the Stochastic Variational Bayes (SVB) algorithm of Hoffman et al. (2010a). Both SCVB0 and SVB focus on efficient and fast inference of the LDA parameters in massive-scale data scenarios. SCVB0 also improves the memory requirements of CVB0. Since CVB0 maintains full, dense probability distributions for each word token, it is unable to leverage sparsity to accelerate the algorithm, unlike CGS (Yao et al., 2009; Li et al., 2014; Yuan et al., 2015; Chen et al., 2016). Inspired by CVB0, in our work we aim to leverage the full distributional uncertainty information per word token, in the context of the parameter estimation step of the CGS algorithm, while maintaining the valuable sparsity properties of that algorithm during the training process.

3. CGS$_p$ for Document-Topic Parameter Estimation

In this section we present our new estimator for the document-topic (θ_d) parameters of LDA that make use of the full distributions of word tokens over topics. For simplicity, we first describe the case of θ_d estimation during prediction and then extend our theory to θ_d estimation during training. We present our estimator for the topic-word parameters (ϕ_k) in the following section.

3.1 Standard CGS θ_d Estimator

The standard estimator for document d's parameters θ_d from a collapsed Gibbs sample $\mathbf{z}_d$ (Equation 3), due to Griffiths and Steyvers (2004), corresponds to the posterior predictive distribution over topic assignments, i.e.,

$$\begin{aligned}
\hat{\theta}_{dk} &\triangleq p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha}) && (7)\\
&= \int p(z^{(new)} = k, \theta_d|\mathbf{z}_d, \boldsymbol{\alpha})\ d\theta_d && (8)\\
&= \int p(z^{(new)} = k|\theta_d) p(\theta_d|\mathbf{z}_d, \boldsymbol{\alpha})\ d\theta_d && (9)\\
&= \int \theta_{dk} p(\theta_d|\mathbf{z}_d, \boldsymbol{\alpha})\ d\theta_d && (10)\\
&= \mathbb{E}_{p(\theta_d|\mathbf{z}_d,\boldsymbol{\alpha})}[\theta_{dk}] && (11)\\
&= \mathbb{E}_{\text{Dirichlet}(\theta_d|\boldsymbol{\alpha}+\mathbf{n}_d)}[\theta_{dk}] && (12)\\
&= \frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}}\ , && (13)
\end{aligned}$$

where the last two lines follow from Dirichlet/multinomial conjugacy, and from the mean of a Dirichlet distribution, respectively. Here, $z^{(new)}$ corresponds to a hypothetical "new" word in the document. The posterior predictive distribution can be understood via the urn process interpretation of collapsed Dirichlet-multinomial models. After marginalizing out the parameters θ of a multinomial distribution $\mathbf{x} \sim \text{Multinomial}(\theta, N)$ with a Dirichlet prior $\theta \sim \text{Dirichlet}(\boldsymbol{\alpha})$, we arrive at an urn process called the Dirichlet-multinomial distribution, a.k.a. the multivariate Polya urn, cf. (Minka, 2000). The urn process is as follows:

- Begin with an empty urn
- For each k, $1 \leq k \leq K$
  - add α_k balls of color k to the urn
- For each i, $1 \leq i \leq N$
  - Reach into the urn and draw a ball uniformly at random
  - Observe its color, k. Count it, i.e., add one to x_k
  - Place the ball back in the urn, along with a *new ball of the same color.*

We can interpret the posterior predictive distribution above as the probability of the next ball in the urn, i.e., the next word in the document, if we were to add one more word, by reaching into the urn once more.

3.2 A Marginalized Estimation Principle

The topic assignment vector $\mathbf{z}_d$ for test document d is a latent variable which typically has quite substantial posterior uncertainty associated with it, and yet the most common practice is to ignore this uncertainty and construct a point estimate of θ_d from a single $\mathbf{z}_d$ sample, which can be detrimental to performance (Nguyen et al., 2014). Following Griffiths and Steyvers (2004), we assume that the predictive probability of a new word's topic assignment $z^{(new)}$ is a principled estimate of θ_d. Differently to previous work, though, we take the perspective that the latent $\mathbf{z}_d$ is a nuisance variable which should be marginalized out. This leads to a *marginalized* version of Griffiths and Steyvers' estimator,

$$\bar{\theta}_{dk} \triangleq p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) = \sum_{\mathbf{z}_d} p(z^{(new)} = k, \mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) \ . \tag{14}$$

Due to its treatment of uncertainty in $\mathbf{z}_d$, we advocate for $\bar{\theta}_d$ as a gold standard principle for constructing a point estimate of θ_d. We will introduce computationally efficient Monte Carlo algorithms for approximating it below. Note that while previous works have considered averaging strategies which correspond to Monte Carlo approximations of this principle, including Griffiths and Steyvers (2004), Asuncion et al. (2009), Nguyen et al. (2014), and references therein, discussion on the estimation principle of Equation 14 that these methods approximate appears to be missing in the literature. Griffiths and Steyvers (2004) mention that such averaging strategies are possible but caution against them due to concerns regarding identifiability, however this identifiability issue does not arise at test time with topics ϕ held fixed, as in the scenario we consider here. Nguyen et al. (2014) empirically explore averaging

procedures for making predictions by approximating the posterior predictive distribution. They do not aim to compute a point estimate from multiple samples, however their *Single Average* prediction strategy can be seen to be equivalent to using a naive Monte Carlo estimate (given in Equation 26) of Equation 14 in the context of predicting held-out words.

3.2.1 Interpretations

We can interpret the estimator from Equation 14 in several other ways.

Expected Griffiths and Steyvers estimator: The estimator $\bar{\theta}_d$ can readily be seen to be the posterior mean of the Griffiths and Steyvers estimator $\hat{\theta}_d$:

$$\begin{aligned}
\bar{\theta}_{dk} = p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) &= \sum_{\mathbf{z}_d} p(z^{(new)} = k, \mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) && (15)\\
&= \sum_{\mathbf{z}_d} p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha}) p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) && (16)\\
&= E_{p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})}[p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha})] && (17)\\
&= E_{p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})}[\hat{\theta}_{dk}] \ . && (18)
\end{aligned}$$

Posterior mean of θ_d: Griffiths and Steyvers' estimator can be viewed as the posterior mean of θ_d, given $\mathbf{z}_d$ (Equation 11). Along these lines, we can interpret $\bar{\theta}_d$ as the marginal posterior mean:

$$\begin{aligned}
\bar{\theta}_{dk} = p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) &= E_{p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})}[\hat{\theta}_{dk}] && (19)\\
&= E_{p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})}\Big[\mathbb{E}_{p(\theta_d|\mathbf{z}_d, \boldsymbol{\alpha})}[\theta_{dk}]\Big] && (20)\\
&= E_{p(\theta_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})}[\theta_{dk}] \ , && (21)
\end{aligned}$$

where the last line follows by the law of total expectation.

Urn model interpretation: To interpret the estimator from an urn model perspective, we can plug in Equation 13:

$$\begin{aligned}
\bar{\theta}_{dk} = p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) &= \sum_{\mathbf{z}_d} p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha}) p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) && (22)\\
&= \sum_{\mathbf{z}_d} \frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) \ . && (23)
\end{aligned}$$

We can view this as a mixture of urn models. It can be simulated by picking an urn with colored balls in it corresponding to the count vector $\mathbf{n}_d + \boldsymbol{\alpha}$, with probability according to the posterior $p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})$, then selecting a colored ball, corresponding to a topic assignment, from this urn uniformly at random. Alternatively, we can model this equation with a single urn, with (fractional) colored balls placed in it according to the count vector,

$$\bar{\theta}_{dk} \propto \sum_{\mathbf{z}_d} (n_{dk} + \alpha_k) p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) = \sum_{\mathbf{z}_d} p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) n_{dk} + \alpha_k \ , \tag{24}$$

and with the next ball (i.e., topic) $z^{(new)}$ selected according to the total number of balls of each color (i.e., topic) in the urn.

3.2.2 Monte Carlo algorithms for computing the estimator

Due to the intractable sum over $\mathbf{z}_d$, we cannot compute $\bar{\theta}_d$ exactly. A straightforward Monte Carlo estimate of $\bar{\theta}_d$ is given by

$$\bar{\theta}_{dk} = E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha})] = E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}\Big[\frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}}\Big] \tag{25}$$

$$\approx \frac{1}{S}\sum_{i=1}^{S} \frac{n_{dk}^{(i)} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}} \ , \tag{26}$$

where each of the count variables $\mathbf{n}_d^{(i)}$ corresponds to a sample $\mathbf{z}_d^{(i)} \sim p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})$. Algorithmically, this corresponds to drawing multiple MCMC samples of $\mathbf{z}_d$ and averaging the Griffiths and Steyvers estimator $\hat{\theta}_d$ over them. Alternatively, by linearity of expectation we can shift the expectation inwards to rewrite the above as

$$E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}\Big[\frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}}\Big] = E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}\Big[\frac{\sum_{j=1}^{N_d} z_{djk} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}}\Big] \tag{27}$$

$$= \frac{\sum_{j=1}^{N_d} E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[z_{djk}] + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}} \ . \tag{28}$$

This leads to another Monte Carlo estimate,

$$\bar{\theta}_{dk} \approx \frac{\sum_{j=1}^{N_d} \frac{1}{S}\sum_{i=1}^{S} z_{djk}^{(i)} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}} \ . \tag{29}$$

In this case we would once again draw multiple MCMC samples of $\mathbf{z}_d$, but average over the samples to compute the proportion of times that each word is assigned to each topic, applying Griffiths and Steyvers' estimator to the resulting expected total counts. It can straightforwardly be shown that this estimator is mathematically equivalent to the estimator of Equation 26, so this algorithm will perform identically to that method. We mention this formulation for expository purposes, as it will be used as a launching point for deriving our proposed CGS$_p$ algorithm.

3.3 CGS$_p$ for θ_d

We aim to design a statistically and computationally efficient Monte Carlo algorithm which improves on the above algorithms. To do this, we first consider a hypothetical Monte Carlo algorithm which is more expensive but easily understood, using Equation 29 as a starting point. We then propose our algorithm, CGS$_p$, as a more computationally efficient version of this hypothetical method. Let $\mathbf{z}_d^{(i)} \sim p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})$, $i \in \{1, \ldots, S\}$ be S samples from the posterior for the topic assignments, and let $\mathbf{z}_d^{(i,l)\to j}$, $l \in \{1, \ldots, L\}$ be L Gibbs samples starting from $\mathbf{z}_d^{(i)}$, where a Gibbs update to the jth topic assignment is performed. The Bayesian posterior distribution is a stationary distribution of the Gibbs sampler, so these Gibbs updated samples are still samples from the posterior, i.e., $\mathbf{z}_d^{(i,l)\to j} \sim p(\mathbf{z}_d|\mathbf{w}_d, \phi, \boldsymbol{\alpha})$.

We can therefore estimate posterior expectations of any quantity of interest using these samples instead of the $\mathbf{z}_d^{(i)}$'s, and in particular:

$$\bar{\theta}_{dk} \approx \frac{\sum_{j=1}^{N_d} \frac{1}{SL}\sum_{i=1}^{S}\sum_{l=1}^{L} z_{djk}^{(i,l)\to j} + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}} \ . \tag{30}$$

This method increases the sample size, and also the effective sample size, relative to the method of Equation 29, but also greatly increases the computational effort to obtain the Monte Carlo estimator, making it relatively impractical. Fortunately, a variant of this procedure exists which is both computationally faster and has lower variance. Let $T(\mathbf{z}_d^{(i)\to j}|\mathbf{z}_d^{(i)}, \phi)$ be the transition operator for a Gibbs update on the jth topic assignment. Holding the other assignments $\mathbf{z}_{d\neg j}^{(i)}$ fixed, we have the partially collapsed Gibbs update

$$T(\mathbf{z}_{djk}^{(i)\to j} = 1|\mathbf{z}_d^{(i)}, \phi) \propto \phi_{kw_{d,j}} \frac{n_{dk\neg j}^{(i)} + \alpha_k}{N_{d\neg j} + \sum_{k'=1}^K \alpha_{k'}} \ . \tag{31}$$

By the strong law of large numbers,

$$\frac{1}{L}\sum_{l=1}^{L} z_{djk}^{(i,l)\to j} \to E_{T(\mathbf{z}_d^{(i)\to j}|\mathbf{z}_d^{(i)},\phi)}[z_{djk}^{(i)\to j}] = T(z_{djk}^{(i)\to j}|\mathbf{z}_d^{(i)}, \phi) \text{ as } L \to \infty \text{ with probability 1.} \tag{32}$$

So for the cost of a single Gibbs sweep through the document, we can obtain an effective number of inner loop samples $L = \infty$ by plugging in the Gibbs sampling probabilities as the expected topic counts in Equation 30. This leads to our proposed estimator for θ_{dk}:

$$\hat{\theta}_{dk}^p \triangleq \frac{\sum_{j=1}^{N_d} \frac{1}{S}\sum_{i=1}^{S} T(\mathbf{z}_{djk}^{(i)\to j}|\mathbf{z}_d^{(i)}, \phi) + \alpha_k}{N_d + \sum_{k'=1}^K \alpha_{k'}} \ . \tag{33}$$

This method is equivalent to averaging over an infinite number of Gibbs samples adjacent to our initial samples $i = 1, \ldots, S$ in order to estimate each word's topic assignment probabilities, and thereby estimate the expected topic counts for the document, which correspond to our estimate of θ_d. By the Rao-Blackwell theorem, it has lower variance than the method in Equation 30 with finite L. We refer to this Monte Carlo procedure as CGS$_p$, for collapsed Gibbs sampling with probabilities maintained.

The above argument makes it clear that $\hat{\theta}_d^p$ is an unbiased Monte Carlo estimator of the posterior predictive distribution, but for added rigor we can also show this directly:

$$\hat{\theta}^p_{dk} \propto \sum_{j=1}^{N_d} \frac{1}{S} \sum_{i=1}^{S} T(z^{(i)\to j}_{djk} | \mathbf{z}^{(i)}_d, \phi) + \alpha_k \tag{34}$$

$$= \sum_{j=1}^{N_d} \frac{1}{S} \sum_{i=1}^{S} E_{T(\mathbf{z}^{(i)\to j}_d | \mathbf{z}^{(i)}_d, \phi)}[z^{(i)\to j}_{djk}] + \alpha_k \tag{35}$$

$$\approx \sum_{j=1}^{N_d} E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}\left[E_{T(\mathbf{z}^{\to j}_d|\mathbf{z}_d,\phi)}[z^{\to j}_{djk}]\right] + \alpha_k \tag{36}$$

$$= \sum_{j=1}^{N_d} E_{p(\mathbf{z}^{\to j}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[z^{\to j}_{djk}] + \alpha_k \qquad \text{(by the law of total expectation)}$$

$$= \sum_{j=1}^{N_d} E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[z_{djk}] + \alpha_k \qquad \text{(by stationarity of the Gibbs sampler)}$$

$$= E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[\sum_{j=1}^{N_d} z_{djk}] + \alpha_k \tag{37}$$

$$= E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[n_{dk} + \alpha_k] \tag{38}$$

$$\propto E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[\frac{n_{dk} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}}] \tag{39}$$

$$= p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha}) \ . \qquad \text{(by Equation 25)}$$

We advocate the use of this procedure even when we can only afford a single burned-in sample, i.e., $S = 1$, as a cheap approximation to $p(z^{(new)} = k|\mathbf{w}_d, \phi, \boldsymbol{\alpha})$ which can be used as a plug-in replacement to Griffiths and Steyvers (2004)'s single sample estimator $p(z^{(new)} = k|\mathbf{z}_d, \boldsymbol{\alpha})$. Indeed, the increased stability of our estimator, due to implicit averaging, is expected to be especially valuable when $S = 1$. We emphasize three primary observations arising from the above analysis.

(1) We have shown that it is valid and potentially beneficial to use "soft" probabilistic counts instead of hard assignment counts when computing parameter estimates from collapsed Gibbs samples. This ports the soft clustering methodology of CVB0 to the CGS setting at estimation time. While our approach computes soft counts via Gibbs sampling transition probabilities and CVB0 uses variational distributions, the corresponding equations to compute them are very similar, cf. Equations 1, 4, and 6.

(2) Averaging these (hard or soft) count matrices over multiple samples can be performed to improve the stability of the estimators, as long as identifiability is resolved, e.g., at test time with the topics held fixed.

(3) Averaging over either hard or soft count matrices will converge to the same solution in the long run: the marginalized version of the Griffiths and Steyvers estimator, given by Equation 14. However, we expect the use of soft counts to be much more efficient in the number of samples S, as it implicitly averages over larger numbers of samples.

This last point is crucial in many common practical applications of topic modeling where we have a limited computational budget per document at prediction time, and can afford only a modest burn-in period, and few samples after burn-in. This situation frequently arises when evaluating topic models, for which a novel approach is typically compared to multiple baseline methods on a test set containing up to tens of thousands of documents, with the entire experiment being repeated across multiple corpora and/or training folds. The computational challenge is greatly exacerbated when evaluating topic model training algorithms, for which the above must be repeated at many stages of the training process (Foulds and Smyth, 2014). For instance, Asuncion et al. (2009) state that "*in our experiments we don't perform averaging over samples for CGS . . . [in part] for computational reasons.*" Computational efficiency at test time is also essential when using topic modeling for multi-label document classification (Ramage et al., 2009, 2011; Rubin et al., 2012), for which a deployed system may need to perform inference on a never-ending stream of incoming test documents.

Pseudocode illustrating the proposed method is provided in Algorithm 1. It should be noted than any existing CGS implementation can very straightforwardly be modified to apply our proposed technique, including MALLET (McCallum, 2002a), Yahoo_LDA (Smola and Narayanamurthy, 2010), and WarpLDA (Chen et al., 2016). Our method is compatible with modern sparse and parallel implementations of CGS, as the final estimation procedure does not need to alter the training process. This can lead to a "best of both worlds" situation, where sparsity is leveraged during the expensive CGS inference process, but the full dense distributions are used during the relatively inexpensive parameter recovery step, which in many topic modeling applications is performed only once. In this setting, the improved performance is typically worth the computational overhead (which is similar to that of a single dense CGS update), as we demonstrate in Section 5.8. A practical implementation of our estimators can further leverage the fact that the count matrices are not modified during the procedure, by computing the sampling distribution only once for each distinct word type in each document, and by performing the computations in parallel. In the following we will sometimes abuse notation and denote the procedure of using $\hat{\theta}^p_d$ to estimate the θ_d's as θ^p (and similarly for the procedure to estimate ϕ, denoted ϕ^p, introduced below).

3.3.1 CGS$_p$ for estimating θ_d for training documents

During the training phase, we can apply the same procedure to estimate θ_d for training documents based on a given collapsed Gibbs sample $\mathbf{z}^{(i)}$:

$$\hat{\theta}^p_{dk} = \frac{\sum_{j=1}^{N_d} T(z^{(i)\to j}_{djk} | \mathbf{z}^{(i)}, \phi) + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} \ . \tag{40}$$

The collapsed Gibbs sampler does not explicitly maintain an estimate of ϕ to plug into the above. However, the Griffiths and Steyvers estimator for ϕ (Equation 2) can be obtained from the same count matrices that CGS computes, as it corresponds almost exactly to the first term on the right hand side of Equation 1. Alternatively, below we propose a novel estimator for ϕ which can also be used here with a little bit more computational effort.

Similarly to the Griffiths and Steyvers estimator, it should be noted that averaging this estimator over multiple samples from different training iterations raises issues with the

identifiability of the topics, which can potentially be problematic (Griffiths and Steyvers, 2004). We do not consider this procedure further here. It is however safe to apply Equation 33 to multiple MCMC samples for $\mathbf{z}_d$ that are generated while holding ϕ fixed, i.e., treating document d as a test document for the purposes of estimating θ_d given the $\hat{\phi}$ from $\mathbf{z}^{(i)}$.

4. CGS$_p$ for Topic - Word Types Parameter Estimation

By applying the same approach as for θ^p, plugging in Gibbs transition probabilities instead of indicator variables into Equation 2, we arrive at an analogous technique for estimating ϕ:

$$\hat{\phi}^p_{kv} = \frac{\sum_{d=1}^{D_{Train}} \sum_{j:w_{d,j}=v} T(z^{(i)\rightarrow j}_{djk}|\mathbf{z}^{(i)}) + \beta_v}{\sum_{d=1}^{D_{Train}} \sum_{j=1}^{N_d} T(z^{(i)\rightarrow j}_{djk}|\mathbf{z}^{(i)}) + \sum_{v'=1}^{V} \beta_{v'}} \ , \tag{41}$$

where $T(z^{(i)\rightarrow j}_{d,j}|\mathbf{z}^{(i)})$ corresponds to the collapsed Gibbs update in Equation 1. While the intuition of the above method is clear, there are several technical complications to an analogous derivation for it. Nevertheless, we show that the same reasoning essentially holds for ϕ, with minor approximations. In the following, we outline a justification for the ϕ^p estimator, with emphasis on the places where the argument from θ^p does not apply, along with well-principled approximation steps to resolve these differences.

First, consider the estimation principle underlying the technique. For topics ϕ, the standard Rao-Blackwellized estimator of Griffiths and Steyvers (2004), given by Equation 2, once again corresponds to the posterior predictive distribution,

$$\begin{aligned}
\hat{\phi}_{kv} &\triangleq p(w^{(new)} = v|\mathbf{z}, \mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k) \\
&= \int p(w^{(new)} = v, \phi_k|\mathbf{z}, \mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k) d\phi_k \\
&= \int p(w^{(new)} = v|\phi_k, z^{(new)} = k) p(\phi_k|\mathbf{w}_{z=k}, \boldsymbol{\beta}) d\phi_k \\
&= E_{Dirichlet(\mathbf{n}_k+\boldsymbol{\beta})}[\phi_{kv}] \\
&= \frac{n_{kv} + \beta_v}{\sum_{v'=1}^{V} (n_{v'k} + \beta_{v'})} \ ,
\end{aligned} \tag{42}$$

where $\mathbf{w}_{z=k}$ is the collection of word tokens assigned to topic k. This estimator again conditions on the latent variable assignments $\mathbf{z}$, which are uncertain quantities. We desire a marginalized estimator, summing out the latent variables $\mathbf{z}$. However, without conditioning on $\mathbf{z}$, the topic index k loses its meaning because the topics are not identifiable. The naive marginalized estimator

$$\bar{\phi}_{kv} \triangleq p(w^{(new)} = v|\mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k) = \sum_{\mathbf{z}} p(w^{(new)} = v, \mathbf{z}|\mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k) \tag{43}$$

sums over all permutations of the (collapsed representation of the) topics, and so conditioning on $z^{(new)} = k$ has no effect. The estimator in Equation 43 is therefore unfortunately not well defined. On the other hand, a sum over $\mathbf{z}$'s *is* meaningful as long as *the topics are aligned*

for all values of $\mathbf{z}$ *considered.* Suppose, by some oracle, we know that $\mathbf{z}$ belongs to some *identified subset* of assignments $\dot{Z}$, for which topic indices are aligned between all elements $\mathbf{z}' \in \dot{Z}$. We are then able to properly define our idealized estimator with respect to $\dot{Z}$,

$$\bar{\phi}^{(\dot{Z})}_{kv} \triangleq p(w^{(new)} = v|\mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k, \mathbf{z} \in \dot{Z}) = \sum_{\mathbf{z} \in \dot{Z}} p(w^{(new)} = v, \mathbf{z}|\mathbf{w}, \boldsymbol{\beta}, z^{(new)} = k, \mathbf{z} \in \dot{Z}) \ . \tag{44}$$

Regarding our proposed technique, the Monte Carlo estimator in Equation 41 implicitly averages over the set of possible Gibbs samples $Z_{Gibbs}(\mathbf{z}^{(i)})$ that are adjacent to sample $\mathbf{z}^{(i)}$, i.e., the candidate $\mathbf{z}$ assignments that differ from $\mathbf{z}^{(i)}$ in a single entry. A difference of a single word is extremely unlikely to cause label switching for a realistic corpus, so the topics will almost certainly be aligned for each of the adjacent Gibbs samples that the estimator implicitly averages over. The empirical results of Nguyen et al. (2014) also support this, as they found that averaging over multiple samples from the same MCMC chain was beneficial to performance, which suggests that identifiability was not a problem even for MCMC samples that are many iterations apart. Hence, we take $\bar{\phi}^{(Z_{Gibbs}(\mathbf{z}^{(i)}))}_{kv}$ as our idealized estimator, under the supposition that $Z_{Gibbs}(\mathbf{z}^{(i)})$ is identified, and we aim to derive Equation 41 as a Monte Carlo algorithm that efficiently approximates it.

To accomplish this, following the derivation for $\hat{\theta}^p$, we would like to show that

(1) we can use a Monte Carlo estimator in which the $z_{d,j}$'s can be sampled individually, as in Equation 29, and

(2) the transition probabilities in Equation 41 can be used to implement this estimator with an effectively infinite number of adjacent Gibbs samples, as in Section 3.3.

While the previous stationarity argument for (2) still applies, there is a further complication for (1). For $\hat{\theta}^p$, linearity of expectation was sufficient to show in Equation 28 that

$$E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}\Big[\frac{\sum_{j=1}^{N_d} z_{djk} + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}}\Big] = \frac{\sum_{j=1}^{N_d} E_{p(\mathbf{z}_d|\mathbf{w}_d,\phi,\boldsymbol{\alpha})}[z_{djk}] + \alpha_k}{N_d + \sum_{k'=1}^{K} \alpha_{k'}} \ .$$

We cannot use this argument directly for $\hat{\phi}^p$ because in this case the denominator of the Griffiths and Stevyers estimator, which is averaged over, also includes $\mathbf{z}$ terms which are involved in the expectation:

$$\bar{\phi}^{(Z_{Gibbs}(\mathbf{z}^{(i)}))}_{kv} = E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}} \sum_{j:w_{d,j}=v} z_{djk} + \beta_v}{\sum_{d=1}^{D_{Train}} \sum_{j=1}^{N_d} z_{djk} + \sum_{v'=1}^{V} \beta_{v'}}\Big] \ . \tag{45}$$

The issue here is that the adjacent Gibbs samples modify the overall counts per topic $n_k \triangleq \sum_{d=1}^{D_{Train}} \sum_{j=1}^{N_d} z_{djk}$. However, between adjacent Gibbs samples $\mathbf{z}$ and $\mathbf{z}^{(i)}$, the corresponding topic counts n_k are within ± 1 of $n^{(i)}_k$ and for a typical corpus we have that $n_k >> 1$, so the

impact of a single word is negigible, i.e.,

$$\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk} \in \Big\{ \sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}, \sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk} \pm 1 \Big\} \approx \sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk} \ ,$$
$$\text{for } \mathbf{z} \in Z_{Gibbs}(\mathbf{z}^{(i)}) \ , \ \sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk} >> 1 \ . \tag{46}$$

In this case, we see from Equation 46 that for a corpus in which $n_k >> 1$, for all practical purposes the denominator in Equation 45 is essentially constant over all adjacent Gibbs samples, and so (1) still holds approximately, and we have

$$\begin{aligned}
\bar{\phi}^{(Z_{Gibbs}(\mathbf{z}^{(i)}))}_{kv} &= E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] \\
&\approx E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] \\
&= \frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}[z_{djk}]+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}} \ .
\end{aligned} \tag{47}$$

A related argument was also made by Asuncion et al. (2009), who note that several topic modeling inference algorithms differ only by offsets of 1 or 0.5 to the counts, and state that "*since n_k is usually large, we do not expect [a small offset] to play a large role in learning.*" To formalize this intuition, as we show in Appendix B, the approximation can be bounded from below and from above as a function of $n^{(i)}_k$ as:

$$\begin{aligned}
&\frac{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}}{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}+1} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] \\
&\qquad\qquad \le E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] \\
\le &\frac{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}}{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}-1} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] \ ,
\end{aligned} \tag{48}$$

for $n^{(i)}_k > 0$. Since $\lim_{n^{(i)}_k\to\infty}\frac{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}}{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}+1}=1$ and $\lim_{n^{(i)}_k\to\infty}\frac{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}}{n^{(i)}_k+\sum_{v'=1}^{V}\beta_{v'}-1}=1$, the left and right hand sides of Equation 47 will converge in the limit as the $n^{(i)}_k$'s go to infinity, e.g., when increasing the counts via a stream of incoming documents. In Appendix C, we provide a further empirical illustration of this approximation, by taking subsets of the documents in the corpus to vary n_k, and observing that as n_k increases the difference between the left and right sides of Equation 47 approaches zero.

Finally, using the same stationarity and law of large numbers arguments as before, we obtain the $\hat{\phi}^p$ estimator by plugging in the transition operator, and then renormalizing,

$$\hat{\phi}^p_{kv} \propto \sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}[z_{djk}]+\beta_v = \sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} T(z^{(i)\to j}_{djk}|\mathbf{z}^{(i)})+\beta_v \ . \tag{49}$$

More formally, the full argument is given mathematically as

$$\begin{aligned}
\hat{\phi}^p_{kv} &\propto \sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} T(z^{(i)\to j}_{djk}|\mathbf{z}^{(i)})+\beta_v && (50)\\
&= \sum_{d=1}^{D_{Train}}\sum_{j:w_{dj}=v} E_{T(\mathbf{z}^{(i)\to j}_d|\mathbf{z}^{(i)}_d)}[z^{(i)\to j}_{djk}]+\beta_v && (51)\\
&= \sum_{d=1}^{D_{Train}}\sum_{j:w_{dj}=v} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}[z_{djk}]+\beta_v \\
&\qquad\qquad \text{(by stationarity of the Gibbs sampler)} \\
&\propto \frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{dj}=v} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}[z_{djk}]+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}} && (52)\\
&= E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{dj}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] && (53)\\
&\approx E_{p(\mathbf{z}|\mathbf{w},\beta,\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{dj}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] && \text{(if } n_k >> 1) \\
&= p(w^{(new)}=v|\mathbf{w},\boldsymbol{\beta},z^{(new)}=k,\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)})) \ . && (54)
\end{aligned}$$

In Algorithm 1, along with θ^p's procedure, we also present the pseudocode for the ϕ^p estimator.

5. Unsupervised Learning Experiments—LDA

This section describes the experiments that we performed to study the behavior of our proposed estimators in the context of unsupervised LDA models. We describe the data sets, the evaluation procedure and the experiments performed in the unsupervised LDA setting. Apart from the experiments reported here, we have performed two additional ones reported in the Appendix, (a) comparing the document-topic counts of the Collapsed Gibbs Sampling (CGS) algorithm against the *soft* document-topic counts, in order to study their differences as the algorithm converges and (b) providing an empirical validation of the approximation that we use in Equation 47 regarding our ϕ^p estimator's derivation. The relevant code of the following experiments (along with the code of the multi-label experiments of Section 6) can be found in `https://github.com/ypapanik/cgs_p`.

Data Set	D_{Train}	D_{Test}	$\overline{N_d}$	V
BioASQ	20,000	10,000	113.55	135,186
New York Times	14,668	7,000	581.13	19,259
Reuters-21578	11,475	4,021	49.68	41,014
TASA	30,121	7,529	107.62	21,970

Table 3: Statistics for the data sets used in the unsupervised learning experiments. Average document length and number of word types refer to the training sets.

5.1 Data Sets

Four data sets were used in the unsupervised setting: a) BioASQ, b) New York Times, c) Reuters-21578 and d) TASA. The number of documents in the training and test sets, the average length of the training documents and the size of the vocabulary of word types found in the training set are presented in Table 3.

The first data set originates from the *BioASQ* challenge (Balikas et al., 2014) that deals with large-scale online multi-label classification of biomedical journal articles. This learning task is particularly challenging as the taxonomy of labels includes around $27,000$ terms, with highly imbalanced frequencies. For the unsupervised experiments of this section, we used the $30,000$ last documents of the BioASQ corpus of the year 2014, using the first $20,000$ as training documents and the rest as test documents. To construct the data set we concatenated the abstract and title of each article and removed common stopwords. The remaining unigrams were used as word types.

The second data set contains articles published by the *New York Times*, manually annotated via their indexing service. We used the same data set as used by Rubin et al. (2012), with the same training set (14,668 documents) and keeping the first 7,000 documents for testing (out of the 15,989 of the original paper).

The third data set[4] contains documents from the *Reuters* news-wire and has been widely used among researchers for almost two decades. The split that we used has 11,475 documents for training and 4,021 documents for testing. We preprocessed the corpus by removing common stopwords.

The *TASA* data set contains $37,650$ documents of diverse educational materials (e.g., health, sciences, etc) collected by Touchstone Applied Science Associates (Landauer et al., 1998). We used the first 30,121 documents as a training set and the remaining as a test set. The corpus already had stopwords and infrequent words removed, so we did not perform any further preprocessing.

5.2 Evaluation

Evaluation of LDA models typically focuses on the probability of a set of held-out documents given an already trained model (Wallach et al., 2009). In this context, one must compute the model's posterior predictive likelihood of all words in the test set, given estimates of the topic parameters ϕ and the document-level mixture parameters θ.

4. `http://disi.unitn.it/moschitti/corpora/Reuters21578-Apte-115Cat.tar.gz`

The log likelihood of a set of test documents D_{Test}, given an already estimated model M, is given by Heinrich (2004) as:

$$\text{Log Likelihood} = \sum_{d=1}^{D_{Test}} \log p(\mathbf{w}_d|M) = \sum_{d=1}^{D_{Test}} \sum_{i=1}^{N_d} \log \sum_{k=1}^{K} (\phi_{kv} \cdot \theta_{dk}) \tag{55}$$

with $w_i = v$. The perplexity will be:

$$\text{Perplexity} = \exp(-\frac{\text{Log Likelihood}}{\sum_{d=1}^{D_{Test}} N_d}) \tag{56}$$

where lower values of perplexity signify a better model.

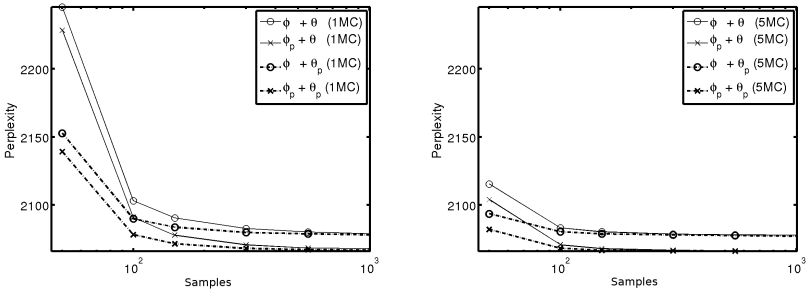
Since θ_d is unknown for test documents, and is intractable to marginalize over, a common practice in the literature in order to compute the above likelihood is to run the CGS algorithm for a few iterations on the first half of each document, and then to compute the perplexity of the held-out data (the second half of each document), based on the trained model's posterior predictive distribution over words (Asuncion et al., 2009). This is the approach we follow.

5.3 Comparison between CGS and CGS$_p$

In this first experiment, the motivation is to validate the previously presented theory behind the ϕ^p and θ^p methods. Specifically, we are interested in verifying the following hypothesis: given a single burned-in sample, $\hat{\phi^p}$ or $\hat{\theta^p}$ will more effectively estimate the respective LDA parameters compared to the standard estimators, since the CGS$_p$ estimators make use of the full dense probabilities, through the infinite l-steps of Eq. 33. This advantage would correspond to lower perplexity values for a single burned-in sample for the CGS$_p$ estimators compared to the standard CGS estimator. Furthermore, when averaging over multiple samples to estimate the θ parameters during prediction, we expect that the θ^p and standard θ estimators will eventually converge to the same solution given enough samples or Markov chains, since θ^p aims to compute the posterior mean. However, we expect that θ^p will converge to the posterior mean more rapidly in the number of samples that are averaged over than the standard estimator θ, with correspondingly faster improvement in perplexity.

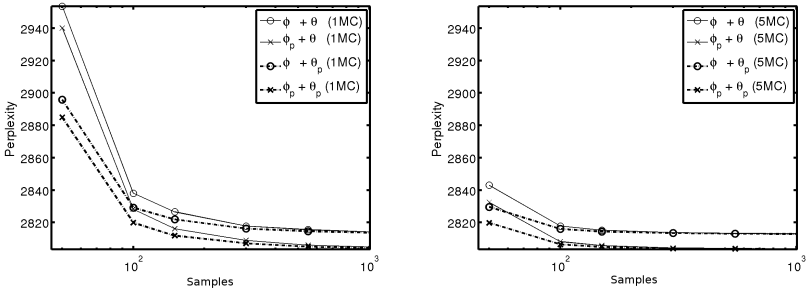
For this experiment we used all four data sets and considered four different topic number configurations (20, 50, 100, 500). For brevity, we report only the results for $K = 100$ and include the rest of the plots in Appendix D. During training, we ran one Markov chain for 200 iterations and took a single sample to calculate ϕ and ϕ^p from the same chain. During prediction, since ϕ is fixed and topics are not exchanged through the Gibbs sampler's iterations, we took multiple samples from multiple Markov chains, and averaged over these samples using the θ (standard CGS) and θ^p estimators. The burn-in period for the Gibbs sampler was set to 50 iterations and a sampling lag of 5 iterations was used. The $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ hyperparameters were symmetrical across all topics and words respectively and set such that $\alpha_k = 0.1$ and $\beta_v = 0.01$. Finally, to ensure fairness between the θ and θ^p estimators, we used the same samples from the same chains to compute the respective estimates.

In Figures 1 and 2 we show the perplexity scores against the number of samples that are averaged over, after burn-in, for one and five Markov chains respectively. All four



combinations of the estimators are depicted. By observing the results we notice some key points across all plots. First, if we consider the case where only one burned-in sample is used, corresponding to the left-most points in the plots, we can notice that both θ^p methods ($\phi + \theta^p$ and $\phi^p + \theta^p$) decisively outperform the other two methods. This observation is particularly important for scenarios where we can't afford to average over many samples due to computational or time limitations, as frequently occurs during the comparative evaluation of topic modeling methods, and in multi-label document classification.

We also see that the ϕ^p methods ($\phi^p + \theta$ and $\phi^p + \theta^p$) have a short but steady advantage over the respective ϕ estimators. This advantage is not diminished for more samples or Markov chains, suggesting that ϕ^p is actually a more accurate estimator than ϕ. We also remind here that in unsupervised scenarios we cannot average over samples to compute a ϕ estimate during training, since topics may be interchanged between iterations. A third remark, also aligned with our theoretical results, is that θ and θ^p converge to the same solution after a sufficient number of samples are averaged over, although θ^p converges much more rapidly. Overall, these findings confirm that indeed both θ^p and ϕ^p constitute improved estimators compared to the respective standard ones: θ^p provides more rapid convergence than using the standard estimator θ when averaging over samples for prediction on test documents, and ϕ^p improves perplexity due to implicit averaging. The rest of the plots in Appendix D are in accordance with the above observations.



5.4 Word Association: ϕ^p vs ϕ

In this experiment, we compare ϕ^p with ϕ on a word association task. In word association, a given word, called the *norm* or *cue* word, is associated with a number of semantically related words, called *targets* or *associates*. We consider the data set provided by Nelson et al. (2004), which contains a set of 5,019 norm words and for each of them a set of associate words provided by human annotators. We aim to see how, given a specific cue word, the two LDA estimators rank the corresponding associates, in order to assess which of the two performs better at predicting the targets, in terms of the median difference in ranks. The word association task provides a useful benchmark for evaluating the extent to which the topic representations are a good model of human semantic representation (Griffiths et al., 2007).

We largely follow the same setup as that described by Griffiths et al. (2007), pages 220-224. Specifically, we use the TASA data set, removing only stopwords and word types with fewer than five and more than ten thousand occurrences in the corpus, resulting in a vocabulary of 26,186 word types. There are 4,506 norms that belong to the obtained vocabulary. Subsequently, we train an LDA model on the corpus for $K = 50, 100, 500, 1000$ and for 250 iterations, obtaining a single point estimate for ϕ^p and ϕ for each value of K at the end of the procedure. Our goal is to see how each of the two estimators rank the five most commonly associated responses to each of the norm words, as given by human subjects. Similarly to Griffiths et al. (2007) (refer to p.220 and Appendix B, p.244), in order to assess semantic association we use the conditional probability $p(w_2|w_1)$ where w_1 stands for a given

(a) BioASQ

(b) New York Times

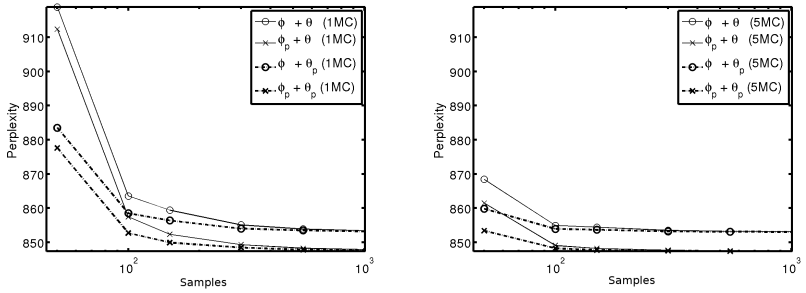


Figure 1: Perplexity against the number of samples averaged over, for the CGS_p estimators and standard CGS. Results are taken by averaging over 5 different runs. Samples are taken after a burn-in period of 50 iterations.

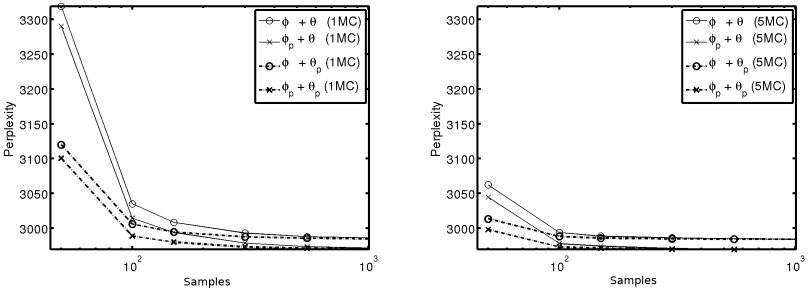
cue word and w_2 denotes each of the rest of the vocabulary word types. Supposing that w_1 and w_2 belong to the same topic z, and assuming a uniform prior on z, we have[5]



$$p(w_2|w_1) = \sum_z p(w_2|z)p(z|w_1) = \sum_z p(w_2|z)\frac{p(w_1|z)p(z)}{\sum_{z'} p(w_1|z')p(z')}$$
$$= \sum_z p(w_2|z)\frac{p(w_1|z)}{\sum_{z'} p(w_1|z')} \,. \tag{57}$$

Next, we consider the first five associate words of the norm w_1 and obtain the rank for each of them according to the probabilities $p(w_2|w_1)$, for each of ϕ^p and ϕ. In Figure 3, we

5. A uniform prior $p(z)$ follows if z is understood to be the first word in a document under the collapsed LDA urn model, with symmetric hyperparameters α. With asymmetric hyperparameters, $p(z = k) \propto \alpha_k$.

(b) TASA

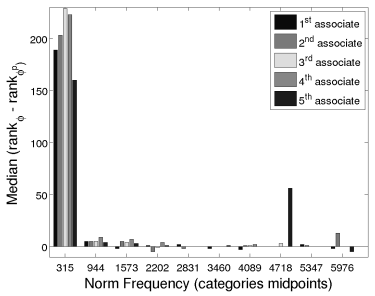

Figure 2: Perplexity against the number of samples averaged over, for the CGS_p methods and standard CGS. Results are taken by averaging over 5 different runs. Samples are taken after a burn-in period of 50 iterations.

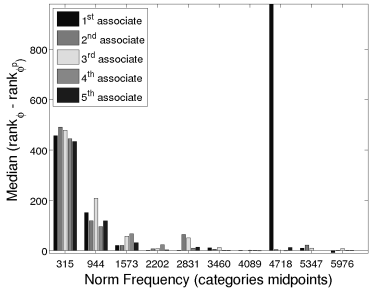
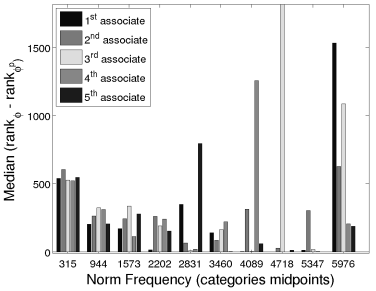
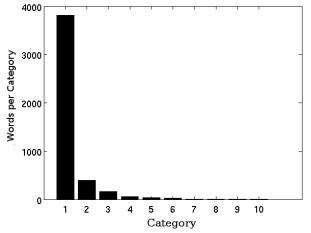
report the median difference in ranks, $rank_\phi - rank_{\phi^p}$ against word frequency, a positive value indicating an advantage for ϕ^p. To enhance readability, we have grouped the norms according to their frequencies within the corpus, into 10 categories.



We observe two steady trends. First, ϕ^p clearly outperforms ϕ for rare norms (the first category), which is also the most populous (3,814 norms). For more frequent norms, ϕ^p and ϕ behave almost on par. This trend reveals the distinctive benefit of our proposed estimator compared to its counterpart, especially if we take into account that word type frequencies typically follow a power law like distribution in document collections. A second trend, consistent with our other experiments, relates to the number of topics K: as K increases and the complexity of the LDA model correspondingly increases, the advantage of ϕ^p becomes wider compared to ϕ. We similarly observe that ϕ^p provides a benefit for increasingly frequent words as K increases.



(a) K = 50



(b) K = 100

(c) K = 500

(d) K = 1000

(e) Norms per category.

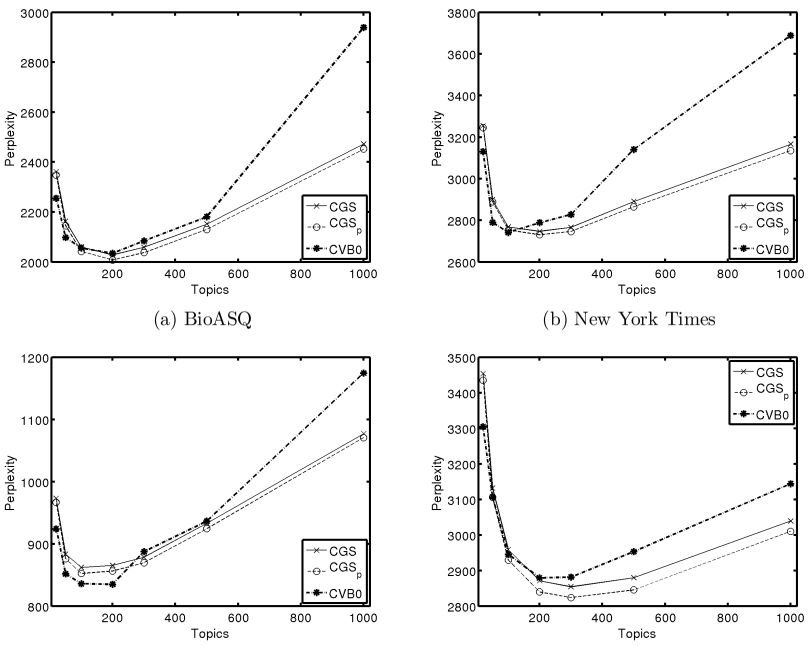
Figure 3: Median difference in ranks produced by ϕ^p and ϕ estimators for the first five associate words, for a set of 4,506 norms (Nelson et al., 2004). The estimators were computed after training LDA on the TASA corpus. A positive value indicates an advantage for ϕ^p.

These results are consistent with our analysis in Section 4 which showed that ϕ^p performs implicit averaging in order to improve the stability of the topics. The nuanced uncertainty

information, and corresponding stability, provided by ϕ^p is most important for less frequent words, and for larger K, for which the posterior uncertainty in the (smaller) count values n_{kv} per (word,topic) pair is most consequential. For larger (word, topic) counts n_{kv}, the expected counts estimated by ϕ^p (Equation 47) approach the observed counts computed by ϕ due to the law of large numbers. Consequently, we typically observe little difference in the top-words lists generated by ϕ^p and ϕ, which are often used to assess the interpretability of the topics. Instead, the results of this experiment suggest that ϕ^p conveys the most benefit for tasks that depend on the word/topic probabilities for the less frequent to moderately frequent words, as in word association, and any other task which requires semantic representations of the words.

5.5 Comparison between CGS, CGS$_p$ and CVB0

In this experiment we compared the CGS, CGS$_p$ and CVB0 algorithms in terms of perplexity, across different numbers of topics. The motivation here was to examine how the CGS$_p$ method would perform compared to the rest of the algorithms, in a variety of configurations and data sets.



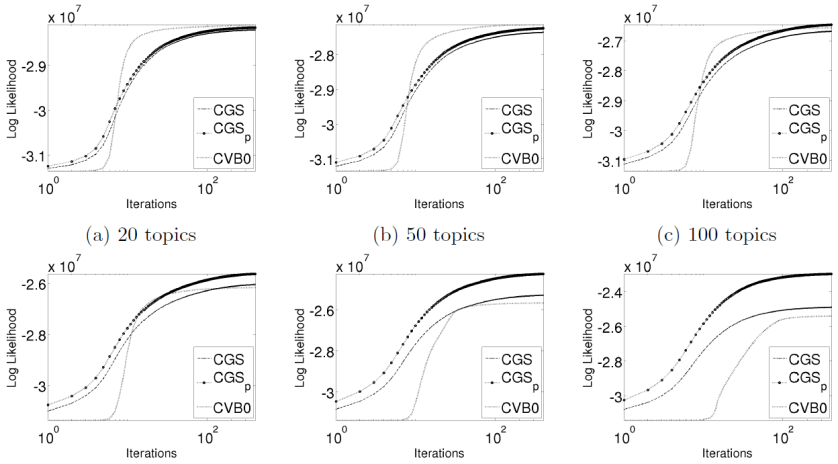
In Appendix E we report also the results of this experiment, comparing the three aforementioned algorithms with Variational Bayes (VB). Since the results for VB were steadily worse, we excluded them from Figure 4, to allow for easier comparison among CVB0, CGS and CGS$_p$. Asuncion et al. (2009) note that the disadvantage of VB versus the other algorithms can potentially be mitigated via hyperparameter learning.

For this experiment we followed a similar approach to the one described by Asuncion et al. (2009). During training we ran each chain for 200 iterations to obtain a single point estimate of the ϕ and ϕ^p distributions. During prediction, using the previously estimated ϕ, we ran 200 iterations from one chain for the first half of each document to obtain an estimate of θ. We followed the same approach to compute θ^p, using ϕ^p in that case.[6] We then computed perplexity on the second half of each document. The α_k and β_v hyperparameters were fixed across all data sets to uniform values, 0.1 and 0.01 respectively. CVB0 was run with the same parameterization.

Figure 4 shows the perplexity results for all data sets across different settings (20, 50, 100, 200, 300, 500 and 1000 topics) for all methods. Each topics configuration was run for five times, obtaining the average perplexity value. There is a strong interaction between the perplexity scores, the data sets, and the number of topics, probably due to the diverse statistics of the data sets, such as the average document length and the average number of features (i.e., word types) per document (see Table 3 in Section 5.1), that characterize the data sets. All algorithms achieve their lowest perplexity values at around 200 topics.

Despite the peculiarities of individual data sets, we can identify a broad general trend in these results. CVB0 outperforms (marginally in three out of four cases) the other methods in all data sets for lower topic number values: for the BioASQ and TASA data sets this happens up to 50 topics, for the New New York Times data set up to 100 topics, while for Reuters-21578 up to 200 topics. As the number of topics increases though, this behavior is reversed and CGS and CGS$_p$ have the upper hand after the aforementioned numbers of topics.

6. When referring to CGS$_p$, we mean that the $\phi^p + \theta^p$ estimators were used.



(a) BioASQ (b) New York Times

(c) Reuters-21578 (d) TASA

Figure 4: Perplexity against number of topics for the CGS$_p$ method, standard CGS and CVB0. Results are taken by averaging over 5 different runs.

A possible explanation for this observation is related to the deterministic nature of CVB0; compared to its stochastic counterpart CGS, CVB0 is more prone to getting stuck in local maxima. As the number of topics increases, we expect the hypothesis space to grow bigger, making it more difficult for CVB0 to find a global optimum. CGS on the other hand, can exploit its stochastic nature to escape local maxima and converge to a better global representation of the data. Therefore, CVB0 seems to be better suited for configurations with a small number of topics (in which case the fact that CVB0 converges a lot faster than CGS as shown by Asuncion et al. (2009) is an additional advantage), while CGS fits better in the opposite case. Similar to the previous section, when comparing CGS and CGS$_p$ we can observe a slight but steady advantage of our method over the standard estimator, across all experimental settings.

(a) 20 topics (b) 50 topics (c) 100 topics

(d) 200 topics (e) 500 topics (f) 1000 topics

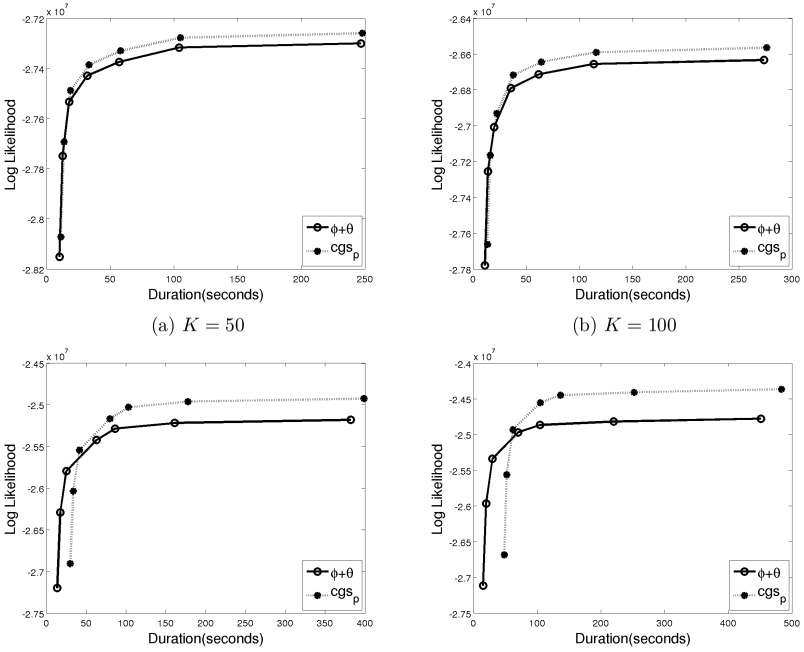
Figure 5: CGS, CGS_p and CVB0 convergence in terms of log likelihood during 400 training iterations in the TASA subset for different numbers of topics. α_k and β_v were fixed to 0.1 and 0.01 respectively.

5.6 Convergence During Estimation for CGS, CGS_p and CVB0

The perplexity results of the previous section motivated us to further investigate the convergence behavior of CGS, CGS_p and CVB0 algorithms. In particular, we wanted to know the conditions under which CGS (and our modification of it) outperformed CVB0 and vice versa. Furthermore, we wanted to see how these differences evolved as the two algorithms converged upon their respective solutions.

Figure 5 presents a comparison of CVB0, CGS and CGS_p (during the estimation phase) on the TASA data set in terms of their log likelihoods over iterations, under different numbers of topics. To calculate the log likelihood for CGS_p we used the ϕ^p and θ^p estimators. For each algorithm and each topics configuration, we performed five runs and obtained the mean log-likelihood values.

The results seem to validate our previous observations with CVB0 converging faster and to a higher log likelihood than CGS and CGS_p when $|K| \leq 100$. As the number of topics grows and the number of training iterations increases, though, the performance of CGS and CGS_p catches up, and after 100 topics, they outperform CVB0. This is consistent with our hypothesis that CVB0 performance is worse than that of CGS and CGS_p as the hypothesis space grows, due to it being a deterministic algorithm and getting stuck in local maxima. These results seem to be consistent with the observations made by Teh et al. (2006, Section 4) and could eventually emerge from either (or both) of the following factors:



Method	Data sets			
	BioASQ	New York Times	Reuters-21578	TASA
		MALLET		
$\phi + \theta$	-1.921	-6.770	-0.590	-2.572
$\phi^p + \theta$	-1.912	-6.763	-0.585	-2.567
$\phi + \theta^p$	-1.911	-6.762	-0.584	-2.562
$\phi^p + \theta^p$	-1.903	-6.751	-0.580	-2.560
		WarpLDA		
$\phi + \theta$	-3.22	-7.092	-1.014	-2.730
$\phi^p + \theta$	-3.207	-7.081	-0.997	-2.724
$\phi + \theta^p$	-3.208	-7.079	-0.992	-2.718
$\phi^p + \theta^p$	-3.203	-7.074	-0.990	-2.716

Table 4: CGS_p vs standard CGS estimator on MALLET and WarpLDA in terms of the Log Likelihood. All values are $\times 10^7$ and represent mean values across five runs.

- Variational inference methods (VB, CVB and CVB0) approximate the true posterior with a more tractable variational distribution (Blei et al., 2003; Teh et al., 2006; Asuncion et al., 2009). Furthermore, in the case of CVB0, as illustrated by (Foulds, 2014, Section 4.4.1), the algorithm is a result of three consecutive approximations of the initial problem. On the other hand, CGS performs exact collapsed Gibbs updates and will eventually sample from the true posterior.

- CVB0 seems to be unable to avoid local maxima due to its deterministic nature, especially as the hypothesis space grows bigger, while CGS takes advantage of its stochastic nature in order to avoid them.

A secondary observation is that CGS_p increases its advantage over CGS as the number of topics grows. A final noteworthy observation from Figure 5 is that CVB0 exhibits very slow convergence behavior in the first 5 – 10 iterations, before reaching a regime of rapid convergence. While this phenomenon was not immediately visible in the results reported by Asuncion et al. (2009) (Figure 2), this apparent discrepancy is readily explained: in those results a linear scale was used on the X-axis, with data points plotted only every 20 iterations. This slow convergence behavior is in alignment with the well-known convergence speed issues for the closely related EM algorithm, which can also be understood as a variational method. For EM, Salakhutdinov et al. (2003) showed that convergence is very slow when the missing data distributions are highly uncertain. This is likely to be the case in the initial stages of CVB0 and CGS, where the count histograms are relatively flat. We hypothesize that the hard assignments of CGS allow the algorithm to escape the slow-converging high-entropy regime more rapidly than CVB0, leading to better convergence behavior in the early iterations, before the determinism of CVB0 once again gives it the upper hand (at least, with a small number of topics).

(a) $K = 50$ (b) $K = 100$

(c) $K = 500$ (d) $K = 1000$

Figure 6: Log Likelihood vs duration for CGS_p against the standard CGS estimators on TASA, with WarpLDA. The time duration for each point in the plot corresponds to the running time of WarpLDA for different numbers of iterations (50, 100, 200, 500, 1000, 2000, 5000), plus the overhead needed to compute each of the estimators at that timestep.

5.7 CGS_p with MALLET and WarpLDA

In order to exhibit how straightforward it is to plug our methods into already existing CGS LDA implementations and, most importantly, in modern CGS variants, we have employed CGS_p on top of the MALLET software package (McCallum, 2002b) and the WarpLDA (Chen et al., 2016) implementation. In all cases, we have used $K = 100$, $\alpha = 0.1$, $\beta = 0.01$. After running the respective implementations on the four datasets for 200 iterations, we have obtained a single sample for the z-assignments. Subsequently, and after calculating the n_{kw} and n_{dk} counters, we have computed the standard estimator and our proposed estimators. Table 4 depicts the results in terms of the training data log-likelihood, showing a steady advantage of our methods compared to the standard estimator.

5.8 Run-time Overhead: CGS_p vs CGS

In the previous experiments, we have observed that our proposed estimators steadily outperformed the standard CGS estimators. Nevertheless, our methods entail a computational time overhead since they require computing the full CGS probability distributions, which is roughly equivalent to a single dense standard CGS update. This overhead is most noticeable when modern sparse CGS implementations are used with a large number of topics K, since these methods can be executed in time sublinear in K, unlike the dense CGS update. In this section, we study the trade-off between the improved performance and the extra cost of our methods, as compared with the standard estimators. In particular, we are interested in examining the performance of our methods when paired with the fastest known CGS implementation, WarpLDA.

In most applications of topic models, especially when dealing with large-scale data, LDA inference is run on a given corpus for a number of iterations and a single point estimate of the ϕ and θ parameters is calculated at the end of the procedure, so we focus on that scenario for our experiment. When considering performance versus running time, based on our previous experiments we expect CGS_p to attain higher log likelihood values, but with the extra overhead of the estimators calculation, while the standard CGS estimators will need more iterations to converge to those same log likelihood values, without the overhead. Therefore, we are interested to see if, and at which point during the process of training an LDA model, employing the CGS_p estimators will be more beneficial time-wise than using the standard estimators.

In this experiment, reported in Figure 6, we run WarpLDA on the TASA data set for $K = 50, 100, 500, 1000$ and plot the training data log likelihood of CGS and CGS_p against time duration. In Appendix F we report the relevant results for the rest of the data sets. The time duration for each point in the plot corresponds to the running time of WarpLDA for different numbers of iterations (50, 100, 200, 500, 1000, 2000, 5000), plus the overhead needed to compute each of the estimators at that timestep. We observe that in the early iterations, while LDA is still converging, the standard estimators attain a higher log likelihood value faster than the CGS_p ones for $K = 500, 1000$ (the two estimators are almost identical during burn-in for $K = 50, 100$). This tendency is reversed after convergence of the procedure, with CGS_p attaining a higher log likelihood value faster than CGS for all topic configurations. In most cases we are interested in obtaining an estimate of the LDA parameters well after convergence, so we consider that the CGS_p estimators are to be preferred over the standard CGS ones, even under limited time resources. We also see that convergence takes longer with more topics, and the time before CGS_p overtakes CGS is correspondingly longer, but the improvement in log-likelihood for CGS_p over CGS becomes greater.

6. Multi-Label Learning Experiments—Prior-LDA

Another important context for comparing different approaches to LDA prediction is in a multi-label, supervised setting. Here, we considered a multi-label learning extension of LDA—Prior-LDA—and used it as a basis for comparisons of model predictions. Following the same organization as the previous section, we present the data sets, the evaluation measures, the experimental setup, and lastly the results with a discussion of their implications.

	Documents			Labels

Table 5: Statistics for the data sets used in the supervised learning experiments. Column "Avg. Freq." refers to the average label frequency. All figures concerning labels and word types are given for the respective training sets.

6.1 Data Sets

In this series of experiments we kept the BioASQ data set and used three additional labeled ones: Delicious, Bibtex and Bookmarks. Table 5 presents their main statistics. These data sets were chosen as representative of the diversity of real-world data, where there are often many labels, and sometimes not many word tokens per training instance.

Delicious, Bibtex and Bookmarks[7], are three widely used multi-label data sets (Katakis et al., 2008; Tsoumakas et al., 2008). We did not perform any further preprocessing of these data sets. A notable aspect of Delicious is that it contains very few word tokens per instance both in the training and test sets, making accurate classification difficult. Concerning the BioASQ data set, we used the same corpus as for the unsupervised learning experiments and the same preprocessing procedure. We did not use the entire labelset of the original data set, filtering out labels appearing in less than 40 instances.

6.2 Evaluation Metrics

We considered three widely-used performance measures: the micro-averaged F1 measure (Micro-F for brevity) and the macro-averaged F1 measure (Macro-F for brevity) and the example-based F1 measure (Tsoumakas et al., 2010). These measures are a weighted function of precision and recall, and emphasize the need for a model to perform well in terms of both of these underlying measures. The Macro-F score is the average of the F1-scores that are achieved across all labels, while the example-based F1 score is the respective average of the F1 score across all test documents. The Micro-F score is the average F1 score weighted by each label's frequency. Macro-F tends to emphasize performance on infrequent labels, while Micro-F tends to emphasize performance on frequent labels.

6.3 Setup of Prior-LDA (CGS and CVB0)

The Prior-LDA model takes into account the relative label frequencies in the corpus. Test documents are biased to assign words to more frequent labels by using a non-symmetric

7. http://mulan.sourceforge.net/datasets-mlc.html

vector α_k on the θ distributions. During training we kept the α_k parameter symmetrical and set it to:

$$\alpha_k = \frac{50}{K} \tag{58}$$

while during prediction we incorporated the label frequencies by setting it to:

$$\alpha_k = 50 \cdot \frac{f_k}{\sum f_k} + \frac{30}{K} \tag{59}$$

with f_k standing for the frequency of label k. The β_v parameter was set to 0.1 across all data sets. For all data sets, we calculated performance under two different configurations:

- First, we wanted to emulate a scenario where only one sample can be afforded both for training and testing. In this case, during training we ran only one Markov chain and took a single estimate from the same chain for both ϕ and ϕ^p. Similarly, during testing, we ran one chain with the estimated ϕ and one with the estimated ϕ^p to obtain a single estimate for θ and θ^p from each chain. In this manner, we obtained the predictions for all combinations of ϕ and θ estimators.

- In the second configuration, we used 5 Markov chains and 30 samples from each chain, both during training and testing, following the same approach as above to obtain predictions from all four combinations of the ϕ and θ estimators. In this case, the motivation was to examine performance with full convergence of the relevant estimators.

In both training and prediction, we used a burn-in period of 50 iterations and a lag of 5 iterations between each sample. All samples from all chains were averaged to obtain the respective parameter estimates for each method.

For CVB0 we used the same setup as the one described above. However, as CVB0 is a deterministic algorithm that does not benefit greatly from averaging samples, in the second configuration each chain was initialized with a different random order of the documents and a different random initialization of the γ parameters.

Finally, in order to obtain a hard assignment of labels to documents from the θ distributions, we used the Meta-Labeler approach (Tang et al., 2009). In particular, we used a linear regression model to predict the number of labels per instance. To train this model, the same feature space as for the LLDA models was employed and the LibLinear package (Fan et al., 2008) was used for the implementation.

6.4 Results and Discussion

Tables 6 – 8 show the Micro-F, the Macro-F and the example-based F1 results respectively for all algorithms on the four data sets. We additionally show the average rank of each model, in terms of how it performs among the models on average across the four data sets. All results represent averages over five runs of the respective Gibbs sampler (or CVB0 algorithm). Also, to test statistical significance of the differences, we performed a one sample z-test for proportions at a significance level of 0.05.

Table 6: Results for the Micro-F1 measure comparing the Prior-LDA models. A △ symbol represents statistically significant difference compared to the best performing model, at a level of 0.05.

First, let us consider the results for when only a single sample was used. A first remark is that CGS_p and $\phi + \theta^p$ are significantly better than CGS and $\phi^p + \theta$ over all data sets and evaluation measures, confirming θ^p's superiority over θ. Secondly, CVB0 has a clear advantage over the rest of the methods, in the majority of the data sets and evaluation measures. Only CGS_p and $\phi + \theta^p$ manage to outperform it in three out of twelve cases (four data sets and three evaluation measures).

At first glance, these results suggest that, when only one sample from one Markov chain can be afforded, CVB0 should be perhaps considered first, followed by CGS_p and $\phi + \theta^p$ as alternatives. In order to more carefully evaluate the two algorithms for scenarios where computational time is a critical parameter, in Appendix G we performed a short investigation in order to study if and when CGS_p performance surpasses that of CVB0. Specifically, we plotted performance (Micro-F, Macro-F, example-based F1) against the number of samples taken, for all four data sets. The results show that CGS_p manages to outperform CVB0 in seven out of twelve cases, by taking only two samples from one Markov chain, while, after taking ten samples from one chain, CGS_p outperforms CVB0 in eleven out of twelve cases. Considering that there exist a number of approaches for CGS that exploit sparsity to speed up LDA estimation and prediction (Porteous et al., 2008; Yao et al., 2009; Li et al., 2014), while this is not the case for CVB0, we could claim that in many cases CGS_p is equally fit or even superior to CVB0, in terms of total computational time.[8]

Let us now focus on the scenario where we have averaged over multiple samples and multiple Markov chains to calculate predictions. In this case, model performance shifts in favor of the CGS-based predictions. Whereas the CGS algorithm benefits from averaging samples—due to the fact that each sample is ideally a draw from the posterior distribution—

8. Note that the stochastic variant SCVB0 (Foulds et al., 2013) is much more scalable than CGS in the amount of data, but less scalable in the number of topics due to dense updates.

Table 7: Results for the Macro-F measure. A △ symbol represents statistically significant difference compared to the best performing model, at a level of 0.05.

CVB0 is deterministic, and achieves very small improvements (if any), presumably since it tends to converge to the same specific maximum. When five chains are used, CGS_p and $\phi + \theta^p$ are significantly better than CVB0 in all data sets and for all evaluation measures. CGS and $\phi^p + \theta$ on the other hand, seem to achieve equivalent performance to CVB0 overall.

Among the CGS-based methods, we observe that, even if θ and θ^p should theoretically converge to the same solution (at least in an unsupervised learning context) even after a total of 150 samples (30 samples from five chains) their difference is significantly large for all evaluation measures and all data sets (the BioASQ data set represents partly an exception with smaller differences between the four methods). Another important note concerns the comparison between models predicting with ϕ^p and those predicting with ϕ. Results are mixed in this case, with models predicting with ϕ^p having a slight, but not statistically significant advantage.

Overall, the supervised experiments show a consistent advantage of the CGS_p and $\phi + \theta^p$ estimators over the respective standard CGS estimator. Also, CGS_p and $\phi + \theta^p$ are competitive with CVB0 in scenarios where only one sample can be afforded. Finally, when averaging over many samples and Markov chains, CGS_p and $\phi + \theta^p$ distinctly outperform CVB0.

7. Conclusions

In this work we proposed a novel method for accurately estimating the document-wise and topic-wise LDA parameters from collapsed Gibbs samples by implicitly averaging over many samples, leading to improved estimation with little extra computational cost. Our algorithm can be interpreted as using soft clustering information, as in the CVB0 collapsed variational inference algorithm, but in a Markov chain Monte Carlo setting. This allows us to use all of

the uncertainty information encoded in the dense Gibbs sampling transition probabilities to recover the parameters from a CGS sample, while still leveraging the sparsity inherent in the CGS algorithm during the training process. We extensively investigated the performance of the proposed estimators for both unsupervised and supervised topic models, and with comparison to CVB0. Our results demonstrate that our θ^p and ϕ^p estimators are more effective than the standard estimator in terms of perplexity, and that θ^p also improves multi-label classification performance for the supervised Prior-LDA model.

Our experiments showed an advantage of our CGS-based estimators over CVB0 in the majority of cases, and also revealed the consequences of the deterministic nature of that algorithm. In the unsupervised scenario, CVB0 has a clear advantage for LDA models with few topics, while this phenomenon is reversed as the posterior landscape becomes more complicated with a greater number of topics. In the multi-label learning case, CVB0 has the upper hand when only one sample can be afforded, while it is decisively outperformed by CGS_p when averaging over multiple samples. The success of our methods illustrates the value of averaging over multiple MCMC samples for LDA, even when only a point estimate is required. In future work, we anticipate that our ideas can be adapted to other models with collapsed representations, including latent variable blockmodels for social networks and other network data (Kemp et al., 2006), and hidden Markov models (Goldwater and Griffiths, 2007).

constructive comments that greatly helped in improving and extending this work. Yannis Papanikolaou and Grigorios Tsoumakas have been partially funded by Atypon Systems Inc., Santa Clara, California, USA.

Appendix A. Hard Counts vs Soft Counts

Algorithmically (refer to Algorithm 1), the difference between the θ and θ^p estimators lies in the difference between the hard counts n_{dk} and the soft counts given by $\sum_{j=1}^{N_d} p(d, j, k)$, p being the sampling update equation of CGS given in equation 1. In this experiment, we examine how similar are the two counts. For this reason, we have run CGS on the four data sets setting $K = 100$, $\alpha = 0.1$, $\beta = 0.01$ for 50 iterations and calculated the sum of the absolute differences between the two counts, or, in other words:

$$\frac{\sum_{d=1}^{D} \sum_{k=1}^{K} |n_{dk} - \sum_{j=1}^{N_d} p(d, j, k)|}{D} \tag{60}$$

(a) *iteration* = 50 (b) *iteration* = 100

(c) *iteration* = 500 (d) *iteration* = 1000

Figure 8: Absolute difference between the hard and the soft counts across the K different topics, for iteration 50, 100 and 1000, for the first document of the TASA collection.

Figure 7 shows the absolute sum of differences across the number of iterations. We can observe a steady difference among the two counts, that diminishes but does not go away with the number of iterations. Furthermore, in Figure 8 we depict for the TASA data set and the first document of the collection, the absolute difference between the hard and the soft counts across the K different topics, for iteration 50, 100 and 1000. Similarly to our previous observations, we see that the two counts are similar, but present a small but steady difference across topics, for all iterations.

Appendix B. Bounding the Approximation for ϕ_p

We wish to bound the error of the approximation step used in the derivation for the ϕ_p technique, given in Equation 47:

$$E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]$$
$$\approx E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] .$$

Assume that all $n_k^{(i)} > 0$. Then, starting from the left hand side of the above, we have:

$$\begin{aligned}
&E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]\\
=&E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\times\frac{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]\\
=&\sum_{\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)})}\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\times\frac{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\\
&\qquad\times p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))\\
\geq&\sum_{\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)})}\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\times\frac{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+1+\sum_{v'=1}^{V}\beta_{v'}}\\
&\qquad\times p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))\\
=&\frac{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+1+\sum_{v'=1}^{V}\beta_{v'}}E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]\\
=&\frac{n_k^{(i)}+\sum_{v'=1}^{V}\beta_{v'}}{n_k^{(i)}+\sum_{v'=1}^{V}\beta_{v'}+1}E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] .
\end{aligned} \tag{61}$$

Similarly, for a lower bound, we have:

$$\begin{aligned}
&E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]\\
\leq&\sum_{\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)})}\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\times\frac{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}-1+\sum_{v'=1}^{V}\beta_{v'}}\\
&\qquad\times p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))\\
=&\frac{n_k^{(i)}+\sum_{v'=1}^{V}\beta_{v'}}{n_k^{(i)}+\sum_{v'=1}^{V}\beta_{v'}-1}E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big] .
\end{aligned} \tag{62}$$

Appendix C. Empirical validation of the approximation for ϕ^p

When deriving our ϕ^p estimator, in order to prove that ϕ^p represents the expected value of the standard CGS ϕ estimator, we take the following approximation: we consider that the denominator of Equation 45 is not changing, between two adjacent Gibbs samples. Since z_{djk} is within ± 1 of $z^{(i)}_{djk}$ when taking adjacent Gibbs samples and in a typical corpus $n_k >> 1$, we can assume that $n_k \simeq n_k \pm 1$. Using this approximation, we are able to consider that the denominator in the left hand of Equation 47 is a constant when taking an adjacent sample. Hence, the expected value of the fraction will be the expected value of the numerator, divided by the denominator.

In order to empirically validate this argument, we considered the following experiment: We have run CGS on the New York Times data set for 100 iterations and for $K = 100$. Next we computed explicitly, the left and the right sides of Equation 47 for all topics and word types. Subsequently, we have measured the accuracy of the approximation of Equation 47 for a varying size of documents (and therefore n_k), by plotting the absolute difference |left hand side - right hand side| for each topic, as a function of the size of D, or $\frac{|a-b|}{K}$ where

$$a = E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}\Big[\frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} z_{djk}+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z_{djk}+\sum_{v'=1}^{V}\beta_{v'}}\Big]$$

$$b = \frac{\sum_{d=1}^{D_{Train}}\sum_{j:w_{d,j}=v} E_{p(\mathbf{z}|\mathbf{w},\boldsymbol{\beta},\mathbf{z}\in Z_{Gibbs}(\mathbf{z}^{(i)}))}[z_{djk}]+\beta_v}{\sum_{d=1}^{D_{Train}}\sum_{j=1}^{N_d} z^{(i)}_{djk}+\sum_{v'=1}^{V}\beta_{v'}} \quad (63)$$

Figure 9 plots the results from the above experiment. As expected, by increasing the considered subset of documents and therefore n_k, the error of the approximation for each topic approaches zero.

Appendix D.

Figures 10 – 13 present additional results for the experiment of Section 5.3, using different topic configurations ($K = 20$, 50, 500) for each of the four data sets (BioASQ, New York Times, Reuters-21578, TASA) respectively. These results are aligned with the conclusions made in Section 5.3 and are reported here as further empirical validation of the theory behind CGS$_p$.

Appendix E.

In this section we report in Figure 14, additionally to the results of Section 5.5, the perplexity across different topic configurations for VB against CVB0, CGS and CGS$_p$. We employed the lda-c package, publicly available at `https://github.com/blei-lab/lda-c`, keeping all parameters to default for the Variational EM procedure.

Apart from the New York Times data set, where VB manages to outperform CVB0 for $K > 200$ and the CGS algorithms for $K = 200$, the algorithm performs worse than other methods in all other cases. These results seem to be aligned with previous results in the literature (Teh et al., 2006; Asuncion et al., 2009).

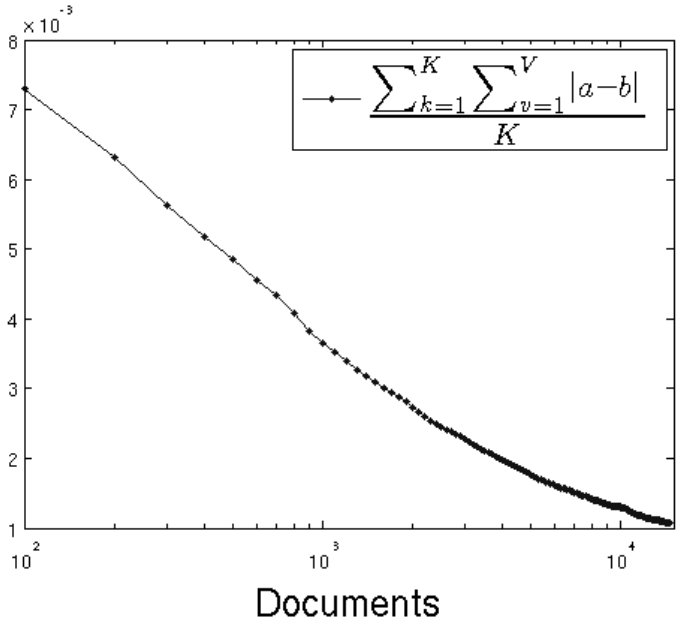

Figure 9: Absolute difference, per topic, between the left and right hand of Equation 47. As the number of documents increases, the difference approaches 0. Here, a, b are given in Equation 63 and the sum is divided by K in order to obtain the per-topic differences.

Appendix F.

We report in Figures 15 - 17 additional results for the rest of the data sets, for our experiment of section 5.8, regarding the run-time overhead of the CGS$_p$ estimators. The results validate the conclusions drawn in section 5.8.

Appendix G.

We report the results of an additional experiment that we performed in order to investigate how many samples CGS$_p$, $\phi + \theta^p$ and $\phi^p + \theta$ would require to outperform CVB0 (Figures 18 – 21). The same parameter setup was used as in the rest of the multi-label experiments of Section 6.

Abstract

We consider the problem of low canonical polyadic (CP) rank tensor completion. A completion is a tensor whose entries agree with the observed entries and its rank matches the given CP rank. We analyze the manifold structure corresponding to the tensors with the given rank and define a set of polynomials based on the sampling pattern and CP decomposition. Then, we show that finite completability of the sampled tensor is equivalent to having a certain number of algebraically independent polynomials among the defined polynomials. Our proposed approach results in characterizing the maximum number of algebraically independent polynomials in terms of a simple geometric structure of the sampling pattern, and therefore we obtain the deterministic necessary and sufficient condition on the sampling pattern for finite completability of the sampled tensor. Moreover, assuming that the entries of the tensor are sampled independently with probability p and using the mentioned deterministic analysis, we propose a combinatorial method to derive a lower bound on the sampling probability p, or equivalently, the number of sampled entries that guarantees finite completability with high probability. We also show that the existing result for the matrix completion problem can be used to obtain a loose lower bound on the sampling probability p. In addition, we obtain deterministic and probabilistic conditions for unique completability. It is seen that the number of samples required for finite or unique completability obtained by the proposed analysis on the CP manifold is orders-of-magnitude lower than that is obtained by the existing analysis on the Grassmannian manifold.

Keywords: Low-rank tensor completion, canonical polyadic (CP) decomposition, finite completability, unique completability, algebraic geometry, Bernstein's theorem.

1. Introduction

The fast progress in data science and technology has given rise to the extensive applications of multi-way datasets, which allow us to take advantage of the inherent correlations across different attributes. The classical matrix analysis limits its efficiency in exploiting the correlations across different features from a multi-way perspective. In contrast, analysis of multi-way data (tensor), which was originally proposed in the field of psychometrics and recently found applications in machine learning and signal processing, is capable of taking full advantage of these correlations (De Lathauwer, 2009; Kolda and Bader, 2009; Abraham et al., 2012; Grasedyck et al., 2013; Muti and Bourennane, 2007; Signoretto et al., 2011). The problem of low-rank tensor completion, i.e., reconstructing a tensor from a subset of its entries given the rank, which is generally NP hard (Hillar and Lim, 2013), arises in compressed sensing (Lim and Comon, 2010; Sidiropoulos and Kyrillidis, 2012; Gandy et al., 2011), visual data reconstruction (Liu et al., 2013, 2016), seismic data processing (Kreimer et al., 2013; Ely et al., 2013), etc. Existing approaches to low-rank data completion mainly focus on convex relaxation of matrix rank (Candès and Recht, 2009; Candès and Tao, 2010; Cai et al., 2010; Ashraphijuo et al., 2016b; Candès et al., 2013; Ashraphijuo et al., 2015) or different convex relaxations of tensor ranks (Gandy et al., 2011; Tomioka et al., 2010; Signoretto et al., 2014; Romera-Paredes and Pontil, 2013). In addition, there are some other works which provide a completion of the given rank using alternating minimization, e.g., for low-CP-rank tensor (Jain and Oh, 2014) and low-TT-rank tensor (Wang et al., 2016).

Tensors consisting of real-world datasets usually have a low rank structure. The manifold of low-rank tensors has recently been investigated in several works (Grasedyck et al., 2013; Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017). In this paper, we focus on the canonical polyadic (CP) decomposition (Harshman, 1970; ten Berge and Sidiropoulos, 2002; Carroll and Chang, 1970; Stegeman and Sidiropoulos, 2007) and the corresponding CP rank, but in general there are other well-known tensor decompositions including Tucker decomposition (Kolda, 2001; Grasedyck, 2010; Kressner et al., 2014), tensor-train (TT) decomposition (Oseledets, 2011; Holtz et al., 2012), tubal rank decomposition (Kilmer et al., 2013) and several other methods (De Lathauwer et al., 2000; Papalexakis et al., 2012). Note that most existing literature on tensor completion based on various optimization formulations use CP rank (Gandy et al., 2011; Krishnamurthy and Singh, 2013).

Deterministic conditions on the locations of the sampled entries (sampling pattern) are obtained through algebraic geometry analyses on Grassmannian manifold that lead to finite/unique solutions to the matrix completion problem (Pimentel-Alarcón et al., 2016d). Also, deterministic conditions on the sampling patterns have been studied for subspace clustering in (Pimentel-Alarcón et al., 2016c, 2015, 2016a,b). In this paper, we study the fundamental conditions on the sampling pattern to ensure finite or unique number of completions, where these fundamental conditions are independent of the correlations of the entries of the tensor, in contrast to the common assumption adopted in literature such as incoherence. Given the rank of a matrix, Pimentel-Alarcón *et. al.* in (Pimentel-Alarcón et al., 2016d) obtains such fundamental conditions on the sampling pattern for finite completability of the matrix. Previously, we treated the same problem for multi-view matrix (Ashraphijuo et al., 2017c,b), tensor given its Tucker rank (Ashraphijuo et al., 2016a, 2017a), and tensor given its TT rank(Ashraphijuo and Wang, 2017). In this paper, the structure of the CP decomposition and the geometry of the corresponding manifold are investigated to obtain the fundamental conditions for finite completability given its CP rank. These recently developed algebraic geometry analyses can also be used to approximate the rank of partially sampled data (Ashraphijuo et al., 2017d).

To emphasize the contribution of this work, we highlight the differences and challenges in comparison with the Tucker and TT tensor models. In CP decomposition, the notion of tensor multiplication is different from those for Tucker and TT, and therefore the geometry of the manifold and the algebraic variety are completely different. Moreover, in CP decomposition we are dealing with the sum of several tensor products, which is not the case in Tucker and TT decompositions, and therefore the equivalence classes or geometric patterns that are needed to study the algebraic variety are different. Moreover, CP rank is a scalar and the ranks of matricizations and unfoldings are not given in contrast with the Tucker and TT models.

Let $\mathcal{U}$ denote the sampled tensor and Ω denote the binary sampling pattern tensor that is of the same dimension and size as $\mathcal{U}$. The entries of Ω that correspond to the observed entries of $\mathcal{U}$ are equal to 1 and the rest of the entries are set as 0. Assume that the entries of $\mathcal{U}$ are sampled

independently with probability p. This paper is mainly concerned with treating the following three problems.

Problem (i): Given the CP rank, characterize the necessary and sufficient conditions on the sampling pattern Ω, under which there exist only finitely many completions of $\mathcal{U}$.

We consider the CP decomposition of the sampled tensor, where all rank-1 tensors in this decomposition are unknown and we only have some entries of $\mathcal{U}$. Then, each sampled entry results in a polynomial such that the variables of the polynomial are the entries of the rank-1 tensors in the CP decomposition. We propose a novel analysis on the CP manifold to obtain the maximum number of algebraically independent polynomials, among all polynomials corresponding to the sampled entries, in terms of the geometric structure of the sampling pattern Ω. We show that if the maximum number of algebraically independent polynomials is a given number, then the sampled tensor $\mathcal{U}$ is finitely completable. Due to the fundamental differences between the CP decomposition and the Tucker or TT decomposition, this analysis is completely different from our previous works (Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017). Moreover, note that our proposed algebraic geometry analysis on the CP manifold is not a simple generalization of the existing analysis on the Grassmannian manifold (Pimentel-Alarcón et al., 2016d) even though the CP decomposition is a generalization of rank factorization of a matrix, as almost every step needs to be developed anew.

Problem (ii): Characterize conditions on the sampling pattern to ensure that there is exactly one completion for the given CP rank.

Similar to Problem (i), our approach is to study the algebraic independence of the polynomials corresponding to the samples. We exploit the properties of a set of minimally algebraically dependent polynomials to add additional constraints on the sampling pattern such that each of the rank-1 tensors in the CP decomposition can be determined uniquely.

As we will observe later, the deterministic conditions for finite or unique completability are combinatorial in nature, which are hard to verify if they hold true in practice. Therefore, we also provide a probabilistic analysis to verify the validity of such conditions based on the number of samples or the sampling probability. However, we cannot guarantee the validity of the constraints with probability one anymore (i.e., not deterministically anymore) and instead we show that the combinatorial conditions hold true with high probability if the sampling probability is above certain threshold.

Problem (iii): Provide a lower bound on the total number of sampled entries or the sampling probability p such that the proposed conditions on the sampling pattern Ω for finite and unique completability are satisfied with high probability.

We develop several combinatorial tools together with our previous graph theory results in (Ashraphijuo et al., 2016a) to obtain lower bounds on the total number of sampled entries, i.e., lower bounds on the sampling probability p, such that the deterministic conditions for Problems (i) and (ii) are met with high probability. Particularly, it is shown in (Krishnamurthy and Singh, 2013), $\mathcal{O}(nr^{\frac{d-1}{2}}d^2\log(r))$ samples are required to recover the tensor $\mathcal{U} \in \mathbb{R}^{\overbrace{n \times \ldots \times n}^{d}}$ of rank r. Recall that in this paper, we obtain the number samples to ensure finite/unique completability that is independent of the completion algorithm. As we show later, using the existing analysis on the Grassmannian manifold results in $\mathcal{O}(n^{\frac{d+1}{2}}\max\{d\log(n)+\log(r), r\})$ samples to ensure finite/unique completability. However, our proposed analysis on the CP manifold results in $\mathcal{O}(n^2\max\{\log(nrd), r\})$ samples to guarantee the finiteness of the number of completions, which is significantly lower than that given in (Krishnamurthy and Singh, 2013). Hence, the fundamental conditions for tensor completion motivate new optimization formulation to close the gap in the number of required samples.

Tucker decomposition consists of a core tensor multiplied by a matrix along each dimension. TT decomposition of a d-way tensor consists of the train-wise multiplication of a matrix and $d-2$ three-way tensors and finally another matrix. Tucker and TT ranks are defined as the vectors consisting of rank of matricizations and rank of unfoldings, respectively. The structure of the manifold of the tensors with a fixed Tucker (or TT) rank vector is fundamentally different with that of the CP manifold.

Note that the general framework of using rank factorization to study the algebraic independence of the polynomials through counting the number of involved variables in the polynomials is indeed similar to that in (Pimentel-Alarcón et al., 2016d; Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017) to some extent. However, since the manifold considered in this paper (CP manifold) is fundamentally different from the Grassmannian or Tucker or TT manifold, all results in this paper are original. In particular, we mention some of the main differences: (i) geometry of the manifold, (ii) the equivalence class for the basis and consequently (iii) the canonical basis, (iv) the structure of the polynomials, etc., are fundamentally different from those in the literature. Hence, the deterministic analyses are fundamentally different (excluding Lemma 7). As a consequence, the probabilistic analysis is also basically different as the combinatorial condition (6) is obtained based on the defined geometry and equivalence class for CP decomposition. However, some lemmas including the generalization of Hall's theorem for bipartite graphs (Lemma 18) or Lemma 17 that applies pigeonhole principle are taken from our previous papers (Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017) in probabilistic analysis.

The remainder of this paper is organized as follows. In Section 2, the preliminaries and problem statement are presented. In Section 3, we develop necessary and sufficient deterministic conditions for finite completability. In Section 4, we develop probabilistic conditions for finite completability. In Section 5, we consider unique completability and obtain both deterministic and probabilistic conditions. Some numerical results are provided in Section 6. Finally, Section 7 concludes the paper.

2. Background

2.1 Preliminaries and Notations

In this paper, it is assumed that a d-way tensor $\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is sampled. Throughout this paper, we use CP rank as the rank of a tensor, which is defined as the minimum number r such that there exist $\mathbf{a}_i^l \in \mathbb{R}^{n_i}$ for $1 \leq i \leq d$ and $1 \leq l \leq r$ and

$$\mathcal{U} = \sum_{l=1}^{r} \mathbf{a}_1^l \otimes \mathbf{a}_2^l \otimes \ldots \otimes \mathbf{a}_d^l, \tag{1}$$

or equivalently,

$$\mathcal{U}(x_1, x_2, \ldots, x_d) = \sum_{l=1}^{r} \mathbf{a}_1^l(x_1)\mathbf{a}_2^l(x_2)\ldots\mathbf{a}_d^l(x_d), \tag{2}$$

where $\otimes$ denotes the tensor product (outer product) and $\mathcal{U}(x_1, x_2, \ldots, x_d)$ denotes the entry of the sampled tensor with coordinates $\vec{x} = (x_1, x_2, \ldots, x_d)$ and $\mathbf{a}_i^l(x_i)$ denotes the x_i-th entry of vector $\mathbf{a}_i^l$. Note that $\mathbf{a}_1^l \otimes \mathbf{a}_2^l \otimes \ldots \otimes \mathbf{a}_d^l \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is a rank-1 tensor, $l = 1, 2, \ldots, r$.

Denote Ω as the binary sampling pattern tensor that is of the same size as $\mathcal{U}$ and $\Omega(\vec{x}) = 1$ if $\mathcal{U}(\vec{x})$ is observed and $\Omega(\vec{x}) = 0$ otherwise. Also define $x^+ \triangleq \max\{0, x\}$.

For a nonempty $I \subset \{1, \ldots, d\}$, define $N_I \triangleq \Pi_{i \in I}\, n_i$ and also denote $\bar{I} \triangleq \{1, \ldots, d\} \backslash I$. Let $\widetilde{\mathbf{U}}_{(I)} \in \mathbb{R}^{N_I \times N_{\bar{I}}}$ be the unfolding of the tensor $\mathcal{U}$ corresponding to the set I such that $\mathcal{U}(\vec{x}) = \widetilde{\mathbf{U}}_{(I)}(\widetilde{M}_I(x_{i_1}, \ldots, x_{i_{|I|}}), \widetilde{M}_{\bar{I}}(x_{i_{|I|+1}}, \ldots, x_{i_d}))$, where $I = \{i_1, \ldots, i_{|I|}\}$, $\bar{I} = \{i_{|I|+1}, \ldots, i_d\}$, $\widetilde{M}_I : (x_{i_1}, \ldots, x_{i_{|I|}}) \to \{1, 2, \ldots, N_I\}$ and $\widetilde{M}_{\bar{I}} : (x_{i_{|I|+1}}, \ldots, x_{i_d}) \to \{1, 2, \ldots, \bar{N}_{\bar{I}}\}$ are two bijective mappings. For $i \in \{1, \ldots, d\}$ and $I = \{i\}$, we denote the unfolding corresponding to I by $\mathbf{U}_{(i)}$ and we call it the i-th matricization of tensor $\mathcal{U}$.

2.2 Problem Statement and A Motivating Example

We are interested in finding necessary and sufficient deterministic conditions on the sampling pattern tensor Ω under which there are infinite, finite, or unique completions of the sampled tensor $\mathcal{U}$ that satisfy the given CP rank constraint. Furthermore, we are interested in finding probabilistic conditions on the number of samples or the sampling probability that ensure the obtained deterministic conditions for finite and unique completability hold with high probability.

To motivate our proposed analysis in this paper on the CP manifold, we compare the following two approaches using a simple example to emphasize the exigency of our proposed analysis: (i) analyzing each of the unfoldings individually, (ii) analyzing based on the CP decomposition.

Consider a three-way tensor $\mathcal{U} \in \mathbb{R}^{2 \times 2 \times 2}$ with CP rank of 1. Assume that the entries $(1,1,1)$, $(2,1,1)$, $(1,2,1)$ and $(1,1,2)$ are observed. As a result of Lemma 11 in this paper, all unfoldings of this tensor are rank-1 matrices. It is shown in Section II of (Ashraphijuo et al., 2016a) that having any 4 entries of a rank-1 2×4 matrix, there are infinitely many completions for it. As a result, any unfolding of $\mathcal{U}$ is infinitely many completable given only the corresponding rank constraint. Next, using the CP decomposition (1), we show that there are only finitely many completions of the sampled tensor of CP rank 1.

Define $\mathbf{a}_1^1 = [x\ x']^\top \in \mathbb{R}^2$, $\mathbf{a}_2^1 = [y\ y']^\top \in \mathbb{R}^2$ and $\mathbf{a}_3^1 = [z\ z']^\top \in \mathbb{R}^2$. Then, according to (1), we have the following

$$\begin{aligned} \mathcal{U}(1,1,1) &= xyz, & \mathcal{U}(2,2,1) &= x'y'z, \\ \mathcal{U}(2,1,1) &= x'yz, & \mathcal{U}(2,1,2) &= x'yz', \\ \mathcal{U}(1,2,1) &= xy'z, & \mathcal{U}(1,2,2) &= xy'z', \\ \mathcal{U}(1,1,2) &= xyz', & \mathcal{U}(2,2,2) &= x'y'z'. \end{aligned} \tag{3}$$

Recall that $(1,1,1), (2,1,1), (1,2,1)$, and $(1,1,2)$ are the observed entries. Hence, the unknown entries can be determined uniquely in terms of the 4 observed entries as

$$\begin{aligned} \mathcal{U}(2,2,1) &= x'y'z = \frac{\mathcal{U}(2,1,1)\mathcal{U}(1,2,1)}{\mathcal{U}(1,1,1)}, \\ \mathcal{U}(2,1,2) &= x'yz' = \frac{\mathcal{U}(2,1,1)\mathcal{U}(1,1,2)}{\mathcal{U}(1,1,1)}, \\ \mathcal{U}(1,2,2) &= xy'z' = \frac{\mathcal{U}(1,2,1)\mathcal{U}(1,1,2)}{\mathcal{U}(1,1,1)}, \\ \mathcal{U}(2,2,2) &= x'y'z' = \frac{\mathcal{U}(2,1,1)\mathcal{U}(1,2,1)\mathcal{U}(1,1,2)}{\mathcal{U}(1,1,1)\mathcal{U}(1,1,1)}. \end{aligned} \tag{4}$$

Therefore, based on the CP decomposition, the sampled tensor $\mathcal{U}$ is finitely (uniquely) many completable. Hence, this example illustrates that collapsing a tensor into a matrix results in loss of information and thus motivate the investigation of the tensor CP manifold.

3. Deterministic Conditions for Finite Completability

In this section, we characterize the necessary and sufficient condition on the sampling pattern for finite completability of the sampled tensor given its CP rank. In Section 3.1, we define a polynomial based on each observed entry and through studying the geometry of the manifold of the corresponding CP rank, we transform the problem of finite completability of $\mathcal{U}$ to the problem of including enough number of algebraically independent polynomials among the defined polynomials for the observed entries. In Section 3.2, a binary tensor is constructed based on the sampling pattern Ω, which allows us to study the algebraic independence of a subset of polynomials among all defined polynomials based on the samples. In Section 3.3, we characterize the connection between the maximum number of algebraically independent polynomials among all the defined polynomials and finite completability of the sampled tensor.

3.1 Geometry

Suppose that the sampled tensor $\mathcal{U}$ is chosen generically from the manifold of the tensors in $\mathbb{R}^{n_1 \times \cdots \times n_d}$ of rank r. Assume that $\mathbf{a}_i^l$ vectors are unknown for $1 \leq i \leq d$ and $1 \leq l \leq r$. For notational simplicity, define the tuples $\mathbb{A}_l = (\mathbf{a}_1^l, \mathbf{a}_2^l, \ldots, \mathbf{a}_d^l)$ for $l = 1, \ldots, r$ and $\mathbb{A} = (\mathbb{A}_1, \ldots, \mathbb{A}_r)$. Moreover, define $\mathbf{A}_i = [\mathbf{a}_i^1 | \mathbf{a}_i^2 | \ldots | \mathbf{a}_i^r] \in \mathbb{R}^{n_i \times r}$. Note that each of the sampled entries results in a polynomials in terms of the entries of $\mathbb{A}$ as in (2).

Here, we briefly mention the following two facts to highlight the fundamentals of our proposed analysis.

