method, including modern variants of the algorithm such as Sparse LDA (Yao et al., 2009), Metropolis-Hastings-Walker (Li et al., 2014), LightLDA (Yuan et al., 2015), or WarpLDA (Chen et al., 2016), allowing for easy and wide adoption of our approach by the research community and in industry applications. Our algorithm is very simple to implement, requiring only slight modifications to existing CGS code. Popular LDA software packages such as MALLET (McCallum, 2002a) and Yahoo_LDA (Smola and Narayanamurthy, 2010) could straightforwardly be extended to incorporate our methods, leading to improved parameter estimation in numerous practical topic modeling applications. In Section 5.7, we provide an application of our estimators to both MALLET's Sparse LDA implementation, and to WarpLDA. When paired with a sparse CGS implementation, our approach gives the best of two worlds: making use of the *full uncertainty information encoded in the dense Gibbs sampling transition probabilities* in the final parameter recovery step, while still leveraging *sparsity to accelerate the CGS training process*.

In extensive experiments, we show that our approach leads to improved performance over standard CGS parameter estimators in both unsupervised and supervised LDA models. Our approach also outperforms the CVB0 algorithm under the majority of experimental conditions. The computational cost of our method is comparable that of a single (dense) CGS iteration, and we show that even when a state-of-the-art sparse implementation of the CGS training algorithm is used, this is a price well worth paying. Our results further illustrate the benefits of averaging over multiple samples for LDA parameter estimation. The contributions of our work can be summarized as follows:

- We propose a novel, theoretically motivated method for improved estimation of the topic-level and document-level parameters of an LDA model based on collapsed Gibbs samples.

- We present an extensive empirical comparison of our proposed estimators against those of standard CGS as well as the CVB0 algorithm (Asuncion et al., 2009) —a variant of the Collapsed Variational Bayesian inference (CVB) method—in both unsupervised and supervised learning settings, demonstrating the benefits of our approach.

- We provide an additional experimental comparison of the CGS and CVB0 algorithms regarding their convergence behavior, to further contextualize our empirical results.

Our theoretical and experimental results lead to three primary conclusions of interest to topic modeling practitioners:

- Averaging over multiple CGS samples to construct a point estimate for LDA parameters is beneficial to performance, in both the unsupervised and supervised settings, in cases where identifiability issues can be safely resolved.

- Using CVB0-style soft clustering to construct these point estimates is both valid and useful in an MCMC setting, and corresponds to implicitly averaging over many samples, thereby improving performance with little extra computational cost. This ports some of the benefits of CVB0's use of dense uncertainty information to CGS, while retaining the sparsity advantages of that algorithm during training.

- Increasing the number of topics increases the benefit of our soft clustering/averaging approach over traditional CGS. While CVB0 outperforms CGS with few topics and a moderate number of iterations, CGS-based methods otherwise outperform CVB0, especially when using our improved estimators.

As this paper deals with LDA in both the unsupervised and the supervised setting, we will treat the following terms as equivalent when describing the procedure of learning an LDA model from training data: 'estimation', 'fitting', and 'training'. Since we are in a Bayesian setting the word 'inference' will refer to the recovery of parameters, which are understood to be random variables, and/or the latent variables, and to the computation of the posterior distributions of parameters and latent variables. The term 'prediction' will be applied to the case of predicting on test data (i.e., data that was unobserved during training). Additionally, since Prior-LDA is essentially a special case of unsupervised LDA, we will focus our algorithm descriptions on the case of standard unsupervised LDA and specify the exceptions as they apply to Prior-LDA. Furthermore, we note here that we will be using the CGS algorithm described by Griffiths and Steyvers (2004), which approximates the LDA parameters of interest through iterative sampling in a Markov chain Monte Carlo (MCMC) procedure, unless otherwise specified.

The rest of this paper is organized as follows: Section 2 describes backround information on the LDA model, Bayesian inference, and the CGS and the CVB0 inference methods, as well as the Prior-LDA model, providing an overview of the related literature. Sections 3 and 4 introduce our estimators for the relevant LDA parameters. Sections 5 and 6 describe our experiments comparing the estimators of our method to those of CGS and CVB0 in unsupervised and supervised learning settings, respectively. Finally, Section 7 summarizes the main contributions and conclusions of our work.