- **Fact** 1: As it can be seen from (2), any observed entry $\mathcal{U}(\vec{x})$ results in an equation that involves one entry of $\mathbf{a}_i^l$, $i = 1, \ldots, d$ and $l = 1, \ldots, r$. Considering the entries of $\mathbb{A}$ as variables (right-hand side of (2)), each observed entry results in a polynomial in terms of these variables. Moreover, for any observed entry $\mathcal{U}(\vec{x})$, the value of x_i specifies the location of the entry of $\mathbf{a}_i^l$ that is involved in the corresponding polynomial, $i = 1, \ldots, d$ and $l = 1, \ldots, r$.
- **Fact** 2: It can be concluded from Bernstein's theorem (Sturmfels, 2002) that in a system of n polynomials in n variables with coefficients chosen generically, the polynomials are

algebraically independent with probability one, and therefore there exist only finitely many solutions.

The following assumption will be used frequently in this paper.

Assumption 1: Each row of the d-th matricization of the sampled tensor, i.e., $\mathbf{U}_{(d)}$ includes at least r observed entries.

Observe that each row of the d-th matricization of the sampled tensor includes $n_1 \times n_2 \times \ldots \times n_{d-1}$ entries. In order to show that Assumption 1 is a very mild assumption, as an example assume that $n_1 = n_2 = \cdots = n_{d-1} = n$. Then, each row of $\mathbf{U}_{(d)}$ has n^{d-1} entries and Assumption 1 requires r sampled entries among them. As we consider the low-rank scenario, we show in Section 4 how realistic this assumption is in terms of the sampling probability.

Lemma 1 *Given $\mathbf{A}_i$'s for $i = 1, \ldots, d-1$ and Assumption 1, $\mathbf{A}_d$ can be determined uniquely.*

Proof Each row of $\mathbf{A}_d$ has r entries and also as it can be seen from (2), each observed entry in the i-th row of $\mathbf{U}_{(d)}$ results in a degree-1 polynomial in terms of the r entries of the i-th row of $\mathbf{A}_d$. Since Assumption 1 holds, for each row of $\mathbf{A}_d$ that has r variables, we have at least r degree-1 polynomials. Genericity of the coefficients of these polynomials results that each row of $\mathbf{A}_d$ can be determined uniquely. ■

As a result of Lemma 1, we can obtain $\mathbf{A}_d$ in terms of the entries of $\mathbf{A}_i$'s for $i = 1, \ldots, d-1$. As mentioned earlier, each observed entry is equivalent to a polynomial in the format of (2). Consider all such polynomials excluding those that have been used to obtain $\mathbf{A}_d$ (r samples at each row of $\mathbf{U}_{(d)}$) and denote this set of polynomials in terms of the entries of $\mathbf{A}_i$'s for $i = 1, \ldots, d-1$ by $\mathcal{P}(\Omega)$.

We are interested in defining an equivalence class such that each class includes exactly one of the decompositions among all rank-r decompositions of a particular tensor and the pattern in Lemma 3 characterizes such an equivalence class. Lemma 2 below is a re-statement of Lemma 1 in (Ashraphijuo and Wang, 2017), which characterizes such an equivalence class or equivalently geometric pattern for a matrix instead of tensor. This lemma will be used to show Lemma 3 later.

Lemma 2 *Let $\mathbf{X}$ denote a generically chosen matrix from the manifold of $n_1 \times n_2$ matrices of rank r and also $\mathbf{Q} \in \mathbb{R}^{r \times r}$ be a given full rank matrix. Then, there exists a unique decomposition $\mathbf{X} = \mathbf{YZ}$ such that $\mathbf{Y} \in \mathbb{R}^{n_1 \times r}$, $\mathbf{Z} \in \mathbb{R}^{r \times n_2}$ and $\mathbf{P} = \mathbf{Q}$, where $\mathbf{P} \in \mathbb{R}^{r \times r}$ represents a submatrix*[1] *of $\mathbf{Y}$.*

In Lemma 3, we generalize Lemma 2 and characterize the similar pattern for a multi-way tensor. Assuming that $\mathbf{P}$ represents the submatrix of $\mathbf{Y}$ consists of the first r columns and the first r rows of $\mathbf{Y}$ and also $\mathbf{Q}$ is equal to the $r \times r$ identity matrix, this pattern is called the canonical decomposition of $\mathbf{X}$. The canonical decomposition is shown for a rank-2 matrix as the following

$$\begin{array}{|c|c|c|c|}\hline 1 & -1 & 0 & -1 \\ \hline 2 & 2 & 4 & 6 \\ \hline -1 & 3 & 2 & 5 \\ \hline 1 & 2 & 3 & 5 \\ \hline \end{array} = \begin{array}{|c|c|}\hline 1 & 0 \\ \hline 0 & 1 \\ \hline y_1 & y_2 \\ \hline y_3 & y_4 \\ \hline \end{array} \times \begin{array}{|c|c|c|c|}\hline x_1 & x_2 & x_3 & x_4 \\ \hline x_5 & x_6 & x_7 & x_8 \\ \hline \end{array},$$

1. Specified by a subset of rows and a subset of columns (not necessarily consecutive).

where x_i's and y_i's can be determined uniquely as

$$\begin{array}{|c|c|}\hline y_1 & y_2 \\ \hline y_3 & y_4 \\ \hline \end{array} = \begin{array}{|c|c|}\hline -2 & \frac{1}{2} \\ \hline -\frac{1}{2} & \frac{3}{4} \\ \hline \end{array} \text{ and } \begin{array}{|c|c|c|c|}\hline x_1 & x_2 & x_3 & x_4 \\ \hline x_5 & x_6 & x_7 & x_8 \\ \hline \end{array} = \begin{array}{|c|c|c|c|}\hline 1 & -1 & 0 & -1 \\ \hline 2 & 2 & 4 & 6 \\ \hline \end{array}.$$

Also, the above canonical decomposition can be written as the following

$$\begin{array}{|c|c|c|c|}\hline 1 & -1 & 0 & -1 \\ \hline 2 & 2 & 4 & 6 \\ \hline -1 & 3 & 2 & 5 \\ \hline 1 & 2 & 3 & 5 \\ \hline \end{array} = \begin{array}{|c|}\hline 1 \\ \hline 0 \\ \hline y_1 \\ \hline y_3 \\ \hline \end{array} \times \begin{array}{|c|c|c|c|}\hline x_1 & x_2 & x_3 & x_4 \\ \hline \end{array} + \begin{array}{|c|}\hline 0 \\ \hline 1 \\ \hline y_2 \\ \hline y_4 \\ \hline \end{array} \times \begin{array}{|c|c|c|c|}\hline x_5 & x_6 & x_7 & x_8 \\ \hline \end{array}.$$

Generalization of the canonical decomposition for multi-way tensor is as the following

$$\mathbf{a}_1^1 = \begin{array}{|c|}\hline 1 \\ \hline 0 \\ \hline \vdots \\ \hline 0 \\ \hline \mathbf{a}_1^1(r+1) \\ \hline \vdots \\ \hline \mathbf{a}_1^1(n_1) \\ \hline \end{array}, \ldots, \mathbf{a}_1^r = \begin{array}{|c|}\hline 0 \\ \hline 0 \\ \hline \vdots \\ \hline 1 \\ \hline \mathbf{a}_1^r(r+1) \\ \hline \vdots \\ \hline \mathbf{a}_1^r(n_1) \\ \hline \end{array},$$

and for $i \in \{2, \ldots, d-1\}$

$$\mathbf{a}_i^1 = \begin{array}{|c|}\hline 1 \\ \hline \mathbf{a}_i^1(2) \\ \hline \vdots \\ \hline \mathbf{a}_i^1(n_i) \\ \hline \end{array}, \ldots, \mathbf{a}_i^r = \begin{array}{|c|}\hline 1 \\ \hline \mathbf{a}_i^r(2) \\ \hline \vdots \\ \hline \mathbf{a}_i^r(n_i) \\ \hline \end{array}.$$

Lemma 3 *Let $j \in \{1, \ldots, d-1\}$ be a fixed number and define $J = \{1, \ldots, d-1\} \backslash \{j\}$. Assume that the full rank matrix $\mathbf{Q}_j \in \mathbb{R}^{r \times r}$ and matrices $\mathbf{Q}_i \in \mathbb{R}^{1 \times r}$ with nonzero entries for $i \in J$ are given. Also, let $\mathbf{P}_i$ denote an arbitrary submatrix of $\mathbf{A}_i$, $i = 1, 2, \ldots, d-1$, where $\mathbf{P}_j \in \mathbb{R}^{r \times r}$ and $\mathbf{P}_i \in \mathbb{R}^{1 \times r}$ for $i \in J$. Then, with probability one, there exists exactly one rank-r decomposition of $\mathcal{U}$ such that $\mathbf{P}_i = \mathbf{Q}_i$, $i = 1, \ldots, d-1$.*

Proof First we claim that there exists at most one rank-r decomposition of $\mathcal{U}$ such that $\mathbf{P}_i = \mathbf{Q}_i$, $i = 1, \ldots, d-1$. We assume that $\mathbf{P}_i = \mathbf{Q}_i$, $i = 1, \ldots, d-1$ and also $\mathcal{U}$ is given. Then, it suffices to show that the rest of the entries of $\mathbb{A}$ can be determined in at most a unique way (no more than one solution) in terms of the given parameters such that (1) holds. Note that if a variable can be determined uniquely through two different ways (two sets of samples or equations), in general either it can be determined uniquely if both ways result in the same value or it does not have any solution otherwise. Let y_i denote the row number of submatrix $\mathbf{P}_i \in \mathbb{R}^{1 \times r}$ for $i \in J$ and $Y_j = \{y_j^1, \ldots, y_j^r\}$ denote the row numbers of submatrix $\mathbf{P}_j \in \mathbb{R}^{r \times r}$.

As the first step of proving our claim, we show that $\mathbf{A}_d$ can be determined uniquely. Consider the subtensor $\mathcal{U}' = \mathcal{U}(y_1, \ldots, y_{j-1}, Y_j, y_{j+1}, \ldots, y_{d-1}, :) \in \mathbb{R}^{\overbrace{1 \times \ldots \times 1}^{j-1} \times r \times \overbrace{1 \times \ldots \times 1}^{d-j-1} \times n_d}$ which

includes rn_d entries. Having CP decomposition (2), each entry of $\mathcal{U}'$ results in one degree-1 polynomial in terms of the entries of $\mathbf{A}_d$ with coefficients in terms of the entries of $\mathbf{Q}_i$'s. Let the matrix $\mathbf{U}' \in \mathbb{R}^{r\times n_d}$ represent the rn_d entries of $\mathcal{U}'$. Moreover, define $\mathbf{C} = [\mathbf{c}_1|\dots|\mathbf{c}_r] \in \mathbb{R}^{r\times r}$ where $\mathbf{c}_l = (\Pi_{i\in J}\mathbf{P}_i(1,l))\,\mathbf{q}_j^l \in \mathbb{R}^{r\times 1}$ for $l = 1,\dots,r$ and $\mathbf{q}_j^l \in \mathbb{R}^{r\times 1}$ is the l-th column of $\mathbf{Q}_j$.

Observe that CP decomposition (2) for the entries of $\mathcal{U}'$ can be written as $\mathbf{U}' = \mathbf{C}\mathbf{A}_d^\top$. Recall that $\mathbf{Q}_j$ is full rank, and therefore $\mathbf{q}_j^l$'s are linearly independent, $l = 1,\dots,r$. Also, a system of equations with at least m linearly independent degree-1 polynomials in m variables does not have more than one solution. Hence, $\mathbf{c}_l$'s are also linearly independent for $l = 1,\dots,r$, and therefore $\mathbf{C}$ is full rank. As a result, $\mathbf{A}_d$ can be determined uniquely. In the second step, similar to the first step, we can show that the rest of $\mathbf{A}_i$'s have at most one solution having one entry of $\mathbf{A}_d$ which has been already obtained.

Finally, we also claim that there exists at least one rank-r decomposition of $\mathcal{U}$ such that $\mathbf{P}_i = \mathbf{Q}_i$, $i = 1,\dots,d-1$. We show this by induction on d. For $d = 2$, this is a result of Lemma 2. Induction hypothesis states that the claim holds for $d = k-1$ and we need to show that it also holds for $d = k$. Since by merging dimension $k-1$ and k for each of the rank-1 tensors of the corresponding CP decomposition and using induction hypothesis this step reduces to showing a rank-1 matrix can be decomposed to two vectors such that one component of one of them is given which is again a special case of Lemma 2 for rank-1 scenario. ■

Assume that $\mathcal{S}$ denotes the set of all possible $\mathbf{A}_i$'s for $i = 1,\dots,d-1$ given $\mathbf{A}_d$ without any polynomial constraint. Lemma 3 results in a pattern that characterizes exactly one rank-r decomposition among all rank-r decompositions, and therefore the dimension of $\mathcal{S}$ is equal to the number of unknowns, i.e., number of entries of $\mathbf{A}_i$'s for $i = 1,\dots,d-1$ excluding those that are involved in the pattern $\mathbf{P}_i$'s in Lemma 3 which is $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$.

Lemma 4 *For almost every $\mathcal{U}$, the sampled tensor is finitely completable if and only if the maximum number of algebraically independent polynomials in $\mathcal{P}(\Omega)$ is equal to $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$.*

Proof The proof is omitted due to the similarity to the proof of Lemma 2 in (Ashraphijuo et al., 2016a) with the only difference that here the dimension is $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ instead of $\left(\Pi_{i=1}^{j} n_i\right)\left(\Pi_{i=j+1}^{d} r_i\right) - \left(\sum_{i=j+1}^{d} r_i^2\right)$ which is the dimension of the core in Tucker decomposition. ■

3.2 Constraint Tensor

In this section, we provide a procedure to construct a binary tensor $\breve{\Omega}$ based on Ω such that $\mathcal{P}(\breve{\Omega}) = \mathcal{P}(\Omega)$ and each polynomial can be represented by one d-way subtensor of $\breve{\Omega}$ which belongs to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$. Using $\breve{\Omega}$, we are able to recognize the observed entries that have been used to obtain the $\mathbf{A}_d$ in terms of the entries of $\mathbf{A}_1,\dots,\mathbf{A}_{d-1}$, and we can study the algebraic independence of the polynomials in $\mathcal{P}(\Omega)$ which is directly related to finite completability through Lemma 4.

For each subtensor $\mathcal{Y}$ of the sampled tensor $\mathcal{U}$, let $N_\Omega(\mathcal{Y})$ denote the number of sampled entries in $\mathcal{Y}$. Specifically, consider any subtensor $\mathcal{Y} \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$ of the tensor $\mathcal{U}$. Then, since r of the polynomials have been used to obtain $\mathbf{A}_d$, $\mathcal{Y}$ contributes $N_\Omega(\mathcal{Y}) - r$ polynomial equations in terms of the entries of $\mathbf{A}_1,\dots,\mathbf{A}_{d-1}$ among all $N_\Omega(\mathcal{U}) - rn_d$ polynomials in $\mathcal{P}(\Omega)$.

The sampled tensor $\mathcal{U}$ includes n_d subtensors that belong to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$ and let $\mathcal{Y}_i$ for $1 \le i \le n_d$ denote these n_d subtensors. Define a binary valued tensor $\breve{\mathcal{Y}}_i \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times k_i}$, where $k_i = N_\Omega(\mathcal{Y}_i) - r$ and its entries are described as the following. We can look at $\breve{\mathcal{Y}}_i$ as k_i tensors each belongs to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$. For each of the mentioned k_i tensors in $\breve{\mathcal{Y}}_i$ we set the entries corresponding to the r observed entries that are used to obtain $\mathbf{A}_d$ equal to 1. For each of the other k_i observed entries that have not been used to obtain $\mathbf{A}_d$, we pick one of the k_i tensors of $\breve{\mathcal{Y}}_i$ and set its corresponding entry (the same location as that specific observed entry) equal to 1 and set the rest of the entries equal to 0. In the case that $k_i = 0$ we simply ignore $\breve{\mathcal{Y}}_i$, i.e., $\breve{\mathcal{Y}}_i = \emptyset$

By putting together all n_d tensors in dimension d, we construct a binary valued tensor $\breve{\Omega} \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times K}$, where $K = \sum_{i=1}^{n_d} k_i = N_\Omega(\mathcal{U}) - rn_d$ and call it the **constraint tensor**. Observe that each subtensor of $\breve{\Omega}$ which belongs to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$ includes exactly $r+1$ nonzero entries. In the following we show this procedure for an example.

Example 1 Consider an example in which $d = 3$ and $r = 2$ and $\mathcal{U} \in \mathbb{R}^{3\times 3\times 3}$. Assume that $\Omega(x,y,z) = 1$ if $(x,y,z) \in \mathcal{S}$ and $\Omega(x,y,z) = 0$ otherwise, where

$$\mathcal{S} = \{(1,1,1),(1,2,1),(2,3,1),(3,3,1),(1,1,2),(2,1,2),(3,2,2),(1,3,3),(3,2,3)\},$$

represents the set of observed entries. Hence, observed entries $(1,1,1),(1,2,1),(2,3,1),(3,3,1)$ belong to $\mathcal{Y}_1$, observed entries $(1,1,2),(2,1,2),(3,2,2)$ belong to $\mathcal{Y}_2$, and observed entries $(1,3,3),(3,2,3)$ belong to $\mathcal{Y}_3$. As a result, $k_1 = 4-2 = 2$, $k_2 = 3-2 = 1$, and $k_3 = 2-2 = 0$. Hence, $\breve{\mathcal{Y}}_1 \in \mathbb{R}^{3\times 3\times 2}$, $\breve{\mathcal{Y}}_2 \in \mathbb{R}^{3\times 3\times 1}$, and $\breve{\mathcal{Y}}_3 = \emptyset$, and therefore the constraint tensor $\breve{\Omega}$ belongs to $\mathbb{R}^{3\times 3\times 3}$.

Also, assume that the entries that we use to obtain $\mathbf{A}_3$ in terms of the entries of $\mathbf{A}_1$ and $\mathbf{A}_2$ are $(2,3,1)$, $(3,3,1)$, $(1,1,2)$, $(2,1,2)$, $(1,3,3)$ and $(3,2,3)$. Note that $\breve{\mathcal{Y}}_1(2,3,1) = \breve{\mathcal{Y}}_1(2,3,2) = \breve{\mathcal{Y}}_1(3,3,1) = \breve{\mathcal{Y}}_1(3,3,2) = 1$ (correspond to entries of $\mathcal{Y}_1$ that have been used to obtain $\mathbf{A}_3$), and also for the two other observed entries we have $\breve{\mathcal{Y}}_1(1,1,1) = 1$ (correspond to $\mathcal{U}(1,1,1)$) and $\breve{\mathcal{Y}}_1(1,2,2) = 1$ (correspond to $\mathcal{U}(1,2,1)$) and the rest of the entries of $\breve{\mathcal{Y}}_1$ are equal to zero. Similarly, $\breve{\mathcal{Y}}_2(1,1,1) = \breve{\mathcal{Y}}_2(2,1,1) = \breve{\mathcal{Y}}_2(3,2,1) = 1$ and the rest of the entries of $\breve{\mathcal{Y}}_2$ are equal to zero.

Then, $\breve{\Omega}(x,y,z) = 1$ if $(x,y,z) \in \breve{\mathcal{S}}$ and $\breve{\Omega}(x,y,z) = 0$ otherwise, where

$$\breve{\mathcal{S}} = \{(1,1,1),(1,2,2),(2,3,1),(2,3,2),(3,3,1),(3,3,2),(1,1,3),(2,1,3),(3,2,3)\}.$$

Note that each subtensor of $\breve{\Omega}$ that belongs to $\mathbb{R}^{n_1\times\dots\times n_{d-1}\times 1}$ represents one of the polynomials in $\mathcal{P}(\Omega)$ besides showing the polynomials that have been used to obtain $\mathbf{A}_d$. More specifically, consider a subtensor of $\breve{\Omega}$ that belongs to $\mathbb{R}^{n_1\times\dots\times n_{d-1}\times 1}$ with $r+1$ nonzero entries. Observe that exactly r of them correspond to the observed entries that have been used to obtain $\mathbf{A}_d$. Hence, this subtensor represents a polynomial after replacing entries of $\mathbf{A}_d$ by the expressions in terms of entries of $\mathbf{A}_1,\dots,\mathbf{A}_{d-1}$, i.e., a polynomial in $\mathcal{P}(\Omega)$.

3.3 Algebraic Independence

In this section, we obtain the maximum number of algebraically independent polynomials in $\mathcal{P}(\breve{\Omega})$ in terms of the simple geometrical structure of nonzero entries of Ω, i.e., the locations of the sampled entries. On the other hand, Lemma 4 provides the required number of algebraically independent polynomials in $\mathcal{P}(\Omega)$ for finite completability. Hence, at the end of this section, we obtain the necessary and sufficient deterministic conditions on the sampling pattern for finite completability.

According to Lemma 3, as we consider one particular equivalence class some of the entries of $\mathbf{A}_i$'s are known, i.e., $\mathbf{P}_1, \ldots, \mathbf{P}_{d-1}$ in the statement of the lemma. Therefore, in order to find the number of variables (unknown entries of $\mathbf{A}_i$'s) in a set of polynomials, we should subtract the number of known entries in the corresponding pattern from the total number of involved entries. Also, recall that the sampled tensor is chosen generically from the corresponding manifold, and therefore according to Fact 2, the independency of the polynomials can be studied through studying the number of variables involved in each subset of them.

Definition 5 *Let $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ be a subtensor of the constraint tensor $\breve{\Omega}$. Let $m_i(\breve{\Omega}')$ denote the number of nonzero rows of $\breve{\mathbf{\Omega}}'_{(i)}$. Also, let $\mathcal{P}(\breve{\Omega}')$ denote the set of polynomials that correspond to nonzero entries of $\breve{\Omega}'$.*

The following lemma gives an upper bound on the maximum number of algebraically independent polynomials in the set $\mathcal{P}(\breve{\Omega}')$ for an arbitrary subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ of the constraint tensor. Note that $\mathcal{P}(\breve{\Omega}')$ includes exactly t polynomials as each subtensor belonging to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$ represents one polynomial.

Lemma 6 *Suppose that Assumption 1 holds. Consider an arbitrary subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ of the constraint tensor $\breve{\Omega}$. The maximum number of algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}')$ is at most*

$$r\left(\left(\sum_{i=1}^{d-1} m_i(\breve{\Omega}')\right) - \min\left\{\max\left\{m_1(\breve{\Omega}'), \ldots, m_{d-1}(\breve{\Omega}')\right\}, r\right\} - (d-2)\right). \tag{5}$$

Proof As a consequence of Fact 2, the maximum number of algebraically independent polynomials in a subset of polynomials of $\mathcal{P}(\breve{\Omega}')$ is at most equal to the total number of variables that are involved in the corresponding polynomials. Note that by observing the structure of (2) and Fact 1, the number of entries of $\mathbf{A}_i$ that are involved in the polynomials $\mathcal{P}(\breve{\Omega}')$ is equal to $rm_i(\breve{\Omega}')$, $i = 1, \ldots, d-1$. Therefore, the total number of entries of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in the polynomials $\mathcal{P}(\breve{\Omega}')$ is equal to $r\left(\sum_{i=1}^{d-1} m_i(\breve{\Omega}')\right)$. However, some of the entries of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ are known and depending on the equivalence class we should subtract them from the total number of involved entries.

For a fixed number j in Lemma 3, it is easily verified that the total number of variables (unknown entries) of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in the polynomials $\mathcal{P}(\breve{\Omega}')$ is equal to $r\sum_{i\in J}\left(m_i(\breve{\Omega}') - 1\right)^+ + r\left(m_j(\breve{\Omega}') - r\right)^+$, with $J = \{1, \ldots, d-1\}\backslash\{j\}$. Note that $\left(m_i(\breve{\Omega}') - 1\right)^+ = m_i(\breve{\Omega}') - 1$, $\left(m_j(\breve{\Omega}') - r\right)^+ = m_j(\breve{\Omega}') - \min\left\{m_j(\breve{\Omega}'), r\right\}$. However, j is not a fixed number in general. Therefore, the maximum number of known entries of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in the polynomials $\mathcal{P}(\breve{\Omega}')$ is equal to $r\left(\min\left\{\max\left\{m_1(\breve{\Omega}'), \ldots, m_{d-1}(\breve{\Omega}')\right\}, r\right\} - (d-2)\right)$, which results that the number of variables of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in the polynomials $\mathcal{P}(\breve{\Omega}')$ is equal to (5). ■

The set of polynomials corresponding to $\breve{\Omega}'$, i.e., $\mathcal{P}(\breve{\Omega}')$ is called minimally algebraically dependent if the polynomials in $\mathcal{P}(\breve{\Omega}')$ are algebraically dependent but polynomials in every of its proper subsets are algebraically independent. The following lemma provides an important property about a set of minimally algebraically dependent $\mathcal{P}(\breve{\Omega}')$. This lemma will be used later to derive the maximum number of algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}')$.

Lemma 7 *Suppose that Assumption 1 holds. Consider an arbitrary subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ of the constraint tensor $\breve{\Omega}$. Assume that polynomials in $\mathcal{P}(\breve{\Omega}')$ are minimally algebraically dependent. Then, the number of variables (unknown entries) of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in $\mathcal{P}(\breve{\Omega}')$ is equal to $t-1$.*

Proof Let the set of polynomials $\{p_1, , p_2 \ldots, p_t\}$ represent $\mathcal{P}(\breve{\Omega}')$. Then, $\mathcal{P}(\breve{\Omega}')\backslash p_i$ (all polynomials in $\mathcal{P}(\breve{\Omega}')$ excluding p_i) is a set of algebraically independent polynomials, $i = 1, \ldots, t$. The number of involved variables in $\mathcal{P}(\breve{\Omega}')\backslash p_i$ is at least equal to the number of polynomials, i.e., $t-1$. Therefore, the number of involved variables in $\mathcal{P}(\breve{\Omega}')$ is at least $t-1$.

By contradiction, assume that the number of variables that are involved in the set of polynomials $\mathcal{P}(\breve{\Omega}')$ is at least t. Then, we claim that for any subset of the polynomials of $\mathcal{P}(\breve{\Omega}')$ the number of involved variables is at least equal to the number of polynomials in that subset. If the subset is equal to $\mathcal{P}(\breve{\Omega}')$, the claim is just the assumption of contradiction. If the subset is a proper subset of $\mathcal{P}(\breve{\Omega}')$, according to the assumption in the statement of Lemma, the polynomials are algebraically independent, and therefore, the claim holds. Hence, the polynomials in $\mathcal{P}(\breve{\Omega}')$ are algebraically independent which contradicts the assumption. ■

Given an arbitrary subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ of the constraint tensor $\breve{\Omega}$, we are interested in obtaining the maximum number of algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}')$ based on the structure of nonzero entries of $\breve{\Omega}'$. The next lemma can be used to characterize this number in terms of a simple geometric structure of nonzero entries of $\breve{\Omega}'$.

Lemma 8 *Suppose that Assumption 1 holds. Consider an arbitrary subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ of the constraint tensor $\breve{\Omega}$. The polynomials in $\mathcal{P}(\breve{\Omega}')$ are algebraically independent if and only if for any $t' \in \{1, \ldots, t\}$ and any subtensor $\breve{\Omega}'' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'}$ of $\breve{\Omega}'$ we have*

$$r\left(\left(\sum_{i=1}^{d-1} m_i(\breve{\Omega}'')\right) - \min\left\{\max\left\{m_1(\breve{\Omega}''), \ldots, m_{d-1}(\breve{\Omega}'')\right\}, r\right\} - (d-2)\right) \geq t'. \tag{6}$$

Proof First, assume that all polynomials in $\mathcal{P}(\breve{\Omega}')$ are algebraically independent. Also, by contradiction assume that there exists a subtensor $\breve{\Omega}'' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'}$ of $\breve{\Omega}'$ that (6) does not hold for. Note that $\mathcal{P}(\breve{\Omega}'')$ includes t' polynomials. On the other hand, according to Lemma 6, the maximum number of algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}'')$ is no greater than the LHS of (6), and therefore the polynomials in $\mathcal{P}(\breve{\Omega}'')$ are not algebraically independent. Hence, the polynomials in $\mathcal{P}(\breve{\Omega}')$ are not algebraically independent as well.

In order to prove the other side of the statement, assume that the polynomials in $\mathcal{P}(\breve{\Omega}')$ are algebraically dependent. Hence, there exists a subset of the polynomials that are minimally algebraically dependent and let us denote it by $\mathcal{P}(\breve{\Omega}'')$, where $\breve{\Omega}'' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'}$ is a subtensor of $\breve{\Omega}'$. As stated in Lemma 7, the number of involved variables in polynomials in $\mathcal{P}(\breve{\Omega}'')$ is equal to $t'-1$. On the other hand, in the proof of Lemma 6, we showed that the number involved variables is at least

equal the LHS of (6). Therefore, the LHS of (6) is less than or equal to $t'-1$ or equivalently

$$r\left(\left(\sum_{i=1}^{d-1} m_i(\breve{\Omega}'')\right) - \min\left\{\max\left\{m_1(\breve{\Omega}''),\ldots,m_{d-1}(\breve{\Omega}'')\right\},r\right\} - (d-2)\right) < t'. \tag{7}$$

■

Finally, the following theorem characterizes the necessary and sufficient condition on $\breve{\Omega}$ for finite completability of the sampled tensor $\mathcal{U}$.

Theorem 9 *Suppose that Assumption* 1 *holds. For almost every $\mathcal{U}$, the sampled tensor $\mathcal{U}$ is finitely completable if and only if $\breve{\Omega}$ contains a subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times t}$ such that (i) $t = r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ and (ii) for any $t' \in \{1,\ldots,t\}$ and any subtensor $\breve{\Omega}'' \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times t'}$ of $\breve{\Omega}'$,* (6) *holds.*

Proof Lemma 4 states that for almost every $\mathcal{U}$, there exist finitely many completions of the sampled tensor if and only if $\mathcal{P}(\breve{\Omega})$ includes $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ algebraically independent polynomials. Moreover, according to Lemma 8, polynomials corresponding to a subtensor $\breve{\Omega}' \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times t}$ of the constraint tensor are algebraically independent if and only if condition (ii) of the statement of the Theorem holds. Therefore, for almost every $\mathcal{U}$, conditions (i) and (ii) hold if and only if the sampled tensor $\mathcal{U}$ is finitely completable. ■

Note that the condition given in (6) is combinatorial in nature and hard to verify in practice. In the next section, we provide a lower bound on the number of samples so that both Assumption 1 and the combinatorial condition given in (6) hold true with high probability (not deterministically, i.e., with probability one anymore).

4. Probabilistic Conditions for Finite Completability

Assume that the entries of the tensor are sampled independently with probability p. In this section, we are interested in obtaining a condition in terms of the number of samples, i.e., the sampling probability, to ensure the finite completability of the sampled tensor with high probability. In Section 4.1, we apply the existing results on the Grassmannian manifold in (Pimentel-Alarcón et al., 2016d) on any of the unfoldings of the sampled tensor to derive the mentioned probabilistic condition. In Section 4.2, we obtain the conditions on the number of samples to ensure that conditions (i) and (ii) in the statement of Theorem 9 hold with high probability or in other words, to ensure the finite completability with high probability. For the notational simplicity in this section, we assume that $n_1 = n_2 = \cdots = n_d$, i.e., $\mathcal{U} \in \mathbb{R}^{n\times n\times\ldots\times n}$.

4.1 Unfolding Approach

In this section, we are interested in applying the existing analysis based on the Grassmannian manifold to obtain probabilistic conditions on the sampling pattern for finite completability with high probability. The following theorem restates Theorem 3 in (Pimentel-Alarcón et al., 2016d).

Theorem 10 *Consider an $n\times N$ matrix with the given rank k and let $0<\epsilon<1$ be given. Suppose $k \le \frac{n}{6}$ and that each* **column** *of the sampled matrix is observed in at least l entries, distributed uniformly at random and independently across entries, where*

$$l > \max\left\{12\ \log\left(\frac{n}{\epsilon}\right) + 12, 2k\right\}. \tag{8}$$

Also, assume that $k(n-k) \le N$. Then, with probability at least $1-\epsilon$, the sampled matrix will be finitely completable.

Observe that in the case of $1<k<n-1$, the assumption $k(n-k)\le N$ results that $n<N$ which is very important to check when we apply this theorem. In order to use Theorem 10, we need the following lemma to obtain an upper bound on the rank of unfoldings of $\mathcal{U}$.

Lemma 11 *Consider an arbitrary nonempty $I \subset \{1,\ldots,d\}$ and recall that r denotes the CP rank of $\mathcal{U}$. Then, rank $\left(\widetilde{\mathbf{U}}_{(I)}\right) \le r$.*

Proof In order to show rank $\left(\widetilde{\mathbf{U}}_{(I)}\right) \le r$, we show the existence of a CP decomposition of $\widetilde{\mathbf{U}}_{(I)}$ with r components, i.e., we show that there exist $\mathbf{a}_i^l \in \mathbb{R}^{m_i}$ for $1\le i\le 2$, $1\le l\le r$, $m_1 \triangleq N_I$ and $m_2 \triangleq N_{\bar{I}}$ such that

$$\widetilde{\mathbf{U}}_{(I)} = \sum_{l=1}^{r} \mathbf{a}_1^l \otimes \mathbf{a}_2^l. \tag{9}$$

In order to do so, recall that since the CP rank of $\mathcal{U}$ is r, there exist $\mathbf{b}_i^l \in \mathbb{R}^{n_i}$ for $1\le i\le d$ and $1\le l\le r$ such that

$$\mathcal{U} = \sum_{l=1}^{r} \mathbf{b}_1^l \otimes \mathbf{b}_2^l \otimes \ldots \otimes \mathbf{b}_d^l. \tag{10}$$

Define $\mathcal{A}_1^l = \mathbf{b}_{i_1}^l \otimes \ldots \otimes \mathbf{b}_{i_{|I|}}^l$ and $\mathcal{A}_2^l = \mathbf{b}_{i_{|I|+1}}^l \otimes \ldots \otimes \mathbf{b}_{i_d}^l$ for $1\le l\le l$, where $I = \{i_1,\ldots,i_{|I|}\}$, $\bar{I} = \{i_{|I|+1},\ldots,i_d\}$. Let $\mathbf{a}_1^l$ and $\mathbf{a}_2^l$ denote the vectorizations of $\mathcal{A}_1^l$ and $\mathcal{A}_2^l$ with the same bijective mappings $\widetilde{M}_I : (x_{i_1},\ldots,x_{i_{|I|}}) \to \{1,2,\ldots,N_I\}$ and $\widetilde{M}_{\bar{I}} : (x_{i_{|I|+1}},\ldots,x_{i_d}) \to \{1,2,\ldots,N_{\bar{I}}\}$ of the unfolding $\widetilde{\mathbf{U}}_{(I)}$. Hence, there exist $\mathbf{a}_i^l \in \mathbb{R}^{m_i}$ for $1\le i\le 2$, $1\le l\le r$ such that (9) holds. ■

Remark 12 *Assume that $k \le k' \le \frac{n}{6}$, $l > \max\left\{12\ \log\left(\frac{n}{\epsilon}\right)+12, 2k'\right\}$ and $k'(n-k') \le N$. Then, we have $l > \max\left\{12\ \log\left(\frac{n}{\epsilon}\right)+12, 2k\right\}$ since $k\le k'$. Moreover, we have $k(n-k)\le N$ since $k+k'<n$ which results $k(n-k)<k'(n-k')$.*

Lemma 13 *Let $I = \{i_1,\ldots,i_{|I|}\}$ be an arbitrary nonempty and proper subset of $\{1,\ldots,d\}$. Assume that $|I| < \frac{d}{2}$ and $r \le \frac{n}{6}$, where r is the CP rank of the sampled tensor $\mathcal{U}$. Moreover, assume that each* **column** *of $\widetilde{\mathbf{U}}_{(I)}$ is observed in at least l entries, distributed uniformly at random and independently across entries, where*

$$l > \max\left\{12\ \log\left(\frac{N_I r}{\epsilon}\right) + 12, 2r\right\}. \tag{11}$$

Then, with probability at least $1-\epsilon$, the sampled tensor will be finitely completable.

Proof According to Lemma 11, $r_I \triangleq \text{rank}\left(\widetilde{\mathbf{U}}_{(I)}\right) \leq r$. Note that $N_I \leq n^{\frac{d-1}{2}} = \frac{n^{\frac{d+1}{2}}}{n} \leq \frac{N_{\bar{I}}}{n}$ which results that $r(N_I - r) \leq N_{\bar{I}}$. Furthermore, according to Remark 12, we have $r_I(N_I - r_I) \leq N_{\bar{I}}$ and also

$$l > \max\left\{12\ \log\left(\frac{N_I r}{\epsilon}\right) + 12, 2r_I\right\}. \tag{12}$$

Therefore, according to Theorem 10, $\widetilde{\mathbf{U}}_{(I)}$ is finitely completable for an arbitrary value of r_I that belongs to $\{1, \ldots, r\}$ with probability at least $1 - \frac{\epsilon}{r}$. Hence, with probability at least $1 - \epsilon$, for all possible values of r_I, $\widetilde{\mathbf{U}}_{(I)}$ is finitely completable, i.e., $\widetilde{\mathbf{U}}_{(I)}$ is finitely completable. In order to complete to proof, it suffices to observe that finite completability of any of the unfoldings of $\mathcal{U}$ results the finite completability of $\mathcal{U}$. ■

Remark 14 *In the case of $|I| > \frac{d}{2}$ in Lemma 13, we can simply consider the transpose of $\widetilde{\mathbf{U}}_{(I)}$ to have the similar results.*

Remark 15 *Lemma 13 requires*

$$n^{d-|I|} \max\left\{12\ \log\left(\frac{n^{|I|}r}{\epsilon}\right) + 12, 2r\right\} \tag{13}$$

samples in total to ensure the finite completability of $\mathcal{U}$ with probability at least $1 - \epsilon$. Hence, the best bound on the total number of samples to ensure the finite completability with probability at least $1 - \epsilon$ will be obtained when $|I| = \lfloor \frac{d-1}{2} \rfloor$, which is

$$n^{\lceil \frac{d+1}{2} \rceil} \max\left\{12\ \log\left(\frac{n^{\lfloor \frac{d-1}{2} \rfloor}r}{\epsilon}\right) + 12, 2r\right\}. \tag{14}$$

4.2 CP Approach

In this section, we present an approach based on the tensor CP decomposition instead of unfolding. Conditions (i) and (ii) in Theorem 9 ensure finite completability with probability one. Here, using combinatorial methods, we derive a lower bound on the number of sampled entries, i.e., the sampling probability, which ensures conditions (i) and (ii) in Theorem 9 hold with high probability. We first provide a few lemmas from our previous works. Lemma 16 below is Lemma 5 in (Ashraphijuo et al., 2017c), which will be used later.

Lemma 16 *Assume that $r' \leq \frac{n}{6}$ and also each column of $\mathbf{\Omega}_{(1)}$ (first matricization of Ω) includes at least l nonzero entries, where*

$$l > \max\left\{9\ \log\left(\frac{n}{\epsilon}\right) + 3\ \log\left(\frac{k}{\epsilon}\right) + 6, 2r'\right\}. \tag{15}$$

Let $\mathbf{\Omega}'_{(1)}$ be an arbitrary set of $n - r'$ columns of $\mathbf{\Omega}_{(1)}$. Then, with probability at least $1 - \frac{\epsilon}{k}$, every subset $\mathbf{\Omega}''_{(1)}$ of columns of $\mathbf{\Omega}'_{(1)}$ satisfies

$$m_1(\Omega'') - r' \geq t, \tag{16}$$

where t is the number of columns of $\mathbf{\Omega}''_{(1)}$ and $m_1(\Omega'')$ is the number of nonzero rows of $\mathbf{\Omega}''_{(1)}$.

The proof of the above lemma is based on a simple combinatorial idea to upper bound the number of possible patterns that do not satisfy the mentioned property.

Lemma 17 *Let $j \in \{1, 2, \ldots, d-1\}$ be a fixed number and $I = \{1, 2, \ldots, j\}$. Consider an arbitrary set $\widetilde{\mathbf{\Omega}}'_{(I)}$ of $n - r'$ columns of $\widetilde{\mathbf{\Omega}}_{(I)}$, where $r' \leq r \leq \frac{n}{6}$. Assume that $n > 200$, and also each column of $\widetilde{\mathbf{\Omega}}_{(I)}$ includes at least l nonzero entries, where*

$$l > \max\left\{27\ \log\left(\frac{n}{\epsilon}\right) + 9\ \log\left(\frac{2k}{\epsilon}\right) + 18, 6r'\right\}, \tag{17}$$

where $k \leq r$. Then, with probability at least $1 - \frac{\epsilon}{2k}$, each column of $\widetilde{\mathbf{\Omega}}'_{(I)}$ includes more than $l_0 \triangleq \max\left\{9\ \log\left(\frac{n}{\epsilon}\right) + 3\ \log\left(\frac{2k}{\epsilon}\right) + 6, 2r'\right\}$ observed entries of Ω with different values of the i-th coordinate, i.e., the i-th matricization of the tensor Ω' that corresponds to $\widetilde{\mathbf{\Omega}}'_{(I)}$ includes more than l_0 nonzero rows, $1 \leq i \leq j$.

Proof The proof is omitted due to the similarity to the proof for Lemma 9 in (Ashraphijuo and Wang, 2017). ■

The following lemma is Lemma 8 in (Ashraphijuo et al., 2016a), which states that if the property in Lemma 16 holds for the sampling pattern Ω, it will be satisfied for $\breve{\Omega}$ as well.

Lemma 18 *Let r' be a given nonnegative integer and $1 \leq i \leq j \leq d-1$ and $I = \{1, 2, \ldots, j\}$. Assume that there exists an $n^j \times (n - r')$ matrix $\widetilde{\mathbf{\Omega}}'_{(I)}$ composed of $n - r'$ columns of $\widetilde{\mathbf{\Omega}}_{(I)}$ such that each column of $\widetilde{\mathbf{\Omega}}'_{(I)}$ includes at least $r' + 1$ nonzero entries and satisfies the following property:*

- *Denote an $n^j \times t$ matrix (for any $1 \leq t \leq n - r'$) composed of any t columns of $\widetilde{\mathbf{\Omega}}'_{(I)}$ by $\widetilde{\mathbf{\Omega}}''_{(I)}$. Then*

$$m_i(\Omega'') - r' \geq t, \tag{18}$$

where $\widetilde{\mathbf{\Omega}}''_{(I)}$ is the unfolding of Ω'' corresponding to the set I.

Then, there exists an $n^j \times (n - r')$ matrix $\widetilde{\breve{\mathbf{\Omega}}}'_{(I)}$ such that: each column has exactly $r' + 1$ entries equal to one, and if $\widetilde{\breve{\mathbf{\Omega}}}'_{(I)}(x, y) = 1$ then we have $\widetilde{\mathbf{\Omega}}'_{(I)}(x, y) = 1$. Moreover, $\widetilde{\breve{\mathbf{\Omega}}}'_{(I)}$ satisfies the above-mentioned property.

The proof of the above lemma is based a novel generalization of Hall's theorem for bipartite graph. This generalization is shown by strong induction on the number of nodes.

Lemma 19 *Assume that $n > 200$, $1 \leq i \leq j \leq d-1$ and $I = \{1, 2, \ldots, j\}$. Consider r disjoint sets $\widetilde{\mathbf{\Omega}}'_{l_{(I)}}$, each with $n - r'_l$ columns of $\widetilde{\mathbf{\Omega}}_{(I)}$ for $1 \leq l \leq r$, where $r'_l \leq r \leq \frac{n}{6}$. Let $\widetilde{\mathbf{\Omega}}'_{(I)}$ denote the union of all r sets of columns $\widetilde{\mathbf{\Omega}}'_{l_{(I)}}$'s. Assume that each column of $\widetilde{\mathbf{\Omega}}_{(I)}$ includes at least l nonzero entries, where*

$$l > \max\left\{27\ \log\left(\frac{n}{\epsilon}\right) + 9\ \log\left(\frac{2rk}{\epsilon}\right) + 18, 6r'_i\right\}. \tag{19}$$

Then, there exists an $n^j \times r(n-r'_i)$ matrix $\widetilde{\breve{\Omega}}'_{(I)}$ such that: each column has exactly r'_i+1 entries equal to one, and if $\widetilde{\breve{\Omega}}'_{(I)}(x,y)=1$ then we have $\widetilde{\Omega}'_{(I)}(x,y)=1$ and also it satisfies the following property: with probability at least $1-\frac{\epsilon}{k}$, every subset $\widetilde{\breve{\Omega}}''_{(I)}$ of columns of $\widetilde{\breve{\Omega}}'_{(I)}$ satisfies the following inequality

$$r\left(m_i(\breve{\Omega}'')-r'_i\right)\geq t, \tag{20}$$

where t is the number of columns of $\widetilde{\breve{\Omega}}''_{(I)}$ and $\breve{\Omega}''$ is the tensor corresponding to unfolding $\widetilde{\breve{\Omega}}''_{(I)}$.

Proof We first claim that with probability at least $1-\frac{\epsilon}{kr}$, every subset $\widetilde{\Omega}''_{l_{(I)}}$ of columns of $\widetilde{\Omega}'_{l_{(I)}}$ satisfies

$$m_i(\Omega''_l)-r'_i\geq t, \tag{21}$$

where t is the number of columns of $\widetilde{\Omega}''_{l_{(I)}}$ and Ω''_l is the tensor corresponding to unfolding $\widetilde{\Omega}''_{l_{(I)}}$. For simplicity we denote the above-mentioned property by Property I. According to Lemma 17, with probability at least $1-\frac{\epsilon}{2kr}$, the i-th matricization of the tensor Ω''_l includes more than $\max\left\{9\ \log\left(\frac{n}{\epsilon}\right)+3\ \log\left(\frac{2kr}{\epsilon}\right)+6, 2r'_i\right\}$ nonzero rows, $1\leq i\leq j$, and we denote this property by Property II. On the other hand, given that Property II holds for Ω''_l and according to Lemma 16, with probability at least $1-\frac{\epsilon}{2kr}$, Property I holds for Ω''_l as well. Hence, with probability at least $1-\frac{\epsilon}{kr}$, Property I holds for Ω''_l, which completes the proof our earlier claim.

Consequently, according to Lemma 18, with probability at least $1-\frac{\epsilon}{kr}$, there exists an $n^j\times(n-r'_i)$ matrix $\widetilde{\breve{\Omega}}'_{l_{(I)}}$ such that: each column has exactly r'_i+1 entries equal to one, and if $\widetilde{\breve{\Omega}}'_{l_{(I)}}(x,y)=1$ then we have $\widetilde{\Omega}'_{l_{(I)}}(x,y)=1$ and also $\breve{\Omega}'_l$ satisfies Property I. Finally define $\widetilde{\breve{\Omega}}'_{(I)}\triangleq\left[\widetilde{\breve{\Omega}}'_{1_{(I)}}|\widetilde{\breve{\Omega}}'_{2_{(I)}}|\ldots|\widetilde{\breve{\Omega}}'_{r_{(I)}}\right]$. Since each $\breve{\Omega}'_l$ satisfies Property I with probability at least $1-\frac{\epsilon}{kr}$, all $\breve{\Omega}'_l$'s satisfy Property I with probability at least $1-\frac{\epsilon}{k}$, simultaneously. Consider an arbitrary subset $\widetilde{\breve{\Omega}}''_{(I)}$ of columns of $\widetilde{\breve{\Omega}}'_{(I)}$. Let $\widetilde{\breve{\Omega}}''_{l_{(I)}}$ denote those columns of $\widetilde{\breve{\Omega}}''_{(I)}$ that belong to $\widetilde{\breve{\Omega}}'_{l_{(I)}}$ and define t_l as the number of columns of $\widetilde{\breve{\Omega}}''_{l_{(I)}}$, $1\leq l\leq r$, and define t as the number of columns of $\widetilde{\breve{\Omega}}''_{(I)}$. Without loss of generality, assume that $t_1\leq t_2\leq\ldots\leq t_r$. Also, assume that all $\breve{\Omega}'_l$'s satisfy Property I. Hence, we have

$$t=\sum_{l=1}^{r}t_l\leq rt_r\leq r\left(m_i(\breve{\Omega}''_r)-r'_i\right)\leq r\left(m_i(\breve{\Omega}'')-r'_i\right). \tag{22}$$

■

Theorem 20 *Assume that $d>2$, $n>\max\{200, r(d-2)\}$, $r\leq\frac{n}{6}$ and $I=\{1,2,\ldots,d-2\}$. Assume that each column of $\widetilde{\breve{\Omega}}_{(I)}$ includes at least l nonzero entries, where*

$$l>\max\left\{27\ \log\left(\frac{n}{\epsilon}\right)+9\ \log\left(\frac{2r(d-2)}{\epsilon}\right)+18, 6r\right\}. \tag{23}$$

Then, with probability at least $1-\epsilon$, for almost every $\mathcal{U}\in\mathbb{R}^{\overbrace{n\times\ldots\times n}^{d}}$, there exist only finitely many completions of the sampled tensor $\mathcal{U}$ with CP rank r.

Proof Define the $(d-1)$-way tensor $\mathcal{U}'\in\mathbb{R}^{\overbrace{n\times\ldots\times n}^{d-2}\times n^2}$ which is obtained through merging the $(d-1)$-th and d-th dimensions of the tensor $\mathcal{U}$. Observe that the finiteness of the number of completions of the tensor $\mathcal{U}'$ of rank r ensures the finiteness of the number of completions of the tensor $\mathcal{U}$ of rank r. For notational simplicity, let Ω and $\breve{\Omega}$ denote the $(d-1)$-way sampling pattern and constraint tensors corresponding to $\mathcal{U}'$, respectively. In order to complete the proof it suffices to show with probability at least $1-\epsilon$, conditions (i) and (ii) in Theorem 9 hold for this modified $(d-1)$-way tensor.

Now, we apply Lemma 19 for each of the numbers $r'_1=1,\ldots,r'_{d-3}=1,r'_{d-2}=r$. Also, note that since $n>r(d-2)$ we conclude $n^2>r(n-r)+(d-3)r(n-1)$, and therefore $\widetilde{\Omega}_{(I)}$ includes more than $r(n-r)+(d-3)r(n-1)$ columns. According to Lemma 19, there exist $\breve{\Omega}'_i$ for $1\leq i\leq d-2$ such that: (i) each column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ includes r'_i+1 nonzero entries for $1\leq i\leq d-2$, and if $\widetilde{\breve{\Omega}}'_{i_{(I)}}(x,y)=1$ then we have $\widetilde{\Omega}'_{i_{(I)}}(x,y)=1$, (ii) $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ includes $r(n-1)$ and $r(n-r)$ columns for $1\leq i\leq d-3$ and $i=d-2$, respectively, (iii) with probability at least $1-\frac{\epsilon}{d-2}$, every subset $\widetilde{\breve{\Omega}}''_{i_{(I)}}$ of columns of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ satisfies (20) for $r'_1=1,\ldots,r'_{d-3}=1,r'_{d-2}=r$.

Recall that each column of $\widetilde{\Omega}_{(I)}$ includes $r+1$ nonzero entries, and therefore for $1\leq i\leq d-3$ that we have $r'_i+1=2$, the column of $\widetilde{\Omega}_{(I)}$ corresponding to an column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ has $r-1$ more nonzero entries.

Observe that $\max\left\{9\ \log\left(\frac{n}{\epsilon}\right)+3\ \log\left(\frac{2kr}{\epsilon}\right)+6, 2r\right\}\geq 2r\geq(r-1)+2$. According to Lemma 17 and given (23), for each column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ there exists another $r-1$ zero entries (x_s,y_s) for $s\in\{1,\ldots,r-1\}$ in different rows of the $(d-2)$-th matricization of $\breve{\Omega}'_i$ from the two nonzero entries such that $\widetilde{\Omega}'_{i_{(I)}}(x_s,y_s)=1, i=1,\ldots,d-3$. Hence, for each column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$, we substitute it with the column of $\widetilde{\Omega}_{(I)}$ that the value of such $r-1$ entries (in different rows of the $(d-2)$-th matricization of $\breve{\Omega}'_i$) is 1 instead of 0 , $i=1,\ldots,d-3$. Therefore, each column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ includes exactly $r+1$ nonzero entries for $1\leq i\leq d-3$ such that if $\widetilde{\breve{\Omega}}'_{i_{(I)}}(x,y)=1$ then we have $\widetilde{\Omega}'_{i_{(I)}}(x,y)=1$.

Let $\widetilde{\breve{\Omega}}'_{(I)}=\left[\widetilde{\breve{\Omega}}'_{1_{(I)}}|\ldots|\widetilde{\breve{\Omega}}'_{d-2_{(I)}}\right]$, which includes $r(n-r)+(d-3)r(n-1)$ columns. Therefore, $\breve{\Omega}'\in\mathbb{R}^{\overbrace{n\times\ldots\times n}^{d-2}\times t}$ is a subtensor of the constraint tensor such that $t=r(\sum_{i=1}^{d-2}n)-r^2-r(d-3)$ and also and with probability at least $1-\epsilon$, every subset $\widetilde{\breve{\Omega}}''_{i_{(I)}}$ of columns of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ satisfies (20) for $r'_1=1,\ldots,r'_{d-3}=1,r'_{d-2}=r$, simultaneously for $i=1,\ldots,d-2$.

Consider an arbitrary subset $\widetilde{\breve{\Omega}}''_{(I)}$ of columns of $\widetilde{\breve{\Omega}}'_{(I)}$. Let $\widetilde{\breve{\Omega}}''_{i_{(I)}}$ denote those columns of $\widetilde{\breve{\Omega}}''_{(I)}$ that belong to $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ and define t_i as the number of columns of $\widetilde{\breve{\Omega}}''_{i_{(I)}}$, $1\leq i\leq d-2$, and define t

as the number of columns of $\widetilde{\breve{\Omega}}''_{(I)}$. Also, assume that all $\breve{\Omega}'_l$'s satisfy (20) for $r'_1 = 1, \ldots, r'_{d-3} = 1, r'_{d-2} = r$. Then, we have the following two scenarios:

(i) $t_{d-2} = 0$: Hence, we have $t = \sum_{i=1}^{d-3} t_i$. Moreover, we have

$$t_i \leq r\left(m_i(\breve{\Omega}''_i) - 1\right)^+ \leq r\left(m_i(\breve{\Omega}'') - 1\right)^+ = r\left(m_i(\breve{\Omega}'') - 1\right), \tag{24}$$

for $1 \leq i \leq d-3$. Recall that each column of $\widetilde{\breve{\Omega}}'_{i_{(I)}}$ includes at least r nonzero entries in different rows of the $(d-2)$-th matricization of $\breve{\Omega}'_i$ for $1 \leq i \leq d-3$. On the other hand, since $\widetilde{\breve{\Omega}}''_{(I)}$ includes at least one column of $\left[\widetilde{\breve{\Omega}}'_{1_{(I)}} | \ldots | \widetilde{\breve{\Omega}}'_{d-3_{(I)}}\right]$ (recall that $t_{d-2} = 0$), we have

$$r \leq m_{d-2}(\breve{\Omega}''), \tag{25}$$

which also results that $\min\left\{\max\left\{m_1(\breve{\Omega}''), \ldots, m_{d-2}(\breve{\Omega}'')\right\}, r\right\} = r$.

Therefore, having (24) and (25), we conclude

$$t = \sum_{i=1}^{d-3} t_i \leq \sum_{i=1}^{d-3} r\left(m_i(\breve{\Omega}'') - 1\right) \leq \sum_{i=1}^{d-3} r\left(m_i(\breve{\Omega}'') - 1\right) + r\left(m_{d-2}(\breve{\Omega}'') - r\right) \tag{26}$$

$$= r\left(\sum_{i=1}^{d-2} m_i(\breve{\Omega}'')\right) - r^2 - r(d-3)$$

$$= r\left(\left(\sum_{i=1}^{d-2} m_i(\breve{\Omega}'')\right) - \min\left\{\max\left\{m_1(\breve{\Omega}''), \ldots, m_{d-2}(\breve{\Omega}'')\right\}, r\right\} - (d-3)\right).$$

(ii) $t_{d-2} > 0$: Hence, we have

$$t_{d-2} \leq r\left(m_{d-2}(\breve{\Omega}''_{d-2}) - r\right) \leq r\left(m_{d-2}(\breve{\Omega}'') - r\right), \tag{27}$$

which also results that $\min\left\{\max\left\{m_1(\breve{\Omega}''), \ldots, m_{d-2}(\breve{\Omega}'')\right\}, r\right\} = r$. Moreover, similar to scenario (i), (24) holds. Therefore, having (24) and (27), we conclude

$$t = \sum_{i=1}^{d-2} t_i \leq \sum_{i=1}^{d-3} r\left(m_i(\breve{\Omega}'') - 1\right) + r\left(m_{d-2}(\breve{\Omega}'') - r\right) = r\left(\sum_{i=1}^{d-2} m_i(\breve{\Omega}'')\right) - r^2 - r(d-3) \tag{28}$$

$$= r\left(\left(\sum_{i=1}^{d-2} m_i(\breve{\Omega}'')\right) - \min\left\{\max\left\{m_1(\breve{\Omega}''), \ldots, m_{d-2}(\breve{\Omega}'')\right\}, r\right\} - (d-3)\right).$$

■

Remark 21 *Observe that each row of the d-matricization of $\mathcal{U}$ consists of exactly n columns of $\widetilde{\mathbf{\Omega}}_{(I)}$, where $I = \{1, 2, \ldots, d-2\}$. Hence, given* (23)*, Assumption* 1 *holds with probability one since Assumption* 1 *only requires r sampled entries at each row of the d-matricization of $\mathcal{U}$. Moreover, note that in the above theorem we showed that given* (23)*, constraint* (6) *holds with high probability and this ensures finite completability with high probability (since Assumption* 1 *holds with probability one).*

Note that for the general values of $n_1, \ldots, n_d$ the same proof will still work, but instead of the assumption $n > \max\{200, r(d-2)\}$, we need another assumption in terms of $n_1, \ldots, n_d$ to ensure that the corresponding unfolding has enough number of columns.

Remark 22 *A tensor $\mathcal{U}$ that satisfies the properties in the statement of Theorem 20 requires*

$$n^2 \max\left\{27\ \log\left(\frac{n}{\epsilon}\right) + 9\ \log\left(\frac{2r(d-2)}{\epsilon}\right) + 18, 6r\right\} \tag{29}$$

samples to be finitely completable with probability at least $1-\epsilon$, which is lower than the number of samples required by the unfolding approach given in (14) *by orders of magnitude.*

The following lemma is taken from (Ashraphijuo et al., 2016a) and is used in Lemma 24 to derive a lower bound on the sampling probability that results (23) with high probability.

Lemma 23 *Consider a vector with n entries where each entry is observed with probability p independently from the other entries. If $p > p' = \frac{k}{n} + \frac{1}{\sqrt[4]{n}}$, then with probability at least $\left(1 - \exp(-\frac{\sqrt{n}}{2})\right)$, more than k entries are observed.*

The proof of the above lemma is simply based on Azuma's inequality.

Lemma 24 *Assume that $d > 2$, $n > \max\{200, r(d-2)\}$ and $r \leq \frac{n}{6}$. Moreover, assume that the sampling probability satisfies*

$$p > \frac{1}{n^{d-2}} \max\left\{27\ \log\left(\frac{n}{\epsilon}\right) + 9\ \log\left(\frac{2r(d-2)}{\epsilon}\right) + 18, 6r\right\} + \frac{1}{\sqrt[4]{n^{d-2}}}. \tag{30}$$

Then, with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, $\mathcal{U}$ is finitely completable.

Proof According to Lemma 23, (30) results that each column of $\widetilde{\mathbf{\Omega}}_{(I)}$ includes at least l nonzero entries, where $I = \{1, 2, \ldots, d-2\}$ and l satisfies (23) with probability at least $\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)$. Therefore, with probability at least $\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, all n^2 columns of $\widetilde{\mathbf{\Omega}}_{(I)}$ satisfy (23). Hence, according to Theorem 20, with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, $\mathcal{U}$ is finitely completable. ■

5. Deterministic and Probabilistic Conditions for Unique Completability

In this section, we are interested in characterizing the deterministic and probabilistic conditions on the sampling pattern for unique completability. In previous sections we characterized the corresponding conditions for finite completability in Theorem 9 and Theorem 20. However, for matrix and tensor completion problems, finite completability does not necessarily imply unique completability (Ashraphijuo et al., 2016a). In this section, we add some additional mild restrictions on

Ω in the statement of Theorem 9 to ensure unique completability (deterministic) and also increase the number of samples given in the statement of Theorem 20 mildly to ensure unique completability with high probability (probabilistic). As the first step of this procedure, we use the following lemma for minimally algebraically dependent polynomials to obtain the variables involved in these polynomials uniquely. Hence, by obtaining all entries of the CP decomposition of the sampled tensor $\mathcal{U}$ we can show the uniqueness of $\mathcal{U}$.

Lemma 25 *Suppose that Assumption 1 holds. Let $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \ldots \times n_{d-1} \times t}$ be an arbitrary subtensor of the constraint tensor $\breve{\Omega}$. Assume that polynomials in $\mathcal{P}(\breve{\Omega}')$ are minimally algebraically dependent. Then, all variables (unknown entries) of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ that are involved in $\mathcal{P}(\breve{\Omega}')$ can be determined uniquely.*

Proof According to Lemma 7, the number of involved variables in polynomials in $\mathcal{P}(\breve{\Omega}') = \{p_1, p_2, \ldots, p_t\}$ is $t-1$ and are denoted by $\{x_1, \ldots, x_{t-1}\}$. Moreover, as mentioned in the proof of Lemma 7, $\mathcal{P}(\breve{\Omega}')\backslash p_i$ is a set of algebraically independent polynomials and the number of involved variables is $t-1, i = 1, \ldots, t$. Consider an arbitrary variable x_1 that is involved in polynomials in $\mathcal{P}(\breve{\Omega}')$ and without loss of generality, assume that x_1 is involved in p_1.

On the other hand, as mentioned all variables $\{x_1, \ldots, x_{t-1}\}$ are involved in algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}')\backslash p_1$. Hence, tuple $(x_1, \ldots, x_{t-1})$ can be determined finitely. Given that one of these finitely many tuples $(x_1, \ldots, x_{t-1})$ satisfy polynomial equation p_1, with probability one there does not exist another tuple $(x_1, \ldots, x_{t-1})$ among them that satisfies polynomial equation p_1. This is because with probability zero a tuple satisfy a polynomial equation in which the coefficients are chosen generically, and also the fact that the number of such tuples is finite. ■

Condition (i) in Theorem 26 results in $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ algebraically independent polynomials in terms of the entries of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$, i.e., results in finite completability. Hence, adding a single polynomial corresponding to any observed entry to these $r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ algebraically independent polynomials results in a set of algebraically dependent polynomials. Then, according to Lemma 25 a subset of the entries of $\mathbf{A}_1, \ldots, \mathbf{A}_{d-1}$ can be determined uniquely and these additional polynomials are captured in the structure of condition (ii) such that all entries of CP decomposition can be determined uniquely.

Theorem 26 *Suppose that Assumption 1 holds. Also, assume that there exist disjoint subtensors $\breve{\Omega}' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t}$ and $\breve{\Omega}'^i \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t_i}$ (for $1 \leq i \leq 2d-2$) of the constraint tensor such that the following conditions hold:*

(i) $t = r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ and for any $t' \in \{1, \ldots, t\}$ and any subtensor $\breve{\Omega}'' \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'}$ of $\breve{\Omega}'$, (6) holds.

(ii) for $i \in \{1, \ldots, d-1\}$ we have $t_i = n_i - 1$ and for $i \in \{d, \ldots, 2d-2\}$ we have $t_i = n_{i-d+1} - r$. Also, for any $t'_i \in \{1, \ldots, t_i\}$ and any subtensor $\breve{\Omega}''^i \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'_i}$ of the tensor $\breve{\Omega}'^i$, the following inequalities hold

$$m_i(\breve{\Omega}''^i) - 1 \geq t'_i, \qquad \text{for } i \in \{1, \ldots, d-1\}, \tag{31}$$

and

$$m_{i-d+1}(\breve{\Omega}''^i) - r \geq t'_i, \qquad \text{for } i \in \{d, \ldots, 2d-2\}. \tag{32}$$

Then, for almost every $\mathcal{U}$, there exists only a unique tensor that fits in the sampled tensor $\mathcal{U}$, and has CP rank r.

Proof As we showed in the proof of Theorem 9, $\mathcal{P}(\breve{\Omega}')$ includes $t = r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ algebraically independent polynomials which results the finite completability of the sampled tensor $\mathcal{U}$. Let $\{p_1, \ldots, p_t\}$ denote these t algebraically independent polynomials in $\mathcal{P}(\breve{\Omega}')$. Now, having $\{p_1, \ldots, p_t\}$ and $\mathcal{P}(\breve{\Omega}'^i)$ for $1 \leq i \leq 2d-2$, and using Lemma 25 several times, we show the unique completability. Recall that t is the number of total variables among the polynomials, and therefore union of any polynomial p_0 and $\{p_1, \ldots, p_t\}$ is a set of algebraically dependent polynomials. Hence, there exists a set of polynomials $\mathcal{P}(\breve{\Omega}'')$ such that $\mathcal{P}(\breve{\Omega}'') \subset \{p_1, \ldots, p_t\}$ and also polynomials in $\mathcal{P}(\breve{\Omega}'') \cup p_0$ are minimally algebraically dependent polynomials. Therefore, according to Lemma 25, all variables involved in the polynomials $\mathcal{P}(\breve{\Omega}'') \cup p_0$ can be determined uniquely, and consequently, all variables involved in p_0 can be determined uniquely.

We can repeat the above procedure for any polynomial $p_0 \in \mathcal{P}(\breve{\Omega}'^i)$ to determine the involved variables uniquely with the help of $\{p_1, \ldots, p_t\}$, $i = 1, \ldots, 2d-2$. Hence, for any polynomial $p_0 \in \mathcal{P}(\breve{\Omega}'^i)$ or $p_0 \in \mathcal{P}(\breve{\Omega}'^{i+d-1})$, we obtain r degree-1 polynomials in terms of the entries of $\mathbf{A}_i$ but some of the entries of CP decomposition are elements of the $\mathbf{Q}_i$ matrices (in the statement of Lemma 3), $i = 1, \ldots, d-1$. In order to complete the proof, we need to show that condition (ii) with the above procedure using $\{p_1, \ldots, p_t\}$ results in obtaining all variables uniquely. In particular, we show that repeating the described procedure for any of the polynomials in $\mathcal{P}(\breve{\Omega}'^i)$ and $\mathcal{P}(\breve{\Omega}'^{i+d-1})$ result in obtaining all variables of the i-th element of CP decomposition uniquely.

According to Lemma 3, we have the following two scenarios for any $i \in \{1, \ldots, d-1\}$:

(i) $\mathbf{Q}_i \in \mathbb{R}^{r \times r}$: In this case, condition (ii) for $\breve{\Omega}'^{i+d-1}$ and for any $t'_{i+d-1} \in \{1, \ldots, n_i - r\}$ and any subtensor $\breve{\Omega}''^{i+d-1} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'_{i+d-1}}$ of the tensor $\breve{\Omega}'^{i+d-1}$ results

$$rm_i(\breve{\Omega}''^{i+d-1}) - r^2 \geq rt'_{i+d-1}. \tag{33}$$

Note that rt'_{i+d-1} is the number of polynomials from the above mentioned procedure corresponding to $\breve{\Omega}''^{i+d-1}$ and $rm_i(\breve{\Omega}''^{i+d-1})$ denotes the number of involved entries of $\mathbf{A}_i$ in these polynomials, and therefore $rm_i(\breve{\Omega}''^{i+d-1}) - r^2$ is the number of involved variables of $\mathbf{A}_i$ in these polynomials. As a result, according to Fact 2, given $\mathcal{P}(\breve{\Omega}'^{i+d-1})$ and $\{p_1, \ldots, p_t\}$, the mentioned procedure results in $rn_i - r^2$ algebraically independent degree-1 polynomials in terms of the unknown entries of $\mathbf{A}_i$. Therefore, $\mathbf{A}_i$ can be determined uniquely.

(ii) $\mathbf{Q}_i \in \mathbb{R}^{1 \times r}$: Similar to scenario (i), condition (ii) for $\breve{\Omega}''^i$ and for any $t'_i \in \{1, \ldots, n_i\}$ and any subtensor $\breve{\Omega}''^i \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times t'_i}$ of the tensor $\breve{\Omega}'^i$ results

$$rm_i(\breve{\Omega}''^i) - r \geq rt'_i, \tag{34}$$

and therefore similar to the previous scenario, $\mathbf{A}_i$ can be determined uniquely. ■

In Theorem 26, we obtained the deterministic condition on the sampling pattern for unique completability. Note that Condition (i) in Theorem 26 is the same condition for finite completability.

In the remainder of this section, we are interested in characterizing the probabilistic conditions on the number of samples to ensure unique completability with high probability. For the sake

of simplicity, as in Section 4 we consider the sampled tensor $\mathcal{U} \in \mathbb{R}^{\overbrace{n \times \ldots \times n}^{d}}$. Recall that for the general values of $n_1, \ldots, n_d$ the same proof will still work, but instead of assumption $n > \max\{200, (r+2)(d-2)\}$, we need another assumption in terms of $n_1, \ldots, n_d$.

Theorem 27 *Assume that $d > 2$, $n > \max\{200, (r+2)(d-2)\}$, $r \leq \frac{n}{6}$ and $I = \{1, 2, \ldots, d-2\}$. Assume that each column of $\widetilde{\mathbf{\Omega}}_{(I)}$ includes at least l nonzero entries, where*

$$l > \max\left\{27 \log\left(\frac{2n}{\epsilon}\right) + 9 \log\left(\frac{8r(d-2)}{\epsilon}\right) + 18, 6r\right\}. \tag{35}$$

Then, with probability at least $1-\epsilon$, for almost every $\mathcal{U} \in \mathbb{R}^{\overbrace{n \times \ldots \times n}^{d}}$, there exist only one completion of the sampled tensor $\mathcal{U}$ with CP rank r.

Proof Similar to the proof of Theorem 20, define the $(d-1)$-way tensor $\mathcal{U}' \in \mathbb{R}^{\overbrace{n \times \ldots \times n}^{d-2} \times n^2}$ which is obtained through merging the $(d-1)$-th and d-th dimensions of the tensor $\mathcal{U}$ and recall that the finiteness of the number of completions of the tensor $\mathcal{U}'$ of rank r ensures the finiteness of the number of completions of the tensor $\mathcal{U}$ with rank r. Similarly, for simplicity, assume that Ω and $\breve{\Omega}$ denote the $(d-1)$-way sampling pattern and constraint tensors corresponding to $\mathcal{U}'$, respectively. Note that since $n > (r+2)(d-2)$, we conclude $n^2 > r(n-r) + (d-3)r(n-1) + 2(d-2)$, and therefore $\widetilde{\mathbf{\Omega}}_{(I)}$ includes more than $r(n-r) + (d-3)r(n-1) + 2n(d-2)$ columns. According to the proof of Theorem 20, considering $r(n-r) + (d-3)r(n-1)$ arbitrary columns of $\widetilde{\mathbf{\Omega}}_{(I)}$ results in existence of $\breve{\Omega}'$ such that condition (i) holds with probability at least $1 - \frac{\epsilon}{2}$. Also, there exist at least $2n(d-2)$ columns other than these $r(n-r) + (d-3)r(n-1)$ columns.

Consider $n-1$ arbitrary columns of $\widetilde{\mathbf{\Omega}}_{(I)}$. By setting $r = 1$ in the statement of Lemma 19, these $n-1$ columns result in $\breve{\Omega}''^{i}$ with $n-1$ columns such that with probability at least $1 - \frac{\epsilon}{4r(d-2)}$, (31) holds. Similarly, consider $n-r$ arbitrary columns of $\widetilde{\mathbf{\Omega}}_{(I)}$. Then, there exists $\breve{\Omega}''^{i+d-2}$ such that with probability at least $1 - \frac{\epsilon}{4r(d-2)}$, (32) holds. Hence, condition (ii) holds (for all $i \in \{1, \ldots, 2d-4\}$) with probability at least $1 - \frac{\epsilon}{2r}$. Therefore, conditions (i) and (ii) hold with probability at least $1 - \left(\frac{\epsilon}{2r} + \frac{\epsilon}{2}\right) \geq 1 - \epsilon$. ■

Remark 28 *A tensor $\mathcal{U}$ that satisfies the properties in the statement of Theorem 27 requires*

$$n^2 \max\left\{27 \log\left(\frac{2n}{\epsilon}\right) + 9 \log\left(\frac{8r(d-2)}{\epsilon}\right) + 18, 6r\right\} \tag{36}$$

samples to be uniquely completable with probability at least $1-\epsilon$, which is orders-of-magnitude lower than the number of samples required by the unfolding approach given in (14)*. Note that the number of samples given in Theorem 3 of (Pimentel-Alarcón et al., 2016d) results in both finite and unique completability, and therefore the number of samples required by the unfolding approach given in Remark 15 is for both finite and unique completability.*

Lemma 29 *Assume that $d > 2$, $n > \max\{200, (r+2)(d-2)\}$ and $r \leq \frac{n}{6}$. Moreover, assume that the sampling probability satisfies*

$$p > \frac{1}{n^{d-2}} \max\left\{27 \log\left(\frac{2n}{\epsilon}\right) + 9 \log\left(\frac{8r(d-2)}{\epsilon}\right) + 18, 6r\right\} + \frac{1}{\sqrt[4]{n^{d-2}}} \tag{37}$$

Then, with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, $\mathcal{U}$ is finitely completable.

Proof The proof is similar to the proof of Lemma 24. ■

Remark 30 *Theorem 27 ensures that there exist enough number of algebraically independent polynomials and according to Theorem 26, these algebraically independent polynomials can be distinguished among all the polynomials, which has a unique solution that leads to the unique completion of the sampled tensor. Hence, Theorem 27 characterizes an information-theoretic sampling rate for completing the sampled data. However, one direction for future research is to propose an algorithm that solves this particular system of polynomials obtained from Theorem 26 in order to achieve the bound in Theorem 27 and close the gap. Note that there are some fast methods to approximate the zero of the system polynomials including generalizations of Newton-Raphson method, which is independent from this work as in this work we find the information-theoretic rate of sampling to ensure the proposed combinatorial deterministic conditions hold.*

6. Numerical Comparisons

In order to show the advantage of our proposed CP approach over the unfolding approach, we compare the lower bound on the total number of samples that is required for finite completability using an example. Since the bound on the number of samples for finiteness and uniqueness are the same for the unfolding approach and they are almost the same for the CP approach, we only consider finiteness bounds for this example. In particular, we consider a 7-way tensor $\mathcal{U}$ ($d = 7$) such that each dimension size is $n = 10^3$. We also consider the CP rank r which varies from 1 to 150. Figure 1 plots the bounds given in (14) (unfolding approach) and in (29) (CP approach) for the corresponding rank value, where $\epsilon = 0.001$. It is seen that the number of samples required by the proposed CP approach is substantially lower than that is required by the unfolding approach.

Observe that the unfolding approach does not take advantage of the structural property of the underlying CP model properly, and therefore our proposed multi-way analysis on CP manifold significantly outperforms the simple two-way analysis.

7. Conclusions

This paper is concerned with the low CP rank tensor completion problem and aims to derive fundamental conditions on the sampling pattern for finite and unique completability of a sampled tensor given its CP rank. In order to do so, a novel algebraic geometry analysis on the CP manifold is proposed. In particular, each sampled entry can be treated as a polynomials in terms of the entries of the components of the CP decomposition. We have defined a geometric pattern which classifies all CP decompositions such that each class includes only one decomposition of any tensor. We have

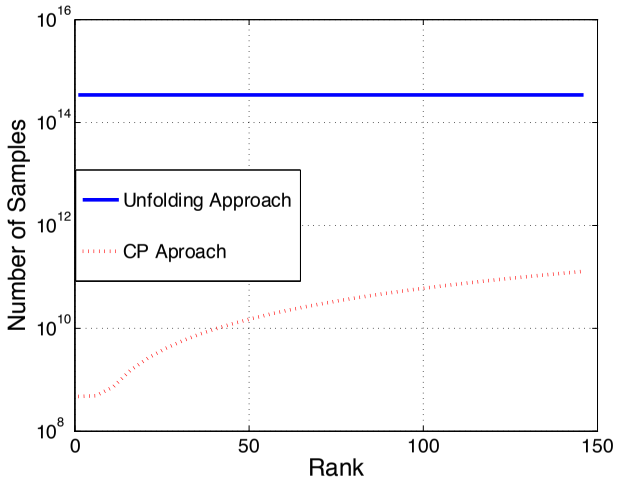

Figure 1: Lower bounds on the number of samples for a 7-way tensor.

shown that finite completability is equivalent to having a certain number of algebraically independent polynomials among all the defined polynomials based on the sampled entries. Furthermore, using the proposed classification, we can characterize the maximum number of algebraically independent polynomials in terms of a simple function of the sampling pattern. Moreover, we have developed several combinatorial tools that are used to bound the number of samples to ensure finite completability with high probability. Using these developed tools, we have treated three problems in this paper: (i) Characterizing the deterministic necessary and sufficient conditions on the sampling pattern, under which there are only finitely many completions given the CP rank, (ii) Characterizing deterministic sufficient conditions on the sampling pattern, under which there exists exactly one completion given the CP rank, (iii) Deriving lower bounds on the sampling probability or the number of samples such that the obtained deterministic conditions in Problems (i) and (ii) are satisfied with high probability. In addition, it is seen that our proposed CP analysis leads to an orders-of-magnitude lower number of samples than the unfolding approach that is based on analysis on the Grassmannian manifold.

Abstract

In machine learning, one often encounters data sets where a general pattern is violated by a relatively small number of exceptions (for example, a rule that says that all birds can fly is violated by examples such as penguins). This complicates the concept learning process and may lead to the rejection of some simple and expressive rules that cover many cases. In this paper we present an approach to this problem in description logic learning by computing partial descriptions (which are not necessarily entirely complete) of both positive and negative examples and combining them. Our *Symmetric Parallel Class Expression Learning* approach enables the generation of general rules with exception patterns included. We demonstrate that this algorithm provides significantly better results (in terms of metrics such as accuracy, search space covered, and learning time) than standard approaches on some typical data sets. Further, the approach has the added benefit that it can be parallelised relatively simply, leading to much faster exploration of the search tree on modern computers.

Keywords: description logic learning, parallel, symmetric, exception

1. Introduction

In machine learning we seek general rules that describe data. However, it is not uncommon for there to be exceptions to general rules, i.e., particular situations where those rules do not apply. In this situation, non-monotonic reasoning can be used, and a default rule that covers most of the cases is retracted if further evidence is provided that overrides the general case. Non-monotonic reason will be discussed more in Section 4.1.

For example, in the classic *Tweety* demonstration of logical proof, the first assertion is that *'Birds fly'*. This is *generally* true, and so the follow-up statement that *'Tweety is a bird'* has the implication that *'Tweety can fly'*. However, there are several species of bird that cannot fly, such as penguins. This type of example can be covered by a set of extra statements: *'Penguins are birds. Penguins do not fly. Tweety is a penguin.'* Non-monotonic reasoning is able to retract the earlier inference that *'Tweety can fly'* given the extra information that *'Tweety is a penguin.'*

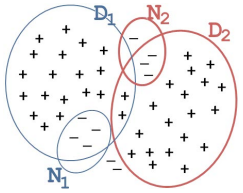
An alternative approach to this is to make the general rules correct by listing the exceptions: *'Birds fly **except** penguins'*. Providing that the complete rule is still 'simpler' (e.g., shorter) than other rules that describe the same situation (i.e., enumerations, or disjunctions of types of birds that can fly), this can provide a net gain in learning. Thus, a short general rule can be augmented by a set of exception rules that make the general rule correct. In the Tweety case this could be a list of counter-examples, possibly by species and genus, such as *'All birds can fly except ratites and penguins'*.

In this paper, we enable such use of exception for description logics by explicitly considering negative examples and building rules for them. As we will show, this leads to a parallel algorithm that treats positive and negative examples in exactly the same way (thus meaning that the learning would be invariant to a switch between positive and negative in the data). Experiments on a variety of standard learning problems demonstrate that this algorithm is statistically significantly faster and more accurate than standard approaches from the literature.

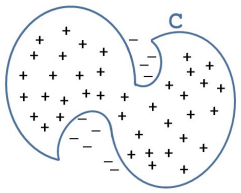
Most existing description logic (DL) learning algorithms, e.g. $\mathcal{AL}$ − CELOE (Lisi and Malerba, 2003), DL-FOIL (Fanizzi et al., 2008), CELOE (Lehmann and Hitzler, 2010) and ParCEL (Tran et al., 2012), only take the definitions of negative examples into account implicitly, by incorporating them into the definitions of positive examples. Learning starts from a very general concept, usually 'top' in DL, and subclasses and sub-properties, conjunction (intersection) and the combination of conjunction and negation (subtraction) are used to remove the negative examples from the candidate concepts.

While this approach is suitable for many concept learning problems and has been used successfully by Hellmann (2008); Lehmann and Hitzler (2010); Tran et al. (2012), it does not use descriptions in the search space efficiently. Consider a top-down approach for learning such as CELOE, which constructs the search tree using a downward refinement operator until it finds a node (expression) that correctly and completely defines the positive examples. Given a concept learning problem with a set of positive (+) and negative (−) examples, the concepts D_1, D_2, N_1, N_2 and their coverage[1] as described in Figure 1(a), CELOE will find the single concept $C = (D_1 \sqcap \neg N_1) \sqcup (D_2 \sqcap \neg N_2)$ (shown in Figure 1(b)).



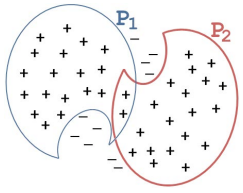
Algorithms that combine both top-down and bottom-up approaches (such as ParCEL and DL-FOIL) find two simpler concepts: $P_1 = D_1 \sqcap \neg N_1$ and $P_2 = D_2 \sqcap \neg N_2$. These concepts are visualised in Figure 1(c). If all of the concepts D_1, D_2, N_1 and N_2 have the same length of 3, then the length of the longest concepts generated by these two approaches are 16 (4 concepts of length 3 plus 4 operators) and 8 (2 concepts of length 3 plus 2 operators) respectively. If a concept is of length 16 then it must occur at a depth of at least 16 in the search tree, and so CELOE will only be able to identify this concept after searching the previous 15 levels of the search tree. As the expansion of the search tree in these approaches is directed by a heuristic that is based upon accuracy, not all branches of the search tree are fully expanded; this prevents 'dummy' breadth-first expansion.

The difference between these two methods is the way that the search tree is constructed: CELOE refines a general concept, while ParCEL searches for partial solutions that provide a correct (true) description of a subset of the data, and combines them to generate a complete solution. This idea of partial solutions can be extended to define exceptions as



1. Coverage of a concept is the set of its instances, see Definition 1

Figure 1: Exception patterns in learning. Pluses (+) denote positive examples, minuses (–) denote negative examples. The ellipses represent coverage of the corresponding class expressions.



(a) The target concept can be constituted from simple descriptions D_1, D_2, N_1 and N_2: $(D_1 \sqcap \neg N_1) \sqcup (D_2 \sqcap \neg N_2)$. The description would be given by the SPaCEL learning algorithm described in this paper.

(b) CELOE learnt concept: a single complex description $C = (D_1 \sqcap \neg N_1) \sqcup (D_2 \sqcap \neg N_2)$ is required

(c) ParCEL learnt concepts: constructed from more complex descriptions $P_1 = D_1 \sqcap \neg N_1$ and $P_2 = D_2 \sqcap \neg N_2$ describe the data set concisely

partial descriptions of negative examples, and this is what we consider in this paper. It enables a learning algorithm to find the solution suggested in Figure 1(a), which is at depth three in the search tree that combines descriptions of positive and negative examples separately. This is the main idea of the algorithm that we propose in this paper, which we call SPaCEL for reasons that will be made clear later, and which treats positive and negative examples equally and can search for their definition in parallel. Definitions of negative examples can then be combined with other concepts in the search tree to construct new partial solutions. In the case of the example in Figure 1, definitions N_1 and N_2 of negative examples, which are ignored by CELOE and ParCEL, are employed by SPaCEL and are combined with concepts D_1 and D_2 to to constitute partial solutions $D_1 \sqcap \neg N_1$ (equivalent to P_1 in CELOE) and $D_2 \sqcap \neg N_2$ (equivalent to P_2 in CELOE). In some cases, definitions of negative examples can be very simple and thus they can be found very early in the search process. In addition, each negative example can be combined with a variety of concepts to constitute several partial solutions. This will result in smaller search trees and faster learning time. Our evaluation shows that this approach works well not only in cases where exceptions exist, but also in normal cases.

Figure 2, which extends the *Tweety* example using the knowledge base shown in Figure 2(a), provides another simple example of the benefits of exceptions. For the instances given in Figure 2(b) (where b_i are instances of Bird, p_i instances of Penguin, c_k instances of Mammal and t_m instances of Bat), the p_i can be considered as exceptions to a rule that says that birds fly, and likewise t_m for a rule that says that mammals do not. Figure 2(c) represents the search tree for the three learning strategies described above. Finding a complete definition (triple-line node, e.g., CELOE) requires a deeper search tree than finding several shorter partial definitions (double-line nodes, e.g. ParCEL, DL-FOIL). However, using definitions of exceptions (dotted-line nodes) can produce even shallower search trees.

Further, since some 'useful' definitions (such as `Bat` in this example) are based on negative examples, they may be ignored by the first two approaches.

Another, more complex example that demonstrates differences between the three approaches is in the uncle relationship for the Forte Uncle data set. The knowledge base of this data set contains concepts and relations that are related to family relationships, such as *Person, Male, Female, married, has parent, has sibling*, etc. It also includes some instances of people and their properties. For example, *Alfred* is a male and is the father of David and Elisa. *Alice* is a female, she is married to Art and is the mother of F14, M13, M15. *Art* is a male and he is the father of F14, M13 and M15. He also has two siblings, Umo and Wendy. *Wendy* is a female and is married to Walt. She has two children, F12 and M11. Her siblings are Art and Umo. In this set, Art is a positive example of an uncle, and Alfred, Alice and Wendy are negative examples (Alfred does not have siblings, Alice and Wendy are female). There are a total of 186 instances in the data set. A detailed description of this data set is provided in Section 3.1.

Written in Manchester syntax (Horridge and Patel-Schneider, 2009) and also in English, definitions of the uncle relationship learnt by the three different approaches are :

- **CELOE:** generates a single complex solution of length 15:

  male AND ((married SOME hasSibling SOME Person) OR
  (married SOME hasSibling SOME hasChild SOME Thing))

  (An uncle is a male who has married someone with a sibling; or a man who married someone's sibling and the sibling has some children)

- **ParCEL:** generates two partial solutions of length 7 and 9:

  1. male AND hasSibling SOME hasChild SOME Thing

     (An uncle is a man who has at least sibling and a sibling has children)

  2. male AND married SOME hasSibling SOME hasChild SOME Thing

     (An uncle is a man who married someone with at least one sibling, and that sibling has a child)

- **SPaCEL:** generates two partial solutions that are created by combining two concepts "hasSibling SOME hasChild SOME Thing" of length 5 and "married SOME hasSibling SOME hasChild SOME Thing" of length 7 with a partial solution "female" of negative examples:

  1. hasSibling SOME hasChild SOME Thing AND (NOT female)

     (An uncle is a person who has a sibling with children, and who is not female)

  2. married SOME hasSibling SOME hasChild SOME Thing AND (NOT female)

     (An uncle is a person who married someone with a sibling who has children and who is not female)

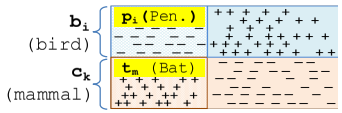


Figure 2: Different approaches to learning the definition for the *extended Tweety* concept learning problem.

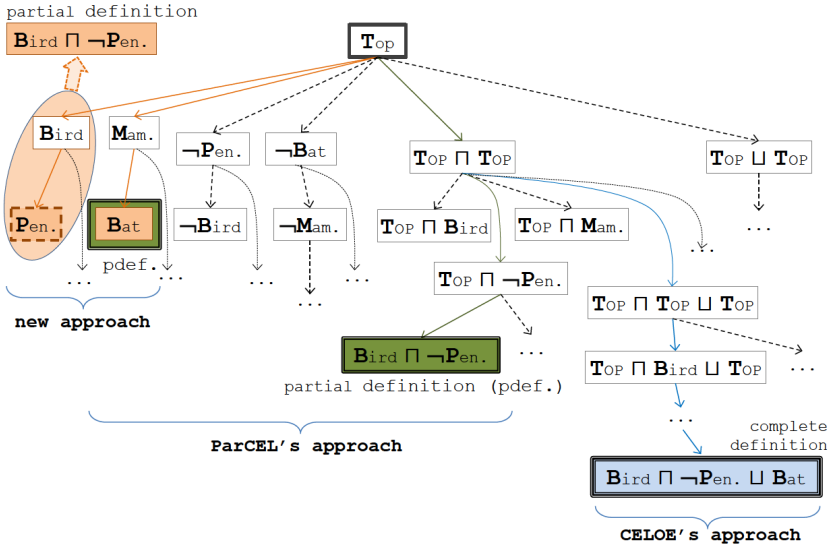
(a) The knowledge base of the learning problem.



Concepts	Instances
Top	
Bird	$\{b_i\}$
Penguin	$\{p_j\}$
Mammal	$\{c_k\}$
Bat	$\{t_m\}$
Fly	$\{b_i, t_m\}$
¬Fly	$\{p_j, c_k\}$

observations

(b) Visualisation of the knowledge base.

(c) The search tree for learning the *extended Tweety* example using three different approaches. *Triple-line nodes* represent complete definitions (e.g., CELOE). *Double-line nodes* represent partial definitions (e.g., ParCEL). *Dashed-line nodes* represent definitions of some negative examples. The *ellipses* represent the combinations of an (incorrect and incomplete) expression with a definition of negative examples that constitutes a partial definition. *Solid arrows* represent the paths to the definitions for positive or negative examples.

The partial solution of negative examples can be found in an early stage of the learning progress. However, it is ignored by CELOE and ParCEL, whereas SPaCEL employs it for later combinations with concepts in the search tree to generate partial solutions if possible. All three solutions are valid, but the SPaCEL one can be found more quickly.

Using exceptions could increase the risk of selective over-fitting, since sub-cases are given high weight, but the emphasis on short descriptions for the general rules, and the fact that the exception cases are also based on short descriptions, ensures that this is unlikely to happen. We present experimental evidence that this method often gives higher predictive accuracy on test data. It is true that logical formulae based on exceptions can quickly become torturous, as a short general description gets progressively more complex caveats added to it, and possibly even exceptions to the exceptions. However, the constraints on search that are implicit in logic programming (such as search tree size, definition length, and learning time) means that these complex cases are very unlikely to ever be found.

One key part of our approach is that positive and negative examples are treated in the same way; this 'symmetry' gives us the name of our algorithm: *Symmetric Parallel Class Expression Learning* (SPaCEL). A secondary point (referred to in the 'parallel' part of the name) is that the algorithm is inherently parallelisable in the first phase of learning, where separate definitions of positive and negative examples are sought. These definitions are combined in the second phase to construct a sufficiently accurate definition. By using rules about negative examples to remove them from the concepts in the search tree it is possible to combine (potentially very short) concepts and so define relatively complex concepts based on much smaller depth traversals. Consequently, concepts in the search tree are used more effectively and thus the learning time can be reduced.

We present a formal definition of our learning algorithm in Section 2, together with a discussion of various strategies for combining partial definitions of positive and negative examples. In addition, we demonstrate the parallelisation strategy that is one part of what makes our algorithm so effective computationally. We then present the data sets that we use for evaluation in Section 3.1, followed by a comparison of the three strategies for combining definitions that we have considered. Following this, in Section 3.3 we report search tree size, predictive accuracy, learning time, and definition length for 15 data sets of varying complexity for CELOE, ParCEL and SPaCEL. In Section 4.1, we summarise some related work before concluding with a summary and discussion of future work in Section 5.

2. Symmetric Parallel Class Expression Learning

Our learning approach constructs definitions of both positive and negative examples and gives them equal weight in order to find the final definition. This is performed in three main steps:

1. Find partial definitions for positive and negative examples separately such that the set of definitions, together, cover all positive and negative examples.
2. Consolidate the partial definitions to remove redundancies (i.e., the partial definitions whose coverage is a subset of the union of other partial definitions) and select the best candidates for constructing a complete definition.
3. Aggregate the best candidates to form the complete definition using disjunction.

In the first step, partial definitions can be produced directly by specialisation using a downward refinement operator, as in algorithms such as DL-FOIL and ParCEL. Definitions for negative examples are constructed side-by-side with definitions for positive examples and are used in combination with existing expressions in the search tree to create further partial definitions.

In the next section we introduce the concepts necessary for our algorithms. The algorithms themselves will be presented in Section 2.2. We follow the definitions used by Lehmann and Hitzler (2010) closely, although some of the concepts have to be extended in order to include negative examples.

2.1 Symmetric class expression learning

A *concept learning problem* in description logics can be described as a structure $\langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$ where $\mathcal{K}$ is a knowledge base (ontology), $\mathcal{E}^+$ is a set of positive examples and $\mathcal{E}^-$ is a set of negative examples such that $\mathcal{E}^+ \cap \mathcal{E}^- = \emptyset$. A learnt concept is also called a *hypothesis* or *definition*. $\mathcal{K} \models C(a)$ denotes that a is an instance of class C with respect to the knowledge base $\mathcal{K}$. If $\mathcal{K} \models C(a)$ is satisfied, C is said to *cover* a with respect to $\mathcal{K}$. The aim of *description logic learning* is to find a concept C such that $\mathcal{K} \models C(e)$ for all $e \in \mathcal{E}^+$ (*completeness*) and $\mathcal{K} \not\models C(e)$ for all $e \in \mathcal{E}^-$ (*correctness*). A learnt concept is called *complete* if it covers all positive examples, *correct* if it does not cover any negative examples, *accurate* if it is both complete and correct, *overly general* if it is complete but incorrect, and *overly specific* if it is correct but incomplete.

In order to define negative examples, we extend the concept *cover* for a set of instances in the form of a function, as follows:

Definition 1 (Cover) *Let $\mathcal{K}$ be a logic knowledge base, $\mathcal{X}$ be a set of instances and* C *be a concept. Then,* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{X})$ *is a function that computes a set of examples in $\mathcal{X}$ covered by* C *with respect to $\mathcal{K}$:*

$$\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{X}) = \{\mathrm{e} \in \mathcal{X} \mid \mathcal{K} \models C(e) (\text{that is:e } \textit{is covered by } \mathrm{C} \textit{ with respect to } \mathcal{K})\}$$

This can be generalised to a set of definitions as:

$$cover(\mathcal{K}, \mathcal{Q}, \mathcal{X}) = \bigcup_{C \in \mathcal{Q}} cover(\mathcal{K}, \mathrm{C}, \mathcal{X})$$

where $\mathcal{K}$ be a knowledge base, $\mathcal{X}$ be a set of instances and $\mathcal{Q}$ be a set of definitions.

Definition 1 enables us to give definitions of positive examples (which are called *partial definitions*) and negative examples (which are called *counter-partial definitions*):

Definition 2 (Partial definition) *For a concept learning problem $\langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$, a concept* C *is called a* partial definition *if* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^+) \neq \emptyset$ *and* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^-) = \emptyset$.

Definition 3 (Counter-partial definition) *For a concept learning problem $\langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$, a concept* C *is called a* counter-partial definition *if* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^+) = \emptyset$ *and* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^-) \neq \emptyset$.

Definitions 2 and 3 are 'ideal' in that they insist on the cover of the opposite set being the empty set. In practice, it is possible to allow a few negative examples to be covered by a partial definition, and a few positive examples by a counter-partial definition; this could potentially help with noisy data.

The first (top-down) step of our algorithm consists of finding partial and counter-partial definitions separately using a refinement operator and a combination strategy to compute further partial definitions from the counter-partial definitions and existing expressions in the search tree. As these searches are performed separately and simultaneously, our approach avoids being over-specific for concept learning problems that contain exceptions.

These sets are then combined, which enables the algorithm to cope with exceptions to general rules through the opposing definitions (so rules made of partial definitions can have counter-partial definitions added, and vice versa). This is simply the use of conjunction and negation, The combination acts as an extra step to deal with the exceptions with the support of counter-partial definitions. In our approach, only one downward refinement operator is used in the specialisation step to generate both partial and counter-partial definitions. The combination strategy essentially consists of checking for the possibility of creating new partial definitions from an expression and counter-partial definitions, using conjunction and negation: a combination of an expression C with a set of counter-partial definitions $\mathcal{X}$ has the form $C \sqcap \neg(\sqcup_{D \in \mathcal{X}} D)$.

Definition 4 (Combinability) *Given a concept learning problem* $\mathrm{LP} = \langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$, *a set of counter-partial definitions $\mathcal{Q}$, and an expression* C *such that* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^+) \neq \emptyset$ *and* $\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^-) \neq \emptyset$, C *is said to be* combinable *with $\mathcal{Q}$ iff:*

$$\mathrm{cover}(\mathcal{K}, \mathrm{C}, \mathcal{E}^-) \subseteq \mathrm{cover}(\mathcal{K}, \mathcal{Q}, \mathcal{E}^-),$$

which means that C *can be "corrected" by $\mathcal{Q}$.*

The main objective of the combination step is to check for the combinability of descriptions in the search tree. Combining definitions can be performed at several stages of the learning algorithm; this is discussed further in Section 2.3.

In this paper, we employ the refinement operator used by Lehmann and Hitzler (2010). However, the combination step helps us avoid the usage of negation in the refinement without any loss of generality, and the use of *partial models* and disjunction in the reduction steps means there is no need for disjunction in the refinement. Therefore, we use only 5 of the 7 basic rules in the original refinement operator described by Lehmann and Hitzler (2010). The two rules which refine the negation and disjunction are not used, thus our refinement operator is defined as:

Definition 5 (SPaCEL refinement operator $\rho_\sqcap$) *Given an expression* C, *a set of concept names* $\mathrm{N_C}$ *and a set of property (role) names* $\mathrm{N_R}$, *then $\rho_\sqcap$ is defined as follows:*

1. *if $C \in N_C$ (C is an atomic concept):*
   $\rho_\sqcap(C) = \{C' \mid C' \sqsubset C \text{ and } \nexists C'' \in N_C : C' \sqsubset C'' \sqsubset C\} \cup \{C \sqcap C' \mid C' \in \rho_\sqcap(\top)\}$
   (if C is an atomic concept, it is specialised by using its proper sub-concepts or creating a conjunction with the refinements of the `TOP` *concept $\rho_\sqcap(\top)$).*

2. *if* $C = \top$ *(*C *is the* TOP *concept):*
$\rho_\sqcap(C) = \{C' \mid C' \in N_C, \nexists C'' \in N_C : C' \sqsubset C'' \sqsubset C\}$
$\cup\ \{\exists r.\top \mid r \in N_R\}\ \cup\ \{\forall r.\top \mid r \in N_R\}$
(if C *is the* TOP *concept, specialise it by using its proper sub-concepts or property restrictions)*

3. *if* $C = C_1 \sqcap ... \sqcap C_n$ *(*C *is a conjunctive of descriptions):*
$\rho_\sqcap(C) = \{C_1 \sqcap ... \sqcap C' \sqcap ... \sqcap C_n \mid C' \in \rho_\sqcap(C_i), 1 \leq i \leq n\}$
(if C *is a conjunction, it is specialised by refinements of its conjuncts)*

4. *if* $C = \forall r.D, r \in N_R$*:* $\rho_\sqcap(C) = \{\forall r.D' \mid D' \in \rho_\sqcap(D)\}$
$\cup\ \{\forall r.\bot \mid D = A \in N_C$ and $\nexists A' \in N_C$ *s.t.* $A' \sqsubset A\}$
(if C *is a 'for all' property restriction, it is specialised by refinements of its range)*

5. *if* $C = \exists r.D, r \in N_R$*:* $\rho_\sqcap(C) = \{\exists r.D' \mid D' \in \rho_\sqcap(D)\}$
(this rule is for the 'there exists' property restriction, and is similar to the 4^{th} *rule.)*

Note that in the expression for $\rho_\sqcap$ in the second rule, negation and disjunction are not used, since they can be generated by *combination* and *aggregation* (steps 2 and 3 of our algorithm) respectively.

The top-down step finishes when either the partial definitions cover all positive examples or the counter-partial definitions cover all negative examples (up to allowable noise), which produces this formal definition (where the first line of this describes as the union of correct descriptions of the positive data and correctable descriptions of the same data):

Definition 6 (SPaCEL top-down learning) *Given a concept learning problem* $LP = \langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-)\rangle$*, the top-down learning step in this approach aims to find a set of partial definitions* $\mathcal{P}$*, a set of counter-partial definitions* $\mathcal{Q}$ *and a set of expressions* $\mathcal{X}$ *such that:*

$$cover(\mathcal{K}, \mathcal{P}, \mathcal{E}^+) \cup cover(\mathcal{K}, \mathcal{X}, \mathcal{E}^+) = \mathcal{E}^+,$$
$$\text{such that } \forall C \in \mathcal{X} \mid C \text{ is combinable with } \mathcal{Q}, \text{ or}$$
$$cover(\mathcal{K}, \mathcal{Q}, \mathcal{E}^-) = \mathcal{E}^-.$$

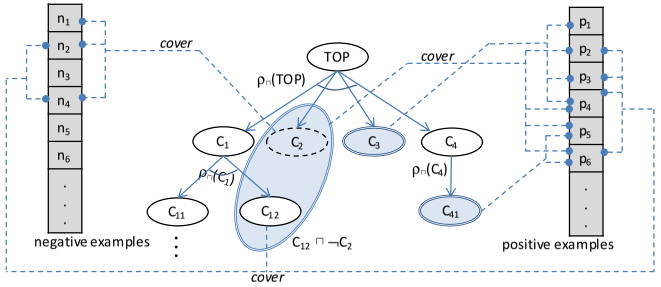


Figure 3 demonstrates the top-down step in our approach that uses the refinement operator $\rho_\sqcap$ to produce both partial and counter-partial definitions. In this example, the combination of the counter-partial definition C_2 and the expression C_{12} creates a partial definition $C_{12} \sqcap \neg C_2$.

As in the ParCEL algorithm, the selection of expressions in the search tree for refinement is controlled by node scores that are computed by a learning heuristic. The particular learning heuristic that we use is adapted from Lehmann and Hitzler (2010). However, the factors involving in the scoring function and their weights are redefined accordingly to our learning strategy:

Definition 7 (SPaCEL score) *Let* $LP = \langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-)\rangle$ *be a concept learning problem,* C *be a class expression and* C' *the parent expression of* C*. The score of* C *is computed as:*

$$score(C) = correctness(C, LP) + \alpha \times gain(C, LP) + \beta \times completeness(C, LP) - \gamma \times length(C, LP)$$
$$(\alpha \geq 0, \beta \geq 0, \gamma \geq 0)$$

Figure 3: The top-down learning step aims to find both partial definitions and counter-partial definitions. *Double-line* nodes are *partial definitions*, *dashed-line nodes* are *counter-partial definitions*. $\rho_\sqcap$ is the refinement operator defined in Definition 5. *Connections* from nodes to examples represent the *coverage* of the expressions.

where $gain(C, LP) = accuracy(C, LP) - accuracy(C', LP)$.

In this definition, correctness, completeness and accuracy have their standard meanings, i.e., (Lehmann and Hitzler, 2010):

$$correctness(C, LP) = \frac{|\mathcal{E}^- \backslash cover(|\mathcal{K}, C, \mathcal{E}^-)|}{|\mathcal{E}^-|},$$
$$completeness(C, LP) = \frac{|cover(\mathcal{K}, C, \mathcal{E}^+)|}{|\mathcal{E}^+|},$$
$$accuracy(C, LP) = \frac{|cover(\mathcal{K}, C, \mathcal{E}^+)| + |\mathcal{E}^- \backslash cover(\mathcal{K}, C, \mathcal{E}^-)|}{|\mathcal{E}^+ \cup \mathcal{E}^-|}.$$

The length of an expression is taken to be the sum of the number of concept names, role names, quantifiers, and connective symbols occurring in the expression, which for expressions in the $\mathcal{ALC}$ language can be defined as:

Definition 8 (Length of an $\mathcal{ALC}$ expression) *The length of an expression* D *or* E *(denoted by* $|D|$*) is defined inductively as follow (where* A *denotes an atomic concept):*

$$|A| = |\top| = |\bot| = 1$$
$$|\neg D| = |D| + 1$$
$$|D \cup E| = |D \cap E| = 1 + |D| + |E|$$
$$|\exists r.D| = |\forall r.D| = 2 + |D|$$

The learning heuristic is mainly based on the correctness of the class expression (in contrast to that of Lehmann and Hitzler (2010), which is based on accuracy). A penalty is applied for long definitions to avoid infinitely deep search (necessary because the refinement operator used in our learning algorithm is infinite). A bonus for accuracy gained by an

expression is also applied, as accurate expressions are more likely to be close to the solution. A bonus is also given for the relatively complete expressions.

Default values for the weightings of the above factors were chosen based on experimental investigations and the work by Lehmann and Hitzler (2010). We chose $\alpha = 0.2, \beta = 0.01, \gamma = 0.05$. These values can be adjusted based on the characteristics of the learning problem, such as decreasing the penalty for learning problems that need long definitions, thus biasing the search to look for deeper solutions.

The last step of our algorithm, the aggregation of the best candidates, can be performed using disjunction.

One optimisation step that can be applied to our learning is to notice *irrelevant concepts* and remove them from the search tree. Irrelevant concepts are those from which no partial or counter-partial definition can be produced, hence they cannot be expanded. An irrelevant concept in SPaCEL is defined as follows:

Definition 9 (Irrelevant concept) *Given a concept learning problem* $LP = \langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$*, a concept* C *is* irrelevant *if* $cover(\mathcal{K}, C, \mathcal{E}^+) = \emptyset$ *and* $cover(\mathcal{K}, C, \mathcal{E}^-) = \emptyset$*, i.e., it covers no positive and no negative examples.*

2.2 The algorithms

The SPaCEL learning algorithm is essentially top-down learning combined with a reduction task. The top-down step is used to solve the sub-problems of the given concept learning problem and the reduction is used to reduce and combine the sub-solutions into an overall solution. The former is performed by the downward refinement operator and a combination strategy, while the latter uses a set coverage algorithm to choose the best partial definitions and disjunction to form the overall solution.

Algorithm 1 describes the main loop of our learning algorithm, the *reducer*. It chooses the best concepts (i.e., those with highest score, based on the search heuristic described in Definition 7) from the search tree and uses the SPECIALISE algorithm (see Algorithm 2) for refinement and evaluation until the completeness of the partial definitions is sufficient. Concepts are scored using an expansion heuristic that is mainly based on the correctness of the concepts. Our reducer is the analogue of the cover removal step in ILP in that it tries to remove redundancies.

The *specialisation*, which performs the refinement and evaluation of the concepts assigned by the learning algorithm, is described in Algorithm 2. It refines the given concept ($\rho_\sqcap(C)$) and evaluates the result ($cover(\mathcal{K}, C, \mathcal{E}^+)$ and $cover(\mathcal{K}, C, \mathcal{E}^-)$). Irrelevant concepts are removed, as no partial definition or counter-partial definition can be computed from them. Then, the specialisation finds new partial definitions, counter-partial definitions and descriptions from the refinements. In practice, new descriptions are checked for redundancy before being evaluated and added to the search tree, as the same description can be generated from different branches of the search tree.

The sets of new descriptions, partial definitions and counter-partial definitions produced by the SPECIALISE algorithm are used to update the corresponding data structures and the set of covered positive and negative examples in the learning algorithm, and the new descriptions are combined with the counter-partial definitions to create new partial definitions

Algorithm 1: Symmetric Class Expression Learning Algorithm– SPACEL($\mathcal{K}, \mathcal{E}^+, \mathcal{E}^-, \varepsilon$)

Input: background knowledge $\mathcal{K}$, a set of positive $\mathcal{E}^+$ and negative $\mathcal{E}^-$ examples, and a noise value $\varepsilon \in [0, 1]$ (0 means no noise)
Output: a definition C such that $|cover(\mathcal{K}, C, \mathcal{E}^+)| \geq (|\mathcal{E}^+| \times (1 - \varepsilon))$ and $cover(\mathcal{K}, C, \mathcal{E}^-) = \emptyset$ (*empty set*)

```
1  begin
2      initialise the search tree ST = {⊤}            /* ⊤: TOP concept in DL */
3      cum_pdefs = ∅            /* set of cumulative partial definitions */
4      cum_cpdefs = ∅  /* set of cumulative counter-partial definitions */
5      cum_cp = ∅        /* set of cumulative covered positive examples */
6      cum_cn = ∅        /* set of cumulative covered negative examples */
       /* cf.  Def.  6 for the meaning of the OR operator */
7      while |cum_cp| < (|E+| × (1 − ε)) or |cum_cn| < |E−| do
8          get and remove the 'best' concept B from ST              /* see text */
9          (pdefs, cpdefs, descriptions) = SPECIALISE(B, E+, E−)      /* cf.Alg.2 */
10         cum_pdefs = cum_pdefs ∪ pdefs
11         cum_cpdefs = cum_cpdefs ∪ cpdefs
12         cum_cp = cum_cp ∪ {e | e ∈ cover(K, P, E+), P ∈ pdefs}
13         cum_cn = cum_cn ∪ {e | e ∈ cover(K, P, E−), P ∈ cpdefs}
           /* online combination, see Sec.2.3 */
14         foreach D ∈ descriptions do
               /* if D can be ''corrected'' by existing cpdefs */
15             if (cover(K, D, E−) \ cum_cn) = ∅ then
                   /* combine D with cpdefs if possible */
16                 candidates = COMBINE(D, cum_cpdefs, E−)          /* cf.Alg.3 */
17                 new_pdef = D ⊓ ¬(⊔_{A∈candidates}(A))      /* new partial def.  */
18                 cum_pdefs = cum_pdefs ∪ new_pdef
19                 cum_cp = cum_cp ∪ cover(K, new_pdef, E+)
20             else
21                 ST = ST ∪ {D}
       /* explore more partial definitions to satisfy completeness */
22     if |cum_cp| < (|E+| × (1 − ε)) then
23         foreach D ∈ ST do
24             candidates = COMBINE(D, cum_cpdefs, E−)
25             new_pdef = D ⊓ ¬(⊔_{A∈candidates}(A))
26             cum_pdefs = cum_pdefs ∪ new_pdef
27     return REDUCE(cum_pdefs)                  /* for description, see text */
```

where possible, a form of theory learning. Concepts that have been refined can be scheduled for further refinements.

The refinement operator given in Definition 5 is infinite (i.e., it can continue to expand the tree without limit), but in practice each refinement step is monotonic and bounded, as it is only allowed to generate descriptions of at most a pre-defined length (see Definition 8). For example, a concept of length N will first be refined to concepts of length $(N+1)$, and later, when it is revisited, to concepts of length $(N+2)$, etc. For the sake of simplicity, we use $\rho_\sqcap$ in the algorithms to refer to one refinement step rather than the entire refinement. This technique is used in DL-Learner and discussed in detail by Lehmann and Hitzler (2010).

When the learning algorithm reaches a sufficient degree of completeness, it stops and reduces the partial definitions to remove the redundancies using the REDUCE function, which is essentially a set coverage algorithm: given a set of partial definitions $\mathcal{X}$ and a set of positive examples $\mathcal{E}^+$, it finds a subset $\mathcal{X}' \subseteq \mathcal{X}$ such that $\mathcal{E}^+ \subseteq \bigcup_{D \in \mathcal{X}'}(cover(\mathcal{K}, D, \mathcal{E}^+))$. The solution returned by the algorithm is a disjunction of the reduced partial definitions. As an alternative, a set of partial definitions could be returned instead. This may be useful in some contexts, such as making the result more readable. The reduction algorithm may be tailored to meet particular requirements, such as the shortest definition or the smallest number of partial definitions. The combination of descriptions and counter-partial definitions that is given in Algorithm 1 is one of the combination strategies implemented in our evaluation. This strategy is called the *on-the-fly* combination strategy; it gave the best performance in our evaluation (see Section 3.2). A description of the various combination strategies we tried is given in Section 2.3.

Algorithm 2: Specialisation algorithm – SPECIALISE($C, \mathcal{K}, \mathcal{E}^+, \mathcal{E}^-$)

Input: a description C and a concept learning problem $LP = \langle \mathcal{K}, (\mathcal{E}^+, \mathcal{E}^-) \rangle$.
Output: a triple consisting of a set of partial definitions $pdefs \subseteq \rho_\sqcap(C)$; a set of counter-partial definitions $cpdefs \subseteq \rho_\sqcap(C)$; and a set of new descriptions $descriptions \subseteq \rho_\sqcap(C)$ such that
$\forall D \in descriptions : D$ is not irrelevant and $D \notin (pdefs \cup cpdefs)$, in which $\rho_\sqcap$ is the refinement operator defined in Definition 5.

begin
  $pdefs = \{D \in \rho_\sqcap(C) \mid cover(\mathcal{K}, D, \mathcal{E}^+) \neq \emptyset \ \wedge \ cover(\mathcal{K}, D, \mathcal{E}^-) = \emptyset\}$
  $cpdefs = \{D \in \rho_\sqcap(C) \mid cover(\mathcal{K}, D, \mathcal{E}^+) = \emptyset \ \wedge \ cover(\mathcal{K}, D, \mathcal{E}^-) \neq \emptyset\}$
  $descriptions = \{D \in \rho_\sqcap(C) \mid cover(\mathcal{K}, D, \mathcal{E}^+) \neq \emptyset \ \wedge \ cover(\mathcal{K}, D, \mathcal{E}^-) \neq \emptyset\}$
  return *(pdefs, cpdefs, descriptions)*

Algorithm 3 describes the *combination algorithm* that is used to combine the descriptions and counter-partial definitions to construct new partial definitions. This is basically a set coverage algorithm. One of the smallest sets of counter-partial definitions that together cover all negative examples covered by the given expression will be returned. This set of counter-partial definitions is then used to correct the given expression.

Algorithm 3: Combination algorithm – COMBINE(C, $cpdefs, \mathcal{E}^-$)

Input: a description C, a set of counter-partial definitions *cpdefs* and a set of negative examples $\mathcal{E}^-$
Output: a set $candidates \subseteq cpdefs$ such that
$cover(\mathcal{K}, C, \mathcal{E}^-) \subseteq \bigcup_{P \in candidates}(cover(\mathcal{K}, P, \mathcal{E}^-))$

begin
  $candidates = \emptyset$ `/* candidate counter-partial definitions */`
  $cn_c = cover(\mathcal{K}, C, \mathcal{E}^-)$ `/* negative examples covered by C */`
  sort *cpdefs* by descending coverage of negative examples
  while $cpdefs \neq \emptyset$ *and* $cn_c \neq \emptyset$ **do**
    get and remove the top counter-partial definition D from *cpdefs*
    if $(cover(\mathcal{K}, D, \mathcal{E}^-) \cap cn_c) \neq \emptyset$ **then**
      $candidates = candidates \cup D$
      $cn_c = cn_c \setminus cover(\mathcal{K}, D, \mathcal{E}^-))$
  if $cn_c \neq \emptyset$ **then**
    return $\emptyset$ `/* return the empty set */`
  else
    return *candidates*

COMPLETENESS OF THE ALGORITHM

The refinement operator used in our algorithm is based on the refinement operator described by Lehmann (2010). In that paper a proof of completeness over the $\mathcal{ALC}$ language is given, i.e., any concepts in the $\mathcal{ALC}$ language can be produced by this operator after a finite number of refinement steps.

Due to our learning strategy, our refinement operator does not generate negation and disjunction. As a result, our refinement operator itself is not complete. However, negation and disjunction can be created by the reduction and combination steps of the algorithm. The combination step uses negation and conjunction to correct an expression with counter-partial definitions (see Algorithm 3 and Definition 4) whereas the reduction step can generate disjunctions. Clearly, the completeness of our algorithm depends upon the combination strategy that produces the negations. Three combination strategies are proposed in Section 2.3, and our learning algorithm is complete when the *on-the-fly* and *delayed* combination strategies are used; completeness is not guaranteed for the *late* combination strategy.

2.3 Counter-partial definitions combination strategies

Counter-partial definitions are combined with expressions in the search tree to create new partial definitions where possible, producing expressions of the form $C \sqcap \neg(\sqcup_{D \in \mathcal{X}} D)$ (for expression C and a set of counter-partial definitions $\mathcal{X}$). The combinability of an expression with respect to a set of counter-partial definitions is given in Definition 4. The combination step can be performed at several stages of the learning algorithm, and different choices have different effects on the learning result. We describe three combination strategies. An evaluation of these strategies is given in Section 3.2.

2.3.1 Late combination

In this strategy, the algorithm maintains sets of partial definitions and counter-partial definitions separately. When all positive or negative examples are covered (or another termination condition is reached, such as maximum time allowed, or a sufficient percentage of examples covered), it will combine descriptions from the search tree and the set of counter-partial definitions.

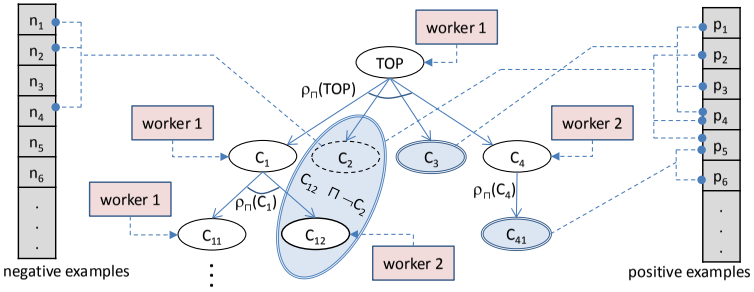
Since the combination is performed after the learning stops, this strategy may provide a better combination, i.e., it may have better choices of counter-partial definitions to use for the combination. However, for concept learning problems in which both positive and negative examples use negation, the algorithm may not be able to find the definition because the refinement operator designed for this algorithm does not use negation. If this is the case and a maximum time timeout is set, then the combination will be made when the timeout is reached in order to find the definition. Otherwise, the algorithm will not terminate.

For example, the concept learning problem shown in Figure 2 may cause this strategy to run out of memory without finding an accurate concept if there is no timeout or no noise is allowed. To cover all positive examples, we need a class expression with negation as follows:

$$\text{Bat} \sqcup (\text{Bird} \sqcap \neg\text{Penguin})$$

and to completely cover all negative examples, the following class expression is needed:

$$\text{Penguin} \sqcup (\text{Mammal} \sqcap \neg\text{Bat})$$



To produce the definition for positive examples, the counter-partial definition `Penguin` needs to be combined with the expression `Bird`, which cannot be performed directly due to the removal of negation from the refinement operator. However, in this strategy, the combination is only called when all positive examples or negative examples are covered, and in the example this condition is never met, as the expression $\neg$`Bat` cannot be produced.

2.3.2 On-the-fly combination

This strategy is used in Algorithm 1. When a new description is generated from the refinement or an existing description is revisited, it is combined with the existing counter-partial definitions if possible. This strategy can avoid the termination problem discussed in the *late combination* strategy because negation is used in the combination. The evaluation suggests that this strategy, overall, gives the best performance and the smallest search tree. However, the final results can be optimised since a counter-partial definition may be combined with many expressions and thus the final definition is unnecessarily long. For example, in the concept learning problem described in Figure 2, when the description `Bird` is generated, there is no counter-partial definition to combine it with. However, when it is revisited for refinement, it will be combined with the new counter-partial definition `Penguin` to produce a partial definition `Bird` $\sqcap$ $\neg$`Penguin`.

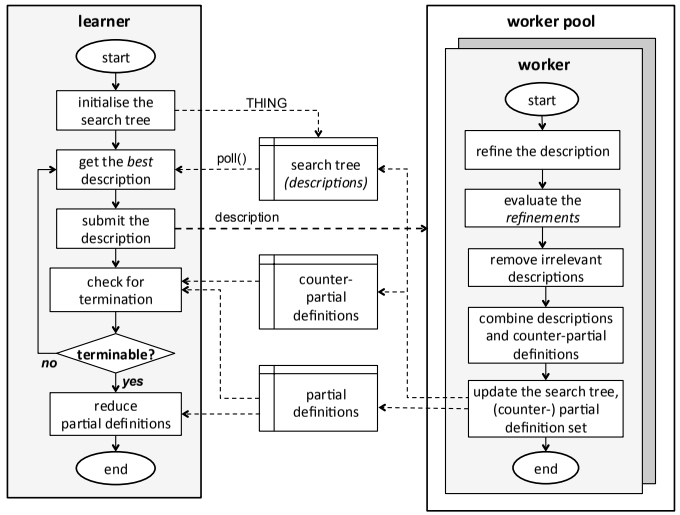
This strategy seems to produce similar results to the original refinement by Lehmann and Hitzler (2010), which can generate negation. However, they are essentially different. In our approach, the negation is only used for counter-partial definitions to remove negative examples from the description in the search tree, while negation may be applied for any description in the original refinement operator. In addition, in our approach, the counter-

Figure 4: Top-down learning in SPaCEL with multiple workers.

partial-definitions are stored to be reused to "correct" the new descriptions in the search tree, while the original refinement may regenerate the same negated description.

2.3.3 Delayed combination

This strategy lies inbetween the previous two, and checks the possibility of combinations when a new description is generated. However, even if the combination is possible, only the set of cumulative covered positive examples is updated (by removing the elements that are covered by the new description), while the new description is put into a *potential partial definitions* set. The combination is executed when the termination condition is reached, i.e., either all positive examples or all negative examples are covered, or the algorithms times out.



This strategy may help to prevent the problem of the late combination strategy, and it may return better combinations in comparison with the *on-the-fly* strategy because it inherits the advantage of the *late combination* strategy. However, as the combinable descriptions in this strategy are not combined until the learning terminates, the search tree is likely to be larger than that of the on-the-fly strategy.

2.4 Parallelisation of the learning algorithm

One benefit of the symmetric approach is that it is inherently parallel: several expressions (branches) in the search tree can be processed (refined and evaluated) in parallel using multiple *workers* to find the partial definitions. A central *reducer*, which is part of the learner, controls the management of partial and counter-partial definitions produced by the workers until the termination condition described in Definition 6 is met. Then it performs the reduction and aggregation steps to create a final definition. The parallel exploration of the search tree by multiple workers is illustrated in Figure 4.

Our organisation of learning tasks described above follows the idea of the map-reduce architecture (Dean and Ghemawat, 2008), which enables the *parallel divide and conquer* strategy. Here, we organise our algorithm architecture into two parts as shown in Figure 5. The computationally heavy parts, including refinement and evaluation of concepts, are

Figure 5: Implementation architecture. Note that the combination step may be performed by the workers or the reducer, depending upon the combination strategy (see Section 2.3).

done by the multiple workers. The combining of descriptions and counter-partial definitions is also performed on the worker side.

3. Evaluation

In order to evaluate the Symmetric Class Expression Learning approach of SPaCEL, we compared it to CELOE and ParCEL using 10-fold cross validation with 15 data sets. These are summarised in Section 3.1, using the search tree size, predictive accuracy and learning time, and the length of the definitions learnt as the metrics for comparison. CELOE is one of the description logic learning algorithms in the DL-Learner framework. It is well-evaluated and has been compared with many other learning algorithms. Therefore, using it for comparison enables an implicit comparison with other learning algorithms; the evaluations by Hellmann (2008); Lehmann (2010) suggest that, overall, CELOE produced better results than the comparators. The implementation of CELOE that we used is publicly available at `https://github.com/tcanvn/SParCEL/`.

Before performing the comparison, we used the same evaluation method to compare the three evaluation strategies described in Section 2.3, meaning that only one of them (the on-the-fly strategy) was used in the comparison experiments.

3.1 Experimental data sets

To ensure the evaluation covers as much as possible of the space of cases, which helps to archive a thorough assessment of the learning algorithms, we chose data sets that vary in: i) size of knowledge base and examples, ii) the length of definitions, and iii) the amount of noise. In some cases, (i) was achieved by using subsets of a particular data set.

The data sets are divided into three groups. The first group includes 7 learning problems that have low to medium complexity and on which all algorithms in the experiment can find solutions on the training set without timing out in the 10 minutes we allowed. The second group contains high to very high complexity learning problems; all algorithms in the experiment can also find accurate solutions on the training set without timing out. The third contains leaning problems for which one of the learning algorithms could not find accurate solution on the training set (i.e. timeout occurred). The complexity of the learning problems is approximately estimated based on the definition length produced by CELOE: i) low: (0, 8]; ii) medium: (8, 15]; iii) high: (15, 20]; and very high: longer than 20. The reason for treating problems learnt with and without timeout separately is that some metrics cannot be compared if the learning algorithm cannot find the solution (e.g. learning time, search space size).

The list of data sets used and their properties are summarised in Table 1, and an overview of them is given next. We use Manchester OWL Syntax (Horridge and Patel-Schneider, 2009) to describe the learning problems' expected definitions.

Moral This data set was first introduced by Wogulis (1994) and is available at the University of California Irvine (UCI) machine learning repository[2] (Frank and Asuncion, 2010). It is intended to be used to learn definitions of harm-doing activities and contains concepts and observations related to the classification of activities as 'guilty' and 'not guilty' through a set of sub-categories such as 'blameworthy' and 'justified'.

Poker A description of 10 classes of poker hands (5 cards drawn from a standard deck) based on 10 predictive attributes (suit and rank of each card). This data set can be customised into binary-class learning and is available at the UCI repository[3].

Family A set of data sets containing observations about family relations such as aunt, brother, cousin, daughter, father, grandson and uncle (Richards and Mooney, 1995). This data set can be found in many repositories. In our evaluation, we use the data set distributed with the DL-Learner package (which can be found in the DL-Learner repository[4]). Each family relation can be treated as a separate learning problem, and we use several of them. We also use the `Forte Uncle` problem used by Lehmann (2007) and available in the DL-Leaner repository.

CarcinoGenesis This data set is used to learn the structure of chemical compounds and bioassays that may cause cancer based on data from the US National Toxicology Program. It was transformed into logic programming and used for evaluation of ILP algorithms by many authors such as Bahler (1993); Srinivasan et al. (1997) and was

2. http://archive.ics.uci.edu/ml/datasets/Moral+Reasoner
3. http://archive.ics.uci.edu/ml/datasets/Poker+Hand
4. https://github.com/AKSW/DL-Learner

transformed into the OWL ontology format and used to evaluate the description logic learning algorithms in the DL-Learner framework (Lehmann, 2010)[5]. It is particularly noisy, which makes it a challenging problem in machine learning for both symbolic and sub-symbolic learning approaches.

MUSE Dataset We employ use case 1 of a set of context-aware smart home simulations by Lyons et al. (2010) for normal and abnormal living behaviours. The data set is available in the SPaCEL repository[6].

ILPD Dataset A data set based on the liver function test records of patients collected from the North East of Andhra Pradesh, India (Indian Liver Patient Dataset). Each record comprises patient information such as age and gender and results of liver function tests including total Bilirubin, Albumin, and total protein, and the target is an expert-assigned label of cancerous or non-cancerous. This data set is also available in the UCI repository[7].

MUBus Dataset A data set developed to demonstrate the SPaCEL algorithm, it is based on a bus timetable that varies according to conditions such as weekday/weekend, university holidays, and school holidays. Data was generated by sampling at 5 minute intervals. Sub-datasets can be created by restricting the sampling times, such as "MUBus12 [07:00 - 09:20]" (shortened as MUBus-1), "MUBus12 [07:00 - 12:00]" (shortened as MUBus-2) and "MUBus12 [07:00 - 21:30]" (shortened as MUBus-3). This data set is available in the SPaCEL repository; for more information about it, see (Tran, 2013).

The timetable makes surprising complicated rules, such as the following description for a weekend bus:

```
(NOT Holiday1) AND ((hasMinute VALUE 0 and hasHour VALUE 9) OR
  (hasMinute VALUE 20 AND
    (hasHour VALUE 10 OR hasHour VALUE 14 OR hasHour VALUE 16)) OR
  (hasMinute VALUE 40 AND
    (hasHour VALUE 11 OR hasHour VALUE 13 OR hasHour VALUE 15)))
```

3.2 Comparison of Combination Strategies

As was described in Section 2.3, three combination strategies were implemented: *late*, *delayed* and *on-the-fly*. We chose to compare these strategies in order to choose one as the most useful for SPaCEL. Table 2 shows the experimental results. It can be seen that the accuracies achieved are similar across all three, but the learning times and search space sizes differ. For example, the late combination strategy did not terminate in some cases: for the MUBus-2 data set the learner was interrupted by timeout after 10 minutes. However, by applying the algorithm after the learner was interrupted, a definition with 100% accuracy on the training data set was produced. This means the solution existed implicitly, but the

In addition, as the late combination strategy performed the combination at the end, only after all positive or negative examples are covered, its learning times were always longer than other strategies. In theory this might produce more concise solutions than the on-the-fly strategy, as can be seen in the following partial definitions produced by the on-the-fly strategy with the UCA1 data set:

1. activityHasDuration SOME hasDurationValue ≤ 15.5 AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≤ 4.5))

8. Partial definitions
9. Average
10. Interrupted

2. activityHasStarttime SOME Autumn AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≤ 4.5)) AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≥ 19.5))

3. activityHasStarttime SOME Summer AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≤ 4.5)) AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≥ 19.5))

4. activityHasDuration SOME hasDurationValue ≥ 4.5 AND
   activityHasStarttime SOME Spring AND
   (NOT (Activity AND activityHasDuration SOME hasDurationValue ≥ 19.5))

In contrast, the delayed strategy found:

activityHasDuration SOME (hasDurationValue ≥ 4.5 AND
hasDurationValue ≤ 19.5) AND
(NOT (activityHasStarttime SOME Winter AND
activityHasDuration SOME hasDurationValue ≥ 15.5))

The difference is between a large number of short expressions and a smaller number of long ones; usually the delayed strategy produced shorter descriptions overall. However, the on-the-fly strategy dominated in most aspects, particularly the learning time and search space covered. Our hope that the delayed strategy would combine the advantages of both of the others was not bourne out, and we therefore chose to use the on-the-fly strategy for the experimental comparison of SPaCEL with other algorithms.

3.3 Comparison Experiment

We measured search tree size (Table 3), predictive accuracy (Table 4), learning time (also Table 4), and definition length (Table 6) for all 15 data sets using CELOE, PaRCEL and SPaCEL. This section reports and discusses the results of this experiment.

The search tree size reported in this experiment is the total number of all descriptions that are inserted into the search tree, including the irrelevant descriptions (the partial and counter-partial definitions which are removed later by the algorithm). If an algorithm can find the solution, the result reported is the search tree size after the learning algorithm has terminated. Otherwise, it is the search tree size at the time when the timeout has occurred. In this case, the comparison should be treated with caution as it depends upon the timeout assigned for the learning algorithm. Only learning problems on which at least one of the algorithms found an accurate definition on the training set were considered. Therefore, the results for the CarcinoGenesis and ILDP learning problems are not reported, since all three algorithms timed out.

In the first group of learning problems, SPaCEL produced smaller search trees than both CELOE and ParCEL for 4 out of 7 learning problems. However, the definitions of these learning problems were short and therefore the search tree sizes were usually small. Consequently, they were sensitive to the parallelisation: as the search tree in our algorithm is expanded by multiple workers, the solution may be found by one of the workers while the other workers are still processing the search tree. The search tree may be therefore

Table 3: Search tree size (*means ± standard deviations of 10 folds*). The underlined values are the search tree size after the *timeout* has occurred. The statistical significance was tested using t-tests: bold values are statistically significantly higher (at the 95% confidence level) than other values; unformatted values are statistically significantly lower than other values; bold italic values are statistically significantly lower than the bold values, and statistically significantly higher than the unformatted values.

Learning problems with at least 1 timeout						
UCA1	1,465,263.2	± 11,515.5	28,676.0	± 14,935.2	**6,998.70**	± **859.7**
MUBus-1	161,832.2	± 3,054.5	643,401.5	± 139,303	**2,130.1**	± **1,179.5**
MUBus-2	79.959.2	± 118.5	879,866.1	± 34,000.4	**8,575.1**	± **4,184.3**
MUBus-3	55,130.4	± 73.7	453,605.1	± 7,565.3	**23,477.0**	± **13,897**

expanded redundantly and thus the reported search tree sizes might be unnecessarily larger than the minimal search tree size required to learn the problem.

In the second and the third groups, SPaCEL always produced the smallest search trees for all learning problems. The search tree sizes generated by the three algorithms for the same learning problem in this group were extremely different. For example, SPaCEL only needed to explore about 2,400 expressions to find the solution for the Uncle learning problem while CELOE had to explore more than 541,081 expressions. Similarly, SPaCEL found a solution after exploring about 2,130 expressions, while ParCEL needed to explore 643,401 expressions on the MUBus-1 learning problem. CELOE could not find an accurate solution for this learning problem and timed out after 10 minutes. The average search tree size at the time of timeout was about 161,832 expressions.

A t-test rejected the null hypothesis for similarity of search tree size of the algorithms on all learning problems at the 99% confidence level, meaning that the search trees generated by SPaCEL were statistically significantly smaller than CELOE in 12 out of 14 learning problems and than ParCEL for 13 out of 14 learning problems.

With regard to predictive accuracy and learning time, which are reported in Table 4, in general, SPaCEL achieved better predictive accuracy in most learning problems. In the first two groups (10 learning problems) all three learning algorithms achieved very high accuracy, including 100% accuracy in 5 of them. In the remaining 5 learning problems, SPaCEL was statistically significantly more accurate than CELOE for 3 out of 5 and ParCEL for 1 out of 5 problems. There were no learning problems in this group where SPaCEL was statistically significantly less accurate than either of the other algorithms.

Table 4: Learning time and predictive accuracy experimental results summary (*means ± standard deviations of 10 folds*). Result of the statistical significance t-test (at the 95% confidence level) is also included: the bold and highlighted values are statistically significantly *better* than other values; the unformatted values are statistically significantly *worse* than other values; the bold and italic and highlighted values are statistically significantly *worse* than the bold and highlighted values, and statistically significantly *better* than the unformatted values; the underlined values represent the values that are not statistically significantly different from the other values.

Note: *: *Interrupted by timeout*

In the last group of problems SPaCEL outperformed CELOE on 5 out of 6 and ParCEL on 3 out of 6 learning problems. The data set MU-Bus is a complex learning problem in which the target definition is very long, as the bus operation time depends upon many conditions. For this data set, SPaCEL outperformed both ParCEL and CELOE. It always found the complete definition on the training set and the accuracy on the test set was always over 99.7%, while CELOE could not find accurate definitions on the training set and the accuracy on the test set was very low, from 11.34% to 53.61%. ParCEL performed better than CELOE and the accuracy was also very high but it was still statistically significantly less accurate than SPaCEL.

For the ILPD data set it appears that CELOE had higher predictive accuracy that SPaCEL, although the difference was not statistically significant. However, as the ILPD and MuBus data sets are unbalanced, it is more appropriate to use balanced accuracy [11] for these learning problems. Table 5 shows the balanced predictive accuracy for ILPD and some other unbalanced learning problems. The balanced accuracy of SPaCEL and ParCEL on the ILDP learning problem were statistically significantly higher than CELOE. The outcome of the statistical significance test on the balanced accuracy of other learning problems did not change.

11. *balanced accuracy* $= \frac{1}{2} \cdot \left(\frac{|true\ positive|}{|positive\ examples|} + \frac{|true\ negative|}{|negative\ examples|} \right)$

Table 5: Balanced predictive accuracy of unbalanced data sets in Table 4. Conventions of the results' representation are similar to that of in Table 4.

Problem	Balanced predictive accuracy (%)					
	CELOE		ParCEL		SPaCEL	
MUBus-1	71.12	± 0.65	**99.68**	± 0.60	**99.74**	± 0.62
MUBus-2	52.09	± 0.06	***91.86***	± *3.02*	**99.78**	± 0.59
MUBus-3	52.18	± 0.03	***73.07***	± *1.91*	**99.02**	± 2.67
ILDP	64.62	± 4.83	**70.94**	± 10.87	**71.73**	± 12.29

Our symmetric approach to class expression learning not only increased the predictive accuracy, but also decreased the learning time, although this effect can only be observed for the medium and high complexity data sets. The t-test result on learning time shows that SPaCEL was statistically significantly faster than CELOE in 13 out of 14 problems and than ParCEL for 10 out of 14 learning problems. It was statistically significantly slower than ParCEL for 2 out of 14 problems, both in the first and second groups. The definition lengths in this group were short and the learning times were very small.

The last metric that we evaluated was the length of the definitions learnt; the results can be seen in Table 6. The definition lengths of ParCEL and SPaCEL are reported by the number of partial definitions and the average length of the partial definitions, the total average length of their definitions is the product of those numbers.

Table 6: Definition length of the learning problems (*means* ± *standard deviations of 10 folds*). The bold values are the definition lengths after the timeout occurred.

The experimental results show that ParCEL and SPaCEL produced longer definitions than CELOE for most learning problems. By manually inspecting the results we identified that this was because partial definitions tend to overlap, and that the creation of sub-solutions leads to more specific definitions. It may also be that since CELOE timed out more often, it had not yet managed to produce completely accurate (and necessarily longer) solutions before the learning was terminated.

For the learning problems in the first two groups, where all three algorithms can find the definition for the training sets without timeout, the differences in definition length between the three algorithms were small, and any difference was caused by the overlap between partial definitions. In some cases, this can be shortened using an optimisation strategy. For example, the definitions produced by CELOE and SPaCEL for the Forte Uncle data set are:

- **CELOE:**

  male AND ((married SOME sibling SOME Person) OR
  (married SOME hasSibling SOME hasChild SOME Thing))

- **SPaCEL** (two partial definitions):

  1. hasSibling SOME hasChild SOME Thing AND (NOT female)

  2. married SOME hasSibling SOME hasChild SOME Thing AND (NOT female)

The length of the definition produced by CELOE is 15 and SPaCEL is 19 (length of two partial definitions plus 1 for disjunction). However, at least 3 axioms in the SPaCEL final definition can be reduced by removing the common part among partial definitions, i.e. `AND NOT female`. That means that if the same normal form (Lloyd, 1984; Gabbay

et al., 1998) is applied for both CELOE and SPaCEL, the difference between their lengths can be reduced. Moreover, `NOT female` can be replaced by `Male` if `male` and `female` are declared as disjoint and jointly exhaustive properties. This is the idea of *optimisation* and *simplification* in description logic (Horrocks and Patel-Schneider, 1999; Baader et al., 2010). Currently, this idea has not yet been implemented in our algorithm. However, rather than applying optimisation and simplication to the definition constructed by combining multiple partial definitions using conjunction, breaking down a long definition into several smaller partial definitions (as in SPaCEL) may help to make the definition more readable, particularly when the definition is long.

For the learning problems on which at least one of the learning algorithms cannot find an accurate definition on the training set, i.e. timeout occurred in the experiments, definitions produced by SPaCEL are significant longer than those of CELOE. An interesting comparison is seen in the definitions produced for the UCA1 data set, which is complex, but noiseless:

- **CELOE**:

  activityHasDuration SOME (hasDurationValue $\geq$ 4.5 AND
  hasDurationValue $\leq$ 21.5)

- **ParCEL**:

  1. activityHasDuration SOME
     (hasDurationValue $\geq$ 4.5 AND hasDurationValue $\leq$ 15.5)

  2. activityHasDuration SOME
     (hasDurationValue $\geq$ 15.5 AND hasDurationValue $\leq$ 19.5) AND
     activityHasStarttime SOME Spring

  3. activityHasDuration SOME
     (hasDurationValue $\geq$ 15.5 AND hasDurationValue $\leq$ 19.5) AND
     activityHasStarttime SOME Summer

  4. activityHasStarttime SOME Autumn AND activityHasDuration SOME
     (hasDurationValue >= 4.5 AND hasDurationValue <= 19.5)

- **SPaCEL** (late combination):

  activityHasDuration SOME (hasDurationValue $\geq$ 4.5 AND
  hasDurationValue $\leq$ 19.5) AND (NOT (activityHasDuration SOME
  hasDurationValue $\geq$ 15.5 AND activityHasStarttime SOME Winter))

Obviously, the short definition (length 9) produced by CELOE does not fully define the positive examples (both training accuracy and predictive accuracy were below 100%). Meanwhile, ParCEL produced a far longer definition (length 51) that describes the positive examples accurately (both training and predictive accuracy were 100%). The definition produced by SPaCEL for this data set better demonstrates the idea of using the symmetric learning approach and exceptions in learning, since it is a combination of an expression:

activityHasDuration SOME
(hasDurationValue $\geq$ 4.5 AND hasDurationValue $\leq$ 19.5)

and a counter-partial definition:

activityHasDuration SOME
(hasDurationValue $\geq$ 15.5 AND activityHasStarttime SOME Winter)

This definition is shorter than the definition produced by ParCEL and it still describes the positive examples accurately.

4. Related Work

4.1 Description logic learning

Learning in description logic is basically a search problem in which the search tree is often dynamically generated by a refinement operator. In contrast to other algorithms, SPaCEL uses a top-down approach to learning both positive and negative patterns. Only YinYang (Iannone et al., 2007) has particularly considered negative patterns previously, and they took a bottom-up approach to them, despite learning top-down for the positive patterns. The bottom-up approach creates concepts by joining most specific concepts created for positive examples using disjunction, which can create large concept definitions that are not truly intentional.

Top-down learning has been used by several algorithms reported in the literature, such as Badea and Nienhuys-Cheng (2000), which uses a refinement operator designed for the $\mathcal{ALER}$ description logic. However, as discussed by Lehmann and Hitzler (2010), this refinement operator cannot be extended to handle more expressive description logic language such as $\mathcal{SRIOQ}(\mathcal{D})$, which is the language on which OWL2 is based.

Lisi and Malerba (2003) proposed an alternative based on the hybrid $\mathcal{AL}$-log language, which combines the $\mathcal{ALC}$ description logic language and Datalog. In Nienhuys-Cheng and De Wolf (1997) an ideal downward refinement operator for the $\mathcal{AL}$-log language was proposed that is based on the notation of $\mathcal{B}$-subsumption. This is a generalisation of the generalised subsumption in the $\mathcal{AL}$-log language and is suitable for the hybrid knowledge representation systems that are constituted by the relational and structural subsystems. It was implemented in the $\mathcal{AL}$-QuIn ($\mathcal{AL}$-log Query Induction) system.

In Esposito et al. (2004); Iannone et al. (2007), a top-down refinement operator for the $\mathcal{ALC}$ language is used in combination with a bottom-up most specific concept (MSC) operator. The essential idea of these studies lies in the concept of *counterfactuals*, that is *errors* within candidate hypotheses. Therefore, for each candidate hypothesis, the learning algorithm uses an MSC operator to find the concept(s) representing errors and remove them from the candidate hypothesis. However, this approach has two disadvantages: i) finding of concept(s) for counterfactuals may be repeated for the same set of errors, and ii) as a result, it tends to generate unnecessarily long concepts.

Some description logic learning algorithms also have been proposed by Lehmann (2010), where two top-down refinement operators have been proposed. One is for the $\mathcal{EL}$ language and the other is for $\mathcal{ALC}$ (although it can be extended to more expressive languages). The latter is the most expressive refinement operator proposed so far. In addition, several learning approaches based on the proposed refinement operators were also developed. Two

interesting algorithms in this framework are Class Expression Learner for Ontology Engineering (CELOE) and OWL Class Expression Learner (OCEL). These algorithms perform very well when compared with other learning approaches (Hellmann, 2008). However, they are sequential algorithms and thus they cannot take advantages of parallel systems such as multi-core processors or cloud computing platforms. In addition, these algorithms focus on generating short descriptions and thus they have another disadvantage: they cannot handle complex learning problems (see Hellmann (2008) and Tran et al. (2012)). Recently, an extension of CELOE has been developed and integrated into the DLLearner framework. This algorithm is the parallelisation of CELOE in which the search tree is expanded by multiple threads. Basically, the learning approach is the same as CELOE, i.e., it looks for a complete definition. Therefore, its performance (learning speed) is improved, but not the capability for learning problems requiring complex (long) concepts.

DL-FOIL (Fanizzi et al., 2008) combines both top-down and bottom-up learning. The top-down step finds a set of *correct concepts* such that each of them correctly defines a subset of the positive examples. Then, the bottom-up step computes a complete concept that defines all positive examples. This approach handles complex concepts better than the top-down or bottom-up approach alone. However, it produces longer concepts in comparison with the approaches proposed by Lehmann (2010). The unnecessarily long learnt concepts are caused by the lack of optimisation in the aggregation step. In addition, like other existing description logic learning algorithms, this approach is serial by nature and thus it cannot take advantage of concurrency.

During the early 90s, a related idea to the overly general descriptions that we use is this paper was proposed by Bain and Muggleton (1990) for first-order theories. Called non-monotonic learning, this approach adopted a specialisation schema based on an existing non-monotonic logic formalism for incremental specialising of over-general beliefs. Although this learning method also employs the negative examples to *correct* the learned beliefs, the use of negative examples in this approach is different from our approach. In Bain and Muggleton's approach, each negative example is intentionally and incrementally used to specialise the learned beliefs. On the other hand, negative examples in our algorithm are mainly used to verify the correctness of the learned beliefs. Their definitions, which are occasionally found in the process of finding the definition for positive examples, are used to correct (specialise) the over-general concepts.

Recent research in description logic learning has focused on the induction instance retrieval cast as a classification problem (Rizzo et al., 2015). They extend the decision tree to describe logic representations (terminological decision trees) by using the nodes to represent conjunctive description logics and left and right branches of the binary tree corresponding to the result of checking some instance against the parent node. In essence, this is a top-down learning approach in which the child nodes are generated by a downward refinement operator.

4.2 Parallelisation in description logic learning

Parallel computing has a history of development since the late 1950s, from multi-processor computer systems to multi-core processors. Parallelisation helps to use computer resources more effectively in order to create fast, efficient scalable algorithms. Currently, parallelisa-

tion can be found in every area of computing, with many parallel frameworks developed, such as Parallel Virtual Machine (PVM) (Sunderam, 2006) and Apache Hadoop (Bhandarkar, 2010).

In logics, parallelisation has been used to develop parallel logic programming languages such as PARLOG (Gregory, 1987) and PEPSys (Ratcliffe and Syre, 1987), allowing parallelised logic deduction. A parallel inductive logic programming approach was proposed by Dehaspe and De Raedt (1995), based on partitioning positive examples into several sets depending on the parallel level of the system and combining the concepts for the partitioned sets at the end. In Matsui et al. (1998), several parallelisation strategies were implemented in FOIL, an inductive logic learning algorithm (Quinlan, 1990). These strategies differ mainly in the dividing strategies, either dividing space among processors (i.e. multiple refinements work in parallel) or partitioning the data and learning the partitions independently, similarly to Dehaspe and De Raedt (1995), although using background knowledge to perform the partition. Our parallel learning approach is similar to the first strategy: we explore the search space in parallel. However, we use a different learning strategy, employing concepts for a subset of positive examples and use a reduction strategy to construct the final concept.

Parallelisation is also used in description logics, but mainly not for reasoning, with only the Deslog reasoner (Wu and Haarslev, 2012), and parallel inferencing algorithms for OWL (Liebig and Müller, 2007; Soma and Prasanna, 2008) being reported to date.

5. Conclusion and Future Work

A symmetric approach to class expression learning has been proposed, where we learn from both positive and negative examples simultaneously. This is motivated by learning scenarios where negative examples can be classified using simple patterns. This is common in practice and our empirical experiments suggest that our approach deals well with this kind of scenario. This approach to class expression learning can deal with other kinds of concept learning problems, as shown in Table 4. For example, the Forte learning problem can be solved by a top-down approach (e.g., CELOE and ParCEL) without using negation. However, this learning problem is solved faster by SPaCEL, which uses the definitions of negative examples, without decreasing the predictive accuracy.

Some current learning algorithms, e.g. CELOE and ParCEL, which were used in our evaluations, can also solve this category of problem by specialising the concepts or using negation and conjunction to remove negative examples from candidate concepts. However, for some data sets with regular exception patterns such as MUBus and UCA1, these algorithms had difficulties in finding the right concept: their learning times were very long in comparison with SPaCEL, which sometimes caused the system to run out of memory before the definition could be found. The most impressive improvements were in the search tree size and learning time. Although SPaCEL often generated longer definitions than other algorithms, there was no over-fitting for the data sets used.

However, the definitions generated by SPaCEL are not optimised. Normalisation and simplification can be used to produce better definitions, i.e. shorter and more readable. This, together with investigations on more data sets, will require further research.

Acknowledgments

Abstract

A popular approach for online decision-making in large MDPs is time-bounded tree search. The effectiveness of tree search, however, is largely influenced by the action branching factor, which limits the search depth given a time bound. An obvious way to reduce action branching is to consider only a subset of potentially good actions at each state as specified by a provided partial policy. In this work, we consider offline learning of such partial policies with the goal of speeding up search without significantly reducing decision-making quality. Our first contribution consists of reducing the learning problem to set learning. We give a reduction-style analysis of three such algorithms, each making different assumptions, which relates the set learning objectives to the sub-optimality of search using the learned partial policies. Our second contribution is to describe concrete implementations of the algorithms within the popular framework of Monte-Carlo tree search. Finally, the third contribution is to evaluate the learning algorithms on two challenging MDPs with large action branching factors. The results show that the learned partial policies can significantly improve the anytime performance of Monte-Carlo tree search.

Keywords: online sequential decision-making, partial policy, partial policy learning, imitation learning, Monte-Carlo tree search, reductions

1. Introduction

Online sequential decision-making involves selecting actions in order to optimize a long-term performance objective while meeting practical decision-time constraints. In many environments, including Chess, Go, computer networks, automobiles and aircraft, it is possible to obtain simulators or learn an accurate model of the environment, whereas in others, no such simulator or model is available. A common approach in both cases is to use learning techniques such as reinforcement learning (RL) (Sutton and Barto, 1998) or imitation learning (Pomerleau, 1989; Sammut et al., 1992) in order to learn reactive policies, which can be used to quickly map any state to an action. While reactive policies support fast decision making, for many complex problems, it can be difficult to represent and learn high-quality reactive policies. For example, in games such as Chess, Go, and other complex problems, the best learned reactive policies are significantly outperformed by the best approaches based on look-ahead search (Gelly and Silver, 2007; Veness et al., 2009; Silver et al., 2016). As another example, recent work has shown that effective reactive policies can be learned for playing a variety of Atari video games using both RL (Mnih et al., 2013) and imitation learning (Guo et al., 2014). However, the performance of these reactive policies are easily outperformed or equaled by a vanilla lookahead planning agent (Guo et al., 2014).

Faced with the choice of a planning agent versus a (model-free) learning agent, a practitioner must consider two key factors. The first is the non-trivial expense of obtaining a simulator or learning a model. The second is that the planning agent requires significantly more time per decision. That is, even when a simulator is available, the computational expense may not be practical for certain applications, including real-time Atari game play.

This paper attempts to make progress in the region between fast reactive decision making and slow lookahead search, when a simulator or model of the world is available. In particular, we study algorithms for learning to improve the anytime performance of lookahead search, allowing for more effective deliberative decisions to be made within practical time bounds. Lookahead tree search constructs a finite-horizon lookahead tree using a (possibly stochastic) model or simulator in order to estimate action values at the current state. A variety of algorithms are available for building such trees, including instances of Monte-Carlo Tree Search (MCTS) such as UCT (Kocsis and Szepesvári, 2006), Sparse Sampling (Kearns et al., 2002), and FSSS (Walsh et al., 2010), along with model-based search approaches such as RTDP (Barto et al., 1995) and AO* (Blai and Hector, 2012). However, under practical time constraints (e.g., one second per root decision), the performance of these approaches strongly depends on the action branching factor. In non-trivial MDPs, the number of possible actions at each state is often considerable, which greatly limits the feasible search depth. An obvious way to address this problem is to provide prior knowledge for explicitly pruning bad actions from consideration. In this paper, we consider the offline learning of such prior knowledge in the form of partial policies [1].

A partial policy is a function that quickly returns an action subset for each state and can be integrated into search by pruning away actions not included in the subsets. Thus, a partial policy can significantly speedup search if it returns small action subsets, provided that the overhead for applying the partial policy is small enough. If those subsets typically include high-quality actions, then we might expect little decrease in decision-making quality. Although learning partial policies to guide tree search is a natural idea, it has received surprisingly little attention, both in theory and practice. In this paper we formalize this learning problem from the perspective of "speedup learning". We are provided with a distribution over search problems in the form of a root state distribution and a search depth bound. The goal is to learn partial policies that significantly speedup depth D search, while bounding the expected regret of selecting actions using the pruned search versus the original search method that does not prune.

In order to solve this learning problem, there are at least two key choices that must be made: 1) Selecting a training distribution over states arising in lookahead trees, and 2) Selecting a loss function that the partial policy is trained to minimize with respect to the chosen distribution. The key contribution of our work is to consider a family of reduction-style algorithms that answer these questions in different ways. In particular, we consider three algorithms that reduce partial policy learning to set learning problems, characterized by choices for (1) and (2). The set learning problems are further reduced to cost-sensitive binary classification. Our main results bound the sub-optimality of tree search using the learned partial policies in terms of the expected loss of the supervised learning problems. Interestingly, these results for learning partial policies mirror similar

reduction-style results for learning (complete) policies via imitation (Ross and Bagnell, 2010; Syed and Schapire, 2010; Ross et al., 2011).

We empirically evaluate our algorithms in the context of learning partial policies to speedup MCTS in two challenging domains with large action branching factors: 1) a real-time strategy game, Galcon and 2) a classic dice game, Yahtzee. The results show that using the learned partial policies to guide MCTS leads to significantly improved anytime performance in both domains. Furthermore, we show that several other existing approaches for injecting knowledge into MCTS are not as effective as using partial policies for action pruning and can often hurt search performance rather than help.

2. Problem Setup

We consider sequential decision-making in the framework of Markov Decision Processes (MDPs). An MDP is a tuple (S, A, P, R), where S is a finite set of states, A is a finite set of actions, $P(s'|s,a)$ is the transition probability of arriving at state s' after executing action a in state s, and $R(s,a) \in [0,1]$ is the reward function giving the reward of taking action a in state s. In environments where the reward is non-deterministic (but still stationary), $R(s,a)$ is taken to be the expected value. The typical goal in MDP planning and learning is to compute a policy for selecting an action in any state, such that following the policy (approximately) maximizes some measure of long-term expected reward. For example, two popular choices are maximizing the expected finite-horizon total reward or expected infinite-horizon discounted reward.

In practice, regardless of the long-term reward measure, for large MDPs, the offline computation of high-quality policies over all environment states is impractical. In such cases, a popular action-selection approach is online tree search, where at each encountered environment state, a time-bounded search is carried out in order to estimate action values. Note that this approach requires the availability of either an MDP model or a simulator in order to construct search trees. In this paper, we assume that a model or simulator is available and that online tree search has been chosen as the action selection mechanism. Next, we formally describe the paradigm of online tree search, introduce the notion of partial policies for pruning tree search, and then formulate the problem of offline learning of such partial policies.

2.1 Online Tree Search

Throughout this paper, we will focus on search that has a depth bound D. Doing so bounds the length of future action sequences to be considered. Given a state s, we denote by $T(s)$ the depth D expectimax tree rooted at s. $T(s)$ alternates between layers of state nodes and action nodes[2], labeled by states and actions respectively. The children of each state node are action nodes for each action in A. The children of an action node a with parent labeled by s are all states s' such that $P(s'|s,a) > 0$. Figure 1(a) shows an example of a depth two expectimax tree. The depth of a state node is the number of action nodes traversed from the root to reach it. Note that leaves of $T(s)$ will always be action nodes.

The optimal value of a state node s at depth d, denoted by $V_d^*(s)$, is equal to the maximum value of its child action nodes, which we denote by $Q_d^*(s,a)$ for child a. $V_d^*(s)$ and $Q_d^*(s,a)$ are formally defined next.

2. Also known as "chance" nodes in the context of expectimax trees.

(a) Unpruned expectimax tree $T(s)$ with $D = 2$

(b) Pruning T with **partial** policy ψ gives T_ψ where a third of the actions have been pruned.

Figure 1: Unpruned and pruned expectimax trees with depth $D = 2$ for an MDP with $|A| = 3$ and two possible next states. The distributions over the transitions to the next state are uniform. The numeric values are the optimal action values Q^*. Nodes for which no value is shown have $Q^*(s,a) = 0$. Nodes marked with an asterisk indicate that the node corresponds to the optimal action choice. In (b), pruning can change the value at the root if nodes on the optimal paths are incorrectly pruned.

$$V_d^*(s) = \max_a Q_d^*(s,a)$$

$$Q_d^*(s,a) = R(s,a) \quad \text{if} \quad d = D-1 \tag{1}$$

$$= R(s,a) + E_{s' \sim P(\cdot \mid s,a)}\left[V_{d+1}^*(s')\right] \quad \text{otherwise} \tag{2}$$

Equation 1 corresponds to leaf action nodes. In Equation 2, $s' \sim P(\cdot|s,a)$ ranges over the children of a. Given these value functions, the optimal action policy for state s at depth d is

$$\pi_d^*(s) = \arg\max_a Q_d^*(s,a)$$

Given an environment state s, online search algorithms such as UCT or RTDP attempt to completely or partially search the tree $T(s)$ in order to approximate the root action values $Q_0^*(s,a)$ well enough to identify the optimal action $\pi_0^*(s)$. It is important to note that optimality in our context is with respect to the specified search depth D, which may be significantly smaller than the number of actions that will be taken in the actual environment (e.g., the length of a full game). This is a practical necessity that is often referred to as receding-horizon control. Here we simply assume that an appropriate search depth D has been specified and our goal is to speedup planning within that depth.

2.2 Search with a Partial Policy

One way to speedup depth D search is to prune actions from $T(s)$. In particular, if a fixed fraction σ of actions are removed from each state node, then the size of the tree would decrease by a factor of $(1-\sigma)^D$, potentially resulting in significant computational savings. In this paper, we will utilize partial policies for pruning actions. A depth D (non-stationary) *partial policy* ψ is a sequence $(\psi_0, \ldots, \psi_{D-1})$ where each ψ_d maps a state to an action subset. In this work, we focus exclusively on non-stationary partial policies, rather than also considering stationary partial policies where $\psi_i = \psi_j$ for all i and j. One reason for this is that optimal solutions to depth-bounded search trees are

non-stationary in general. In addition, considering non-stationary policies allows for defining and analyzing relatively simple training algorithms as described in section 3. In some applications, however, where the planning depth is not known in advance, it may be desirable to learn stationary partial policies. Extending our work to the stationary scenario is a point of future work, which we expect can draw on ideas for learning stationary policies in imitation learning (Ross and Bagnell, 2010; Ross et al., 2011).

Given a partial policy ψ and root state s, we can define a pruned tree $T_\psi(s)$ that is identical to $T(s)$, except that each state s at depth d only has subtrees for actions in $\psi_d(s)$, pruning away subtrees for any child $a \notin \psi_d(s)$. The phrase "root state" is not to be confused with the starting state of a sequential problem (e.g., the initial board in Chess). Rather, "root state" refers to *any* state in which the search agent is required to act and must therefore place the state at the root of the search tree. Figure 1(b) shows a pruned tree $T_\psi(s)$, where ψ prunes away one action at each state. It is straightforward to incorporate ψ into a search algorithm by only expanding actions at state nodes that are consistent with ψ.

We define the state and action values relative to $T_\psi(s)$ the same as before and let $V_d^\psi(s)$ and $Q_d^\psi(s,a)$ denote the depth d state and action value functions, as follows.

$$\begin{aligned} V_d^\psi(s) &= \max_{a \in \psi_d(s)} Q_d^\psi(s,a) \\ Q_d^\psi(s,a) &= R(s,a) && \text{if} \quad d = D-1 \\ &= R(s,a) + E_{s' \sim P(\cdot \mid s,a)}\left[V_{d+1}^\psi(s')\right] && \text{otherwise} \end{aligned}$$

We will denote the highest-valued, or greedy, root action of $T_\psi(s)$ as

$$\pi^\psi(s) = \arg\max_{a \in \psi_0(s)} Q_0^\psi(s,a)$$

This is the root action that a depth D search procedure would attempt to return in the context of ψ. We say that a partial policy ψ subsumes a partial policy ψ' if for each s and d, $\psi'_d(s) \subseteq \psi_d(s)$. In this case, it is straightforward to show that for any s and d, $V_d^{\psi'}(s) \leq V_d^\psi(s)$. This is simply because planning under ψ allows for strictly more action choices than planning under ψ'. Note that a special case of partial policies is when $|\psi_d(s)| = 1$ for all s and d, which means that ψ defines a traditional (complete) deterministic MDP policy. In this case, V_d^ψ and Q_d^ψ represent the traditional depth d state value and action value functions for policies. The second special case occurs at the other extreme where $\psi_d = A$ for all d. This corresponds to full-width search and we have $V^* = V^\psi$ and $Q^* = Q^\psi$.

Clearly, a partial policy can reduce the complexity of search by eliminating some actions. However, we are also concerned with the quality of decision-making using $T_\psi(s)$ versus $T(s)$, which we will quantify in terms of expected regret. The regret of selecting action a at state s relative to $T(s)$ is equal to $V_0^*(s) - Q_0^*(s,a)$. Note that the regret of the optimal action $\pi_0^*(s)$ is zero. We prefer partial policies that result in root decisions with small regret over the root state distribution that we expect to encounter, while also supporting significant pruning. For this purpose, if μ_0 is a distribution over root states, we define the expected regret of ψ with respect to μ_0 as

$$\text{REG}(\mu_0, \psi) = E\left[V_0^*(s_0) - Q_0^*(s_0, \pi^\psi(s_0))\right] \quad \text{where } s_0 \sim \mu_0 \tag{3}$$

2.3 Learning Problem

We consider an offline learning setting where we are provided with a model or simulator of the MDP in order to train a partial policy that will be used later for online decision-making. As an illustrative example, consider the domain of Chess, where we wish to learn a partial policy for pruning the search tree. Our approach is to use expensive search offline to play many full games of Chess and to record the sequence of states encountered during those games. Each state encountered during actual play is called a *root state* of a search tree. The collected root states and associated trees are then used to learn a partial policy that can be used to speedup future online search.

More formally, the learning problem provides us with a distribution μ_0 over root states (or a representative sample from μ_0) and a depth bound D. In our Chess example, μ_0 would be a distribution over the states encountered along games played using the expensive search. The intention is for μ_0 to be representative of the states that will be encountered during online use. In this work, we are agnostic about how μ_0 is defined for an application. A typical choice of μ_0 is the distribution of states encountered along trajectories of a receding-horizon controller that makes decisions based on unpruned depth D search. We use this definition of μ_0 in our experiments. This setup is closely related to imitation learning (Syed and Schapire, 2010; Ross and Bagnell, 2010; Ross et al., 2011) since we are essentially treating unpruned, expensive search as the expert to be imitated by a pruned search. Other choices of the initial state distribution μ_0 are the state distributions that arise from more complex imitation learning algorithms such as DAGGER (Ross et al., 2011).

Given μ_0 and D, our "speedup learning" goal is to learn a partial policy ψ with small expected regret $\text{REG}(\mu_0, \psi)$, while providing significant pruning. That is, we want to imitate the decisions of depth D unpruned search via a much less expensive depth D pruned search. In general, there will be a tradeoff between the potential speedup and expected regret. At one extreme, it is always possible to achieve zero expected regret by selecting a partial policy that does not prune. At the other extreme, we can remove the need for any search by learning a partial policy that always returns a single action, which corresponds to a complete policy. However, for many complex MDPs, it can be difficult to learn computationally efficient, or reactive, policies that achieve small regret. Rather, it may be much easier to learn partial policies that prune away many, but not all actions, yet still retain high-quality actions. While such partial policies lead to more search than a reactive policy, the regret may be much less.

In practice, we seek a good tradeoff between the two extremes. The tradeoff between a reactive policy versus a full depth D search-based policy is application-specific. Instead of specifying a particular trade-off point as our learning objective, we develop learning algorithms in the next section that provide some ability to explore different points. In particular, the algorithms are associated with regret bounds in terms of supervised learning objectives that measurably vary with different amounts of pruning.

3. Learning Partial Policies

Given μ_0 and D, we now develop reduction-style algorithms for learning partial policies. The algorithms reduce partial policy learning to a sequence of D i.i.d. supervised *set learning* problems, each producing one partial policy component ψ_d. Informally, a supervised set learning problem is similar to a traditional classification problem, except that the learned functions (partial policies, in this case) return sets of labels rather than a single label. In our work, labels will correspond to actions and the designer will specify the size of the label/action sets that the learned function

should return. The quality of a learned set function will be evaluated in terms of a cost function that provides a measure of whether a set returned by the function contains "good" labels/actions.

More formally, the set learning problem for partial policy component ψ_d will be characterized by a pair (μ_d, C_d), where μ_d is a distribution over states, and C_d is a cost function that, for any state s and action subset $A' \subseteq A$ assigns a prediction cost $C_d(s, A')$. The cost function is intended to measure the quality of A' with respect to including actions that are high quality for s. Typically, the cost function will be a monotone decreasing set function of A' with zero pruning having zero cost, $C_d(s, A) = 0$. Note that a trivial solution to the learning problem, which achieves zero cost, would be to learn a function that always returns the complete action set A. However, such solutions will be avoided by having the designer specify the amount of pruning that they desire, or equivalently the size of the action sets returned. Note that constraining the set to contain exactly one action would correspond to learning complete policies.

We begin by assuming the availability of a set learning algorithm called SETLEARN that takes three inputs, namely, a set of states drawn from μ_d, cost function C_d, and a pruning percentage $0 < \sigma_d < 1$. The output of SETLEARN is a partial policy component ψ_d that returns action sets that contain at most a fraction $1 - \sigma_d$ of the available actions while attempting to minimize the expected cost of ψ_d on μ_d. That is, the goal is to return a ψ_d that minimizes $E[C_d(s, \psi_d(s))]$ for $s \sim \mu_d$. The designer's choice of pruning percentage σ_d (e.g., prune 75% of the actions in each state) is related to the time constraints of the decision problem, with smaller time constraints requiring more pruning.

Given access to SETLEARN we first present our generic reduction algorithm for learning partial policies in Algorithm 1. This algorithm template simply calls SETLEARN on a sequence of

Algorithm 1 A template for learning a partial policy $\psi = (\psi_0, \ldots, \psi_{D-1})$. The template is instantiated by specifying the pairs of distributions and cost functions (μ_d, C_d) for $d \in \{0, \ldots, D-1\}$. SETLEARN is a set learning algorithm that aims to minimize the expected cost of each ψ_d relative to C_d and μ_d. σ_d is a pruning fraction such that SETLEARN returns at most $1 - \sigma_d$ actions. Each partial policy ψ_d is a set function that maps states to action sets of size $(1 - \sigma_d)|A|$.

```
procedure PARTIALPOLICYLEARNER({(μ_d, C_d)}, σ_d)
    for d = 0, 1, ..., D − 1 do
        Sample a training set of states S_d from μ_d
        ψ_d ← SETLEARN(S_d, C_d, σ_d)
    end for
    return ψ = (ψ_0, ψ_1, ..., ψ_{D−1})
end procedure
```

set learning problems and returns a list of the learned partial policies. In order to instantiate this template, it is necessary to specify SETLEARN and the individual set learning problems (μ_d, C_d). We defer details of our implementation of SETLEARN until section 4. Rather, we proceed with the definition of our learning reductions. Each reduction is specified by a particular choice of (μ_d, C_d), such that we can bound the expected regret of ψ (when used for search) by the expected (i.i.d.) costs of the ψ_d returned by SETLEARN.

We begin with the state distributions μ_d. These are specified in terms of distributions induced by (complete) policies. In particular, given a policy π, we let $\mu_d(\pi)$ denote the state distribution produced by the following procedure: Draw an initial state from μ_0, execute π for d steps and return the final state. Since we have assumed an MDP model or simulator, it is straightforward to sample

from $\mu_d(\pi)$ for any provided π. Before proceeding, we state two simple lemmas that will be used to prove our regret bounds.

Lemma 1 *If a complete policy π is subsumed by partial policy ψ, then for any initial state distribution μ_0, REG$(\mu_0, \psi) \leq E[V_0^*(s_0)] - E[V_0^\pi(s_0)]$, for $s_0 \sim \mu_0$.*

Proof Since π is subsumed by ψ, we know that $Q_0^\psi(s, \pi^\psi(s)) = V_0^\psi(s) \geq V_0^\pi(s)$. Since for any a, $Q_0^*(s, a) \geq Q_0^\psi(s, a)$, we have for any state s, $Q_0^*(s, \pi^\psi(s)) \geq V_0^\pi(s)$. The result follows by negating each side of the inequality, followed by adding $V_0^*(s)$, and taking expectations. ■

Thus, we can bound the regret of a learned ψ if we can guarantee that it subsumes a policy whose expected value has bounded sub-optimality. Our three reduction algorithms, presented below, provide different approaches for making such a guarantee.

The second lemma will be used to bound the sub-optimality of complete polices that are subsumed by our learned partial policies, which then allows the application of Lemma 1. Versions of this "performance difference lemma" have been used in prior work (Kakade and Langford, 2002; Bagnell et al., 2003; Ross and Bagnell, 2014).

Lemma 2 *For any two complete policies π and π' and any initial state distribution μ_0,*

$$E\left[V_0^{\pi'}(s_0) - V_0^{\pi}(s_0)\right] = \sum_{d=0}^{D-1} E\left[V_d^{\pi'}(s_d) - Q_d^{\pi'}(s_d, \pi(s_d))\right], \text{where } s_d \sim \mu_d(\pi_{0:d-1})$$

.

Proof Following a prior proof (Ross and Bagnell, 2014), define π_d to be a policy that follows π for d steps and then at step $d+1$ switches to following π' until the maximum depth D. Using the observations that $\pi_0 = \pi'$ and $\pi_D = \pi$, we can derive the following.

$$\begin{aligned}
E\left[V_0^{\pi'}(s_0) - V_0^{\pi}(s_0)\right] &= E\left[\sum_{d=0}^{D-1} V_0^{\pi_d}(s_0) - V_0^{\pi_{d+1}}(s_0)\right] \\
&= \sum_{d=0}^{D-1} E\left[V_0^{\pi_d}(s_0) - V_0^{\pi_{d+1}}(s_0)\right] \\
&= \sum_{d=0}^{D-1} E\left[V_d^{\pi'}(s_d) - Q_d^{\pi'}(s_d, \pi(s_d))\right], \text{where } s_d \sim \mu_d(\pi_{0:d-1})
\end{aligned}$$

The first equality is simply a telescoping sum. The third equality follows due the fact that π_d and π_{d+1} both follow π for the first d steps, which yields the same distribution over s_d. ■

We will use this lemma when the reference policy π' is optimal, that is, $\pi' = \pi^*$. Thus, the sub-optimality of π can be bounded by accumulating the expected sub-optimality of its action choices along trajectories generated by π. Next, we present our three reduction algorithms, which are summarized in Table 1.

3.1 OPI : Optimal Partial Imitation

Perhaps the most straightforward idea for learning a partial policy is to attempt to find a partial policy that is usually consistent with trajectories of the optimal policy π^*. That is, each ψ_d should

OPI	$\mu_d = \mu_d(\pi^*)$ $C_d(s, \psi_d(s)) = 0$ if $\pi^*_d(s) \in \psi_d(s)$, otherwise 1
FT-OPI	$\mu_d = \mu_d(\psi^+_{0:d-1})$ $C_d(s, \psi_d(s)) = 0$ if $\pi^*_d(s) \in \psi_d(s)$, otherwise 1
FT-QCM	$\mu_d = \mu_d(\psi^*)$ $C_d(s, \psi_d(s)) = Q(s, \pi^*_d(s)) - Q(s, \psi^*_d(s))$

Table 1: Instantiations for OPI, FT-OPI and FT-QCM in terms of the template in Algorithm 1. Note that ψ_d is a partial policy while π^*_d, ψ^+_d and ψ^*_d are complete policies.

be learned so as to maximize the probability of containing actions selected by π^*_d with respect to the optimal state distribution $\mu_d(\pi^*)$. This approach is followed by our first algorithm called Optimal Partial Imitation (OPI). In particular, Algorithm 1 is instantiated with $\mu_d = \mu_d(\pi^*)$ (noting that $\mu_0(\pi^*)$ is equal to μ_0 as specified by the learning problem) and C_d equal to zero-one cost. Here $C_d(s, A') = 0$ if $\pi^*_d(s) \in A'$ and $C_d(s, A') = 1$ otherwise. Note that the expected cost of ψ_d in this case is equal to the probability that ψ_d does not contain the optimal action. We refer to this as the pruning error and denote it by

$$e^*_d(\psi) = \Pr_{s \sim \mu_d(\pi^*)}(\pi^*_d(s) \notin \psi_d(s)) \tag{4}$$

A naive implementation of OPI is straightforward. We can generate length D trajectories by drawing an initial state from μ_0 and then selecting actions (approximately) according to π^*_d using standard unpruned search. Defined like this, OPI has the nice property that it only requires the ability to reliably compute actions of π^*_d, rather than requiring that we also estimate action values accurately. This allows us to exploit the fact that search algorithms such as UCT often quickly identify optimal actions, or sets of near-optimal actions, well before the action values have converged. This is an important point since we will approximate π^* using long, computationally expensive runs of UCT, described in section 4.

Intuitively, if the expected cost e^*_d is small for all d, then the regret of ψ should be bounded, since the pruned search trees will generally contain optimal actions for state nodes. The following proof clarifies this dependence. For the proof, given a partial policy ψ, it is useful to define a corresponding complete policy ψ^+ such that $\psi^+_d(s) = \pi^*_d(s)$ whenever $\pi^*_d(s) \in \psi_d(s)$ and otherwise $\psi^+_d(s)$ is the lexicographically least action in $\psi_d(s)$. Note that ψ^+ is subsumed by ψ.

Theorem 3 *For any initial state distribution μ_0 and partial policy ψ, if for each $d \in \{0, \ldots, D-1\}$, $e^*_d(\psi) \leq \epsilon$, then REG$(\mu_0, \psi) \leq \epsilon D^2$.*

Proof Given the assumption that $e^*_d(\psi) \leq \epsilon$ and that ψ^+ selects the optimal action whenever ψ contains it, we know that $e^*_d(\psi^+) \leq \epsilon$ for each $d \in \{0, \ldots, D-1\}$. Given this constraint on ψ^+, we can apply Lemma 3 from (Syed and Schapire, 2010)[3], which implies $E[V_0^{\psi^+}(s_0)] \geq E[V^*_0(s_0)] - \epsilon D^2$, where $s_0 \sim \mu_0$. The result follows by combining this with Lemma 1. ■

This result mirrors work on reducing imitation learning to supervised classification (Ross and Bagnell, 2010; Syed and Schapire, 2010), showing the same dependence on the planning horizon. Borrowing again from imitation learning, it is straightforward to construct an example problem where the above regret bound is shown to be tight. This result motivates a learning approach where each ψ_d returned by SETLEARN attempts to maximize pruning (returns small action sets) while maintaining a small expected cost.

3.2 FT-OPI : Forward Training OPI

OPI has a potential weakness, similar in nature to issues identified in prior work on imitation learning (Ross and Bagnell, 2010; Ross et al., 2011). In short, OPI does not train ψ to recover from its own pruning mistakes. Consider a node n in the optimal subtree of a tree $T(s_0)$. Now suppose that the learned ψ erroneously prunes the optimal child action of n. This means that the optimal subtree under n will be pruned from $T_\psi(s)$, increasing the potential regret. Ideally, we would like the pruned search in $T_\psi(s)$ to recover from the error gracefully and return an answer based on the best remaining subtree under n. Unfortunately, the distribution used to train ψ by OPI was not necessarily representative of this alternate subtree under n, since it was not an optimal subtree of $T(s)$. Thus, no guarantees about the pruning accuracy of ψ can be made under node n.

In imitation learning, this type of problem has been dealt with via "forward training" of non-stationary policies (Ross et al., 2011). We employ a similar idea in the Forward Training OPI (FT-OPI) algorithm. FT-OPI differs from OPI only in the state distributions used for training. The key idea is to learn the partial policy components ψ_d in sequential order from $d = 0$ to $d = D - 1$. Each ψ_d is trained on a distribution induced by $\psi_{0:d-1} = (\psi_0, \ldots, \psi_{d-1})$, which will account for pruning errors made by $\psi_{0:d-1}$. Specifically, recall that for a partial policy ψ, we defined ψ^+ to be a complete policy that selects the optimal action if it is consistent with ψ and otherwise the lexicographically least action. The state distributions used to instantiate FT-OPI in Algorithm 1 are $\mu_d = \mu_d(\psi^+_{0:d-1})$ and the cost function remains zero-one cost as for OPI. Thus, the expected cost of ψ_d is $e^+_d(\psi) = \Pr_{s \sim \mu_d(\psi^+_{0:d-1})}(\pi^*_d(s) \notin \psi_d(s))$, which gives the probability of pruning the optimal action with respect to the state distribution of $\psi^+_{0:d-1}$.

Note that as for OPI, we only require the ability to compute π^* in order to sample from $\mu_d(\psi^+_{0:d-1})$. In particular, note that when learning ψ_d, we have $\psi_{0:d-1}$ available. Hence, we can sample a state from μ_d by executing a trajectory of $\psi^+_{0:d-1}$. Actions for ψ^+_d can be selected by first computing π^*_d and selecting it if it is in ψ_d and otherwise selecting the lexicographically least action.

As shown for the forward training algorithm for imitation learning (Ross et al., 2011), we give below an improved regret bound for FT-OPI under an assumption on the maximum sub-optimality

3. The main result of (Syed and Schapire, 2010) holds for stochastic policies and requires a more complicated analysis that results in a looser bound. Lemma 3 is strong enough for deterministic policies.

of any action. The intuition is that if it is possible to discover high-quality subtrees, even under sub-optimal action choices, then FT-OPI can learn on those trees and recover from errors.

Theorem 4 *Assume that for any state s, depth d, and action a, we have $V_d^*(s) - Q_d^*(s,a) \leq \Delta$. For any initial state distribution μ_0 and partial policy ψ, if for each $d \in \{0,\ldots,D-1\}$, $e_d^+(\psi) \leq \epsilon$, then REG$(\mu_0,\psi) \leq \epsilon\Delta D$.*

Proof We first bound the sub-optimality of ψ^+. By applying Lemma 2 with $\pi' = \pi^*$ and $\pi = \psi'$ we can infer

$$E\left[V_0^*(s_0) - V_0^{\psi^+}(s_0)\right] = \sum_{d=0}^{D-1} E\left[V_d^*(s_d) - Q_d^*(s_d, \psi^+(s_d))\right], \text{where } s_d \sim \mu_d(\psi^+_{0:d-1}). \quad (5)$$

Since we have assumed that $e_d^+(\psi) \leq \epsilon$, we know that for each d the probability that ψ^+ does not select an optimal action for states $s_d \sim \mu_d(\psi^+_{0:d-1})$ is no more than ϵ. In addition, by assumption, the worst case regret of such erroneous action choices is bounded by Δ. Thus, each expectation term of the right-hand-side of Equation 5 can be bounded by $\epsilon\Delta$. Summing these D terms then implies that

$$E\left[V_0^*(s_0) - V_0^{\psi^+}(s_0)\right] \leq \epsilon\Delta D.$$

Since ψ^+ is subsumed by ψ, we can apply Lemma 1 to yield the result. ■

This result implies that if Δ is significantly smaller than D, then FT-OPI has the potential to outperform OPI given the same bound on zero-one cost. In the worst case $\Delta = D$ and the bound will equal to that of OPI.

3.3 FT-QCM: Forward Training Q-Cost Minimization

While FT-OPI addressed one potential problem with OPI, they are both based on zero-one cost, which raises other potential issues. The primary weakness of zero-one cost is its inability to distinguish between large pruning errors and small pruning errors. It was for this reason that FT-OPI required the assumption that *all* action values had sub-optimality bounded by Δ. However, in many problems, including those in our experiments, that assumption is unrealistic, since there can be many highly sub-optimal actions. For example, in Chess, some actions might lead to unavoidable defeat. This motivates using a cost function that is sensitive to the sub-optimality of pruning decisions.

In addition, it can often be difficult to learn a ψ that has small zero-one cost while also providing significant pruning. For example, in many domains, in some states there will often be many near-optimal actions that are difficult to distinguish from the slightly better optimal action. In such cases, achieving low zero-one cost may require producing large action sets. However, learning a ψ that provides significant pruning while reliably retaining at least one near-optimal action may be easily accomplished. This again motivates using a cost function that is sensitive to the sub-optimality of pruning decisions, which is accomplished via our third algorithm, Forward Training Q-Cost Minimization (FT-QCM)

The cost function of FT-QCM is the minimum sub-optimality, or Q-cost, over unpruned actions. In particular, we use $C_d(s,A') = V_d^*(s) - \max_{a\in A'} Q_d^*(s,a)$. Our state distribution will be defined similarly to that of FT-OPI, only we will use a different reference policy. Given a partial policy ψ, define a new complete policy $\psi^* = (\psi_0^*,\ldots,\psi_{D-1}^*)$ where $\psi_d^*(s) = \arg\max_{a\in\psi_d(s)} Q_d^*(s,a)$, so

that ψ^* always selects the best unpruned action. We define the state distributions for FT-QCM as the state distribution induced by ψ^*, i.e. $\mu_d = \mu_d(\psi^*_{0:d-1})$. We will denote the expected Q-cost of ψ at depth d to be $\Delta_d(\psi) = E\left[V_d^*(s_d) - \max_{a\in\psi_d(s_d)} Q_d^*(s_d,a)\right]$, where $s_d \sim \mu_d(\psi^*_{0:d-1})$.

Unlike OPI and FT-OPI, this algorithm requires the ability to estimate action values of sub-optimal actions in order to sample from μ_d. That is, sampling from μ_d requires generating trajectories of ψ_d^*, which means we must be able to accurately detect the action in $\psi_d(s)$ that has maximum value, even if it is a sub-optimal action. The additional overhead for doing this during training depends on the search algorithm being used. For many algorithms, near-optimal actions will tend to receive more attention than clearly sub-optimal actions. In those cases, as long as $\psi_d(s)$ includes reasonably good actions, there may be little additional regret. We use long runs of UCT to approximate ψ_d^* and use UCT's Q estimates in the cost function. The full implementation is described in section 4.

There is a significant theoretical benefit to using expected Q-cost for learning compared to zero-one cost. The following bound, which motivates the FT-QCM algorithm, shows that the dependence on D decreases from worst-case quadratic (for OPI and FT-OPI) to linear.

Theorem 5 *For any initial state distribution μ_0 and partial policy ψ, if for each $d \in \{0,\ldots,D-1\}$, $\Delta_d(\psi) \leq \Delta$, then REG$(\mu_0,\psi) \leq \Delta D$.*

Proof Applying Lemma 2 with $\pi' = \pi^*$ and $\pi = \psi^*$ we get that

$$E\left[V_0^*(s_0) - V_0^{\psi^*}(s_0)\right] = \sum_{d=0}^{D-1} E\left[V_d^*(s_d) - Q_d^*(s_d, \psi^*(s_d))\right], \text{where } s_d \sim \mu_d(\psi^*_{0:d-1}).$$

By our assumption that $\Delta_d(\psi) \leq \Delta$ for all d, we can combine this with the above to obtain

$$E\left[V_0^*(s_0) - V_0^{\psi^*}(s_0)\right] \leq \Delta D.$$

Since ψ^* is subsumed by ψ we can apply Lemma 1 to get the result. ■

FT-QCM tries to minimize this regret bound by minimizing $\Delta_d(\psi)$ via supervised learning at each depth. As we will show in our experiments, it is possible to maintain small expected Q-cost with significant pruning, while the same amount of pruning would result in a much larger zero-one cost. When this is true, the benefits of FT-QCM over OPI and FT-OPI can be significant, which is shown in our experiments.

4. Implementation Details

This section first describes the UCT algorithm, which is the base planner used in all the experiments. We then describe the partial policy representation and the learning algorithm. Finally, we specify how we generate the training data.

4.1 UCT

UCT (Kocsis and Szepesvári, 2006) is an online planning algorithm. Given the current state s, UCT selects an action by building a sparse lookahead tree over the state space reachable from s. Thus, s is at the root of the tree. Edges from s correspond to actions and their outcomes so that the tree

consists of alternating layers of state and action nodes. Finally, leaf nodes correspond to terminal states. Each state node in the tree stores Q estimates for each of the available actions. During search, the Q values are used to select the next action to be executed. The algorithm is anytime, which means that a decision can be obtained by querying the root at any time. A common practice is to run the algorithm for a fixed number of trajectories and then select the root action which has the largest Q value.

UCT became famous for advancing the state-of-the-art in Computer Go (Gelly et al., 2006; Gelly and Silver, 2007). Since then, however, many additional successful applications have been reported, including but not limited to the IPCC planning competitions (Keller and Helmert, 2013), general game playing (Méhat and Cazenave, 2010; Finnsson, 2012), Klondike Solitaire (Bjarnason et al., 2009), tactical battles in real-time strategy games (Balla and Fern, 2009) and feature selection (Gaudel and Sebag, 2010). See Browne et al. (2012) for a comprehensive survey.

The algorithm is unique in the way that it constructs the tree and estimates action values. Unlike standard minimax search or sparse sampling (Kearns et al., 2002), which build depth-bounded trees and apply evaluation functions at the leaves, UCT neither imposes a depth bound nor does it require an evaluation function. Rather, UCT incrementally constructs a tree and updates action values by carrying out a sequence of Monte-Carlo rollouts of entire trajectories from the root to the terminal state. The key idea in UCT is to bias the rollout trajectories towards promising ones, indicated by prior trajectories, while continuing to explore. The outcome is that the most promising parts of the tree are grown first while still guaranteeing that an optimal decision will be made given sufficient time and memory. Tree construction is incremental since each rollout introduces only a small number of additional nodes to the tree, typically one state node and its immediate children (action nodes).

There are two key algorithmic choices in UCT. The first is the policy used to conduct each rollout. We employ the popular method of random action selection which is simple, fast, and requires no domain knowledge. The second choice is the method for updating the value estimates in the tree in response to the outcome produced by the rollout. A commonly used technique requires that each node store: a) the number of times the state (or action) node has been visited in previous rollouts $n(s)$ (or $n(s,a)$), b) the current estimate of each action value $Q(s,a)$. Given this information at each state node, UCT performs a rollout starting at the root state of the tree. If there exist actions that have yet to be tried, then a random choice is made over these untried actions. Otherwise, when all actions have been tried at least once, the algorithm selects the action that maximizes an upper confidence bound given by

$$Q_{UCB}(s,a) = Q(s,a) + c\sqrt{\frac{\log n(s)}{n(s,a)}} \tag{6}$$

where c is a positive constant that controls the exploration bonus. In practice, c is often tuned separately on a per-domain basis. The selected action is then executed and the resulting state is added to the tree if it is not already present. This action selection rule is based on the UCB rule (Auer et al., 2002) for multi-armed bandits, which seeks to balance exploration and exploitation. The first term $Q(s,a)$ is large for actions with high Q value estimates (exploitation), while the second term is large for actions that have been visited less often (exploration), relative to the number of visits to the parent state. The exploration bonus decreases as the action is visited more often.

Having described a procedure to generate trajectories, we now describe the method used to update the tree. After the trajectory reaches a terminal state and receives a reward R, the action values and counts of each state along the trajectory are updated. In particular, for any state action pair (s,a), the update rules are,

$$n(s) \leftarrow n(s) + 1 \tag{7}$$

$$n(s,a) \leftarrow n(s,a) + 1 \tag{8}$$

$$Q(s,a) \leftarrow Q(s,a) + \frac{1}{n(s,a)}(R - Q(s,a)) \tag{9}$$

The equation computes the average reward of rollout trajectories that pass through the node (s,a). As previously mentioned, the algorithm is run for some fixed number of simulations before selecting the best action at the root, typically, the action with the largest Q value, although selecting the action with the most visits is also popular. This particular algorithm has two parameters, the exploration constant c, and the number of rollout trajectories.

The above version is the most basic form of UCT, which has received a very large amount of attention in the game-playing and planning community. See Browne et al. (2012) for a comprehensive survey of the MCTS family of algorithms. We defer the discussion of the MCTS family and relevant UCT variants to section 5. Next, we describe the partial policy representation and learning framework used in our experiments.

4.2 Partial Policy Representation and Learning

We begin by reducing partial policy learning to set learning. As mentioned before, the designer chooses a fixed fraction of actions to prune in each state. The pruning fraction σ_d can vary from 0 to 1, where $\sigma_d = 1$ indicates maximum pruning. The choice of σ_d allows the designer to tradeoff the time constraints of the decision problem with the expected cost achievable by the SETLEARN algorithm. In this work, we perform a post-hoc analysis of the expected cost of ψ_d for a range of pruning values and select values of σ_d that yield reasonably small costs. In section 6, we give details of the selections used in our experiments.

Once σ_d is fixed, we have induced a set learning problem. Next, we convert the set learning problem to a ranking problem. That is, for states at depth d, we seek to learn a scoring function over actions that will allow us to prune away the bottom σ_d fraction of actions. In this work, we use linear ranking functions for their computational efficiency and simplicity, although non-linear approaches (e.g., deep neural networks) may also be used. Formally, we have a n-dimensional weight vector w_d and a user-provided feature vector $\phi(s,a)$ over state-action pairs. The linear ranking function $f_d(s,a) = w_d^T\phi(s,a)$ allows us to define a total order over actions, breaking ties lexicographically. Thus, w_d along with the pruning fraction σ_d fully parameterizes the partial policy component ψ_d, which is defined as the set of $\lceil(1-\sigma_d)\times|A|\rceil$ highest ranked actions.

Next, we specify how we implement the SETLEARN procedure. Each training set will consist of pairs $\{(s_i,c_i)\}$, where s_i is a state and c_i is a vector that assigns a cost to each action. We first describe the reduction to cost-sensitive binary classification and then specify the method by which the training data is generated from long runs of UCT. For OPI and FT-OPI, the cost vector assigns 0 to the optimal action and 1 to all other actions. For FT-QCM, the c_i give the Q-costs of each action, obtained from the Q estimates during offline UCT. We learn the partial policy by first learning the

ranking function in a way that attempts to rank the optimal action as highly as possible and then select an appropriate pruning fraction based on the learned ranker.

For rank learning, we follow a common approach of converting the problem to cost-sensitive binary classification. In particular, for a given example (s, c) with optimal action a^*, we create a cost-sensitive classification example for each action $a_j \neq a^*$ of the form,

$$(s, c) \quad \longrightarrow \quad \{(\phi(s, a^*) - \phi(s, a_j)\ ,\ c(a^*) - c(a_j)) \quad | \quad a_j \neq a^*\}$$

Learning a linear classifier for such an example will attempt to rank a^* above a_j according to the cost difference. This produces $m - 1$ training examples for a state with m actions. We apply an existing cost-sensitive learner (VW, (Langford, 2011)) to learn a weight vector based on the pairwise data. The learning algorithm is standard binary classification with squared loss and L_2 regularization, set to 0.01. We also randomly flip the ranking constraints with uniform probability in order to balance the binary class labels. In VW format, each training example consists of a cost, binary label, and feature difference vector. Finally, we experimented with other methods of generating ranking constraints for the reduction from set learning to ranking (e.g., all pairs, unpruned vs pruned). The simple technique described above performed best in this experimental setup. Note that this implies that the training of f_d is independent of σ_d.

4.3 Generating Training States

Each of our algorithms requires sampling training states from trajectories of particular policies. OPI and FT-OPI require approximately computing π^*_d. FT-QCM has the additional requirement of approximating the action values for sub-optimal actions. Our implementation of this is to first generate a set of trees using substantial search, which provides us with the required policy or action values. We then sample trajectories from those trees.

More specifically, our learning algorithm is provided with a set of root states by using expensive runs of UCT to select actions along complete trajectories, starting from a state drawn from the initial state distribution of a domain. We let S_0 denote the set of states encountered along these trajectories, noting that we can view S_0 as being drawn from the target distribution μ_0. For each $s_0 \in S_0$, we store the tree produced by UCT, noting that the resulting trees will typically have a large number of nodes on the tree fringe that have been infrequently visited. Since such states are not useful for learning, we select a depth bound D such that nodes at depth $d < D$ have been sufficiently explored and have meaningful action values. The trees are then pruned to depth D.

Given this set of depth D trees, we can now generate execution trajectories using the action selection rule for each algorithm (Table 1) and the MDP simulator to sample subsequent states. For example, OPI simply requires running trajectories through the trees based on selecting actions according to the optimal action estimates at each tree node. The state at depth d along each trajectory is added to the data set for training ψ_d. FT-QCM samples states for training ψ_d by generating length d trajectories of $\psi^*_{0:d-1}$.

Each such action selection requires referring to the estimated action values and returning the highest-valued action that is not pruned. The final state on the trajectory is then added to the training set for ψ_d. Note that since our approach assumes i.i.d. training sets for each ψ_d, we only sample a single trajectory from each tree. However, our experiments indicate that multiple trajectories can be sampled from the tree without significant performance loss (although the guarantee is lost). Doing so allows many additional examples to be generated per tree, avoiding the need for additional expensive tree construction.

Algorithm	Action cost vector	Sample trajectory
OPI	$[..., I_{a^*=a_i}, ...]$	$s_0 \xrightarrow{\pi^*_0(s_0)} s_1 \xrightarrow{\pi^*_1(s_1)} s_2 \ ...$
FT-OPI	$[..., I_{a^*=a_i}, ...]$	$s_0 \xrightarrow{\psi^+_0(s_0)} s_1 \xrightarrow{\psi^+_1(s_1)} s_2 \ ...$
FT-QCM	$[... , Q^*_d(s, a^*) - Q^*_d(s, a_i),\ ...]$	$s_0 \xrightarrow{\psi^*_0(s_0)} s_1 \xrightarrow{\psi^*_1(s_1)} s_2 \ ...$

Figure 2: Training data generation and ranking reduction for each algorithm. Start by sampling s_0 from the same initial state distribution μ_0. OPI uses the optimal policy at each depth whereas FT-OPI and FT-QCM use the most recently learned complete policy (at depth $d - 1$). OPI and FT-OPI use 0-1 costs. Only FT-QCM uses the Q cost function, which turns out to be critical for good performance.

5. Related Work

While there is a large body of work on integrating learning and planning, we do not know of any work on learning partial policies for speeding up online MDP planning.

There are a number of efforts that study model-based reinforcement learning (RL) for large MDPs that utilize tree search methods for planning with the learned model. Examples include RL using FSSS (Walsh et al., 2010), Monte-Carlo AIXI (Veness et al., 2011), and TEXPLORE (Hester and Stone, 2013). However, these methods focus on model/simulator learning and do not attempt to learn to speedup tree search, which is the focus of our work.

Work on learning search control knowledge in deterministic planning and games is more related. One research direction has been on learning knowledge for STRIPS-style deterministic planners. Examples of this approach are learning heuristics and policies for guiding best-first search (Yoon et al., 2008) or state ranking functions (Xu et al., 2009). The problem of learning leaf evaluation heuristics has also been studied in the context of deterministic real-time heuristic search (Bulitko and Lee, 2006). As another example, evaluation functions for game tree search have been learned from the "principle variations" of deep searches (Veness et al., 2009). A related body of work involves iterative deepening heuristic search and its variants (Korf, 1985; Reinefeld and Marsland, 1994). Control knowledge is typically leveraged using heuristic scoring functions, transposition tables and principal variations. These methods often improve search by using memory-intensive control knowledge (e.g., hash tables) and incrementally expanding the search, but do not provide theoretical guarantees. Nevertheless, the idea of progressive widening and iterative deepening is extremely appealing and one that we intend to explore more in future work.