2. Background and Related Work

In this section we provide the background necessary to describe our methods, and also establish the relevant notation.

2.1 Latent Dirichlet Allocation

LDA is a hierarchical Bayesian model that describes how a corpus of documents is generated via a set of unobserved *topics*. Each topic is parameterized by a discrete probability distribution over word types, which captures some coherent semantic theme within the corpus[1]. Here, we assume that this set of word types is the same for all topics (i.e., we have a single, shared vocabulary). Furthermore, LDA assumes that each document can be described as a discrete distribution over these topics. The process for generating each document then involves first sampling a topic from the document's distribution over topics, and then sampling a word token from the corresponding topic's distribution over word types.

Formally, let us denote as V the size of the vocabulary (the set of unique word types) and as $D_{Train} = |\mathcal{D}_{Train}|$ and $D_{Test} = |\mathcal{D}_{Test}|$ the number of training and testing documents respectively. We will use K to denote the number of topics. Similarly, v denotes a word type, w_i a word token, k a topic (or in the case of Prior-LDA, a label), and z_i a topic assignment. The parameter ϕ_{kv}, $k \in \{1...K\}$, $v \in \{1...V\}$ represents the probability of word type v under topic (or label) k, and θ_{dk} represents the probability of topic (or label) k for document d. Additionally α_k will denote the parameter of the Dirichlet prior on θ for topic k and β_v the parameter of the Dirichlet prior on ϕ for word type v. Unless otherwise noted we assume for simplicity that the two priors are symmetric, so all the elements of the parameter vector $\boldsymbol{\alpha}$ will have the same value (the same holds for the parameter vector $\boldsymbol{\beta}$). The term N_d denotes the number of word tokens in a given document d. Lastly, in the multi-label setting, $\mathcal{K}_d$ stands for the set of labels that are associated with d. This notation is summarized in Table 2.

LDA assumes that a given corpus of documents has been generated as follows:

- For each topic $k \in \{1 \dots K\}$, sample a discrete distribution ϕ_k over the word types of the corpus from a Dirichlet($\boldsymbol{\beta}$).
- For each document d,
  - Sample a discrete distribution θ_d over topics from a Dirichlet($\boldsymbol{\alpha}$).
  - Sample a document length N_d from a Poisson(ξ), with $\xi \in \mathbb{R}_{>0}$
  - For each word token w_i in document d, $i \in \{1...N_d\}$:
    - Sample a topic $z_i = k$ from discrete(θ_d).
    - Sample a word type $w_i = v$ from discrete(ϕ_{z_i}).

The goal of inference is to estimate the aforementioned θ and ϕ parameters—the discrete distributions for documents over topics, and topics over word types, respectively. In doing so, we learn a lower-dimensional representation of the structure of all documents in the corpus in terms of the topics. In the unsupervised learning context, this lower-dimensional

1. A discrete distribution a multinomial distribution for which a single value is drawn, i.e., where $N = 1$.

V	the size of the vocabulary
K	the number of topics (or labels)
D_{Train}	the number of training documents (similarly D_{Test})
$\mathcal{D}_{Train}$	the set of training documents (similarly $\mathcal{D}_{Test}$)
d	a document
v	a word type
w_i	a single word token, i.e., an instance of a word type
$\mathbf{w}_d$	the vector of word assignments in document d
k	a topic (label)
z_i	the topic assignment to a word token w_i
$\mathbf{z}_d$	the vector of topic assignments to all word tokens of a document
z_{djk}	binary indicator variable, equals 1 IFF the jth word in document d is assigned to topic k
N_d	number of word tokens in d
$\mathcal{K}_d$	set of topics (or labels) in d
n_{kv}	number of times that word type v has been assigned to topic k across the corpus
n_{dk}	number of word tokens in d that have been assigned to topic k
ϕ_k	word type distribution for topic k
θ_d	topic distribution for document d
ϕ_{kv}	topic-word type probability
θ_{dk}	document-topic probability
α_k	Dirichlet prior hyperparameter on θ for topic k
β_v	Dirichlet prior hyperparameter on ϕ for word type v
γ_{dik}	CVB0 variational probability of word token w_i in document d being assigned to topic k

Table 2: Notation used throughout the article.

representation of documents is useful for both summarizing documents and for generating predictions about future, unobserved documents. In the supervised, multi-label learning context, extensions of the basic LDA model—such as Prior-LDA —put topics into one-to-one correspondence with labels, and the model is used for assigning labels to test documents.