The idea of using deep UCT search to generate high-quality state-action training pairs has been proposed recently (Guo et al., 2014). This work is intuitively similar to the work in this paper. The high-quality training data is used to train a stationary reactive policy using a deep neural network (DNN) policy. This is standard imitation learning, where the goal is to learn a reactive policy. The resulting DNN policy performs very well on a number of ATARI games. However, even this sophisticated reactive policy cannot outperform deep (but slower) UCT search. This work provides examples of domains in which an advanced reactive controller is outperformed by sufficiently deep lookahead tree search. Our work attempts to provide a rigorous middle ground between reactive decision-making and expensive unpruned search.

There have been a number of efforts for utilizing domain-specific knowledge in order to improve/speedup MCTS, many of which are covered in recent surveys (Browne et al., 2012; Gelly et al., 2012). The two main methods involve progressive bias and progressive widening. The core idea of progressive bias involves adding a quantity $f(s, a)$ for guiding action selection during search. $f(s, a)$ may be hand-provided (Chaslot et al., 2007), or learned (Gelly and Silver, 2007; Sorg et al., 2011). Generally, there are a number of parameters that dictate how strongly $f(s, a)$ influences search and how that influence decays as search progresses. In Sorg et al. (2011), control knowledge is learned via policy-gradient techniques in the form of a reward function and used to guide MCTS with the intention of better performance given a time budget. So far, however, the approach has not been analyzed formally and has not been demonstrated on large MDPs. Experiments in small MDPs have also not demonstrated improvement in terms of wall clock time over vanilla MCTS. The second method, progressive widening, is more popular in problems with large or continuous action spaces. The main idea here is to start the search with small action sets and introduce new actions as search progresses (Couëtoux et al., 2011a,b). For example, one may add a new action (sometimes called "unpruning") when the number of visits to a state exceeds a heuristically chosen threshold. Although progressive widening is intuitively appealing and clearly required for anytime search in large action spaces, we were unable to find any existing method that leverages control knowledge or works in a principled manner.

Finally, MCTS methods often utilize hand-coded or learned rollout policies (sometimes called "default policies") to improve anytime performance. A very well-known example is MoGo (Gelly et al., 2006). While this approach has shown promise in specific domains such as Go, where the policies can be highly engineered for efficiency, we have found that the large computational overhead of a learned rollout policy makes its usage hard to justify. The key issue is that the use of any learned rollout policy requires the evaluation of a feature vector at each state (or state-action pair) encountered during the rollout. Rollouts are typically far longer than the depth of the search tree, especially during the initial part of the sequential problem. This results in a massive number of additional feature evaluations, far greater than the number of evaluations performed by the heuristic bias methods discussed above which only require a feature evaluation once for every new action node added to the tree. Thus, the use of learned rollout policies may cause orders of magnitude fewer trajectories to be executed, compared to vanilla MCTS. In our experience, this can easily lead to degraded performance per unit time. Furthermore, there is little formal understanding about how to learn such rollout policies in principled ways, with straightforward approaches often yielding decreased performance (Silver and Tesauro, 2009).

6. Experiments

We perform a large-scale empirical evaluation of the partial policy learning algorithms on two challenging MDP problems. The first, Galcon, is a variant of a popular real-time strategy game, while the second is Yahtzee, a classic dice game. Both problems pose a serious challenge to MCTS algorithms, for different reasons. However, in both domains, UCT, enhanced with learned partial policies, is able to significantly improve real-time search performance over every baseline. The key experimental findings are listed next.

1. The search performance of UCT using a partial policy learned by the FT-QCM algorithm, denoted as UCT(FT-QCM), is significantly better than that of FT-OPI and OPI in both domains.

2. UCT(FT-QCM) performs significantly better than vanilla UCT and other "informed" UCT variants when the search budget is small. Given a larger search budget, UCT(FT-QCM) wins in Galcon and achieves parity in Yahtzee.

3. The average regret of the pruning policies on a supervised dataset of states is strongly correlated with the search performance, which is in line with our formal results. FT-QCM has significantly lower regret than FT-OPI and OPI.

4. The quality of the training data deteriorates quickly as depth d increases. Regret increases as d increases.

5. It is critical to incorporate the computational cost of using control knowledge into the search budget during evaluation. Ignoring the computational cost of knowledge can significantly change the perceived relative performance of different algorithms.

6.1 Experimental Domains

Galcon: The first domain is a variant of a popular two-player real-time strategy game, illustrated in Figure 3. The agent seeks to maximize its population by launching variable-sized population fleets from one of the planets currently under its control. The intention may be to either reinforce planets already controlled, attack an enemy planet, or capture an unclaimed planet. This produces a large action space ($O(|\text{planets}|^2)$), where an action is defined as the triple (source planet, destination planet, fleet size). In our experiments, we use maps with 20 planets and three discrete levels of fleet size (small, medium, large). This often leads to game states where the action space contains hundreds of actions. The exact set of actions varies during the game as control over planets changes. State transitions are typically deterministic, unless a battle occurs. During each battle, a unit is randomly chosen from the two armies for termination. The battle ends when only one army remains. The maximum length of a game is restricted to 90 moves.

The search complexity caused by the large action branching factor is exacerbated by the relatively slow simulator and the length of the game. In this setting, UCT can only perform a small number of rollouts even when the search budget is as large as eight seconds per move. In fact, even at the largest search budgets, UCT only sparsely expands the tree beyond depths two or three. Note, however, that the rollout component of UCT is run to the end of the game and hence provides information well beyond these shallow depths. Finally, the second player or adversary is fixed to be a UCT agent with a budget of one second per move. All evaluations are performed against this fixed adversary. Note that at one second per decision, the fixed adversary effectively acts randomly, especially during the initial part of the game. However, further increase in the adversary's search budget is impractical because of the significant computational cost of evaluating search agents in this domain.

The agent's performance can be measured in terms of the final population difference. This value is zero when the game is tied, a large positive value when the agent wins convincingly and a negative value when the agent is much weaker than the adversary. The rollout policy used is random unless mentioned otherwise, while the exploration bias c is set to 0.75 in Galcon, after a brief grid search showed that search performance was relatively invariant to the exploration bonus as long as the parameter was set sufficiently high. The exploration bias was not optimized in favor of any of the three algorithms presented in this paper and is kept constant.

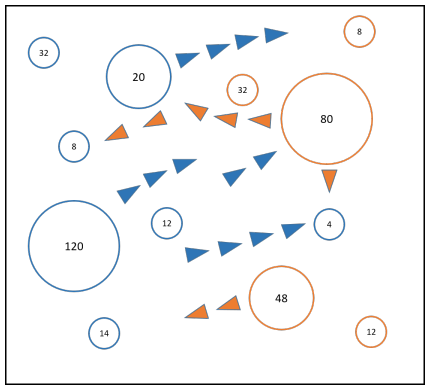

Figure 3: A visualization of a Galcon game in progress. The agent must direct variable-sized fleets to either reinforce planets under its control, take over enemy planets, or unoccupied ones. The decision space is large, often involving hundreds of actions.

Yahtzee: The second domain is a classic dice game which consists of thirteen stages. In each stage, the agent may roll any subset of the five dice at most twice, after which the player must select one of the empty categories. A category, once selected, may not be reselected in later stages. This produces a total of 39 decisions that must be made per game, where the last action trivially assigns the only remaining category. The categories are divided into upper and lower categories with each one scored differently. The lower categories roughly correspond to poker-style conditions ("full house", "three of a kind", "straight", etc.), while the upper categories seek to maximize the individual dice faces (ones, twos, ..., sixes). A bonus of 35 points is awarded when the sum of the upper category scores exceeds 63. This ensures that the player must very carefully assign categories since the loss of the bonus has a large impact on the final score. The maximum score at the end of any game is 375, which is very hard to achieve. The above implementation is the simplest version of the game, restricted to a single "Yahtzee" (all five dice faces are identical). Our implementation for the simulator will be made available upon request[4]. Figure 4 shows a summary of the rules of the game. The UCT algorithm, including all parameter values, is identical to the one used in Galcon.

The trees generated by UCT differ significantly in the two domains. Compared to Galcon, Yahtzee has a relatively small action branching factor, smaller time horizon and a fast simulator. Furthermore, the available actions and the branching factor in Yahtzee decrease as categories are filled, whereas in Galcon, the agent occupying more planets has a larger action set. Thus, we can play many more games of Yahtzee per unit time compared to Galcon. However, Yahtzee poses a difficult challenge for MCTS algorithms due to the dice rolls which increase the state branching factor and add variance to the Q value estimates. Consequently, even deep search with the UCT algorithm is error-prone and struggles to improve performance with larger search budgets. As in Galcon, the search quality of UCT degrades significantly at depths beyond two or three. Note, however, that

4. We are also in the process of open-sourcing the entire code base.

UPPER CATEGORIES

Aces	= 3	COUNT AND ADD ONLY ACES

Chance		SCORE TOTAL OF ALL 5 DICE	
TOTAL	OF LOWER HALF	➡	L

TOTAL SCORE = U + B + L

Figure 4: A typical scoring sheet for Yahtzee, consisting of five dice and 13 categories. In each game, all 13 categories must be scored, one per stage. Each stage consists of at most three dice rolls (original roll + two more controlled by the player). The objective is to maximize the total score. The dice rolls increase the tree size and adds variance during rollouts. Our simulator implements the variant where at most one "Yahtzee" (all five dice faces are identical) can be recorded.

the performance degradation in Yahtzee is primarily caused by the transition stochasticity from the dice rolls, although the action branching factor remains significant. As in Galcon, UCT rolls out trajectories to the end of the game. Doing so provides information from states much deeper than the depth of the tree.

Normalizing rewards

The final score is always non-negative for Yahtzee, but may be negative for Galcon if the agent loses the game. In order to achieve a consistent comparison between the supervised metrics and search performance, we perform a linear rescaling of the score so that the performance measure now lies in the interval $[0, 1]$. In our experiments, we provide this measure as reward to the agent at the end of each trajectory. That is, rewards are zero everywhere except in terminal state-action pairs. Note that a reward above 0.5 indicates a win in Galcon. In Yahtzee, a reward value of 1.0 is the theoretical upper limit achievable in the best possible outcome, which rarely occurs in practice. Furthermore, even a small increase in the reward (e.g., 0.1) is a significant improvement in Yahtzee.

6.2 Partial Policy Learning Setup

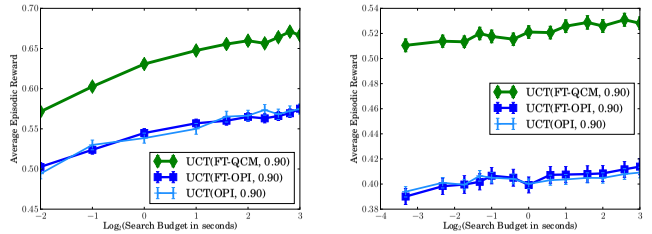
We now describe the procedure used to generate training data for the three learning algorithms, OPI, FT-OPI, and FT-QCM. Each algorithm is provided with root states generated by playing approximately 200 full games. In Galcon, UCT is allowed to search for 600 seconds per move, whereas in Yahtzee, UCT is given 120 seconds per move. Each game results in a trajectory of states visited during the game. All of those states across all games constitute the set of root states used for training as described in section 4. Despite the enormous search budget, depths beyond two or three are sparsely expanded, due to the large state and action branching factors. We therefore set the search depth bound (D) to 3 for learning, since the value estimates produced by UCT for deeper nodes are often inaccurate. Thus, the learned partial policy has the form $\psi = (\psi_0, \psi_1, \psi_2)$. When UCT generates tree nodes at depths greater than D, we prune using ψ_2. As previously mentioned, we do not limit the rollouts of UCT to depth D. Rather, the rollouts proceed until terminal states, which provide a longer-term heuristic evaluation for tree nodes. However, we have confirmed experimentally that such nodes are not visited frequently enough for pruning to have a significant impact.

As previously mentioned, we learn partial policies by learning linear scoring functions. This requires us to compute state-action features $\phi(s, a)$ that capture salient attributes. We now describe the features used in each domain.

Galcon features: The features are defined over the next state (or "afterstate") produced by simulating the action in the current state. The salient attributes of the next state for launch actions include attributes of the source and destination planet like the planet size, its current population, the growth rate, and the incoming enemy threat. All real-valued features are discretized into 100 bins, using a one-hot encoding. For destination planets, the feature vector consists of the concatenation of three one-hot sub-vectors, corresponding to whether the destination planet is occupied by the current player, by the adversary, or unoccupied by either player. Note that exactly one of the three sub-vectors is non-zero for a particular destination planet. For "do nothing" actions, we have a single indicator feature. Finally, we also have a constant (bias) feature. This leads to a total feature space of size 1602, but only a small number (typically nine) are active for a given state-action pair. However, the computation of $\phi(s, a)$ is still slow due to the simulator call to obtain the next state.

Yahtzee features: The features for the current state-action pair are defined over the next state, which is sampled by calling the simulator on the current state-action pair. The state-action feature vector is specified using a sparse one-hot encoding, where each of the 13 categories has 100 features assigned to it with one additional bias feature. The feature value for each unfilled category is a measure of how "close" the dice are to achieving the maximum score for that category, discretized into 100 bins. A perfect score returns a feature value of 1, whereas a category selection that does not add to the game score returns a feature value of 0. However, "select" actions for the upper categories that achieve binary outcomes (e.g., either a "full house" is achieved or not), are encoded using binary indicator features. All "roll" actions use discretized features, encoding how close the roll action brings the dice to a desired configuration. Note that there is large variance in the state-action features due to the dice rolls. This variance may be reduced by sampling more states and averaging. However, doing so would significantly increase the computational overhead of computing $\phi(s, a)$.

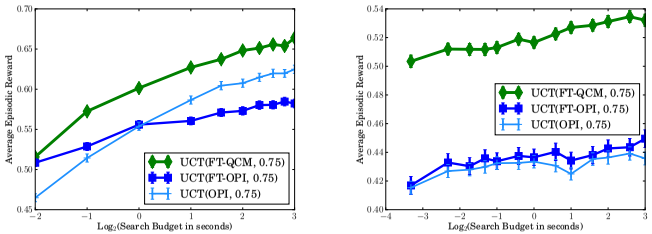
Evaluation metrics: We report the search budget in real-time (e.g., 4 seconds per move) instead of the number of simulations. Each point on the anytime curve is the average of 1000 final game scores, with 95% confidence intervals. This large-scale evaluation has massive computational cost and requires access to a cluster. The use of time-based search budgets in a cluster environment adds variance, requiring additional evaluations and averaging. However, an important result of the following experiments is that the use of time to measure budgets is essential for a fair comparison of "knowledge-injected" search algorithms.



6.3 Comparing OPI, FT-OPI, and FT-QCM

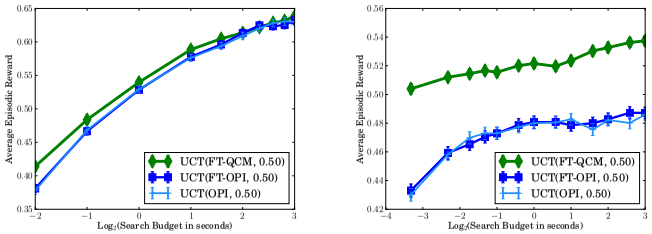
We learn ranking functions using each of the three learning algorithms, as described in section 4.2. We obtain a set of partial policies by varying the pruning thresholds σ_d. Recall from section 4.2 that our implementation of rank function learning does not depend on σ_d. The learned partial policies are used to prune actions during search. Figure 5 shows the impact on search performance using UCT as the fixed base search algorithm. The first row shows the results for a large amount of pruning ($\sigma_d = 0.90$) while the second and third rows have progressively smaller pruning thresholds.

The first observation is that FT-QCM is clearly better than FT-OPI and OPI in both domains. FT-OPI and OPI are only competitive with FT-QCM in Galcon if small pruning is applied (bottom left). In Yahtzee, FT-QCM is significantly better even when the pruning is reduced to 50%.



Second, we observe that all search algorithms perform better as the search budget is increased. However, the pruning thresholds significantly impact the performance gain across the anytime curve. In Galcon, this impact is highlighted by the steep curves for $\sigma_d = 0.5$, compared to the relatively flat curves for larger pruning thresholds. In Yahtzee, although performance appears to increase very slowly, this small increase corresponds to a significant improvement in playing strength.

The clear superiority of FT-QCM merits further investigation. Recall that FT-QCM differs from FT-OPI only in terms of the cost function. Given the near-identical performance of FT-OPI and OPI, it seems that forward training is less relevant to performance. Therefore, we conclude that the performance improvement comes from incorporating the Q-cost instead of zero-one cost. Next, we analyze the learned partial policies to gain additional insight into the impact of Q-cost learning, compared to zero-one cost and forward training.



(a) Galcon, $\sigma_d = 0.90$

(b) Yahtzee, $\sigma_d = 0.90$

(c) Galcon, $\sigma_d = 0.75$

(d) Yahtzee, $\sigma_d = 0.75$

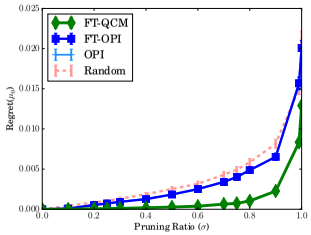
(e) Galcon, $\sigma_d = 0.50$

(f) Yahtzee, $\sigma_d = 0.50$

Figure 5: The search performance of UCT using partial policies learned by FT-QCM, FT-OPI, and OPI as a function of the search budget. The results for Galcon are in the first column, the results for Yahtzee in the second. Each row corresponds to a different set of pruning thresholds. The top row shows the results of pruning 90% of the actions whereas the bottom row prunes 50%. FT-QCM easily outperforms FT-OPI and OPI in five instances and is tied in the sixth. As mentioned in section 6.1, the reward (bounded by $[0, 1]$) is a linear function of the raw score, measured at the end of the game.

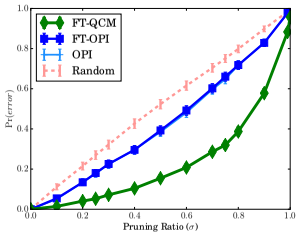
6.4 Relating search and regret

In order to better understand how search performance is related to the quality of the pruning policies, we analyze the learned partial policies on a held-out dataset of trajectories. In particular, for each linear partial policy, we compute its average pruning error and average regret as the level of pruning is increased from none ($\sigma_d = 0$) to maximum ($\sigma_d = 1.0$). Recall the definition of pruning error from Equation 4, which is the probability of ψ pruning away the optimal action (w.r.t. the expert policy). The definition for regret is given in Equation 3. These supervised metrics are computed by averaging over a held-out dataset of root states taken from at least one thousand trajectories. Figure 6 shows these supervised metrics on Galcon for each of the three depths. The left column shows the average regret while the right column is the average pruning error rate. The result of pruning randomly is also shown since it corresponds to pruning with random action subsets. Figure 7 shows the corresponding results for Yahtzee.



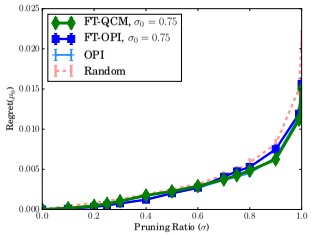
We start at the root, which is the first row in both figures. As expected, both regret and error increase as more actions are pruned. The key result here is that FT-QCM has significantly lower regret than FT-OPI and OPI for both domains. The lower regret is unsurprising given that FT-QCM uses the regret-based cost function while FT-OPI and OPI use zero-one costs. However, FT-QCM also demonstrates the least pruning error in both problems. Given that the same state distribution is used at the root, this observation merits additional analysis.

There are two main reasons why FT-OPI and OPI do not learn good policies. First, the linear policy space has very limited representational capacity. Second, the expert trajectories are noisy. The poor quality of the policy space is highlighted by the spike in the regret at maximum pruning, indicating that all three learners have difficulty imitating the expert. We also observe this at the end of training, where the final 0-1 error rate remains high. The expert's shortcomings lie in the difficulty of the problems themselves. For instance, in Galcon, very few action nodes at depths $d > 0$ receive sufficient visits. In Yahtzee, the stochasticity in dice rolls makes it very difficult to estimate action values accurately. Furthermore, in states where many actions are qualitatively similar (e.g., roll actions with nearly identical Q values), the expert's choice of action is effectively random. This adds noise to the training examples, which makes the imitation learning problem harder. However, FT-QCM's use of regret-based costs allows it to work well in Yahtzee at all depths, but only at the root in Galcon. In Galcon, the expert deteriorates rapidly away from the root policy and the training dataset becomes very noisy. Given the dominating performance of FT-QCM over OPI and FT-OPI, we focus on FT-QCM for the remainder of the experiments.

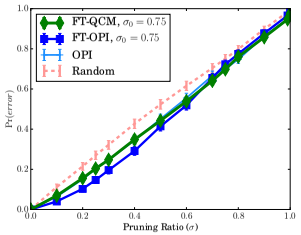


6.5 Selecting σ_d

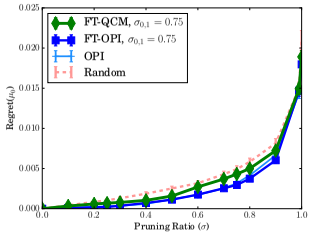
We will now describe a simple technique for selecting σ_d. Recall that a good pruning threshold must "pay for itself". That is, in order to justify the time spent evaluating knowledge, a sufficient number of sub-optimal actions must be pruned so that the improvement produced is larger than what would have been achieved by simply searching more. At one extreme, too much pruning incurs large regret and little performance improvement with increasing search budgets. At the other extreme, if insufficient actions are pruned, search performance may be worse than that of uninformed (vanilla) search due to the additional overhead of computing state-action features.



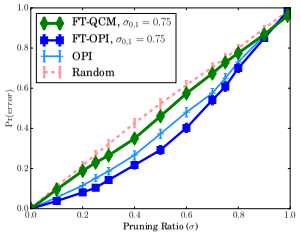
The key to selecting good values lies in the supervised metrics discussed above, where the regret and search graphs are correlated. Thus, one simple technique for selecting σ_d is to use the largest value that has sufficiently small regret. For instance, in Galcon, regret is near-zero for $\sigma_0 < 0.75$ and



(a) Galcon: Regret at the root (d=0)

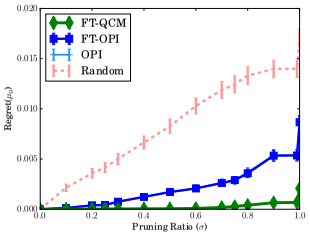


(b) Galcon: Pruning error rate at the root (d=0)

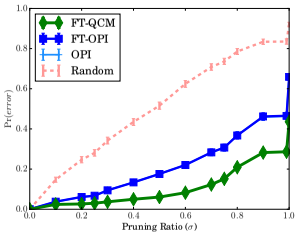


(c) Galcon: Regret at d=1

(d) Galcon: Pruning error rate at d=1



(e) Galcon: Regret at d=2



(f) Galcon: Pruning error rate at d=2

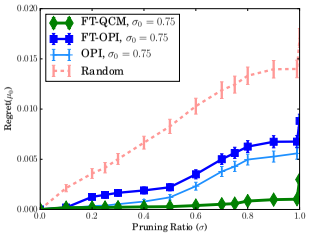


Figure 6: Average regret and pruning error for the learned partial policies ψ_d as a function of the pruning ratio in Galcon. The metrics are evaluated with respect to a held-out test set of states obtained from at least 1000 trajectories with root states sampled from μ_0. FT-QCM has the least error and regret at the root. At depths $d > 0$, performance degrades towards random due to noisy training data.

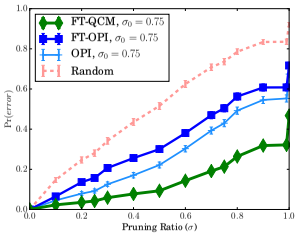
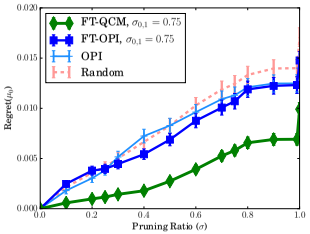
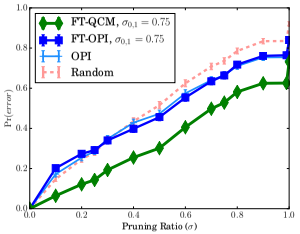


(a) Yahtzee: Regret at the root (d=0)



(b) Yahtzee: Pruning error rate at the root (d=0)



(c) Yahtzee: Regret at d=1

(d) Yahtzee: Pruning error rate at d=1

(e) Yahtzee: Regret at d=2

(f) Yahtzee: Pruning error rate at d=2

Figure 7: Average regret and pruning error for the learned partial policies ψ_d as a function of the pruning ratio in Yahtzee. The metrics are evaluated with respect to a held-out test set of states obtained from at least 1000 trajectories with root states sampled from μ_0. At depths $d > 0$, FT-QCM continues to perform better than FT-OPI and OPI due to the relatively higher quality of training data at deeper states.

increases sharply thereafter. The regret is practically zero for Yahtzee until the pruning threshold exceeds 0.5 and only seems to increase significantly around 0.75. For simplicity, we choose a constant pruning threshold and set σ_d to 0.75 for every value of d. As we will see next, using FT-QCM partial policies with $\sigma_d = 0.75$ results in large performance gains across the anytime curve. A more computationally expensive method of selecting σ_d would require the evaluation of the planning performance of a number of different pruning thresholds.

6.6 Comparing FT-QCM with baselines

We will now compare FT-QCM with other search-based and reactive agents. Most of the baselines require control knowledge in the form of either a policy or a heuristic evaluation function. Since the partial policy learned by FT-QCM at the root has the least regret, we will use it in every technique [5]. We denote this partial policy as ψ_G and its linear scoring function as $h_G(s,a) = w_G^T \phi(s,a)$.

Heuristic Bias (HB): Our first baseline is a popular technique for injecting a heuristic into the MCTS framework. HB first adds a bias to an action node's score and then slowly reduces it as the node is visited more often. This has the effect of favoring high-scoring actions early on and slowly switching to unbiased search for large budgets. This technique can be viewed as a form of progressive widening (Chaslot et al., 2007) with biased action selection and encompasses a large body of search variants. For example, one method uses the visit counts to explicitly control the branching factor at each node (Couëtoux et al., 2011a). However, none of these methods come with formal regret bounds and are agnostic to the choice of heuristic, if one is used. In our experiments, we observed that search performance is extremely sensitive to the interaction between the reward estimate, non-stationary exploration bonus, and the non-stationary bias term. In our domains, the following heuristic worked better than the other variations considered.

$$\begin{aligned} q(s,a) &= K h_G(s,a) && \text{if } n_a = 0 \\ &= Q_{UCB}(s,a) + (1-k_n) K h_G(s,a) && n_a > 0 \end{aligned}$$

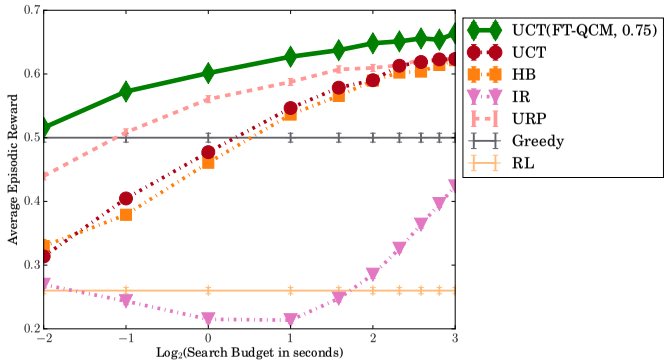
where K is a domain-specific constant and $k_n = n(s,a)/(n(s,a)+1)$ is zero for an unvisited action and increases towards one as the action is visited more. Thus, the exploration scaling term $(1-k_n)$ is maximum (one) initially and decreases towards zero with each subsequent visit. Next, $Q_{UCB}(s,a)$ is the UCB score of an action node from Equation 6, combining the Q estimate with an exploration bonus for infrequently visited action nodes. The best values of K and the exploration constant c were obtained through a computationally expensive grid search.

Informed Rollout (IR): Another popular technique for using knowledge in UCT involves using an "informed" rollout policy. The underlying idea is that a biased rollout policy can produce more accurate state evaluations than uniform random action selection. Typically, this policy is hand-engineered using expert knowledge (e.g., MoGo (Gelly et al., 2006)), but it can also be learned offline using domain knowledge (Silver and Tesauro, 2009) or online in a domain-independent manner (Finnsson and Björnsson, 2010). Here, we use a MoGo-like strategy of selecting randomly from the partial policy ψ_G using a pruning ratio of 0.75. That is, at each state during a rollout from a leaf node, an action is randomly sampled from the top 25% of the action set with respect to the scoring function h_G. From the experiments in section 6.4, we expect this policy to have very small regret.

5. We also tried regression and RL techniques to learn an evaluation function but none of the approaches worked as well as FT-QCM.

However, "informed" rollout policies have significantly larger computational costs compared to random action selection, since each rollout requires knowledge to be evaluated a very large number of times. That is, the number of knowledge evaluations performed during policy rollouts is massive, compared to the number of knowledge evaluations performed for tree nodes. We experimented with other informed rollout policies, such as softmax as well as a complete policy that prunes all but one action. However, none of these approaches were able to perform significantly better.

UCT with Random pruning (URP): A simple yet interesting baseline is the UCT algorithm that prunes randomly. We use $\sigma_d = 0.75$ for consistency. URP avoids the cost of feature computation while simultaneously reducing the number of actions under consideration. URP is motivated by the insight obtained in the previous section, where performance at small search budgets improved with additional pruning. An important observation is that searching with random action subsets corresponds to evaluating the search performance of a random partial policy which we analyzed in Figure 6 and Figure 7.



Reactive policies: Finally, we consider policies that do not search. The first, "Greedy", is simply $\arg\max_a h_G(s,a)$, acting greedily w.r.t. ψ_G. The second is a linear policy learned using the SARSA(λ) RL algorithm (Barto et al., 1995) over the same features used to learn ψ_G. We experimented with different values of λ, exploration and learning rates, and report the best settings for each domain. For Galcon, we observe that learning is negligible after 8000 games with exploration rate $\epsilon = 0.25$, decay $\lambda = 0.75$, with a constant learning rate of 0.01. For Yahtzee, which has a much faster simulator, we play 10^5 games using $\epsilon = 0.2$, $\lambda = 0.1$, and the same constant learning rate of 0.01. In both cases, RL is run until improvement becomes negligible.

Results

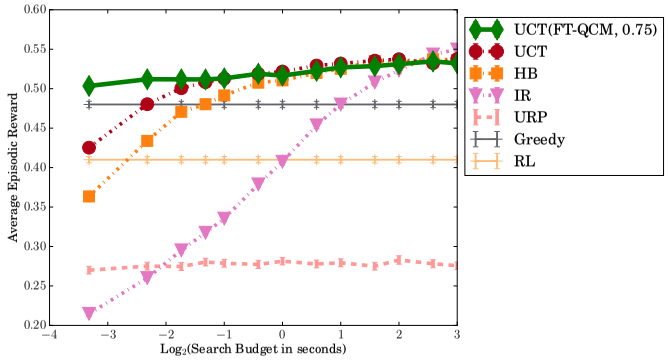


Figure 8(a) and Figure 8(b) show the results for Galcon and Yahtzee, respectively. They constitute the main experimental result of this paper. We discuss the results for each domain separately below.

Galcon: The key observation in Figure 8(a) is that FT-QCM injected into UCT significantly outperforms all other baselines at small search budgets and moderately large search budgets. The search budget is measured in real time. As the search budget increases, the FT-QCM injection continues to show slow improvement, whereas uninformed UCT fails to match performance even at eight seconds per move. We were unable to get HB and IR to perform well, which is surprising given prior reports of successful applications of these methods. IR performs particularly poorly and is worse than even the reactive policies (Greedy, SARSA). The main reason for IR's poor performance is the massive computational overhead of its "informed" rollouts. In Galcon, games (and therefore rollouts) are long which means that computing features for every legal state-action pair incurs significant computational cost. Random rollout policies are much faster in comparison and provide non-trivial value estimates. However, we observe that IR appears to be improving rapidly and may eventually outperform UCT, but only at unreasonably large search budgets (e.g., ten minutes per move).

In contrast, heuristic bias (HB) is relatively inexpensive since it must only be computed once for each state added to the tree. That is, HB has the same overhead as partial policy injection, which allows HB to perform better than IR. However, HB is unable to improve over uninformed UCT. This is surprising since prior work has described search agents that successfully leverage HB. In our experiments, we observe that HB is sensitive to the particular choice of bias decay. Getting HB to work well across the anytime curve is challenging and time-consuming. Next, we consider

(a) Galcon, FT-QCM v baselines

(b) Yahtzee, FT-QCM v baselines

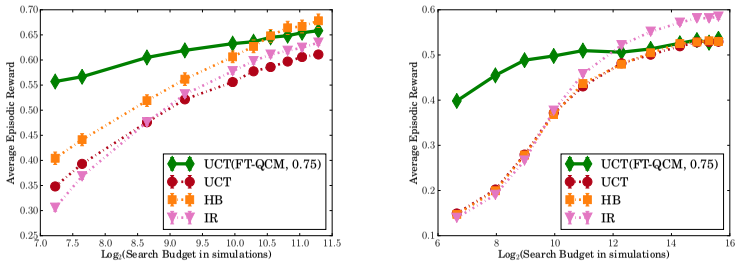
Figure 8: The key empirical result of this paper shows that the search performance of UCT injected with FT-QCM significantly outperforms all other baselines at small budgets. At larger budgets, it either continues to win or achieves parity.

uninformed UCT which has zero overhead. As suspected, UCT is near-random at small time scales, getting outperformed by the variant that prunes randomly (URP). The difficulty of planning in large action spaces is highlighted by the strong performance of URP, which is second only to FT-QCM across the anytime curve. Finally, the reactive policies (Greedy, SARSA) perform reasonably well, but are incapable of utilizing larger time budgets. Greedy, in particular, appears to perform as well as UCT with a search budget of one second per move. This is much better than the policy learned

by the RL algorithm. Finally, at the smallest search budget, Greedy outperforms all other baselines and is second only to FT-QCM.

Yahtzee: FT-QCM easily outperforms all baselines in this domain. However, compared to Galcon, the baselines are far more competitive at larger time scales and a number of methods achieve parity with FT-QCM. Vanilla UCT is particularly good and quickly matches FT-QCM as the search budget is increased. However, it is important to note that despite pruning 75% of the actions, FT-QCM is able to significantly outperform vanilla UCT (and other baselines) for small decision times and does not lose to vanilla UCT at larger search budgets. This result also confirms that small supervised regret (Figure 6) translates into good performance as demonstrated by the strong performance of Greedy. However, as in Galcon, both reactive policies are outperformed by search-based techniques given sufficient time.

HB and IR are uncompetitive in this domain. IR performs very poorly at first, for reasons discussed previously. However, IR eventually overtakes all methods and the graph indicates that performance may improve further, given additional time. However, HB is worse than UCT and only manages to achieve parity at large time scales. The challenges of planning in Yahtzee are clearly visible in the relatively flat anytime curves for each search variant and the high residual variance, despite averaging over a thousand games. Given the relatively small action branching factor compared to Galcon, it is notable that in Yahtzee, FT-QCM is able to perform significantly better than all competing knowledge injections and reactive policies.



Finally, URP performs very poorly in Yahtzee, in contrast to its good performance in Galcon. The underlying reason is the relatively small percentage of good actions in a typical Yahtzee state. In Yahtzee, URP's random pruning will often result in the elimination of all reasonable actions, which decreases performance. In Galcon, this is less likely to occur since there are a much larger fraction of good actions.

6.7 The cost of knowledge

Given that many successful applications of biased initialization methods like HB and biased rollout methods like IR have exhibited improved search performance in the literature, we were surprised when HB and IR failed to improve over vanilla MCTS in our domains. Much tuning was required for HB to balance the effect of different score components. In contrast, it is relatively simple to bias rollouts and the results indicate that state-of-the-art performance is achievable with IR if one is prepared to search for very long periods of time.

The key issue seems to be the high computational cost of knowledge compared to conducting additional search. In order to evaluate the true cost of knowledge in IR and HB, we switch to measuring performance in terms of the number of simulated trajectories rather than wall-clock time. This evaluation approach ignores the time-cost of applying either the evaluation heuristic or the biased rollout policy. This reporting method has the advantage of being invariant to the architecture and implementation and is widely used in the MCTS literature. Note that we cannot re-compute these results by simply translating the time-based evaluations, since each rollout can take a variable amount of time to finish. For example, rollouts from states at the start of a game take more time compared to rollouts from near-terminal states. We therefore re-evaluate the agents, where each search is now allowed to perform a fixed number of simulations from the root. The impact of measuring search budgets using simulations instead of time is shown in Figure 9.

UCT(FT-QCM) continues to win easily at search budgets that are relatively small. However, as the search budget increases, HB and IR now demonstrate better performance. At the largest search budgets, HB outperforms UCT in Galcon and achieves parity in Yahtzee. IR eventually outperforms all other variants in Yahtzee. This improvement is noteworthy, given that IR performed very poorly in the time-based evaluation. These experiments show that using biased rollouts can improve search performance but only at exorbitant and unpredictable runtimes, varying with the particular state at the root of the tree. A broader observation is that it seems very important to correctly incorporate the cost of knowledge when comparing different injections, which has not always been the case in prior work on MCTS.

(a) Galcon, # of simulations (b) Yahtzee, # of simulations

Figure 9: The results of measuring search performance using the number of simulations, instead of time. Doing so eliminates the computational cost of using control knowledge. IR (UCT with biased rollouts) now appears to perform much better. However, UCT with FT-QCM continues to perform the best across significant portions of the anytime curve.

7. Summary and Future Work

We have shown algorithms for offline learning of partial policies, which can be used to reduce the action branching factor in time-bounded tree search. The algorithms leverage a reduction to i.i.d. supervised learning and the expected regret is shown to be bounded. Experiments in two challenging domains show significantly improved anytime performance in Monte-Carlo Tree Search.

There are a number of promising directions to explore next. The first improvement is to the base learner for the set learning problems. Recent work has studied more principled approaches for such set learning problems via a list learning approach (Dey et al., 2013; Ross et al., 2013). While the simplicity of the ranking approach used in our work is appealing, more sophisticated approaches may yield significant performance gains in certain cases. Importantly, a major benefit of studying algorithms within a reduction framework is that we can easily incorporate any such improvements to base learners without needing to change the overall algorithm.

Another important implementation detail that requires additional exploration is the use of non-stationary partial policies. As mentioned previously, imitation learning algorithms, such as DAGGER (Ross et al., 2011), provide the same regret bounds as forward training using a stationary policy, with data from different distributions combined into a single dataset. It is certainly appealing to have a single policy that shares data and parameters across depth instead of the depth-indexed non-stationary partial policies considered here. However, one practical difficulty that arises in our setting is that the training data extracted from long runs of UCT gets noisier with increasing depth. Our initial attempts to mix data across depths led to poor performance. One way to control noise in the supervised datasets, irrespective of depth, might be to run a separate, long UCT from any state that is to be included in the dataset. It may be feasible to do so given sufficient computational resources. The performance of stationary partial policies compared to non-stationary partial policies is worth future consideration.

Next, we seek a method than can replace the fixed-width forward pruning with a theoretically justified progressive widening method. Doing so would allow the search to smoothly transition from reactive decision-making to full-width search at larger time scales. It would also eliminate the need to specify σ_d upfront. Ideally, the pruning level should depend on the remaining search budget. Such a time-aware search procedure has the potential to produce state-of-the-art anytime search performance. We are unaware of any method that leverages control knowledge for performing time-aware search on a per-decision basis in a principled manner.

We would like to use the learned control knowledge to improve the expert policy, which was responsible for generating the deep trees used for training. The learned partial policy is only as good as the expert, so improvements to the expert may produce large improvements in search quality, particularly at small time scales. For instance, in Yahtzee, we observe that the expert makes serious, irreversible mistakes (for example, in category assignment at the end of the rolls). Avoiding expert mistakes seems crucial to further improvement. An iterative method, alternating between learning control knowledge and using the learned information to improve the expert, is likely to produce good results. However, FT-QCM can only obtain good value estimates for unpruned actions. Thus, it is important to analyze the regret bounds and performance from training only on a subset of actions.

Finally, we are interested in exploring principled learning algorithms for other types of control knowledge that can be shown to have guarantees similar to those in this paper. It can be argued that a huge part of the success of MCTS methods is their flexibility to incorporate different forms of knowledge, which are typically engineered for each application. Automating these processes in a principled way seems to be an extremely promising direction for improving planning systems.

Abstract

We propose a novel class of kernels to alleviate the high computational cost of large-scale nonparametric learning with kernel methods. The proposed kernel is defined based on a hierarchical partitioning of the underlying data domain, where the Nyström method (a globally low-rank approximation) is married with a locally lossless approximation in a hierarchical fashion. The kernel maintains (strict) positive-definiteness. The corresponding kernel matrix admits a recursively off-diagonal low-rank structure, which allows for fast linear algebra computations. Suppressing the factor of data dimension, the memory and arithmetic complexities for training a regression or a classifier are reduced from $O(n^2)$ and $O(n^3)$ to $O(nr)$ and $O(nr^2)$, respectively, where n is the number of training examples and r is the rank on each level of the hierarchy. Although other randomized approximate kernels entail a similar complexity, empirical results show that the proposed kernel achieves a matching performance with a smaller r. We demonstrate comprehensive experiments to show the effective use of the proposed kernel on data sizes up to the order of millions.

Keywords: Hierarchical kernels, Nonparametric Learning

1. Introduction

Kernel methods (Schölkopf and Smola, 2001; Hastie et al., 2009) constitute a principled framework that extends linear statistical techniques to nonparametric modeling and inference. Applications of kernel methods span the entire spectrum of statistical learning, including classification, regression, clustering, time-series analysis, sequence modeling (Song et al., 2013), dynamical systems (Boots et al., 2013), hypothesis testing (Harchaoui et al., 2013), and causal modeling (Zhang et al., 2011). Under a Bayesian treatment, kernel methods also admit a parallel view in Gaussian processes (GP) (Rasmussen and Williams, 2006; Stein, 1999) that find broad applications in statistics and computational sciences, including geostatistics (Chilès and Delfiner, 2012), design of experiments (Koehler and Owen, 1996), and uncertainty quantification (Smith, 2013).

This power and generality of kernel methods, however, are limited to moderate sized problems because of the high computational costs. The root cause of the bottleneck is the fact that kernel matrices generated by kernel functions are typically dense and unstructured. For n training examples, storing the matrix costs $O(n^2)$ memory and performing matrix factorizations requires $O(n^3)$ arithmetic operations. One remedy is to resort to compactly supported kernels (e.g., splines (Monaghan and Lattanzio, 1985) and Wendland functions (Wendland, 2004)) that potentially lead to a sparse matrix. In practice, however, the support of the kernel may not be sufficiently narrow for sparse linear algebra computations to be competitive. Moreover, prior work (Anitescu et al., 2012) revealed a subtle drawback of compactly supported kernels in the context of parameter estimation, where the likelihood surface is bumpy and the optimum is difficult to locate. For this reason, we focus on the dense setting in this paper and the goal is to exploit structures that can reduce the prohibitive cost of dense linear algebra computations.

1.1 Preliminary

Let $\mathcal{X}$ be a set and let $k(\cdot,\cdot) : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a symmetric and strictly positive-definite function. Denote by $X = \{\boldsymbol{x}_i \in \mathcal{X}\}_{i=1,\ldots n}$ a set of points. We write $K(X,X)$, or sometimes K for short when the context is clear, to denote the kernel matrix of elements $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$. *Because of the confusing terminology on functions and their counterparts on matrices, here, we follow the convention that a strictly positive-definite function k corresponds to a positive-definite matrix K, whereas a positive-definite function corresponds to a positive semi-definite matrix.* For notational convenience, we write $k(\boldsymbol{x}, X)$ to denote the row vector of elements $k(\boldsymbol{x}, \boldsymbol{x}_j)$ and similarly $k(X, \boldsymbol{x})$ to denote the column vector. In the context of regression/classification, the set $\mathcal{X}$ is often the d-dimensional Euclidean space $\mathbb{R}^d$ or a domain $S \subset \mathbb{R}^d$. Some of the methods discussed in this paper naturally generalize to a more abstract space. Associated to each point $\boldsymbol{x}_i$ is a target value $y_i \in \mathbb{R}$. We write $\boldsymbol{y}$ for the vector of all target values.

The Reproducing Kernel Hilbert Space $\mathcal{H}_k$ associated to a kernel k is the completion of the function space

$$\left\{ \sum_{i=1}^{m} \alpha_i k(\boldsymbol{z}_i, \cdot) \mid \boldsymbol{z}_i \in \mathcal{X},\, \alpha_i \in \mathbb{R},\, m \in \mathbb{Z}_+ \right\}$$

equipped with the inner product

$$\left\langle \sum_i \alpha_i k(\boldsymbol{z}_i, \cdot),\ \sum_j \beta_j k(\boldsymbol{w}_j, \cdot) \right\rangle = \sum_{ij} \alpha_i \beta_j k(\boldsymbol{z}_i, \boldsymbol{w}_j).$$

Given training data $\{(\boldsymbol{x}_i, y_i)\}_{i=1,\ldots,n}$, a typical kernel method finds a function $f \in \mathcal{H}_k$ that minimizes the following risk functional

$$\mathcal{L}(f) = \sum_{i=1}^{n} V(f(\boldsymbol{x_i}), y_i) + \lambda \|f\|^2_{\mathcal{H}_k}, \tag{1}$$

where V is a loss function and $\lambda > 0$ is a regularization. When V is the squared loss $V(t,y) = (t-y)^2$, the Representer Theorem (Schölkopf et al., 2001) implies that the minimizer is

$$f(\boldsymbol{x}) = k(\boldsymbol{x}, X)[K(X,X) + \lambda I]^{-1} \boldsymbol{y}, \tag{2}$$

which is nothing but the well-known kernel ridge regression. Similarly, when V is the hinge loss, the minimizer leads to support vector machines.

In the GP view, the kernel k serves as a covariance function. Assuming a zero-mean Gaussian prior with covariance k, for any separate set of points X_* and the associated vector of target values $\boldsymbol{y}_*$, the joint distribution of $\boldsymbol{y}$ and $\boldsymbol{y}_*$ is thus

$$\begin{bmatrix} \boldsymbol{y} \\ \boldsymbol{y}_* \end{bmatrix} \sim \mathcal{N}\left(\boldsymbol{0}, \begin{bmatrix} K(X,X) & K(X,X_*) \\ K(X_*,X) & K(X_*,X_*) \end{bmatrix}\right).$$

Because of the Gaussian assumption, the posterior is the conditional $\boldsymbol{y}_*|X_*, X, \boldsymbol{y} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$ where

$$\boldsymbol{\mu} = K(X_*, X)K(X,X)^{-1}\boldsymbol{y}, \tag{3}$$

and

$$\Sigma = K(X_*, X_*) - K(X_*, X)K(X,X)^{-1}K(X, X_*). \tag{4}$$

A white noise of variance λ may be injected to the observations $\boldsymbol{y}$ so that the mean prediction $\boldsymbol{\mu}$ in (3) is identical to (2). One may also impose a nonzero-mean model in the prior to capture the trend in the observations (see, e.g., the classic paper O'Hagan and Kingman (1978) and also Rasmussen and Williams (2006, Section 2.7)).

Equations (2)–(4) exemplify the demand for kernels that may simplify computations for a large $K(X,X)$. We discuss a few popular approaches in the following. To motivate the discussion, we consider stationary kernels whose function value depends on only the difference of the two input arguments; that is, we can write by abuse of notation $k(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{r})$, where $\boldsymbol{r} = \boldsymbol{x} - \boldsymbol{x}'$; for example, the Gaussian kernel

$$k(\boldsymbol{x}, \boldsymbol{x}') = \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{x}'\|_2^2}{2\sigma^2}\right) \tag{5}$$

parameterized by σ. The Fourier transform of $k(\boldsymbol{r})$, coined *spectral density*, in a sense characterizes the decay of eigenvalues of the finitely dimensional covariance matrix K (Stein, 1999; Chen, 2013). The decay is known to be the fastest among the Matérn class of kernels (Stein, 1999; Rasmussen and Williams, 2006; Chilès and Delfiner, 2012), where Gaussian being a special case is the smoothest. Additionally, the range parameter σ also affects the decay. When $\sigma \to \infty$, K tends to a rank-1 matrix; whereas when $\sigma \to 0$, K tends to the identity. The numerical rank of the matrix varies when σ moves between the two extremes. The decay of eigenvalues plays an important role on the effectiveness of the approximate kernels discussed below.

1.2 Approximate Kernels

The first approach is low-rank kernels. Examples are Nyström approximation (Williams and Seeger, 2000; Schölkopf and Smola, 2001; Drineas and Mahoney, 2005), random Fourier features (Rahimi and Recht, 2007), and variants (Yang et al., 2014). The Nyström approximation is based on a set of landmark points, $\underline{X}$, randomly sampled from the training data X. Then, the kernel can be written as

$$k_{\text{Nyström}}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \underline{X})K(\underline{X}, \underline{X})^{-1}k(\underline{X}, \boldsymbol{x}'). \tag{6}$$

For the convenience of deriving approximation bounds, Drineas and Mahoney (2005) consider sampling with repetition, which makes $\underline{X}$ possibly a multiset and the matrix inverse

in (6) necessarily replaced by a pseudo inverse. Various approaches for choosing the landmark points were compared in Zhang and Kwok (2010). For random Fourier features, let $\hat{k}(\boldsymbol{\omega})$ be the Fourier transform of $k(\boldsymbol{r})$ and let $\hat{k}$ be normalized such that it integrates to unity; that is, $\hat{k}$ is the normalized spectral density of k. Then, the kernel is

$$k_{\text{Fourier}}(\boldsymbol{x}, \boldsymbol{x}') = \frac{2}{r}\sum_{i=1}^{r} \cos(\boldsymbol{\omega}_i^T \boldsymbol{x} + b_i)\cos(\boldsymbol{\omega}_i^T \boldsymbol{x}' + b_i), \tag{7}$$

where r is the rank, and b_i and $\boldsymbol{\omega}_i$ are iid samples of Uniform$(0, 2\pi)$ and of a distribution with density $\hat{k}$, respectively. Note that (6) applies to any kernel whereas (7) applies to only stationary ones.

The Nyström approximation admits a conditional interpretation in the context of GP. The covariance kernel (6) can be equivalently written as

$$k_{\text{Nyström}}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}') - k(\boldsymbol{x}, \boldsymbol{x}'|\underline{X}),$$

where

$$k(\boldsymbol{x}, \boldsymbol{x}'|\underline{X}) = k(\boldsymbol{x}, \boldsymbol{x}') - k(\boldsymbol{x}, \underline{X})K(\underline{X}, \underline{X})^{-1}k(\underline{X}, \boldsymbol{x}')$$

is nothing but the covariance of $\boldsymbol{x}$ and $\boldsymbol{x}'$ conditioned on $\underline{X}$. In other words, the covariance kernel of Nyström approximation comes from a deduction of the original covariance by a conditional covariance. The conditional covariance for any $\boldsymbol{x}$ (or symmetrically, $\boldsymbol{x}'$) within $\underline{X}$ vanishes and hence the approximation is lossless. Intuitively speaking, the closer the sites are to $\underline{X}$, the smaller the loss is. This explains frequent observations that when the size of the set $\underline{X}$ is small, using the centers of a k-means clustering as the landmark points often improves the approximation (Zhang et al., 2008; Yang et al., 2012). A caveat is that the time cost of performing k-means clustering is often much higher than that of the Nyström calculation itself. Hence, the improvement gained from clustering may not be as significant as that from increasing the size of the conditioned set $\underline{X}$. When $\underline{X}$ is large, the improvement brought about by clustering is less significant (see, e.g., Rasmussen and Williams (2006, Section 8.3.7)).

A limitation of the low-rank kernels is that the size of the conditioned set, or equivalently the rank, needs to correlate with the decay of the spectrum of K in order to yield a good approximation. For a slow decay, it is not rare to see in practice that the rank r grows to thousands (Yen et al., 2014) or even several hundred thousands (Huang et al., 2014; Avron and Sindhwani, 2016) in order to yield comparable results with other methods, for a data set of size on the order of millions. See also the experimental results in Section 5.

The second approach is a cross-domain independent kernel. Simply speaking, the kernel matrix is approximated by keeping only the diagonal blocks of the matrix. In a GP language, we partition the domain S into m sub-domains S_j, $j = 1, \ldots, m$, and make an independence assumption across sub-domains. Then, the covariance between $\boldsymbol{x}$ and $\boldsymbol{x}'$ vanishes when the two sites come from different sub-domains. That is,

$$k_{\text{independent}}(\boldsymbol{x}, \boldsymbol{x}') = \begin{cases} k(\boldsymbol{x}, \boldsymbol{x}'), & \text{if } \boldsymbol{x}, \boldsymbol{x}' \in S_j \text{ for some } j, \\ 0, & \text{otherwise.} \end{cases} \tag{8}$$

Whereas such a kernel appears ad hoc and associated theory is possibly limited, the scenarios when it exhibits superiority over a low-rank kernel of comparable sizes are not rare (see the

likelihood comparison in Stein (2014) and also the experimental results in Section 5). An intuitive explanation exists in the context of classification. The cross-domain independent kernel works well when geographically nearby points possess a majority of the signal for classifying points within the domain. This happens more often when the kernel has a reasonably centralized bandwidth (outside of which the kernel value becomes marginal). In such a case, nearby points are the most influential.

The third approach is covariance tapering (Furrer et al., 2006; Kaufman et al., 2008). It amounts to defining a new kernel by multiplying the original kernel k with a compactly supported kernel k_{compact}:

$$k_{\text{taper}}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}') \cdot k_{\text{compact}}(\boldsymbol{x}, \boldsymbol{x}').$$

The tapered kernel matrix is an elementwise product of two positive-definite matrices; hence, it is positive-definite, too (Horn and Johnson, 1994, Theorem 5.2.1). The primary motivation of this kernel is to introduce sparsity to the matrix. The supporting theory is drawn on the confidence interval (cf. (4)) rather than on the prediction (3). It is cast in the setting of fixed-domain asymptotics, which is similar to a usual practice in machine learning—a prescaling of each attribute to within a finite interval. The theory hints that if the spectral density of k_{compact} has a lighter tail (i.e., the spectrum of the corresponding kernel matrix decays faster) than that of k, then the ratio between the prediction variance by using the tapered kernel k_{taper} and that by using the original kernel k tends to a finite limit, as the number of training data increases to infinity in the domain. The theory holds a guarantee on the prediction confidence if we choose k_{compact} judiciously. Tapering is generally applicable to heavy-tailed kernels (e.g., Matérn kernels with low smoothness) rather than light-tailed kernels such as the Gaussian. Nevertheless, a drawback of this approach is similar to the one we stated earlier for using a compactly supported kernel alone: the range of the support must be sufficiently small for sparse linear algebra to be efficient.

1.3 Proposed Kernel

In this paper, we propose a novel approach for constructing approximate kernels motivated by low-rank kernels and cross-domain independent kernels. The construction aims at deriving a kernel that (a) maintains the (strict) positive-definiteness, (b) leverages the advantages of low-rank and independent approaches, (c) facilitates the evaluation of the kernel matrix $K(X, X)$ and the out-of-sample extension $k(X, \boldsymbol{x})$, and (d) admits fast algorithms for a variety of matrix operations. The premise of the idea is a hierarchical partitioning of the data domain and a recursive approximation across the hierarchy. Space partitioning is a frequently encountered idea for kernel matrix approximations (Si et al., 2014; March et al., 2014; Yu et al., 2017; Si et al., 2017), but maintaining positive definiteness is quite challenging. Moreover, when the approximation is performed in a hierarchical fashion and is focused on only the matrix, it is not always easy to generalize to out of samples. A particularly intriguing property of the approach proposed in this article is that both positive definiteness and out-of-sample extensions are guaranteed, because the construction acts on the kernel function itself.

2. Hierarchically Compositional Kernel

The low-rank kernel (in particular, the Nyström approximation $k_{\text{Nyström}}$) and the cross-domain independent kernel $k_{\text{independent}}$ are complementary to each other in the following sense: the former acts on the global space, where the covariance at every pair of points $\boldsymbol{x}$ and $\boldsymbol{x}'$ are deducted by a conditional covariance based on the conditioned set $\underline{X}$ chosen globally; whereas the latter preserves all the local information but completely ignores the interrelationship outside the local domain. We argue that an organic composition of the two will carry both advantages and alleviate the shortcomings. Further, a hierarchical composition may reduce the information loss in nearby local domains.

2.1 Composition of Low-Rank Kernel with Cross-Domain Independent Kernel

Let the domain S be partitioned into disjoint sub-domains $\bigcup S_j = S$. Let $\underline{X}$ be a set of landmark points in S. For generality, $\underline{X}$ needs not be a subset of the training data X. Consider the function

$$k_{\text{compositional}}(\boldsymbol{x}, \boldsymbol{x}') = \begin{cases} k(\boldsymbol{x}, \boldsymbol{x}'), & \text{if } \boldsymbol{x}, \boldsymbol{x}' \in S_j \text{ for some } j, \\ k(\boldsymbol{x}, \underline{X}) K(\underline{X}, \underline{X})^{-1} k(\underline{X}, \boldsymbol{x}'), & \text{otherwise.} \end{cases}$$

Clearly, $k_{\text{compositional}}$ leverages both (6) and (8). When two points $\boldsymbol{x}$ and $\boldsymbol{x}'$ are located in the same domain, they maintain the full covariance (8); whereas when they are located in separate domains, their covariance comes from the low-rank kernel $k_{\text{Nyström}}$ (6). Such a composition complements missing information across domains in $k_{\text{independent}}$ and also complements the information loss in local domains caused by the Nyström approximation. The following result is straightforward in light of the fact that if $\boldsymbol{x} \in \underline{X}$, then $K(\underline{X}, \underline{X})^{-1} k(\underline{X}, \boldsymbol{x})$ is a column of the identity matrix where the only nonzero element (i.e., 1) is located with respect to the location of $\boldsymbol{x}$ inside $\underline{X}$.

Proposition 1 *We have*

$$k_{compositional}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}'),$$

if $\boldsymbol{x}, \boldsymbol{x}' \in S_j$ for some j, or if either of $\boldsymbol{x}, \boldsymbol{x}'$ belongs to $\underline{X}$.

An alternative view of the kernel $k_{\text{compositional}}$ is that it is an additive combination of a globally low-rank approximation and local Schur complements within each sub-domain. Hence, the kernel is (strictly) positive-definite. See Lemma 2 and Theorem 3 in the following.

Lemma 2 *The Schur-complement function*

$$k_{Schur}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}') - k(\boldsymbol{x}, \underline{X}) K(\underline{X}, \underline{X})^{-1} k(\underline{X}, \boldsymbol{x}')$$

is positive-definite, if k is strictly positive-definite, or if k is positive-definite and $K(\underline{X}, \underline{X})$ is invertible.

Proof For any set X, let $Y = X \cup \underline{X}$. It amounts to showing that the corresponding kernel matrix $K_{\text{Schur}}(Y, Y)$ is positive semi-definite; then, $K_{\text{Schur}}(X, X)$ as a principal submatrix is also positive semi-definite.

Denote by $\underline{X}^c = Y \backslash \underline{X}$, which could possibly be empty, and let the points in $\underline{X}$ be ordered before those in $\underline{X}^c$. Then,

$$K_{\text{Schur}}(Y,Y) = \begin{bmatrix} 0 & 0 \\ 0 & K(\underline{X}^c,\underline{X}^c) - K(\underline{X}^c,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},\underline{X}^c) \end{bmatrix}.$$

By the law of inertia, the matrices

$$\begin{bmatrix} K(\underline{X},\underline{X}) & K(\underline{X},\underline{X}^c) \\ K(\underline{X}^c,\underline{X}) & K(\underline{X}^c,\underline{X}^c) \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} K(\underline{X},\underline{X}) & 0 \\ 0 & K(\underline{X}^c,\underline{X}^c) - K(\underline{X}^c,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},\underline{X}^c) \end{bmatrix}$$

have the same number of positive, zero, and negative eigenvalues, respectively. If k is strictly positive-definite, then the eigenvalues of both matrices are all positive. If k is positive-definite, then the eigenvalues of both matrices are all nonnegative. In both cases, the Schur-complement matrix $K(\underline{X}^c,\underline{X}^c) - K(\underline{X}^c,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},\underline{X}^c)$ is positive semi-definite and thus so is $K_{\text{Schur}}(Y,Y)$. ■

Theorem 3 *The function $k_{compositional}$ is positive-definite if k is positive-definite and $K(\underline{X},\underline{X})$ is invertible. Moreover, $k_{compositional}$ is strictly positive-definite if k is so.*

Proof Write $k_{\text{compositional}} = k_1 + k_2$, where $k_1(\boldsymbol{x},\boldsymbol{x}') = k(\boldsymbol{x},\underline{X})K(\underline{X},\underline{X})^{-1}k(\underline{X},\boldsymbol{x}')$ and

$$k_2(\boldsymbol{x},\boldsymbol{x}') = \begin{cases} k(\boldsymbol{x},\boldsymbol{x}') - k(\boldsymbol{x},\underline{X})K(\underline{X},\underline{X})^{-1}k(\underline{X},\boldsymbol{x}'), & \boldsymbol{x},\boldsymbol{x}' \in S_j \text{ for some } j, \\ 0, & \text{otherwise.} \end{cases}$$

Clearly, k_1 is positive-definite; by Lemma 2, k_2 is so, too. Thus, $k_{\text{compositional}}$ is positive-definite.

We next show the strict definiteness when k is strictly positive-definite. That is, for any set of points $\{\boldsymbol{x}_i\}$ and any set of coefficients $\{\alpha_i\}$ that are not all zero, the bilinear form $\sum_{il}\alpha_i\alpha_l k_{\text{compositional}}(\boldsymbol{x}_i,\boldsymbol{x}_l)$ cannot be zero. Note that $k_2(\boldsymbol{x},\boldsymbol{x}') = 0$ whenever $\boldsymbol{x}$ or $\boldsymbol{x}' \in \underline{X}$. Moreover, we have seen in the proof of Lemma 2 that the Schur-complement matrix $K(\underline{X}^c,\underline{X}^c) - K(\underline{X}^c,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},\underline{X}^c)$ is positive-definite when k is strictly positive-definite. Therefore, we have $\sum_{il}\alpha_i\alpha_l k_2(\boldsymbol{x}_i,\boldsymbol{x}_l) = 0$ only when $\alpha_i = 0$ for all i satisfying $\boldsymbol{x}_i \notin \underline{X}$. In such a case,

$$\sum_{il}\alpha_i\alpha_l k_1(\boldsymbol{x}_i,\boldsymbol{x}_k) = \sum_{\boldsymbol{x}_i,\boldsymbol{x}_l \in \underline{X}} \alpha_i\alpha_l k(\boldsymbol{x}_i,\underline{X})K(\underline{X},\underline{X})^{-1}k(\underline{X},\boldsymbol{x}_l).$$

Because of the strict positive-definiteness of k, the above summation cannot be zero if any of the involved α_i (that is, those satisfying $\boldsymbol{x}_i \in \underline{X}$) is nonzero. Then, $\sum_{il}\alpha_i\alpha_l[k_1(\boldsymbol{x}_i,\boldsymbol{x}_l) + k_2(\boldsymbol{x}_i,\boldsymbol{x}_l)] = 0$ only when all α_i are zero. ■

Since the composition replaces the Nyström approximation in local domains by the full covariance, it bares no surprise that $k_{\text{compositional}}$ improves over $k_{\text{Nyström}}$ in terms of matrix approximation.

Theorem 4 *Given a set $\underline{X}$ of landmark points and for any set $X \neq \underline{X}$,*

$$\|K(X,X) - K_{compositional}(X,X)\| < \|K(X,X) - K_{Nyström}(X,X)\|,$$

where $\|\cdot\|$ is the 2-norm or the Frobenius norm.

Proof Based on the split $k_{\text{compositional}} = k_1 + k_2$ in the proof of Theorem 3, one easily sees that

$$K - K_{\text{compositional}} = (K - K_{\text{Nyström}}) - \text{block-diag}(K - K_{\text{Nyström}}),$$

where block-diag means keeping only the diagonal blocks of a matrix. Denote by $A = K - K_{\text{Nyström}}$ and $D = \text{block-diag}(A)$. In what follows we show that

$$\|A - D\| < \|A\|. \tag{9}$$

Because $A = K(X,X) - K(X,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},X)$ is positive semi-definite and nonzero, its diagonal cannot be zero. Then, eliminating the block-diagonal part D reduces the Frobenius norm. Thus, (9) holds for the Frobenius norm. To see that (9) also holds for the 2-norm, let $Y = X\backslash\underline{X}$ and let the points in Y be ordered before those in $X\backslash Y$. Then,

$$A = \begin{bmatrix} K(Y,Y) - K(Y,\underline{X})K(\underline{X},\underline{X})^{-1}K(\underline{X},Y) & 0 \\ 0 & 0 \end{bmatrix}.$$

Because the zero rows and columns do not contribute to the 2-norm, and because the top-left block of A is positive-definite, it suffices to prove (9) for any positive-definite matrix A.

Note the following two straightforward inequalities

$$\lambda_{\min}(A - D) \geq \lambda_{\min}(A) - \lambda_{\max}(D), \tag{10}$$
$$\lambda_{\max}(A - D) \leq \lambda_{\max}(A) - \lambda_{\min}(D). \tag{11}$$

Because D consists of the diagonal blocks of A, the interlacing theorem of eigenvalues states that for each diagonal block D_i, we have

$$\lambda_{\min}(A) \leq \lambda_{\min}(D_i) \leq \lambda_{\max}(D_i) \leq \lambda_{\max}(A).$$

Then, taking the max/min eigenvalues of all blocks, we obtain

$$\lambda_{\min}(A) \leq \lambda_{\min}(D) \leq \lambda_{\max}(D) \leq \lambda_{\max}(A). \tag{12}$$

Substituting (12) into (10) and (11), together with $\lambda_{\min}(A) > 0$, we obtain

$$\lambda_{\min}(A - D) > -\lambda_{\max}(A) \quad \text{and} \quad \lambda_{\max}(A - D) < \lambda_{\max}(A),$$

which immediately implies that $\|A - D\|_2 < \|A\|_2$. ■

2.2 Hierarchical Composition

While $k_{\text{compositional}}$ maintains the full information inside each domain S_j, the information loss across domains caused by the low-rank approximation may still be dramatic. Consider the scenario of a large number of disjoint domains S_j; such a scenario is necessarily typical for the purpose of reducing the computational cost. If each domain is adjacent to only a few neighboring domains, it is possible to reduce the information loss in nearby domains.

The idea is to form a hierarchy. Let us first take a two-level hierarchy for example. A few of the neighboring domains S_j form a super-domain $S_J = \bigcup_{j\in J} S_j$. These super-domains are formed such that they are disjoint and they collectively partition the whole domain; i.e., $\bigcup S_J = S$. Under such a hierarchical formation, instead of using landmark points $\underline{X}$ in S to define the covariance across the bottom-level domains S_j, we may use landmark points $\underline{X}_J$ chosen from the super-domain S_J to define the covariance. The intuition is that the conditional covariance $k(\boldsymbol{x}, \boldsymbol{x}'|\underline{X}_J)$ for $\boldsymbol{x}, \boldsymbol{x}' \in S_J$ tends to be smaller than $k(\boldsymbol{x}, \boldsymbol{x}'|\underline{X})$, because $\boldsymbol{x}$ and $\boldsymbol{x}'$ are geographically closer to $\underline{X}_J$ than to $\underline{X}$. Then, the information loss is reduced for points inside the same super-domain S_J.

To formalize this idea, we consider an arbitrary hierarchy, which is represented by a rooted tree T. See Figure 1 for an example. The root node 1 is associated with the whole domain $S =: S_1$. Each nonleaf node i possesses a set of children $Ch(i)$; correspondingly, the associated domain S_i is partitioned into disjoint sub-domains S_j satisfying $\bigcup_{j\in Ch(i)} = S_i$. The partitioning tree T is almost the most general rooted tree, except that no nodes in T have exactly one child.

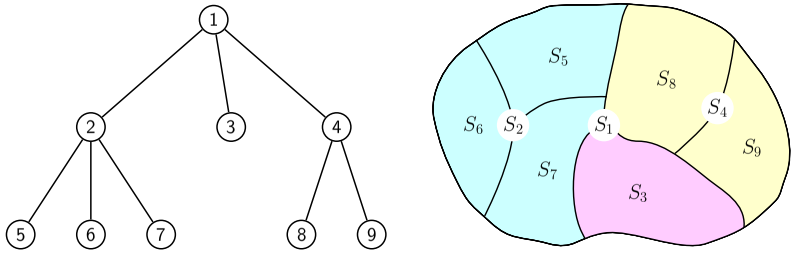

Figure 1: Partitioning tree T and the domain S.

Each nonleaf node i is associated with a set $\underline{X}_i$ of landmark points, located within the domain S_i. We now recursively define the kernel on domains across levels. Continuing the example of Figure 1, node 4 has two children 8 and 9. Since these two children are leaf nodes, the covariance within S_8 (or S_9) comes from the original kernel k, whereas the covariance across S_8 and S_9 comes from the Nyström approximation by using landmark points $\underline{X}_4$. That is, the kernel is equal to $k(\boldsymbol{x}, \boldsymbol{x}')$ if $\boldsymbol{x}$ and $\boldsymbol{x}'$ are both in S_8 (or in S_9), and equal to $k(\boldsymbol{x}, \underline{X}_4)K(\underline{X}_4, \underline{X}_4)^{-1}k(\underline{X}_4, \boldsymbol{x}')$ if they are in S_8 and S_9 separately. Such a covariance bares less information loss caused by the conditioned set, compared with the use of landmark points located within the whole domain S.

Next, consider the covariance between child domains of S_2 and those of S_4 (say, S_6 and S_9, respectively). At a first glance, we could have used $k(\boldsymbol{x}, \underline{X}_1)K(\underline{X}_1, \underline{X}_1)^{-1}k(\underline{X}_1, \boldsymbol{x}')$ to define the kernel, because $\underline{X}_1$ consists of landmark points located in the domain that covers both S_6 and S_9. However, such a definition cannot guarantee the positive-definiteness of the overall kernel. Instead, we approximate $k(\boldsymbol{x}, \underline{X}_1)$ by using the Nyström approximation $k(\boldsymbol{x}, \underline{X}_2)K(\underline{X}_2, \underline{X}_2)^{-1}K(\underline{X}_2, \underline{X}_1)$ based on the landmark points $\underline{X}_2$. Then, the covariance for $\boldsymbol{x} \in S_6$ and $\boldsymbol{x}' \in S_9$ is defined as

$$\Big[k(\boldsymbol{x}, \underline{X}_2)K(\underline{X}_2, \underline{X}_2)^{-1}K(\underline{X}_2, \underline{X}_1)\Big]K(\underline{X}_1, \underline{X}_1)^{-1}\Big[K(\underline{X}_2, \underline{X}_1)K(\underline{X}_2, \underline{X}_2)^{-1}k(\underline{X}_2, \boldsymbol{x}')\Big].$$

Formally, for a leaf node j and $\boldsymbol{x}, \boldsymbol{x}' \in S_j$, define $k^{(j)}(\boldsymbol{x}, \boldsymbol{x}') \equiv k(\boldsymbol{x}, \boldsymbol{x}')$. For a nonleaf node i and $\boldsymbol{x}, \boldsymbol{x}' \in S_i$, define

$$k^{(i)}(\boldsymbol{x}, \boldsymbol{x}') := \begin{cases} k^{(j)}(\boldsymbol{x}, \boldsymbol{x}'), & \text{if } \boldsymbol{x}, \boldsymbol{x}' \in S_j \text{ for some } j \in Ch(i), \\ \psi^{(i)}(\boldsymbol{x}, \underline{X}_i)K(\underline{X}_i, \underline{X}_i)^{-1}\psi^{(i)}(\underline{X}_i, \boldsymbol{x}'), & \text{otherwise,} \end{cases} \tag{13}$$

where if j is a child of i and if $\boldsymbol{x} \in S_j$, then

$$\psi^{(i)}(\boldsymbol{x}, \underline{X}_i) := \begin{cases} k(\boldsymbol{x}, \underline{X}_i), & \text{if } j \text{ is a leaf node,} \\ \psi^{(j)}(\boldsymbol{x}, \underline{X}_j)K(\underline{X}_j, \underline{X}_j)^{-1}K(\underline{X}_j, \underline{X}_i), & \text{otherwise.} \end{cases} \tag{14}$$

The $k^{(i)}$ at the root level gives the *hierarchically compositional kernel* of this paper:

$$k_{\text{hierarchical}} := k^{(\text{root})}. \tag{15}$$

Clearly, the kernel $k_{\text{compositional}}$ in Section 2.1 is a special case of $k_{\text{hierarchical}}$ when the partitioning tree consists of only the root and the leaf nodes (which are children of the root).

Expanding the recursive formulas (13) and (14), for two distinct leaf nodes j and l, we see that the covariance between $\boldsymbol{x} \in S_j$ and $\boldsymbol{x}' \in S_l$ is

$$\begin{aligned} &k_{\text{hierarchical}}(\boldsymbol{x}, \boldsymbol{x}') = k^{(r)}(\boldsymbol{x}, \boldsymbol{x}') \\ &= \underbrace{k(\boldsymbol{x}, \underline{X}_{j_1})K(\underline{X}_{j_1}, \underline{X}_{j_1})^{-1}K(\underline{X}_{j_1}, \underline{X}_{j_2})\cdots K(\underline{X}_{j_s}, \underline{X}_{j_s})^{-1}K(\underline{X}_{j_s}, \underline{X}_r)}_{\psi^{(r)}(\boldsymbol{x}, \underline{X}_r)} K(\underline{X}_r, \underline{X}_r)^{-1} \\ &\qquad \cdot \underbrace{K(\underline{X}_r, \underline{X}_{l_t})K(\underline{X}_{l_t}, \underline{X}_{l_t})^{-1}\cdots K(\underline{X}_{l_2}, \underline{X}_{l_1})K(\underline{X}_{l_1}, \underline{X}_{l_1})^{-1}k(\underline{X}_{l_1}, \boldsymbol{x}')}_{\psi^{(r)}(\underline{X}_r, \boldsymbol{x}')}, \end{aligned} \tag{16}$$

where r is the least common ancestor of j and l, and $(j, j_1, j_2, \ldots, j_s, r)$ and $(l, l_1, l_2, \ldots, l_t, r)$ are the paths connecting r and the two leaf nodes, respectively. Therefore, we have the following result.

Proposition 5 *Based on the notation in the preceding paragraph, for $\boldsymbol{x} \in S_j$ and $\boldsymbol{x}' \in S_l$, we have*

$$k_{hierarchical}(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}'),$$

whenever $\boldsymbol{x} \in \underline{X}_j \cap \underline{X}_{j_1} \cdots \cap \underline{X}_{j_s}$, $\boldsymbol{x}' \in \underline{X}_l \cap \underline{X}_{l_1} \cdots \cap \underline{X}_{l_t}$, and either of $\boldsymbol{x}, \boldsymbol{x}'$ belongs to $\underline{X}_r$.

Proof On (16), recursively apply the fact that if $\boldsymbol{x} \in \underline{X}$, then $K(\underline{X}, \underline{X})^{-1} k(\underline{X}, \boldsymbol{x})$ is a column of the identity matrix where the only nonzero element (i.e., 1) is located with respect to the location of $\boldsymbol{x}$ inside $\underline{X}$. ■

The following theorem guarantees the validity of the kernel. Its proof strategy is similar to that of Theorem 3, but it is complex because of recursion. We defer the proof to Appendix A.

Theorem 6 *The function $k_{hierarchical}$ is positive-definite if k is positive-definite and $K(\underline{X}_i, \underline{X}_i)$ is invertible for all sets of landmark points $\underline{X}_i$ associated with the nonleaf nodes i. Moreover, $k_{hierarchical}$ is strictly positive-definite if k is so.*

3. Matrix View

The kernel matrix $K_{\text{hierarchical}}(X, X)$ for a set of training points X exhibits a hierarchical block structure. Figure 2 pictorially shows such a structure for the example in Figure 1. To avoid degenerate empty blocks, we assume that $X \cap S_j \neq \emptyset$ for all leaf nodes j in the partitioning tree T.

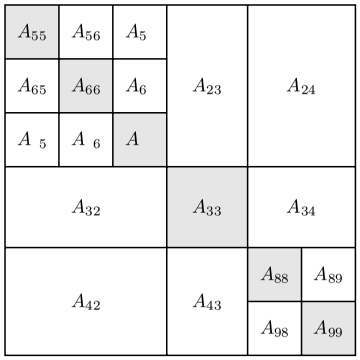

Figure 2: The matrix $K_{\text{hierarchical}}$ corresponding to the partitioning tree T in Figure 1.

Formally, for any node i, let $X_i = X \cap S_i$; that is, X_i consists of the training points that fall within the domain S_i. Then, define a matrix $A \in \mathbb{R}^{n \times n}$ with the following structure:

1. For every node i, A_{ii} is a diagonal block whose rows and columns correspond to X_i; for every pair of sibling nodes i and j, A_{ij} is an off-diagonal block whose rows correspond to X_i and columns to X_j.
2. For every leaf node i, $A_{ii} = K(X_i, X_i)$.
3. For every pair of sibling nodes i and j, $A_{ij} = U_i \Sigma_p U_j^T$, where p is the parent of i and j, with Σ_p and U_i defined next.

4. For every nonleaf node p, $\Sigma_p = K(\underline{X}_p, \underline{X}_p)$.
5. For every leaf node i, $U_i = K(X_i, \underline{X}_p) K(\underline{X}_p, \underline{X}_p)^{-1}$, where p is the parent of i.
6. For every pair of child node i and parent node p not being the root, the block of U_p corresponding to node i is $U_i W_p$, where $W_p = K(\underline{X}_p, \underline{X}_r) K(\underline{X}_r, \underline{X}_r)^{-1}$ and r is the parent of p. That is, in the matrix form,

$$U_p = \begin{bmatrix} \vdots \\ U_i \\ \vdots \end{bmatrix}_{i \in Ch(p)} \cdot W_p.$$

One sees that A is exactly equal to $K_{\text{hierarchical}}(X, X)$ by verifying against the definition of $k_{\text{hierarchical}}$ in (13)–(15).

Such a hierarchical block structure is a special case of the *recursively low-rank compressed matrix* studied in Chen (2014b). In this matrix, off-diagonal blocks are recursively compressed into low rank through change of basis, while the main-diagonal blocks at the leaf level remain intact. Its connections and distinctions with related matrices (e.g., FMM matrices (Sun and Pitsianis, 2001) and hierarchical matrices (Hackbusch, 1999)) were discussed in detail in Chen (2014b). The signature of a recursively low-rank compressed matrix is that many matrix operations can be performed with a cost, loosely speaking, linear in n. The matrix structure in this paper, which results from the kernel $k_{\text{hierarchical}}$, specializes a general recursively low-rank compressed matrix in the following aspects: (a) the matrix is symmetric; (b) the middle factor Σ_p in each A_{ij} is the same for all child pairs i, j of p; and (c) the change-of-basis factor W_p is the same for all children i of p. Hence, storage and time costs of matrix operations are reduced by a constant factor compared with those of the algorithms in Chen (2014b). In what follows, we discuss the algorithmic aspects of the matrix operations needed to carry out kernel method computations, but defer the complexity analysis in Section 4. Discussions of additional matrix operations useful in a general machine learning context are made toward the end of the paper.

3.1 Matrix-Vector Multiplication

First, we consider computing the matrix-vector product $y = Ab$. Let the blocks of a vector be labeled in the same manner as those of the matrix A. That is, for any node i, b_i denotes the part of b that corresponds to the point set X_i. Then, the vector y is clearly an accumulation of the smaller matrix-vector products $A_{ij} b_j$ in the appropriate blocks, for all sibling pairs i, j and for all leaf nodes $i = j$ (cf. Figure 2). When $i = j$ is a leaf node, the computation of $A_{ij} b_j$ is straightforward. On the other hand, when i and j constitute a pair of sibling nodes, we consider a descendant leaf node l of i. The block of $A_{ij} b_j$ corresponding to node l admits an expanded expression

$$U_l W_{l_1} W_{l_2} \cdots W_{l_s} W_i \Sigma_p W_j^T \left(\sum_{q_t \in Ch(j)} W_{q_t}^T \cdots \left(\sum_{q_2 \in Ch(q_3)} W_{q_2}^T \left(\sum_{q_1 \in Ch(q_2)} W_{q_1}^T \left(\sum_{q \in Ch(q_1)} U_q^T b_q \right) \right) \right) \right), \tag{17}$$

where $(l, l_1, l_2, \ldots, l_s, i, p)$ is the path connecting l and the parent p of i. This expression assumes that all the leaf descendants of j are on the same level so that the expression is not overly complex; but the subsequent reasoning applies to the general case. The terms inside the nested parentheses of (17) motivate the following recursive definition:

$$c_i = \begin{cases} U_i^T b_i, & i \text{ is a leaf node,} \\ W_i^T \sum_{j \in Ch(i)} c_j, & \text{otherwise.} \end{cases}$$

Clearly, all c_j's can be computed within one pass of a post-order tree traversal. Upon the completion of the traversal, we rewrite (17) as $U_l W_{l_1} W_{l_2} \cdots W_{l_s} W_i \Sigma_p c_j$. Then we note that for any leaf node l, y_l is a sum of these expressions with all p along the path connecting l and the root, and additionally, of $A_{ll} b_l$. In other words, we have

$$y_l = A_{ll} b_l + \left(\sum_{l' \in Ch(l_1) \setminus \{l\}} U_l \Sigma_{l_1} c_{l'} \right) + \left(\sum_{l' \in Ch(l_2) \setminus \{l_1\}} U_l W_{l_1} \Sigma_{l_2} c_{l'} \right) + \cdots + \left(\sum_{l' \in Ch(\text{root}) \setminus \{l_t\}} U_l W_{l_1} W_{l_2} \cdots W_{l_t} \Sigma_{\text{root}} c_{l'} \right),$$

where $(l, l_1, l_2, \ldots, l_t, \text{root})$ is the path connecting l and the root. Therefore, we recursively define another quantity

$$d_j = W_i d_i + \sum_{j' \in Ch(i) \setminus \{j\}} \Sigma_i c_{j'}$$

for all nonroot nodes j with parent i. Clearly, all d_j's can also be computed within one pass of a pre-order tree traversal. Upon the completion of this second traversal, we have $y_l = A_{ll} b_l + U_l d_l$, which concludes the computation of the whole vector y.

As such, computing the matrix-vector product $y = Ab$ consists of one post-order tree traversal, followed by a pre-order one. We refer the reader to Chen (2014b) for a full account of the computational steps. For completeness, we summarize the pesudocode in Algorithm 1 as a reference for computer implementation.

3.2 Matrix Inversion

Next, we consider computing A^{-1}, for which we use the tilded notation $\tilde{A} := A^{-1}$. One can show (Chen, 2014b) that $\tilde{A}$ has exactly the same hierarchical block structure as does A. In other words, the structure of $\tilde{A}$ can be described by reusing the verbatim at the beginning of Section 3, with the factors A_{ii}, A_{ij}, U_i, Σ_p, W_p replaced by the tilded version $\tilde{A}_{ii}$, $\tilde{A}_{ij}$, $\tilde{U}_i$, $\tilde{\Sigma}_p$, $\tilde{W}_p$, respectively. The proof is both inductive and constructive, providing explicit formulas to compute $\tilde{A}_{ii}$, $\tilde{A}_{ij}$, $\tilde{U}_i$, $\tilde{\Sigma}_p$, $\tilde{W}_p$ level by level. The essential idea is that if $(A_{ii} - U_i \Sigma_p U_i^T)^{-1} = \tilde{A}_{ii} - \tilde{U}_i \tilde{\Sigma}_p \tilde{U}_i^T$ have been computed for all children i of a node p, and if r is the parent of p, then

$$A_{pp} - U_p \Sigma_r U_p^T = \begin{bmatrix} \ddots & & \\ & A_{ii} - U_i \Sigma_p U_i^T & \\ & & \ddots \end{bmatrix} + \begin{bmatrix} \vdots \\ U_i \\ \vdots \end{bmatrix} \Sigma_p \begin{bmatrix} \cdots & U_i^T & \cdots \end{bmatrix} - U_p \Sigma_r U_p^T.$$

Algorithm 1 Computing $y = Ab$

```
Initialize c_i ← 0, d_i ← 0 for each nonroot node i of the tree
Upward(root)
Downward(root)

function Upward(i)
    if i is leaf then
        c_i ← U_i^T b_i;   y_i ← A_ii b_i
    else
        for all children j of i do
            Upward(j)
            c_i ← c_i + W_i^T c_j, if i is not root
        end for
    end if
    if i is not root then
        for all siblings l of i do d_l ← d_l + Σ_p c_i end for        ▷ p is parent of i
    end if
end function

function Downward(i)
    if i is leaf then y_i ← y_i + U_i d_i and return end if
    for all children j of i do
        d_j ← d_j + W_i d_i, if i is not root
        Downward(j)
    end for
end function
```

Hence, the inversion of $A_{pp} - U_p \Sigma_r U_p^T$ can be done by applying the Sherman–Morrison–Woodbury formula, which results in a form $\tilde{A}_{pp} - \tilde{U}_p \tilde{\Sigma}_r \tilde{U}_p^T$, where $\tilde{W}_r$ is determined based on the change of basis from $\tilde{U}_i$ to $\tilde{U}_p$ and the middle factor $\tilde{\Sigma}_r$ is also determined. In addition, the factors $\tilde{\Sigma}_j$ (computed previously) for all descendants j of r must be corrected because the diagonal block of $\tilde{A}_{pp}$ corresponding to node j is a low-rank correction of the corresponding diagonal block of $\tilde{A}_{ii}$ with the same basis. Such a down-cascading correction occurs whenever the induction proceeds from one child level to the parent level; but computationally, the correction on any node can be accumulated during the whole induction process. The net result of the accumulation is that each $\tilde{\Sigma}_i$ needs be corrected only once, which ensures an efficient computation.

We refer the reader to Chen (2014b) for a full account of the computational steps. Similar to the matrix-vector multiplication, the overall computation here consists of one post-order tree traversal (corresponding to the induction), followed by a pre-order one (corresponding to the down-cascading correction). For completeness, we summarize the pseudocode in Algorithm 2 as a reference for computer implementation.

3.3 (Implicit) Out-of-Sample Construction

Now, we consider the vector $k_{\text{hierarchical}}(X, \boldsymbol{x})$ for an existing training set X and a new point $\boldsymbol{x}$ in the testing set. Generally, this vector is not used alone but it appears in the inner product with some other vector w (see (2)). Whereas the construction of $k_{\text{hierarchical}}(X, \boldsymbol{x})$ can be done at $O(n)$ cost (details omitted here), we shall consider instead the computation of the inner product $w^T k_{\text{hierarchical}}(X, \boldsymbol{x})$, because the cost of computing this inner product is proportional to only the height of the tree per $\boldsymbol{x}$ after an $O(n)$ preprocessing. The

preprocessing cost is amortized on each $\boldsymbol{x}$ and thus is generally negligible for a large number of $\boldsymbol{x}$'s.

The computation of $w^T k_{\text{hierarchical}}(X, \boldsymbol{x})$ was not described in Chen (2014b), but the idea is similar to that of the matrix-vector multiplication in Section 3.1. To simplify notation, let $v \equiv k_{\text{hierarchical}}(X, \boldsymbol{x})$. Assume that $\boldsymbol{x}$ falls in the domain S_j for some leaf node j. Then, $v_j = k(X_j, \boldsymbol{x})$ and for any leaf node $l \neq j$,

$$v_l = U_l W_{l_1} W_{l_2} \cdots W_{l_s} \Sigma_p W_{j_t}^T \cdots W_{j_2}^T W_{j_1}^T K(\underline{X}_{j_1}, \underline{X}_{j_1})^{-1} k(\underline{X}_{j_1}, \boldsymbol{x}),$$

where p is the least common ancestor of l and j, and $(l, l_1, l_2, \ldots, l_s, p)$ and $(j, j_1, j_2, \ldots, j_t, p)$ are the paths connecting l and p, and j and p, respectively. Therefore, if we define

$$d_{j_u} = W_{j_u}^T d_{j_{u-1}}, \quad \cdots \quad d_{j_2} = W_{j_2}^T d_{j_1}, \quad d_{j_1} = W_{j_1}^T d_j, \quad d_j = K(\underline{X}_{j_1}, \underline{X}_{j_1})^{-1} k(\underline{X}_{j_1}, \boldsymbol{x}), \tag{18}$$

where $(j, j_1, j_2, \ldots, j_u, \text{root})$ is the path connecting j and the root, then we have

$$w^T v = w_j^T k(X_j, \boldsymbol{x}) + \sum_{l \neq j,\ l \text{ is leaf}} w_l^T U_l W_{l_1} W_{l_2} \cdots W_{l_s} \Sigma_p d_{j_t}. \tag{19}$$

If we further define

$$e_l = \begin{cases} U_l^T w_l, & l \text{ is leaf}, \\ \displaystyle\sum_{i \in Ch(l)} W_l^T e_i, & \text{otherwise}, \end{cases} \qquad \text{and} \qquad c_q = \Sigma_p^T e_l, \tag{20}$$

where p is the parent of the sibling pair q and l, then (19) is simplified to

$$w^T v = w_j^T k(X_j, \boldsymbol{x}) + \sum_{j_t \in \text{path}(j, \text{root})} c_{j_t}^T d_{j_t}. \tag{21}$$

Based on (18)–(21), we see that $w^T v \equiv w^T k_{\text{hierarchical}}(X, \boldsymbol{x})$ can be computed in the following two phases. In the first phase, we compute e_l and c_l for all nonleaf nodes l according to (20). Such a computation can be done by using a post-order tree traversal and is independent of $\boldsymbol{x}$. Thus, this computation is the preprocessing step. In the second phase, we compute d_{j_t} for all j_t along the path $(j, j_1, j_2, \ldots, j_u, \text{root})$ according to (18). Once they are computed, the summation (21) is straightforward and we thus conclude the computation. Note that the second phase is always conducted along a certain path connecting the root and the leaf j. As long as the determination of which leaf j the point $\boldsymbol{x}$ falls in is restricted on this path, the cost of the second phase is always asymptotically smaller than that of a tree traversal. We summarize the pseudocode in Algorithm 3.

4. Practical Considerations

Sections 2 and 3 provide a general framework for the interpretation of and the computation with the proposed kernel $k_{\text{hierarchical}}$; they, however, have not covered a range of practical issues. Some issues are dimension dependent (this paper concerns particularly dimensions higher than three, which dominates the use of related matrices, e.g., FMM and hierarchical matrices, in scientific computing); whereas others are numerically related. In this section, we discuss the handling of several of these issues and ensure that the proposed kernel is computationally efficient.

Algorithm 3 Computing $z = w^T k_{\text{hierarchical}}(X, \boldsymbol{x})$ for $\boldsymbol{x} \notin X$

Prefactorize $K(\underline{X}_p, \underline{X}_p)$ for all parents p of leaf nodes
Initialize $c_i \leftarrow 0$, $d_i \leftarrow 0$ for each nonroot node i of the tree
Common-Upward(`root`)
▷ The above three steps are independent of $\boldsymbol{x}$ and are treated as precomputation. In computer implementation, the intermediate results c_i are carried over to the next step Second-Upward, whereas the contents of d_i are discarded and the allocated memory is reused.
Second-Upward(`root`)

function Common-Upward(i)
  if i is leaf **then**
    $d_i \leftarrow U_i^T w_i$
  else
    for all children j of i **do**
      Common-Upward(j)
      $d_i \leftarrow d_i + W_i^T d_j$, **if** i is not root
    end for
  end if
  if i is not root **then**
    for all siblings l of i **do** $c_l \leftarrow \Sigma_p^T d_i$ **end for** ▷ p is parent of i
  end if
end function

function Second-Upward(i)
  if i is leaf **then**
    $d_i \leftarrow K(\underline{X}_p, \underline{X}_p)^{-1} k(\underline{X}_p, \boldsymbol{x})$ ▷ p is parent of i
    $z \leftarrow w_i^T k(X_i, \boldsymbol{x})$
  else
    Find the child j (among all children of i) where $\boldsymbol{x}$ lies on
    Second-Upward(j)
    $d_i \leftarrow W_i^T d_j$ if i is not root
  end if
  $z \leftarrow z + c_i^T d_i$ if i is not root
end function

4.1 Partitioning of Domain

Whereas the partitioning of a low-dimensional domain can be made regular, the partitioning of a high-dimensional domain is inherently difficult because of the curse of dimensionality. Several data-driven approaches appear to be natural choices but they have pros and cons.

The k-d tree (Bentley, 1975) approach is known to be efficient for nearest neighbor search. Generally, the approach iteratively selects an axis of the bounding box that contains the training points and partitions the axis such that the numbers of points on both sides are balanced. A drawback of this approach, particularly in the context of classification, lies in

the case that some attributes of the data are binary and the counts are highly imbalanced. These attributes sometimes result from a conversion of categorical attributes to numeric ones. Partitioning on these axes is unlikely to be balanced. An alternative is to partition the axis into two segments of equal length. This approach often results in highly imbalanced partitioning because data are generally not evenly distributed.

The k-means (MacQueen, 1967) approach partitions a point set through a k-means clustering and hence the partitioning is a Voronoi diagram of the cluster centers. The resulting tree is not necessarily binary if there exhibits more than two natural clusters in the data on some level. An advantage of this approach is that the clustering often results in a tight grouping of the points, such that the subsequent Nyström approximations bare a good quality. A disadvantage is that the approach suffers from loss of clusters during iterations and it is less robust if only one set of initial guesses is used. Our experience indicates that a robust implementation of k-means sometimes costs much more than does the rest of the training computation.

The PCA (Pearson, 1901) approach recursively partitions the data according to the principal axis (the direction along which the data varies the most). This approach is based on a Gaussian assumption and often results in compact partitions if the data indeed conforms to this assumption. However, it ignores the skewness and other higher order moments, which are also crucial to the shape of data in high dimensions. In the standard case, the hyperplane that partitions the data passes through the mean, which may result in highly imbalanced partitions. An alternative is to move the hyperplane along the principal direction such that the two partitions are always balanced. Computationwise, this approach requires computing the dominant singular vectors of the shifted data matrix (Chen et al., 2009), which can be achieved by using a power iteration (Golub and Van Loan, 1996) or the Lanczos algorithm (Saad, 2003). However, even if we compute the singular vectors only approximately, we find that the cost is still too high (see e.g., Section 5.2).

For computational efficiency, we recommend the random projection (Johnson and Lindenstrauss, 1984) approach. This approach uses a random vector as the normal direction of the partitioning hyperplane and positions the hyperplane such that the numbers of points on the two sides are balanced. Computationwise, it amounts to projecting the points along the random direction and splitting them in two halves around the median. This approach is motivated by the study of dimension reduction, where it was observed that the projection quality on a random subspace is as good as that on the space spanned by the dominant singular vectors, in the sense that Euclidean distances are approximately preserved (Dasgupta and Gupta, 2002). Moreover, the heuristic use of a one-dimensional subspace for projection is robust and is computationally highly efficient. In such a case, the purpose is not to preserve the Euclidean distance, but rather, to serve as an efficient procedure for partitioning. In our experience, the eventual regression/classification performance of using this approach is almost identical to that of the PCA approach (see Section 5.2).

Under random projection, one can quickly determine which partition a new point $\boldsymbol{x}$ lies in, by comparing its projected coordinate with the median of those of the training points.

4.2 Choice of Landmark Points

The set of landmark points $\underline{X}_i$ associated to each domain S_i simply consists of uniformly random samples of the point set X_i.

Some alternatives exist. Using the k-means centers of X_i as the landmark points may improve the Nyström approximations, but computing them for every nonleaf node i is often much more expensive than the rest of the training computation. On the other hand, using the uniformly random samples of the domain S_i as the landmark points may sound theoretically preferable, but they are difficult to compute because the domains are polyhedra rather than regular shapes (e.g., boxes).

We mentioned in Section 2.2 that the compositional kernel $k_{\text{compositional}}$ is a special case of $k_{\text{hierarchical}}$, if in the partitioning tree every child of the root is a leaf node. Interestingly, another interpretation exists. If we relax the requirement that the landmark points $\underline{X}_i$ must reside within the domain S_i, then for any partitioning tree, using the same set of landmark points $\underline{X}_i$ for every i also results in the compositional kernel $k_{\text{compositional}}$. By following the proof of Theorem 6, one sees that the relation $\underline{X}_i \subset S_i$ is in fact nonessential. Hence, the requirement $\underline{X}_i \subset S_i$ reflects only the modeling desire of a better kernel approximation in local domains; it is not a necessary condition for kernel validity.

4.3 Numerical Stability

A notorious numerical challenge for kernel matrices K is that they are exceedingly ill-conditioned as the size increases. Hence, the regularization λI serves as an important rescue of matrix inversion. This challenge is less severe for the matrix of the proposed kernel, $K_{\text{hierarchical}}(X, X)$, but since the components of this matrix are defined with the term $K(\underline{X}_i, \underline{X}_i)^{-1}$ for nonleaf nodes i, one must ensure that each $K(\underline{X}_i, \underline{X}_i)$ is not too ill conditioned. Generally, when the set $\underline{X}_i$ is not large, the conditioning of $K(\underline{X}_i, \underline{X}_i)$ is acceptable; however, for a robust safeguard, we use a small $\lambda' < \lambda$ for help. Instead of treating $k(\boldsymbol{x}, \boldsymbol{x}')$ as the base kernel and λ as the amount of regularization, we treat $k'(\boldsymbol{x}, \boldsymbol{x}') = k(\boldsymbol{x}, \boldsymbol{x}') + \lambda' \delta_{\boldsymbol{x}, \boldsymbol{x}'}$ as the base kernel and $\lambda - \lambda'$ the regularization, where δ is the Kronecker delta. Then, we use k' to build the kernel $k'_{\text{hierarchical}}$ and add to the matrix $K'_{\text{hierarchical}}$ a regularization $(\lambda - \lambda')I$.

4.4 Sizes

Two parameters exist for the proposed kernel. First, the recursive partitioning needs a stopping criterion; we say that a set of points is not further partitioned when the cardinality is less than or equal to n_0. Second, we need to specify the sizes of the conditioned sets $\underline{X}_i$. Whereas one may argue that the conditioned set needs to grow with the size of the point set for maintaining the approximation quality, a substantial increase in the size of $\underline{X}_i$ across levels will result in too high a computational cost, forfeiting the purpose of the kernel. Therefore, we mandate that each conditioned set have the same size r.

It will be convenient if we can consolidate the two parameters so that different approximate kernels are comparable. It will also be beneficial to have a guided choice of them. These requirements are indeed achievable. Under a balanced binary partitioning, n_0 can effectively take only these values: $\lceil n/2^j \rceil$, for $j = 0, 1, \ldots \lfloor \log_2 n \rfloor$. On the other hand, it

is not sensible to have the rank r greater than n_0 because the smallest off-diagonal blocks have a size at most $n_0 \times n_0$. Then, we take

$$n_0 = \lceil n/2^j \rceil \quad \text{and} \quad r = \lfloor n/2^j \rfloor \quad \text{for some } j. \tag{22}$$

4.5 Cost Analysis

We are now ready to perform a full analysis of the computational costs based on the practical choices made in the preceding subsections.

Memory Cost Let us first consider the memory cost of storing the matrix A. For simplicity, assume that n is a power of 2 (and thus $n_0 = r$). Then, the partitioning tree has n/n_0 leaf nodes and $n/n_0 - 1$ nonleaf nodes. Hence, the memory costs for the factors A_{ii}, U_i, Σ_p, and W_p are $n_0^2 n/n_0$, nr, $r^2(n/n_0 - 1)$, and $r^2(n/n_0 - 1)$, respectively. Therefore, the total memory cost is approximately $4nr$.

Arithmetic Cost, Algorithm 1 The arithmetic cost of matrix-vector multiplication (Algorithm 1) is $O(nr)$, because the subroutines Upward and Downward for each node performs $O(r^2)$ calculations, discounting the recursion calls. These recursions essentially constitute a tree traversal, which visits all the $2n/n_0 - 1$ nodes. Therefore, the total cost is $O(nr)$. In fact, a more detailed analysis may reveal the constant inside the big-O notation. Note that the matrix-vector multiplications $W_i^T c_j$ and $W_i d_i$ occur for each node j, $\Sigma_p c_i$ occurs for each node i, and $U_i^T b_i$, $A_{ii} b_i$, and $U_i d_i$ occur for each leaf node i. The matrix size of all these multiplications is $r \times r$. Therefore, if each multiplication requires $2r^2$ arithmetic operations, then the total cost is approximately $2r^2 \times (2n/n_0 + 2n/n_0 + 2n/n_0 + n/n_0 + n/n_0 + n/n_0) = 18nr$, ignoring lower-order terms.

Arithmetic Cost, Algorithm 2 Based on a similar argument, the arithmetic cost of matrix inversion (Algorithm 2) is $O(nr^2)$. A more precise estimate is $37nr^2$, if factorizing a general $r \times r$ matrix, factorizing a symmetric positive-definite matrix, performing a triangular solve, and multiplying two $r \times r$ matrices require $2r^3/3$, $r^3/3$, r^2, and $2r^3$ operations, respectively. As before, we ignore the lower-order terms.

Arithmetic Cost, Algorithm 3, Precomputation Phase Now consider the precomputation phase of the inner product $w^T k_{\text{hierarchical}}(X, \boldsymbol{x})$ (Algorithm 3). In computer implementation, we move the first line (prefactorizing $K(\underline{X}_p, \underline{X}_p)$) to the matrix construction part (to be discussed in Section 4.5). Hence, the precomputation of Algorithm 3 is dominated by the third line Common-Upward(`root`). The arithmetic cost is $O(nr)$, or $10nr$ in a more precise account.

Arithmetic Cost, Algorithm 3, $\boldsymbol{x}$-Dependent Phase Assume that evaluating the kernel function $k(\boldsymbol{x}, \boldsymbol{x}')$ requires $O(\text{nz}(\boldsymbol{x}) + \text{nz}(\boldsymbol{x}'))$ arithmetic operations, where $\text{nz}(\cdot)$ denotes the number of nonzeros of a data point. Further assume that for two point sets Y and Z of sizes n_Y and n_Z respectively, evaluating the vector $k(Y, \boldsymbol{x})$ requires $O(n_Y \text{ nz}(\boldsymbol{x}) + \text{nz}(Y))$ operations, and evaluating the matrix $K(Y, Z)$ requires $O(n_Y \text{ nz}(Z) + n_Z \text{ nz}(Y))$ operations, where the notation $\text{nz}(\cdot)$ is extended for point sets in a straightforward manner.

Now we consider the cost of the $\boldsymbol{x}$-dependent phase of Algorithm 3. Line 20 costs $O(r \text{ nz}(\boldsymbol{x}) + \text{nz}(\underline{X}_p)) + O(r^2)$, where the first term comes from evaluating $k(\underline{X}_p, \boldsymbol{x})$ and the

second term a linear-solve. Note that the matrix $K(\underline{X}_p, \underline{X}_p)$ has already been evaluated and prefactorized prior to this phase. In fact, such a computation is done when constructing $K_{\text{hierarchical}}$. Similarly, line 21 costs $O(n_0 \operatorname{nz}(\boldsymbol{x}) + \operatorname{nz}(X_i)) + O(n_0)$. Line 23 costs $O(\operatorname{nz}(\boldsymbol{x}))$, because it amounts to projecting $\boldsymbol{x}$ on a direction. Then, the overall cost of the $\boldsymbol{x}$-dependent phase of Algorithm 3 is

$$O\Big(r \operatorname{nz}(\boldsymbol{x}) + \operatorname{nz}(X_i) + \operatorname{nz}(\underline{X}_p) + (r^2 + \operatorname{nz}(\boldsymbol{x})) \log_2(n/r)\Big), \tag{23}$$

where $\boldsymbol{x}$ lies in the leaf node i and p is its parent.

Arithmetic Cost, Matrix Construction We shall also consider the cost of hierarchical partitioning and the instantiation of the matrix $A = K_{\text{hierarchical}}$. In the partitioning of a set of n points X, generating a random projection direction costs $O(d)$, computing the projected coordinates costs $O(\operatorname{nz}(X))$, finding the median costs $O(n)$, and permuting the points costs $O(\operatorname{nz}(X))$. Then, counting recursion, the total cost is $O((d + n + \operatorname{nz}(X)) \log_2(n/r))$. On the other hand, in the instantiation of the matrix A, computing A_{ii} for all leaf nodes i costs $O(r \operatorname{nz}(X))$, computing U_i for all leaf nodes i costs $O(r[n + \operatorname{nz}(X) + \sum_{i \text{ is leaf}} \operatorname{nz}(\underline{X}_p)])$, computing Σ_p for all nonleaf nodes p costs $O(r[\sum_{p \text{ is nonleaf}} \operatorname{nz}(\underline{X}_p)])$, factorizing these Σ_p's costs $O(nr^2)$, computing W_i for all nonleaf and nonroot nodes i costs $O(r[n + \sum_{i \text{ is not leaf and not root}} \operatorname{nz}(\underline{X}_i) + \operatorname{nz}(\underline{X}_p)])$, and finding all landmark point sets costs $O(n)$. Therefore, the total cost of instantiating A is $O(r[nr + \operatorname{nz}(X) + \sum_{i \text{ is not leaf}} \operatorname{nz}(\underline{X}_i)])$.

Arithmetic Cost Summary, Training and Testing Summarizing the above analysis, we see that the overall cost of training (including partitioning, instantiating A, matrix inversion, matrix-vector multiplication, and preprocessing of Algorithm 3) is

$$O\left((d + n + \operatorname{nz}(X)) \log_2(n/r) + nr^2 + r\left[\operatorname{nz}(X) + \sum_{i \text{ is not leaf}} \operatorname{nz}(\underline{X}_i)\right]\right). \tag{24}$$

The overall cost of testing per $\boldsymbol{x}$ has been given in (23).

We remark that the term $\log_2(n/r)$ in both (23) and (24) is dominated by r when $n \leq r2^r$. Moreover, when the data X is dense, the training cost (24) simplifies to $O(nr^2 + ndr)$ and the testing cost per point (23) simplifies to $O(r^3 + dr)$. Suppressing the data dimension d, these costs are further simplified to $O(nr^2)$ and $O(r^3)$, respectively.

5. Experimental Results

In this section, we present comprehensive experiments to demonstrate the effectiveness of the proposed kernel. The experiments were performed on one node of a computing cluster with 512 GB memory and an IBM POWER8 12-core processor, unless otherwise stated. The programs were implemented in C++. The linear algebra routines (BLAS and LAPACK) were linked against the IBM ESSL library and some obviously parallelizable for-loops were decorated by OpenMP pragmas, so that the experiments with large data sets can be completed in a reasonable time frame. However, the programs were neither fully optimized nor fully parallelized, leaving room for improvement on both memory consumption and execution time.

Table 1: Data sets.

Name	Type	d	n Train	n' Test
cadata	regression	8	16,512	4,128
YearPredictionMSD	regression	90	463,518	51,630
ijcnn1	binary classification	22	35,000	91,701
covtype.binary	binary classification	54	464,809	116,203
SUSY	binary classification	18	4,000,000	1,000,000

acoustic	3 classes	50	78,823	19,705
covtype	7 classes	54	464,809	116,203

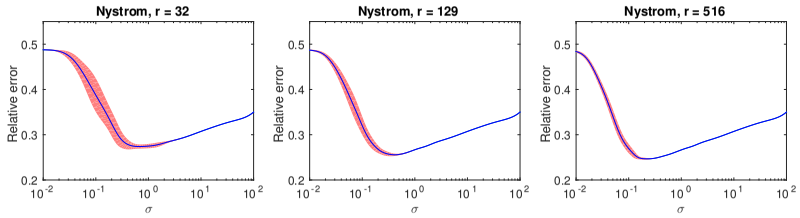

Table 1 summarizes the data sets used for experiments. They were all downloaded from `http://www.csie.ntu.edu.tw/~cjlin/libsvm/` and are widely used as benchmarks of kernel methods. We selected these data sets primarily because of their varying sizes. Some of the data sets come with a training and a testing part; for those not, we performed a 4:1 split to create the two parts, respectively. In some of the data sets, the attributes had already been normalized to within $[0, 1]$ or $[-1, 1]$; for those not, we performed such a normalization. We also preprocessed the data sets by removing duplicate and conflicting records (whose labels are inconsistent) in the training sets. Such records are infrequent.

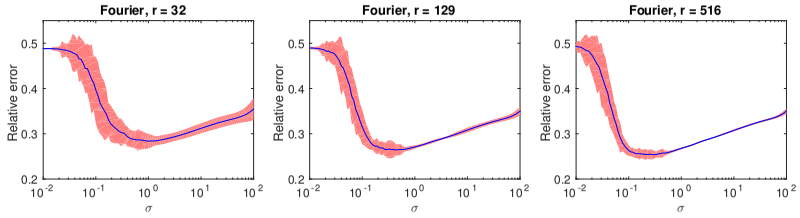
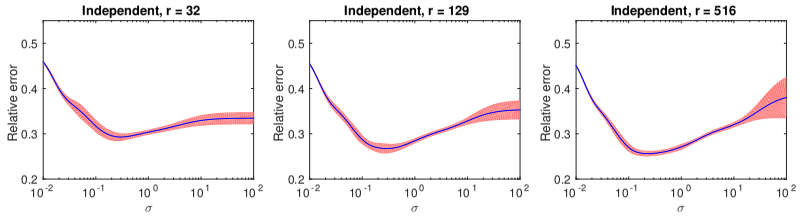
5.1 Effect of Randomness

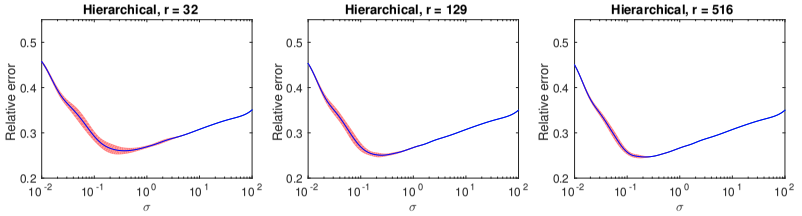


Throughout Section 5, we will compare various approximate kernels: Nyström approximation $k_{\text{Nyström}}$, random Fourier features k_{Fourier}, cross-domain independent kernel $k_{\text{independent}}$, and the proposed kernel $k_{\text{hierarchical}}$. The partitioning in the cross-domain independent kernel is the same as that in the proposed kernel, except that the hierarchy is flattened. Because of the random nature of all these kernels (e.g., landmark points, sampling, and partitioning), we first study how the performance is affected by randomization. Note that the quantity r is comparable across kernels, even though its specific meaning is different.

The data set for demonstration is cadata. We use the Gaussian kernel (5) as an example. As hinted earlier, the choice of the range parameter σ affects the quality of various kernels. Therefore, the experiment setup is to use a reasonable regularization $\lambda = 0.01$ and to vary the choice of σ in a large interval (between 0.01 and 100) such that the optimal σ falls within the interval. We set the rank r (and the leaf size n_0) according to (22) with three particular choices: $r = 32$, 129, and 516.



For each r, we repeat 30 times with different random seeds; but the seed always stays the same every time when the range of σ is swept. The results (relative testing error versus σ) are summarized in Figure 3, with mean (blue curve) and standard deviation (red band) plotted. One sees that the red bands of random Fourier features are not smooth; this is because each single error curve from a fixed seed is nonsmooth. Moreover, the error curves for Nyström approximation have a nonnegligible variation when σ is small, whereas those for the independent kernel vary significantly when σ is large. The error curves of the proposed kernel are the most stable, with the narrowest standard deviation band. Generally



(a) Nyström approximation

(b) random Fourier features

(c) Cross-domain independent kernel

(d) Hierarchically compositional kernel

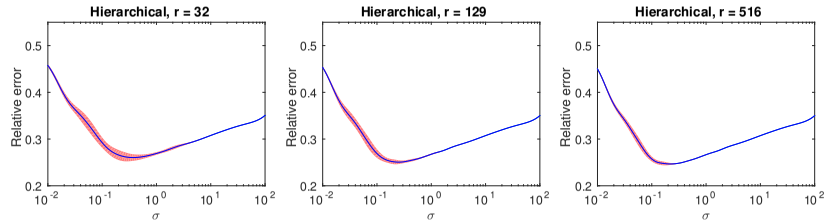


Figure 3: Regression error curves versus σ. Results are summarized from 30 repeated runs and the red bands show three times standard deviation. Data set: cadata.

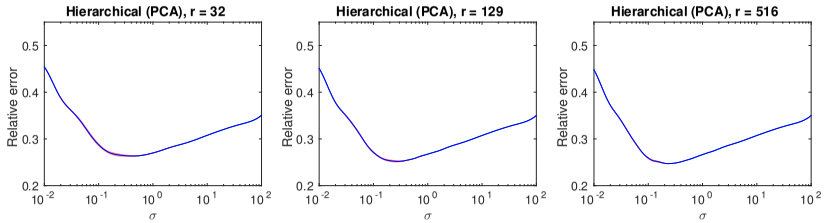
speaking, as r increases, all approximate kernels yield a more and more stable error curve, except the peculiar case of the independent kernel at large σ.



The unstable performance caused by randomness is unfavorable for parameter estimation, because the valley, where the optimal parameter stands, may move substantially. The nonsmoothness exhibited in the Fourier approach also renders difficulty. Although the unfavorable behaviors are substantially alleviated when r increases to 516 in this particular data set, to our experience, the relieving size for r correlates with the data size; that is, the larger n, the higher r needs to increase to. In this regard, the proposed kernel is the most favorable because its performance is relatively stable even for small r.

5.2 Partitioning Approaches

We further compare the methods for partitioning needed by the proposed kernel. The comparison focuses on three aspects: effect of randomness, testing error, and computational efficiency. Among the several possible choices discussed in Section 4.1, only the PCA approach and the random projection approach (which is recommended) yield a balanced partitioning; hence, we compare only these two.

(a) Random partitioning

(b) PCA partitioning

Figure 4: Regression error curves of the proposed method. Data are recursively partitioned by using random projections (top row) and by PCA (bottom row), respectively.

Figure 4 summarizes the error curves (mean and standard deviation) resulting from the two approaches, based on the same setting as in the preceding subsection. The top row corresponds to the recommended approach whereas the bottom row PCA. One sees that

the mean error curves are almost identical in both approaches. PCA is less influenced by randomization. Such a result should not be surprising, because PCA bares no randomness at all on partitioning; the only randomness comes from the landmark points. Although the variation of the error curves of the random projection approach is higher, such a variation is acceptable, particularly when it is compared with that of other approximate kernels in the preceding subsection.

The essential reason why random projection is favored over PCA comes from the consideration of computational efficiency. To generate the normal direction of a partitioning hyperplane, random projection amounts to only generating d random numbers, whereas PCA requires computing the dominant singular vector of the shifted data matrix. Table 2 presents the time costs of the additional singular vector computation, against the partitioning cost and the overall training cost by using random projection. We call the singular vector computation "overhead." The overhead is much higher with respect to the partitioning step, because such a step has a negligible cost compared to the overall training. The overhead is also generally higher when r is smaller because there requires more partitioning. The overhead with respect to partitioning easily exceeds 100% for quite a few of the data sets, and sometimes it is even a few thousand percents. For the data set mnist, which has the largest dimension d, the overhead with respect to overall training ranges from approximately 50% to 800%.

5.3 Performance Results for Various Data Sets

We now compare various approximate kernels on all the data sets listed in Table 1. For each kernel and each r, we obtain the performance result through a grid search of the optimal parameters σ and λ. Because of the high cost of parameter tuning, no repetitions are run and hence the performances may be susceptible to randomization. Hence, conclusions are drawn across data sets and we refrain from over-interpreting the results of an individual data set. We run experiments with a few r's and we are particularly interested in the performance trend as r increases.

The results are summarized in Figures 5 and 6. In the panel of the plots, each row corresponds to one data set. The three columns are performance versus r, training time, and memory consumption, respectively. The performance is measured as the relative error in the regression case and the accuracy in the classification case. The memory cost is estimated and normalized. According to the analysis in Section 4.5, the memory cost of the proposed kernel is approximately $4r$ per training point, whereas for the other approximate kernels we use an estimation of r per point.

A few observations follow. First, the proposed kernel almost always yields the best performance versus r, except for the data set YearPredictionMSD. Such an observation confirms the effectiveness of the proposed method, which combines the advantages of the Nyström method globally and the cross-domain independent kernel locally.

Second, the Fourier method generally runs the fastest, followed by Nyström and independent, whose speeds are comparably similar; and the proposed method falls behind. Although all methods have the same asymptotic cost $O(nr^2)$, in a finer level of analysis, Fourier wins over Nyström because the generation of random features in the former is often less expensive than the kernel evaluation in the latter. Of course, such a fact could also be

Table 2: PCA overhead with respect to partitioning and to overall training, under different r.

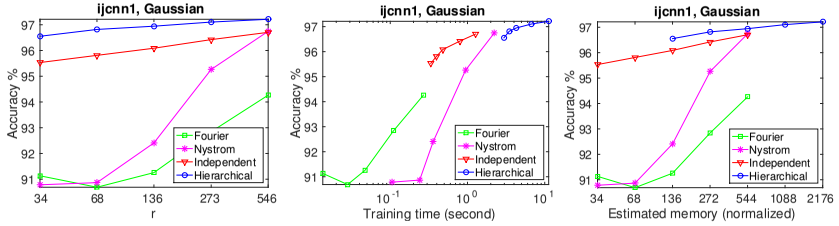
interpreted on the other hand as a weakness of the Fourier method: It is applicable to only a numeric data representation, whereas Nyström assumes no numeric form of data but a kernel. Nyström has a similar time cost as does the independent kernel; the former requires more kernel evaluations but the latter needs computing the sequence of subdomains each point belongs to. The independent kernel and the proposed kernel need similar computations (small matrix multiplications and factorizations), but the number of such operations is a constant times more for the proposed kernel; hence, not surprisingly it requires more computational effort.



Note that in the Fourier and the Nyström methods, large matrices are operated in a small number of times. The implementation straightforwardly makes use of sophisticated linear algebra libraries, where parallelism and cache reuse have been aggressively optimized (Anderson et al., 1999; Goto and Geijn, 2008). On the other hand, in the independent and the proposed kernels, small matrices are operated in a large number of times. Moreover, there exist fragmented computations such as tree traversals and data shuffles. Optimizing these computations in terms of parallelism and cache reuse is possible and the executation times have the potential to be substantially improved.

(c) acoustic, multiclass classification

(d) covtype, multiclass classification

Figure 6: (Continued) Performance versus r, time, and memory. Gaussian kernel.

The third observation of Figures 5 and 6 focuses on the performance versus memory consumption. Since all the other methods are estimated to use the same amount of memory, the plots are essentially moving only the curve of the proposed kernel to the right compared with the performance-versus-r plots. Then, with the same amount of memory, some methods behave better than others in some data sets. There does not exist a consistent winner. One sees that the proposed method is the best performing for the data sets ijcnn1 and SUSY.

The last observation is that for the data set covtype (both the binary and the multiclass case), a significant performance gap occurs between the low-rank (Fourier and Nyström) and the full-rank (independent and hierarchical) kernels. This is the exemplified case where the eigenvalues in the kernel matrix decay too slowly, such that low-rank kernels with an insufficiently large rank r are clearly underperforming.

5.4 A Different Base Kernel

We consider using a different base kernel and inspect whether the observations made in the preceding subsection still hold. Here, we use the Laplace kernel

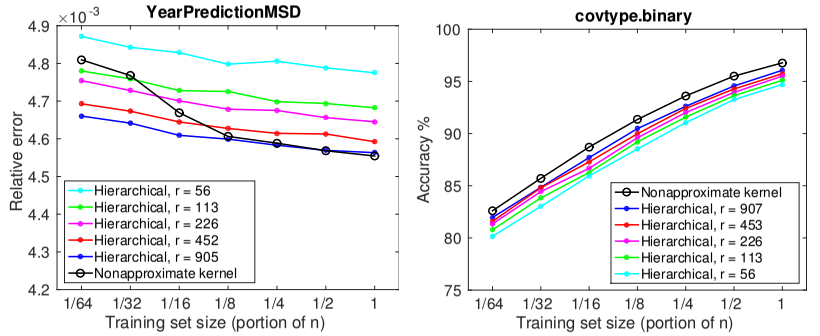
$$k(\boldsymbol{x}, \boldsymbol{x}') = \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{x}'\|_1}{\sigma}\right)$$

popularized by Rahimi and Recht (2007). Clearly, this kernel is the tensor product of one-dimensional exponential kernels $\exp(-|x_i - x_i'|/\sigma)$ for all attributes i. In the GP context, the exponential kernel gives rise to the well-known Ornstein-Uhlenbeck process. Both the exponential kernel and the Gaussian kernel are special cases of the Matérn family of kernels, but their characteristics are opposite: the latter yields an extremely smooth process whereas the former highly rough (Stein, 1999). Hence, one might expect that their results substantially differ.

However, the answer is to the contrary. To avoid cluttering, we leave the plots to the appendix (see Figures 9 and 10); they are similar to those shown in Figures 5 and 6 of the Gaussian kernel. Specifically, the general trends and the specific performance values are quite close across the two base kernels. A possible reason is that the (optimal) regularization λ generally lies on the order of 0.01 to 0.1, which is relatively large compared with the kernel values, whose peak occurs at $k(0) = 1$. In the GP context, the noise level λ is so high that it eclipses the effect of smoothness—the rough variation of data may as well be interpreted as noise instead. Then, the smoothness of the kernel matters little and thus the results of different base kernels look similar.

Based on this observation, we additionally perform experiments with the inverse multiquadric kernel

$$k(\boldsymbol{x}, \boldsymbol{x}') = \frac{\sigma^2}{\sqrt{\|\boldsymbol{x} - \boldsymbol{x}'\|_2^2 + \sigma^2}}.$$



The strict positive definiteness of this kernel is proved in Micchelli (1986); but its Fourier transform is little known and hence we do not compare with the random Fourier method. The results are shown in the appendix (see Figures 11 and 12). One sees again that they are quite similar to those of the Gaussian and Laplace kernels.

5.5 Trade-Off between n and r

A folk wisdom in machine learning is that more data beats a more complex model (Domingos, 2012). The applicability of this knowledge lies in the regime where the hypothesis space has not been saturated by data. For kernel methods, a natural question to ask is whether subsampling is viable, considering that the computational effort is nontrivial with respect to the data size n. A relevant question in the context of approximate kernels is whether a trade-off exists between n and r, given a fixed budget nr. This budget comes from the memory constraint, because the memory cost is $O(nr)$ in various approximate kernels. Note that if nr is fixed, the arithmetic cost $O(nr^2)$ will increase when n becomes smaller, but the kernels tend to admit a better approximation quality.

Another scenario that resolves the interplay between n and r is the following: Suppose the current computational resources have been fully leveraged for computation and one is offered an upgrade such that the memory capacity is increased t times. To expect the best performance improvement, should one seek t times more training samples (provided feasible), or a smaller increase in training samples but meanwhile also an increase in r?

To answer this question, we use two data sets, YearPredictionMSD and covtype.binary, and progressively downsize them by a factor of two. Recall that the former is a regression problem whereas the latter classification. We plot in Figure 7 the performance curves versus the training size, for a few r's in the progression of approximately a factor of two. For comparison, we also perform the full-fledged computation with the nonapproximate kernel through solving (2) directly by using a preconditioned Krylov method on a cluster of AWS EC2 machines (see Avron et al. (2016) for details). The performance curve is black with circle markers.

(a) YearPredictionMSD, regression (b) covtype.binary, binary classification

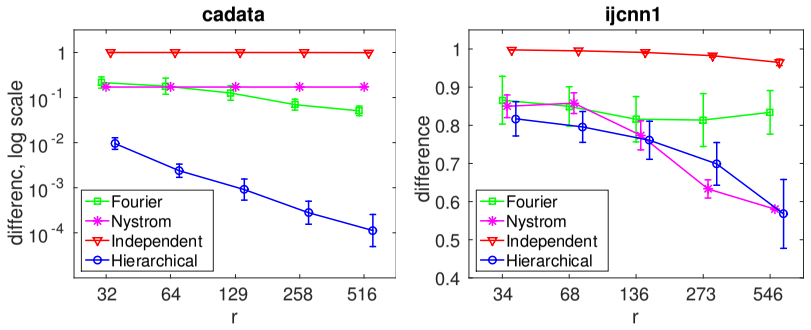


Figure 7: Performance under different training sizes and r. Kernel: Gaussian.

The question does not seem to bare a clear and simple answer after one investigates the two plots in Figure 7. Commonly, the performance of the proposed kernel improves in a consistent pace as r increases. For covtype.binary, the curves approach that of the nonapproximate kernel; however, such is not the case for YearPredictionMSD. In this data

set, when the training size is small, increasing r may surpass the performance of the non-approximate kernel. Furthermore, for covtype.binary, increasing the training size clearly yields a much higher performance than does increasing r by the same factor; however, for YearPredictionMSD, increasing r is to the contrary more beneficial. Hence, what the trade-off between n and r favors appears to be data set dependent.

5.6 Kernel PCA

Kernel principal component analysis (kernel PCA; see Schölkopf et al. (1998)) is another popular application of kernel methods. The standard PCA defines the embedding of a point $\boldsymbol{x}$ as the projected coordinates along the principal components of the training set X; whereas kernel PCA defines the embedding as the projected coordinates of $\phi(\boldsymbol{x})$ along the principal components of $\phi(X)$, where ϕ denotes the mapping from the input space to the feature space. For low-rank kernels (e.g., Nyström and Fourier) that give the explicit feature map ϕ, kernel PCA may be straightforwardly computed through singular value decomposition of the feature points $\phi(X)$ after centering. For other kernels (e.g., cross-domain independent kernel and the proposed kernel), one may leverage the relation $k(\boldsymbol{x},\boldsymbol{x}') = \langle\phi(\boldsymbol{x}),\phi(\boldsymbol{x}')\rangle$ and compute the embedding through eigenvalue decomposition of the kernel matrix $K(X,X)$ after centering.

(a) cadata, $n = 16,512$ (b) ijcnn1, $n = 35,000$

Figure 8: Kernel PCA: Embedding alignment difference (embedding dimension = 3). The horizontal placement of each curve is slightly jittered to avoid cluttering.

We follow Zhang et al. (2008) and evaluate the embedding quality of different kernels against that of the base kernel. Specifically, let U be the embedding matrix, where each row corresponds to the embedding of one point $\boldsymbol{x}$; similarly, let $\widetilde{U}$ be the embedding matrix resulting from an approximate kernel. We use a matrix M to align $\widetilde{U}$ with U; that is, M minimizes $\|U - \widetilde{U}M\|_F$. Then, we show in Figure 8 the alignment difference $\|U - \widetilde{U}M\|_F/\|U\|_F$ for different approximate kernels with various (rank) r. The embedding dimension is fixed to 3 and the base kernel is Gaussian, with the choice of bandwidth σ approximately equal to the optimum found in the preceding experiments. One sees that generally the proposed kernel results in the smallest alignment difference.

6. Concluding Remarks

Kernel methods enjoy a strong theoretical support for data interpretation and predictive modeling; however, they come with a prohibitive computational price. Substantial efforts exist in the search of approximate kernels. Low-rank kernels are one of the most popular approaches because their costs have a linear dependency on the data size n and because of their relatively simple linear algebra implementation. From the matrix angle, the effectiveness of a low-rank approximation, however, depends heavily on the decay of eigenvalues, which is often found to be insufficiently fast for large data. We may interpret that low-rank approximations tackle the problem globally, because its purpose is to approximate the whole matrix. On the other hand, block diagonal approximations (e.g., the cross-domain independent kernel) focus on the preservation of local information only. They may approximate very poorly the kernel matrix, but they often produce surprisingly good results for regression and classification (see the covtype example in Section 5). Hence, the hierarchically compositional kernel proposed in this paper is motivated by the separate characteristics of these approximations: it preserves the full information in local domains and gradually applies low-rank approximations when the domains expand in a hierarchical fashion. The net effect is that the kernel admits an $O(nr)$ storage and an $O(nr^2)$ arithmetic cost similar to that of others, but the factor r may be reduced for a matching performance when n is large. This is favorable when computational resources are constrained; that is, as the data size n increases, the additional factor r must remain small in order for computation to be affordable.

The computational efficiency of the proposed kernel is supported by a delicate matrix structure. The resulting kernel matrix $K_{\text{hierarchical}}$ is a special case of the *recursively low-rank compressed matrices* studied in Chen (2014b). Such a hierarchical structure allows many otherwise $O(n^2)$–$O(n^3)$ dense matrix operations done with an $O(nr)$–$O(nr^2)$ cost. Examples of these matrix operations are matrix-vector multiplication, matrix inversion, log-determinant calculation (Chen, 2014b), and square-root decomposition (Chen, 2014a). In addition to the focus of this paper—regression and classification, such matrix operations are crucial in many machine learning and statistical settings, including Gaussian process modeling, simulation of random processes, likelihood calculation, Markov Chain Monte Carlo, and Bayesian inference. The proposed kernel hints a direction for performing scalable computations facing an ever increasing n.

The recursively low-rank compressed structure is not a unique discovery in the prosperous literature of structured matrix computations. Many practically useful structures in scientific computing (e.g., FMM matrices (Sun and Pitsianis, 2001) and hierarchical matrices (Hackbusch, 1999)) exploit the same low-rank property exhibited in the off-diagonal blocks of the matrix, but they differ from ours in fine details, including the admissibility of low-rank approximation, the method of approximation, the nesting of basis, the shape of the hierarchy tree, and the supported matrix operations. Apart from these differences, the most distinguishing feature of our work is that the matrix structure is amenable for high dimensional data, an arena where other structured matrix methods are rarely applicable.

This peculiarity roots in the fact that the decay of singular values of the off-diagonal blocks becomes much slower when the data dimension increases. These blocks generally have a full, or nearly full, rank when the data dimension is larger than three or four. Hence, it is challenging to develop computational methods from the angle of matrix approximations, if evaluation of quality is based on the approximation error. Instead, we develop theory from the perspective of kernels and ensure the preservation of positive-definiteness. Although the new kernel arises from some approximation of the old one, we may bypass the approximation interpretation and consider them separate kernels. The choice of kernels will then be justified via model selection. An additional benefit is that out-of-sample extension is straightforward.

Although the setting of this paper casts the data domain $\mathcal{X}$ as an Euclidean space for simplicity, it is possible to generalize the proposed method to a more abstract space (e.g., a metric space). In fact, the construction of the proposed kernel and the instantiation of the kernel matrix requires as minimal as the fact that the base kernel k is strictly positive-definite. The only exception is the partitioning of the data domain, where the partition membership must be inferred for every data point (including out of samples). In a metric space, one solution is the k-means clustering, because the clustering straightforwardly defines the partitions for the training data; moreover, the partition membership for a testing point is determined by the minimal distance (metric) from the point to the cluster centers.

Through experimentation, we have demonstrated the complex performance curves with respect to kernel parameters. The curves may vary significantly due to randomization, may be multimodal, and may even be nonsmooth. These phenomena pose a challenge for selecting the optimal parameters through cross validation and grid search. To make things worse, grid search is applicable only when the number of parameters is very small. An example when one may want more parameters is to introduce anisotropy to the kernel through specifying one range parameter for each or a few attributes. Hence, a more principled approach, which in theory can incorporate an arbitrary number of parameters, is to take the GP view and to maximize the Gaussian log-likelihood

$$L(\boldsymbol{\theta}) = -\frac{1}{2}\boldsymbol{y}^T K(\boldsymbol{\theta})^{-1}\boldsymbol{y} - \frac{1}{2}\log\det K(\boldsymbol{\theta}) - \frac{n}{2}\log 2\pi \tag{25}$$

through numerical optimization, where $\boldsymbol{\theta}$ is the vector of unknown parameters and $K(\boldsymbol{\theta})$ is the kernel matrix depending on $\boldsymbol{\theta}$. This approach, coined *maximum likelihood estimation* (MLE), is also a central subject in estimation theory. Optimizing (25) nevertheless is nontrivial because of the $O(n^3)$ cost for evaluating the objective function and its derivatives when K is dense. Existing research (Anitescu et al., 2012; Stein et al., 2013) solves an approximate problem and bounds the variance of the result against that of the original problem (25). Fortunately, most of the approximate kernels discussed in this paper allow an $O(nr^2)$ cost for evaluating $L(\boldsymbol{\theta})$. For example, the algorithm for computing the log-determinant term for a recursively low-rank compressed matrix is described in Chen (2014b). An avenue of future work is to adapt the log-determinant calculation discussed in Chen (2014b) to the proposed kernel and to develop robust optimization for parameter estimation.

Appendix A. Proof of Theorem 6

The proof technique is similar to that of Theorem 3: we decompose the kernel $k_{\text{hierarchical}}$ as a sum of positive-definite terms and show that if k is strictly positive-definite, then the bilinear form cannot be zero if the coefficients are not all zero. To prevent cluttering, we use the short-hand notation $K_{\underline{i},\underline{j}}$ to denote $K(\underline{X}_i, \underline{X}_j)$.

For any node i with parent p (if any), define a function $\xi^{(i)}$ for $\boldsymbol{x}, \boldsymbol{x}' \in S_i$:

$$\xi^{(i)}(\boldsymbol{x},\boldsymbol{x}') = \begin{cases} k(\boldsymbol{x},\boldsymbol{x}') - k(\boldsymbol{x},\underline{X}_p)K^{-1}_{\underline{p},\underline{p}}k(\underline{X}_p,\boldsymbol{x}'), & i \text{ is leaf,} \\ \psi^{(i)}(\boldsymbol{x},\underline{X}_i)K^{-1}_{\underline{i},\underline{i}}[K_{\underline{i},\underline{i}} - K_{\underline{i},\underline{p}}K^{-1}_{\underline{p},\underline{p}}K_{\underline{p},\underline{i}}]K^{-1}_{\underline{i},\underline{i}}\psi^{(i)}(\underline{X}_i,\boldsymbol{x}'), & i \text{ is neither leaf nor root,} \\ \psi^{(i)}(\boldsymbol{x},\underline{X}_i)K^{-1}_{\underline{i},\underline{i}}\psi^{(i)}(\underline{X}_i,\boldsymbol{x}'), & i \text{ is root.} \end{cases} \tag{26}$$

Through telescoping, one sees that $k_{\text{hierarchical}}(\boldsymbol{x},\boldsymbol{x}') = k^{(\text{root})}(\boldsymbol{x},\boldsymbol{x}')$ is a sum of $\xi^{(i)}(\boldsymbol{x},\boldsymbol{x}')$ for all nodes i where $\boldsymbol{x},\boldsymbol{x}' \in S_i$. Because each $\xi^{(i)}$ is clearly positive-definite, so is $k_{\text{hierarchical}}$.

We now show the strict definiteness when k is strictly positive-definite. For any set of points $\{\boldsymbol{x}_i\}$ and any set of coefficients $\{\alpha_i\}$, the bilinear form $\sum_{jl}\alpha_j\alpha_l k_{\text{hierarchical}}(\boldsymbol{x}_j,\boldsymbol{x}_l)$ is zero if and only if

$$\sum_{\boldsymbol{x}_j,\boldsymbol{x}_l\in S_i}\alpha_j\alpha_l\xi^{(i)}(\boldsymbol{x}_j,\boldsymbol{x}_l) = 0, \quad \forall \text{ nodes } i. \tag{27}$$

If (27) holds, we shall prove the following statement:

> (Q) If i is not the root, it holds that $\alpha_j = 0$ for all j satisfying
>
> $$\boldsymbol{x}_j \in S_i \setminus \left[\bigcap_{q\in Des(i)} \underline{X}_q \cap \underline{X}_p\right],$$
>
> where p is the parent of i and $Des(i)$ means all the descendant nonleaf nodes of i, including i itself.

Once we prove this statement, we see that the only α_j that can possibly be nonzero are those satisfying $\boldsymbol{x}_j \in S \cap_{\text{all nodes } q} \underline{X}_q$. However, if any of these α_j is nonzero, then applying the third case of (26) on the root yields

$$\begin{aligned}\sum_{\boldsymbol{x}_j,\boldsymbol{x}_l\in S_{\text{root}}}\alpha_j\alpha_l\xi^{(\text{root})}(\boldsymbol{x}_j,\boldsymbol{x}_l) &= \sum_{\boldsymbol{x}_j,\boldsymbol{x}_l\in S_{\text{root}}}\alpha_j\alpha_l\psi^{(\text{root})}(\boldsymbol{x}_j,\underline{X}_{\text{root}})K^{-1}_{\underline{\text{root}},\underline{\text{root}}}\psi^{(\text{root})}(\underline{X}_{\text{root}},\boldsymbol{x}_l) \\ &= \sum_{\boldsymbol{x}_j,\boldsymbol{x}_l\in S\cap_{\text{all nodes } q}\underline{X}_q}\alpha_j\alpha_l e_j^T K_{\underline{\text{root}},\underline{\text{root}}}e_l \neq 0,\end{aligned}$$

contradicting (27). Here, e_j means the jth column of the identity matrix. Therefore, the bilinear form $\sum_{jl}\alpha_j\alpha_l k_{\text{hierarchical}}(\boldsymbol{x}_j,\boldsymbol{x}_l)$ cannot be zero if the coefficients are not all zero.

We now prove statement (Q) by induction. The base case is when i is a leaf node. Applying the same argument as that in the proof of Theorem 3 on the first case of (26), we have that $\alpha_j = 0$ for all j satisfying $\boldsymbol{x}_j \in S_i \backslash \underline{X}_p$. In the induction step, if (Q) holds for all children nodes i of p and if r is the parent of p, we apply the second case of (26) and obtain

$$0 = \sum_{\boldsymbol{x}_j, \boldsymbol{x}_l \in S_p} \alpha_j \alpha_l \xi^{(p)}(\boldsymbol{x}_j, \boldsymbol{x}_l) = \sum_{\boldsymbol{x}_j, \boldsymbol{x}_l \in S_p} \alpha_j \alpha_l \psi^{(p)}(\boldsymbol{x}_j, \underline{X}_p) K_{\underline{p},\underline{p}}^{-1} [K_{\underline{p},\underline{p}} - K_{\underline{p},\underline{r}} K_{\underline{r},\underline{r}}^{-1} K_{\underline{r},\underline{p}}] K_{\underline{p},\underline{p}}^{-1} \psi^{(p)}(\underline{X}_p, \boldsymbol{x}_l)$$
$$= \sum_{\boldsymbol{x}_j, \boldsymbol{x}_l \in S_p \backslash \cap_{q \in Des(p)} \underline{X}_q} \alpha_j \alpha_l e_j^T [K_{\underline{p},\underline{p}} - K_{\underline{p},\underline{r}} K_{\underline{r},\underline{r}}^{-1} K_{\underline{r},\underline{p}}] e_l. \qquad (28)$$

For the matrix $K_{\underline{p},\underline{p}} - K_{\underline{p},\underline{r}} K_{\underline{r},\underline{r}}^{-1} K_{\underline{r},\underline{p}}$ inside the square bracket, the block corresponding to $\underline{X}_p \backslash \underline{X}_r$ has full rank, whereas the rest is zero. Then, in order for (28) to be zero, one must have that $\alpha_j = 0$ for all j satisfying $\boldsymbol{x}_j \in \underline{X}_p \backslash \underline{X}_r$. Making a disjunction of this relation with that in the induction hypothesis: $\boldsymbol{x}_j \in S_p \backslash \cap_{q \in Des(p)} \underline{X}_q$, we obtain

$$\boldsymbol{x}_j \in S_p \Bigg\backslash \left[\bigcap_{q \in Des(p)} \underline{X}_q \cap \underline{X}_r \right],$$

which concludes the induction and subsequently concludes the proof of Theorem 6.

Abstract

We study a set of regularization methods for high-dimensional linear regression models. These penalized estimators have the square root of the residual sum of squared errors as loss function, and any weakly decomposable norm as penalty function. This fit measure is chosen because of its property that the estimator does not depend on the unknown standard deviation of the noise. On the other hand, a generalized weakly decomposable norm penalty is very useful in being able to deal with different underlying sparsity structures. We can choose a different sparsity inducing norm depending on how we want to interpret the unknown parameter vector β. Structured sparsity norms, as defined in Micchelli et al. (2010), are special cases of weakly decomposable norms, therefore we also include the square root LASSO (Belloni et al., 2011), the group square root LASSO (Bunea et al., 2014) and a new method called the square root SLOPE (in a similar fashion to the SLOPE from Bogdan et al. 2015). For this collection of estimators our results provide sharp oracle inequalities with the Karush-Kuhn-Tucker conditions. We discuss some examples of estimators. Based on a simulation we illustrate some advantages of the square root SLOPE.

Keywords: Square root LASSO, structured sparsity, Karush-Kuhn-Tucker, sharp oracale inequality, weak decomposability

1. Introduction and Model

The recent development of new technologies makes data gathering not a big problem any more. In some sense there is more data than we can handle, or than we need. The problem has shifted towards finding useful and meaningful information in the big sea of data. An example where such problems arise is the high-dimensional linear regression model

$$Y = X\beta^0 + \epsilon. \tag{1.1}$$

Here Y is the $n-$dimensional response variable, X is the $n \times p$ design matrix and ϵ is the identical and independent distributed noise vector. The noise has $\mathrm{E}(\epsilon_i) = 0, \mathrm{Var}(\epsilon_i) = \sigma^2, \ \forall i \in \{1, ..., n\}$. Assume that σ is **unknown**, and that β^0 is the "true" underlying $p-$dimensional parameter vector of the linear regression model with active set $S_0 := \mathrm{supp}(\beta^0)$.

While trying to explain Y through different other variables, in the high-dimensional linear regression model, we need to set less important explanatory variables to zero. Otherwise we would have overfitting. This is the process of finding a trade-off between a good fit and a sparse solution. In other words we are trying to find a solution that explains our data well, but at the same time only uses more important variables to do so.
The most famous and widely used estimator for the high-dimensional regression model is the ℓ_1-regularized version of least squares, called LASSO (Tibshirani, 1996)

$$\hat{\beta}_L(\sigma) := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n^2 + 2\lambda_1 \sigma \|\beta\|_1 \right\}.$$

Here λ_1 is a constant called the regularization level, which regulates how sparse our solution should be. Also note that the construction of the LASSO estimator depends on the unknown noise level σ. We moreover let $\|a\|_1 := \sum_{i=1}^p |a_i|$ for any $a \in \mathbb{R}^p$ denote the ℓ_1-norm and for any $a \in \mathbb{R}^n$ we write $\|a\|_n^2 = \sum_{j=1}^n a_j^2/n$, the ℓ_2- norm squared and divided by n. The LASSO uses the ℓ_1-norm as a measure of sparsity. This measure as regulizer sets a number of parameters to zero.
Let us rewrite the LASSO into the following form

$$\hat{\beta}_L = \arg\min_{\beta \in \mathbb{R}^p} \left\{ \left(\|Y - X\beta\|_n + \lambda'(\beta)\|\beta\|_1 \right) \cdot \frac{2\lambda_1 \sigma}{\lambda'(\beta)} \right\},$$

where $\lambda'(\beta) := \frac{2\lambda_1 \sigma}{\|Y - X\beta\|_n}$. Instead of minimizing with $\lambda'(\beta)$, a function of β, let us assume that we keep $\lambda'(\beta)$ a fixed constant. Then we get the Square Root LASSO method

$$\hat{\beta}_{srL} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda \|\beta\|_1 \right\}.$$

So in some sense the λ for the Square Root LASSO is a scaled version, scaled by an adaptive estimator of σ, of λ_1 from the LASSO. By the optimality conditions it is true that

$$\hat{\beta}_L(\|Y - X\hat{\beta}_{srL}\|_n) = \hat{\beta}_{srL}.$$

The Square Root LASSO was introduced by Belloni et al. (2011) in order to get a pivotal method. An equivalent formulation as a joint convex optimization program can be found in Owen (2007). This method has been studied under the name Scaled LASSO in Sun and Zhang (2012). Pivotal means that the theoretical λ does not depend on the unknown standard deviation σ or on any estimated version of it. The estimator does not require the estimation of the unknown σ. Belloni et al. (2014) also showed that under Gaussian noise the theoretical λ can be chosen of order $\Phi^{-1}(1 - \alpha/2p)/\sqrt{n-1}$, with Φ^{-1} denoting the inverse of the standard Gaussian cumulative distribution function, and α being some small probability. This is independent of σ and achieves a near oracle inequality for the prediction norm of convergence rate $\sigma\sqrt{(|S_0|/n)\log p}$. In contrast to that, the theoretical penalty level of the LASSO depends on knowing σ in order to achieve similar oracle inequalities for the prediction norm.

The idea of the square root LASSO was further developed in Bunea et al. (2014) to the group square root LASSO, in order to get a selection of groups of predictors. The group LASSO norm is another way to describe an underlying sparsity, namely if groups of parameters should be set to zero, instead of individual parameters. Another extension for the the square root LASSO in the case of matrix completion was given by Klopp (2014).
Now in this paper we go further and generalize the idea of the square root LASSO to any sparsity inducing norm. From now on we will look at the family of norm penalty regularization methods, which are of the following square root type

$$\hat{\beta} := \arg\min_{\beta \in \mathbb{R}^p} \{\|Y - X\beta\|_n + \lambda\Omega(\beta)\},$$

where Ω is any norm on $\mathbb{R}^p$. This set of regularization methods will be called square root regularization methods. Furthermore, we introduce the following notations

$\hat{\epsilon} := Y - X\hat{\beta}$	the residuals,
$\Omega^*(x) := \max_{z,\Omega(z)\leq 1} z^T x,\ x \in \mathbb{R}^p$	the dual norm of the norm Ω, and
$\beta_S = \{\beta_j : j \in S\}$	$\forall S \subset \{1, ..., p\}$ and all vectors $\beta \in \mathbb{R}^p$.

Later we will see that describing the underlying sparsity with an appropriate sparsity norm can make a difference in how good the errors will be. Therefore in this paper we extend the idea of the square root LASSO with the ℓ_1-penalty to more general weakly decomposable norm penalties. The theoretical λ of such an estimator will not depend on σ either. We introduce the Karush-Kuhn-Tucker conditions for these estimators and give sharp oracle inequalities. In the last two sections we will give some examples of different norms and simulations comparing the square root LASSO with the square root SLOPE.

2. Karush-Kuhn-Tucker Conditions

As we already have seen before, these estimators need to calculate a minimum over β. The Karush-Kuhn-Tucker conditions characterize this minimum. In order to formulate these optimality conditions we need some concepts of convex optimization. For the reader who is not familiar with this topic, we will introduce the subdifferential, which generalizes the differential, and give a short overview of some properties, as can be found for example in Bach et al. (2012). For any convex function $g : \mathbb{R}^p \to \mathbb{R}$ and any vector $w \in \mathbb{R}^p$ we define its subdifferential as

$$\partial g(w) := \{z \in \mathbb{R}^p;\ g(w') \geq g(w) + z^T(w' - w)\ \forall w' \in \mathbb{R}^p\}.$$

The elements of $\partial g(w)$ are called the subgradients of g at w.
Let us remark that all convex functions have non empty subdifferentials at every point. Moreover by the definition of the subdifferential any subgradient defines a tangent space $w' \mapsto g(w) + z^T \cdot (w' - w)$, that goes through $g(w)$ and is at any point lower than the function g. If g is differentiable at w, then its subdifferential at w is the usual gradient. Now the

next lemma, which dates back to Pierre Fermat (see Bauschke and Combettes 2011), shows how to find a global minimum for a convex function g.

Lemma 1 (Fermat's Rule) *For all convex functions $g : \mathbb{R}^p \to \mathbb{R}$ it holds that*

$$v \in \mathbb{R}^p \text{ is a global minimum of } g \ \Leftrightarrow 0 \in \partial g(v).$$

For any norm Ω on $\mathbb{R}^p$ with $\omega \in \mathbb{R}^p$ it holds true that its subdifferential can be written as (see Bach et al. 2012 Proposition 1.2)

$$\partial\Omega(\omega) = \begin{cases} \{z \in \mathbb{R}^p; \Omega^*(z) \leq 1\} & \text{if } \omega = 0 \\ \{z \in \mathbb{R}^p; \Omega^*(z) = 1 \bigwedge z^T w = \Omega(\omega)\} & \text{if } \omega \neq 0. \end{cases} \tag{2.1}$$

We are able to apply these properties to our estimator $\hat{\beta}$. Lemma 1 implies that

$$\hat{\beta} \text{ is optimal } \Leftrightarrow -\frac{1}{\lambda}\nabla\|Y - X\hat{\beta}\|_n \in \partial\Omega(\hat{\beta}).$$

This means that, in the case $\|\hat{\epsilon}\|_n > 0$, for the square root regularization estimator $\hat{\beta}$ it holds true that

$$\hat{\beta} \text{ is optimal } \Leftrightarrow \frac{X^T(Y - X\hat{\beta})}{n\lambda\|Y - X\hat{\beta}\|_n} \in \partial\Omega(\hat{\beta}). \tag{2.2}$$

By combining equation (2.1) with (2.2) we can write the KKT conditions as

$$\hat{\beta} \text{ is optimal } \Leftrightarrow \begin{cases} \Omega^*\left(\frac{\hat{\epsilon}^T X}{n\|\hat{\epsilon}\|_n}\right) \leq \lambda & \text{if } \hat{\beta} = 0 \\ \Omega^*\left(\frac{\hat{\epsilon}^T X}{n\|\hat{\epsilon}\|_n}\right) = \lambda & \text{if } \hat{\beta} \neq 0. \\ \bigwedge \frac{\hat{\epsilon}^T X\hat{\beta}}{n\|\hat{\epsilon}\|_n} = \lambda\Omega(\hat{\beta}) \end{cases} \tag{2.3}$$

What we might first remark about equation (2.3) is that in the case of $\hat{\beta} \neq 0$ the second part can be written as

$$\hat{\epsilon}^T X\hat{\beta}/n = \Omega(\hat{\beta}) \cdot \Omega^*\left(\frac{\hat{\epsilon}^T X}{n}\right).$$

This means that we in fact have equality in the generalized Cauchy-Schwartz Inequality for these two $p-$dimensional vectors. Furthermore let us remark that the equality

$$\hat{\epsilon}^T X\hat{\beta}/n = \Omega(\hat{\beta})\lambda\|\hat{\epsilon}\|_n$$

trivially holds true for the case where $\hat{\beta} = 0$. It is important to remark here that, in contrast to the KKT conditions for the LASSO, we have an additional $\|\hat{\epsilon}\|_n$ term in the expression $\Omega^*\left(\frac{\hat{\epsilon}^T X}{n\|\hat{\epsilon}\|_n}\right)$. This nice scaling leads to the property that the theoretical λ is independent of σ.
With the KKT conditions we are able to formulate a generalized type of KKT conditions. This next lemma is needed for the proofs in the next chapter.

Lemma 2 *For the square root type estimator $\hat{\beta}$ we have for any $\beta \in \mathbb{R}^p$ and when $\|\hat{\epsilon}\|_n \neq 0$*

$$\frac{1}{\|\hat{\epsilon}\|_n}\hat{\epsilon}^T X(\beta - \hat{\beta})/n + \lambda\Omega(\hat{\beta}) \leq \lambda\Omega(\beta).$$

Proof First we need to look at the inequality from the KKT's, which holds in any case

$$\Omega^*\left(\frac{\hat{\epsilon}^T X}{n\|\hat{\epsilon}\|_n}\right) \leq \lambda. \tag{2.4}$$

And by the definition of the dual norm and the maximum, we have with (2.4)

$$\begin{aligned}\frac{1}{\|\hat{\epsilon}\|_n}\hat{\epsilon}^T X\beta/n &\leq \Omega(\beta)\cdot \max_{\beta\in\mathbb{R}^p,\Omega(\beta)\leq 1}\frac{\hat{\epsilon}^T}{\|\hat{\epsilon}\|_n}X\beta/n \\ &= \Omega(\beta)\cdot\Omega^*\left(\frac{\hat{\epsilon}^T X}{n\|\hat{\epsilon}\|_n}\right) \\ &\leq \Omega(\beta)\lambda. \end{aligned}\tag{2.5}$$

The second equation from the KKT's, which again holds in any case, is

$$\frac{1}{\|\hat{\epsilon}\|_n}\hat{\epsilon}^T X\hat{\beta}/n = \lambda\Omega(\hat{\beta}). \tag{2.6}$$

Now putting (2.5) and (2.6) together we get the result.

■

3. Sharp Oracle Inequalities for the square root regularization estimators

We provide sharp oracle inequalities for the estimator $\hat{\beta}$ with a norm Ω that satisfies a so called weak decomposability condition. An oracle inequality is a bound on the estimation and prediction errors. This shows how good these estimators are in estimating the parameter vector β^0. This is an extension of the sharp oracle results given in van de Geer (2014) for LASSO type of estimators, which in turn was an generalization of the sharp oracle inequalities for the LASSO and nuclear norm penalization in Koltchinskii (2011) and Koltchinskii et al. (2011).

3.1 Concepts and Assumptions

Let us first introduce all the necessary definitions and concepts. Some normed versions of values need to be introduced:

$$\begin{aligned} f &= \frac{\lambda\Omega(\beta^0)}{\|\epsilon\|_n} \\ \lambda^{S^c} &= \frac{\Omega^{S^c *}((\epsilon^T X)_{S^c})}{n\|\epsilon\|_n} \\ \lambda^S &= \frac{\Omega^*((\epsilon^T X)_S)}{n\|\epsilon\|_n} \\ \lambda^m &= \max(\lambda^S, \lambda^{S^c}) \\ \lambda^0 &= \frac{\Omega^*(\epsilon^T X)}{n\|\epsilon\|_n}. \end{aligned}$$

For example the quantity f gives the measure of the true underlying normalized sparsity. Ω^{S^c} denotes a norm on $\mathbb{R}^{p-|S|}$ which will shortly be defined in Assumption II. Furthermore λ^m will take the role of the theoretical (unknown) λ. If we compare this to the case of the LASSO we see that instead of the $\ell_\infty-$norm we generalized it to the dual norm of Ω. Also remark that in λ^m a term $\frac{1}{\|\epsilon\|_n}$ appears. This scaling is due to the square root regularization, which will be the reason that λ can be chosen independently of the unknown standard deviation σ. Now we will give the two main assumptions that need to hold in order to prove the oracle inequalities. Assumption I deals with avoiding overfitting, and the main concern of Assumption II is that the norm has the desired property of promoting a structured sparse solution $\hat{\beta}$. We will later see, that the structured sparsity norms in Micchelli et al. (2010) and Micchelli et al. (2013) are all of this form. Thus, Assumption II is quite general.

3.1.1 Assumption I (overfitting)

If $\|\hat{\epsilon}\|_n = 0$, then $\hat{\beta}$ does the same thing as the Ordinary Least Squares (OLS) estimator β_{OLS}, namely it overfits. That is why we need a lower bound on $\|\hat{\epsilon}\|_n$. In order to achieve this lower bound we make the following assumptions:

$$P\left(Y \in \{\widetilde{Y} : \min_{\beta,\text{s.t.}X\beta=\widetilde{Y}}\Omega(\beta) \leq \|\epsilon\|_n\}\right) = 0.$$

$$\frac{\lambda^0}{\lambda}\big(1+2f\big) < 1.$$

The $\frac{\lambda^0}{\lambda}$ term makes sure that we introduce enough sparsity (no overfitting).

3.1.2 Assumption II (weak decomposability)

Assumption II is fulfilled for a set $S \subset \{1,...,p\}$ and a norm Ω on $\mathbb{R}^p$ if this norm is weakly decomposable, and S is an allowed set for this norm. This was used by van de Geer (2014) and goes back to Bach et al. (2012). It is an assumption on the structure of the sparsity inducing norm. By the triangle inequality we have:

$$\Omega(\beta_{S^c}) \geq \Omega(\beta) - \Omega(\beta_S).$$

But we will also need to lower bound this by another norm evaluated at β_{S^c}. This is motivated by relaxing the following decomposability property of the ℓ_1-norm:

$$\|\beta\|_1 = \|\beta_S\|_1 + \|\beta_{S^c}\|_1, \forall \text{ sets } S \subset 1,...,p \text{ and all } \beta \in \mathbb{R}^p.$$

This decomposability property is used to get oracle inequalities for the LASSO. But we can relax this property, and introduce weakly decomposable norms.

Definition 3 (Weak decomposability) *A norm Ω in $\mathbb{R}^p$ is called weakly decomposable for an index set $S \subset \{1,...,p\}$, if there exists a norm Ω^{S^c} on $\mathbb{R}^{|S^c|}$ such that*

$$\forall\beta \in \mathbb{R}^p \quad \Omega(\beta) \geq \Omega(\beta_S) + \Omega^{S^c}(\beta_{S^c}).$$

Furthermore we call a set S allowed if Ω is a weakly decomposable norm for this set.

Remark 4 *In order to get a good oracle bound, we will choose the norm Ω^{S^c} as large as possible. We will also choose the allowed sets S in such a way to reflect the active set S_0. Otherwise we would of course be able to choose as a trivial example the empty set $S = \varnothing$.*

Now that we have introduced the two main assumptions, we can introduce other definitions and concepts also used in van de Geer (2014).

Definition 5 *For S an allowed set of a weakly decomposable norm Ω, and $L > 0$ a constant, the $\Omega-$eigenvalue is defined as*

$$\delta_\Omega(L,S) := \min\left\{\|X\beta_S - X\beta_{S^c}\|_n : \Omega(\beta_S) = 1, \Omega^{S^c}(\beta_{S^c}) \leq L\right\}.$$

Then the $\Omega-$effective sparsity is defined as

$$\Gamma^2_\Omega(L,S) := \frac{1}{\delta^2_\Omega(L,S)}.$$

The $\Omega-$eigenvalue is the distance between the two sets (van de Geer and Lederer, 2013) $\{X\beta_S : \Omega(\beta_S) = 1\}$ and $\{X\beta_{S^c} : \Omega^{S^c}(\beta_{S^c}) \leq L\}$, see Figure 2. The additional discussion about these definitions will follow after the main theorem. The $\Omega-$eigenvalue generalizes the compatibility constant (van de Geer, 2007).
For the proof of the main theorem we need some small lemmas. For any vector $\beta \in \mathbb{R}^p$ the $(L,S)-$cone condition for a norm Ω is satisfied if $\Omega^{S^c}(\beta_{S^c}) \leq L\Omega(\beta_S)$, with $L > 0$ a constant and S an allowed set.
The proof of Lemma 6 can be found in van de Geer (2014). It shows the connection between the $(L,S)-$cone condition and the $\Omega-$eigenvalue. We bound $\Omega(\beta_S)$ by a multiple of $\|X\beta\|_n$.

Lemma 6 *Let S be an allowed set of a weakly decomposable norm Ω and $L > 0$ a constant. Then we have that the $\Omega-$eigenvalue is of the following form:*

$$\delta_\Omega(L,S) = \min\left\{\frac{\|X\beta\|_n}{\Omega(\beta_S)}, \beta \text{ satisfies the cone condition and } \beta_S \neq 0\right\}.$$

We have $\Omega(\beta_S) \leq \Gamma_\Omega(L,S)\|X\beta\|_n$.

We will also need a lower and an upper bound for $\|\hat\epsilon\|_n$, as already mentioned in Assumption I. The next Lemma 7 gives such bounds.

Lemma 7 *Suppose that Assumption I holds true. Then*

$$1 + f \geq \frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n} \geq \frac{1 - \frac{\lambda^0}{\lambda}(1+2f)}{f+2} > 0.$$

Proof The upper bound is obtained by the definition of the estimator

$$\|Y - X\hat\beta\|_n + \lambda\Omega(\hat\beta) \leq \|Y - X\beta^0\|_n + \lambda\Omega(\beta^0).$$

Therefore we get

$$\|\hat\epsilon\|_n \leq \|\epsilon\|_n + \lambda\Omega(\beta^0).$$

Dividing by $\|\epsilon\|_n$ and by the definition of f we get the desired upper bound. The main idea for the lower bound is to use the triangle inequality

$$\|\hat\epsilon\|_n = \|\epsilon - X(\hat\beta - \beta^0)\|_n \geq \|\epsilon\|_n - \|X(\hat\beta - \beta^0)\|_n,$$

and then upper bound $\|X(\hat\beta - \beta^0)\|_n$. With Lemma 2 we get an upper bound for $\|X(\hat\beta - \beta^0)\|_n$,

$$\begin{aligned}
\|X(\hat\beta - \beta^0)\|_n^2 &\leq \epsilon^T X(\hat\beta - \beta^0)/n + \lambda\|\hat\epsilon\|_n(\Omega(\beta^0) - \Omega(\hat\beta)) \\
&\leq \lambda^0\|\epsilon\|_n\Omega(\hat\beta - \beta^0) + \lambda\|\hat\epsilon\|_n(\Omega(\beta^0) - \Omega(\hat\beta)) \\
&\leq \lambda^0\|\epsilon\|_n(\Omega(\hat\beta) + \Omega(\beta^0)) + \lambda\|\hat\epsilon\|_n(\Omega(\beta^0) - \Omega(\hat\beta)) \\
&\leq \lambda^0\|\epsilon\|_n\Omega(\hat\beta) + \Omega(\beta^0)(\lambda^0\|\epsilon\|_n + \lambda\|\hat\epsilon\|_n).
\end{aligned}$$

In the second line we used the definition of the dual norm, and the Cauchy-Schwartz inequality. Again by the definition of the estimator we have

$$\Omega(\hat\beta) \leq \frac{\|\epsilon\|_n}{\lambda} + \Omega(\beta^0).$$

And we are left with

$$\|X(\hat\beta - \beta^0)\|_n \leq \|\epsilon\|_n\sqrt{\frac{\lambda^0}{\lambda}\left(1 + 2\frac{\lambda\Omega(\beta^0)}{\|\epsilon\|_n} + \frac{\lambda}{\lambda^0}\cdot\frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}\cdot\frac{\lambda\Omega(\beta^0)}{\|\epsilon\|_n}\right)}.$$

By the definition of f we get

$$\begin{aligned}
\|X(\hat\beta - \beta^0)\|_n &\leq \|\epsilon\|_n\sqrt{\frac{\lambda^0}{\lambda}\left(1 + 2f + \frac{\lambda}{\lambda^0}\frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}f\right)}. \\
&= \|\epsilon\|_n\sqrt{\frac{\lambda^0}{\lambda} + 2\frac{\lambda^0}{\lambda}f + \frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}f}.
\end{aligned}$$

Now we get

$$\begin{aligned}
\|\hat\epsilon\|_n &\geq \|\epsilon\|_n - \|X(\hat\beta - \beta^0)\|_n \\
&\geq \|\epsilon\|_n - \|\epsilon\|_n\sqrt{\frac{\lambda^0}{\lambda} + 2\frac{\lambda^0}{\lambda}f + \frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}f}
\end{aligned} \tag{3.1}$$

Let us rearrange equation (3.1) further in the case $\frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n} < 1$

$$\frac{\lambda^0}{\lambda} + 2\frac{\lambda^0}{\lambda}f + \frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}f \geq \left(1 - \frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}\right)^2$$

$$\frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n}f \geq 1 - 2\frac{\|\hat\epsilon\|_n}{\|\epsilon\|_n} + \frac{\|\hat\epsilon\|_n^2}{\|\epsilon\|_n^2} - \frac{\lambda^0}{\lambda}(1+2f)$$

$$\frac{\|\hat{\epsilon}\|_n}{\|\epsilon\|_n} f + 2\frac{\|\hat{\epsilon}\|_n}{\|\epsilon\|_n} \geq 1 - \frac{\lambda^0}{\lambda}(1+2f)$$

$$\frac{\|\hat{\epsilon}\|_n}{\|\epsilon\|_n} \geq \frac{1-\frac{\lambda^0}{\lambda}(1+2f)}{f+2} \overset{\text{Assumption I}}{>} 0.$$

On the other hand if $\frac{\|\hat{\epsilon}\|_n}{\|\epsilon\|_n} > 1$, we already get a lower bound which is bigger than $\frac{1-\frac{\lambda^0}{\lambda}(1+2f)}{f+2}$. ■

3.2 Sharp Oracle Inequality

Finally we are able to present the main theorem. This theorem gives sharp oracle inequalities on the prediction error expressed in the ℓ_2-norm, and the estimation error expressed in the Ω and Ω^{S^c} norms.

Remark 8 *Let us first briefly remark that in the Theorem 9 we need to assure that $\lambda^* - \lambda^m > 0$. The assumption $\frac{\lambda^m}{\lambda} < 1/a$, with a chosen as in Theorem 9, together with the fact that $\lambda^0 \leq \lambda^m$ leads to the desired inequality*

$$\frac{\lambda^*}{\lambda} = \frac{1-\frac{\lambda^0}{\lambda}(1+2f)}{f+2} \geq \frac{1-\frac{\lambda^m}{\lambda}(1+2f)}{f+2} > \frac{\lambda^m}{\lambda}.$$

Theorem 9 *Assume that $0 \leq \delta < 1$, and also that $a\lambda^m < \lambda$, with the constant $a = 3(1+f)$. We invoke also Assumption I (overfitting) and Assumption II (weak decomposability) for S and Ω. Here the allowed set S is chosen such that the active set $S_\beta := \text{supp}(\beta)$ is a subset of S. Then it holds true that*

$$\begin{aligned}
&\|X(\hat{\beta}-\beta^0)\|_n^2 + 2\delta\|\epsilon\|_n \left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta) + (\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right] \\
&\leq \|X(\beta-\beta^0)\|_n^2 + \|\epsilon\|_n^2 \left[(1+\delta)(\tilde{\lambda}+\lambda^m)\right]^2 \Gamma_\Omega^2(L_S, S), \qquad (3.2)
\end{aligned}$$

with $L_S := \frac{\tilde{\lambda}+\lambda^m}{\lambda^*-\lambda^m}\frac{1+\delta}{1-\delta}$ and

$$\lambda^* := \lambda\left(\frac{1-\frac{\lambda^0}{\lambda}(1+2f)}{f+2}\right), \qquad \tilde{\lambda} \quad := \lambda(1+f).$$

Furthermore we get the two oracle inequalities

$$\begin{aligned}
\|X(\hat{\beta}-\beta^0)\|_n^2 &\leq \|X(\beta_\star-\beta^0)\|_n^2 + \|\epsilon\|_n^2(1+\delta)^2(\tilde{\lambda}+\lambda^{S_\star^c})^2 \cdot \Gamma_\Omega^2(L_{S_\star}, S_\star) \\
\Omega(\hat{\beta}_{S_\star}-\beta_\star) + \Omega^{S_\star^c}(\hat{\beta}_{S_\star^c}) &\leq \frac{1}{2\delta\|\epsilon\|_n} \cdot \frac{\|X(\beta_\star-\beta^0)\|_n^2}{\lambda^*-\lambda^m} + ... \\
&\quad + \frac{(1+\delta)^2\|\epsilon\|_n}{2\delta} \cdot \frac{(\tilde{\lambda}+\lambda^m)^2}{\lambda^*-\lambda^m} \cdot \Gamma_\Omega^2(L_{S_\star}, S_\star).
\end{aligned}$$

For all fixed allowed sets S define

$$\beta_\star(S) := \underset{\beta:\ \text{supp}(\beta)\subseteq S}{\arg\min} \left(\|X(\beta-\beta^0)\|_n^2 + \|\epsilon\|_n^2 \left[(1+\delta)(\tilde{\lambda}+\lambda^m)\right]^2 \Gamma_\Omega^2(L_S, S)\right).$$

Then $S_\star$ is defined as

$$S_\star := \underset{S\ \text{allowed}}{\arg\min} \left(\|X(\beta_\star(S)-\beta^0)\|_n^2 + \|\epsilon\|_n^2 \left[(1+\delta)(\tilde{\lambda}+\lambda^m)\right]^2 \Gamma_\Omega^2(L_S, S)\right), \quad (3.3)$$

$$\beta_\star := \beta_\star(S_\star) \quad (3.4)$$

it attains the minimal right hand side of the oracle inequality (3.2). An improtant special case of equation (3.2) is to choose $\beta \equiv \beta^0$ with $S \supseteq S_0$ allowed. The term $\|X(\beta-\beta^0)\|_n^2$ vanishes in this case and only the $\Omega-$effective sparsity term remains for the upper bound. But it is not obvious in which cases and whether $\beta_\star$ leads to a substantially lower bound than β^0.

Proof Let $\beta \in \mathbb{R}^p$ and let S be an allowed set containing the active set of β. We need to distinguish 2 cases. The second case is the more substantial one.
Case 1: Assume that

$$\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n \leq -\delta\|\epsilon\|_n \left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta) + (\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right].$$

Here $\langle u, v\rangle_n := v^T u/n$, for any two vectors $u, v \in \mathbb{R}^n$. In this case we can simply use the following calculations to verify the theorem.

$$\begin{aligned}
&\|X(\hat{\beta}-\beta^0)\|_n^2 - \|X(\beta-\beta^0)\|_n^2 + ... \\
&\quad + 2\delta\|\epsilon\|_n \left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta) + (\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right] \\
&\quad = 2\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n - \|X(\beta-\hat{\beta})\|_n^2 \\
&\quad\quad + 2\delta\|\epsilon\|_n \left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta) + (\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right] \\
&\quad \leq -\|X(\beta-\hat{\beta})\|_n^2 \\
&\quad \leq 0
\end{aligned}$$

Now we can turn to the more important case.
Case 2: Assume that

$$\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n \geq -\delta\|\epsilon\|_n \left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta) + (\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right].$$

We can reformulate Lemma 2 with $Y - X\hat{\beta} = X(\beta^0-\hat{\beta}) + \epsilon$, then we get:

$$\frac{\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n}{\|\hat{\epsilon}\|_n} + \lambda\Omega(\hat{\beta}) \leq \frac{\langle \epsilon, X(\hat{\beta}-\beta)\rangle_n}{\|\hat{\epsilon}\|_n} + \lambda\Omega(\beta).$$

This is equivalent to

$$\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n + \|\hat{\epsilon}\|_n\lambda\Omega(\hat{\beta}) \leq \langle \epsilon, X(\hat{\beta}-\beta)\rangle_n + \|\hat{\epsilon}\|_n\lambda\Omega(\beta). \quad (3.5)$$

By the definition of the dual norm and the generalized Cauchy-Schwartz inequality we have

$$\begin{aligned}\langle \epsilon, X(\hat{\beta}-\beta)\rangle_n &\leq \|\epsilon\|_n \left(\lambda^S \Omega(\hat{\beta}_S-\beta)+\lambda^{S^c}\Omega^{S^c}(\hat{\beta}_{S^c})\right)\\ &\leq \|\epsilon\|_n \left(\lambda^m \Omega(\hat{\beta}_S-\beta)+\lambda^m\Omega^{S^c}(\hat{\beta}_{S^c})\right)\end{aligned}$$

Inserting this inequality into (3.5) we get

$$\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n + \|\hat{\epsilon}\|_n\lambda\Omega(\hat{\beta}) \leq \|\epsilon\|_n \left(\lambda^m\Omega(\hat{\beta}_S-\beta)+\lambda^m\Omega^{S^c}(\hat{\beta}_{S^c})\right) + \|\hat{\epsilon}\|_n\lambda\Omega(\beta). \tag{3.6}$$

Then by the weak decomposability and the triangle inequality in (3.6)

$$\begin{aligned}&\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n + \|\hat{\epsilon}\|_n\lambda\left(\Omega(\hat{\beta}_S)+\Omega^{S^c}(\hat{\beta}_{S^c})\right)\\ &\leq \|\epsilon\|_n \left(\lambda^m\Omega(\hat{\beta}_S-\beta)+\lambda^m\Omega^{S^c}(\hat{\beta}_{S^c})\right) + \|\hat{\epsilon}\|_n\lambda\left(\Omega(\hat{\beta}_S-\beta)+\Omega(\hat{\beta}_S)\right).\end{aligned} \tag{3.7}$$

By inserting the assumption of case 2

$$\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n \geq -\delta\|\epsilon\|_n\left[(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta)+(\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\right],$$

into (3.7) we get

$$\left(\lambda\|\hat{\epsilon}\|_n-\lambda^m\|\epsilon\|_n-\delta\|\epsilon\|_n(\lambda^*-\lambda^m)\right)\Omega^{S^c}(\hat{\beta}_{S^c}) \leq \left(\lambda\|\hat{\epsilon}\|_n+\lambda^m\|\epsilon\|_n+\delta\|\epsilon\|_n(\tilde{\lambda}+\lambda^m)\right)\Omega(\hat{\beta}_S-\beta).$$

By assumption $a\lambda^m < \lambda$ we have that $\lambda^* > \lambda^m$ (see Remark 8) and therefore

$$\Omega^{S^c}(\hat{\beta}_{S^c}) \leq \left(\frac{\tilde{\lambda}+\lambda^m}{\lambda^*-\lambda^m}\right)\cdot\frac{1+\delta}{1-\delta}\cdot\Omega(\hat{\beta}_S-\beta).$$

We have applied Lemma 7 in the last step, in order to replace the estimate $\|\hat{\epsilon}\|_n$ with $\|\epsilon\|_n$. By the definition of L_S we have

$$\Omega^{S^c}(\hat{\beta}_{S^c}) \leq L_S\Omega(\hat{\beta}_S-\beta). \tag{3.8}$$

Therefore with Lemma 6 we get

$$\Omega(\hat{\beta}_S-\beta) \leq \Gamma_\Omega(L_S,S)\|X(\hat{\beta}-\beta)\|_n. \tag{3.9}$$

Inserting (3.9) into (3.7), together with Lemma 7 and $\delta<1$, we get

$$\begin{aligned}&\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n + \delta\|\epsilon\|_n(\lambda^*-\lambda^m)\Omega^{S^c}(\hat{\beta}_{S^c})\\ &\leq (1+\delta-\delta)\|\epsilon\|_n(\lambda\|\hat{\epsilon}\|_n/\|\epsilon\|_n+\lambda^m)\Omega(\hat{\beta}_S-\beta)\\ &\leq (1+\delta)\|\epsilon\|_n(\tilde{\lambda}+\lambda^m)\Gamma_\Omega(L_S,S)\|X(\hat{\beta}-\beta)\|_n - \delta\|\epsilon\|_n(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta)\end{aligned}$$

Because $\forall u,v\in\mathbb{R},\ 0\leq(u-v)^2$ it holds true that $uv \leq 1/2(u^2+v^2)$.

Therefore with $a=(1+\delta)\|\epsilon\|_n(\tilde{\lambda}+\lambda^m)\Gamma_\Omega(L_S,S)$ and $b=\|X(\hat{\beta}-\beta)\|_n$ we have

$$\begin{aligned}&\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n + \delta\|\epsilon\|_n(\lambda^*-\lambda^m)\Omega(\hat{\beta}_{S^c})^{S^c} + \delta\|\epsilon\|_n(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta)\\ &\leq \frac{1}{2}(1+\delta)^2\|\epsilon\|_n^2(\tilde{\lambda}+\lambda^m)^2\Gamma_\Omega^2(L_S,S)+\frac{1}{2}\|X(\hat{\beta}-\beta)\|_n^2.\end{aligned}$$

Since

$$2\langle X(\hat{\beta}-\beta^0), X(\hat{\beta}-\beta)\rangle_n = \|X(\hat{\beta}-\beta^0)\|_n^2 - \|X(\beta-\beta^0)\|_n^2 + \|X(\hat{\beta}-\beta)\|_n^2,$$

we get

$$\begin{aligned}&\|X(\hat{\beta}-\beta^0)\|_n^2 + 2\delta\|\epsilon\|_n\left((\lambda^*-\lambda^m)\Omega(\hat{\beta}_{S^c})^{S^c}+(\lambda^*+\lambda^m)\Omega(\hat{\beta}_S-\beta)\right)\\ &\leq (1+\delta)^2\|\epsilon\|_n^2(\tilde{\lambda}+\lambda^m)^2\Gamma_\Omega^2(L_S,S)+\|X(\beta-\beta^0)\|_n^2.\end{aligned} \tag{3.10}$$

This gives the sharp oracle inequality. The two oracle inequalities mentioned are just a split up version of inequality (3.10), where for the second oracle inequality we need to see that $\lambda^*-\lambda^m \leq \lambda^*+\lambda^m$. ■

Remark that the sharpness in the oracle inequality of Theorem 9 is the constant one in front of the term $\|X(\beta-\beta^0)\|_n^2$. Because we measure a vector on $S_\star$ by Ω and on the inactive set $S_\star^c$ by the norm $\Omega^{S_\star^c}$, we take here $\Omega(\hat{\beta}_{S_\star}-\beta_\star)$ and $\Omega^{S_\star^c}(\hat{\beta}_{S_\star^c})$ as estimation errors.
If we choose λ of the same order as λ^m (i.e. $a\lambda=\lambda^m$, with $a>0$ a constant), then we can simplify the oracle inequalities. This is comparable to the oracle inequalities for the LASSO, see for example Bickel et al. (2009), Bunea et al. (2006), Bunea et al. (2007), van de Geer (2007) and further references can be found in Bühlmann and van de Geer (2011).

Corollary 10 *Take λ of the order of λ^m (i.e. $\lambda^m = C\lambda$, with $0<C<\frac{1}{3(f+1)}$ a constant). Invoke the same assumptions as in Theorem 9. Here we also use the same notation of an optimal $\beta_\star$ with $S_\star$ as in equation* (3.3) *and* (3.4)*. Then we have*

$$\begin{aligned}\|X(\hat{\beta}-\beta^0)\|_n^2 &\leq \|X(\beta_\star-\beta^0)\|_n^2 + C_1\lambda^2\cdot\Gamma_\Omega^2(L_{S_\star},S_\star)\\ \Omega(\hat{\beta}_{S_\star}-\beta_\star)+\Omega^{S_\star^c}(\hat{\beta}_{S_\star^c}) &\leq C_2\left(\frac{\|X(\beta_\star-\beta^0)\|_n^2}{\lambda}+C_1\lambda\cdot\Gamma_\Omega^2(L_{S_\star},S_\star)\right).\end{aligned}$$

Here C_1 and C_2 are the constants:

$$C_1 := (1+\delta)^2\cdot\|\epsilon\|_n^2(f+C+1)^2, \tag{3.11}$$

$$C_2 := \frac{1}{2\delta\|\epsilon\|_n}\cdot\frac{1}{\sqrt{1-2C(1+2f)}-C}. \tag{3.12}$$

First let us explain some of the parts of Theorem 9 in more detail. We can also study what happens to the bound if we additionally assume Gaussian errors, see Proposition 11.

3.3 On the two parts of the oracle bound

The oracle bound is a trade-off between two parts, which we will discuss now. Let us first remember that if we set $\beta \equiv \beta^0$ in the sharp oracle bound, only the term with the $\Omega-$effective sparsity will not vanish on the right hand side of the bound. But due to the minimization over β in the definition of $\beta_\star$ we might even do better than that bound.
The first part consisting of minimizing $\|X(\beta - \beta^0)\|_n^2$ can be thought of the error made due to approximation, hence we call it the approximation error. If we fix the support S, which can be thought of being determined by the second part, then minimizing $\|X(\beta - \beta^0)\|_n^2$ is just a projection onto the subspace spanned by S, see Figure 1. So if S has a similar structure than the true unknown support S_0 of β^0, this will be small.

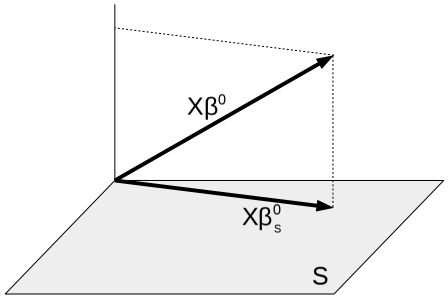

Figure 1: approximation error

The second part containing $\Gamma_\Omega^2(L_S, S)$ is due to estimation errors. There, minimizing over β will affect the set S. We have already mentioned that. It is one over the squared distance between the two sets $\{X\beta_S : \Omega(\beta_S) = 1\}$ and $\{X\beta_{S^c} : \Omega^{S^c}(\beta_{S^c}) \leq L\}$. Figure 2 shows this distance. This means that if the vectors in X_S and X_{S^c} show a high correlation the distance will shrink and the $\Omega-$effective sparsity will blow up, which we try to avoid. This distance depends also on the two chosen sparsity norms Ω and Ω^{S^c}. It is crucial to choose norms that reflect the true underlying sparsity in order to get a good bound. Also the constant L_S should be small.

3.4 On the randomness of the oracle bound

Until now, the bound still contains some random parts, for example in λ^m. In order to get rid of that random part we need to introduce the following sets

$$\mathcal{T} := \left\{ \max\left(\frac{\Omega^*((\epsilon^T X)_W)}{n\|\epsilon\|_n}, \frac{\Omega^{W^c*}((\epsilon^T X)_{W^c})}{n\|\epsilon\|_n} \right) \leq d \right\}, \text{ where } d \in \mathbb{R}, \text{ and any allowed set } W.$$

We need to choose the constant d in such a way, that we have a high probability for this set. In other words we try to bound the random part by a non random constant with a

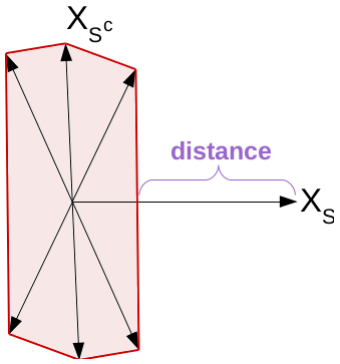

Figure 2: The Ω-eigenvalue

very high probability. In order to do this we need some assumptions on the errors. Here we assume Gaussian errors. Let us also remark that $\frac{\Omega^*((\epsilon^T X)_W)}{n\|\epsilon\|_n}$ is normalized by $\|\epsilon\|_n$. This normalization occurs due to the special form of the Karush-Kuhn-Tucker conditions. Thus the square root of the residual sum of squared errors is responsible for this normalization. In fact, this normalization is the main reason why λ does not contain the unknown variance. So the square root part of the estimator makes the estimator pivotal. Now in the case of Gaussian errors, we can use the concentration inequality from Theorem 5.8 in Boucheron et al. (2013) and get the following proposition. Define first:

$$\begin{array}{lllll} Z_1 := & \frac{\Omega^*((\epsilon^T X)_W)}{n\|\epsilon\|_n} & V_1 := & Z_1\|\epsilon\|_n/\sigma \\ Z_2 := & \frac{\Omega^{W^c*}((\epsilon^T X)_{W^c})}{n\|\epsilon\|_n} & V_2 := & Z_2\|\epsilon\|_n/\sigma \\ Z := & \max(Z_1, Z_2) & V := & \max(V_1, V_2) \end{array}$$

Proposition 11 *Suppose that we have i.i.d. Gaussian errors $\epsilon \sim \mathcal{N}(0, \sigma^2 I)$, and that the following normalization $(X^T X/n)_{i,i} = 1, \forall i \in \{1, ..., p\}$ holds true. Let $B := \{z \in \mathbb{R}^p : \Omega(z) \leq 1\}$ be the unit $\Omega-$ball, and $B_2 := \sup_{b \in B} b^T b$ an $\Omega-$ball and ℓ_2-ball comparison. Then we have for all $d > \mathrm{E}V$ and $\Delta > 1$*

$$\mathrm{P}(\mathcal{T}) \geq 1 - 2e^{-\frac{(d - \mathrm{E}V)^2 \Delta^2}{2B_2/n}} - 2e^{-\frac{n}{4}(1-\Delta^2)^2}.$$

Proof Let us define $\Sigma^2 := \sup_{b\in B} \mathrm{E}\left(\frac{(\epsilon^T X)_W b}{n\sigma}\right)^2$ and calculate it

$$\begin{aligned}
\Sigma^2 &= \sup_{b\in B} \mathrm{Var}\left(\frac{(\epsilon^T X)_W b}{n\sigma}\right) \\
&= \sup_{b\in B} \mathrm{Var}\left(\sum_{w\in W}\sum_{i=1}^{n} \frac{\epsilon_i}{n} X_{wi} b_w\right) \frac{1}{\sigma^2} \\
&= \sup_{b\in B} \left(\sum_{w\in W} b_w^2 \sum_{i=1}^{n} X_{wi}^2 \,\mathrm{Var}\left(\frac{\epsilon_i}{n}\right)\right) \frac{1}{\sigma^2} \\
&= \sup_{b\in B} b_W^T \cdot b_W / n \sum_{i=1}^{n} X_{wi}^2 / n \\
&= \sup_{b\in B} b_W^T \cdot b_W / n \le B_2/n. \qquad (3.13)
\end{aligned}$$

These calculations hold true as well for W^c instead of W. Furthermore in the subsequent inequalities we can subsitute W with W^c and use Z_2, V_2 instead of Z_1, V_1 to get an analogous result. We have $\frac{(\epsilon^T X)_W b}{\sigma n} \sim \mathcal{N}(0, b_W^2/n)$. This is an almost surely continuous centred Gaussian process. Therefore we can apply Theorem 5.8 from Boucheron et al. (2013)

$$\mathrm{P}(V_1 - \mathrm{E}\, V_1 \ge c) \le e^{-\frac{c^2}{2B_2/n}}. \qquad (3.14)$$

Now to get to a probability inequality for Z_1 we use the following calculations

$$\begin{aligned}
\mathrm{P}\left(Z_1 - \mathrm{E}\, V_1 \ge d\right) &\le \mathrm{P}\left(\frac{V_1\sigma}{\|\epsilon\|_n} - \mathrm{E}\, V_1 \ge d \wedge \|\epsilon\|_n > \sigma\Delta\right) + \mathrm{P}(\|\epsilon\|_n \le \sigma\Delta) \\
&\le \mathrm{P}\left(V_1 - \mathrm{E}\, V_1 \Delta > d\Delta\right) + \mathrm{P}(\|\epsilon\|_n \le \sigma\Delta) \\
&\le \mathrm{P}\left(V_1 - \mathrm{E}\, V_1 > d\Delta\right) + \mathrm{P}(\|\epsilon\|_n \le \sigma\Delta) \\
&\le e^{-\frac{d^2\Delta^2}{2B_2/n}} + \mathrm{P}(\|\epsilon\|_n \le \sigma\Delta). \qquad (3.15)
\end{aligned}$$

The calculations above use the union bound and that a bigger set containing another set has a bigger probability. Furthermore we have applied equations (3.13) and (3.14). Now we are left to give a bound on $\mathrm{P}(\|\epsilon\|_n/\sigma \le \Delta)$. For this we use the corollary to Lemma 1 from Laurent and Massart (2000) together with the fact that $\|\epsilon\|_n/\sigma = \sqrt{R/n}$ with $R = \sum_{i=1}^n (\epsilon_i/\sigma)^2 \sim \chi^2(n)$. We obtain

$$\begin{aligned}
\mathrm{P}\left(R \le n - 2\sqrt{nx}\right) &\le \exp(-x) \\
\mathrm{P}\left(\sqrt{\frac{R}{n}} \le \sqrt{1 - 2\sqrt{\frac{x}{n}}}\right) &\le \exp(-x) \\
\mathrm{P}\left(\frac{\|\epsilon\|_n}{\sigma} \le \Delta\right) &\le e^{-\frac{n}{4}(1-\Delta^2)^2}. \qquad (3.16)
\end{aligned}$$

Combining equations (3.15) and (3.16) finishes the proof:

$$\begin{aligned}
\mathrm{P}(\mathcal{T}) &= \mathrm{P}(\max(Z_1, Z_2) \le d) \\
&= \mathrm{P}(Z_1 \le d \cap Z_2 \le d) \\
&\ge \mathrm{P}(Z_1 \le d) + \mathrm{P}(Z_2 \le d) - 1 \\
&\ge 1 - \mathrm{P}(Z_1 \ge d) - \mathrm{P}(Z_2 \ge d) \\
&\ge 1 - 2e^{-\frac{(d-\mathrm{E}\, V)^2\Delta^2}{2B_2/n}} - 2e^{-\frac{n}{4}(1-\Delta^2)^2}.
\end{aligned}$$

■

So the probability that the event $\mathcal{T}$ does not occur decays exponentially. This is what we mean by having a very high probability. Therefore we can take $d = t \cdot \sqrt{\frac{\frac{2}{n}B_2}{\Delta^2}} + \mathrm{E}\,[V]$ with $\Delta^2 = 1 - t\frac{2}{\sqrt{n}}$, where $t = \sqrt{\log\left(\frac{4}{\alpha}\right)}$ and $2e^{-n/2} < \alpha$ to ensure $\Delta^2 > 0$. With this we get

$$\mathrm{P}(\mathcal{T}) \ge 1 - \alpha. \qquad (3.17)$$

First remark that the term $\frac{\epsilon^T}{\sigma}$ is now of the right scaling, because $\epsilon_i/\sigma \sim \mathcal{N}(0,1)$. This is the whole point of the square root regularization.
Here B_2 can be thought of comparing the $\Omega-$ball in direction W to the ℓ_2-ball in direction W, because if the norm Ω is the ℓ_2-norm, then $B_2 = 1$. Moreover, for every norm there exists a constant D such that for all β it holds

$$\|\beta\|_2 \le D\Omega(\beta).$$

Therefore the B_2 of Ω satisfies

$$B_2 \le D^2 \sup_{b\in B} \Omega(b_W)^2 \le D^2.$$

Thus we can take

$$\boxed{d = t \cdot \frac{D}{\Delta}\sqrt{\frac{2}{n}} + \mathrm{E}\,[V]}$$

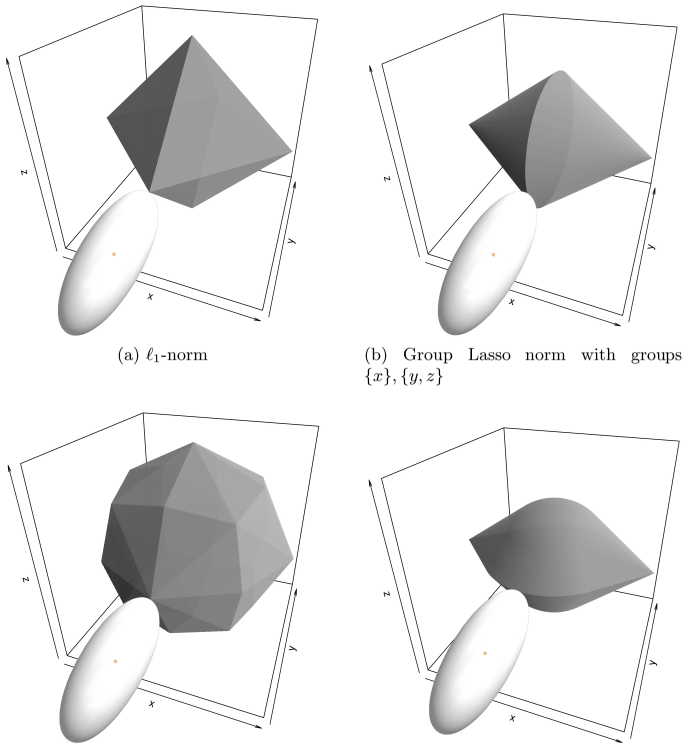
$$\boxed{\Delta^2 = 1 - t\sqrt{\frac{2}{n}},\ \text{with } t = \sqrt{\log\left(\frac{4}{\alpha}\right)}}.$$

What is left to be determined is $\mathrm{E}\,[V]$. In many cases we can use a adjusted version of the main theorem in Maurer and Pontil (2012) for Gaussian complexities to obtain this expectation. All the examples below can be calculated in this way. So, in the case of Gaussian errors, we have the following new version of Corollary 10.

Corollary 12 *Take $\lambda = t/\Delta \cdot D\sqrt{\frac{2}{n}} + \mathrm{E}\,[V]$, where t, δ, V and D are defined as above. Invoke the same assumptions as in Theorem 9 and additionally assume Gaussian errors. Use the*

notation from Corollary 10. Then with probability $1-\alpha$ *the following oracle inequalities hold true*

$$\|X(\hat{\beta}-\beta^0)\|_n^2 \leq \|X(\beta_\star-\beta^0)\|_n^2 + C_1\lambda^2\cdot\Gamma_\Omega^2(L_{S_\star},S_\star)$$
$$\Omega(\hat{\beta}_{S_\star}-\beta_\star)+\Omega^{S_\star^c}(\hat{\beta}_{S_\star^c}) \leq C_2\left(\frac{\|X(\beta_\star-\beta^0)\|_n^2}{\lambda}+C_1\lambda\cdot\Gamma_\Omega^2(L_{S_\star},S_\star)\right).$$



Now we still have a $\|\epsilon\|_n^2$ term in the constants (3.11), (3.12) of the oracle inequality. In order to handle this we need Lemma 1 from Laurent and Massart (2000). Which translates in our case to the probability inequality

$$\mathrm{P}\left(\|\epsilon\|_n^2 \leq \sigma^2\left(1+2x+2x^2\right)\right) \geq 1-\exp\left(-n\cdot x^2\right).$$

Here $x>0$ is a constant. Therefore we have that $\|\epsilon\|_n^2$ is of the order of σ^2 with exponentially decaying probability in n. We could also write this in the following form

$$\mathrm{P}\left(\|\epsilon\|_n^2 \leq \sigma^2\cdot C\right) \geq 1-\exp\left(-\frac{n}{2}\left(C-\sqrt{2C-1}\right)\right).$$

Here we can choose any constant $C>1$ big enough and take the bound $\sigma^2\cdot C$ for $\|\epsilon\|_n^2$ in the oracle inequality. A similar bounds can be found in Laurent and Massart (2000) for $1/\|\epsilon\|_n^2$. This takes care of the random part in the sharp oracle bound with the Gaussian errors.

(a) ℓ_1-norm

(b) Group Lasso norm with groups $\{x\},\{y,z\}$

(c) sorted ℓ_1-norm with a λ sequence $1>0.5>0.3$

(d) wedge norm

Figure 3: Pictorial description of how the estimator $\hat{\beta}$ works, with unit balls of different sparsity inducing norms.

4. Examples

Here we will give some examples of estimators where our sharp oracle inequalities hold. Figure 3 shows the unit balls of some sparsity inducing norms that we will use as examples. In order to give the theoretical λ for these examples we will again assume Gaussian errors. Theorem 9 still holds for all the examples even for non Gaussian errors. Some of the examples will introduce new estimators inspired by methods similar to the square root LASSO.

4.1 Square Root LASSO

First we examine the square root LASSO,

$$\hat{\beta}_{srL} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda \|\beta\|_1 \right\}.$$

Here we use the ℓ_1-norm as a sparsity measure. We know that the ℓ_1-norm has the nice property to be able to set certain unimportant parameters individually to zero. As already mentioned the ℓ_1-norm has the following decomposability property for any set S

$$\|\beta\|_1 = \|\beta_S\|_1 + \|\beta_{S^c}\|_1, \forall \beta \in \mathbb{R}^p.$$

Therefore we also have weak decomposability for all subsets $S \subset \{1, ..., p\}$ with Ω^{S^c} being the ℓ_1-norm again. Thus Assumption II is fulfilled for all sets S and so we are able to apply Theorem 9.
Furthermore for the square root LASSO we have that $D = 1$. This is because the ℓ_2-norm is bounded by the ℓ_1-norm without any constant. So in order to get the value of λ we need to calculate the expectation of the dual norm of $\frac{\epsilon^T X}{\sigma n}$. The dual norm of ℓ_1 is the $\ell_\infty-$norm. By Maurer and Pontil (2012), we also have

$$\max\left(\mathrm{E}\left[\frac{\left\| (\epsilon^T X)_{S_\star^c} \right\|_\infty}{n\sigma} \right], \mathrm{E}\left[\frac{\left\| (\epsilon^T X)_{S_\star} \right\|_\infty}{n\sigma} \right] \right) \leq \sqrt{\frac{2}{n}} \left(2 + \sqrt{\log(|p|)} \right).$$

Therefore the theoretical λ for the square root LASSO can be chosen as

$$\boxed{\lambda = \sqrt{\frac{2}{n}} \left(t/\Delta + 2 + \sqrt{\log(|p|)} \right).}$$

Even though this theoretical λ is very close to being optimal, it is not optimal, see for example van de Geer (2016). In the special case of the ℓ_1-norm penalization, we can simplify Corollary 12:

Corollary 13 (Square Root LASSO) *Take* $\lambda = \sqrt{\frac{2}{n}} \left(t/\Delta + 2 + \sqrt{\log(|p|)} \right)$, *where* $t > 0$ *and* $\Delta > 1$ *are chosen as in* (3.17). *Invoke the same assumptions as in Corollary 12. Then for* $\Omega(\cdot) = \|\cdot\|_1$, *we have with probability* $1 - \alpha$ *that the following oracle inequalities hold true:*

$$\|X(\hat{\beta}_{srL} - \beta^0)\|_n^2 \leq \|X(\beta_\star - \beta^0)\|_n^2 + C_1 \lambda^2 \cdot \Gamma_\Omega^2(L_{S_\star}, S_\star)$$
$$\|\hat{\beta}_{srL} - \beta_\star\|_1 \leq C_2 \left(\frac{\|X(\beta_\star - \beta^0)\|_n^2}{\lambda} + C_1 \lambda \cdot \Gamma_\Omega^2(L_{S_\star}, S_\star) \right).$$

Remark that in Corollary 13 we have an oracle inequality for the estimation error $\|\hat{\beta}_{srL} - \beta_\star\|_1$ in ℓ_1. This is due to the decomposability of the ℓ_1-norm. In other examples we will have the sum of two norms.