2.2 Bayesian Inference, Prediction, and Parameter Estimation

LDA models are typically trained using Bayesian inference techniques. Given the observed training documents $\mathcal{D}_{Train}$, the goal of Bayesian inference is to "invert" the assumed generative process of the model, going "backwards" from the data to recover the parameters, by inferring the posterior distribution over them. In the case of LDA, the posterior distribution over parameters and latent variables is given by Bayes' rule as

$$p(\phi, \theta, \mathbf{z}|\mathcal{D}_{Train}, \boldsymbol{\alpha}, \boldsymbol{\beta}) = \frac{p(\mathcal{D}_{Train}|\phi, \theta, \mathbf{z}) p(\phi, \theta, \mathbf{z}|\boldsymbol{\alpha}, \boldsymbol{\beta})}{p(\mathcal{D}_{Train}|\boldsymbol{\alpha}, \boldsymbol{\beta})} \ .$$

Being able to make use of the uncertainty encoded in the posterior distribution is a key benefit of the Bayesian approach. In the ideal procedure, having computed the posterior it can be used to make predictions on held-out data via the posterior predictive distribution, which computes the probability of new data by averaging over the parameters, weighted by their posterior probabilities. For a test document $\mathbf{w}^{(new)}$, under the LDA model we have

$$p(\mathbf{w}^{(new)}|\mathcal{D}_{Train}, \boldsymbol{\alpha}, \boldsymbol{\beta}) = \int\int p(\mathbf{w}^{(new)}|\phi, \theta^{(new)}) p(\theta^{(new)}|\boldsymbol{\alpha}) d\theta^{(new)} p(\phi|\mathcal{D}_{Train}, \boldsymbol{\alpha}, \boldsymbol{\beta}) d\phi \ .$$

Similarly, for supervised variants of LDA (discussed below), the ideal procedure is to average over all possible parameter values when predicting labels of new documents. In practice, however, it is intractable to compute or marginalize over the posterior, necessitating approximate inference techniques such as MCMC methods, which sample from the posterior using an appropriate Markov chain, and hence approximate it with the resulting set of samples. In particular, Nguyen et al. (2014) advocate using multiple samples to approximate the posterior, and averaging over the corresponding approximation to the posterior predictive distribution in order to make predictions for new data.

However, in the LDA literature it is much more common practice to simply approximate the posterior (and hence posterior predictive) distribution based on a single estimated value of the parameters (a *point estimate*). Although not ideal from a Bayesian perspective, a point estimate $\hat{\phi}$, $\hat{\theta}$ of the parameters is convenient to work with as it is much easier for a human analyst to interpret, and is computationally much cheaper to use at test time when making predictions than using a collection of samples. In this paper, while strongly agreeing with the posterior predictive-based approach of Nguyen et al. (2014) in principle, we take the perspective that a point estimate is in many cases useful and desirable to have.

Following Nguyen et al. (2014), we do, however, have substantial reservations regarding the ubiquitous standard practice of using *a single MCMC sample* to obtain a point estimate. By interpreting MCMC as a "stochastic mode-finding algorithm" we can view this procedure as a poor-man's approximation to the mode of the posterior. For many models, with a sufficiently large amount of data the posterior will approach a multivariate Gaussian under the Bernstein-von Mises theorem, and eventually become concentrated at a single point under certain general regularity conditions, cf. (Kass et al., 1990; Kleijn and van der Vaart, 2012). In this regime, a point estimate based on a single sample will in fact suffice. More generally, however, due to posterior uncertainty this procedure is unstable and consequently statistically inefficient: a parameter estimate from a posterior sample has an *asymptotic relative efficiency (ARE) of 2*, meaning, roughly speaking, that the variance of the estimator requires twice as many observations to match the variance of the ideal estimator, in the asymptotic Gaussian regime, under general regularity conditions, cf. (Wang et al., 2015).