4.2 Group Square Root LASSO

In order to set groups of variables simultaneously to zero, and not only individual variables, we will look at a different sparsity inducing norm. Namely a ℓ_1-type norm for grouped variables, called the group LASSO norm. The group square root LASSO was introduced by Bunea et al. (2014) as

$$\hat{\beta}_{gsrL} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda \sum_{j=1}^{g} \sqrt{|G_j|} \|\beta_{G_j}\|_2 \right\}.$$

Here g is the total number of groups, and G_j is the set of variables that are in the jth group. Of course the ℓ_1-norm is a special case of the group LASSO norm, when $G_j = \{j\}$ and $g = p$.
The group LASSO penalty is also weakly decomposable with $\Omega^{S^c} = \Omega$, for any $S = \bigcup_{j \in \mathcal{J}} G_j$, with any $\mathcal{J} \subset \{1, ..., g\}$. So here the sparsity structure of the group LASSO norm induces the sets S to be of the same sparsity structure in order to fulfil Assumption II. Therefore the Theorem 9 can also be applied in this case.
How do we need to choose the theoretical λ? For the group LASSO norm we have $B_2 \leq 1$. One can see this due to the fact that $\sqrt{a_1} + ... + \sqrt{a_g} \geq \sqrt{a_1 + ... + a_g}$ for g positive constants. And also $|G_j| \geq 1$ for all groups. Therefore

$$\sum_{j=1}^{g} \sqrt{|G_j|} \|\beta_{G_j}\|_2 \geq \sqrt{\sum_{i=1}^{p} \beta_i^2}.$$

Remark that the dual norm is $\Omega^*(\beta) = \max_{1 \leq j \leq g} \|\beta_{G_j}\|_2 / \sqrt{|G_j|}$. With Maurer and Pontil (2012) we have

$$\max\left(\mathrm{E}\left[\frac{\Omega^*\left((\epsilon^T X)_{S_\star^c} \right)}{n\sigma} \right], \mathrm{E}\left[\frac{\Omega^*\left((\epsilon^T X)_{S_\star} \right)}{n\sigma} \right] \right) \leq \sqrt{\frac{2}{n}} \left(2 + \sqrt{\log(g)} \right).$$

That is why λ can be taken of the following form

$$\boxed{\lambda = \sqrt{\frac{2}{n}} \left(t/\Delta + 2 + \sqrt{\log(g)} \right).}$$

And we get a similar corollary for the group square root LASSO like the Corollary 13 for the square root LASSO. In the case of the group LASSO, there are better results for the theoretical penalty level available, see for example Theorem 8.1 in Bühlmann and van de Geer (2011). This takes the minimal group size into account.

4.3 Square Root SLOPE

Here we introduce a new method called the square root SLOPE estimator, which is also part of the square root regularization family. Let us thus take a look at the sorted ℓ_1 norm with some decreasing sequence $\lambda_1 \geq \lambda_2 \geq ... \geq \lambda_p > 0$,

$$J_\lambda(\beta) := \lambda_1 |\beta|_{(1)} + ... + \lambda_p |\beta|_{(p)}.$$

This was shown to be a norm by Zeng and Figueiredo (2014).
Let π be a permutation of $\{1,\dots,p\}$. The identity permutation is denoted by id. In order to show weak decomposability for the norm J_λ we need the following lemmas.

Lemma 14 (Rearrangement Inequality) *Let $\beta_1 \geq \cdots \geq \beta_p$ be a decreasing sequence of non-negative numbers. The sum $\sum_{i=1}^p \lambda_i \beta_{\pi(i)}$ is maximized over all permutations π at $\pi = id$.*

Proof. The result is obvious when $p = 2$. Suppose now that it is true for sequences of length $p-1$. We then prove it for sequences of length p as follows. Let π be an arbitrary permutation with $j := \pi(p)$. Then

$$\sum_{i=1}^{p} \lambda_i \beta_{\pi(i)} = \sum_{i=1}^{p-1} \lambda_i \beta_{\pi(i)} + \lambda_p \beta_j.$$

By induction

$$\begin{aligned}\sum_{i=1}^{p-1} \lambda_i \beta_{\pi(i)} &\leq \sum_{i=1}^{j-1} \lambda_i \beta_i + \sum_{i=j+1}^{p} \lambda_{i-1} \beta_i \\ &= \sum_{i \neq j} \lambda_i \beta_i + \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i) \beta_i \\ &= \sum_{i=1}^{p} \lambda_i \beta_i + \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i) \beta_i - \lambda_j \beta_j.\end{aligned}$$

Hence we have

$$\begin{aligned}\sum_{i=1}^{p} \lambda_i \beta_{\pi(i)} &\leq \sum_{i=1}^{p} \lambda_i \beta_i + \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i) \beta_i + (\lambda_j - \lambda_p) \beta_j \\ &= \sum_{i=1}^{p} \lambda_i \beta_i + \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i) \beta_i - \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i) \beta_j \\ &= \sum_{i=1}^{p} \lambda_i \beta_i + \sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i)(\beta_i - \beta_j).\end{aligned}$$

Since $\lambda_{i-1} \geq \lambda_i$ for all $1 \leq i \leq p$ (defining $\lambda_0 = 0$) and $\beta_i \leq \beta_j$ for all $i > j$ we know that

$$\sum_{i=j+1}^{p} (\lambda_{i-1} - \lambda_i)(\beta_i - \beta_j) \leq 0.$$

□

Lemma 15 *Let*

$$\Omega(\beta) = \sum_{i=1}^{p} \lambda_i |\beta|_{(i)},$$

and

$$\Omega^{S^c}(\beta_{S^c}) = \sum_{l=1}^{r} \lambda_{p-r+l} |\beta|_{(l,S^c)},$$

where $r = p - s$ and $|\beta|_{(1,S^c)} \geq \cdots \geq |\beta|_{(r,S^c)}$ is the ordered sequence in β_{S^c}. Then $\Omega(\beta) \geq \Omega(\beta_S) + \Omega^{S^c}(\beta_{S^c})$. Moreover Ω^{S^c} is the strongest norm among all $\underline{\Omega}^{S^c}$ for which $\Omega(\beta) \geq \Omega(\beta_S) + \underline{\Omega}^{S^c}(\beta_{S^c})$

Proof. Without loss of generality assume $\beta_1 \geq \cdots \geq \beta_p \geq 0$. We have

$$\Omega(\beta_S) + \Omega^{S^c}(\beta_{S^c}) = \sum_{i=1}^{p} \lambda_i \beta_{\pi(i)}$$

for a suitable permutation π. It follows that

$$\Omega(\beta_S) + \Omega^{S^c}(\beta_{S^c}) \leq \Omega(\beta).$$

To show Ω^{S^c} is the strongest norm it is clear we need only to search among candidates of the form

$$\underline{\Omega}^{S^c}(\beta_{S^c}) = \sum_{l=1}^{r} \underline{\lambda}_{p-r+l} \beta_{\pi^{S^c}(l)}$$

where $\{\underline{\lambda}_{p-r+l}\}$ is a decreasing positive sequence and where $\pi^{S^c}(1),\dots,\pi^{S^c}(r)$ is a permutation of indices in S^c.
This is then maximized by ordering the indices in S^c in decreasing order. But then it follows that the largest norm is obtained by taking $\underline{\lambda}_{p-r+l} = \lambda_{p-r+l}$ for all $l = 1,\dots,r$. □
The SLOPE was introduced by Bogdan et al. (2015) in order to better control the false discovery rate, and is defined as:

$$\hat{\beta}_{SLOPE} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n^2 + \lambda J_\lambda(\beta) \right\}.$$

Now we are able to look at the square root SLOPE, which is the estimator of the form:

$$\hat{\beta}_{srSLOPE} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda J_\lambda(\beta) \right\}.$$

The square root SLOPE replaces the squared ℓ_2-norm with a ℓ_2-norm. With Theorem 9 we have provided a sharp oracle inequality for this new estimator, the square root SLOPE. For the SLOPE penalty we have $B_2 \leq \frac{1}{\lambda_p}$, if $\lambda_p > 0$. This is because

$$\begin{aligned}\frac{J_\lambda(\beta)}{\lambda_p} &= \frac{\lambda_1}{\lambda_p} |\beta|_{(1)} + \ldots + \frac{\lambda_p}{\lambda_p} |\beta|_{(p)} \\ &\geq \sum_{i=1}^{p} |\beta_i| = \|\beta\|_1 \\ &\geq \|\beta\|_2.\end{aligned}$$

So the bound gets scaled by the smallest λ. The dual norm of the SLOPE is by Lemma 1 of Zeng and Figueiredo (2015)

$$J_{\lambda}^{*}(\beta) = \max_{k=1,...,p} \left\{ \left(\sum_{j=1}^{k} \lambda_j \right)^{-1} \cdot \|\beta^{(k)}\|_1 \right\},$$

Here $\beta^{(k)} := (\beta_{(1)}, ..., \beta_{(k)})^T$ is the vector which contains the k largest elements of β. Again by Maurer and Pontil (2012) we have

$$\max \left(\mathrm{E} \left[\frac{J_{\lambda}^{*}\left((\epsilon^T X)_{S_\star}\right)}{n\sigma} \right], \left[\frac{J_{\lambda}^{S_\star^c *}\left((\epsilon^T X)_{S_\star^c}\right)}{n\sigma} \right] \right) \leq \sqrt{\frac{2}{n}} \left(\frac{2\sqrt{2}+1}{\sqrt{2}} + \sqrt{\log(|R^2|)} \right).$$

Here we denote by $R^2 := \sum_i \frac{1}{\lambda_i^2}$. Therefore we can choose λ as

$$\boxed{\lambda = \sqrt{\frac{2}{n}} \left(\frac{t}{\lambda_p \Delta} + \frac{2\sqrt{2}+1}{\sqrt{2}} + \sqrt{\log(|R^2|)} \right).}$$

Let us remark that the asymptotic minimaxity of SLOPE can be found in Su and Candès (2016).

4.4 Sparse Group Square Root LASSO

The sparse group square root LASSO can be defined similarly to the sparse group LASSO, see Simon et al. (2013). This new method is defined as:

$$\hat{\beta}_{srSGLASSO} := \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda \|\beta\|_1 + \eta \sum_{t=1}^{T} \|\beta_{I_t}\|_2 \sqrt{|G_t|} \right\},$$

where we have a partition as follows, $G_t \subset \{1, ..., p\}\ \forall t \in 1, ..., T$, $\bigcup_{t=1}^{T} G_t = \{1, ..., p\}$ and $G_i \cap G_j = \varnothing\ \forall i \neq j$. This penalty is again a norm and it not only chooses sparse groups by the group LASSO penalty, but also sparsity inside of the groups with the ℓ_1-norm. Define $R(\beta) := \lambda \|\beta\|_1 + \eta \sum_{t=1}^{T} \|\beta_{I_t}\|_2 \sqrt{|G_t|}$ and $R^{S^c}(\beta) := \lambda \|\beta\|_1$. Then we have weak decomposability for any set S

$$R(\beta_S) + R^{S^c}(\beta_{S^c}) \leq R(\beta).$$

This is due to the weak decomposability property of the ℓ_1-norm and $\|\beta_S\|_2 = \sqrt{\sum_{j \in S} \beta_j^2} \leq \sqrt{\sum_{j \in S} \beta_j^2 + \sum_{j \in S^c} \beta_j^2} = \|\beta\|_2$. Now in order to get the theoretical λ let us note that if we sum two norms, it is again a norm. Then the dual of this added norm is, because of the supremum taken over the unit ball, smaller than dual norm of each one of the two norms individually. So we can invoke the same theoretical λ as with the square root LASSO

$$\boxed{\lambda = \sqrt{\frac{2}{n}} \left(t/\Delta + 2 + \sqrt{\log(|p|)} \right).}$$

And also the theoretical η like the group square root LASSO

$$\boxed{\eta = \sqrt{\frac{2}{n}} \left(t/\Delta + 2 + \sqrt{\log(g)} \right).}$$

But of course we will not get the same Corollary, because the $\Omega-$effective sparsity will be different.

4.5 Structured Sparsity

Here we will look at the very general concept of structured sparsity norms. Let $\mathcal{A} \subset [0, \infty)^p$ be a convex cone such that $\mathcal{A} \cap (0, \infty)^p \neq \varnothing$. Then

$$\Omega(\beta) = \Omega(\beta; \mathcal{A}) := \min_{a \in \mathcal{A}} \frac{1}{2} \sum_{j=1}^{p} \left(\frac{\beta_j^2}{a_j} + a_j \right),$$

is a norm by Micchelli et al. (2010). Some special cases are for example the ℓ_1-norm or the wedge or box norm. Define

$$\mathcal{A}_S := \{a_S : a \in \mathcal{A}\}.$$

Then van de Geer (2014) also showed that for any $\mathcal{A}_S \subset \mathcal{A}$ we have that the set S is allowed and we have weak decomposability for the norm $\Omega(\beta)$ with $\Omega^{S^c}(\beta_{S^c}) := \Omega(\beta_{S^c}, \mathcal{A}_{S^c})$. Hence the estimator

$$\hat{\beta}_s = \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|Y - X\beta\|_n + \lambda \min_{a \in \mathcal{A}} \frac{1}{2} \sum_{j=1}^{p} \left(\frac{\beta_j^2}{a_j} + a_j \right) \right\},$$

has also the sharp oracle inequality. The dual norm is given by

$$\Omega^{*}(\omega; \mathcal{A}) = \max_{a \in \mathcal{A}(1)} \sqrt{\sum_{j=1}^{p} a_j \omega_j^2}, \quad \omega \in \mathbb{R}^p,$$

$$\Omega^{S^c *}(\omega; \mathcal{A}_{S^c}) = \max_{a \in \mathcal{A}_{S^c}(1)} \sqrt{\sum_{j=1}^{p} a_j \omega_j^2},\ \omega \in \mathbb{R}^p.$$

Here $\mathcal{A}_{S^c}(1) := \{a \in \mathcal{A}_{S^c} : \|a\|_1 = 1\}$ and $\mathcal{A}(1) := \{a \in \mathcal{A} : \|a\|_1 = 1\}$. Then once again by Maurer and Pontil (2012) we have

$$\max \left(\mathrm{E} \left[\frac{\Omega^{*}\left((\epsilon^T X)_{S_\star}; \mathcal{A}_{S_\star}\right)}{n\sigma} \right], \mathrm{E} \left[\frac{\Omega^{*}\left((\epsilon^T X)_{S_\star^c}; \mathcal{A}_{S_\star^c}\right)}{n\sigma} \right] \right) \leq \sqrt{\frac{2}{n}} \widetilde{\mathcal{A}}_{S_\star} \left(2 + \sqrt{\log(|\,\mathrm{E}(\mathcal{A})|)} \right).$$

Here $\mathrm{E}(\mathcal{A})$ are the extreme points of the closure of the set $\left\{ \frac{a}{\|a\|_1} : a \in \mathcal{A} \right\}$. With the definition $\widetilde{\mathcal{A}}_{S_\star} := \max \left(\sqrt{\sum_{i=1}^{n} \Omega(X_{i,S_\star}; \mathcal{A}_{S_\star})}, \sqrt{\sum_{i=1}^{n} \Omega(X_{i,S_\star^c}; \mathcal{A}_{S_\star^c})} \right)$. That is why λ can be taken of the following form

$$\boxed{\lambda = \sqrt{\frac{2}{n}} \left(tD/\Delta + \widetilde{\mathcal{A}}_{S_\star} \left(2 + \sqrt{\log(|\,\mathrm{E}(\mathcal{A})|)} \right) \right).}$$

Since we do not know $S_\star$ we can either upper bound $\widetilde{\mathcal{A}}_{S_\star}$ for a given norm, or use the fact that $\Omega(\beta) \geq \|\beta\|_1$ and $\Omega^*(\beta) \leq \|\beta\|_\infty$ for all $\beta \in \mathbb{R}^p$. Therefore use the same λ as for the square root LASSO. And we get similar corollaries for the structured sparsity norms like the Corollary 13 for the square root LASSO.

5. Simulation: Comparison between srLASSO and srSLOPE

The goal of this simulation is to see how the estimation and prediction errors for the square root LASSO and the square root SLOPE behave under some Gaussian designs. We propose Algorithm 1 to solve the square root SLOPE:

Algorithm 1: srSLOPE

input : β^0 a starting parameter vector,
λ a desired penalty level with a decreasing sequence,
Y the response vector,
X the design matrix.

output: $\hat{\beta}_{srSLOPE} = \underset{\beta\in\mathbb{R}^p}{\arg\min}\left(\|Y - X\beta\|_n + \lambda J_\lambda(\beta)\right)$

1 **for** $i \leftarrow 0$ **to** i_{stop} **do**
2 $\quad \sigma_{i+1} \leftarrow \|Y - X\beta_i\|_n$;
3 $\quad \beta_{i+1} \leftarrow \underset{\beta\in\mathbb{R}^p}{\arg\min}\left(\|Y - X\beta\|_n^2 + \sigma_{i+1}\lambda J_\lambda(\beta)\right)$;
4 **end**

Note that in Algorithm 1 Line 3 we need to solve the usual SLOPE. To solve the SLOPE we have used the algorithm provided in Bogdan et al. (2015). For the square root LASSO we have used the R-Package flare by Li et al. (2014).
We consider a high-dimensional linear regression model:

$$Y = X\beta^0 + \epsilon,$$

with $n = 100$ response variables and $p = 500$ unknown parameters. The design matrix X is chosen with the rows being fixed i.i.d. realizations from $\mathcal{N}(0, \Sigma)$. Here the covariance matrix Σ has a Toeplitz structure

$$\Sigma_{i,j} = 0.9^{|i-j|}.$$

We choose i.i.d. Gaussian errors ϵ with a variance of $\sigma^2 = 1$. For the underlying unknown parameter vector β^0 we choose different settings. For each such setting we calculate the square root LASSO and the square root SLOPE with the theoretical λ given in this paper and the λ from a 8-fold Cross-validation on the mean squared prediction error. We use $r = 100$ repetitions to calculate the ℓ_1-estimation error, the sorted ℓ_1-estimation error and the ℓ_2-prediction error. As for the definition of the sorted ℓ_1-norm, we chose a regular decreasing sequence from 1 to 0.1 with length 500. The results can be found in Table 1,2,3 and 4.

Decreasing Case:
Here the active set is chosen as $S_0 = \{1, 2, 3, ..., 7\}$, and $\beta^0_{S_0} = (4,\ 3.\overline{6},\ 3.\overline{3},\ 3,\ 2.\overline{6},\ 2.\overline{3},\ 2)^T$ is a decreasing sequence.

Table 1: Decreasing β

	theoretical λ			Cross-validated λ		
	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$
srSLOPE	2.06	0.21	4.12	2.37	0.26	3.88
srLASSO	1.85	0.19	5.51	1.78	0.19	5.05

Decreasing Random Case:
The active set was randomly chosen to be $S_0 = \{154, 129, 276, 29, 233, 240, 402\}$ and again $\beta^0_{S_0} = (4,\ 3.\overline{6},\ 3.\overline{3},\ 3,\ 2.\overline{6},\ 2.\overline{3},\ 2)^T$.

Table 2: Decreasing Random β

	theoretical λ			Cross-validated λ		
	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$
srSLOPE	4.50	0.49	7.74	7.87	1.09	7.68
srLASSO	8.48	0.89	29.47	7.81	0.85	9.19

Grouped Case:
Now in order to see if the square root SLOPE can catch grouped variables better than the square root LASSO we look at an active set $S_0 = \{1, 2, 3, ..., 7\}$ together with $\beta^0_{S_0} = (4, 4, 4, 3, 3, 2, 2)^T$.

Table 3: Grouped β

	theoretical λ			Cross-validated λ		
	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$
srSLOPE	2.81	0.29	6.43	1.71	0.18	3.65
srLASSO	3.02	0.31	8.37	1.83	0.19	4.25

Grouped Random Case:
Again we take the same randomly chosen set $S_0 = \{154, 129, 276, 29, 233, 240, 402\}$ with $\beta^0_{S_0} = (4, 4, 4, 3, 3, 2, 2)^T$.

Table 4: Grouped Random β

	theoretical λ			Cross-validated λ		
	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$	$\|\beta^0 - \hat{\beta}\|_{\ell_1}$	$J_\lambda(\beta^0 - \hat{\beta})$	$\|X(\beta^0 - \hat{\beta})\|_{\ell_2}$
srSLOPE	6.05	0.66	12.84	5.80	0.66	5.78
srLASSO	16.90	1.77	66.68	6.14	0.67	6.67

The random cases usually lead to larger errors for both estimators. This is due to the correlation structure of the design matrix. The square root SLOPE seems to outperform

the square root LASSO in the cases where β^0 is somewhat grouped (grouped in the sense that amplitudes of same magnitude appear). This is due to the structure of the sorted ℓ_1-norm, which has some of the sparsity properties of ℓ_1 as well as some of the grouping properties of ℓ_∞, see Zeng and Figueiredo (2014). Therefore the square root SLOPE reflects the underlying sparsity structure in the grouped cases. What is also remarkable is that the square root SLOPE always has a better mean squared prediction error than the square root LASSO. This is even in cases, where square root LASSO has better estimation errors. The estimation errors seem to be better for the square root LASSO in the decreasing cases.

6. Discussion

Sparsity inducing norms different from ℓ_1 may be used to facilitate the interpretation of the results. Depending on the sparsity structure we have provided sharp oracle inequalities for square root regularization. Due to the square root regularizing we do not need to estimate the variance, the estimators are all pivotal. Moreover, because the penalty is a norm the optimization problems are all convex, which is a practical advantage when implementing the estimation procedures. For these sharp oracle inequalities we only needed the weak decomposability and not the decomposability property of the ℓ_1-norm. The weak decomposability generalizes the desired property of promoting an estimated parameter vector with a sparse structure. The structure of the $\Omega-$ and $\Omega^{S^c}-$norms influence the oracle bound. Therefore it is useful to use norms that reflect the true underlying sparsity structure.

Abstract

In this paper, we show that the popular C-SVM, soft-margin support vector classifier is equivalent to minimization of Buffered Probability of Exceedance (bPOE), a recently introduced characterization of uncertainty. To show this, we introduce a new SVM formulation, called the EC-SVM, which is derived from a simple bPOE minimization problem that is easy to interpret with a meaningful free parameter, optimal objective value, and probabilistic derivation. Over the range of its free parameter, the EC-SVM has both a convex and non-convex case which we connect to existing SVM formulations. We first show that the C-SVM, formulated with any regularization norm, is equivalent to the convex EC-SVM. Similarly, we show that the Eν-SVM is equivalent to the EC-SVM over its entire parameter range, which includes both the convex and non-convex case. These equivalences, coupled with the interpretability of the EC-SVM, allow us to gain surprising new insights into the C-SVM and fully connect soft margin support vector classification with superquantile and bPOE concepts. We also show that the EC-SVM can easily be cast as a robust optimization problem, where bPOE is minimized with data lying in a fixed uncertainty set. This reformulation allows us to clearly differentiate between the convex and non-convex case, with convexity associated with pessimistic views of uncertainty and non-convexity associated with optimistic views of uncertainty. Finally, we address some practical considerations. First, we show that these new insights can assist in making parameter selection more efficient. Second, we discuss optimization approaches for solving the EC-SVM. Third, we address the issue of generalization, providing generalization bounds for both bPOE and misclassification rate.

Keywords: Support Vector Machines, Buffered Probability of Exceedance, Conditional Value-at-Risk, Binary Classification, Robust Optimization

1. Introduction

In the machine learning community, the Soft Margin Support Vector Machine (C-SVM) has proven to be an extremely popular tool for classification, spawning generalizations for regression, robust optimization, and a host of other applications. With its connection to statistical learning theory, intuitive geometric interpretation, and efficient extensions to non-linear classification, the C-SVM has proven to be a flexible tool based on sound theory and intuition. Still, there are insights left to be gained with regard to soft margin support vector classification.

One such insight was revealed by Takeda and Sugiyama (2008), where it was shown that the Eν-SVM, an extension of the ν-SVM, is equivalent to superquantile minimization. Superquantiles, popularized in the financial engineering literature under the name Conditional Value-at-Risk (CVaR), were developed by Rockafellar and Uryasev (2002) as means for dealing with optimization of quantiles. Utilizing the popular calculation formula for superquantiles, Takeda and Sugiyama (2008) showed that the Eν-SVM was equivalent to superquantile minimization, with the free parameter of the Eν-SVM being equivalent to the free choice of probability level in superquantile minimization.

In this paper, we provide insights in a similar direction by utilizing the inverse of the superquantile, so called Buffered Probability of Exceedance (bPOE). More specifically, bPOE is a generalization of *buffered Probability of Failure* (bPOF) which was introduced by Rockafellar (2009) and further studied in Rockafellar and Royset (2010). This generalization, recently studied by Mafusalov and Uryasev (2015); Norton and Uryasev (2014); Norton et al. (2015); Davis and Uryasev (2014); Uryasev (2014), has shown a great deal of promise as generating numerically tractable methods for probability minimization.

Utilizing the bPOE concept, we introduce a new SVM formulation called the Extended Soft Margin Support Vector Machine (EC-SVM). Being derived as a bPOE minimization problem, the EC-SVM is simple to interpret. First, we show that the EC-SVM has a free parameter interpretable as a specific statistical quantity related to the optimal loss distribution. Second, we show that the value of the optimal objective function (divided by sample size) is equal to a probability level. Lastly, we show that the EC-SVM can be interpreted as having a hard-margin criterion. Additionally, with the EC-SVM formulated with any general norm, we show that the choice of norm implies a distance metric which defines the hard-margin criterion.

After introducing the EC-SVM, we then connect it to existing SVM formulations. In our main result, we show that the C-SVM and EC-SVM, when formulated with any general norm and non-negative parameter values, produce the same set of optimal hyperplanes. This result implies that the original soft-margin SVM formulation, derived in great part from geometric intuition, is equivalent to minimization of bPOE, a probabilistic concept. This result also implies that the interpretation of the EC-SVM's parameter, optimal objective, and hard-margin criterion can be applied to the C-SVM. This includes the surprising result that the optimal objective value of the C-SVM, divided by sample size, equals a probability level.

We also connect the EC-SVM and Eν-SVM, showing that these SVM formulations produce the same set of optimal hyperplanes over their entire parameter range. With bPOE being the inverse of the superquantile, this relationship follows immediately from the derivation of the EC-SVM as a bPOE minimization problem and the results of Takeda and Sugiyama (2008). This result also makes it clear that the EC-SVM is an extension of the C-SVM in the same way that the Eν-SVM is an extension of the ν-SVM.

Additionally, we provide a novel interpretation of the EC-SVM as a robust optimization (RO) problem, where bPOE is minimized with data points lying in a fixed uncertainty set. With the EC-SVM having both a convex and non-convex case, depending on the value of the free parameter, we find that the RO representation reveals a unique interpretation to

help distinguish these cases. Specifically, the RO representation reveals that the convex case corresponds to bPOE minimization with worst-case *pessimistic* data uncertainty, while the non-convex case corresponds to bPOE minimization with best-case *optimistic* data uncertainty. The RO representation also provides other insights. For the convex case, the RO representation is similar to existing equivalences for the C-SVM presented in Xu et al. (2009), but with a much simpler proof, definition of uncertainty set, and correspondence between equivalent parameter values. For the non-convex case, this new representation suggests an efficient alternating minimization method for finding a local minimum. Furthermore, the RO representation reveals that this seemingly heuristic optimization method is related to the DC Algorithm, a popular algorithm for finding the local minimum of DC (difference of convex functions) optimization problems.

Finally, we consider some practical implications of these new theoretical insights. We show that the new interpretation of the C tradeoff parameter suggests a range that should be used to select the C parameter. This helps to improve grid selection for cross validation so that one can partially avoid solving the EC-SVM for values of C that yield trivial or redundant optimal solutions. Furthermore, using the RO representation of the EC-SVM, we show that there may be situations where prior knowledge about data uncertainty suggests, at-best, a fixed C or, at-worst, much tighter bounds for the range of interesting C values for cross-validation.

We also address the practical issue of generalization. In classification, generalization bounds are typically provided for misclassification rate because classification algorithms are viewed as attempts to find classifiers which minimize this performance metric. In this regard, we utilize results from Takeda and Sugiyama (2008); Schölkopf et al. (2000) to show that generalization bounds for misclassification rate of EC-SVM classifiers can be posed in terms of empirical estimates of bPOE, the quantile, and the superquantile. However, with the new insight that the EC-SVM and C-SVM directly minimize bPOE, we also provide generalization bounds for this metric. We apply the stability arguments of Bousquet and Elisseeff (2002) to provide tight generalization bounds on the true bPOE of EC-SVM and C-SVM classifiers and show that bPOE threshold plays an important role in these bounds.

This paper is organized as follows. Note that in order to make this paper as self-contained as possible, we include a significant amount of review in the first three sections. Section 2 reviews some existing SVM formulations relevant to our discussion, specifically the C-SVM, ν-SVM, and Eν-SVM. Section 3 briefly reviews the concept of a superquantile and the results of Takeda and Sugiyama (2008), which show that the Eν-SVM is equivalent to superquantile minimization. Section 4 reviews the bPOE concept, which is critical to our contribution. Additionally, we present a new formulation for minimizing bPOE in the presence of Positive Homogenous (PH) random functions. The necessity of this new formulation is discussed in more detail in Appendix A. Section 5 introduces the EC-SVM as a bPOE minimization problem and discusses the properties of the EC-SVM and its interpretation as a hard-margin optimization problem. Section 6 connects the C-SVM and EC-SVM. Section 7 connects the EC-SVM and Eν-SVM and presents the results of this and previous papers in a cohesive framework connecting soft margin support vector classification and superquantile concepts. Section 8 presents dual formulations of the C-SVM and EC-SVM formulated with any general norm, discusses application of the kernel trick, and shows that the optimal objective of the C-SVM, divided by sample size, equals a probability level.

Section 9 shows that the EC-SVM has a novel interpretation as a RO problem, with a distinction between the convex and non-convex cases. Section 10.1 discusses the issue of parameter selection. Section 10.2 discusses optimization of the EC-SVM. Section 10.3 provides generalization bounds for misclassification rate and bPOE.

2. C-SVM, ν-SVM, Eν-SVM

In this section, we review three existing SVM formulations; C-SVM, ν-SVM, and Eν-SVM. We begin with a review of the C-SVM and ν-SVM, reviewing the fact that they share the same optimal solution sets. We then review the interpretation of the ν-SVM parameter, its limitations, and the Eν-SVM formulation which serves to resolve these limitations.

2.1 The C-SVM

Consider the task of binary classification where we have a set of N feature vectors $X_i \in \mathbb{R}^n$ and associated class labels $y_i \in \{-1, +1\}$ and we need to choose a hyperplane $w \in \mathbb{R}^n$ with intercept $b \in \mathbb{R}$ to properly classify feature vectors via the linear decision function $d(w, b, X_i) = sign(w^T X_i + b)$.

One of the most successful algorithms for accomplishing this task is the soft-margin SVM from Cortes and Vapnik (1995), also referred to as the C-SVM. The C-SVM is formulated as (1), where $C \geq 0 \in \mathbb{R}$ is chosen as a fixed tradeoff parameter and the norm is typically the L_2, $\|\cdot\|_2$, or L_1, $\|\cdot\|_1$, norm.[1] Below, we present it with the general norm, $\|\cdot\|$.

$$\begin{aligned} \min_{w,b,\xi} \quad & C\|w\| + \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) + 1, \quad \forall i \in \{1, ..., N\}, \\ & \xi \geq 0. \end{aligned} \tag{1}$$

2.2 The ν-SVM

After introduction of the C-SVM, the ν-SVM was introduced by Schölkopf et al. (2000) as an equivalent formulation with more intuitive parameter choices. C-SVM and ν-SVM, with the L_2 norm, are equivalent in that they provide the same set of optimal solutions over the space of all possible parameter choices, see Chang and Lin (2001). These algorithms are different, though, in the meaning of the value of the free parameter. For the C-SVM, there was no direct interpretation for the meaning of the C-parameter other than as a trade-off between margin size and classification errors. The ν-SVM, on the other hand, provided a more interpretable parameter.

1. Often, the squared norm is utilized. We use non-squared for ease of presentation. Many of the ideas in this paper are also valid for the squared case, however, the proofs are more involved and the correspondence between formulations is less straight-forward.

The ν-SVM is traditionally formulated as (2) with the L_2 norm, where $\nu \in [0,1]$ instead of $C \in [0,+\infty)$ is chosen as a fixed tradeoff parameter.

$$\begin{aligned} \min_{w,b,\rho,\xi} \quad & \frac{1}{2}\|w\|_2^2 - \nu\rho + \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) + \rho, \quad \forall i \in \{1,...,N\}, \\ & \xi \geq 0. \end{aligned} \tag{2}$$

As already mentioned, the ν-SVM advantageously gives us a free parameter, $\nu \in [0,1]$, with implied meaning. The meaning of ν is shown in Schölkopf et al. (2000) by proving a variant of Property 1.

Property 1 *Assume that there exists a feasible solution (w,b,ρ,ξ) for (2) for parameter choice $\nu \in [0,1]$. Then the following bounds apply:*

- *The choice of ν acts as an upper bound on the fraction of errors in the margin:*

$$1-\alpha < \nu, \quad \textit{where} \quad 1-\alpha = \frac{1}{N}\left|\{i : y_i(w^T X_i + b) < \rho\}\right|.$$

- *The choice of ν acts as a lower bound on the fraction of support vectors (SV's), support vectors being errors that lie in the margin or on the margin boundary:*

$$\%SV's > \nu, \quad \textit{where} \quad \%SV's = \frac{1}{N}\left|\{i : y_i(w^T X_i + b) \leq \rho\}\right|.$$

2.3 The Eν-SVM

Given the natural interpretation for the meaning of the ν-parameter, it would seem normal to assume that all the values of $\nu \in [0,1]$ will yield non-trivial, feasible solutions satisfying the bounds stated in Property 1. This, though, is not the case. In Chang and Lin (2001), it was shown that the ν-parameter has a limited range. Specifically, a variant of Property 2 is proved in Chang and Lin (2001).

Property 2

- *There exists a minimum and maximum value such that $\nu \in (\nu_{\min}, \nu_{\max}]$ yields feasible (2) with non-trivial solutions, $\nu \leq \nu_{\min}$ yields (2) with trivial optimal solution $w = b = 0$, and $\nu > \nu_{\max}$ yields infeasible (2).*

- *Furthermore, this limitation in parameter range applies to the C-SVM as well. Specifically, there exists a correspondence in allowable range such that $\nu \to \nu_{\min}$ corresponds to $C \to \infty$ and $\nu \to \nu_{\max}$ corresponds to $C \to 0$.*

To solve this issue, extending the valid range of the ν-parameter to be the entire $[0,1]$ interval, Pérez-Cruz et al. (2003) developed an extended ν-SVM formulation called Eν-SVM (3). The Eν-SVM is traditionally formulated as follows with the L_2 norm. We

present it with the general norm as follows:

$$\begin{aligned} \min_{w,b,\rho,\xi} \quad & -\nu\rho + \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) + \rho, \quad \forall i \in \{1,...,N\}, \\ & \xi \geq 0, \\ & \|w\| = 1. \end{aligned} \tag{3}$$

One can view (3) as an **extension** of (2) in that Pérez-Cruz et al. (2003); Chang and Lin (2001) showed that the optimal solution to (2), formulated with L_2 norm and any $\nu_0 \in (\nu_{\min}, v_{\max}]$, is also an optimal solution to (3), formulated with L_2 norm, for some $\nu_1 \leq \nu_0$. Problem (3), though, can achieve solutions that (2) cannot because of its extended range of the ν-parameter.

3. Superquantiles and the Eν-SVM

In this section, we first give a brief review of the superquantile concept as introduced by Rockafellar and Uryasev (2002). We then review the results of Takeda and Sugiyama (2008), showing that the Eν-SVM is equivalent to superquantile minimization.

3.1 Superquantiles and Tail Probabilities

When working with optimization of tail probabilities, one frequently works with constraints or objectives involving *probability of exceedance* (POE), $p_z(Z) = P(Z > z)$, or its associated quantile $q_\alpha(Z) = \min\{z | P(Z \leq z) \geq \alpha\}$, where $\alpha \in [0,1]$ is a probability level and $z \in \mathbb{R}$ is a fixed threshold level. The quantile is a popular measure of tail probabilities in financial engineering, called within this field Value-at-Risk by its interpretation as a measure of tail risk. The quantile, though, when included in optimization problems via constraints or objectives is quite difficult to treat with continuous (linear or non-linear) optimization techniques.

A significant advancement was made by Rockafellar and Uryasev (2002) in the development of an approach to combat the difficulties raised by the use of the quantile function in optimization. They explored a replacement for the quantile, called CVaR within the financial literature and called the superquantile in a general context. The superquantile is a measure of uncertainty similar to the quantile, but with superior mathematical properties. Formally, the superquantile (CVaR) for a continuously distributed real valued random variable Z is defined as,

$$\bar{q}_\alpha(Z) = E\left[Z | Z > q_\alpha(Z)\right]. \tag{4}$$

For general distributions, the superquantile can be defined by the following formula,

$$\bar{q}_\alpha(Z) = \min_{\gamma} \quad \gamma + \frac{E[Z-\gamma]^+}{1-\alpha}, \tag{5}$$

where $[\cdot]^+ = \max\{\cdot, 0\}$. For a discretely distributed random variable Z with equally probable realizations $\{Z_1, Z_2, ..., Z_N\}$ we can write this formula as the following Linear Program-

ming problem,

$$\begin{aligned} \bar{q}_\alpha(Z) = \min_{\gamma,\xi} \quad & \gamma + \frac{1}{N(1-\alpha)} \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq Z_i - \gamma, \forall i \in \{1, ..., N\}, \\ & \xi \geq 0. \end{aligned} \tag{6}$$

Similar to $q_\alpha(Z)$, the superquantile can be used to assess the tail of the distribution. The superquantile, though, is far easier to handle in optimization contexts. It also has the important property that it considers the magnitude of events within the tail. Therefore, in situations where a distribution may have a heavy tail, the superquantile accounts for magnitudes of low-probability large-loss tail events while the quantile does not account for this information.

3.2 Eν-SVM as Superquantile Minimization

In Takeda and Sugiyama (2008), the meaning of the ν-parameter was solidified by showing that the Eν-SVM, (3), is equivalent to superquantile minimization. Specifically, they proved a variant of Property 3.

Property 3 *Consider optimization problem (3). Let $\alpha = 1 - \nu$ and $\gamma = -\rho$. Also, let $L(w, b, X, y) = -y(w^T X + b)$ be a discretely distributed random variable with equally probable realizations $\{-y_1(w^T X_1 + b), ..., -y_N(w^T X_N + b)\}$. With this notation, (3) can be rewritten as (7), which is equivalent to (8), minimization of the α-superquantile:*

$$\begin{aligned} \min_{w,b,\gamma,\xi} \quad & (1-\alpha)\left(\gamma + \frac{1}{N}\sum_{i=1}^{N} \xi_i\right) \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) - \gamma, \quad \forall i \in \{1, ..., N\}, \\ & \xi \geq 0, \\ & \|w\| = 1. \end{aligned} \tag{7}$$

$$\begin{aligned} \min_{w,b} \quad & (1-\alpha)\bar{q}_\alpha\left(-y(w^T X + b)\right) \\ s.t. \quad & \|w\| = 1. \end{aligned} \tag{8}$$

With this, one can see that the Eν-SVM is simply minimization of the value (5) multiplied by $1 - \alpha$ with the real valued discretely distributed random loss $L(w, b, X, y) = -y(w^T X + b)$ in place of the real valued random variable Z.

4. Buffered Probability of Exceedance (bPOE)

In this section, we first review the concept of bPOE. We show how it is simply one minus the inverse of the superquantile and review its surprising calculation formula. We then review how minimization of bPOE integrates quite nicely into optimization frameworks. Finally, we present a slightly altered formulation for minimization of bPOE in the presence of Positive

Homogenous (PH) random functions. For the interested reader, we discuss the necessity of this alteration and derive the formulation in Appendix A. We move this discussion to the appendix, as it is slightly distracting from the discussion related to support vector machines.

4.1 bPOE: Inverse of the Superquantile

As mentioned in Section 3, when working with optimization of tail probabilities, one frequently works with constraints or objectives involving POE, $p_z(Z) = P(Z > z)$, or its associated quantile $q_\alpha(Z) = \min\{z | P(Z \leq z) \geq \alpha\}$, where $\alpha \in [0, 1]$ is a probability level and $z \in \mathbb{R}$ is a fixed threshold level. The superqunatile was developed to alleviate difficulties associated with optimization problems involving quantiles. Working to extend this concept, bPOE was developed as the inverse of the superquantile in the same way that POE is the inverse of the quantile.

Specifically, there exist two slightly different variants of bPOE, namely Lower and Upper bPOE. Mafusalov and Uryasev (2015) mainly work with so called Lower bPOE while Norton and Uryasev (2014) work with so called Upper bPOE. These definitions do not differ dramatically and a discussion of these differences is beyond the scope of this paper. Thus, for the remainder of this paper when we refer to bPOE, we are utilizing Upper bPOE. With this in mind, bPOE is defined in the following way, where $\sup Z$ denotes the essential supremum of random variable Z. In this paper we assume all random variables to be L_1-finite, $Z \in \mathcal{L}^1(\Omega)$, i.e. $E|Z| < \infty$.

Definition 1 *Upper bPOE for a random variable Z at a threshold z equals,*

$$\bar{p}_z(Z) = \begin{cases} \max\{1 - \alpha | \bar{q}_\alpha(Z) \geq z\}, & \text{if } z \leq \sup Z, \\ 0, & \text{otherwise.} \end{cases}$$

In words, for any threshold $z \in (E[Z], \sup Z)$, bPOE can be interpreted as one minus the probability level at which the superquantile equals z. Although bPOE seems troublesome to calculate, Norton and Uryasev (2014) provide the following calculation formula for bPOE.

Proposition 1 *Given a real valued random variable Z and a fixed threshold z, bPOE for random variable Z at z equals,*

$$\bar{p}_z(Z) = \inf_{\gamma < z} \frac{E[Z-\gamma]^+}{z-\gamma} = \begin{cases} \lim\limits_{\gamma \to -\infty} \frac{E[Z-\gamma]^+}{z-\gamma} = 1, & \text{if } z \leq E[Z], \\ \min\limits_{\gamma < z} \frac{E[Z-\gamma]^+}{z-\gamma}, & \text{if } z \in (E[Z], \sup Z), \\ \lim\limits_{\gamma \to z^-} \frac{E[Z-\gamma]^+}{z-\gamma} = P(Z = \sup Z), & \text{if } z = \sup Z, \\ \min\limits_{\gamma < z} \frac{E[Z-\gamma]^+}{z-\gamma} = 0, & \text{if } \sup Z < z. \end{cases} \tag{9}$$

It is also important to note that formula (9) has the following property, Property 4, proved in Mafusalov and Uryasev (2015) and Norton and Uryasev (2014). This property will become important in later sections when we begin to interpret the EC-SVM. Note that for Property 4, we must distinguish between the *lower* quantile $q_\alpha(Z)$ and *upper* quantile $q^+_\alpha(Z) = \inf\{z | P(Z \leq z) > \alpha\}$. However, the difference in these quantities will likely

be small or zero. For continuously distributed Z, we will have $q_\alpha(Z) = q^+_\alpha(Z)$ or if Z is discretely distributed with N equally probably events, and N is reasonably large, the difference $q^+_\alpha(Z) - q_\alpha(Z)$ will likely be small, possibly zero.

Property 4 *If* $z \in (E[Z], \sup Z)$ *and* $\min_{\gamma<z} \frac{E[Z-\gamma]^+}{z-\gamma} = \frac{E[Z-\gamma^*]^+}{z-\gamma^*} = 1-\alpha^*$*, then:*

$$\bar{p}_z(Z) = 1-\alpha^*, \qquad \bar{q}_{\alpha^*}(Z) = z, \qquad \gamma^* \in [q_{\alpha^*}(Z), q^+_{\alpha^*}(Z)],$$

where $[q_{\alpha^*}(Z), q^+_{\alpha^*}(Z)]$ *is the entire set of minimizers.*

Thus, using formula (9), bPOE can be efficiently calculated. Additionally, Property 4 shows that we can recover quantile and superquantile information. As we demonstrate in the next section, formula (9) also allows for convenient optimization of bPOE.

4.2 Optimization of bPOE for Random PH Functions

Norton and Uryasev (2014) considered the following optimization setup to demonstrate the ease with which bPOE can be minimized directly. Assume we have a real valued positive homogenous (PH) random function $f(w, X)$ determined by a vector of control variables $w \in \mathbb{R}^n$ and a random vector X. By definition, a function $f(w, X)$ is PH w.r.t. w if it satisfies the following condition: $af(w, X) = f(aw, X)$ for any $a \geq 0, a \in \mathbb{R}$.

Now, assume that we would like to find the vector of control variables, $w \in \mathbb{R}^n$, that minimizes the probability of $f(w, X)$ exceeding a threshold $z \in \mathbb{R}$. We would like to solve the POE optimization problem,

$$\min_{w\in\mathbb{R}^n} \quad p_z(f(w, X)). \tag{10}$$

Here we have a discontinuous and non-convex objective function (assuming a discretely distributed X) that is numerically difficult to minimize. Consider alternatively minimization of bPOE instead of POE at the same threshold z. This is posed as the optimization problem,

$$\min_{w\in\mathbb{R}^n} \quad \bar{p}_z(f(w, X)). \tag{11}$$

Given Proposition 1, (11) can be transformed into the following:

$$\min_{w\in\mathbb{R}^n,\gamma<z} \quad \frac{E[f(w, X)-\gamma]^+}{z-\gamma}. \tag{12}$$

Paper Norton and Uryasev (2014), though, limit consideration to only a threshold of $z = 0$, in which case formulation (12) reduces to,

$$\min_{w\in\mathbb{R}^n} \quad E[f(w, X)+1]^+. \tag{13}$$

As we discuss in Appendix A, formulation (12) has shortcomings for nonzero thresholds. Specifically, it fails to achieve varying optimal solutions for varying threshold levels. To address these issues, the next section provides an alternative formulation for bPOE minimization with PH functions $f(w, X)$ that allows effective variation of threshold levels.

4.3 An Altered Formulation

With (12) failing to achieve varying optimal solutions as the threshold z varies, we find that adding a constraint on the norm of w remedies this situation (because w can no longer rescale as the threshold changes). Here $\|\cdot\|$ denotes any general norm. This gives us

$$\begin{array}{ll} \min\limits_{w\in\mathbb{R}^n,\gamma<z} & \dfrac{E[f(w, X)-\gamma]^+}{z-\gamma} \\ s.t. & \|w\| = 1 \end{array} \quad \equiv \quad \min_{w\in\mathbb{R}^n} \bar{p}_z\left(\frac{f(w, X)}{\|w\|}\right). \tag{14}$$

Furthermore, the following Proposition 2 shows that (14) can be simplified, yielding

$$\min_{w\in\mathbb{R}^n} \quad E[f(w, X) - z\|w\| + 1]^+. \tag{15}$$

Proposition 2 *Assume* $f(w, X)$ *is PH with respect to* w*. If* (w^*, γ^*) *is optimal to (14) with optimal objective* $1-\alpha^*$*, then* $w = \frac{w^*}{z-\gamma^*}$ *is optimal to (15) with optimal objective* $1-\alpha^*$*.*

Proof For this, we show that (15) is formed only by making a change of variable in (14). We start with (14). Since $\gamma < z$ is an explicit constraint and thus $z - \gamma > 0$, we bring the denominator into the expectation in the numerator to get

$$\begin{array}{ll} \min\limits_{w\in\mathbb{R}^n,\gamma<z} & E\left[f\left(\dfrac{w}{z-\gamma}, X\right) - \left(\dfrac{\gamma}{z-\gamma}\right)\right]^+ \\ s.t. & \|w\| = 1. \end{array} \tag{16}$$

Now, make the change of variable $w_{new} = \frac{w}{z-\gamma}$. Since we have the explicit constraint $\|w\| = 1$, we have that $\|w_{new}\| = \left\|\frac{w}{z-\gamma}\right\| = \frac{\|w\|}{z-\gamma} = \frac{1}{z-\gamma}$. We can then make the change of variable to get

$$\min_{w_{new}\in\mathbb{R}^n,\gamma<z} \quad E\left[f(w_{new}, X) - \|w_{new}\|\gamma\right]^+. \tag{17}$$

We can also rearrange $\|w_{new}\| = \frac{1}{z-\gamma}$ to get $\gamma = z - \frac{1}{\|w_{new}\|}$ and thus that $\|w_{new}\|\gamma = \|w_{new}\|\left(z - \frac{1}{\|w_{new}\|}\right) = z\|w_{new}\| - 1$. Plugging this into our formulation, we arrive at

$$\min_{w_{new}\in\mathbb{R}^n} \quad E[f(w_{new}, X) - z\|w_{new}\| + 1]^+, \tag{18}$$

where due to our change in variable, we see that if we have optimal solution w^*_{new}, then $\left(w = \frac{w^*_{new}}{\|w_{new}\|}, \gamma = z - \frac{1}{\|w^*_{new}\|}\right)$ is optimal to (14) before the change of variable. ■

Thus, we can turn to (15) as our formulation for bPOE minimization of a PH function for varying threshold choices. Notice from the proof of Proposition 2 that if w^* is optimal to (15) then $(w = \frac{w^*}{\|w^*\|}, \gamma = z - \frac{1}{\|w^*\|})$ is optimal to (14). Also, let us call $f\left(\frac{w^*}{\|w^*\|}, X\right)$ the normalized loss distribution at w^*. Given Property 4, if

$$E[f(w^*, X) - z\|w^*\| + 1]^+ = 1-\alpha^*,$$

we know the following about the normalized loss distribution at the optimal point w^*:

$$\bar{p}_z(F) = 1-\alpha^*, \quad \bar{q}_{\alpha^*}(F) = z, \quad z-\frac{1}{\|w^*\|} \in [q_{\alpha^*}(F), q^+_{\alpha^*}(F)], \quad \text{where } F := f\left(\frac{w^*}{\|w^*\|}, X\right).$$

5. Extended C-SVM

In this section, we use formula (15) to introduce the EC-SVM. We approach the classification problem via a natural bPOE minimization problem. Utilizing the interpretability of optimization problem (15), we show that the EC-SVM is also simple to interpret. Specifically, we show that application of Property 4 allows us to interpret the choice of parameter and the value of the optimal objective in interesting, purely statistical ways.

We also point out that the traditional *hinge loss function* naturally occurs when minimizing bPOE, meaning that we do not need to explicitly specify it as a loss function. This can be seen clearly by considering minimization of bPOE at threshold $C = 0$. Additionally, it is interesting to notice that we do not explicitly attempt to regularize via use of norms, as the use of norms naturally arises from (14).

5.1 bPOE Minimization with SVM Loss

Consider the formula for bPOE minimization (15) with discretely distributed random loss $L(w, b, X, y) = -y(w^T X+b)$ with equally probable realizations $\{-y_1(w^T X_1+b), ..., -y_N(w^T X_N+b)\}$ and threshold $z \in \mathbb{R}$. If we let $C = -z$ and multiply the objective function by N, this gives us the following optimization problem, which we call the EC-SVM:

$$\begin{array}{ll} \min\limits_{w,b,\xi} & \sum\limits_{i=1}^{N} \xi_i \\ s.t. & \xi_i \geq -y_i(w^T X_i + b) + C\|w\| + 1, \quad \forall i \in \{1, \ldots, N\}, \\ & \xi \geq 0. \end{array} \tag{19}$$

Notice that the norm $\|\cdot\|$, just as in (15), is an arbitrary norm in $\mathbb{R}^n$. Notice also that the EC-SVM is a very natural formulation. It is simply a *buffered* way of minimizing the probability that misclassification errors exceed our threshold $-C$. Put specifically, instead of finding the classifier (w, b) that minimizes $p_{-C}\left(-y(w^T X + b)\right) = P\left(-y(w^T X + b) > -C\right)$, we are minimizing its buffered variant, $\bar{p}_{-C}\left(-y(w^T X + b)\right)$.

5.2 Occurrence of Hinge Loss

When discussing SVM's, it is traditional for people to say that the C-SVM minimizes a *hinge loss function* plus a regularization term on the vector w. For the EC-SVM, though, we see that this is not an accurate description, as we do not need to explicitly specify a hinge loss function. We see that it naturally arises when minimizing bPOE. Specifically, minimizing bPOE of the loss function $L(w, b, X, y) = -y(w^T X + b)$ at threshold $C = 0$ yields the following problem, which is exactly minimization of hinge losses:

$$\min_{w,b} \quad \sum_{i=1}^{N} \left[-y_i(w^T X_i + b) + 1\right]^+. \tag{20}$$

One can see this more generally by looking at (13), where we are minimizing bPOE of a PH loss function $f(w, X)$ at threshold zero.

5.3 Interpretability of EC-SVM

Since the EC-SVM is simply bPOE minimization, we can utilize Property 4 to interpret the C-parameter and the value of the optimal objective in an exact way. Specifically, let us put Property 4 in terms of the EC-SVM.

Property 5 *Suppose (19), with any general norm, yields optimal hyperplane (w^*, b^*) and the optimal objective value equal to obj^*. Considering $L(w^*, b^*, X, y) = -y(w^{*T} X + b^*)$ as a discretely distributed random loss, we know the following about the normalized loss distribution.*

- $\bar{p}_{-C}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right) = 1 - \alpha^* = \frac{obj^*}{N}$,
- $\bar{q}_{\alpha^*}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right) = -C$,
- $q_{\alpha^*}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right) \leq -C - \frac{1}{\|w^*\|} \leq q^+_{\alpha^*}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right)$.

5.3.1 The C-parameter as Superquantile Threshold Choice

For the C-SVM, the non-negative C-parameter is typically discussed as being a tradeoff between errors and margin size. In the broad scheme of Empirical Risk Minimization (ERM), this parameter is discussed as the tradeoff between risk and regularization. For the EC-SVM, we provide a much more concrete interpretation. With the EC-SVM being exactly bPOE minimization, the C-parameter is a choice of threshold $z = -C$. Specifically, looking at Property 5, we have that

$$\bar{q}_{\alpha^*}\left(\frac{L(w^*, b^*, X, y)}{\|w^*\|}\right) = -C,$$

where $\alpha^* = 1 - \frac{obj^*}{N} = 1 - \bar{p}_{-C}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right)$.

5.3.2 The Optimal Objective Value as bPOE

The EC-SVM also has the surprising property that the optimal objective value, divided by the number of samples, is a probability level. More specifically, as shown in Property 5, we have that $\frac{obj^*}{N} = \bar{p}_{-C}\left(\frac{L(w^*,b^*,X,y)}{\|w^*\|}\right)$. In words, the optimal objective value divided by the number of samples equals bPOE of the optimal normalized loss distribution at threshold $-C$.

5.4 Norm Choice and Margin Interpretation

In this section, we show that the EC-SVM has a clear interpretation of 'margin,' which is dependent on the choice of norm. This interpretation shows, in an exact way, how the C parameter determines the margin of the separating hyperplane.

Looking back to formula (14), using loss function $f(w, X) = -y(w^T X + b)$, and making the change of variable $w \to \frac{w}{C}, b \to \frac{b}{C}$ we are able to formulate the following equivalent problem (for the full derivation, see Appendix E):

$$\begin{aligned} \min_{\gamma<-C,w,b} \quad & \sum_{i=1}^{n} \left[\left(\frac{1}{-C-\gamma} \right) \left(\frac{-y_i(w^T X_i + b) + 1}{\|w\|} \right) + 1 \right]^+ \\ s.t. \quad & \frac{1}{\|w\|} = C. \end{aligned} \tag{21}$$

From this formulation, we can form an interpretation of the EC-SVM within the context of selecting an optimal hyperplane under a 'hard margin' criterion. To make this interpretation clear, we can start by analyzing (21) formulated with the L_2 norm, traditional to the C-SVM and discussions of 'maximal margin hyperplanes.' In this context, we see that the constraint $\frac{1}{\|w\|_2} = C$ is fixing the *euclidean* distance between hyperplanes $w^T X + b = 1$ and $w^T X + b = -1$, i.e. fixing the margin to be equal to C. Also, we see that the directional distance from X_i to the corresponding "separating" hyperplane is equal to $\frac{-y_i(w^T X_i + b) + 1}{\|w\|_2}$. The optimization problem above, therefore, fixes the margin between "separating" hyperplanes and minimizes the buffered probability of margin violations. If the classes are linearly separable with a margin of at least C, then the optimal objective is 0, meaning that "separating" hyperplanes are indeed separating. However, when classes are not separable with a margin of at least C, optimization problem (21) finds the number of worst classified objects such that the average of their directional distances to corresponding hyperplanes equals to 0. This number of worst classified objects is then minimized subject to the fixed margin size.

This interpretation, though, extends to any general norm within formulation (21). Using euclidean distance as our metric for measuring distances in $\mathbb{R}^n$, geometry tells us that the distance between hyperplanes is given by $\frac{2}{\|w\|_2}$ and that the directional distance from X_i to the corresponding "separating" hyperplane equals to $\frac{-y_i(w^T X_i + b) + 1}{\|w\|_2}$. But what if we were to use a different metric to measure distances within $\mathbb{R}^n$? For example, what if we were to say that the 'distance' between two points X_1, X_2 was $\|X_1 - X_2\|_1$ instead of $\|X_1 - X_2\|_2$? In this case, the distance between hyperplanes is given by $\frac{2}{\|w\|_\infty}$. This follows from the concept of the dual norm.

Denote by $\|\cdot\|^*$ the norm dual to the norm $\|\cdot\|$. In the general case, we know that if the 'distance' between two points X_1, X_2 is $\|X_1 - X_2\|^*$, then the distance between hyperplanes $w^T X + b = 1$ and $w^T X + b = -1$ is equal to $\frac{2}{\|w\|}$ and that the directional distance from X_i to the corresponding "separating" hyperplane equals to $\frac{-y_i(w^T X_i + b) + 1}{\|w\|}$. Thus, for the EC-SVM formulated with general norm $\|\cdot\|$, the constraint $\frac{1}{\|w\|} = C$ is fixing the 'margin' equal to C in $\mathbb{R}^n$ under the implied distance metric defined by the dual norm, $\|\cdot\|^*$.

Note that the problem above is equivalent to the EC-SVM, (19), having the same optimal objective and (up to some scaling factor) equivalent optimal hyperplane when parameter C is the same for both problems. Therefore, the interpretation above is also valid for the EC-SVM. In particular, if a certain norm $\|\cdot\|$ is used in the optimization problem setting, then it is implied that distances between objects represent object similarities in a better fashion when measured according to the dual norm. The correspondence between C-SVM and EC-SVM, described further by Theorems 1 and 2, is not as direct as the correspondence

between (21) and the EC-SVM. However, the presence of this correspondence should also imply that the use of $\|\cdot\|$ in optimization problem is closely related to the choice of norm $\|\cdot\|^*$ for the considered space.

Thus, as opposed to the C-SVM formulation, the EC-SVM formulation has a clear interpretation as hard margin separation problem for the case of non-separable classes.

6. Connecting the EC-SVM and C-SVM

In this section, we prove the equivalence of the EC-SVM and C-SVM when formulated with any general norm. Theorems 1 and 2 present the main result, providing a direct correspondence between parameter choices and optimal solutions. We emphasize the critical implication, which is that solving the C-SVM with any parameter $\hat{C} \geq 0$ is equivalent to solving the EC-SVM (i.e. minimizing bPOE) for some parameter $C \geq 0$.

Below be prove the equivalence of C-SVM and EC-SVM with two theorems. We leave the lengthy proofs to Appendix B. Theorem 1 begins with the assumption that one has solved the C-SVM and then provides the proper parameter value for which the EC-SVM will yield the same optimal hyperplane, up to a specific scaling factor, which we also provide. Theorem 2 is analogous to Theorem 1, but begins with the assumption that one has solved the EC-SVM. It should be noted that the theorems reference dual variables, which are discussed more explicitly (via KKT conditions) within the proofs of the theorems.

Theorem 1 *Assume that the data set is not linearly separable and suppose optimization problem (1) is formulated with any general norm $\|\cdot\|$ and some parameter $\hat{C} \geq 0$ and that it has optimal primal variables (w^*, b^*, ξ^*) and optimal dual variables (α^*, β^*). Then (19), formulated with corresponding norm and parameter $C = \frac{\hat{C}}{\sum_{i=1}^N \beta_i^*}$, will have optimal primal variables $(w = \mu w^*, b = \mu b^*, \xi = \mu \xi^*)$ and optimal dual variables $(\alpha = \alpha^*, \beta = \beta^*)$, where $\mu = \frac{\sum_{i=1}^N \beta_i^*}{\sum_{i=1}^N \beta_i^* - \hat{C}\|w^*\|} > 0$.*

Theorem 2 *Suppose optimization problem (19) is formulated with any general norm $\|\cdot\|$ and some parameter $C \geq 0$ and that it has optimal primal variables (w^*, b^*, ξ^*) and optimal dual variables (α^*, β^*). Then (1), formulated with corresponding norm and parameter $\hat{C} = C \sum_{i=1}^N \beta_i^*$, will have optimal primal variables $(w = \mu w^*, b = \mu b^*, \xi = \mu \xi^*)$ and optimal dual variables $(\alpha = \alpha^*, \beta = \beta^*)$, where $\mu = \frac{1}{1 + C\|w^*\|} > 0$.*

7. Presentation as Cohesive Structure

Here, we show exactly why it is appropriate to call formulation (19) the EC-SVM. Specifically, we show that the EC-SVM is equivalent to the Eν-SVM, producing the same set of optimal solutions. This follows directly from the fact that bPOE is the inverse of the superquantile. This fact helps solidify the idea that the EC-SVM is an **extension** of the C-SVM in the same way that the Eν-SVM is an extension of the ν-SVM. First, as was proved in Section 6, the optimal solution set produced by the C-SVM over $C \in [0, \infty)$ is contained in the optimal solution set produced by the EC-SVM over $C \in (-\infty, \infty)$. Second, the EC-SVM extends the allowable range of the C parameter to negative C-values. Thus,

just as the Eν-SVM extends the parameter range and optimal solution set of the ν-SVM, the EC-SVM does the same for the C-SVM.

Proposition 3 *The EC-SVM and Eν-SVM, formulated with the same general norm, produce the same set of optimal hyperplanes.*

Proof First, recall that the EC-SVM is equivalent to bPOE minimization. Second, recall that the Eν-SVM is equivalent to superquantile minimization. Using these two facts, the equivalence follows immediately from Mafusalov and Uryasev (2015), which shows that (w, b) is a minimizer of bPOE at some threshold level if and only if (w, b) is a minimizer of the superquantile at some probability level. ■

To help gather all of the results we have discussed, we can present them as a cohesive structure in the following table:

$\hat{C} \in [0, +\infty)$		$C \in (-\infty, +\infty)$	$=$	$-z$
$\uparrow$		$\uparrow$		$\uparrow$
C-SVM	$\subset$	EC-SVM	$\equiv$	$\min\limits_{w,b} \ \bar{p}_z\left(-y(w^T X + b)\right)$
$\Updownarrow$		$\Updownarrow$		$\Updownarrow$
ν-SVM	$\subset$	Eν-SVM	$\equiv$	$\min\limits_{w,b} \ \bar{q}_\alpha\left(-y(w^T X + b)\right)$
$\downarrow$		$\downarrow$		$\downarrow$
$\hat{\nu} \in (\nu_{\min}, \nu_{\max}]$		$\nu \in [0, 1]$	$=$	$1 - \alpha$

Key:

- $\Updownarrow$ Formulations generate the same set of optimal solutions.
- $\subset$ The right hand side formulation is an "extension" of the left hand formulation. (i.e. in the way that Eν-SVM is an extension of ν-SVM)
- $\equiv$ Formulations are objectively equivalent.
- $\uparrow$ or $\downarrow$ Arrow points to parameter values for the formulation.

8. Dual Formulations and Kernalization

Typically, the C-SVM is presented first in its primal form, then in its dual form, as the latter provides insights into selection of support vectors via dual variables while additionally providing a quadratic optimization problem for solving the C-SVM (in the case of the L_2 regularization norm). This quadratic optimization problem also allows one to use the 'kernel trick,' utilizing the presence of dot products to introduce a non-linear mapping to a high dimensional feature space.

In this section, we present the dual formulations of the C-SVM, (1), and EC-SVM, (19), formulated with any general norm. We leave the derivation of these dual formulations to Appendix C. We use these formulations to enlighten our perspective in two ways. First, in conjunction with Theorems 1 and 2, we use the dual formulations to show that the optimal objective value of the C-SVM and EC-SVM coincide when yielding the same optimal hyperplane. This effectively yields the surprising result that the optimal value of the C-SVM objective function, divided by sample size, equals a probability level. Second, we use these dual formulations to present kernalization of the EC-SVM when formulated with the L_2 norm.

Assume the EC-SVM, (19), is formulated with some norm $\|\cdot\|$ and $C \geq 0$. Let $\|\cdot\|^*$ be the corresponding dual norm, then the dual formulation is as follows:

$$\begin{aligned} \max_{\beta} \quad & \sum_{i=1}^{N} \beta_i \\ s.t. \quad & \left\| \sum_{i=1}^{N} \beta_i y_i X_i \right\|^* \leq C \sum_{i=1}^{N} \beta_i, \\ & \sum_{i=1}^{N} \beta_i y_i = 0, \\ & 0 \leq \beta_i \leq 1, \quad \forall i \in \{1, \ldots, N\}. \end{aligned} \tag{22}$$

Assume the C-SVM, (1), is formulated with some norm $\|\cdot\|$ and $C \geq 0$. Let $\|\cdot\|^*$ be the corresponding dual norm, then the dual formulation is as follows:

$$\begin{aligned} \max_{\beta} \quad & \sum_{i=1}^{N} \beta_i \\ s.t. \quad & \left\| \sum_{i=1}^{N} \beta_i y_i X_i \right\|^* \leq C, \\ & \sum_{i=1}^{N} \beta_i y_i = 0, \\ & 0 \leq \beta_i \leq 1, \quad \forall i \in \{1, \ldots, N\}. \end{aligned} \tag{23}$$

Given the dual formulations, it follows immediately from Theorems 1 and 2 that the optimal dual objective solutions coincide when parameters are chosen so that the EC-SVM and C-SVM produce the same optimal hyperplane. Additionally, this result applies to the primal formulations via strong duality. Thus, since the EC-SVM objective, divided by sample size, equals a probability level (as seen in Property 6), we can conclude that the optimal objective value of the C-SVM primal formulation, divided by sample size, also equals a probability level.

8.1 Kernalization of EC-SVM

Here we briefly present various methods for utilizing the kernel trick with the EC-SVM. First, the most obvious way is for the L_2 norm case and the dual EC-SVM formulation. To effectively apply the kernel trick[2], we need only to square the constraint in the dual formulation

$$\left\| \sum_{i=1}^{N} \beta_i y_i X_i \right\|^* \leq C \sum_{i=1}^{N} \beta_i \ ,$$

2. Recall that the L_2 norm is self-dual.

forming the following convex quadratically constrained quadratic program (QCQP) (24), where $\phi(X_i)$ represents a non-linear kernel mapping of the i_{th} data vector. Note that this can be efficiently solved with most convex optimization software.

$$\begin{aligned} \max_{\beta} \quad & \sum_{i=1}^{N} \beta_i \\ s.t. \quad & \sum_{i=1}^{N}\sum_{i=1}^{N} \beta_i\beta_j \left(y_i y_j \phi(X_i)^T\phi(X_j) - C^2\right) \leq 0, \\ & \sum_{i=1}^{N} \beta_i y_i = 0, \\ & 0 \leq \beta_i \leq 1, \quad \forall i \in \{1,\ldots,N\}. \end{aligned} \tag{24}$$

The application of the kernel trick, though, is not limited to the dual formulation. Mimicking the work of Chapelle (2007), we can apply the kernel in the primal formulated with the L_2 norm by using the representers theorem of Schölkopf et al. (2001). Since the representers theorem applies to the C-SVM, it indeed can be applied to the equivalent convex EC-SVM.[3] Thus, we know that in the high dimensional feature space we can represent the optimal solution of the convex EC-SVM as $w = \sum_i \theta_i y_i \phi(X_i)$. Therefore, using this representation, we can write the primal EC-SVM with $C \geq 0$ and the L_2 norm as the following unconstrained non-smooth convex program, where $K_{ij} = \phi(X_i)^T\phi(X_j)$.

$$\min_{\theta,b} \sum_{i=1}^{N}[-y_i(\sum_j \theta_j y_j K_{ij} + b) + C\left(\sum_i\sum_j \theta_i\theta_j y_i y_j K_{ij}\right)^{\frac{1}{2}} + 1]^+ . \tag{25}$$

Furthermore, this can be reformulated as the following convex QCQP.

$$\begin{aligned} \min_{\theta,b,\xi,t} \quad & \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq -y_i(\sum_j \theta_j y_j K_{ij} + b) + Ct + 1, \quad \forall i \in \{1,\ldots,N\}. \\ & \xi \geq 0 \\ & t^2 \geq \sum_i\sum_j \theta_i\theta_j y_i y_j K_{ij}. \end{aligned} \tag{26}$$

So far, we have discussed the case of the L_2 norm and $C \geq 0$. Here, for the interest of the reader, we briefly mention how to apply a standard technique which allows approximate kernelization of the EC-SVM with any norm and $C \in \mathbb{R}$. Here, we explicitly map the data vectors into the high dimensional feature space by approximating the kernel map. Let $K \in \mathbb{R}^{N\times N}$ be the positive semi-definite (PSD) matrix such that $K_{ij} = \phi(X_i)^T\phi(X_j)$ and, with abuse of notation, let $X = [X_1, ..., X_N]$ be the matrix of data vectors. Let

3. In other words, because the EC-SVM and C-SVM produce the same set of optimal solutions for $C \geq 0$, we can say that their optimal solutions can be represented in the same way.

$V = [V_1, ..., V_N]$ and $\Lambda = diag\{\lambda_1, ..., \lambda_n\}$ be the matrix of eigenvectors and associated eigenvalues of K with $\lambda_1 \geq \lambda_2 \geq ... \geq \lambda_n$. With K being symmetric PSD, we then have the eigendecomposition,

$$K = \phi(X)^T\phi(X) = V\Lambda V^T = (\Lambda^{\frac{1}{2}}V^T)^T(\Lambda^{\frac{1}{2}}V^T) .$$

Thus, we can approximate $\phi(X)$ by taking the top d eigenvectors and eigenvalues to get

$$\hat{X} = diag\{\lambda_1, ..., \lambda_d\}^{\frac{1}{2}}[V_1, ..., V_d]^T \approx \Lambda^{\frac{1}{2}}V^T = \phi(X) .$$

Then, we can simply use $\hat{X}$ as our data in the linear EC-SVM, (19), with any norm or parameter value and solve using the standard methods that will be discussed in Section 10.2.

9. Interpretation as Robust Optimization, Pessimistic vs. Optimistic Uncertainty

In this section, we present an equivalent representation of the convex and non-convex case of the EC-SVM as robust optimization (RO) problems. This equivalence is enlightening for both the convex and non-convex case. In general, we find that the RO representation reveals a unique interpretation, showing that the convex case corresponds to bPOE minimization with worst-case *pessimistic* data uncertainty, while the non-convex case corresponds to bPOE minimization with best-case *optimistic* data uncertainty. For the convex case, the RO representation is similar to existing equivalences for the C-SVM in Xu et al. (2009), but with a much simpler proof, definition of uncertainty set, and correspondence between equivalent parameter values. For the non-convex case, this new representation reveals a connection with the Total Support Vector Classifier (T-SVC) proposed in Bi and Zhang (2005) and suggests an efficient heuristic for the optimization. Furthermore, the RO representation reveals that this seemingly heuristic optimization method, which was shown to work well in the T-SVC case, is related to DCA, a popular algorithm for locally minimizing DC (difference of convex) functions.

9.1 Convex Case and Pessimism

For the convex case of the EC-SVM, (19), when we have $C \geq 0$, it is simple to show that it is equivalent to (27) and (28). Notice that we are minimizing bPOE, as we did before, but with threshold equal to zero and data subject to *pessimistic* disturbances δ_i. We call this *pessimism*, because we are maximizing w.r.t. the disturbance and looking at the worst case. This is the traditional viewpoint of robust optimization, leading to a special case of the Wald's minimax model.

$$\begin{aligned} \min_{w,b} \quad & \max_{\delta_i} \quad \bar{p}_0\left(-y(w^T(X+\delta)+b)\right) \\ & s.t. \quad \|\delta_i\|^* \leq C \, , i = 1, ..., N \end{aligned} \tag{27}$$

$$\begin{aligned} \min_{w,b} \quad & \max_{\delta_i} \quad \sum_i [-y_i(w^T(X_i+\delta_i)+b)+1]^+ \\ & s.t. \quad \|\delta_i\|^* \leq C, \; i = 1, ..., N \end{aligned} \tag{28}$$

To see the equivalence between (19) and (28), one only needs to observe that for any $w \in \mathbb{R}^n$, if $C \geq 0$, we have that

$$C\|w\| = C \max_{\|\delta\|^* \leq 1} w^T\delta = \max_{\|\delta\|^* \leq C} w^T\delta = \max_{\|\delta\|^* \leq C} -yw^T\delta \ .$$

Furthermore, to see the equivalence between (28) and (27), a simple application of the bPOE formula (9) and multiplication by N transforms (27) into (28).

This provides us with three things. First, we see that the bPOE threshold can be interpreted as controlling the size of the uncertainty set. Following from the transformation of (19) to (28) via the simple algebra, we see that this correspondence is exact, meaning that a threshold of C in the EC-SVM implies an uncertainty set with "size" C in (28) (i.e. optimal solutions are the same when parameters are the same). Second, we see that regularization with norm $\|\cdot\|$ implies uncertainty w.r.t. the corresponding dual norm $\|\cdot\|^*$. Third, we see that the convex case can be interpreted as pessimistic, or risk averse, following the traditional RO framework.

9.2 Nonconvex Case and Optimism

For the non-convex case, we find a similar robust reformulation, but instead of pessimistic disturbances we have *optimistic* disturbances. Specifically, for the EC-SVM (19), when we have $C < 0$, it is simple to show that it is equivalent to (29) and (30). Notice again that we are minimizing bPOE, as we did before, but with threshold equal to zero and data subject to *optimistic* disturbances δ_i. We call this *optimistic*, because we are minimizing w.r.t. the disturbance and looking at the best case.

$$\begin{aligned} \min_{w,b,\delta_i} \quad & \bar{p}_0\left(-y(w^T(X+\delta)+b)\right) \\ s.t. \quad & \|\delta_i\|^* \leq -C \ , i = 1, ..., N \end{aligned} \tag{29}$$

$$\begin{aligned} \min_{w,b,\delta_i} \quad & \sum_i [-y_i(w^T(X_i+\delta_i)+b)+1]^+ \\ s.t. \quad & \|\delta_i\|^* \leq -C \ , i = 1, ..., N \end{aligned} \tag{30}$$

To see the equivalence between (19) and (30), one only needs to observe that for any $w \in \mathbb{R}^n$, if $C < 0$, we have that

$$\begin{aligned} C\|w\| &= C \max_{\|\delta\|^* \leq 1} w^T\delta \\ &= -\max_{\|\delta\|^* \leq 1} -Cw^T\delta \\ &= -\max_{\|\delta\|^* \leq -C} w^T\delta \\ &= \min_{\|\delta\|^* \leq -C} w^T(-\delta) \\ &= \min_{\|\delta\|^* \leq -C} w^T\delta \quad = \min_{\|\delta\|^* \leq -C} -yw^T\delta \ . \end{aligned}$$

Furthermore, to see the equivalence between (30) and (29), a simple application of the bPOE formula (9) and multiplication by N transforms (29) into (30).

This formulation is enlightening for two reasons. First, as already mentioned, we see that the non-convex EC-SVM can be viewed from the RO lens as minimizing bPOE with an optimistic view of the data set. The optimistic perspective makes sense if one assumes, for example, that your data observations have been contaminated by noise. This view is supported by Bi and Zhang (2005), which proposes the Total Support Vector Classifier (T-SVC). Specifically, as revealed by the RO formulation, we see that the T-SVC is equivalent to the non-convex EC-SVM with L_2 norm. In their paper, they show that by using an alternating minimization strategy to solve this problem, a special case of the non-convex EC-SVM performs better than the C-SVM if data have been contaminated by noise. Second, as we will discuss in the next section, the RO formulation suggests that the simple alternating minimization algorithm for finding the local minimum is equivalent to DCA in a certain sense.

10. Practical Considerations

In this section, we consider some practical implications of the theoretical insights connecting soft margin SVM's and bPOE minimization. We first discuss the most obvious use, which is for the selection of the threshold parameter. We show that the new interpretation of the C tradeoff parameter suggests a range that should be used to select the C parameter. This helps to improve grid selection for cross validation so that one can partially avoid solving the EC-SVM for values of C that yield trivial or redundant optimal solutions. Furthermore, using the robust interpretation of the EC-SVM, we show that there may be situations where prior knowledge about data uncertainty suggests, at-best, a fixed C or, at-worst, much tighter bounds for the range of interesting C values for cross-validation.

Another practical consideration is the optimization of the EC-SVM for the convex and non-convex case. For the convex case, we discuss alternative formulations that can be efficiently solved by standard convex optimization tools. With some of these approaches not well suited for large scale problems, we briefly mention recent work on subgradient methods that can be efficiently applied to the EC-SVM. For the non-convex case, we suggest a simple alternating minimization algorithm and show that this procedure has appealing connections with DCA, the Difference of Convex Functions Algorithm; see Tao and An (1997) or Dinh and Le Thi (2014).

Finally, with most learning applications, the true distribution of (X, y) is unknown and thus we must deal with only a finite sample. For example, throughout this paper, we assumed that we had N observations. Thus, in this case, we work with empirical estimates of bPOE, the quantile, the superquantile, and misclassification rate of the true distribution. A practical question, therefore, is regarding generalization. Given an optimal classifier by solving the EC-SVM (or equivalently the C-SVM), what can we say about the true rate of misclassification, $P(-y(w^TX+b) > 0)$, or the true value of bPOE, $\bar{p}_z(-y(w^TX+b))$? With regard to misclassification rate, we utilize results from Takeda and Sugiyama (2008); Schölkopf et al. (2000) to show that generalization bounds can be posed in terms of empirical estimates of bPOE, the quantile, and the superquantile, i.e. the information provided by Property 5. With regard to bPOE, we apply the stability arguments of Bousquet and Elisseeff (2002) to provide tight generalization bounds on the true bPOE at any non-positive threshold and show that the SVM parameter, C, plays an important role in these bounds.

10.1 Parameter Selection

10.1.1 Bounds for the Threshold

With the EC-SVM having a parameter interpretable as the bPOE threshold, we use this to select bounds on the admissible range of the parameter C. From (9), we see that for a random variable Z, the only interesting values of the parameter are $-C = z \in [E[Z], \sup Z]$. Finding this range, or a range containing it, can assist in performing grid search for model selection where we are trying to find the best choice of C without unnecessary iterations over meaningless or redundant parameter values (e.g. different parameter values all yielding bPOE equal to 1). First, we consider the EC-SVM with unbiased linear classifier, where $b = 0$. Then, using this result and some geometric intuition, we are able to formulate a similar bound for biased classifiers, where b is a free variable.

Since the EC-SVM is minimizing bPOE of $\frac{-y(w^T X+b)}{\|w\|}$, we know from (9) that the threshold parameter C achieves varying solutions only for

$$-C \in \left[\inf_{w,b} E\left[\frac{-y(w^T X+b)}{\|w\|}\right], \inf_{w,b}\left\{\sup_{X,y}\left(\frac{-y(w^T X+b)}{\|w\|}\right)\right\}\right] .$$

For the case where $b = 0$, we can use simple algebraic arguments to find data dependent upper and lower bounds for this range. First, we have the lower bound,

$$-C \geq \min_w \frac{1}{N}\sum_i \frac{-y_i(w^T X_i)}{\|w\|} \geq -\max_{i,w} \frac{w^T X_i}{\|w\|} = -\max_i \|X_i\|^* .$$

Next, we find an upper bound for this range.

$$-C \leq \min_w \max_i \frac{-y_i(w^T X_i)}{\|w\|} \leq \max_{i,w} \frac{w^T X_i}{\|w\|} = \max_i \|X_i\|^* .$$

Therefore, when the EC-SVM is formulated with unbiased hyperplane $w^T X$, we only need to do a grid search for $-C \in [-\max_i \|X_i\|^*, \max_i \|X_i\|^*]$. Now, consider the case of the biased hyperplane. To find a lower bound of this range, first note, importantly, that by having a biased hyperplane (i.e. by including the b term), we have that the lower bound can be trivially unbounded with $\inf_{w,b} E\left[\frac{-y(w^T X+b)}{\|w\|}\right] = -\infty$. But this is unreasonable since this hyperplane trivially classifies all points as belonging to the same class. We know that any reasonable hyperplane should at least intersect the norm ball supporting the data set, i.e. the norm ball with radius $\max_i \|X_i\|^*$. Therefore, any non-trivial hyperplane should have an expected margin error larger than the margin error of the best classified point. Because the hyperplane at least intersects the norm ball at one point, the best classified point will have margin error no smaller than $-2\max_i \|X_i\|^*$. Therefore, a reasonable lower bound for $-C$ is,

$$-C \geq -2\max_i \|X_i\|^* .$$

For the upper bound, the exact same logic applies but w.r.t. the worst classified point for any hyperplane intersecting the norm ball containing all data points. Therefore, a reasonable upper bound for $-C$ is,

$$-C \leq 2\max_i \|X_i\|^* .$$

Thus, when the EC-SVM is formulated with biased hyperplane $w^T X + b$, we only need to do a grid search for $-C \in [-2\max_i \|X_i\|^*, 2\max_i \|X_i\|^*]$.

10.1.2 Using the Robust Interpretation

For specific situations, one can actually use the RO representation of the EC-SVM to select the proper parameter value. Since the parameter does not change value, along with the optimal (w, b), when moving from formulation (19) to (28) or (19) to (30), we can use the RO interpretation, exactly, to select parameter values for (19).

A situation where this would be ideal is if each data point X_i is given by some measurement and we know the maximum amount by which this measurement can deviate from the true value. Consider the following two dimensional example, where we use some equipment to measure blood pressure $X^{(1)}$ and weight $X^{(2)}$ where $X = [X^{(1)}, X^{(2)}] \in \mathbb{R}^2$. Assume that we know that the equipment to measure blood pressure is off by at most ± 2 and that the equipment to measure weight is off by at most ± 2. In this case, for any specific measurement X_i, we know that a representative uncertainty set would be $\|\delta_i\|_\infty \leq 2$. This immediately implies that $C = 2$ is desirable if one chooses to be *pessimistic* about the uncertainty or that $C = -2$ is desirable if one chooses to be *optimistic* about the uncertainty. Furthermore, this implies that one should use the EC-SVM formulated with the L_1 norm $\|w\|_1$ since its dual norm is the L_∞ norm.

Furthermore, in less idealistic situations when knowledge of the deviation of measurement is not so exact, the same intuition can be used to, at least, select a range of C values for cross validation that is smaller than the interval $[-2\max_i \|X_i\|^*, 2\max_i \|X_i\|^*]$ provided in the previous section.

10.2 Optimization of the EC-SVM

10.2.1 Convex Case

The primal and dual EC-SVM formulated with any general norm and $C \geq 0$ are convex optimization problems and, thus, there are many options for efficient optimization. Essentially, since from the optimization viewpoint the difference between C-SVM and EC-SVM is minor, the complexity of convex EC-SVM is exactly the same as that of C-SVM. For a general norm, due to convexity, gradient methods may be successfully implemented. For particular norms, we may reformulate the problem as a specific type of convex optimization problem to target available solvers. Below, we detail some problem reformulations into Quadratically Constrained Quadratic Programs (QCQP), Second-Order Cone Programs (SOCP), and Linear Programs (LP). If we assume that the norm is the euclidean norm, the EC-SVM with $C \geq 0$ can be written as the convex QCQP,

$$\begin{aligned} \min_{w,b,\xi,t} \quad & \sum_{i=1}^N \xi_i \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) + Ct + 1, \quad \forall i \in \{1,\dots,N\}. \\ & \xi \geq 0 \\ & t^2 \geq w^T w. \end{aligned} \tag{31}$$

Note that if we simply write $t \geq \|w\|_2$, it is a convex SOCP. If the norm is LP representable (e.g. the L_1 or L_∞ norm), the problem can be reformulated as an LP. For example, with the L_1 norm, the EC-SVM with $C \geq 0$ can be written as,

$$\begin{aligned} \min_{w,\hat{w},b,\xi,t} \quad & \sum_{i=1}^{N} \xi_i \\ s.t. \quad & \xi_i \geq -y_i(w^T X_i + b) + Ct + 1, \quad \forall i \in \{1,\ldots,N\}. \\ & \xi \geq 0 \\ & t \geq \sum_{j=1}^{n} \hat{w}_j \\ & \hat{w}_j \geq w_j \\ & \hat{w}_j \geq -w_j. \end{aligned} \tag{32}$$

Note that the convex dual EC-SVM can also be written as a QCQP, SOCP, or LP in a similar manner depending on the choice of norm.

For large-scale problems, though, these reformulations may suffer. For the C-SVM, this issue has garnered much attention. Although we leave in-depth exploration to future work, we note that many techniques used to solve large scale SVM's are directly applicable to the convex EC-SVM. Note that the primal EC-SVM with $C \geq 0$ can be formulated as the following convex, non-smooth optimization problem.

$$\min_{w,b} \sum_{i=1}^{N} [-y_i(w^T X_i + b) + C\|w\| + 1]^+ \tag{33}$$

This formulation lends itself to subgradient methods, particularly stochastic variants which have been shown to work well for large-scale SVMs. In fact, methods mirroring Pegasos Shalev-Shwartz et al. (2011), a solver using a subgradient method which finds an ϵ-accurate solution, with high probability, for the primal C-SVM in runtime $O(\frac{1}{C\epsilon})$, have been successfully applied to large-scale robust SVM's taking a similar form to (33) in Wang et al. (2016).[4] Note, also, that the EC-SVM can be formulated as a decomposable consensus problem which can be solved in a distributed way via the Alternating Direction Method of Multipliers; see Chapter 7 and 8 of Boyd et al. (2011).

10.2.2 Non-Convex Case

For the EC-SVM with $C < 0$, solving for a global optimum is much more difficult. We can, though, solve for a local minimum by using the optimistic RO formulation (30) and implementing the simple, seemingly heuristic, approach of alternating minimization. While this approach was shown to be effective for the T-SVC special case of the EC-SVM presented in Bi and Zhang (2005), we show here that its effectiveness may be explained, on the surface at least, by its connection with DCA. Specifically, we have the following alternating algorithm, where at each step one solves an LP followed by a convex optimization problem:

4. Ignoring some details for simplicity, the robust SVM of similar form is formulated as $\min_{w,b} \sum_i [-y_i(w^T X_i + b) + C\|\Sigma^{\frac{1}{2}} w\| + 1]^+$, where Σ is a particular covariance matrix.

- **Initialize:** Minimize (30) w.r.t. (w, b), fixing $\delta_i = 0$ for all $i = 1, ..., N$. Denote optimal point as (w^*, b^*).
- **Step 1:** Let $\hat{\delta}_i = \underset{\|\delta_i\|^* \leq -C}{\operatorname{argmax}} w^{*T}\delta_i$ for all $i = 1, ..., N$.
- **Step 2:** Minimize (30) w.r.t. (w, b), fixing $\delta_i = \hat{\delta}_i$ for all $i = 1, ..., N$. Denote the optimal point as (w^*, b^*).
- **Step 3:** If iteration limit reached or convergence criteria is satisfied, STOP. Else, return to Step 1.

This algorithm, at worst, seems like a simple heuristic approach to a non-convex problem with intuitive appeal. In Step 1, we start with the data $X+\delta$, which is an optimistic version of the original data X if $\delta \neq 0$. We then find a classifier (w, b) that minimizes bPOE at threshold zero on the optimistic version of the data set. Then, in Step 2, we look for a new, optimistic view of the data that is optimistic w.r.t. the new classifier found in Step 1.

In addition to its intuitive appeal, however, this alternating minimization has theoretical justification. We can show that this alternating minimization algorithm is essentially implementing DCA, a commonly used algorithm for solving DC optimization problems. In short, a DC function h, is such that $h(v) = h_1(v) - h_2(v)$ where h_1, h_2 are both convex. To find a local minimum for the problem $\min_v h(v)$, DCA performs the following steps[5] :

- **Initialize:** $\hat{v} = \underset{v}{\operatorname{argmin}}\ h_1(v)$.
- **Step 1:** Set δ equal to a subgradient of h_2 at $\hat{v}$: $\delta \in \partial h_2(\hat{v})$.
- **Step 2:** Set $\hat{v} = \underset{v}{\operatorname{argmin}}\ h_1(v) - v^T\delta$.
- **Step 3:** If iteration limit reached or convergence criteria is satisfied, STOP. Else, return to Step 1.

Thus, DCA can be seen as first linearizing the concave term at the current solution via a subgradient and then solving a convex subproblem which replaces the concave term with the linear approximation.

To see how the alternating minimization procedure is related to DCA, first notice that when $C < 0$, the function $-y_i(w^T X_i + b) + C\|w\| + 1$ is DC; the sum of the convex function $-y_i(w^T X_i + b) + 1$ and the concave function $C\|w\|$. Therefore, $\sum_i [-y_i(w^T X_i + b) + C\|w\| + 1]^+$ is also DC.[6] Second, notice that $-C\|w\|$ can be viewed as the support function of the convex set $S = \{\delta | \|\delta\|^* \leq -C\}$, meaning that $-C\|w\| = \max_{\delta \in S} w^T\delta$. By the properties of support functions[7] we then know that if $\delta \in \underset{\|\delta\|^* \leq -C}{\operatorname{argmax}} w^T\delta$, then $\delta \in \partial(-C\|w\|)$.

Therefore, we see that we initialize the alternating minimization algorithm by setting the concave part to zero and minimizing the convex part. Then, in Step 1, because of the

5. Note that for brevity, we present a very simplified view of DCA and ignore the underlying duality results which produce this algorithm.
6. This follows from the property that the maximum of DC functions is DC and that the sum of DC functions is DC.
7. See e.g. Chapter 13 of Rockafellar (2015).

properties of the support function, we are equivalently solving for $\hat{\delta}_i \in \partial(-C\|w\|)$. Finally, in Step 2, we linearize the concave part using this subgradient and solve the resulting convex problem. Thus, not only is the alternating minimization algorithm simple, but it is also theoretically appealing with its relation to DCA.

10.3 Generalization of POE and bPOE for SVM Classifiers

In machine learning, particularly in the context of empirical risk minimization, statistical learning theory is a popular tool for analyzing the predictive ability of a learning algorithm $A : S \to \mathcal{F}$ which maps a sample S onto a function $A_S \in \mathcal{F}$, with $\mathcal{F}$ being some class of functions such that the score $A_S(X) \in \mathbb{R}$ is used to predict y given X. For example, in classification, we can consider the prediction of y given X to be $sign\{A_S(X)\}$. Statistical learning theory addresses the fact that the true distribution of (X, y) is usually unknown and we are only given access to a finite sample $S = \{(X_1, y_1), ..., (X_N, y_N)\}$. Thus, if we have, for example, a real valued random loss $V(A_S, (X, y))$ for the output A_S of the learning algorithm trained on S, we need to estimate the true risk

$$\mathcal{R}_{true}(A, S) = E_{X,y}[V(A_S, (X, y))] \,,$$

given only the empirical estimate,

$$\mathcal{R}_{emp}(A, S) = \frac{1}{N} \sum_i V(A_S, (X_i, y_i)) \,.$$

The risk can be viewed as a type of performance metric we would like to minimize, like bPOE or misclassification rate. Given a training algorithm and a training set S, statistical learning theory helps to determine the expected value of the difference $|\mathcal{R}_{true}(A, S) - \mathcal{R}_{emp}(A, S)|$.

In the context of binary classification, we consider two different types of risk (or performance metrics) for the EC-SVM (or equivalently C-SVM) learning algorithm. We first consider the true misclassification rate, which is the typical object of study for classification algorithms in statistical learning theory. Drawing on results from Takeda and Sugiyama (2008), we show that, given a solution to the EC-SVM, the true misclassification rate can be upper bounded by a function of the empirical estimates of bPOE, the superquantile, and the quantile of the random loss $\left(\frac{-y(w^T X+b)}{\|w\|}\right)$. Furthermore, given Property 5, we find that we can state these bounds in terms of the value of the EC-SVM objective function, C, and $\frac{1}{\|w\|}$.

Next, instead of misclassification rate, we consider generalization bounds for the true bPOE of the random loss $\left(\frac{-yw^T X}{\|w\|}\right)$. Using the stability arguments of Bousquet and Elisseeff (2002), given a solution to the EC-SVM or C-SVM, we provide tight upper bounds for the true bPOE at any non-positive threshold. In general, for binary classification, we find that using these stability arguments to bound bPOE is more intuitive than the use of the clipped loss function from Bousquet and Elisseeff (2002). Note that we only consider the unbiased case with $b = 0$, as it is unclear whether this bound holds for the biased case. Furthermore, in Section 10.3.2 we consider only the L_2 norm and in Section 10.3.3 we only consider norms possessing a variant of strong convexity.

In the following sections, given a sample $S = \{(X_1, y_1), ..., (X_N, y_N)\}$, we consider $L(w, b, S)$ to be a discretely distributed random loss with equally probable realizations $\{-y_1(w^T X_1 + b), ..., -y_N(w^T X_N + b)\}$. Therefore, we have that

$$\bar{p}_{-C}\left(\frac{L(w,b,S)}{\|w\|}\right), \bar{q}_\alpha\left(\frac{L(w,b,S)}{\|w\|}\right), \text{ and } q_\alpha\left(\frac{L(w,b,S)}{\|w\|}\right)$$

are empirical estimates of the *true* bPOE, superquantile, and quantile

$$\bar{p}_{-C}\left(\frac{-y(w^T X+b)}{\|w\|}\right), \bar{q}_\alpha\left(\frac{-y(w^T X+b)}{\|w\|}\right), q_\alpha\left(\frac{-y(w^T X+b)}{\|w\|}\right) \,.$$

10.3.1 Generalization of POE

Takeda and Sugiyama (2008) provide bounds on the true misclassification rate of the Eν-SVM classifier. Given the equivalence between the Eν-SVM and EC-SVM provided in Section 7, we can apply these results directly to the EC-SVM. Although these results are pulled directly from Takeda and Sugiyama (2008), hence we do not provide the proofs, we find that we can pose their bounds on the true misclassification rate strictly in terms of the empirical estimates of bPOE, the superquantile, and the quantile of the random loss $\left(\frac{-y(w^T X+b)}{\|w\|_2}\right)$. Furthermore, given Property 5, we find that we can state these bounds in terms of the value of the EC-SVM objective function, C, and $\frac{1}{\|w\|_2}$. Note also that we are able to provide bounds for the non-convex case where $C < 0$.

For the following theorems, let $P_{true} = P\left(-y(w^T X + b) > 0\right)$, i.e. the true misclassification rate for the classifier (w, b), and let

$$G(\tau) = \sqrt{\frac{2}{N}\left(\frac{4k^2(R^2+1)^2}{\tau^2}\log_2(2N) - 1 + \ln\frac{2}{\rho}\right)} \,.$$

Theorem 3 *Suppose that (w, b) is an optimal solution to the EC-SVM trained on sample S, that the optimal objective value divided by sample size N equals $1 - \alpha$, and that either $C > 0$ or $C < 0$ and $-C - \frac{1}{\|w\|_2} < 0$. If the support $\mathcal{X}$ of X is contained in a ball of radius R, then there exists a positive constant k such that the following bound holds with probability at least $1 - \rho$:*

$$P_{true} \le \bar{p}_{-C}\left(\frac{L(w,b,S)}{\|w\|_2}\right) + G\left(q_\alpha\left(\frac{L(w,b,S)}{\|w\|_2}\right)\right) \,.$$

Furthermore, given Property 5, this can be written simply as:

$$P_{true} \le 1 - \alpha + G\left(-C - \frac{1}{\|w\|_2}\right) \,.$$

Theorem 4 *Make the same assumptions as in Theorem 3, but suppose that $C < 0$ and $-C - \frac{1}{\|w\|_2} > 0$. Then there exists a positive constant k such that the following bound holds with probability at least $1 - \rho$:*

$$P_{true} \ge \bar{p}_{-C}\left(\frac{L(w,b,S)}{\|w\|_2}\right) - G\left(q_\alpha\left(\frac{L(w,b,S)}{\|w\|_2}\right)\right) \,.$$

Furthermore, given Property 5, this can be written simply as:

$$P_{true} \geq 1 - \alpha - G\left(-C - \frac{1}{\|w\|_2}\right) .$$

Given these theorems, we see that the EC-SVM is directly minimizing the the lower (or upper) bound on P_{true}, while simultaneously trading off w.r.t. the choice in parameter C.