As a compromise between the expensive full Bayesian posterior estimation procedure and noisy "stochastic mode-finding" with one sample, in this paper we propose to use the *posterior mean*, approximated via multiple MCMC samples, as an estimator of choice in many cases. The posterior mean, if it can be precisely computed, is asymptotically efficient (i.e., it has an ARE of 1), under the conditions necessary for the Bernstein-von Mises theorem to hold, cf. (Kleijn and van der Vaart, 2012). Although we cannot compute the posterior mean exactly, and the conditions necessary for the Bernstein-von Mises theorem have not been rigorously verified for LDA, these results provide a useful intuition for why we should

Algorithm 1 Pseudocode for our proposed estimators. For simplicity, we consider only the case where a single CGS sample $\mathbf{z}$ is used.

function θ^p
Input: Burned-in CGS sample $\mathbf{z}$ with associated count matrices, documents $\mathcal{D}$
for $d = 1$ to D **do**
$\hat{\theta}^p_{d,:} := \alpha^\intercal$
for $j = 1$ to N_d **do**
$v := w_{dj}$ ▷ Retrieve the word token from the word position j in d.
for $k = 1$ to K **do**
$p_{djk} := \frac{n_{kv\neg dj} + \beta_v}{\sum_{v'=1}^{V} (n_{kv'\neg dj} + \beta_{v'})} \cdot (n_{dk\neg dj} + \alpha_k)$ ▷ During testing, the first term is replaced by ϕ_{kv}
end for
$p_{dj,:} := p_{dj,:} \ ./ \ \text{sum}(p_{dj,:})$ ▷ Normalize such that $\sum_{k=1}^{K} p_{djk} = 1$, ./ denotes elementwise division.
$\hat{\theta}^p_{d,:} := \hat{\theta}^p_{d,:} + p^\intercal_{dv,:}$
end for
$\hat{\theta}^p_{d,:} := \hat{\theta}^p_{d,:} \ ./ \ \text{sum}(\hat{\theta}^p_{d,:})$ ▷ Normalize $\hat{\theta}^p_{d,:}$ such that $\sum_{k=1}^{K} \hat{\theta}^p_{dk} = 1$
end for
return $\hat{\theta}^p$
end function

function ϕ^p
Input: Burned-in CGS sample $\mathbf{z}$ with associated count matrices, documents $\mathcal{D}_{Train}$
for $k = 1$ to K **do**
$\hat{\phi}^p_{k,:} := \beta^\intercal$
end for
for $d = 1$ to D **do**
for $j = 1$ to N_d **do**
$v := w_{dj}$
for $k = 1$ to K **do**
$p_{djk} = \frac{n_{kv\neg dj} + \beta_v}{\sum_{v'=1}^{V} (n_{kv'\neg dj} + \beta_{v'})} \cdot (n_{dk\neg dj} + \alpha_k)$
end for
$p_{dj,:} := p_{dj,:} \ ./ \ \text{sum}(p_{dj,:})$ ▷ Normalize such that $\sum_{k=1}^{K} p_{djk} = 1$.
$\hat{\phi}^p_{:,v} := \hat{\phi}^p_{:,v} + p_{dj,:}$
end for
end for
for $k = 1$ to K **do**
$\hat{\phi}^p_k := \hat{\phi}^p_{k,:} \ ./ \ \text{sum}(\hat{\phi}^p_{k,:})$ ▷ Normalize $\hat{\phi}^p_{k,:}$ such that $\sum_{v=1}^{V} \hat{\phi}^p_{kv} = 1$
end for
return $\hat{\phi}^p$
end function

prefer this approach over an estimator based on a single sample. We expect a sample-based approximation to the posterior mean to be much more stable than an estimator based on a single sample, and our empirical results below will show that this is indeed the case in practice. In our proposed algorithm, we will show how to effectively average over multiple samples almost "for free", based on samples and their Gibbs sampling transition probabilities. This is valuable in the very common setting where we are able to afford a moderate number of burn-in MCMC iterations, but we are not able to afford the much larger number of iterations to compute enough samples required to accurately estimate the posterior mean of the parameters.

It should be noted that averaging over MCMC samples for LDA, without care, can be invalidated due to a lack of *identifiability*. Multiple samples can each potentially encode different permutations of the topics, thereby destroying any correspondences between them, and Griffiths and Steyvers (2004) strongly warn against this. However, in this work, we will identify certain cases for which it is safe, and indeed highly beneficial, to average over samples in order to construct a point estimate, such as when estimating θ at test time with the topics held fixed.

2.3 Collapsed Gibbs Sampling for LDA

The Collapsed Gibbs Sampling (CGS) algorithm for LDA, introduced by Griffiths and Steyvers (2004), marginalizes out the parameters ϕ and θ, and operates only on the latent variable assignments $\mathbf{z}$. This leads to a simple but effective MCMC algorithm which mixes much more quickly than the naive Gibbs sampling algorithm. To compute the CGS updates efficiently, the algorithm maintains and makes use of several count matrices during sampling. We will employ the following notation for these count matrices: n_{kv} represents the number of times that word type v is assigned to topic k across the corpus, and n_{dk} represents the number of word tokens in document d that have been assigned to topic k. The notation for these count matrices is included in Table 2.

During sampling, CGS updates the hard assignment z_i of a word token w_i to one of the topics $k \in \{1...K\}$. This update is performed sequentially for all word tokens in the corpus, for a fixed number of iterations. The update equation giving the probability of setting z_i to topic k, conditional on w_i, d, the hyperparameters $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$, and the current topic assignments of all other word tokens (represented by $\cdot$) is:

$$p(z_i = k | \, w_i = v, \, d, \, \boldsymbol{\alpha}, \, \boldsymbol{\beta}, \, \cdot) \propto \frac{n_{kv\neg i} + \beta_v}{\sum_{v'=1}^{V} (n_{kv'\neg i} + \beta_{v'})} \cdot \frac{n_{dk\neg i} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} \, . \tag{1}$$

In the above equation, one excludes from all count matrices the current topic assignment of w_i, as indicated by the $\neg i$ notation. A common practice is to run the Gibbs sampler for a number of iterations before retrieving estimates for the parameters, as the Markov chain is typically in a low probability state initially and so early estimates are expected to be of poor quality. After this *burn-in* period, we can retrieve estimates for both the topic assignments

z_i as well as for the θ and ϕ parameters. Samples are taken at a regular interval, often called *sampling lag*.[2]

To compute point estimates for θ and ϕ, Rao-Blackwell estimators were employed in (Griffiths and Steyvers, 2004). Specifically, a point estimate of the probability of word type v given topic k is computed as:

$$\hat{\phi}_{kv} = \frac{n_{kv} + \beta_v}{\sum_{v'=1}^{V} (n_{kv'} + \beta_{v'})} \, . \tag{2}$$

Similarly, a point estimate for the probability of the topic k given document d is given by:

$$\hat{\theta}_{dk} = \frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} \, . \tag{3}$$

During prediction (i.e., when applying CGS on documents that were unobserved during training), a common practice is to fix the ϕ distributions and set them to the ones learned during estimation. The sampling update equation presented in Equation 1 thus becomes:

$$p(z_i = k | \, w_i = v, \, d, \, \boldsymbol{\alpha}, \, \hat{\phi}, \, \cdot) \propto \hat{\phi}_{kv} \cdot \frac{n_{dk\neg i} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} \, . \tag{4}$$

2.4 Labeled LDA

An extension to unsupervised LDA for supervised multi-label document classification was proposed by Ramage et al. (2009). Their algorithm, Labeled LDA (LLDA), employs a one-to-one correspondence between topics and labels. During estimation of the model, the possible assignments for a word token to a topic are constrained to the training document's observed labels. Therefore, during training, the sampling update of Equation 1, becomes:

$$p(z_i = k | \, w_i = v, \, d, \, \boldsymbol{\alpha}, \, \boldsymbol{\beta}, \, \cdot) \propto \begin{cases} \frac{n_{kv\neg i} + \beta_v}{\sum_{v'=1}^{V} (n_{kv'\neg i} + \beta_{v'})} \cdot \frac{n_{dk\neg i} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}}, & \text{if } k \in \mathcal{K}_d \\ 0, & \text{otherwise.} \end{cases} \tag{5}$$