10.3.2 Generalization of Buffered Probability

Here, we use the stability arguments of Bousquet and Elisseeff (2002) to provide generalization bounds on bPOE for optimal solutions of the C-SVM and convex EC-SVM. We provide tight bounds for bPOE of the normalized loss distribution of the classifier given by an SVM trained on a finite sample. This shows that while the C-SVM and EC-SVM directly minimize bPOE, this statistic does, in fact, generalize to unseen samples.

For brevity, we avoid a full introduction of uniform stability and the associated generalization theorems and refer readers to Bousquet and Elisseeff (2002). Thus, we confine most details to the proof. Theorem 5 considers the C-SVM, but with squared norm, and shows that we can provide tight bounds on the true bPOE of the loss $\left(\frac{-yw^TX}{\|w\|}\right)$ at any non-positive threshold. We present the C-SVM with squared norm in the main theorem, as opposed to the EC-SVM, because the bound expression is much more straightforward. Corollary 1 shows how this result applies to the case of the EC-SVM with L_2 norm.

In general, both bound expressions provide the same intuitive result. The uncertainty regarding the estimate of bPOE will grow as the bPOE threshold considered in the SVM minimization shrinks. As the SVM parameter grows larger, the threshold for the equivalent bPOE minimization problem decreases. Thus, we are considering a growing portion of the tail of the loss distribution in our minimization. This means that the SVM objective function will get larger, but the uncertainty will grow smaller since a larger portion of the tail will be easier to estimate than a smaller portion (it contains more samples). The opposite holds true as the SVM parameter shrinks, getting closer to zero. This implies that we are considering a shrinking portion of the tail of the loss distribution in our minimization. Thus, the SVM objective function will grow smaller, but the uncertainty will grow larger since a smaller portion of the tail will be more difficult to empirically estimate (it contains less samples).

We note that we assume that the classifier is unbiased with $b = 0$ and that the squared norm is differentiable and m-strongly convex w.r.t. itself.[8] For example, the squared L_2 norm is strongly convex w.r.t. itself with $m = 2$. A bias term can be included by concatenating a feature equal to one onto the data, but this would then be included in the regularization norm. It is unclear whether these bounds hold for the truly unbiased case. Although we do not present it, we also point out that this can easily be generalized to consider functions in a Reproducing Kernel Hilbert Space such that the kernel function $K(\cdot,\cdot)$ is bounded with $\sup_{X\in\mathcal{X}} K(X,X) \leq R$, as is done in Bousquet and Elisseeff (2002). For the following proposition, recall that $\bar{p}_{-C}\left(\frac{-yw^TX}{\|w\|}\right)$ denotes the true bPOE while $\bar{p}_{-C}\left(\frac{L(w,S)}{\|w\|}\right)$ denotes empirical bPOE.

8. A differentiable function f is m-strongly convex w.r.t. the norm $\|\cdot\|$ if for any w_1, w_2 we have that $\frac{m}{2}\|w_1 - w_2\|^2 \leq f(w_1) - f(w_2) - \langle \nabla f(w_2), w_1 - w_2\rangle$.

Theorem 5 *Assume that the squared norm $\|\cdot\|^2$ is differentiable and m-strongly convex w.r.t. itself and that $\sup_{x\in\mathcal{X}}\|x\|^* \leq R$, meaning that the support $\mathcal{X}$ of X is contained in a $\|\cdot\|^*$-norm ball of radius R. Assume we solve the C-SVM with squared norm on training set $S = \{(X_1, y_1), ..., (X_N, y_N)\}$, yielding*

$$w_S \in \underset{w}{argmin}\ \frac{1}{N}\sum_i [-y_i w^T X_i + 1]^+ + \lambda\|w\|^2 ,$$

where $\lambda > 0$. Then for any $a, C \geq 0$, with probability $1-\rho$,

$$\bar{p}_{-C}\left(\frac{-yw_S^TX}{\|w_S\|}\right) \leq \frac{1}{N}\sum_i [-y_i a w_S^T X_i + C\|aw_S\| + 1]^+ + \frac{U_{\frac{1}{2}}(a,\lambda,C)\sqrt{\ln\frac{1}{\rho}}}{\sqrt{N}} + \frac{U_1(a,\lambda,C)}{N} ,$$

where $U_{\frac{1}{2}}(a,\lambda,C) = \frac{1}{\sqrt{2}} + \frac{a(R+C)}{\sqrt{2\lambda}}\left(1 + \frac{4R}{m\sqrt{\lambda}}\right)$, $U_1(a,\lambda,C) = \frac{2aR(R+C)}{m\lambda}$. In particular,

$$\bar{p}_{-C}\left(\frac{-yw_S^TX}{\|w_S\|}\right) \leq \bar{p}_{-C}\left(\frac{L(w_S,S)}{\|w_S\|}\right) + \frac{U_{\frac{1}{2}}(\bar{a}_S,\lambda,C)\sqrt{\ln\frac{1}{\rho}}}{\sqrt{N}} + \frac{U_1(\bar{a}_S,\lambda,C)}{N},$$

with probability $1-\rho$, when $\bar{a}_S \in \underset{a\geq 0}{argmin}\ \frac{1}{N}\sum_i [-y_i a w_S^T X_i + C\|aw_S\| + 1]^+$.

Proof Let $V(w,(X,y),a,C) = [-yaw^TX + C\|aw\| + 1]^+$. First, note that, for any $C \geq 0$,

$$\begin{aligned}
\bar{p}_{-C}(\frac{-yw_S^TX}{\|w_S\|}) &= \min_{a\geq 0} E[a\left(\frac{-yw_S^TX}{\|w_S\|} + C\right) + 1]^+ \\
&= \min_{a\geq 0} E[\frac{a}{\|w_S\|}\left(-yw_S^TX + C\|w_S\|\right) + 1]^+ \\
&= \min_{a\geq 0} E[-yaw_S^TX + C\|aw_S\| + 1]^+ \\
&\leq E[V(w_S,(X,y),a,C)] \ , \forall\ a \geq 0 .
\end{aligned}$$

Given any $a \geq 0$, we can upper bound $E[V(w_S,(X,y),a,C)]$ by using stability arguments of Bousquet and Elisseeff (2002).

We first prove that the C-SVM with squared norm is uniformly stable, as defined in Bousquet and Elisseeff (2002), w.r.t. loss function $V(w,(X,y),a,C)$, showing that there exists θ such that for any sample S,

$$\sup_{X,y}|V(w_S,(X,y),a,C) - V(w_{S^j},(X,y),a,C)| \leq \theta$$

where

$$w_S \in \operatorname*{argmin}_w \frac{1}{N}\sum_i [-y_i w^T X_i + 1]^+ + \lambda\|w\|^2$$

$$w_{S^j} \in \operatorname*{argmin}_w \frac{1}{N}\sum_{i\neq j} [-y_i w^T X_i + 1]^+ + \lambda\|w\|^2 .$$

First, note that for any $w_1, w_2 \in \mathbb{R}^n$, $X, y \in \mathcal{X} \times \{-1, 1\}$ we have that

$$\begin{aligned}
|V(w_1,(X,y),a,C) - V(w_2,(X,y),a,C)| &= |[-y(aw_1^TX) + C\|aw_1\| + 1]^+ \\
&\quad - [-y(aw_2^TX) + C\|aw_2\| + 1]^+| \\
&\le |-y(aw_1^TX) + C\|aw_1\| + 1 \\
&\quad - \left(-y(aw_2^TX) + C\|aw_2\| + 1\right)| \\
&= \left|-ya(w_1-w_2)^TX + Ca(\|w_1\| - \|w_2\|)\right| \\
&\le \left|-ya(w_1-w_2)^TX\right| + Ca\,|\|w_1\| - \|w_2\|| \\
&\le \left|-ya(w_1-w_2)^TX\right| + Ca\|w_1 - w_2\| \\
&\le a\left|(w_1-w_2)^TX\right| + Ca\|w_1 - w_2\| \\
&\le \sup_{X\in\mathcal{X}} a\left|(w_1-w_2)^TX\right| + Ca\|w_1 - w_2\| \\
&\le \sup_{\|X\|^*\le R, X\in\mathbb{R}^n} a\left|(w_1-w_2)^TX\right| + Ca\|w_1 - w_2\| \\
&= Ra\|w_1 - w_2\| + Ca\|w_1 - w_2\| \\
&= a(R+C)\|w_1 - w_2\|
\end{aligned}$$

We show now that $\|w_S - w_{S^j}\| \le \frac{R}{mN\lambda}$. Let $d_f, \bar{d}_f$ denote the Bregman divergence and the generalized Bregman divergence of a convex function f with subderivatives at any w denoted as $\nabla f(w) \in \partial f(w)$. (See Appendix F for definition and properties of divergence). Let $g(w) = \|w\|^2$, $h_S(w) = \frac{1}{N}\sum_i [-y_i w^T X_i + 1]^+$, and $h_{S^j}(w) = \frac{1}{N}\sum_{i\neq j}[-y_i w^T X_i + 1]^+$. First, since $g(w)$ is assumed to be m-strongly convex w.r.t. itself, by definition we have $\frac{m}{2}\|w_S - w_{S^j}\|^2 \le d_g(w_S, w_{S^j})$. Next, we have that

$$\begin{aligned}
\lambda m\|w_S - w_{S^j}\|^2 &\le \lambda\left(d_g(w_{S^j}, w_S) + d_g(w_S, w_{S^j})\right) \\
&= d_{\lambda g}(w_{S^j}, w_S) + d_{\lambda g}(w_S, w_{S^j}) \\
\text{(following from (44))} &= \bar{d}_{\lambda g}(w_{S^j}, \nabla\lambda g(w_S)) + \bar{d}_{\lambda g}(w_S, \nabla\lambda g(w_{S^j}))
\end{aligned}$$

Since generalized divergence is linear and non-negative (see Appendix F and (45)), we have for any $\nabla(h_S(w_S) + \lambda g(w_S)) \in \partial(h_S(w_S) + \lambda g(w_S))$ and any $\nabla(h_{S^j}(w_{S^j}) + \lambda g(w_{S^j})) \in \partial(h_{S^j}(w_{S^j}) + \lambda g(w_{S^j}))$, that

$$\begin{aligned}
\bar{d}_{\lambda g}(w_{S^j}, \nabla\lambda g(w_S)) + \bar{d}_{\lambda g}(w_S, \nabla\lambda g(w_{S^j})) &\le \bar{d}_{(h_S+\lambda g)}(w_{S^j}, \nabla(h_S(w_S) + \lambda g(w_S))) \\
&\quad + \bar{d}_{(h_{S^j}+\lambda g)}(w_S, \nabla(h_{S^j}(w_{S^j}) + \lambda g(w_{S^j}))) .
\end{aligned}$$

Now, since $0 \in \partial(h_S(w_S) + \lambda g(w_S))$ and $0 \in \partial(h_{S^j}(w_{S^j}) + \lambda g(w_{S^j}))$, we have

$$\begin{aligned}
\bar{d}_{\lambda g}(w_{S^j}, \nabla\lambda g(w_S)) + \bar{d}_{\lambda g}(w_S, \nabla\lambda g(w_{S^j})) &\le \bar{d}_{(h_S+\lambda g)}(w_{S^j}, 0) + \bar{d}_{(h_{S^j}+\lambda g)}(w_S, 0) \\
\text{(following from (46))} &= h_S(w_{S^j}) + \lambda g(w_{S^j}) - h_S(w_S) - \lambda g(w_S) \\
&\quad + h_{S^j}(w_S) + \lambda g(w_S) - h_{S^j}(w_{S^j}) - \lambda g(w_{S^j}) \\
&= h_S(w_{S^j}) - h_S(w_S) + h_{S^j}(w_S) - h_{S^j}(w_{S^j}) \\
&= \frac{1}{N}\left(V(w_{S^j},(X_j,y_j),1,0) - V(w_S,(X_j,y_j),1,0)\right) \\
&\le \frac{R\|w_{S^j} - w_S\|}{N}
\end{aligned}$$

This then implies that $\|w_S - w_{S^j}\|^2 \le \|w_S - w_{S^j}\|\frac{R}{mN\lambda}$ which further implies that $\|w_S - w_{S^j}\| \le \frac{R}{N\lambda m}$. Together with the previous result, we have that

$$|V(w_S,(X,y),a,C) - V(w_{S^j},(X,y),a,C)| \le a(R+C)\|w_S - w_{S^j}\| \le \frac{aR(R+C)}{N\lambda m} .$$

Thus, the learning algorithm is uniformly θ-stable w.r.t. loss function V with $\theta = \frac{aR(R+C)}{N\lambda m}$.

To apply Theorem 12 of Bousquet and Elisseeff (2002), which gives us the final generalization bound, we need to show that $V(w_S,(X,y),a,C)$ is bounded. To see this, first notice that

$$\lambda\|w_S\|^2 \le h_S(w_S) + \lambda\|w_S\|^2 \le h_S(0) + \lambda\|0\|^2 = \frac{1}{N}\sum_i V(0,(X_i,y_i),1,0) = 1 .$$

Second, combining this with the first result of the proof yields,

$$\begin{aligned}
V(w_S,(X,y),a,C) &\le |V(w_S,(X,y),a,C) - V(0,(X,y),a,C)| + V(0,(X,y),a,C) \\
&\le a(R+C)\|w_S - 0\| + 1 \\
&\le \frac{a(R+C)}{\sqrt{\lambda}} + 1 .
\end{aligned}$$

Thus, applying Theorem 12 of Bousquet and Elisseeff (2002), for any $a \ge 0$ yields the first generalization bound. The second generalization bound follows from the fact that if

$$\bar{a} \in \operatorname*{argmin}_{a\ge 0} \frac{1}{N}\sum_i [-y_i a w_S^T X_i + C\|aw_S\| + 1]^+ ,$$

then,

$$\frac{1}{N}\sum_i [-y_i \bar{a} w_S^T X_i + C\|\bar{a}w_S\| + 1]^+ = \bar{p}_{-C}\left(\frac{L(w_S,S)}{\|w_S\|}\right) .$$

■

Corollary 1 *Make the same assumptions as in Theorem 5, but solve the EC-SVM with* $\|\cdot\| = \|\cdot\|_2$ *and* $\hat{C} > 0$*, which yields,*

$$w_S \in \operatorname*{argmin}_w \frac{1}{N}\sum_i [-y_i(w^TX_i) + 1 + \hat{C}\|w\|_2]^+ .$$

Then, for any $a, C \ge 0$*, with probability* $1-\rho$*,*

$$\bar{p}_{-C}\left(\frac{-yw_S^TX}{\|w_S\|}\right) \le \frac{1}{N}\sum_i [-y_i a\mu w_S^T X_i + C\|a\mu w_S\| + 1]^+ + \frac{U_{\frac{1}{2}}(a,\lambda_S,C)\sqrt{\ln\frac{1}{\rho}}}{\sqrt{N}} + \frac{U_1(a,\lambda_S,C)}{N},$$

where $\lambda_S = \frac{\hat{C}\sum_i \beta_i}{2\|w_S\|_2}$, $\mu = \frac{1}{1+\hat{C}\|w_S\|_2}$, *and* β_i *are the optimal dual variables of the EC-SVM. In particular, when* $\bar{a}_S \in \underset{a\geq 0}{argmin}\ \frac{1}{N}\sum_i [-y_i a\mu w_S^T X_i + C\|a\mu w_S\| + 1]^+$, *with probability* $1-\rho$,

$$\bar{p}_{-C}\left(\frac{-yw_S^T X}{\|w_S\|}\right) \leq \bar{p}_{-C}\left(\frac{L(w_S,S)}{\|w_S\|}\right) + \frac{U_{\frac{1}{2}}(\bar{a}_S,\lambda_S,C)\sqrt{\ln\frac{1}{\rho}}}{\sqrt{N}} + \frac{U_1(\bar{a}_S,\lambda_S,C)}{N}.$$

Proof From Theorem 2, we know that if w is optimal for the EC-SVM with $\hat{C} \geq 0$, then solving the EC-SVM is equivalent to solving the C-SVM with parameter $\hat{C}\sum_i \beta$ and will yield optimal solution μw_S. Furthermore, it is easy to see by looking at the KKT system (34) that if w is optimal for the C-SVM with parameter $\hat{C} \geq 0$, then solving the C-SVM is equivalent to solving the C-SVM with squared norm with parameter $\frac{\hat{C}}{2\|w\|_2}$ and will yield optimal solution w. Therefore, if w_S is optimal for the EC-SVM with $\hat{C} \geq 0$, then solving the EC-SVM is equivalent to solving the C-SVM with squared norm with parameter $\frac{\hat{C}\sum_i \beta_i}{2\|w_S\|_2}$ and will yield optimal solution μw. Thus, we can apply Theorem 5 with $\lambda = \frac{\hat{C}\sum_i \beta_i}{2\|w_S\|_2}$ and μw_S. ■

11. Conclusion

In this paper we have introduced a new SVM formulation called the EC-SVM to help provide theoretical insights into the nature of the C-SVM, soft margin support vector classifier. Much like the Eν-SVM, this new formulation acts as an extension of the C-SVM. The main contribution of this paper, though, is not a new SVM formulation with computational or generalization benefits.

The main contribution of this paper is proof that soft margin support vector classification is equivalent to simple bPOE minimization. Additionally, we show that the C-SVM, EC-SVM, ν-SVM, and Eν-SVM fit nicely into the general framework of superquantile and bPOE minimization problems. This allows us to gain interesting and surprising insights, interpreting soft margin support vector optimization with newly developed statistical tools. For example, we were able to show that the C-parameter of the C-SVM has a statistical interpretation and that the optimal objective value, divided by sample size, equals a probability level.

Additionally, we were able to provide two useful interpretations of the EC-SVM. First, we showed that it can be considered to be a hard-margin optimization problem, showing that the choice of regularization norm implies a metric used to define the margin. Second, we showed that the convex and non-convex case can be interpreted as Robust Optimization problems, with convexity implying pessimistic views of data uncertainty and non-convexity implying optimistic views of data uncertainty.

We also address some practical implications of these theoretical insights. We show that the new interpretations imply that the interesting values of C lie in a limited range. We also suggest methods for solving the convex and non-convex case of the EC-SVM, using the robust interpretation in particular for solving the non-convex case in an efficient and theoretically justifiable way. Finally, we also show that we can provide generalization bounds

for both misclassification rate and bPOE. We provide tight bounds for bPOE of the loss distribution of the classifier given by the C-SVM and EC-SVM trained on a finite sample. This shows that while the C-SVM and EC-SVM minimize bPOE, this statistic does, in fact, generalize to unseen samples.

In the broad scheme, we were able to show that the C-SVM formulation, derived traditionally from geometric intuition, can also be derived from purely statistical tools, with little geometric intuition involved. Specifically, we show that these statistical tools are superquantiles and the related bPOE.

Appendix A. Ineffective Variation of Threshold Levels

In application, it may be desirable that bPOE is minimized for different thresholds $z \in \mathbb{R}$ yielding a selection of optimal distributions $f(w_z^*, X)$, where $w_z^* = \arg\min \bar{p}_z(f(w,X))$ for some chosen value of threshold z. This way, one could do some type of model selection or analysis based upon the behavior of the optimal distribution over different thresholds. In doing so, one would expect to achieve different solutions for different threshold choices. As shown in the following propositions, the naive construction of formulation (12) combined with the positive homogeneity of $f(w,X)$ causes formulation (12) to achieve only two possible optimal solutions.

Proposition 4 and Corollary 2 show that for any threshold $z \leq 0$, formulation (12) becomes equivalent to

$$\min_{w\in\mathbb{R}^n} \quad \bar{p}_0(f(w,X)),$$

effectively yielding the solution for threshold $z = 0$. Proposition 5 shows that for any threshold $z > 0$, formulation (12) yields a trivial solution.

Proposition 4 *If* $f(w,X)$ *is PH w.r.t.* w *and minimizing bPOE at* $z \leq 0$ *yields*

$$1-\alpha^* = \min_{w,\gamma<z} \quad \frac{E[f(w,X)-\gamma]^+}{z-\gamma},$$

with optimal solution vector (w^*,γ^*), *then for any* $a \geq 1$, $\bar{z} = az$ *we have*

$$1-\alpha^* = \min_{w,\gamma<\bar{z}} \quad \frac{E[f(w,X)-\gamma]^+}{\bar{z}-\gamma},$$

with optimal solution vector $(aw^*, a\gamma^*)$.

Proof Assume that for $z \leq 0$,

$$1 - \alpha^* = \min_{w \in \mathbb{R}^n} \quad \bar{p}_z(f(w, X)) = \min_{w \in \mathbb{R}^n, \gamma < z} \quad \frac{E[f(w, X) - \gamma]^+}{z - \gamma} = \frac{E[f(w^*, X) - \gamma^*]^+}{z - \gamma^*}.$$

This means that $\bar{p}_z(f(w^*, X)) \leq \bar{p}_z(f(w, X))$ for every $w \in \mathbb{R}^n$. Now, notice that for $\bar{z} = az$, where $a \geq 1$,

$$\begin{aligned}
\bar{p}_{\bar{z}}(f(aw^*, X)) &= \frac{E[f(aw^*, X) - a\gamma^*]^+}{\bar{z} - a\gamma^*} \\
&= \frac{a}{a} \frac{E[f(w^*, X) - \gamma^*]^+}{z - \gamma^*} \\
&= 1 - \alpha^* \\
&= \bar{p}_z(f(w^*, X)).
\end{aligned}$$

Since $\bar{p}_z(f(w, X))$ is a monotonically decreasing function w.r.t. z, we also know that $\bar{p}_z(f(w^*, X)) \leq \bar{p}_{\bar{z}}(f(w^*, X))$ for every $\bar{z} = az$, $a \geq 1$. Therefore, if $\min_{w \in \mathbb{R}^n} \bar{p}_z(f(w, X)) = 1 - \alpha^*$ at (w^*, γ^*), then for any $\bar{z} = az$, $a \geq 1$ we have that $\min_{w \in \mathbb{R}^n} \bar{p}_{\bar{z}}(f(w, X)) = 1 - \alpha^*$ at $(aw^*, a\gamma^*)$. ■

Corollary 2 *Given Proposition 4, we can say that if $z \leq 0$, then*

$$\min_{w \in \mathbb{R}^n, \gamma < z} \quad \frac{E[f(w, X) - \gamma]^+}{z - \gamma} = \min_{w \in \mathbb{R}^n} \quad \bar{p}_0(f(w, X)).$$

Proof Let (z_n) be a strictly decreasing sequence such that $z_0 < 0$ and $\lim_{n \to \infty} z_n = 0$. Proposition 2 implies that

$$\min_{w \in \mathbb{R}^n} \bar{p}_{z_0}(f(w, X)) = \min_{w \in \mathbb{R}^n} \bar{p}_{z_1}(f(w, X)) = ... = \min_{w \in \mathbb{R}^n} \bar{p}_0(f(w, X)).$$

Intuitively, this corollary simply follows from application of Proposition 2 to any $z < 0$ arbitrarily close to zero. ■

Proposition 5 *If $z > 0$, then*

$$\min_{w \in \mathbb{R}^n, \gamma < z} \quad \frac{E[f(w, X) - \gamma]^+}{z - \gamma} = 0.$$

Proof Objective is a non-negative function. If $z > 0$, then for $\gamma \in (0, z)$ the objective is 0, hence, optimal. ■

Appendix B. Proofs for Theorems 1 and 2

B.1 Theorem 1

Proof To prove Theorem 1, we compare the KKT systems of (1) and (19) formulated with the same general norm, $\|\cdot\|$. We assume that the C-SVM with parameter $\hat{C} \geq 0$ yields optimal primal variables (w^*, b^*, ξ^*) and optimal dual variables (α^*, β^*). Thus, this is the same as assuming that $(w^*, b^*, \xi^*, \alpha^*, \beta^*)$ satisfies the following KKT system of (1):

$$\xi^* \geq 0, \tag{34a}$$
$$\beta^* \geq 0, \tag{34b}$$
$$\alpha^* \geq 0, \tag{34c}$$
$$-\alpha^* - \beta^* + 1 = 0, \tag{34d}$$
$$\xi_i^* \geq -y_i({w^*}^T x_i + b^*) + 1, \tag{34e}$$
$$0 \in -\hat{C}\partial\|w^*\| + \sum_{i=1}^N y_i \beta_i^* x_i, \tag{34f}$$
$$\sum_{i=1}^N -y_i \beta_i^* = 0, \tag{34g}$$
$$\alpha_i^* \xi_i^* = 0 = (1 - \beta_i^*)\xi_i^*, \tag{34h}$$
$$\beta_i^* \left[-y_i({w^*}^T x_i + b^*) + 1 - \xi_i^*\right] = 0. \tag{34i}$$

Now, we show that with $\mu = \frac{\sum_{i=1}^N \beta_i^*}{\sum_{i=1}^N \beta_i^* - \hat{C}\|w^*\|}$, the variables $(\mu w^*, \mu b^*, \mu \xi^*, \alpha^*, \beta^*)$ satisfy the KKT system of (19). We then show that indeed $\mu > 0$ when the data set is not linearly separable. The KKT system of (19) formulated with parameter $C \geq 0$ is as follows:

$$\xi \geq 0, \tag{35a}$$
$$\beta \geq 0, \tag{35b}$$
$$\alpha \geq 0, \tag{35c}$$
$$-\alpha - \beta + 1 = 0, \tag{35d}$$
$$\xi_i \geq -y_i(w^T x_i + b) + 1 + C\|w\|, \tag{35e}$$
$$0 \in -C\partial\|w\| \sum_{i=1}^N \beta_i + \sum_{i=1}^N y_i \beta_i x_i, \tag{35f}$$
$$\sum_{i=1}^N -y_i \beta_i = 0, \tag{35g}$$
$$\alpha_i \xi_i = 0 = (1 - \beta_i)\xi_i, \tag{35h}$$
$$\beta_i \left[-y_i(w^T x_i + b) + 1 + C\|w\| - \xi_i\right] = 0. \tag{35i}$$

When now show that $\left(w = \mu w^*, b = \mu b^*, \xi = \mu \xi^*, \alpha = \alpha^*, \beta = \beta^*, C = \frac{\hat{C}}{\sum_{i=1}^N \beta_i^*}\right)$ satisfy all of these conditions and is thus a solution to the KKT system (35).

1. $\xi \geq 0$: True, since $\xi = \mu\xi^*$, $\xi^* \geq 0$, $\mu \geq 0$.
2. $\beta \geq 0$: True, since $\beta = \beta^* \geq 0$.
3. $\alpha \geq 0$: True, since $\alpha = \alpha^*$.
4. $-\alpha - \beta + 1 = 0$: True, since $-\alpha - \beta + 1 = -\alpha^* - \beta^* + 1 = 0$.
5. $\xi_i \geq -y_i(w^T x_i + b) + 1 + C\|w\| \longrightarrow \mu\xi_i^* \geq -y_i(w^{*T}x_i + b^*)\mu + 1 + \mu C\|w^*\|$
   $\longrightarrow \xi^* \geq -y_i(w^{*T}x_i + b^*) + \left(\frac{1}{\mu} + C\|w^*\|\right) = -y_i(w^{*T}x_i + b^*)$
   $+\left(1 - \frac{\hat{C}}{\sum_{i=1}^N \beta^*}\|w^*\| + \frac{\hat{C}}{\sum_{i=1}^N \beta^*}\|w^*\|\right) = -y_i(w^{*T}x_i + b^*) + 1$: True, following from (34e).
6. $0 \in -C\partial\|w\| \sum_{i=1}^N \beta_i + \sum_{i=1}^N y_i\beta_i x_i$: True, following from
   $C\partial\|w\| \sum_{i=1}^N \beta_i = \hat{C}\partial\|\mu w^*\| = \hat{C}\partial\|w^*\|$, $\sum_{i=1}^N y_i\beta_i x_i = \sum_{i=1}^N y_i\beta_i^* x_i$, and (34f).
7. $\sum_{i=1}^N -y_i\beta_i = 0$: True, since $\beta = \beta^*$ and (34g).
8. $\alpha_i\xi_i = 0$: True, since $\alpha = \alpha^*$, $\xi = \mu\xi^*$, $\mu > 0$, and (34h).
9. $\beta_i\left[-y_i(w^T x_i + b) + 1 + C\|w\| - \xi_i\right] = 0 \iff \beta_i\xi_i = -\beta_i y_i(w^T x_i + b) + \beta_i + \beta_i C\|w\|$.
   Notice then that (35h) $\implies \beta_i\xi_i = \xi_i$. This gives us $\xi_i = \mu\xi^* = -\mu\beta_i^* y_i(w^{*T}x_i + b^*) + \beta_i^* + \beta_i^* C\|\mu w^*\| = \beta_i^* + \beta_i^* \frac{\hat{C}\mu}{\sum_{i=1}^N \beta_i^*}\|w^*\| + \mu\left[\xi_i^* - \beta_i^*\right]$ where $-\mu\beta_i^* y_i(w^{*T}x_i + b^*) = \mu\left[\xi_i^* - \beta_i^*\right]$ is implied by (35i). Furthermore, notice that this last equality is true $\iff$ $\beta_i^*\left[1 + \frac{\hat{C}\mu}{\sum_{i=1}^N \beta_i^*}\|w^*\| - \mu\right] = 0 \iff 1 + \frac{\hat{C}\|w^*\|}{\sum_{i=1}^N \beta_i^* - \hat{C}\|w^*\|} - \frac{\sum_{i=1}^N \beta_i^*}{\sum_{i=1}^N \beta_i^* - \hat{C}\|w^*\|} = 0$. Clearly, the last equality is true.

Now we show that for non-linearly separable data sets, $\mu > 0$. We use the KKT system (34) to form the dual via the Lagrangian. We then show that $\sum_{i=1}^N \beta_i^* > \hat{C}\|w^*\|$, which proves that $\mu > 0$.

We first have that the Lagrangian of (1) is the following:

$$L(w, b, \xi, \alpha, \beta) = \hat{C}\|w\| + \sum_{i=1}^N \xi_i + \sum_{i=1}^N \beta_i\left[-y_i(w^T x_i + b) + 1 - \xi_i\right] - \sum_{i=1}^N \alpha_i\xi_i$$

Using (34d,g), we can then simplify, also maximizing w.r.t. the dual variables and minimizing w.r.t. the primal variables, to form the following dual. Here, the constraints are implied by (34d,g).

$$\begin{aligned} \max_{\beta} \quad & \sum_{i=1}^N \beta_i + \left(\inf_{w,b} \hat{C}\|w\| + \sum_{i=1}^N \beta_i\left[-y_i(w^T x_i + b)\right]\right) \\ s.t. \quad & 0 \leq \beta \leq 1. \\ & \sum_{i=1}^N y_i\beta_i = 0. \end{aligned} \tag{36}$$

Notice that since $w = 0, b = 0$ is a feasible solution, we know that

$$\inf_{w,b} \quad \hat{C}\|w\| + \sum_{i=1}^N \beta_i\left[-y_i(w^T x_i + b)\right] \leq 0.$$

Finally, noting that with the optimal variables assumed to be $(w^*, b^*, \xi^*, \alpha^*, \beta^*)$, we see that

$$\sum_{i=1}^N \beta_i^* + \left(\inf_{w,b} \quad \hat{C}\|w\| + \sum_{i=1}^N \beta_i^*\left[-y_i(w^T x_i + b)\right]\right) = \hat{C}\|w^*\| + \sum_{i=1}^N \xi^*.$$

But since the data set is not linearly separable $\sum_{i=1}^N \xi^* > 0$. This implies that $\sum_{i=1}^N \beta_i^* > \hat{C}\|w^*\|$, which shows that $\mu = \frac{\sum_{i=1}^N \beta_i^*}{\sum_{i=1}^N \beta_i^* - \hat{C}\|w^*\|} > 0$. ■

B.2 Theorem 2

Proof To prove Theorem 2, we compare the KKT systems of (1) and (19) formulated with the same general norm, $\|\cdot\|$. We assume that the EC-SVM with parameter $C \geq 0$ yields optimal primal variables (w^*, b^*, ξ^*) and optimal dual variables (α^*, β^*). Thus, this is the same as assuming that $(w^*, b^*, \xi^*, \alpha^*, \beta^*)$ satisfies the following KKT system of (19):

$$\xi^* \geq 0, \tag{37a}$$
$$\beta^* \geq 0, \tag{37b}$$
$$\alpha^* \geq 0, \tag{37c}$$
$$-\alpha^* - \beta^* + 1 = 0, \tag{37d}$$
$$\xi_i^* \geq -y_i(w^{*T}x_i + b^*) + 1 + C\|w^*\|, \tag{37e}$$
$$0 \in -C\partial\|w^*\| \sum_{i=1}^N \beta_i^* + \sum_{i=1}^N y_i\beta_i^* x_i, \tag{37f}$$
$$\sum_{i=1}^N -y_i\beta_i^* = 0, \tag{37g}$$
$$\alpha_i^*\xi_i^* = 0 = (1 - \beta_i^*)\xi_i^*, \tag{37h}$$
$$\beta_i^*\left[-y_i(w^{*T}x_i + b^*) + 1 + C\|w^*\| - \xi_i^*\right] = 0. \tag{37i}$$

Now, we show that with $\mu = \frac{1}{1 + C\|w^*\|} > 0$, the variables $(\mu w^*, \mu b^*, \mu\xi^*, \alpha^*, \beta^*)$ satisfy the KKT system of (1). We then show that indeed $\mu > 0$ when the data set is not linearly

separable. The KKT system of (1) formulated with parameter $\hat{C} \geq 0$ is as follows:

$$\xi \geq 0, \tag{38a}$$
$$\beta \geq 0, \tag{38b}$$
$$\alpha \geq 0, \tag{38c}$$
$$-\alpha - \beta + 1 = 0, \tag{38d}$$
$$\xi_i \geq -y_i(w^T x_i + b) + 1, \tag{38e}$$
$$0 \in -\hat{C}\partial\|w\| + \sum_{i=1}^{N} y_i \beta_i x_i, \tag{38f}$$
$$\sum_{i=1}^{N} -y_i \beta_i = 0, \tag{38g}$$
$$\alpha_i \xi_i = 0 = (1 - \beta_i)\xi_i, \tag{38h}$$
$$\beta_i \left[-y_i(w^T x_i + b) + 1 - \xi_i\right] = 0. \tag{38i}$$

When now show, one by one, that $(w = \mu w^*, b = \mu b^*, \xi = \mu\xi^*, \alpha = \alpha^*, \beta = \beta^*, \hat{C} = C\sum_{i=1}^{N} \beta_i^*)$ satisfy all of these conditions and is thus a solution to the KKT system (38):

1. $\xi \geq 0$: True, since $\xi = \mu\xi^*$, $\xi^* \geq 0$, $\mu \geq 0$.
2. $\beta \geq 0$: True, since $\beta = \beta^* \geq 0$.
3. $\alpha \geq 0$: True, since $\alpha = \alpha^*$.
4. $-\alpha - \beta + 1 = 0$: True, since $-\alpha - \beta + 1 = -\alpha^* - \beta^* + 1 = 0$.
5. $\xi_i \geq -y_i(w^T x_i + b) + 1 \longrightarrow \mu\xi_i^* \geq -y_i(w^{*T} x_i + b^*)\mu + 1 \iff \xi^* \geq -y_i(w^{*T} x_i + b^*) + (1 + C\|w^*\|)$: True, following from (37e).
6. $0 \in -\hat{C}\partial\|w^*\| + \sum_{i=1}^{N} y_i\beta_i x_i$: True, following from $\hat{C}\partial\|w^*\| = C\partial\|w\| \sum_{i=1}^{N} \beta_i$, $\sum_{i=1}^{N} y_i\beta_i x_i = \sum_{i=1}^{N} y_i\beta_i^* x_i$, and (37f).
7. $\sum_{i=1}^{N} -y_i\beta_i = 0$: True, since $\beta = \beta^*$ and (37g).
8. $\alpha_i\xi_i = 0$: True, since $\alpha = \alpha^*$, $\xi = \mu\xi^*$, $\mu > 0$, and (37h).
9. $\beta_i \left[-y_i(w^T x_i + b) + 1 - \xi_i\right] = \beta_i^* \left[-\mu y_i(w^{*T} x_i + b^*) + 1 - \mu\xi_i^*\right] = \beta_i^* + \frac{\beta_i^*\left(-y_i(w^{*T} x_i + b^*) - \xi_i^*\right)}{1 + C\|w^*\|} = 0 \iff \beta_i^* \left[-y_i(w^{*T} x_i + b^*) + 1 + C\|w^*\| - \xi_i^*\right] = 0$, which is True, following from (37i).

Now we point out that $\mu > 0$. This follows immediately from the assumption that $C \geq 0$ and the fact that $\|w^*\| \geq 0$. ■

Appendix C. Derivation of EC-SVM Dual Formulation

The dual of the EC-SVM is formulated as follows, via the Lagrangian:

$$\begin{aligned}
&\max_{\substack{\alpha \geq 0 \\ \beta \geq 0}} \min_{w,b} \quad \sum_{i=1}^{N} \xi_i + \sum_{i=1}^{N} \beta_i \left[-y_i(w^T x_i + b) + 1 - \xi_i + C\|w\|\right] - \sum_{i=1}^{N} \alpha_i \xi_i \\
&= \max_{\substack{0 \leq \beta \leq 1 \\ \sum_{i=1}^{N} \beta_i y_i = 0}} \quad \sum_{i=1}^{N} \beta_i + \left[\min_{w} \quad C\|w\| \sum_{i=1}^{N} \beta_i + \sum_{i=1}^{N} -\beta_i y_i w^T x_i\right] \\
&= \max_{\substack{0 \leq \beta \leq 1 \\ \sum_{i=1}^{N} \beta_i y_i = 0}} \quad \sum_{i=1}^{N} \beta_i + \left[\min_{w \neq 0, a \geq 0} \quad aC \sum_{i=1}^{N} \beta_i + \frac{a\sum_{i=1}^{N} -\beta_i y_i w^T x_i}{\|w\|}\right] \\
&= \max_{\substack{0 \leq \beta \leq 1 \\ \sum_{i=1}^{N} \beta_i y_i = 0}} \quad \sum_{i=1}^{N} \beta_i + \left[\min_{a \geq 0} \quad aC \sum_{i=1}^{N} \beta_i + a \min_{w \neq 0} \frac{\sum_{i=1}^{N} -\beta_i y_i w^T x_i}{\|w\|}\right] \\
&= \max_{\substack{0 \leq \beta \leq 1 \\ \sum_{i=1}^{N} \beta_i y_i = 0}} \quad \sum_{i=1}^{N} \beta_i + \left[\min_{a \geq 0} aC \sum_{i=1}^{N} \beta_i - a \min_{w \neq 0} \quad \frac{\sum_{i=1}^{N} \beta_i y_i w^T x_i}{\| - w\|}\right] \\
&= \max_{\substack{0 \leq \beta \leq 1 \\ \sum_{i=1}^{N} \beta_i y_i = 0}} \quad \sum_{i=1}^{N} \beta_i + \left[\min_{a \geq 0} \quad aC \sum_{i=1}^{N} \beta_i - a \left\|\sum_{i=1}^{N} -\beta_i y_i x_i\right\|^*\right] \\
&\quad = \max_{\beta} \quad \sum_{i=1}^{N} \beta_i \\
&\qquad s.t. \quad \left\|\sum_{i=1}^{N} \beta_i y_i x_i\right\|^* \leq C \sum_{i=1}^{N} \beta_i, \\
&\qquad\qquad \sum_{i=1}^{N} \beta_i y_i = 0, \\
&\qquad\qquad 0 \leq \beta_i \leq 1, \quad \forall i \in \{1, \ldots, N\}.
\end{aligned}$$

Appendix D. Derivation of C-SVM Dual Formulation

The dual of the C-SVM is formulated as follows, via the Lagrangian:

$$
\begin{aligned}
&\max_{\substack{\alpha\geq 0\\ \beta\geq 0}} \quad \min_{w,b} \quad \sum_{i=1}^{N}\xi_i + C\|w\| + \sum_{i=1}^{N}\beta_i\left[-y_i(w^Tx_i+b)+1-\xi_i\right] - \sum_{i=1}^{N}\alpha_i\xi_i \\
&= \max_{\substack{0\leq\beta\leq 1\\ \sum_{i=1}^N\beta_iy_i=0}} \quad \sum_{i=1}^{N}\beta_i + \left[\min_{w} \quad C\|w\| + \sum_{i=1}^{N}-\beta_iy_iw^Tx_i\right] \\
&= \max_{\substack{0\leq\beta\leq 1\\ \sum_{i=1}^N\beta_iy_i=0}} \quad \sum_{i=1}^{N}\beta_i + \left[\min_{w\neq 0,a\geq 0} \quad aC + \frac{a\sum_{i=1}^{N}-\beta_iy_iw^Tx_i}{\|w\|}\right] \\
&= \max_{\substack{0\leq\beta\leq 1\\ \sum_{i=1}^N\beta_iy_i=0}} \quad \sum_{i=1}^{N}\beta_i + \left[\min_{a\geq 0} \quad aC + a\min_{w\neq 0}\frac{\sum_{i=1}^{N}-\beta_iy_iw^Tx_i}{\|w\|}\right] \\
&= \max_{\substack{0\leq\beta\leq 1\\ \sum_{i=1}^N\beta_iy_i=0}} \quad \sum_{i=1}^{N}\beta_i + \left[\min_{a\geq 0} \quad aC - a\min_{w\neq 0}\frac{\sum_{i=1}^{N}\beta_iy_iw^Tx_i}{\|-w\|}\right] \\
&= \max_{\substack{0\leq\beta\leq 1\\ \sum_{i=1}^N\beta_iy_i=0}} \quad \sum_{i=1}^{N}\beta_i + \left[\min_{a\geq 0} \quad aC - a\left\|\sum_{i=1}^{N}-\beta_iy_ix_i\right\|^*\right] \\
&= \max_{\beta} \quad \sum_{i=1}^{N}\beta_i \\
&\qquad s.t. \quad \left\|\sum_{i=1}^{N}\beta_iy_ix_i\right\|^* \leq C, \\
&\qquad\qquad \sum_{i=1}^{N}\beta_iy_i = 0, \\
&\qquad\qquad 0\leq\beta_i\leq 1, \quad \forall i\in\{1,\ldots,N\}.
\end{aligned}
$$

Appendix E. Derivation of Formula (21)

To see how we derive (21), we begin with formula (14) with $f(w,X) = -y(w^TX+b)$ and $z=-C$:

$$
\begin{aligned}
\min_{\gamma<-C,w,b} \quad & \sum_{i=1}^{n}\left[\frac{-y_i(w^TX_i+b)}{-C-\gamma} - \frac{\gamma}{-C-\gamma}\right]^+ \\
s.t. \quad & \|w\| = 1.
\end{aligned} \tag{39}
$$

We then make the change of variable $w_{new} = \frac{w}{C}, b_{new} = \frac{b}{C}$. Note then that

$$
\begin{aligned}
\frac{-y_i(w^TX_i+b)}{-C-\gamma} &= C\frac{-y_i(w_{new}^TX_i+b_{new})}{-C-\gamma} \\
&= \frac{-y_i(w_{new}^TX_i+b_{new})}{\|w_{new}\|(-C-\gamma)}.
\end{aligned}
$$

Plugging this and the new variables into (41), we get:

$$
\begin{aligned}
\min_{\gamma<-C,w_{new},b_{new}} \quad & \sum_{i=1}^{n}\left[\frac{-y_i(w_{new}^TX_i+b_{new})}{\|w_{new}\|(-C-\gamma)} - \frac{\gamma}{-C-\gamma}\right]^+ \\
s.t. \quad & \|w_{new}\| = \frac{1}{C}.
\end{aligned} \tag{40}
$$

Finally, note that

$$
\begin{aligned}
\frac{1}{\|w_{new}\|(-C-\gamma)} + 1 &= \frac{1+\|w_{new}\|(-C-\gamma)}{\|w_{new}\|(-C-\gamma)} \\
&= \frac{1+(-1-\frac{\gamma}{C})}{(-1-\frac{\gamma}{C})} \\
&= \frac{-\gamma}{C}\left(\frac{C}{-C-\gamma}\right) \\
&= \frac{-\gamma}{-C-\gamma}.
\end{aligned}
$$

Plugging this into (40), we finally arrive at

$$
\begin{aligned}
\min_{\gamma<-C,w_{new},b_{new}} \quad & \sum_{i=1}^{n}\left[\left(\frac{1}{-C-\gamma}\right)\left(\frac{-y_i(w_{new}^TX_i+b_{new})+1}{\|w_{new}\|}\right)+1\right]^+ \\
s.t. \quad & \frac{1}{\|w_{new}\|} = C.
\end{aligned} \tag{41}
$$

Appendix F. Bregman Divergence

For a convex function $f:\mathbb{R}^n\to\mathbb{R}$, let $\partial f(w)$ denote the set of subderivatives $\nabla f(w)\in\partial f(w)$ at a point $w\in\mathbb{R}^n$. For a differentiable, convex f the Bregman Divergence at $w_1,w_2\in\mathbb{R}^n$ is defined as

$$
d_f(w_1,w_2) = f(w_1) - f(w_2) - \langle\nabla f(w_2), w_1-w_2\rangle\ . \tag{42}
$$

Since f is differentiable, $\nabla f(w)$ is the unique subderivative, and thus the divergence is well defined. If f is convex, but not differentiable, $\nabla f(w)$ may not be unique. In this case, however, following Appendix C of Bousquet and Elisseeff (2002), we can define a generalized Bregman Divergence. Letting the function $f^*(a) = \sup_w\langle w,a\rangle - f(w)$ denote the conjugate of f, we define the generalized Bregman Divergence at $w_1, a\in\mathbb{R}^n$ as,

$$
\bar{d}_f(w_1,a) = f(w_1) + f^*(a) - \langle w_1,a\rangle\ . \tag{43}
$$

As it relates to the normal Bregman Divergence, it is easy to check that for convex differentiable f,

$$d_f(w_1, w_2) = \bar{d}_f(w_1, \nabla f(w_2)) \; . \tag{44}$$

which follows from the property that

$$a \in \partial f(w) \iff f^*(a) = \langle a, w \rangle - f(w) \; .$$

As for its other properties, first note that the generalized divergence is non-negative. Second, notice that we have linearity, such that if $f = g + h$, for convex functions g, h, and we choose subderivatives of f, g, h satisfying $\nabla f(w_2) = \nabla g(w_2) + \nabla h(w_2)$, then

$$\bar{d}_f(w_1, \nabla f(w_2)) = \bar{d}_g(w_1, \nabla g(w_2)) + \bar{d}_h(w_1, \nabla h(w_2) \; . \tag{45}$$

To see this, we simply need to expand the right hand side in the following manner, where we use the fact that $a \in \partial f(w) \iff f^*(a) = \langle a, w \rangle - f(w)$ in the third and fifth equality.

$$\begin{aligned}
\bar{d}_f(w_1, \nabla f(w_2)) &= \bar{d}_{(g+h)}(w_1, \nabla(g+h)(w_2)) \\
&= (g+h)(w_1) + (g+h)^*(\nabla(g+h)(w_2)) - \langle w_1, \nabla(g+h)(w_2) \rangle \\
&= [(g+h)(w_1) - \langle w_1, \nabla(g+h)(w_2) \rangle] + \langle w_2, \nabla(g+h)(w_2) \rangle - (g+h)(w_2) \\
&= [(g+h)(w_1) - \langle w_1, \nabla(g+h)(w_2) \rangle] + (\langle w_2, \nabla g(w_2) \rangle - g(w_2)) \\
&\qquad + (\langle w_2, \nabla h(w_2) \rangle - h(w_2)) \\
&= [(g+h)(w_1) - \langle w_1, \nabla(g+h)(w_2) \rangle] + g^*(\nabla g(w_2)) + h^*(\nabla h(w_2)) \\
&= (g(w_1) + g^*(\nabla g(w_2)) - \langle w_1, \nabla g(w_2) \rangle) \\
&\qquad + (h(w_1) + h^*(\nabla h(w_2)) - \langle w_1, \nabla h(w_2) \rangle) \\
&= \bar{d}_g(w_1, \nabla g(w_2)) + \bar{d}_h(w_1, \nabla h(w_2) \; .
\end{aligned}$$

Finally, assume that w_f is a minimizer of f, meaning that $0 \in \partial f(w_f)$. Then, we have for any w_1,

$$\bar{d}_f(w_1, 0) = f(w_1) - f(w_f) \; . \tag{46}$$

Abstract

Approximate inference in high-dimensional, discrete probabilistic models is a central problem in computational statistics and machine learning. This paper describes discrete particle variational inference (DPVI), a new approach that combines key strengths of Monte Carlo, variational and search-based techniques. DPVI is based on a novel family of particle-based variational approximations that can be fit using simple, fast, deterministic search techniques. Like Monte Carlo, DPVI can handle multiple modes, and yields exact results in a well-defined limit. Like unstructured mean-field, DPVI is based on optimizing a lower bound on the partition function; when this quantity is not of intrinsic interest, it facilitates convergence assessment and debugging. Like both Monte Carlo and combinatorial search, DPVI can take advantage of factorization, sequential structure, and custom search operators. This paper defines DPVI particle-based approximation family and partition function lower bounds, along with the sequential DPVI and local DPVI algorithm templates for optimizing them. DPVI is illustrated and evaluated via experiments on lattice Markov Random Fields, nonparametric Bayesian mixtures and block-models, and parametric as well as non-parametric hidden Markov models. Results include applications to real-world spike-sorting and relational modeling problems, and show that DPVI can offer appealing time/accuracy trade-offs as compared to multiple alternatives.

Keywords: Bayesian inference, variational methods, Dirichlet process mixture model, Ising model, hidden Markov model, infinite relational model

1. Introduction

Probabilistic models defined over large collections of discrete random variables have arisen in multiple fields. Examples include hidden Markov models for sequential data; Bayesian networks; mixture models for tabular and relational data; and discrete Markov random field models, which have become popular in fields ranging from computer vision to information extraction. These models are typically specified in terms of a probability distribution $P(x)$ defined over a collection of variables $x = \{x_n\}$ occupying points in an underlying discrete space $\mathcal{X}$. One key approximate inference problem that arises in many applications is identifying high-probability configurations of the discrete variables.

Most approximate inference algorithms fall into two classes: Monte Carlo methods and variational methods. Monte Carlo methods generate samples from approximations to the posterior distribution that grow more accurate as the technique is given more compute time. The flexibility and simplicity of Monte Carlo methods have made them the workhorse of statistical computation (Robert and Casella, 2004). There are two basic approaches to Monte Carlo inference for discrete probabilistic models. The first, Markov chain Monte Carlo methods, work by running a Markov chain with transition operator T whose equilibrium distribution asymptotically approaches $P(x)$—that is, $T^k P_0(x) \approx P(x)$ for any initial distribution on states $P_0(x)$. The second, sequential Monte Carlo methods, build up a sample from a distribution that approximates $P(x)$ by sampling from a sequence of more tractable distributions, typically defined over subspaces of $\mathcal{X}$. However, their accuracy is difficult to measure, and the amount of computation required for satisfactory accuracy can be prohibitive in practice.

Variational methods (Wainwright and Jordan, 2008) treat probabilistic inference as an optimization problem over a set of distributions. This set is typically constrained (e.g., to factorized conjugate exponential distributions), thereby attaining efficiency at the expense of bias. In particular, variational methods tend to converge quickly and supply an easily monitored objective function (unlike Monte Carlo methods). However, for complex discrete models, the bias induced by variational approximations can sometimes lead to poor predictive performance. For example, consider a discrete probabilistic model where two binary variables x_1 and x_2 are constrained to take the same value, i.e. $P(x_1, x_2) = 0$ if $x_1 \neq x_2$. All the probability mass is on the states $x_1 = x_2 = 0$ and $x_1 = x_2 = 1$. In "mean-field" variational inference, this distribution might be approximated as $Q_{\theta_1}(x_1)Q_{\theta_2}(x_2)$, with θ_1 and θ_2 representing coin weights that used to model x_1 and x_2 as independent Bernoulli distributions. This family of variational approximations to $P(x_1, x_2)$ cannot capture the true distribution, and in fact cannot qualitatively capture the simple constraint that $x_1 = x_2$. These limitations prompted the development of more sophisticated approximations (e.g., Bouchard-Côté and Jordan, 2009; Jaakkola and Jordan, 1998), but these incur additional computational cost and can be difficult or impossible to apply to a given problem.

This paper introduces a new approximate inference method, called *discrete particle variational inference* (DPVI), that aims to combine key strengths of both Monte Carlo and variational inference. The key insight in DPVI is to use a weighted collection of samples—the kind of "particle approximation" output by Monte Carlo methods—as the approximating family for variational inference. Suppose we got to pick where to place the particles in the hypothesis space; where would we put them? Intuitively, we would want to distribute them in such a way that they cover high probability regions of the target distribution, but without the particles all devolving onto the mode of the distribution. This problem can be formulated precisely within the framework of variational inference. We derive a coordinate

ascent update for particle approximations that iteratively minimizes the Kullback-Leibler (KL) divergence between the particle approximation and the target distribution.

In DPVI, the location of the particles become the parameters of the approximating family. This simple choice has appealing consequences. Like Monte Carlo, DPVI can handle problems where the posterior has multiple modes, and yields exact results in a well-defined limit (as the number of particles goes to infinity). Like standard mean-field variational methods, DPVI is based on optimizing a lower bound on the partition function; when this quantity is not of intrinsic interest, it facilitates convergence assessment and debugging. Like both Monte Carlo and combinatorial search, DPVI can take advantage of factorization, sequential structure, and custom search operators.

The rest of the paper is organized as follows. After introducing our general framework, we describe how it can be applied to filtering and smoothing problems. We then show experimentally that variational particle approximations can overcome a number of problems that are challenging for conventional Monte Carlo methods. In particular, our approach is able to produce a diverse, high probability set of particles in situations where Monte Carlo and mean-field variational methods sometimes degenerate.

2. Background

Consider the problem of approximating a probability distribution $P(x)$ over discrete latent variables $x = \{x_1, \ldots, x_N\}, x_n \in \{1, \ldots, M_n\}$, where the target distribution is known only up to a normalizing constant Z: $P(x) = f(x)/Z$. We will refer to $f(x) \geq 0$ as the *score* of x and Z as the *partition function*. We further assume that $P(x)$ is a Markov network defined on a graph G, so that $f(x)$ factorizes according to:

$$f(x) = \prod_c f_c(x_c), \tag{1}$$

where $c \subseteq \{1, \ldots, N\}$ indexes the maximal cliques of G.

2.1 Importance sampling and sequential Monte Carlo

A general way to approximate $P(x)$ is with a weighted collection of K particles, $\{x^1, \ldots, x^K\}$:

$$P(x) \approx Q(x) = \sum_{k=1}^{K} w^k \delta[x, x^k], \tag{2}$$

where $x^k = \{x_1^k, \ldots, x_N^k\}, x_n^k \in \{1, \ldots, M_n\}$ and $\delta[\cdot, \cdot] = 1$ if its arguments are equal and 0 otherwise. Importance sampling is a Monte Carlo method that stochastically generates particles from a proposal distribution, $x^k \sim \phi(\cdot)$, and computes the weight according to $w^k \propto f(x^k)/\phi(x^k)$. Importance sampling has the property that the particle approximation converges to the target distribution as $K \to \infty$ (Robert and Casella, 2004).

Sequential Monte Carlo methods such as particle filtering (Doucet et al., 2001) apply importance sampling to stochastic dynamical systems (where n indexes time) by sequentially sampling the latent variables at each time point using a proposal distribution $\phi(x_n|x_{n-1})$. This procedure can produce conditionally low probability particles; therefore, most algorithms include a resampling step which replicates high probability particles and kills off

low probability particles. The downside of resampling is that it can produce degeneracy: the particles become concentrated on a small number of hypotheses, and consequently the effective number of particles is low.

2.2 Variational Inference

Variational methods (Wainwright and Jordan, 2008) define a parametrized family of probability distributions $\mathcal{Q}$ and then choose $Q \in \mathcal{Q}$ that maximizes the *negative variational free energy*:

$$\mathcal{L}[Q] = \sum_x Q(x) \log \frac{f(x)}{Q(x)}. \tag{3}$$

The negative variational free energy is related to the partition function Z and the KL divergence through the following identity:

$$\log Z = \mathrm{KL}[Q||P] + \mathcal{L}[Q], \tag{4}$$

where

$$\mathrm{KL}[Q||P] = \sum_x Q(x) \log \frac{Q(x)}{P(x)}. \tag{5}$$

Since $\mathrm{KL}[Q||P] \geq 0$, the negative variational free energy is a lower bound on the log partition function, achieving equality when the KL divergence is minimized to 0. Maximizing $\mathcal{L}[Q]$ with respect to Q is thus equivalent to minimizing the KL divergence between Q and P.

Unlike the Monte Carlo methods described in the previous section, variational methods do not in general converge to the target distribution, since typically P is not in $\mathcal{Q}$. The advantage of variational methods is that they guarantee an improved bound after each iteration, and convergence is easy to monitor (unlike most Monte Carlo methods). In practice, variational methods are also often more computationally efficient.

We next consider particle approximations from the perspective of variational inference. We then turn to the application of particle approximations to inference in stochastic dynamical systems.

3. Variational Particle Approximations

Variational inference can be connected to Monte Carlo methods by viewing the particles as a set of variational parameters parameterizing Q. For the particle approximation defined in Eq. 2, the negative variational free energy takes the following form:

$$\mathcal{L}[Q] = \sum_{k=1}^{K} w^k \log \frac{f(x^k)}{w^k V^k}, \tag{6}$$

where $V^k = \sum_{j=1}^{K} \delta[x^j, x^k]$ is the number of times an identical replica of x^k appears in the particle set. We wish to find the set of K particles and their associated weights that maximize $\mathcal{L}[Q]$, subject to the constraint that $\sum_{k=1}^{K} w^k = 1$. This constraint can be implemented

by defining a new functional with Lagrange multiplier λ:

$$\tilde{\mathcal{L}}[Q] = \mathcal{L}[Q] + \lambda\left(\sum_{k=1}^{K} w^k - 1\right). \tag{7}$$

Taking the functional derivative of the Lagrangian with respect to w^k and equating to zero, we obtain:

$$\begin{aligned}\frac{\partial\tilde{\mathcal{L}}[Q]}{\partial w^k} &= \log f(x^k) - \log w^k - \log V^k + \lambda - 1 = 0\\ &\implies w^k = Z_Q^{-1} f(x^k)/V^k,\end{aligned} \tag{8}$$

where

$$Z_Q = \exp(\lambda - 1)^{-1} = \sum_{k=1}^{K} \frac{f(x^k)}{V^k}. \tag{9}$$

We can plug the above result back into the definition of $\mathcal{L}[Q]$:

$$\begin{aligned}\mathcal{L}[Q] &= Z_Q^{-1}\sum_{k=1}^{K}\frac{f(x^k)}{V^k}\log\frac{f(x^k)V^k}{Z_Q^{-1}f(x^k)V^k}\\ &= Z_Q^{-1}\sum_{k=1}^{K}\frac{f(x^k)}{V^k}\log Z_Q\\ &= \log Z_Q.\end{aligned} \tag{10}$$

Thus, $\mathcal{L}[Q]$ is maximized by choosing the K values of x with the highest score. The following theorem shows that allowing $V^k > 1$ (i.e., having replica particles) can never improve the bound.

Theorem 1 *Let Q and Q' denote two particle approximations, where Q consists of unique particles ($V_Q^k = 1$ for all k) and Q' is identical to Q except that particle $x_{Q'}^j$ is replicated $V_{Q'}^j$ times (displacing $V_{Q'}^j$ other particles with cumulative score F). For any choice of particles, $\mathcal{L}[Q] \geq \mathcal{L}[Q']$.*

Proof We first apply Jensen's inequality to obtain an upper bound on $\mathcal{L}[Q']$:

$$\mathcal{L}[Q'] \leq \log\sum_{k=1}^{K} w_{Q'}^k Z_{Q'} = \log\sum_{k=1}^{K}\frac{f(x_{Q'}^k)}{V_{Q'}^k}. \tag{11}$$

Since $\mathcal{L}[Q] = \log Z_Q$, we wish to show that $Z_Q \geq \sum_{k=1}^{K}\frac{f(x_{Q'}^k)}{V_{Q'}^k}$. All the particles in Q and Q' are identical except for the $V_{Q'}^j$ particles in Q that were displaced by replicas of $x_{Q'}^j$ in Q'; thus we only need to establish that $f(x_{Q'}^j) + F \geq \frac{V_{Q'}^j f(x_{Q'}^j)}{V_{Q'}^j} = f(x_{Q'}^j)$, where the left hand side of the inequality is the change in negative variational free energy after the replication

of particles. Since the score $f(x)$ can never be negative, the cumulative score F can also never be negative ($F \geq 0$) and the inequality holds for any choice of particles. ■

The variational bound can be optimized by coordinate ascent, as specified in Algorithm 1, which we refer to as *discrete particle variational inference* (DPVI). This algorithm takes advantage of the fact that when optimizing the bound with respect to a single variable, only potentials local to that variable need to be computed. In particular, let $\tilde{x}^k$ be a replica of x^k with a single-variable modification, $\tilde{x}_n^k = m$. We can compute the unnormalized probability of this particle efficiently using the following equation:

$$f(\tilde{x}^k) = f(x^k)\frac{\mathcal{F}_n(\tilde{x}^k)}{\mathcal{F}_n(x^k)}, \tag{12}$$

where $\mathcal{F}_n(x) = \prod_{c:n\in c} f_c(x_c)$. The variational bound for the modified particle can then be computed using Eq. 10. Particles can be initialized arbitrarily. When repeatedly iterated, DPVI will converge to a local maximum of the negative variational free energy.[1] Note that in principle more sophisticated methods can be used to find the top K modes (e.g., Flerova et al., 2012; Yanover and Weiss, 2003); however, we have found that this coordinate ascent algorithm is fast, easy to implement, and very effective in practice (as our experiments below demonstrate).

An important aspect of this framework is that it maintains one of the same asymptotic guarantees as importance sampling: Q converges to P as $K \to \infty$, since in this limit DPVI is equivalent to exact inference. Thus, DPVI combines advantages of variational methods (monotonically decreasing KL divergence between Q and P) with the asymptotic correctness of Monte Carlo methods. It is important to note that asymptotic correctness might be useless in practice unless something is known about the convergence rate. This issue is not unique to DPVI; it also applies to Monte Carlo and variational methods. For certain Markov chain Monte Carlo (MCMC) samplers, it can be shown that the chain converges to the posterior at a geometric rate (Mengersen et al., 1996; Meyn and Tweedie, 1993). A small amount of work has investigated convergence properties of variational methods for specific models (Hall et al., 2011; Wang et al., 2006), but in general the issue of convergence rate for variational methods is an open question.

The asymptotic complexity of DPVI in the sequential setting is $O(SNK)$ where S is the maximum support size of the latent variables. For the iterative update of the particles the complexity is $O(TCSK)$, where T is the maximum number of iterations until convergence and C is the maximum clique size. In our experiments, we empirically observed that we only need a small number of iterations and particles in order to outperform our baselines.

1. Naturally, initialization affects performance, since the objective function has local optima. For example, if the posterior is multimodal and none of the particles are initialized near the dominant mode, then the particle approximation will likely miss a significant portion of the probability mass. Studying the effects of initialization is an important practical challenge for the application of DPVI. In our experiments, we report averages across multiple random initializations.

Algorithm 1 Discrete particle variational inference

/*N is the number of latent variables */

4. Filtering and Smoothing in Hidden Markov Models

We now describe how variational particle approximations can be applied to filtering and smoothing in hidden Markov models (HMMs). Consider a hidden Markov model with observations $y = \{y_1, \ldots, y_N\}$ generated by the following stochastic process:

$$P(y, x, \theta) = P(\theta) \prod_n P(y_n|x_n, \theta) P(x_n|x_{n-1}, \theta), \tag{13}$$

where θ is a set of transition and emission parameters. We are particularly interested in *marginalized* HMMs where the parameters are integrated out: $P(y, x) = \int_\theta P(y, x, \theta) d\theta$. This induces dependencies between observation n and all previous observations, making inference challenging.

Filtering is the problem of computing the posterior over the latent variables at time n given the history $y_{1:n}$. To construct the variational particle approximation of the filtering distribution, we need to compute the product of potentials for variable n:

$$\mathcal{F}_n(x) = P(y_n|x_{1:n}, y_{1:n-1}) P(x_n|x_{1:n-1}). \tag{14}$$

Recall from the previous section that $\mathcal{F}_n(x)$ is the joint probability of the maximal cliques to which x_n belongs. We can then apply the coordinate ascent update described in the previous section. This update is simplified in the filtering context due to the underlying Markov structure. Specifically, Eq. 12 is given by:

$$f(\tilde{x}^k) = f(x^k) P(y_n|x_n^k = m, x_{1:n-1}^k, y_{1:n-1}) P(x_n^k = m|x_{1:n-1}^k). \tag{15}$$

At each time step, the algorithm selects the K continuations (new variable assignments of the current particle set) that maximize the negative variational free energy.

Smoothing is the problem of computing the posterior over the latent variables at time n given data from both the past and the future, $y_{1:N}$. The product of potentials is given by:

$$\mathcal{F}_n(x) = P(y_n|x_{1:n}, y_{-n}) P(x_n|x_{-n}), \tag{16}$$

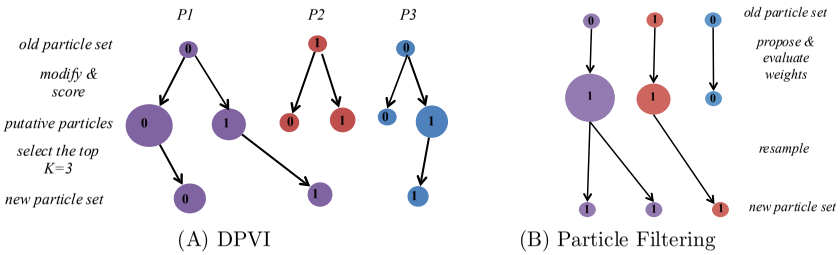
where x_{-n} refers to all the latent variables except x_n (and likewise for y_{-n}). This potential can be plugged into the updates described in the previous section.

To understand DPVI applied to filtering problems, it is helpful to contemplate three possible fates for a particle at time n (illustrated in Figure 1):

- **Selection**: A single continuation of particle k has non-zero weight. This can be seen as a deterministic version of particle filtering, where the sampling operation is replaced with a max operation.
- **Splitting**: Multiple continuations of particle k have non-zero weight. In this case, the particle is split into multiple particles at the next iteration.
- **Deletion**: No continuations of particle k have non-zero weight. In this case, the particle is deleted from the particle set.

Similar to particle filtering with resampling, DPVI deletes and propagates particles based on their probability. However, as we show later, DPVI is able to escape some of the problems associated with resampling.

5. Related Work



DPVI is related to several other ideas in the statistics literature:

- DPVI is a special case of a *mixture mean-field variational approximation* (Jaakkola and Jordan, 1998; Lawrence, 2000):

$$Q(x) = \sum_{k=1}^K Q(k) \prod_{n=1}^N Q(x_n|k). \tag{17}$$

  In DPVI, $Q(k) = w^k$ and $Q(x_n|k) = \delta[x_n, x_n^k]$. From the simple restriction that the component distributions must be delta functions, we derived a new algorithm that is simpler and more efficient than mixture mean-field (which requires separate updates for the mixture weights), while sacrificing some of its expressivity. Another distinct advantage of DPVI is that the variational updates do not require the additional lower bound used in general mixture mean-field, due to the intractability of the mean-field updates.

- When $K = 1$, DPVI is equivalent to *iterated conditional modes* (ICM; Besag, 1986), which iteratively maximizes each latent variable conditional on the rest of the variables. This algorithm is simple to implement, efficient (relative to variational and Monte Carlo algorithms), and has been successfully applied to computer vision tasks

(A) DPVI (B) Particle Filtering

Figure 1: Schematic of DPVI versus particle filtering for filtering problems. Illustration of different filtering scenarios over 2 time steps in a binary state space with $K = 3$ particles. The number in each circle indicates the binary value of the corresponding variable. Arrows indicate the evolution of the particles. (A) DPVI: The size of the putative particles represents the score of the particle. The K continuations with highest score are selected for propagation to the next time step. The size of the new particle set corresponds to the normalized score. Particle $P1$ is split, $P2$ is deleted and one putative particle from $P3$ is selected. (B) Particle filtering: The size of the node represents the weight of the particle for the resampling step.

such as reconstruction and segmentation of Markov random fields. However, the algorithm is susceptible to local optima without the aid of relaxation techniques like simulated annealing (Greig et al., 1989).

- DPVI is conceptually similar to nonparametric variational inference (Gershman et al., 2012), which approximates the posterior over a continuous state space using a set of particles convolved with a Gaussian kernel (see Miller et al., 2016, for more sophisticated extensions of this idea). This approach was shown to be effective for probabilistic models that lack the conjugate-exponential structure required for exact mean-field inference. Because nonparametric variational inference approximates continuous densities, it is inapplicable to the discrete problems considered here.

- Frank et al. (2009) used particle approximations within a variational message passing algorithm. The resulting approximation is "local" in the sense that the particles are used to approximate messages passed between nodes in a factor graph, in contrast to the "global" approximation produced by DPVI, which attempts to capture the distribution over the entire set of variables. It is an interesting question for future research to understand what classes of probabilistic models are better approximated using local vs. global approaches.

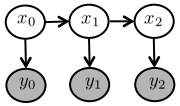
- Ionides (2008) described a truncated version of importance sampling in which weights falling below some threshold are set to the threshold value. Ionides (2008) showed that truncation reduced sensitivity to the proposal distribution and derived optimal

truncations as a function of the number of samples. This is similar (though not equivalent) to the DPVI setting where latent variables are sampled exhaustively and without replacement.

- Schniter et al. (2008) described an approximate inference algorithm, *fast Bayesian matching pursuit*, which can be viewed as a special case of DPVI applied to Gaussian mixture models.

- In Jones et al. (2005), a *shotgun stochastic search* algorithm is suggested, which proposes local changes to the latent variables with probability proportional to the unnormalized posterior. While this method of evaluating local changes is similar to our coordinate algorithm for the DPVI objective, it is important to note that DPVI is not a stochastic search algorithm (unless $K = 1$): It maintains a collection of particles in order to approximate the posterior distribution, which is important for applications that require a representation of uncertainty.

- Finally, DPVI is closely related to the problem of finding the K most probable latent variable assignments (Flerova et al., 2012; Yanover and Weiss, 2003). We view this problem through the lens of particle approximations, connecting it to both Monte Carlo and variational methods. The techniques developed for finding the K-best assignments could be fruitfully applied to optimizing the DPVI objective function.



Our experimental strategy is to compare DPVI with popular algorithms that have similar computational complexity, which is why we focus on particle filtering, Gibbs sampling and mean-field approximations. Although mixture mean-field will by definition lead to a better approximation, its computational complexity is considerably greater, which may explain why it is has never achieved the popularity of standard mean-field approaches. Some of the approaches listed above are not applicable to the discrete setting (nonparametric variational inference and fast Bayesian matching pursuit), and some are point estimators instead of true probabilistic approximations (iterated conditional modes and shotgun stochastic search).

6. Experiments

In this section, we compare the performance of DPVI to several widely used approximate inference algorithms, including particle filtering, Gibbs sampling and variational methods. We first present a didactic example to illustrate how DPVI can sometimes succeed where particle filtering fails. We then apply DPVI to four popular but intractable probabilistic models: the Dirichlet process mixture model (DPMM; Antoniak, 1974; Escobar and West, 1995), the infinite HMM (iHMM; Beal et al., 2002; Teh et al., 2006), the infinite relational model (IRM; Kemp et al., 2006) and the Ising model.

(A)

DPVI	Monte Carlo	Mean-Field
$Q(x) = \sum_{k=1}^{K} w^k \prod_{n=1}^{N} \delta[x_n, x_n^k]$	$Q(x) = \frac{1}{K} \sum_{k=1}^{K} \prod_{n=1}^{N} \delta[\hat{x}_n, \hat{x}_n^k]$	$Q(x) = \prod_{n=1}^{N} Q(x_n)$

(B)

DPVI		Monte Carlo	Mean-Field
State Seq. $[x_0, x_1, x_2]$	Weight	State Seq. $[x_0, x_1, x_2]$	Mean-Field Parameters
[0,0,0]	0.15	[1,0,1]	$Q(x_0 = 0) = 0.4$
[0,1,1]	0.03	[1,1,1]	$Q(x_1 = 0) = 0.63$
[1,1,1]	0.32	[1,1,1]	$Q(x_2 = 0) = 0.15$
[1,0,0]	0.15	[1,1,1]	
[1,0,1]	0.35	[1,0,1]	
$Pr(x_0 = 1, x_1 = 0, x_2 = 1\|y) \approx 0.35$		$Pr(x_0 = 1, x_1 = 0, x_2 = 1\|y) \approx 0.4$	$Pr(x_0 = 1, x_1 = 0, x_2 = 1\|y) \approx 0.32$

Figure 2: Comparison of approximate inference schemes. (A) Approximating families for DPVI, Monte Carlo and mean-field. (B) Approximating the posterior probability of a sequence $(x_0 = 1, x_1 = 0, x_2 = 1)$ for the above 3 schemes on a binary HMM. Given the weights for different sequences in DPVI the posterior probability is the weight corresponding to that sequence. For Monte Carlo approximation, the posterior can be approximated from the normalized counts of sampled $(x_0 = 1, x_1 = 0, x_2 = 1)$ sequences. Finally, for the mean-field approximation, we have $Pr(x_0 = 1, x_1 = 0, x_2 = 1|y) = Q(x_0 = 1)Q(x_1 = 0)Q(x_2 = 1)$.

6.1 Didactic Example: Binary HMM

As a didactic example, we use a simple HMM with binary hidden states (x) and observations (y):

$$\begin{aligned} P(x_{n+1} = 0|x_n = 0) &= \alpha_0 \\ P(x_{n+1} = 1|x_n = 1) &= \alpha_1 \\ P(y_n = 0|x_n = 0) &= \beta_0 \\ P(y_n = 1|x_n = 1) &= \beta_1, \end{aligned} \tag{18}$$

with α_0, α_1, β_0, and β_1 all less than 0.5. Constraining the parameters to be less than 0.5 makes some sequences more likely; approximating the posterior using a particle filter (with resampling) may result in capturing only these sequences. We will use this model to illustrate how DPVI differs from particle filtering. Figure 2 compares several inference schemes for this model.

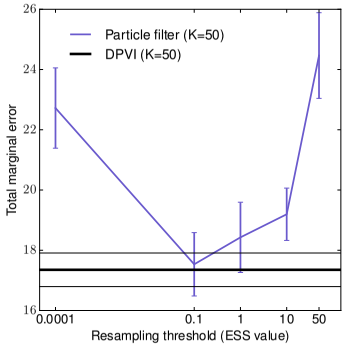


Figure 3: HMM with binary hidden states and observations. Total marginal error computed for a sequence of length 200. For particle filtering the total error for every ESS value is averaged over 5 sequences generated from the HMM; in addition, for each sequence we reran the particle filter 5 times (thus 25 runs total). Note the logarithmic scale of the x-axis. Error bars and the thin black lines correspond to standard error of the mean.

For illustration, we use the following parameters: $\alpha_0 = 0.2$, $\alpha_1 = 0.1$, $\beta_0 = 0.3$, and $\beta_1 = 0.2$. Suppose you observe a sequence generated from this model. For a sufficiently long sequence, a particle filter with resampling will eventually delete most conditionally unlikely particles, due to the fact that there is some probability on each step that any given unlikely particle will be deleted. The particle filter will thus suffer from degeneracy for long sequences. On the other hand, without resampling the approximation will degrade over time because conditionally unlikely particles are never replaced by better particles. For this reason, it is sometimes suggested that resampling only be performed when the effective sample size (ESS) falls below some threshold.

The ESS is calculated as $\text{ESS} = \frac{1}{\sum_{k=1}^{K}(w^k)^2}$. A low ESS means that most of the weight is being placed on a small number of particles, and hence the approximation may be degenerate (although in some cases this may mean that the target distribution is peaky). We evaluated particle filtering with multinomial resampling on synthetic data generated from the HMM described above. Approximation accuracy was measured by using the forward-backward algorithm to compute the hidden state posterior marginals exactly and then comparing these marginals to the particle approximation. Figure 3 shows performance as a function of ESS threshold, demonstrating that there is a fairly narrow range of thresholds for which performance is good. Thus in practice, successful applications of particle filtering may require computationally expensive tuning of this threshold.

In contrast, DPVI achieves performance comparable to the optimal particle filter, but without a tunable threshold. This occurs because DPVI uses an implicit threshold that

is automatically tuned to the problem. Instead of resampling particles, DPVI deletes or propagates particles deterministically based on their relative contribution to the variational bound. We can always incrementally add particles, unlike tuning the threshold. So although K can be viewed as a tuning parameter, we can adapt it with relatively little expense, monotonically increasing the approximation quality in a way that can be easily quantified.

6.2 Dirichlet Process Mixture Model

A DPMM generates data from the following process (Antoniak, 1974; Escobar and West, 1995):

$$G \sim \mathrm{DP}(\alpha, G_0), \qquad \theta_n | G \sim G, \qquad y_n | \theta_n \sim F(\theta_n),$$

where $\alpha \geq 0$ is a concentration parameter and G_0 is a base distribution over the parameter θ_n of the observation distribution $F(y_n|\theta_n)$. Since the Dirichlet process induces clustering of the parameters θ into K distinct values, we can equivalently express this model in terms of a distribution over cluster assignments, $x_n \in \{1, \ldots, C\}$. The distribution over x is given by the Chinese restaurant process (Aldous, 1985):

$$P(x_n = c | x_{1:n-1}) \propto \begin{cases} t_c & \text{if } k \leq C_+ \\ \alpha & \text{if } c = C_+ + 1, \end{cases} \tag{19}$$

where t_c is the number of data points prior to n assigned to cluster c and C_+ is the number of clusters for which $t_c > 0$.

6.2.1 Synthetic Data

We first demonstrate our approach on synthetic data sets drawn from various mixtures of bivariate Gaussians (see Table 1). The model parameters for each simulated data set were chosen to create a spectrum of increasingly overlapping clusters. In particular, we constructed models out of the following building blocks:

$$\mu_1 = \begin{pmatrix} 0.0, & 0.0 \end{pmatrix}, \qquad \mu_2 = \begin{pmatrix} 0.5, & 0.5 \end{pmatrix}$$
$$\Sigma_1 = \begin{pmatrix} 0.25, & 0.0 \\ 0.0, & 0.25 \end{pmatrix}, \qquad \Sigma_2 = \begin{pmatrix} 0.5, & 0.0 \\ 0.0, & 0.5 \end{pmatrix}.$$

For the DPMM, we used a Normal likelihood with a Normal-Inverse-Gamma prior on the component parameters:

$$y_{nd} | x_n = k \sim \mathcal{N}(m_{kd}, \sigma^2_{kd}), \qquad m_{kd} \sim \mathcal{N}(0, \sigma^2_{kd}/\tau), \qquad \sigma^2_{kd} \sim \mathrm{IG}(a, b), \tag{20}$$

where $d \in \{1, 2\}$ indexes observation dimensions and $\mathrm{IG}(a, b)$ denotes the Inverse Gamma distribution with shape a and scale b. We used the following hyperparameter values: $\tau = 25, a = 1, b = 1, \alpha = 0.5$.

Clustering accuracy was measured quantitatively using V-measure (Rosenberg and Hirschberg, 2007). V-measure is an entropy-based measure which explicitly measures how successfully the criteria of homogeneity and completeness have been satisfied. Figure 4 graphically demonstrates the discovery of latent clusters for both DPVI as well as particle filtering. As

Data set	PF ($K = 20$)	MF	DPVI ($K = 1$)	DPVI ($K = 20$)

Table 1: Clustering accuracy (V-Measure) for DPMM. Each data set consisted of 200 points drawn from a mixture of 3 Gaussians. For each data set, we repeated the experiment 150 times by iterating through random seeds, reporting mean and standard error. The left column shows the ground truth mean for each cluster and the covariance matrix (shared across clusters). PF denotes particle filtering and MF denotes mean-field.

Number of particles	**DPVI**	**Particle Filtering**
$K = 10$	15.20s	14.71s
$K = 50$	153.75s	184.17s
$K = 100$	567.84s	699.43s

Table 2: Run time comparison for DPMM with synthetic data using data set from Table 1. The run time of DPVI is slightly better than particle filtering for a single pass through the data set.

shown in Table 1, we observe only marginal improvements when the means are farthest from each other and variances are small, as these parameters leads to well-separated clusters in the training set. However, the relative accuracy of DPVI increases considerably when the clusters are overlapping, either due to the fact that the means are close to each other or the variances are high. One factor contributing to greater performance of DPVI might be the diversity term in the variational formulation.

An interesting special case is when $K = 1$. In this case, DPVI is equivalent to the greedy algorithm proposed by Daume (2007) and later extended by Wang and Dunson (2011). In fact, this algorithm was independently proposed in cognitive psychology by Anderson (1991). As shown in Table 1, DPVI with 20 particles outperforms the greedy algorithm, as well as particle filtering with 20 particles. We also demonstrate the run-time performance of DPVI compared to particle filtering in Table 2. It can be seen in our experiments that DPVI tends to be comparable to particle filtering or sometimes more efficient in terms of run-time for the same task, although the theoretical complexity is the same.

6.2.2 Spike Sorting

Spike sorting is an important problem in experimental neuroscience settings where researchers collect large amounts of electrophysiological data from multi-channel tetrodes.

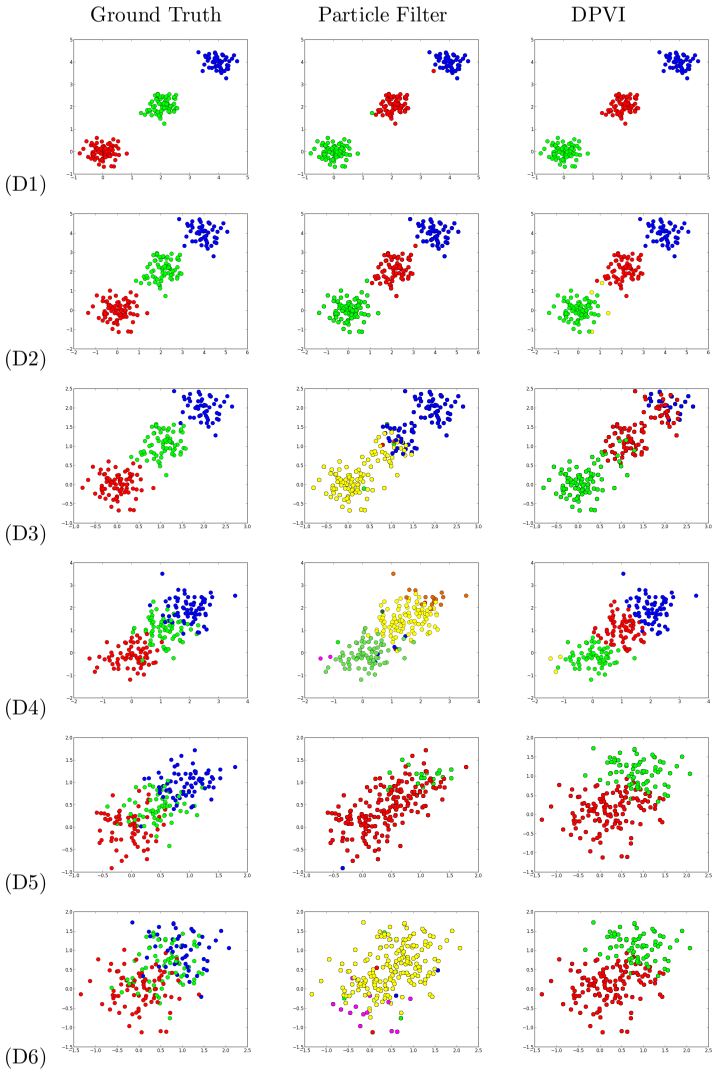

Figure 4: DPMM clustering of synthetic data sets. We treat DPMM as a filtering problem, analyzing one randomly chosen data point at a time. Colors indicate cluster assignments. Each row corresponds to one synthetic data set; refer to Table 1 for corresponding quantitative results. Column 1: Ground truth; Column 2: particle filtering; Column 3: DPVI. The DPVI filter scales similarly to the particle filter but does not underfit as severely.

The goal is to extract from noisy spike recordings attributes such as the number of neurons, and cluster spikes belonging to the same neuron. This problem naturally motivates the use of DPMM, since the number of neurons recorded by a single tetrode is unknown. Previously, Wood and Black (2008) applied the DPMM to spike sorting using particle filtering and Gibbs sampling. Here we show that DPVI can outperform particle filtering, achieving high accuracy even with a small number of particles.

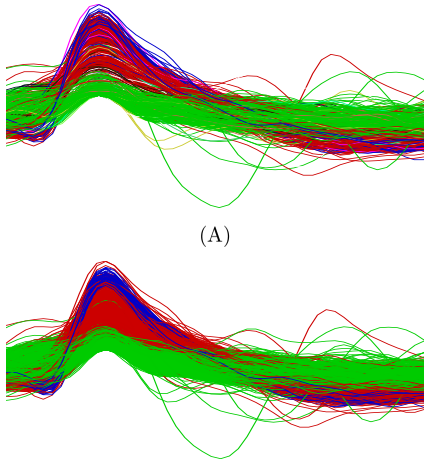
We used data collected from a multiunit recording from a human epileptic patient (Quiroga et al., 2004). The raw spike recordings were preprocessed following the procedure proposed by Quiroga et al. (2004), though we note that our inference algorithm is agnostic to the choice of preprocessing. The original data consist of an input vector with $D = 10$ dimensions and 9196 data points. Following Wood and Black (2008), we used a Normal likelihood with a Normal-Inverse-Wishart prior on the component parameters:

$$\mathbf{y}_n|x_n = k \sim \mathcal{N}(\mathbf{m}_k, \Lambda_k), \qquad \mathbf{m}_k \sim \mathcal{N}(0, \Lambda_k/\tau), \qquad \Lambda_k \sim \mathrm{IW}(\Lambda_0, \nu), \tag{21}$$

where $\mathrm{IW}(\Lambda_0, \nu)$ denotes the Inverse Wishart distribution with degrees of freedom ν and scale matrix Λ_0. We used the following hyperparameter values: $\nu = D + 1, \Lambda_0 = \mathbf{I}, \tau = 0.01, \alpha = 0.1$.

We compared our algorithm to the current best particle filtering baseline, which uses stratified resampling (Wood and Black, 2008; Fearnhead, 2004). The same model parameters were used for all comparisons. Qualitative results, shown in Figure 5B, demonstrate that DPVI is better able to separate the spike waveforms into distinct clusters, despite running DPVI with 10 particles and particle filtering with 100 particles. We also provide quantitative results by calculating the held-out log-likelihood on an independent test set of spike waveforms. The quantitative results (summarized in Table 5C) demonstrate that even with only 10 particles DPVI can outperform particle filtering with 1000 particles.

6.3 Infinite HMM



An iHMM generates data from the following process (Teh et al., 2006):

$$G_0 \sim \mathrm{DP}(\gamma, H), \qquad G_k|G_0 \sim \mathrm{DP}(\alpha, G_0),$$
$$x_n|x_{n-1} \sim G_{x_{n-1}}, \qquad \theta_k \sim H, \qquad y_n|x_n \sim F(\theta_{x_n}).$$

Like the DPMM, the iHMM induces a sequence of cluster assignments. The distribution over cluster assignments is given by the Chinese restaurant franchise (Teh et al., 2006). Letting t_{jc} denote the number of times cluster j transitioned to cluster c, x_n is assigned to cluster c with probability proportional to $t_{x_{n-1}c}$, or to a cluster never visited from x_{n-1} ($t_{x_{n-1}c} = 0$) with probability proportional to α. If an unvisited cluster is selected, x_n is assigned to cluster c with probability proportional to $\sum_j t_{jc}$, or to a new cluster (i.e., one never visited from any state, $\sum_j t_{jc} = 0$) with probability proportional to γ.

6.3.1 Synthetic Data

We generated 50 sequences with length 500 from 50 different HMMs, each with 10 hidden and 5 observed states. For the rows of the transition and initial probability matrices of the

Figure 6: Infinite HMM on the synthetic data set. (A) Results on 500 synthetic data points generated from an HMM with 10 hidden states. Error is the Hamming distance between the true hidden sequence and the sampled sequence, averaged over 50 data sets. M: multinomial resampling; S: stratified resampling. Lower bound is the expected Hamming distance between data-generating distribution and ground truth. Upper bound is the expected Hamming distance between uniform distribution and ground truth. (B) Run time comparison for the synthetic iHMM data set. We denote particle filtering method by PF.

HMMs we used a symmetric Dirichlet prior with concentration parameter 0.1; for the emission probability matrix, we used a symmetric Dirichlet prior with concentration parameter 10.

Figure 6A illustrates the performance of DPVI and particle filtering (with multinomial and stratified resampling) for varying numbers of particles ($K = 1, 10, 100$). Performance error was quantified by computing the Hamming distance between the true hidden sequence and the sampled sequence. The Munkres algorithm was used to maximize the overlap between the two sequences. The results show that DPVI outperforms particle filtering in all three cases.

When the data consist of long sequences, resampling at every step will produce degeneracy in particle filtering; this tends to result in a smaller number of clusters relative to DPVI. The superior accuracy of DPVI suggests that a larger number of clusters is necessary to capture the latent structure of the data. Not surprisingly, this leads to longer run times (Figurets 6B), but it is important to note that particle filtering and DPVI have comparable per-cluster time complexity.

(B)

Figure 7: Infinite HMM for the text analysis task. (A) Predictive log-likelihood for the Alice in Wonderland data set. (B) Results using the "Alice in Wonderland" data set. The maximum number of inferred clusters is $\hat{C} = 147$ for DPVI ($K = 100$) and $\hat{C} = 21$ for particle filter ($K = 100$). As expected, the per cluster runtime of the two methods are comparable.

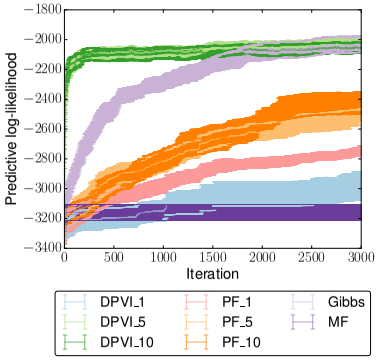
6.3.2 Text Analysis

We next analyzed a real-world data set, text taken from the beginning of "Alice in Wonderland", with 31 observation symbols (letters). We used the first 1000 characters for training,

and the subsequent 4000 characters for test. Performance was measured by calculating the predictive log-likelihood. We fixed the hyperparameters α and γ to 1 for both DPVI and the particle filtering.

We ran one pass of DPVI (filtering) and particle filtering over the training sequence. We then sampled 50 data sets from the distribution over the sequences. We truncated the number of states and used the learned transition and emission matrices to compute the predictive log-likelihood of the test sequence. To handle the unobserved emissions in the test sequence we used "add-δ" smoothing with $\delta = 1$. Finally, we averaged over all the 50 data sets.

We also compared DPVI to the beam sampler (Van Gael et al., 2008), a combination of dynamic programming and slice sampling, which was previously applied to this data set. For the beam sampler, we followed the setting of Van Gael et al. (2008). We run the sampler for 10000 iterations and collect a sample of hidden state sequence every 200 iterations. Figure 6B shows the predictive log-likelihood for varying numbers of particles. Even with a small number of particles, DPVI can outperform both particle filtering and the beam sampler.



6.3.3 User Behavior Analysis

We analyzed a data set of user behavior in a photo editing software application. The data set contains sequences of edits applied by users to different photos. An iHMM can be utilized for better understanding the high-level tasks of the users. That is, a sequence of multiple edits may be required to perform a high-level task such as cropping or masking a photo. Our data set contains 30000 edits from which we use 1000 data points as a held-out set. There are 23 possible observations (edits) in the data set. We compare DPVI with 1, 5 and 10 particles with particle filtering, Gibbs sampling and mean field inference schemes. For all the inference schemes, we set the hyperparameters α and γ to 1. In every iteration of DPVI and particle filtering, we do a forward filtering-backward smoothing pass over all the sequences of the data set. Our results, shown in Figure 8(B), demonstrate that DPVI with 5 and 10 particles can converge in fewer iterations compared to other reasonable baselines. We illustrate the lower bound (Eq. 10) convergence in Figure 9. The results are computed over 20 runs and for 1, 5 and 10 particles.

It is important to note here that we do not expect DPVI to outperform Gibbs sampling in all scenarios; when computation time is not strongly limited, we expect DPVI and Gibbs to perform similarly. This point applies here as well as to the experiments reported in the sections below. We see DPVI as a useful alternative to Gibbs when the computational budget is low and the required fidelity of the approximation can be satisfied by capturing a few of the posterior modes.

6.4 Infinite Relational Model (IRM)

The IRM (Kemp et al., 2006) is a nonparametric model of relational systems. The model simultaneously discovers the clusters of entities and the relationships between the clusters. A key assumption of the model is that each entity belongs to exactly one cluster.

(A)

Method	Predictive LL
DPVI ($K = 1$)	-2983.24 ± 93.77
DPVI ($K = 5$)	$\mathbf{-2018.02 \pm 9.23}$
DPVI ($K = 10$)	$\mathbf{-2058.75 \pm 33.62}$
PF ($K = 1$)	-2743.60 ± 28.49
PF ($K = 5$)	-2503.95 ± 40.46
PF ($K = 10$)	-2424.01 ± 72.72
Mean field	-3158.69 ± 52.67
Gibbs	$\mathbf{-2030.50 \pm 56.55}$

(B)

Figure 8: Infinite HMM results for the user behavior analysis task. (A) Predictive log-likelihood vs iteration for the user behavior data set. The error bars correspond to the standard error and are computed over 20 runs. In every iteration of DPVI and particle filtering, we do a forward filtering-backward smoothing pass over all the sequences of the data set. (B) Predictive log-likelihood after 3000 iterations of DPVI, Gibbs, particle filter and mean field for the user behavior data set (with 1000 data points as held-out). The best performance is achieved by DPVI with 5-10 particles and also the Gibbs sampler. Run time for each epoch is as follows: 0.726 sec for mean field, 0.593 sec for Gibbs, 4.52 sec for particle filter with 10 particles, and 4.74 sec for DPVI with 10 particles.

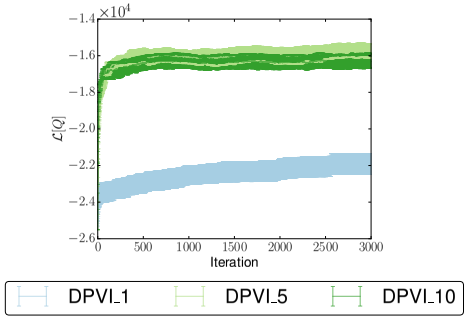


Figure 9: Infinite HMM results for the user behavior analysis task. Lower bound vs iteration for the user behavior data set. The error bars correspond to the standard error and are computed over 20 runs. In every iteration of DPVI, we do a forward filtering-backward smoothing pass over all the sequences of the data set.

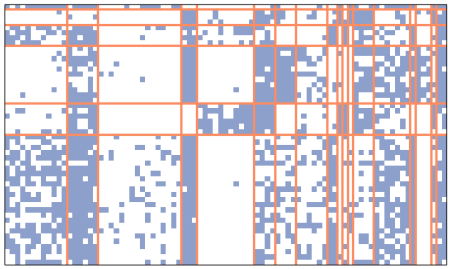
Given a relation R involving J types of entities, the goal is to infer a vector of cluster assignments x^j for all the entities of each type $j = 1, \ldots, J$.[2] Assuming the cluster assignments for each type are independent, the joint density of the relation and the cluster assignment vectors can be written as:

$$P(R, x^1, \ldots, x^J) = P(R|x^1, \ldots, x^J) \prod_{j=1}^{J} P(x^j). \tag{22}$$

The cluster assignment vectors are drawn from a CRP(α) prior. Given the cluster assignment vectors, the relations are drawn from a Bernoulli distribution with a parameter η that depends on the clusters involved in that relation. For instance, in a single two-place relation, $\eta(a, b)$ is the probability of having a link between any given pair (i, j) where i is in cluster a and j is in cluster b.



More formally, let us define an M dimensional relation $R : T^{d_1} \times \ldots T^{d_M} \mapsto \{0, 1\}$, over J different types. Each relational value is generated according to:

$$R(i_1, \ldots, i_M)|x^1, \ldots, x^J \sim \text{Bernoulli}(\eta(x^{d_1}_{i_1}, \ldots, x^{d_M}_{i_M})), \tag{23}$$

where d_m denotes the label of the type (i.e., $d_m \in \{1, \cdots, J\}$) and i_m is the entity occupying position m in the relation. Each entry of parameter matrix η is drawn from a Beta(β, β) distribution. By using a conjugate Beta-Bernoulli model, we can analytically marginalize the parameters η (see Kemp et al., 2006), allowing us to directly compute the likelihood of the relational matrix given the cluster assignments, $P(R|x^1, \ldots, x^J)$.

We compared the performance of DPVI with Gibbs sampling, using predictive log-likelihood on held-out data as a performance metric. The "animals" data set analyzed in

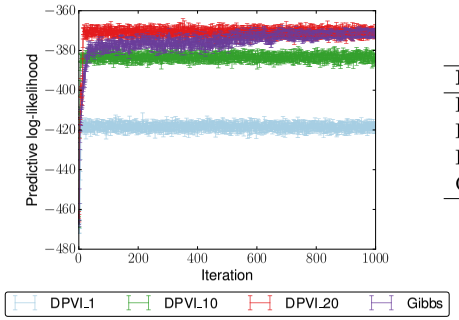
2. The IRM model can be defined for multiple relations but for simplicity we only describe the single relation case.