Inference on test documents is performed similarly to standard LDA; estimates of the label–word types distributions, ϕ, are learned on the training data and are fixed, and then the test documents' θ distributions are estimated using Equation 3. Unlike in unsupervised LDA, where topics can change from iteration to iteration (the label switching problem), in LLDA topics remain steady (anchored to a label) and therefore it is possible to average point estimates of ϕ and θ over multiple Markov chains, thereby improving performance.

Ramage et al. (2011) have introduced PLDA to relax the constraints of LLDA and exploit the unsupervised and supervised forms of LDA simultaneously. Their algorithm attempts to model hidden topics within each label, as well as unlabeled, corpus-wide latent topics.

2. Averaging over dependent samples does not introduce any bias. Using a sampling lag (a.k.a. "thinning") is merely convenient for reducing memory requirements and computation at test time.

Rubin et al. (2012) presented two extensions of the LLDA model. The first one, Prior-LDA, takes into account the label frequencies in the corpus via an informative Dirichlet prior over parameter θ (we describe this process in detail in Section 6.3). The second extension, Dependency LDA, takes into account label dependencies by following a two stage approach: first, an unsupervised LDA model is trained on the observed labels. The estimated θ' parameters incorporate information about the label dependencies. Second, the LLDA model is trained as described in the previous paragraph. During prediction, the previously estimated θ' parameters of the unsupervised LDA model are used to calculate an asymmetrical hyperparameter α_{dk}, which is in turn used to compute the θ parameters of the LLDA model.

2.5 Collapsed Variational Bayes with Zero Order Information – CVB0

Collapsed Variational Bayesian (CVB) inference (Teh et al., 2006) is a deterministic inference technique for LDA. The key idea is to improve on Variational Bayes (VB) by marginalizing out θ and ϕ as in a collapsed Gibbs sampler. The key parameters in CVB are the γ_{di} variational distributions over the topics, with γ_{dik} representing the probability of the assignment of topic k to the word token w_i in document d, under the variational distribution. As the exact implementation of CVB is computationally expensive, the authors propose a second-order Taylor expansion as an approximation to compute the parameters of interest, which nevertheless improves over VB inference with respect to prediction performance.

Asuncion et al. (2009) presented a further approximation for CVB, by using a zero order Taylor expansion approximation.[3] The update equation for CVB0 is given by:

$$\gamma_{dik} \propto \frac{n'_{kw_i\neg i} + \beta_{w_i}}{\sum_{v'=1}^{V} (n'_{kv'\neg i} + \beta_{v'})} (n'_{dk\neg i} + \alpha_k) \tag{6}$$

with $n'_{kv} = \sum_{d=1}^{D} \sum_{j:w_{dj}=v} \gamma_{djk}$, $n'_{dk} = \sum_{j=1}^{N_d} \gamma_{djk}$.

Point estimates for θ and ϕ are retrieved from the same equations as in CGS (Equations 2 and 3). Even though the above update equation looks very similar to the one for CGS, the two algorithms have a couple of key differences. First, the counts n'_{kv} and n'_{dk} for CVB0 differ from the respective ones for CGS; the former are summations over the variational probabilities while the latter sum over the topic assignments z_i of topics to words. Second, CVB0 differs from CGS in that in every pass, instead of probabilistically sampling a hard topic-assignment for every token based on the sampling distribution in Equation 1, it keeps (and updates) that probability distribution for every word token. A consequence of this procedure is that CVB0 is a deterministic algorithm, whereas CGS is a stochastic algorithm (Asuncion, 2010). The deterministic nature of CVB0 allows it to converge faster than other inference techniques.

On the other hand, the CVB0 algorithm has significantly larger memory requirements as it needs to store the variational distribution γ for every token in the corpus. More recently, a stochastic extension of CVB0, SCVB0, was presented by Foulds et al. (2013), inspired by

3. The first-order terms are zero, so this is actually equivalent to a first-order Taylor approximation.