Sample animal clusters:
A1: Hippopotamus, Elephant, Rhinoceros
A2: Seal, Walrus, Dolphins, Blue Whale, Killer Whale, Humpback Whale
A3: Beaver, Otter, Polar Bear

Sample feature clusters:
F1: Hooves, Long neck, Horns
F2: Inactive, Slow, Bulbous Body, Tough Skin
F3: Lives in Fields, Lives in Plains, Grazer
F4: Walks, Quadrupedal, Ground
F5: Fast, Agility, Active, Tail

Figure 10: Co-clustering of animals (rows) and features (columns) after 50 iterations of DPVI with 10 particles in the infinite relational model.

Kemp et al. (2006), was used for this task. This data set (Osherson et al., 1991) is a two type data set $R : T_1 \times T_2 \to \{0, 1\}$ with animals and features as it types; it contains 50 animals and 85 features.



We removed 20% of the relations from the data set and computed the predictive log-likelihood for the held-out data. We ran DPVI with 1, 10 and 20 particles for 1000 iterations. Given the weights of the particles, we computed the weighted log-likelihood. We also ran 20 independent runs of the Gibbs sampler and DPVI for 1000 iterations and computed the average predictive log-likelihood. Every iteration scans all the data points in all the types sequentially. We set the hyperparameters α and β to 1. Figure 10 illustrates the co-clustering discovered by DPVI for the data set, demonstrating intuitively reasonable animal and feature clusters.

The results after 1000 iterations are presented in Table 11B. The best performance is achieved by DPVI with 20 particles. Figure 11A shows the predictive log-likelihood for every iteration of DPVI and Gibbs sampling. DPVI with 10 and 20 particles converge in 11 and 18 iterations, respectively. In terms of computation time per iteration of DPVI versus Gibbs, the only difference for DPVI with one particle and Gibbs is the sorting cost. Hence, for the multiple particle versus multiple runs of Gibbs sampling, the only additional cost is the sorting cost for multiple particles (e.g. 10 or 20). However, this insignificant additional cost is compensated for by a faster convergence rate in our experiments.

6.5 Ising Model

So far, we have been studying inference in directed graphical models, but DPVI can also be applied to undirected graphical models. We illustrate this using the Ising model for binary vectors $x \in \{-1, +1\}^N$:

$$f(x) = \exp\left\{\frac{1}{2} x W x^\top + \theta x^\top\right\}, \tag{24}$$

(A)

Method	Predictive LL
DPVI ($K = 1$)	-418.49 ± 4.24
DPVI ($K = 10$)	-382.46 ± 7.34
DPVI ($K = 20$)	$\mathbf{-370.67 \pm 6.23}$
Gibbs (avg. of 20 runs)	$\mathbf{-371.74 \pm 5.07}$

(B)

Figure 11: Infinite relational model results for the animals data set. (A) Predictive log-likelihood vs iteration for the animals data set. The error bars correspond to the standard error and for both methods are computed over 20 runs. (B) Predictive log-likelihood after 1000 iterations of DPVI and Gibbs (with 50 burnin iterations) for the animals data set (with 20 % held-out). DPVI with 20 particles performs in par with the Gibbs sampler.

where $W \in \mathbb{R}^{N \times N}$ and $\theta \in \mathbb{R}^N$ are fixed parameters. In particular, we study a square lattice ferromagnet, where $W_{ij} = \beta$ for neighboring nodes (0 otherwise) and $\theta_i = 0$ for all nodes. We refer to β as the *coupling strength*. This model has two global modes: when all the nodes are set to 1, and when all the nodes are set to 0. As the coupling strength increases, the probability mass becomes increasingly concentrated at the two modes.

We applied DPVI to this model, varying the number of particles and the coupling strength. At each iteration, we evaluated the change in log probability that would result from setting $\tilde{x}_n^k = 1$:

$$a_n^k = \sum_{n' \in c_n} W_{n,n'} x_{n'}^k + \theta_n, \tag{25}$$

and likewise the change for setting $\tilde{x}_n^k = 1$ can be computing by simply flipping the sign of a_n^k. Ordering these changes, we then took the top K to determine the new particle set.

To quantify performance, we computed the DPVI variational lower bound on the partition function and compared this to the lower bound furnished by the mean-field approximation (see Wainwright and Jordan, 2008). Figure 12A shows the results of this analysis for low coupling strength ($\beta = 0.01$) and high coupling strength ($\beta = 100$). DPVI consistently achieves a better lower bound than mean-field, even with a single particle, and this advantage is especially conspicuous for high coupling strength. Adding more particles improves the results, but more than 3 particles does not appear to confer any additional improvement for high coupling strength. These results illustrate how DPVI is able to capture multimodal target distributions, where mean-field approximations break down (since they cannot effectively handle multimodality).

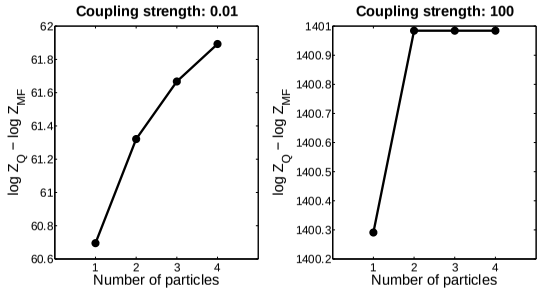


Figure 12: Ising model results. Difference between DPVI and mean-field lower bounds on the partition function. Positive values indicates superior DPVI performance. (A) Low coupling strength; (B) high coupling strength.

To illustrate the performance of DPVI further, we compared several posterior approximations for the Ising model in Figure 13. In addition to the mean-field approximation, we also compared DPVI with two other standard approximations: the Swendsen-Wang Monte Carlo sampler (Swendsen and Wang, 1987) and loopy belief propagation (Murphy et al., 1999). The sampler tended to produce noisy results, whereas mean-field and BP both failed to capture the multimodal structure of the posterior. In contrast, DPVI with two particles perfectly captured the two modes.

7. Conclusions

This paper introduced a particle-based variational method that applies to a broad class of inference problems in discrete models. We described a practical algorithm for optimizing the particle approximation, and showed empirically that it can outperform widely-used Monte Carlo and variational algorithms. The key to the success of this approach is an intentional selection of particles: rather than generating them randomly (as in Monte Carlo algorithms), we deterministically choose a set of unique particles that optimizes the KL divergence between the approximation and the target distribution.

This approach leads to an interesting view on the problem of resampling in sequential Monte Carlo. Resampling is necessary to remove conditionally unlikely particles, but the resulting loss of particle diversity can lead to degeneracy. As we showed in our experiments, tuning an ESS threshold for resampling can improve performance, but requires finding a relatively narrow sweet spot for the threshold. DPVI achieves comparable performance to the best particle filter by using a deterministic strategy for deleting and replacing particles and does not require tuning thresholds. Each particle is guaranteed to be unique and have high probability among all states discovered so far.

DPVI also suggests new hybrids of ideas from Monte Carlo and variational inference. Consider models where all particle extensions cannot be enumerated. In this setting, one could randomly choose particle extensions. To use these particles in a Monte Carlo scheme

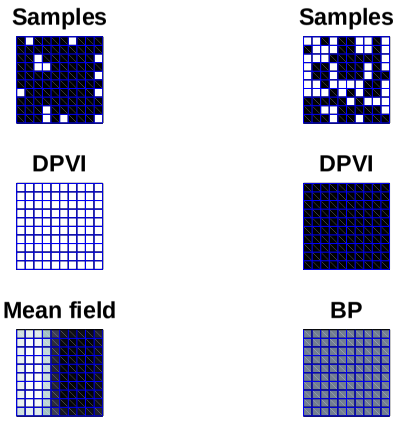

Figure 13: Ising model simulations. Examples of posteriors for the ferromagnetic lattice at low coupling strength. (Top) Two configurations from a Swendsen-Wang sampler. (Middle) Two DPVI particles. (Bottom left) Mean-field expected value. (Bottom right) Loopy belief propagation expected value.

we may need to know the output probability density of the particle extension mechanism. However, if we use the results in DPVI, we just need to be able to score the results under the joint probability distribution. No proposal distribution is needed. This could make it possible to use proposal mechanisms that can be seen to work well empirically but that are difficult to analyze *a priori*.

Although our empirical results are promising, much more empirical and theoretical work is needed to understand the fundamental tradeoffs between variational and Monte Carlo inference. However, the results for DPVI on several problems are promising, and the approach to defining variational approximations may be more broadly applicable. We hope this work encourages others to develop different hybrids of Monte Carlo and variational inference that overcome the limitations of each approach when used in isolation.

Abstract

We present a machine learning algorithm for building classifiers that are comprised of a *small* number of *short* rules. These are restricted disjunctive normal form models. An example of a classifier of this form is as follows: *If* X satisfies (condition A AND condition B) OR (condition C) OR $\cdots$, *then* $Y = 1$. Models of this form have the advantage of being interpretable to human experts since they produce a set of rules that concisely describe a specific class. We present two probabilistic models with prior parameters that the user can set to encourage the model to have a desired size and shape, to conform with a domain-specific definition of interpretability. We provide a scalable MAP inference approach and develop theoretical bounds to reduce computation by iteratively pruning the search space. We apply our method (Bayesian Rule Sets – *BRS*) to characterize and predict user behavior with respect to in-vehicle context-aware personalized recommender systems. Our method has a major advantage over classical associative classification methods and decision trees in that it does not greedily grow the model.

Keywords: disjunctive normal form, statistical learning, data mining, association rules, interpretable classifier, Bayesian modeling

1. Introduction

When applying machine learning models to domains such as medical diagnosis and customer behavior analysis, in addition to a reliable decision, one would also like to understand how this decision is generated, and more importantly, what the decision says about the data itself. For classification tasks specifically, a few summarizing and descriptive rules will provide intuition about the data that can directly help domain experts understand the decision process.

Our goal is to construct rule set models that serve this purpose: these models provide predictions and also descriptions of a class, which are reasons for a prediction. Here is an example of a rule set model for predicting whether a customer will accept a coupon for a nearby coffee house, where the coupon is presented by their car's mobile recommendation device:

if a customer (goes to coffee houses $\geq$ once per month AND destination = no urgent place AND passenger $\neq$ kids)
OR (goes to coffee houses $\geq$ once per month AND the time until coupon expires = one day)
then
predict the customer will accept the coupon for a coffee house.

This model makes predictions and provides characteristics of the customers and their contexts that lead to an acceptance of coupons.

Formally, a rule set model consists of a set of *rules*, where each rule is a conjunction of *conditions*. Rule set models predict that an observation is in the positive class when at least one of the rules is satisfied. Otherwise, the observation is classified to be in the negative class. Rule set models that have a small number of conditions are useful as non-black-box (interpretable) machine learning models. Observations come with predictions and also reasons (e.g., this observation is positive *because* it satisfies a particular rule).

This form of model appears in various fields with various names. First, they are sparse disjunctive normal form (DNF) models. In operations research, there is a field called "logical analysis of data" (Boros et al., 2000; Crama et al., 1988), which constructs rule sets based on combinatorics and optimization. Similar models are called "consideration sets" in marketing (see, e.g., Hauser et al., 2010), or "disjunctions of conjunctions." Consideration sets are a way for humans to handle information overload. When confronted with a complicated decision (such as which television to purchase), the theory of consideration sets says that humans tend to narrow down the possibilities of what they are willing to consider into a small disjunction of conjunctions ("only consider TV's that are small AND inexpensive, OR large and with a high display resolution"). In PAC learning, the goal is to learn rule set models when the data are non-noisy, meaning there exists a model within the class that perfectly classifies the data. The field of "rule learning" aims to construct rule set models. We prefer the terms "rule set" models or "sparse DNF" for this work as our goal is to create interpretable models for non-experts, which are not necessarily consideration sets, not other forms of logical data analysis, and pertain to data sets that are potentially noisy, unlike the PAC model.

For many decisions, the space of good predictive models is often large enough to include very simple models (Holte, 1993). This means that there may exist very sparse but accurate rule set models; the challenge is determining how to find them efficiently. Greedy methods used in previous works (Malioutov and Varshney, 2013; Pollack et al., 1988; Friedman and Fisher, 1999; Gaines and Compton, 1995), where rules are added to the model one by one, do not generally produce high-quality sparse models.

We create a Bayesian framework for constructing rule sets, which provides priors for controlling the size and shape of a model. These methods strike a nice balance between accuracy and interpretability through user-adjustable Bayesian prior parameters. To control interpretability, we introduce two types of priors on rule set models, one that uses beta-binomials to model the rule selecting process, called BRS-BetaBinomial, and one that uses Poisson distributions to model rule generation, called BRS-Poisson. Both can be adjusted to suit a domain-specific notion of interpretability; it is well-known that interpretability comes in different forms for different domains (Martens and Baesens, 2010; Martens et al., 2011; Huysmans et al., 2011; Allahyari and Lavesson, 2011; Rüping, 2006; Freitas, 2014).

We provide an approximate inference method that uses association rule mining and a randomized search algorithm (which is a form of stochastic coordinate descent or simulated annealing) to find optimal BRS maximum a posteriori (MAP) models. This approach is motivated by a theoretical bound that allows us to iteratively reduce the size of the computationally hard problem of finding a MAP solution. This bound states that we need only mine rules that are sufficiently fre-

quent in the database and as the search continues, the bound becomes tighter and further reduces the search space. This greatly reduces computational complexity and allows the problem to be solved in practical settings. The theoretical result takes advantage of the strength of the Bayesian prior.

Our applied interest is to understand user responses to personalized advertisements that are chosen based on user characteristics, the advertisement, and the context. Such systems are called *context-aware recommender systems* (see surveys Adomavicius and Tuzhilin, 2005, 2008; Verbert et al., 2012; Baldauf et al., 2007, and references therein). One major challenge in the design of recommender systems, reviewed in Verbert et al. (2012), is the *interaction challenge*: users typically wish to know *why* certain recommendations were made. Our work addresses precisely this challenge: our models provide rules in data that describe conditions for a recommendation to be accepted.

The main contributions of our paper are as follows:

- We propose a Bayesian approach for learning rule set (DNF) classifiers. This approach incorporates two important aspects of performance, accuracy, and interpretability, and balance between them via user-defined parameters. Because of the foundation in Bayesian methodology, the prior parameters are meaningful; they represent the desired size and shape of the rule set.

- We derive bounds on the support of rules and number of rules in a MAP solution. These bounds are useful in practice because they safely (and drastically) reduce the solution space, improving computational efficiency. The bound on the size of a MAP model guarantees a sparse solution if prior parameters are chosen to favor smaller sets of rules. More importantly, the bounds become tighter as the search proceeds, reducing the search space until the search finishes.

- The simulation studies demonstrate the efficiency and reliability of the search procedure. Losses in accuracy usually result from a misspecified rule representation, not generally from problems with optimization. Separately, using publicly available data sets, we compare rule set models to interpretable and uninterpretable models from other popular classification methods. Our results suggest that BRS models can achieve competitive performance, and are particularly useful when data are generated from a set of underlying rules.

- We study in-vehicle mobile recommender systems. Specifically, we used Amazon Mechanical Turk to collect data about users interacting with a mobile recommendation system. We used rule set models to understand and analyze consumers' behavior and predict their response to different coupons recommended in different contexts. We were able to generate interpretable results that can help domain experts better understand their customers.

The remainder of our paper is structured as follows. In Section 2, we discuss related work. In Section 3, we present Bayesian Rule Set modeling. In Section 4, we introduce an approximate MAP inference method using associative rule mining and randomized search. We also present theoretical bounds on the support and the number of rules in an optimal MAP solution. In Section 5, we show the simulation studies to justify the inference methods. We then report experimental results using publicly available data, including the in-vehicle recommendation system data set we created, to show that BRS models are on-par with black-box models while under strict size restrictions for the purpose of being interpretable.

A shorter version of this work appeared at the International Conference on Data Mining (Wang et al., 2016).

2. Related Work

The models we are studying have different names in different fields: "disjunctions of conjunctions" in marketing, "classification rules" in data mining, "disjunctive normal forms" (DNF) in artificial intelligence, and "logical analysis of data" in operations research. Learning logical models of this form has an extensive history in various settings. The LAD techniques were first applied to binary data in (Crama et al., 1988) and were later extended to non-binary cases (Boros et al., 2000). In parallel, Valiant (1984) showed that DNFs could be learned in polynomial time in the PAC (probably approximately correct - non-noisy) setting, and recent work has improved those bounds via polynomial threshold functions (Klivans and Servedio, 2001) and Fourier analysis (Feldman, 2012). Other work studies the hardness of learning DNF (Feldman, 2006). None of these theoretical approaches considered the practical aspects of building a *sparse* model with realistic noisy data.

In the meantime, the data-mining literature has developed approaches to building logical conjunctive models. Associative classification and rule learning methods (e.g., Ma et al., 1998; Li et al., 2001; Yin and Han, 2003; Chen et al., 2006; Cheng et al., 2007; McCormick et al., 2012; Rudin et al., 2013; Dong et al., 1999; Michalski, 1969; Clark and Niblett, 1989; Frank and Witten, 1998) mine for frequent rules in the data and combine them in a heuristic way, where rules are ranked by an interestingness criteria. Some of these methods, like CBA, CPAR and CMAR (Li et al., 2001; Yin and Han, 2003; Chen et al., 2006; Cheng et al., 2007) still suffer from a huge number of rules. Inductive logic programming (Muggleton and De Raedt, 1994) is similar, in that it mines (potentially complicated) rules and takes the simple union of these rules as the rule set, rather than optimizing the rule set directly. This is a major disadvantage over the type of approach we take here. Another class of approaches aims to construct rule set models by greedily adding the conjunction that explains the most of the remaining data (Malioutov and Varshney, 2013; Pollack et al., 1988; Friedman and Fisher, 1999; Gaines and Compton, 1995; Cohen, 1995). Thus, again, these methods do not directly aim to produce globally optimal conjunctive models.

There are few recent techniques that do aim to fully learn rule set models. Hauser et al. (2010); Goh and Rudin (2014) applied integer programming approaches to solving the full problems but would face a computational challenge for even moderately sized problems. There are several branch-and-bound algorithms that optimize different objectives than ours (e.g., Webb, 1995). Rijnbeek and Kors (2010) proposed an efficient way to exhaustively search for short and accurate decision rules. That work is different than ours in that it does not take a generative approach, and their global objective does not consider model complexity, meaning they do not have the same advantage of reduction to a smaller problem that we have. Methods that aim to globally find decision lists or rule lists can be used to find optimal DNF models, as long as it is possible to restrict all of the labels in the rule list (except the default) to the same value. A rule list where all labels except the default rule are the same value is exactly a DNF formula. We are working on extending the CORELS algorithm (Angelino et al., 2017) to handle DNF.

Note that logical models are generally robust to outliers and naturally handle missing data, with no imputation needed for missing attribute values. These methods can perform comparably with traditional convex optimization-based methods such as support vector machines or lasso (though linear models are not always considered to be interpretable in many domains).

One could extend any method for DNF learning of binary classification problems to multi-class classification. A conventional way to directly extend a binary classifier is to decompose the multi-class problem into a set of two-class problems. Then for each binary classification problem, one could build a separate BRS model, e.g., by the one-against-all method. One would generate different rule sets for each class. For this approach, the issue of overlapping coverage of rule sets for different classes is handled, for instance, by an error correcting output codes (Schapire, 1997).

The main application we consider is in-vehicle context-aware recommender systems. The most similar works to ours include that of Baralis et al. (2011), who present a framework that discovers relationships between user context and services using association rules. Lee et al. (2006) create interpretable context-aware recommendations by using a decision tree model that considers location context, personal context, environmental context and user preferences. However, they did not study some of the most important factors we include, namely contextual information such as the user's destination, relative locations of services along the route, the location of the services with respect to the user's destination, passenger(s) in the vehicle, etc. Our work is related to recommendation systems for in-vehicle context-aware music recommendations (see Baltrunas et al., 2011; Wang et al., 2012), but whether a user will accept a music recommendation does not depend on anything analogous to the location of a business that the user would drive to. The setup of in-vehicle recommendation systems are also different than, for instance, mobile-tourism guides (Noguera et al., 2012; Schwinger et al., 2005; Van Setten et al., 2004; Tung and Soo, 2004) where the user is searching to accept a recommendation, and interacts heavily with the system in order to find an acceptable recommendation. The closest work to ours is probably that of Park et al. (2007) who also consider Bayesian predictive models for context aware recommender systems to restaurants. They also consider demographic and context-based attributes. They did not study advertising, however, which means they did not consider the locations to the coupon's venue, expiration times, etc.

3. Bayesian Rule Sets

We work with standard classification data. The data set S consists of $\{\mathbf{x}_n, y_n\}_{n=1,...N}$, where $y_n \in \{0,1\}$ with N_+ positive and N_- negative, and $\mathbf{x}_n \in \mathcal{X}$. $\mathbf{x}_n$ has J features. Let a represent a rule and $a(\cdot)$ with a corresponding Boolean function

$$a(\cdot) : \mathcal{X} \to \{0,1\}.$$

$a(\mathbf{x})$ indicates if $\mathbf{x}$ satisfies rule a. Let A denote a rule set and let $A(\cdot)$ represent a classifier,

$$A(\mathbf{x}) = \begin{cases} 1 & \exists a \in A, a(\mathbf{x}) = 1 \\ 0 & \text{otherwise.} \end{cases}$$

$\mathbf{x}$ is classified as positive if it satisfies at least one rule in A.

Figure 1 shows an example of a rule set. Each rule is a yellow patch that covers a particular area, and the rule applies to the area it covers. In Figure 1, the white oval in the middle indicates the positive class. Our goal is to find a set of rules A that covers mostly the positive class, but little of the negative class, while keeping A as a small set of short rules.

We present a probabilistic model for selecting rules. Taking a generative approach allows us to flexibly incorporate users' expectations on the "shape" of a rule set through the prior. The user can guide the model toward more domain-interpretable solutions by specifying the desired balance between the size and lengths of rules without committing to any particular value for these parameters.

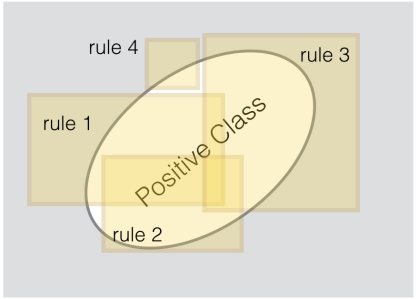

Figure 1: Illustration of Rule Sets. Area covered by any of rules is classified as positive. Area not covered by any rules is classified as negative.

We propose two models for the prior, a Beta-Binomial prior and a Poisson prior, which characterize the interpretability from different perspectives. The likelihood ensures that the model explains the data well and ensures good classification performance. We detail the priors and likelihood below.

3.1 Prior

We propose two priors. In the BRS-BetaBinomial model, the maximum length L of rules is predetermined by a user. Rules of the same length are placed into the same rule *pool*. The model uses L beta priors to control the probabilities of selecting rules from different pools. In a BRS-Poisson model, the "shape" of a rule set, which includes the number of rules and lengths of rules, is decided by drawing from Poisson distributions parameterized with user-defined values. Then the generative process fills it in with conditions by first randomly selecting attributes and then randomly selecting values corresponding to each attribute. We present the two prior models in detail.

3.1.1 BETA-BINOMIAL PRIOR

Rules are drawn randomly from a set $\mathcal{A}$. Assuming the interpretability of a rule is associated with the *length* of a rule (the number of conditions in a rule), the rule space $\mathcal{A}$ is divided into L pools indexed by the lengths, L being the maximum length the user allows.

$$\mathcal{A} = \cup_{l=1}^{L} \mathcal{A}_l. \tag{1}$$

Then, rules are drawn independently in each pool, and we assume in $\mathcal{A}_l$ each rule has probability p_l to be drawn, which we place a beta prior on. For $l \in \{1, ..., L\}$,

$$\text{Select a rule from } \mathcal{A}_l \sim \text{Bernoulli}(p_l) \tag{2}$$

$$p_l \sim \text{Beta}(\alpha_l, \beta_l). \tag{3}$$

In reality, it is not practical to enumerate all possible rules within $\mathcal{A}_l$ when ℓ is even moderately large. However, since we aim for intuitive models, we know that the optimal MAP model will consist of a small number of rules, each of which has sufficiently large support in the data (this

is formalized later within proofs). Our approximate inference technique thus finds and uses high support rules to use within $\mathcal{A}_l$. This effectively makes the beta-binomial model non-parametric.

Let M_l notate the number of rules drawn from $\mathcal{A}_l$, $l \in \{1, ..., L\}$. A BRS model A consists of rules selected from each pool. Then

$$p(A; \{\alpha_l, \beta_l\}_l) = \prod_{l=1}^{L} \int p_l^{M_l}(1-p_l)^{(|\mathcal{A}_l|-M_l)} dp_l$$
$$= \prod_{l=1}^{L} \frac{B(M_l + \alpha_l, |\mathcal{A}_l| - M_l + \beta_l)}{B(\alpha_l, \beta_l)}, \quad (4)$$

where $B(\cdot)$ represents a Beta function. Parameters $\{\alpha_l, \beta_l\}_l$ govern the prior probability of selecting a rule set. To favor smaller models, we would choose α_l, β_l such that $\frac{\alpha_l}{\alpha_l+\beta_l}$ is close to 0. In our experiments, we set $\alpha_l = 1$ for all l.

3.1.2 POISSON PRIOR

We introduce a data independent prior for the BRS model. Let M denote the total number of rules in A and L_m denote the lengths of rules for $m \in \{1, ...M\}$. For each rule, the length needs to be at least 1 and at most the number of all attributes J. According to the model, we first draw M from a Poisson distribution. We then draw L_m from truncated Poisson distributions (which only allow numbers from 1 to J), to decide the "shape" of a rule set. Then, since we know the rule sizes, we can now fill in the rules with conditions. To generate a condition, we first randomly select the attributes then randomly select values corresponding to each attribute. Let $v_{m,k}$ represent the attribute index for the k-th condition in the m-th rule, $v_{m,k} \in \{1, ...J\}$. $K_{v_{m,k}}$ is the total number of values for attribute $v_{m,k}$. Note that a "value" here refers to a category for a categorical attribute, or an interval for a discretized continuous variable. To summarize, a rule set is constructed as follows:

1: Draw the number of rules: $M \sim \text{Poisson}(\lambda)$
2: **for** $m \in \{1, ...M\}$ **do**
3: Draw the number of conditions in m-th rule: $L_m \sim$ Truncated-Poisson$(\eta), L_m \in \{1, ...J\}$
4: Randomly select L_m attributes from J attributes without replacement
5: **for** $k \in \{1, ...L_m\}$ **do**
6: Uniformly at random select a value from $K_{v_{m,k}}$ values corresponding to attribute $v_{m,k}$
7: **end for**
8: **end for**

We define the normalization constant $\omega(\lambda, \eta)$, so the probability of generating a rule set A is

$$p(A; \lambda, \eta) = \frac{1}{\omega(\lambda, \eta)} \text{Poisson}(M; \lambda) \prod_{m=1}^{M} \text{Poisson}(L_m; \eta) \frac{1}{\binom{J}{L_m}} \prod_{k=1}^{L_m} \frac{1}{K_{v_{m,k}}}. \quad (5)$$

3.2 Likelihood

Let $A(\mathbf{x}_n)$ denote the classification outcome for $\mathbf{x}_n$, and let y_n denote the observed outcome. Recall that $A(\mathbf{x}_n) = 1$ if $\mathbf{x}_n$ obeys any of the rules $a \in A$. We introduce likelihood parameter ρ_+ to represent the prior probability that $y_n = 1$ when $A(\mathbf{x}_n) = 1$, and ρ_- to represent the prior probability

that $y_n = 0$ when $A(\mathbf{x}_n) = 0$. Thus:

$$y_n | \mathbf{x}_n, A \sim \begin{cases} \text{Bernoulli}(\rho_+) & A(\mathbf{x}_n) = 1 \\ \text{Bernoulli}(1-\rho_-) & A(\mathbf{x}_n) = 0 \end{cases},$$

with ρ_+ and ρ_- drawn from beta priors:

$$\rho_+ \sim \text{Beta}(\alpha_+, \beta_+) \text{ and } \rho_- \sim \text{Beta}(\alpha_-, \beta_-). \quad (6)$$

Based on the classification outcomes, the training data are divided into four cases: true positives (TP $= \sum_n A(\mathbf{x}_n) y_n$), false positives (FP $= \sum_n A(\mathbf{x}_n)(1-y_n)$), true negatives (TN $= \sum_n (1-A(\mathbf{x}_n))\,(1-y_n)$) and false negatives (FN $= \sum_n (1-A(\mathbf{x}_n))\, y_n$). Then, it can be derived that

$$p(S|A; \alpha_+, \beta_+, \alpha_-, \beta_-) = \int \rho_+^{\text{TP}}(1-\rho_+)^{\text{FP}} \rho_-^{\text{TN}}(1-\rho_-)^{\text{FN}} d\rho_+ d\rho_-$$
$$= \frac{B(\text{TP}+\alpha_+, \text{FP}+\beta_+)}{B(\alpha_+, \beta_+)} \frac{B(\text{TN}+\alpha_-, \text{FN}+\beta_-)}{B(\alpha_-, \beta_-)}. \quad (7)$$

According to (6), $\alpha_+, \beta_+, \alpha_-, \beta_-$ govern the probability that a prediction is correct on training data, which determines the likelihood. To ensure the model achieves the maximum likelihood when all data points are classified correctly, we need $\rho_+ \geq 1-\rho_+$ and $\rho_- \geq 1-\rho_-$. So we choose $\alpha_+, \beta_+, \alpha_-, \beta_-$ such that $\frac{\alpha_+}{\alpha_+ + \beta_+} > 0.5$ and $\frac{\alpha_-}{\alpha_- + \beta_-} > 0.5$. Parameter tuning for the prior parameters will be shown in experiments section. Let H denote a set of parameters for a data S,

$$H = \left\{\alpha_+, \beta_+, \alpha_-, \beta_-, \theta_{\text{prior}}\right\},$$

where θ_{prior} depends on the prior model, our goal is to find an optimal rule set A^* that

$$A^* \in \arg\max_A p(A|S; H). \quad (8)$$

Solving for a MAP model is equivalent to maximizing

$$F(A, S; H) = \log p(A; H) + \log p(S|A; H), \quad (9)$$

where either of the two priors provided above can be used for the first term, and the likelihood is in (7). We write the objective as $F(A)$, the prior probability of selecting A as $p(A)$, and the likelihood as $p(S|A)$, omitting dependence on parameters when appropriate.

4. Approximate MAP Inference

In this section, we describe a procedure for approximately solving for the maximum *a posteriori* (MAP) solution to a BRS model.

Inference in Rule Set modeling is challenging because it involves a search over exponentially many possible sets of rules: since each rule is a conjunction of conditions, the number of rules increases exponentially with the number of conditions, and the number of sets of rules increases exponentially with the number of rules. This is the reason learning a rule set has always been a difficult problem in theory.

Inference becomes easier, however, for our BRS model, due to the computational benefits brought by the Bayesian prior, which can effectively reduce the original problem to a much more manageable size and significantly improve computational efficiency. Below, we detail how to exploit the Bayesian prior to derive useful bounds during any search process. Here we use a stochastic coordinate descent search technique, but the bounds hold regardless of what search technique is used.

4.1 Search Procedure

Given an objective function $F(A)$ over discrete search space of different sets of rules and a temperature schedule function over time steps, $T^{[t]} = T_0^{1-\frac{t}{N_{\text{iter}}}}$, a simulated annealing (Hwang, 1988) procedure is a discrete time, discrete state Markov Chain where at step t, given the current state $A^{[t]}$, the next state $A^{[t+1]}$ is chosen by first randomly selecting a proposal from the neighbors, and the proposal is accepted with probability $\min\left\{1, \exp\left(\frac{F(A^{[t+1]})-F(A^{[t]})}{T^{[t]}}\right)\right\}$, in order to find an optimal rule set A^*. Our version of simulated annealing is similar also to the ϵ-greedy algorithm used in multi-armed bandits (Sutton and Barto, 1998).

Similar to the Gibbs sampling steps used by Letham et al. (2015); Wang and Rudin (2015) for rule-list models, here a "neighboring" solution is a rule set whose edit distance is 1 to the current rule set (one of the rules is different). Our simulated annealing algorithm proposes a new solution via two steps: choosing an action from ADD, CUT and REPLACE, and then choosing a rule to perform the action on.

In the first step, the selection of which rules to ADD, CUT or REPLACE is not chosen uniformly. Instead, the simulated annealing proposes a neighboring solution that aims to do better than the current model with respect to a randomly chosen misclassified point. At iteration $t+1$, an example k is drawn from data points misclassified by the current model $A^{[t]}$. Let $\mathcal{R}_1(\mathbf{x}_k)$ represent a set of rules that $\mathbf{x}_k$ satisfies, and let $\mathcal{R}_0(\mathbf{x}_k)$ represent a set of rules that $\mathbf{x}_k$ does not satisfy. If example k is positive, it means the current rule set fails to cover it so we propose a new model that covers example k, by either adding a new rule from $\mathcal{R}_1(\mathbf{x}_k)$ to $A^{[t]}$, or replacing a rule from $A^{[t]}$ with a rule from $\mathcal{R}_1(\mathbf{x}_k)$. The two actions are chosen with equal probabilities. Similarly, if example k is negative, it means the current rule set covers wrong data, and we then find a neighboring rule set that covers less, by removing or replacing a rule from $A^{[t]} \cap \mathcal{R}_0(\mathbf{x}_k)$, each with probability 0.5.

In the second step, a rule is chosen to perform the action on. To choose the best rule, we evaluate the *precision* of tentative models obtained by performing the selected action on each candidate rule. This precision is:

$$Q(A) = \frac{\sum_i A(\mathbf{x}_i) y_i}{\sum_i A(\mathbf{x}_i)}.$$

Then a choice is made between exploration, which means choosing a random rule (from the ones that improve on the new point), and exploitation, which means choosing the best rule (the one with the highest precision). We denote the probability of exploration as p in our search algorithm. This randomness helps to avoid local minima and helps the Markov Chain to converge to a global minimum. We detail the three actions below.

- ADD
  1. Select a rule z according to $\mathbf{x}_k$
     - With probability p, draw z randomly from $\mathcal{R}_1(\mathbf{x}_k)$. (Explore)
     - With probability $1-p$, $z = \underset{a \in \mathcal{R}_1(\mathbf{x}_k)}{\arg\max}\ Q(A^{[t]} \cup a)$. (Exploit)
  2. Then $A^{[t+1]} \leftarrow A^{[t]} \cup z$.
- CUT
  1. Select a rule z according to $\mathbf{x}_k$
     - With probability p, draw z randomly from $A^{[t]} \cap \mathcal{R}_0(\mathbf{x}_k)$. (Explore)
     - With probability $1-p$, $z = \underset{a \in A^{[t]} \cap \mathcal{R}_0(\mathbf{x}_k)}{\arg\max}\ Q(A^{[t]} \backslash a)$. (Exploit)
  2. Then $A^{[t+1]} \leftarrow A^{[t]} \backslash z$.
- REPLACE: first CUT, then ADD.

To summarize: the proposal strategy uses an ϵ-greedy strategy to determine when to explore and when to exploit, and when it exploits, the algorithm uses a randomized coordinate descent approach by choosing a rule to maximize improvement.

4.2 Iteratively reducing rule space

Another approach to reducing computation is to directly reduce the set of rules. This dramatically reduces the search space, which is the power set of the set of rules. We take advantage of the Bayesian prior and derive a deterministic bound on MAP BRS models that exclude rules that fail to satisfy the bound.

Since the Bayesian prior is constructed to penalize large models, a BRS model tends to contain a small number of rules. As a small number of rules must cover the positive class, each rule in the MAP model must cover enough observations. We define the number of observations that satisfy a rule as the *support* of the rule:

$$\text{supp}(a) = \sum_{n=1}^{N} \mathbf{1}(a(\mathbf{x}_n) = 1). \tag{10}$$

Removing a rule will yield a simpler model (and a smaller prior) but may lower the likelihood. However, we can prove that the loss in likelihood is bounded as a function of the support. For a rule set A and a rule $z \in A$, we use $A_{\backslash z}$ to represent a set that contains all rules from A except z, i.e.,

$$A_{\backslash z} = \{a | a \in A, a \neq z\}.$$

Define

$$\Upsilon = \frac{\beta_-(N_+ + \alpha_+ + \beta_+ - 1)}{(N_- + \alpha_- + \beta_-)(N_+ + \alpha_+ - 1)}.$$

Then the following holds:

Lemma 1 $p(S|A) \geq (\Upsilon)^{\text{supp}(z)} p(S|A_{\backslash z})$.

All proofs in this paper are in Appendix A. This lemma shows that if $\Upsilon \leq 1$, removing a rule with high support lowers the likelihood.

We wish to derive lower bounds on the support of rules in a MAP model. This will allow us to remove (low-support) rules from the search space without any loss in posterior. This will simultaneously yield an upper bound on the maximum number of rules in a MAP model. The bounds will be updated as the search proceeds.

Recall that $A^{[\tau]}$ denotes the rule set at time τ, and let $v^{[t]}$ denote the best solution found until iteration t, i.e.,

$$v^{[t]} = \max_{\tau \leq t} F(A^{[\tau]}).$$

We first look at BRS-BetaBinomial models. In a BRS-BetaBinomial model, rules are selected based on their lengths, so there are separate bounds for rules of different lengths, and we notate the upper bounds of the number of rules at step t as $\{m_l^{[t]}\}_{l=1,\ldots,L}$, where $m_l^{[t]}$ represents the upper bound for the number of rules of length l.

We then introduce some notations that will be used in the theorems. Let $\mathcal{L}^*$ denote the maximum likelihood of data S, which is achieved when all data are classified correctly (this holds when $\alpha_+ > \beta_+$ and $\alpha_- > \beta_-$), i.e. TP $= N_+$, FP $= 0$, TN $= N_-$, and FN $= 0$, giving:

$$\mathcal{L}^* := \max_A p(S|A) = \frac{B(N_+ + \alpha_+, \beta_+)}{B(\alpha_+, \beta_+)} \frac{B(N_- + \alpha_-, \beta_-)}{B(\alpha_-, \beta_-)}. \tag{11}$$

For a BRS-BetaBinomial model, the following is true.

Theorem 1 *Take a BRS-BetaBinomial model with parameters*

$$H = \{L, \alpha_+, \beta_+, \alpha_-, \beta_-, \{\mathcal{A}_l, \alpha_l, \beta_l\}_{l=1,..L}\},$$

where $L, \alpha_+, \beta_+, \alpha_-, \beta_-, \{\alpha_l, \beta_l\}_{l=1,...L} \in \mathbb{N}^+$, $\alpha_+ > \beta_+, \alpha_- > \beta_-$ *and* $\alpha_l < \beta_l$. *Define* $A^* \in \arg\max_A F(A)$ *and* $M^* = |A^*|$. *If* $\Upsilon \leq 1$, *we have:* $\forall a \in A^*$, *supp*$(a) \geq C^{[t]}$ *and*

$$C^{[t]} = \left\lceil \frac{\log \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t-1]} + \beta_l}{m_l^{[t-1]} - 1 + \alpha_l} \right)}{\log \Upsilon} \right\rceil, \tag{12}$$

where

$$m_l^{[t]} = \left\lfloor \frac{\log \mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log \frac{|\mathcal{A}_l| + \beta_l - 1}{\alpha_l + m_l^{[t-1]} - 1}} \right\rfloor,$$

and $m_l^{[0]} = \left\lfloor \frac{\log \mathcal{L}^* - \log p(S|\emptyset)}{\log \frac{|\mathcal{A}_l| + \beta_l - 1}{\alpha_l + |\mathcal{A}_l| - 1}} \right\rfloor$ *and* $v^{[0]} = F(\emptyset)$. *The size of* A^* *is upper bounded by*

$$M^* \leq \sum_{l=1}^{L} m_l^{[t]}.$$

In the equation for $m_l^{[t]}$, $p(\emptyset)$ is the prior of an empty set, which is also the maximum prior for a rule set model, which occurs when we set $\alpha_l = 1$ for all l. Since $\mathcal{L}^*$ and $p(\emptyset)$ upper bound the likelihood and prior, respectively, $\log \mathcal{L}^* + \log p(\emptyset)$ upper bounds the optimal objective value. The difference between this value and $v^{[t]}$, the numerator, represents the room for improvement from the current solution $v^{[t]}$. The smaller the difference, the smaller the $m_l^{[t]}$, and thus the larger the minimum support bound. In the extreme case, when an empty set is the optimal solution, i.e., the likelihood and the prior achieve the upper bound $\mathcal{L}^*$ and $p(\emptyset)$ at the same time, and the optimal solution is discovered at time t, then the numerator becomes zero and $m_l^{[t]} = 0$ which precisely refers to an empty set. Additionally, parameters α_l and β_l jointly govern the probability of selecting rules of length l, according to formula (3). When α_l is set to be small and β_l is set to be large, p_l is small since $\mathbb{E}(p_l) = \frac{\alpha_l}{\alpha_l + \beta_l}$. Therefore the resulting $m_l^{[t]}$ is small, guaranteeing that the algorithm will choose a smaller number of rules overall.

Specifically, at step 0 when there is no $m_l^{[t-1]}$, we set $m_l^{[t-1]} = |\mathcal{A}_l|$, yielding

$$m_l^{[0]} = \left\lfloor \frac{\log \mathcal{L}^* - \log p(S|\emptyset)}{\log \frac{|\mathcal{A}_l| + \beta_l - 1}{\alpha_l + |\mathcal{A}_l| - 1}} \right\rfloor, \tag{13}$$

which is the upper bound we obtain before we start learning for A^*. This bound uses an empty set as a comparison model, which is a reasonable benchmark since the Bayesian prior favors smaller models. (It is possible, for instance, that the empty model is actually close to optimal, depending on the prior.) As $\log p(S|\emptyset)$ increases, $m_l^{[0]}$ becomes smaller, which means the model's maximum possible size is smaller. Intuitively, if an empty set already achieves high likelihood, adding rules will often hurt the prior term and achieve little gain on the likelihood.

Using this upper bound, we get a minimum support which can be used to reduce the search space before simulated annealing begins. As $m^{[t]}$ decreases, the minimum support increases since the rules need to jointly cover positive examples. Also, if fewer rules are needed it means each rule needs to cover more examples.

Similarly, for BRS-Poisson models, we have:

Theorem 2 *Take a BRS-Poisson model with parameters*

$$H = \{L, \alpha_+, \beta_+, \alpha_-, \beta_-, \lambda, \eta\},$$

where $L, \alpha_+, \beta_+, \alpha_-, \beta_- \in \mathbb{N}^+$, $\alpha_+ > \beta_+, \alpha_- > \beta_-$. *Define* $A^* \in \arg\max_A F(A)$ *and* $M^* = |A^*|$. *If* $\Upsilon \leq 1$, *we have:* $\forall a \in A^*$, *supp*$(a) \geq C^{[t]}$ *and*

$$C^{[t]} = \left\lceil \frac{\log \frac{x}{M^{[t]}}}{\log \Upsilon} \right\rceil, \tag{14}$$

where

$$x = \frac{e^{-\eta} \lambda \max\left\{ \left(\frac{\eta}{2}\right) \Gamma(J+1), \left(\frac{\eta}{2}\right)^J \right\}}{\Gamma(J+1)},$$

and

$$M^{[t]} = \left\lfloor \frac{\log \frac{(\lambda+1)^\lambda}{\Gamma(\lambda+1)}}{\log \frac{\lambda+1}{x}} + \frac{\log \mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log \frac{\lambda+1}{x}} \right\rfloor.$$

The size of A^* is upper bounded by

$$M^* \leq M^{[t]}.$$

Similar to Theorem 1, $\log \mathcal{L}^* + \log p(\emptyset)$ upper bounds the optimal objective value and $\log \mathcal{L}^* + \log p(\emptyset) - v^{[t]}$ is an upper bound on the room for improvement from the current solution $v^{[t]}$. The smaller the bounds becomes, the larger is the minimum support, thus reducing the rule space iteratively whenever a new maximum solution is discovered.

The algorithm, which applies the bounds above, is given as Algorithm 1.

Algorithm 1 Inference algorithm.

procedure SIMULATED ANNEALING(N_{iter})
  $\mathcal{A} \leftarrow$ FP-Growth(S)
  $A^{[0]} \leftarrow$ a randomly generated rule set

  end for
  return A_{max}
end procedure

4.3 Rule Mining

We mine a set of candidate rules $\mathcal{A}$ before running the search algorithm and only search within $\mathcal{A}$ to create an approximate but more computationally efficient inference algorithm. For categorical attributes, we consider both positive associations (e.g., x_j='blue') and negative associations (x_j='not green') as conditions. (The importance of negative conditions is stressed, for instance, by Brin et al., 1997; Wu et al., 2002; Teng et al., 2002). For numerical attributes, we create a set of binary variables for each numerical attribute, by comparing it with a set of thresholds (usually quantiles), and add their negations as separate attributes. For example, we discretize age with three thresholds, creating six binary variables in total, i.e., age≥25, age≥50, age≥ 75 and the negations for each of

them, i.e., age<25, age<50 and age<75. We then mine for frequent rules within the set of positive observations S^+. To do this, we use the FP-growth algorithm (Borgelt, 2005), which can in practice be replaced with any desired frequent rule-mining method.

Sometimes for large data sets with many features, even when we restrict the length of rules and the minimum support, the number of generated rules could still be too large to handle, as it can be exponential in the number of attributes. For example, for one of the advertisement data sets, a million rules are generated when the minimum support is 5% and the maximum length is 3. In that case, we use a second criterion to screen for the most potentially useful M_0 rules, where M_0 is user-defined and depends on the user's computational capacity. We first filter out rules on the lower right plane of ROC space, i.e., their false positive rate is greater than true positive rate. Then we use *information gain* to screen rules, similarly to other works (Chen et al., 2006; Cheng et al., 2007). For a rule a, the information gain is

$$\text{InfoGain}(S|a) = H(S) - H(S|a), \tag{15}$$

where $H(S)$ is the entropy of the data and $H(S|a)$ is the conditional entropy of data that split on rule a. Given a data set S, entropy $H(S)$ is constant; therefore our screening technique chooses the M_0 rules that have the smallest $H(S|a)$.

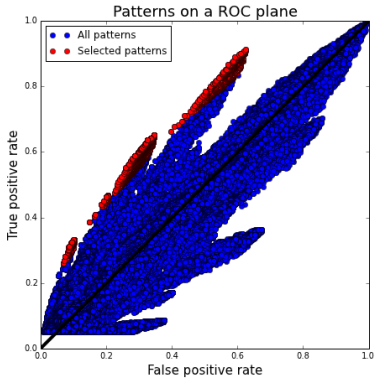

Figure 2: All rules and selected rules on a ROC plane

We illustrate the effect of screening on one of our mobile advertisement data sets. We mined all rules with minimum support 5% and maximum length 3. For each rule, we computed its true positive rate and false positive rate on the training data and plotted it as a dot in Figure 2. The top 5000 rules with highest information gains are colored in red, and the rest are in blue. As shown in the figure, information gain indeed selected good rules as they are closer to the upper left corner in ROC space. For many applications, this screening technique is not needed, and we can simply use the entire set of pre-mined rules that have support above the required threshold for the optimal solution provided in the theorems above.

5. Simulation Studies

We present simulation studies to show the interpretability and accuracy of our model and the efficiency of the simulated annealing procedure. We first demonstrate the efficiency of the simulated annealing algorithm by searching within candidate rules for a "true rule set" that generates the data. Simulations show that our algorithm can recover the true rule set with high probability within a small number of iterations despite the large search space. We then designed the second set of simulations to study the trade-off between accuracy and simplicity. BRS models may lose accuracy to gain model simplicity when the number of attributes is large. Combining the two simulations studies, we were able to hypothesize that possible losses in accuracy are often due to the choice of model representation as a rule set, rather than simulated annealing. In this section, we choose the BRS-BetaBinomial model for the experiments. BRS-Poisson results would be similar; the only difference is the choice of prior.

5.1 Simulation Study 1: Efficiency of Simulated Annealing

In the first simulation study, we would like to test if simulated annealing is able to recover a true rule set given that these rules are in a candidate rule set, and we would like to know how efficiently simulated annealing finds them. Thus we omit the step of rule mining for this experiment and directly work with generated candidate rules, which we know in this case contains a true rule set.

Let there be N observations, $\{\mathbf{x}_n\}_{n=1,...,N}$ and a collection of M candidate rules, $\{a_m\}_{m=1,...M}$. We can construct an $N \times M$ binary matrix where the entry in the n-th row and m-th column is the Boolean function $a_m(x_n)$ that represents whether the n-th observation satisfies the m-th rule. Let the true rule set be a subset of the candidate rules, $A^* \subset \{a_m\}_{m=1,...M}$. The labels $\{y_n\}_{n=1,...N}$ satisfy

$$y_n = \begin{cases} 1 & \exists a \in A^*, a(\mathbf{x}_n) = 1 \\ 0 & \text{otherwise.} \end{cases} \tag{16}$$

We ran experiments with varying N and M. Each time, we first generated an $N \times M$ binary matrix by setting the entries to 1 with probability 0.035, and then selected 20 columns to form A^*. (Values 0.035 and 20 are chosen so that the positive class contains roughly 50% of the observations. We also ensured that the 20 rules do not include each other.) Then $\{y_n\}_{n=1,...N}$ were generated as above. We randomly assigned lengths from 1 to 5 to $\{a_m\}_{m=1,...M}$. Finally, we ran Algorithm 1 on the data set. The prior parameters were set as below for all simulations:

$$\alpha_l = 1, \beta_l = |\mathcal{A}_l| \text{ for } l = 1, ..., 3,$$
$$\alpha_+ = \alpha_- = 1000, \beta_+ = \beta_- = 1.$$

For each pair of N and M, we repeated the experiment 100 times and recorded intermediate output models at different iterations. Since multiple different rule sets can cover the same points, we compared labels generated from the true rule set and the recovered rule set: a label is 1 if the instance satisfies the rule set and 0 otherwise. We recorded the training error for each intermediate output model. The mean and standard deviation of training error rate are plot Figure 3, along with run time to convergence in seconds on the right figure.

Comparing the three sets of experiments, we notice that different sizes of the binary matrix led to differing convergence times due to different computation cost of handling the matrices, yet the three error rate curves in Figure 3 almost completely overlap. Neither the size of the data set N nor

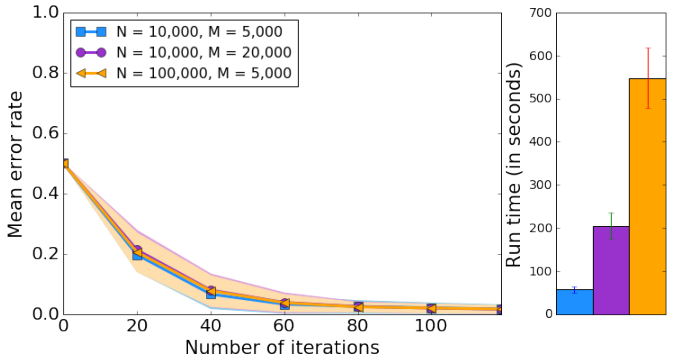

Figure 3: Convergence of mean error rate with number of iterations for data with varying N and M and running time (in seconds), obtained by the BRS-BetaBinomial.

the size of the rule space M affected the search. This is because the strategy based on curiosity and bounds chose the best solution efficiently, regardless of the size of data or the rule space.

More importantly, this study shows that simulated annealing is able to recover a true rule set A^*, or an equivalent rule set with optimal performance, with high probability, with few iterations.

5.2 Simulation Study 2: Accuracy-Interpretability Trade-off

We observe from the first simulation study that simulated annealing does not tend to cause losses in accuracy. In the second simulation study, we would like to identify whether the rule representation causes losses in accuracy. In this study, we used the rule mining step and directly worked with data $\{\mathbf{x}_n\}_{n=1,...,N}$. Without loss of generality, we assume $\mathbf{x}_n \in \{0,1\}^J$.

In each experiment, we first constructed an $N \times J$ binary matrix $\{\mathbf{x}_n\}_{n=1,...N}$ by setting the entries to 1 with probability 0.5, then randomly generated 20 rules from $\{\mathbf{x}_n\}_{n=1,...,N}$ to form A^* and finally generated labels $\{y_n\}_{n=1,...,N}$ following formula (16). We checked the balance of the data before pursuing the experiment. The data set was used only if the positive class was within $[30\%, 70\%]$ of the total data, and otherwise regenerated.

To constrain computational complexity, we set the maximum length of rules to be 7 and then selected the top 5000 rules with highest information gain. Then we performed Algorithm 1 on these candidate rules to generate a BRS model $\tilde{A}$. Ideally, $\tilde{A}$ should be simpler than A^*, with a possible loss in its accuracy as a trade-off.

To study the influence of the dimensions of data on accuracy and simplicity, we varied N and J and repeated each experiment 100 times. Figure 4 shows the accuracy and number of rules in $\tilde{A}$ in each experiment. The number of rules in $\tilde{A}$ was almost always less than the number of rules in A^* (which was 20). On average, $\tilde{A}$ contained 12 rules, which was 60% of the size of A^*, slightly compromising accuracy. BRS needed to compromise more when J was large since it became harder to maintain the same level of simplicity.

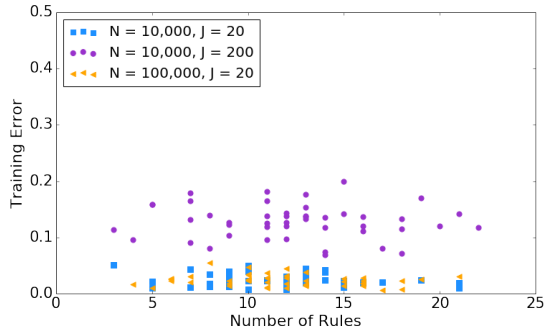

Figure 4: Accuracy and complexity of output BRS models for data with varying N and J, obtained from the BRS-BetaBinomial.

We show in Figure 5 the average training error at different iterations to illustrate the convergence rate. Simulated annealing took less than 50 iterations to converge. Note that it took fewer iterations than simulation study 1 since the error rate curve started from less than 0.5, due to rule pre-screening using information gain.

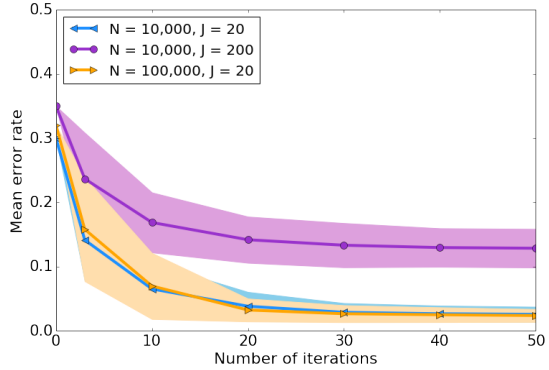

Figure 5: Convergence of mean error rate with varying N and J, obtained by BRS-BetaBinomial.

Figure 4 and Figure 5 both indicate that increasing the number of observations did not affect the performance of the model. BRS is more sensitive to the number of attributes. The larger J is, the less informative a short rule becomes to describe and distinguish a class in the data set, and the more BRS has to trade-off, in order to keep simple rules within the model.

To summarize: when we model using fewer rules, it benefits interpretability but can lose information. Rules with a constraint on the maximum length tend to be less accurate when dealing with

high dimensional feature spaces. The loss increases with the number of features. This is the price paid for using an interpretable model. There is little price paid for using our optimization method.

6. Experiments

Our main application of interest is mobile advertising. We collected a large advertisement data set using Amazon Mechanical Turk that we made publicly available (Wang et al., 2015), and we tested BRS on other publicly available data sets. We show that our model can generate interpretable results that are easy for humans to understand, without losing too much (if any) predictive accuracy. In situations where the ground truth consists of deterministic rules (similarly to the simulation study), our method tends to perform better than other popular machine learning techniques.

6.1 UCI Data Sets

We test BRS on ten data sets from the UCI machine learning repository (Bache and Lichman, 2013) with different types of attributes; four of them contain categorical attributes, three of them contain numerical attributes and three of them contain both. We performed 5-fold cross validation on each data set. Since our goal was to produce models that are accurate and interpretable, we set the maximum length of rules to be 3 for all experiments. We compared with interpretable algorithms: Lasso (without interaction terms to preserve interpretability), decision trees (C4.5 and CART), and inductive rule learner RIPPER (Cohen, 1995), which produces a rule list greedily and anneals locally afterward. In addition to interpretable models, we also compare BRS with uninterpretable models from random forests and SVM to set a benchmark for expected accuracy on each data set. We used implementations of baseline methods from R packages, and tuned model parameters via 5-fold nested cross validation.

Table 1: Accuracy of each comparing algorithm (mean ± std) on ten UCI data sets.

and the rank of their average performance. Table 2 displays the runtime. BRS1 represents BRS-BetaBinomial and BRS2 represents BRS-Poisson. While BRS models were under strict restriction for interpretability purposes ($L = 3$), BRS's performance surpassed that of the other interpretable methods and was on par with uninterpretable models. This is because, firstly, BRS has Bayesian priors that favor rules with a large support (Theorem 1, 2) which naturally avoids overfitting of the data; and secondly, BRS optimizes a global objective while decision trees and RIPPER rely on local greedy splitting and pruning methods, and interpretable versions of Lasso are linear in the base features. Decision trees and RIPPER are local optimization methods and tend not to have the same level of performance as globally optimal algorithms, such as SVM, Random Forests, BRS, etc. The class of rule set models and decision tree models are the same: both create regions within input space consisting of a conjunction of conditions. The difference is the choice of optimization method: global vs. local.

For the tic-tac-toe data set, the positive class can be classified using exactly eight rules. BRS has the capability to exactly learn these conditions, whereas the greedy splitting and pruning methods that are pervasive throughout the data mining literature (e.g., CART, C4.5) and convexified approximate methods (e.g., SVM) have difficulty with this. Both linear models and tree models exist that achieve perfect accuracy, but the heuristic splitting/pruning and convexification of the methods we compared with prevented these perfect solutions from being found.

BRS achieves accuracies competitive to uninterpretable models while requiring a much shorter runtime, which grows slowly with the size of the data, unlike Random forest and SVM. This indicates that BRS can reliably produce a good model within a reasonable time for large data sets.

6.1.1 PARAMETER TUNING

A MAP solution maximizes the sum of logs of prior and likelihood. The scale of the prior and likelihood directly determines how the model trades off between fitting the data and achieving the desired sparsity level. Again, we choose the BRS-BetaBinomial for this demonstration. The Bayesian model uses parameters $\{\alpha_l, \beta_l\}_{l=1}^{L}$ to govern the prior for selecting rules and parameters $\alpha_+, \beta_+, \alpha_-, \beta_-$ to govern the likelihood of data. We study how sensitive the results are to different

parameters and how to tune the parameters to get the best performing model. We choose one data set from each category from Table 1.

We fixed the prior parameters $\alpha_l = 1, \beta_l = |\mathcal{A}_l|$ for $l = 1, .., L$, and only varied likelihood parameters $\alpha_+, \beta_+, \alpha_-, \beta_-$ to analyze how the performance changes as the magnitude and ratio of the parameters change. To simplify the study, we took $\alpha_+ = \alpha_- = \alpha$, and $\beta_+ = \beta_- = \beta$. We let $s = \alpha + \beta$ and s was chosen from $\{100, 1000, 10000\}$. We let $\rho = \frac{\alpha}{\alpha+\beta}$ and ρ varied within $[0, 1]$. Here, s and ρ uniquely define α and β. We constructed models for different s and ρ and plotted the average out-of-sample accuracy as s and ρ changed in Figure 6 for three data sets representative of categorical, numerical and mixed data types. The X axis represents ρ and Y axis represents s. Accuracies increase as ρ increases, which is consistent with the intuition of ρ_+ and ρ_-. The highest accuracy is always achieved at the right half of the curve. The performance is less sensitive to the magnitude s and ratio ρ, especially when $\rho > 0.5$. For tic-tac-toe and diabetes, the accuracy became flat once ρ becomes greater than a certain threshold, and the performance was not sensitive to ρ either after that point; it is important as it makes tuning the algorithm easy in practice. Generally, taking ρ close to 1 leads to a satisfactory output. Table 1 and 2 were generated by models with $\rho = 0.9$ and $s = 1000$.

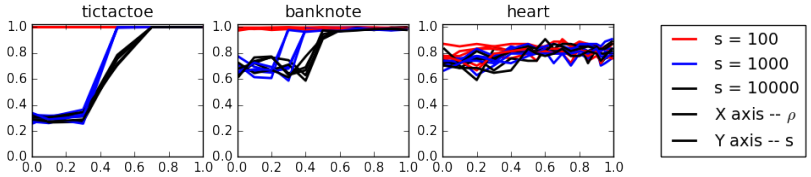

Figure 6: Parameter tuning experiments. Accuracy vs. ρ for all data sets. X axis represents ρ and Y axis represents accuracy.

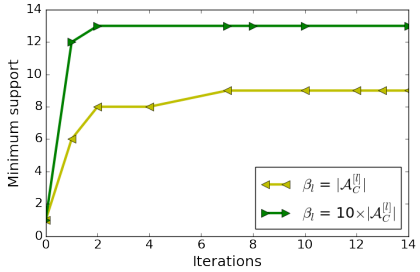
6.1.2 DEMONSTRATION WITH TIC-TAC-TOE DATA

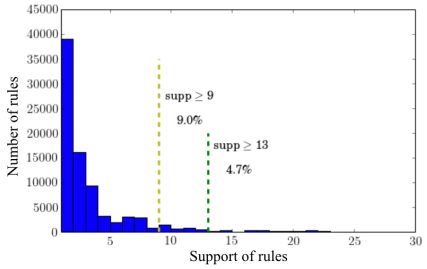
Let us illustrate the reduction in computation that comes from the bounds in the theorems in Section 4. For this demonstration, we chose the tic-tac-toe data set since the data can be classified exactly by eight rules which are naturally an underlying true rule set, and our method recovered the rules successfully, as shown in Table 1. We use BRS-BetaBinomial for this demonstration.

First, we used FP-Growth (Borgelt, 2005) to generate rules. At this step, we find all possible rules with length between 1 to 9 (the data has 9 attributes) and has minimum support of 1 (the rule's itemset must appear at least once int the data set). FP-growth generates a total of 84429 rules. We then set the hyper-parameters as:

$$\alpha_l = 1, \beta_l = |\mathcal{A}_l| \text{ for } l = 1, ..., 9,$$
$$\alpha_+ = N_+ + 1, \beta_+ = N_+, \alpha_- = N_- + 1, \beta_- = N_-.$$

We ran Algorithm 1 on this data set. We kept a list of the best solutions $v^{[t]}$ found until time t and updated $m_l^{[t-1]}$ and the minimum support with the new $v^{[t]}$ according to Theorem 1. We show in Figure 7 the minimum support at different iterations whenever a better $v^{[t]}$ is obtained. Within





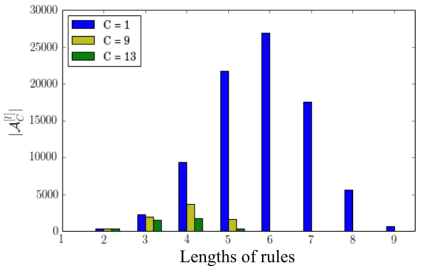


Figure 7: Updated minimum support at different iterations

ten iterations, the minimum support increased from 1 to 9. If, however, we choose a stronger prior for small models by increasing β_l to 10 times $|\mathcal{A}_l|$ for all l and keeping all the other parameters unchanged, then the minimum support increases even faster and reached 13 very quickly. This is consistent with the intuition that if the prior penalizes large models more heavily, the output tends to have a smaller size. Therefore each rule will need to cover more data.

Placing a bound on the minimum support is critical for computation since the number of possible rules decays exponentially with the support, as shown in Figure 8a. As the minimum support is increased, more rules are removed from the original rule space. Figure 8a shows the percentage of rules left in the solution space as the minimum threshold is increased from 1 to 9 and to 13. At a minimum support of 9, the rule space is reduced to 9.0% of its original size; at a minimum support of 13, the rule space is reduced to 4.7%. This provides intuition of the benefit of Theorem 1.

(a) Reduced rule space as the minimum support increases

(b) Number of rules of different lengths mined at different minimum support.

Figure 8: Demonstration with Tic-Tac-Toe data set

Although rules are filtered out based on their support, we observe that longer rules are more heavily reduced than shorter rules. This is because the support of a rule is negatively correlated with its length, as the more conditions a rule contains, the fewer observations can satisfy it. Figure 8b shows distributions of rules across different lengths when mined at different minimum support levels. Before any filtering (i.e., C = 1), more than half of the rules have lengths greater than 5. As C is increased to 9 and 13, these long rules are almost completely removed from the rule space.

To summarize, the strength of the prior is important for computation, and changes the nature of the problem: a stronger prior can dramatically reduce the size of the search space. Any increase in minimum support, that the prior provides, leads to a smaller search by the rule mining method and a smaller optimization problem for the BRS algorithm. These are multiple order-of-magnitude decreases in the size of the problem.

6.2 Application to In-vehicle Recommendation System

For this experiment, our goal was to understand customers' response to recommendations made in an in-vehicle recommender system that provides coupons for local businesses. The coupons would be targeted to the user in his/her particular context. Our data were collected on Amazon Mechanical Turk via a survey that we will describe shortly. We used Turkers with high ratings (95% or above). Out of 752 surveys, 652 were accepted, which generated 12684 data cases (after removing rows containing missing attributes).

The prediction problem is to predict if a customer is going to accept a coupon for a particular venue, considering demographic and contextual attributes. Answers that the user will drive there 'right away' or 'later before the coupon expires' are labeled as '$Y = 1$' and answers 'no, I do not want the coupon' are labeled as '$Y = 0$'. We are interested in investigating five types of coupons: bars, takeaway food restaurants, coffee houses, cheap restaurants (average expense below $20 per person), expensive restaurants (average expense between $20 to $50 per person). In the first part of the survey, we asked users to provide their demographic information and preferences. In the second part, we described 20 different driving scenarios (see examples in Appendix B) to each user along with additional context information and coupon information (see Appendix B for a full description of attributes) and asked the user if s/he will use the coupon.

For this problem, we wanted to generate simple BRS models that are easy to understand. So we restricted the lengths of rules and the number of rules to yield very sparse models. Before mining rules, we converted each row of data into an item which is an attribute and value pair. For categorical attributes, each attribute-value pair was directly coded into a condition. Using marital status as an example, 'marital status is single' was converted into (MaritalStatus: Single), (MaritalStatus: Not Married partner), and (MaritalStatus: Not Unmarried partner), (MaritalStatus: Not Widowed). For discretized numerical attributes, the levels are ordered, such as: age is '20 to 25', or '26 to 30', etc.; additionally, each attribute-value pair was converted into two conditions, each using one side of the range. For example, age is '20 to 25' was converted into (Age:>=20) and (Age:<=25). Then each condition is a half-space defined by threshold values. For the rule mining step, we set the minimum support to be 5% and set the maximum length of rules to be 4. We used information gain in Equation (15) to select the best 5000 rules to use for BRS. We ran simulated annealing for 50000 iterations to obtain a rule set.

We compared with interpretable classification algorithms that span the space of widely used methods that are known for interpretability and accuracy, C4.5, CART, Lasso, RIPPER, and a naïve baseline using top K rules, referred to as Top$K$. For C4.5, CART, Lasso, and RIPPER, we used the RWeka package in R and tuned the hyper-parameters to generate different models on a ROC plane. For the Top$K$ method, we varied K from 1 to 10 to produce ten models using best K pre-mined rules ranked by the information gain in Equation (15). For BRS, We varied the hyperparameters

$\alpha_+, \beta_+, \alpha_-, \beta_-$ to obtain different sets of rules. For all methods, we picked models on their ROC frontiers and reported their performance below.

Performance in accuracy To compare their predictive performance, we measured out-of-sample AUC (the Area Under The ROC Curve) from 5-fold testing for all methods, reported in Table 3. The BRS classifiers, while restricted to produce sparse disjunctions of conjunctions, had better performance than decision trees and RIPPER, which use greedy splitting and pruning methods, and do not aim to globally optimize. Top$K$'s performance was substantially below that of other methods. BRS models are also comparable to Lasso, but the form of the model is different. BRS models do not require users to cognitively process coefficients.

	Bar	Takeaway Food	Coffee House	Cheap Restaurant	Expensive Restaurant
BRS1	0.773 (0.013)	0.682 (0.005)	0.760 (0.010)	0.736 (0.022)	0.705 (0.025)
BRS2	0.776 (0.011)	0.667 (0.023)	0.762 (0.007)	0.736 (0.019)	0.707 (0.030)
C4.5	0.757 (0.015)	0.602 (0.051)	0.751 (0.018)	0.692 (0.033)	0.639 (0.027)
CART	0.772 (0.019)	0.615 (0.035)	0.758 (0.013)	0.732 (0.018)	0.657 (0.010)
Lasso	0.795 (0.014)	0.673 (0.042)	0.786 (0.011)	0.769 (0.024)	0.706 (0.017)
RIPPER	0.762 (0.015)	0.623 (0.048)	0.762(0.012)	0.705(0.023)	0.689 (0.034)
Top$K$	0.562 (0.015)	0.523 (0.024)	0.502(0.012)	0.582(0.023)	0.508 (0.011)

Table 3: AUC comparison for mobile advertisement data set, means and standard deviations over folds are reported.

Performance in complexity For the same experiment, we would also like to know the complexity of all methods at different accuracy levels. Since the methods we compare have different structures, there is not a straightforward way to directly compare complexity. However, decision trees can be converted into equivalent rule set models. For a decision tree, an example is classified as positive if it falls into any positive leaf. Therefore, we can generate equivalent models in rule set form for each decision tree, by simply collecting branches with positive leaves. Therefore, the four algorithms we compare, C4.5, CART, RIPPER, and BRS have the same form. To measure the complexity, we count the total number of conditions in the model, which is the sum of lengths for all rules. This loosely represents the cognitive load needed to understand a model. For each method, we take the models that are used to compute the AUC in Table 3 and plot their accuracy and complexity in Figure 9. BRS models achieved the highest accuracy at the same level of complexity. This is not surprising given that BRS performs substantially more optimization than other methods.

To show that the benefits of BRS did not come from rule mining or screening using heuristics, we compared the BRS models with Top$K$ models that rely solely on rule mining and ranking with heuristics. Figure 10 shows there is a substantial gain in the accuracy of BRS models compared to Top$K$ models.

From Table 3 we observe that Lasso achieved consistently good AUC. For the five coupons, the average number of nonzero coefficients for lasso models in different folds are 93, 94.6, 90.2, 93.2 and 93.4, which is on the order of $\sim$20 times larger than the number of conditions used in BRS and other rule based models; in this case, the lasso models are not interpretable.

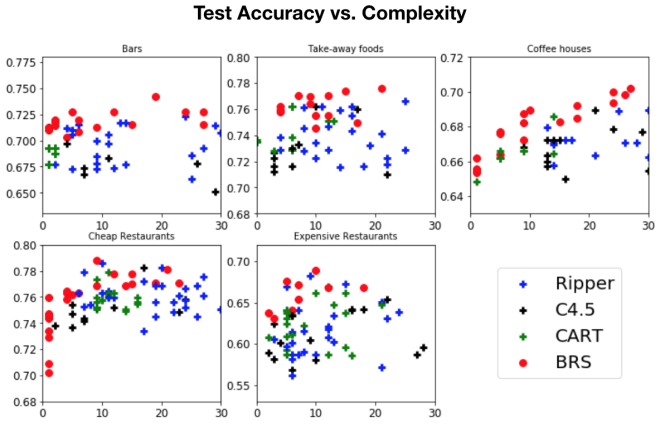

Figure 9: Test accuracy vs complexity for BRS and other models on mobile advertisement data sets for different coupons

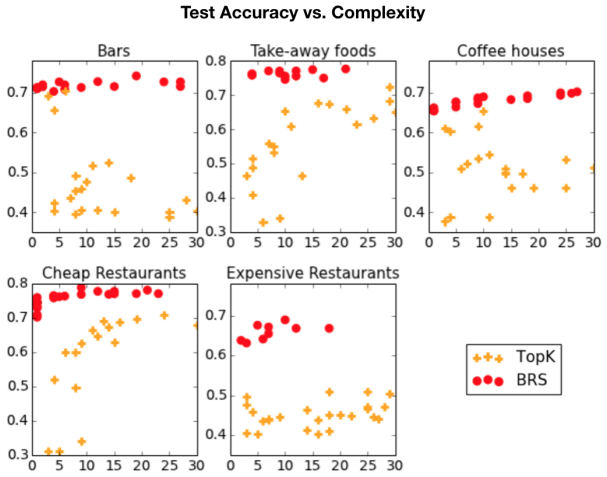

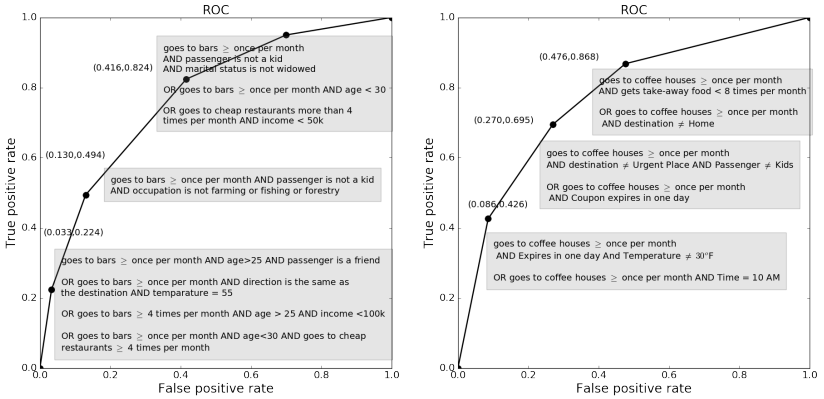

Figure 10: Test accuracy vs complexity for BRS and Top$K$ on mobile advertisement data sets for different coupons

Examples of BRS models In practice, for this particular application, the benefits of interpretability far outweigh small improvements in accuracy. An interpretable model can be useful to a vender

choosing whether to provide a coupon and what type of coupon to provide, it can be useful to users of the recommender system, and it can be useful to the designers of the recommender system to understand the population of users and correlations with successful use of the system. As discussed in the introduction, rule set classifiers are particularly natural for representing consumer behavior, particularly consideration sets, as modeled here.

We show several classifiers produced by BRS in Figure 11, where the curves were produced by models from the experiments discussed above. Example rule sets are listed in each box along the curve. For instance, the classifier near the middle of the curve in Figure 11 (a) has one rule, and reads "If a person visits a bar at least once per month, is not traveling with kids, and their occupation is not farming/fishing/forestry, then predict the person will use the coupon for a bar before it expires." In these examples (and generally), we see that a user's general interest in a coupon's venue (bar, coffee shop, etc.) is the most relevant attribute to the classification outcome; it appears in every rule in the two figures.

(a) Coupons for bars

(b) Coupons for coffee houses

Figure 11: ROC for data set of coupons for bars and coffee houses.

7. Conclusion

We presented a method that produces rule set (disjunctive normal form) models, where the shape of the model can be controlled by the user through Bayesian priors. In some applications, such as those arising in customer behavior modeling, the form of these models may be more useful than traditional linear models. Since finding sparse models is computationally hard, most approaches take severe heuristic approximations (such as greedy splitting and pruning in the case of decision trees, or convexification in the case of linear models). These approximations can severely hurt performance, as is easily shown experimentally, using data sets whose ground truth formulas are not difficult to find. We chose a different type of approximation, where we make an up-front statistical assumption in building our models out of pre-mined rules, and aim to find the globally optimal

solution in the reduced space of rules. We then find theoretical conditions under which using pre-mined rules provably does not change the set of MAP optimal solutions. These conditions relate the size of the data set to the strength of the prior. If the prior is sufficiently strong and the data set is not too large, the set of pre-mined rules is provably sufficient for finding an optimal rule set. We showed the benefits of this approach on a consumer behavior modeling application of current interest to "connected vehicle" projects. Our results, using data from an extensive survey taken by several hundred individuals, show that simple rules based on a user's context can be directly useful in predicting the user's response.

Appendix A.

Proof 1 *(of Lemma 1) Let TP, FP, TN, and FN be the number of true positives, false positives, true negatives and false negatives in S classified by A. We now compute the likelihood for model $A_{\setminus z}$. The most extreme case is when rule z is an 100% accurate rule that applies only to real positive data points and those data points satisfy only z. Therefore once removing it, the number of true positives decreases by supp(z) and the number of false negatives increases by supp(z). That is,*

$$\begin{aligned} p(S|A_{\setminus z}) \geq & \frac{B(TP - supp(z) + \alpha_+, FP + \beta_+)}{B(\alpha_+, \beta_+)} \frac{B(TN + \alpha_-, FN + supp(z) + \beta_-)}{B(\alpha_-, \beta_-)} \\ = & p(S|A) \cdot g_3(supp(z)), \end{aligned} \tag{17}$$

where

$$g_3(supp(z)) = \frac{\Gamma(TP + \alpha_+ - supp(z))}{\Gamma(TP + \alpha_+)} \frac{\Gamma(TP + FP + \alpha_+ + \beta_+)}{\Gamma(TP + FP + \alpha_+ + \beta_+ - supp(z))} \tag{18}$$

$$\frac{\Gamma(FN + \beta_- + supp(z))}{\Gamma(FN + \beta_-)} \frac{\Gamma(TN + FN + \alpha_- + \beta_-)}{\Gamma(TN + FN + \alpha_- + \beta_- + supp(z))}. \tag{19}$$

Now we break down $g_3(supp(z))$ to find a lower bound for it. The first two terms in (18) become

$$\begin{aligned} & \frac{\Gamma(TP + \alpha_+ - supp(z))}{\Gamma(TP + \alpha_+)} \frac{\Gamma(TP + FP + \alpha_+ + \beta_+)}{\Gamma(TP + FP + \alpha_+ + \beta_+ - supp(z))} \\ = & \frac{(TP + FP + \alpha_+ + \beta_+ - supp(z)) \ldots (TP + FP + \alpha_+ + \beta_+ - 1)}{(TP + \alpha_+ - supp(z)) \ldots (TP + \alpha_+ - 1)} \\ \geq & \left(\frac{TP + FP + \alpha_+ + \beta_+ - 1}{TP + \alpha_+ - 1} \right)^{supp(z)} \\ \geq & \left(\frac{N_+ + \alpha_+ + \beta_+ - 1}{N_+ + \alpha_+ - 1} \right)^{supp(z)}. \end{aligned} \tag{20}$$

Equality holds in (20) when TP $= N_+$, FP $= 0$. Similarly, the last two terms in (18) become

$$\begin{aligned}
&\frac{\Gamma(FN+\beta_- + supp(z))}{\Gamma(FN+\beta_-)}\frac{\Gamma(TN+FN+\alpha_-+\beta_-)}{\Gamma(TN+FN+\alpha_-+\beta_-+supp(z))}\\
=&\frac{(FN+\beta_-)\dots(FN+\beta_-+supp(z)-1)}{(TN+FN+\alpha_-+\beta_-)\dots(TN+FN+\alpha_-+\beta_-+supp(z)-1)}\\
\geq&\left(\frac{FN+\beta_-}{FN+TN+\alpha_-+\beta_-}\right)^{supp(z)}\\
\geq&\left(\frac{\beta_-}{N_-+\alpha_-+\beta_-}\right)^{supp(z)}. \qquad (21)
\end{aligned}$$

Equality in (21) holds when TN $= N_-$, FN $= 0$. Combining (17), (18), (20) and (21), we obtain

$$\begin{aligned}
P(S|A_{\setminus z}) &\geq \left(\frac{N_+ + \alpha_+ + \beta_+ - 1}{N_+ + \alpha_+ - 1}\frac{\beta_-}{N_- + \alpha_- + \beta_-}\right)^{supp(z)} \cdot p(S|A)\\
&= \Upsilon^{supp(z)} p(S|A). \qquad (22)
\end{aligned}$$

Proof 2 *(of Theorem 1)*

Step 1 *We first prove the upper bound $m_l^{[t]}$. Since $A^* \in \arg\max_A F(A)$, $F(A^*) \geq v^{[t]}$, i.e.,*

$$\log p(S|A^*) + \log p(A^*) \geq v^{[t]}. \qquad (23)$$

We then upper bound the two terms on the left-hand-side.

Let M_l^* denote the number of rules of length l in A^*. The prior probability of selecting A^* from $\mathcal{A}$ is

$$p(A^*) = p(\emptyset)\prod_{l=1}^{L}\frac{B(M_l+\alpha_l, |\mathcal{A}_l| - M_l + \beta_l)}{B(\alpha_l, |\mathcal{A}_l|+\beta_l)}.$$

We observe that when $0 \leq M_l^* \leq |\mathcal{A}_l|$,

$$B(M_l+\alpha_l, |\mathcal{A}_l| - M_l + \beta_l) \leq B(\alpha_l, |\mathcal{A}_l|+\beta_l),$$

giving

$$\begin{aligned}
p(A^*) &\leq p(\emptyset)\frac{B(M_{l'}+\alpha_{l'}, |\mathcal{A}_{l'}| - M_{l'} + \beta_{l'})}{B(\alpha_{l'}, |\mathcal{A}_{l'}|+\beta_{l'})}\\
&= p(\emptyset)\frac{\alpha_{l'}\cdot(\alpha_{l'}+1)\cdots(M_{l'}^*+\alpha_{l'}-1)}{(|\mathcal{A}_{l'}| - M_{l'}^* + \beta_{l'})\cdots(|\mathcal{A}_{l'}|+\beta_{l'}-1)}\\
&\leq p(\emptyset)\left(\frac{M_{l'}^*+\alpha_{l'}-1}{|\mathcal{A}_{l'}|+\beta_{l'}-1}\right)^{M_{l'}^*} \qquad (24)
\end{aligned}$$

for all $l' \in \{1, ..., L\}$. The likelihood is upper bounded by

$$p(S|A^*) \leq \mathcal{L}^*. \qquad (25)$$

Substituting (24) and (25) into (23) we get

$$\log\mathcal{L}^* + \log p(\emptyset) + M_{l'}^*\log\left(\frac{M_{l'}^*+\alpha_{l'}-1}{|\mathcal{A}_{l'}|+\beta_{l'}-1}\right) \geq v^{[t]}, \qquad (26)$$

which gives

$$\begin{aligned}
M_{l'}^* &\leq \frac{\log\mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log\left(\frac{|\mathcal{A}_{l'}|+\beta_{l'}-1}{M_{l'}^*+\alpha_{l'}-1}\right)}\\
&\leq \frac{\log\mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log\left(\frac{|\mathcal{A}_{l'}|+\beta_{l'}-1}{m_{l'}^{[t-1]}+\alpha_{l'}-1}\right)}, \qquad (27)
\end{aligned}$$

where (27) follows because $m_{l'}^{[t-1]}$ is an upper bound on $M_{l'}^*$. Since $M_{l'}^*$ has to be an integer, we get

$$\begin{aligned}
M_{l'}^* &\leq \left\lfloor\frac{\log\mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log\left(\frac{|\mathcal{A}_{l'}|+\beta_{l'}-1}{m_{l'}^{[t-1]}+\alpha_{l'}-1}\right)}\right\rfloor\\
&= m_{l'}^{[t]} \text{ for all } l' \in \{1, ..., L\}. \qquad (28)
\end{aligned}$$

Thus

$$M^* = \sum_{l=1}^{L} M_l^* \leq \sum_{l=1}^{L} m_l^{[t]}. \qquad (29)$$

Step 2: *Now we prove the lower bound on the support. We would like to prove that a MAP model does not contain rules of support less than a threshold. To show this, we prove that if any rule z has support smaller than some constant C, then removing it yields a better objective, i.e.,*

$$F(A) \leq F(A_{\setminus z}). \qquad (30)$$

Our goal is to find conditions on C such that this inequality holds. Assume in rule set A, M_l comes from pool $\mathcal{A}_l$ of rules with length l, $l \in \{1, ...L\}$, and rule z has length l' so it is drawn from $\mathcal{A}_{l'}$.

$A_{\setminus z}$ consists of the same rules as A except missing one rule from $\mathcal{A}_{l'}$. We must have:

$$\begin{aligned}
p(A_{\setminus z}) =& \frac{B(M_{l'}+\alpha_{l'}, |\mathcal{A}_{l'}| - M_{l'} + \beta_{l'})}{B(\alpha_{l'}, \beta_{l'})}\cdot\prod_{l\neq l'}\frac{B(M_l+\alpha_l, |\mathcal{A}_l| - M_l + \beta_l)}{B(\alpha_l, \beta_l)}\\
=& p(A)\cdot\frac{B(M_{l'}+\alpha_{l'}, |\mathcal{A}_{l'}| - M_{l'} + \beta_{l'})}{B(M_{l'}+1+\alpha_{l'}, |\mathcal{A}_{l'}| - M_{l'} - 1 + \beta_{l'})}\\
=& p(A)\cdot\frac{|\mathcal{A}_{l'}| - M_{l'} + \beta_{l'}}{M_{l'} - 1 + \alpha_{l'}}.
\end{aligned}$$

$\frac{|\mathcal{A}_{l'}| - M_{l'} + \beta_{l'}}{M_{l'} - 1 + \alpha_{l'}}$ decreases monotonically as $M_{l'}$ increases, so it is lower bounded at the upper bound on $M_{l'}$, $m_{l'}^{[t]}$, obtained in step 1. Therefore

$$\frac{|\mathcal{A}_{l'}| - M_{l'} + \beta_{l'}}{M_{l'} - 1 + \alpha_{l'}} \geq \frac{|\mathcal{A}_{l'}| - m_{l'}^{[t]} + \beta_{l'}}{m_{l'}^{[t]} - 1 + \alpha_{l'}} \text{ for } l' \in \{1, ...L\}.$$

Thus

$$p(A_{\setminus z}) \geq \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right) p(A). \tag{31}$$

Combining (31) and Lemma 1, the joint probability of S and $A_{\setminus z}$ is bounded by

$$\begin{aligned} P(S, A_{\setminus z}) =& p(A_{\setminus z}) P(S|A_{\setminus z}) \\ \geq& \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right) (\Upsilon)^{supp(z)} \cdot P(S, A). \end{aligned}$$

In order to get $P(S, A_{\setminus z}) \geq P(S, A)$, and with $\Upsilon \leq 1$ from the assumption in the theorem's statement, we must have

$$supp(z) \leq \frac{\log \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right)}{\log \Upsilon}.$$

This means if $\exists z \in A$ such that $supp(z) \leq \frac{\log \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right)}{\log \Upsilon}$, then $A \notin \arg\max_{A'} F(A')$, which is equivalent to saying, for any $z \in A^*$,

$$supp(z) \geq \frac{\log \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right)}{\log \Upsilon}.$$

Since the support of a rule has to be integer,

$$supp(z) \geq \left\lceil \frac{\log \max_l \left(\frac{|\mathcal{A}_l| - m_l^{[t]} + \beta_l}{m_l^{[t]} - 1 + \alpha_l} \right)}{\log \Upsilon} \right\rceil.$$

Before proving Theorem 2, we first prove the following lemma that we will need later.

Lemma 2 *Define a function $g(l) = \left(\frac{\lambda}{2}\right)^l \Gamma(J - l + 1), \lambda, J \in \mathbb{N}^+$. If $1 \leq l \leq J$,*

$$g(l) \leq \max \left\{ \left(\frac{\lambda}{2}\right) \Gamma(J+1), \left(\frac{\lambda}{2}\right)^J \right\}.$$

Proof 3 *(Of Lemma 2) In order to bound $g(l)$, we will show that $g(l)$ is convex, which means its maximum value occurs at the endpoints of the interval we are considering. The second derivative of $g(l)$ respect to l is*

$$g''(l) = g(l) \left[\left(\ln \frac{\lambda}{2} + \gamma - \sum_{k=1}^{\infty} \frac{1}{k} - \frac{1}{k + J - L_m} \right)^2 + \sum_{k=1}^{\infty} \frac{1}{(k + J - l)^2} \right] > 0, \tag{32}$$

since at least one of the terms $\frac{1}{(k+J-l)^2} > 0$. Thus $g(l)$ is strictly convex. Therefore the maximum of $g(l)$ is achieved at the boundary of L_m, namely 1 or J. So we have

$$\begin{aligned} g(l) &\leq \max \{g(1), g(J)\} \\ &= \max \left\{ \left(\frac{\lambda}{2}\right) \Gamma(J+1), \left(\frac{\lambda}{2}\right)^J \right\}. \end{aligned} \tag{33}$$

Proof 4 *(Of Theorem 2) We follow similar steps in the proof for Theorem 1.*
Step 1 *We first derive an upper bound M^* at time t, denoted as $M^{[t]}$.*

The probability of selecting a rule set A^* depends on the number of rules M^* and the length of each rule, which we denote as $L_m, m \in \{1, ..., M^*\}$, so the prior probability of selecting A^* is

$$\begin{aligned} P(A^*; \theta) &= \omega(\lambda, \eta) Poisson(M^*; \lambda) \prod_m^{M^*} Poisson(L_m; \eta) \frac{1}{\binom{J}{L_m}} \prod_k^{L_m} \frac{1}{K_{v_{m,k}}} \\ &= p(\emptyset) \frac{\lambda^{M^*}}{\Gamma(M^*+1)} \prod_m^{M^*} \frac{e^{-\eta} \eta^{L_m} \Gamma(J - L_m + 1)}{\Gamma(J+1)} \prod_k^{L_m} \frac{1}{K_{v_{m,k}}} \\ &\leq p(\emptyset) \frac{1}{\Gamma(M^*+1)} \left(\frac{e^{-\eta} \lambda}{\Gamma(J+1)} \right)^{M^*} \prod_m^{M^*} \left(\frac{\eta}{2}\right)^{L_m} \Gamma(J - L_m + 1). \end{aligned} \tag{34}$$

(34) follows from $K_{v_{m,k}} \geq 2$ since all attributes have at least two values. Using Lemma 2 we have that

$$\left(\frac{\eta}{2}\right)^{L_m} \Gamma(J - L_m + 1) \leq \max \left\{ \left(\frac{\eta}{2}\right) \Gamma(J+1), \left(\frac{\eta}{2}\right)^J \right\}. \tag{35}$$

Combining (34) and (35), and the definition of x, we have

$$P(A^*; \theta) \leq p(\emptyset) \frac{x^{M^*}}{\Gamma(M^*+1)}. \tag{36}$$

Now we apply (23) combining with (36) and (25), we get

$$\log \mathcal{L}^* + \log p(\emptyset) + \log \frac{x^{M^*}}{\Gamma(M^*+1)} \geq v^{[t]} \tag{37}$$

Now we want to upper bound $\frac{x^{M^*}}{\Gamma(M^*+1)}$.

If $M^* \leq \lambda$, the statement of the theorem holds trivially. For the remainder of the proof we consider, if $M^* > \lambda$, $\frac{x^{M^*}}{\Gamma(M^*+1)}$ is upper bounded by

$$\frac{x^{M^*}}{M^*!} \leq \frac{x^\lambda}{\lambda!} \frac{x^{(M^*-\lambda)}}{(\lambda+1)^{(M^*-\lambda)}},$$

where in the denominator we used $\Gamma(M^*+1) = \Gamma(\lambda+1)(\lambda+1) \cdots M^* \geq \Gamma(\lambda+1)(\lambda+1)^{(M^*-\lambda)}$. So we have

$$\log \mathcal{L}^* + \log p(\emptyset) + \log \frac{x^\lambda}{\Gamma(\lambda+1)} + (M - \lambda) \log \frac{x}{\lambda+1} \geq v^{[t]}. \tag{38}$$

We have $\frac{x}{\lambda+1} \leq 1$. *To see this, note* $\frac{\Gamma(J)}{\Gamma(J+1)} < 1, e^{-\eta}\left(\frac{\eta}{2}\right) < 1$ *and* $\frac{e^{-\eta}\left(\frac{\eta}{2}\right)^J}{\Gamma(J+1)} < 1$ *for every* η *and* J. *Then solving for* M^* *in (38), using* $\frac{x}{\lambda+1} < 1$ *to determine the direction of the inequality yields:*

$$M^* \leq M^{[t]} = \left\lfloor \lambda + \frac{\log \mathcal{L}^* + \log p(\emptyset) + \log \frac{x^\lambda}{\Gamma(\lambda+1)} - v^{[t]}}{\log \frac{\lambda+1}{x}} \right\rfloor \tag{39}$$

$$= \left\lfloor \frac{\log \frac{(\lambda+1)^\lambda}{\Gamma(\lambda+1)}}{\log \frac{\lambda+1}{x}} + \frac{\log \mathcal{L}^* + \log p(\emptyset) - v^{[t]}}{\log \frac{\lambda+1}{x}} \right\rfloor. \tag{40}$$

Step 2 *Now we prove the lower bound on the support of rules in an optimal set* A^*. *Similar to the proof for Theorem 1, we will show that for a rule set* A, *if any rule* a_z *has support* $supp(z) < C$ *on data* S, *then* $A \notin \arg\min_{A' \in \Lambda_S} F(A')$. *Assume rule* a_z *has support less than C and* $A_{\setminus z}$ *has the* k*-th rule removed from* A. *Assume* A *consists of* M *rules, and the* z*-th rule has length* L_z.

We relate $P(A_{\setminus z}; \theta)$ *with* $P(A; \theta)$. *We multiply* $P(A_{\setminus z}; \theta)$ *with 1 in disguise to relate it to* $P(A; \theta)$:

$$P(A_{\setminus z}) = \frac{M^*\Gamma(J+1)}{\lambda e^{-\eta}\eta^{L_z}\Gamma(J-L_z+1)\prod_k^{L_z}\frac{1}{K_{v_{z,k}}}} P(A)$$

$$\geq \frac{M^*\Gamma(J+1)}{\lambda e^{-\eta}\left(\frac{\eta}{2}\right)^{L_z}\Gamma(J-L_z+1)} P(A) \tag{41}$$

$$= \frac{M^*\Gamma(J+1)}{\lambda e^{-\eta} g(L_z; \eta, J)} P(A) \tag{42}$$

$$\geq \frac{M^* P(A)}{x} \tag{43}$$

where (41) follows that $K_{v_{m,k}} \geq 2$ *since all attributes have at least two values, (42) follows the definition of* $g(l)$ *in Lemma 2 and (43) uses the upper bound in Lemma 2 and. Then combining (22) with (42), the joint probability of* S *and* $A_{\setminus z}$ *is lower bounded by*

$$P(S, A_{\setminus z}) = P(A_{\setminus z})P(S|A_{\setminus z})$$

$$\geq \frac{M^*\Upsilon^{supp(z)}}{x} P(S, A).$$

In order to get $P(S, A_{\setminus z}) \geq P(S, A)$, *we need*

$$\frac{M^*\Upsilon^{supp(z)}}{x} \geq 1,$$

i.e.,

$$\Upsilon^{supp(z)} \geq \frac{x}{M^*} \geq \frac{x}{M^{[t]}},$$

We have $\Upsilon \leq 1$, *thus*

$$supp(z) \leq \frac{\log \frac{x}{M^{[t]}}}{\log \Upsilon}. \tag{44}$$

Therefore, for any rule z *in a MAP model* A^*,

$$supp(z) \geq \left\lceil \frac{\log \frac{x}{M^{[t]}}}{\log \Upsilon} \right\rceil. \tag{45}$$

Appendix B. Mobile Advertisement data sets

The attributes of this data set include:

1. User attributes
   - Gender: male, female
   - Age: below 21, 21 to 25, 26 to 30, etc.
   - Marital Status: single, married partner, unmarried partner, or widowed
   - Number of children: 0, 1, or more than 1
   - Education: high school, bachelors degree, associates degree, or graduate degree
   - Occupation: architecture & engineering, business & financial, etc.
   - Annual income: less than $12500, $12500 - $24999, $25000 - $37499, etc.
   - Number of times that he/she goes to a bar: 0, less than 1, 1 to 3, 4 to 8 or greater than 8
   - Number of times that he/she buys takeaway food: 0, less than 1, 1 to 3, 4 to 8 or greater than 8
   - Number of times that he/she goes to a coffee house: 0, less than 1, 1 to 3, 4 to 8 or greater than 8
   - Number of times that he/she eats at a restaurant with average expense less than $20 per person: 0, less than 1, 1 to 3, 4 to 8 or greater than 8
   - Number of times that he/she goes to a bar: 0, less than 1, 1 to 3, 4 to 8 or greater than 8
2. Contextual attributes
   - Driving destination: home, work, or no urgent destination
   - Location of user, coupon and destination: we provide a map to show the geographical location of the user, destination, and the venue, and we mark the distance between each two places with time of driving. The user can see whether the venue is in the same direction as the destination.
   - Weather: sunny, rainy, or snowy
   - Temperature: 30F°, 55F°, or 80F°
   - Time: 10AM, 2PM, or 6PM
   - Passenger: alone, partner, kid(s), or friend(s)
3. Coupon attributes
   - time before it expires: 2 hours or one day

All coupons provide a 20% discount. The survey was divided into different parts, so that Turkers without children would never see a scenario where their “kids" were in the vehicle. Figure 12 and 13 show two examples of scenarios in the survey.

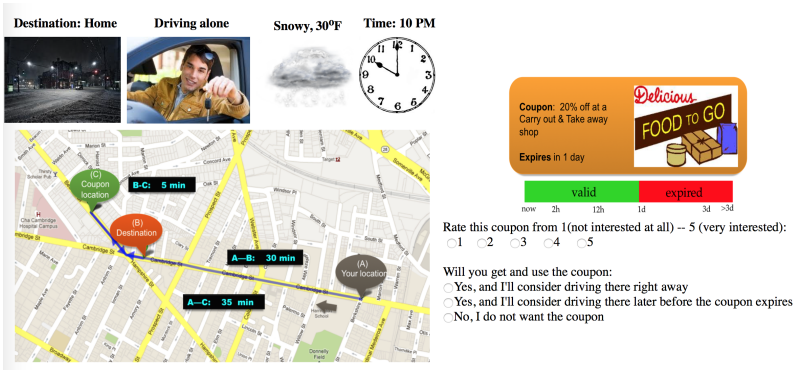

Figure 12: Example 1 of scenario in the survey

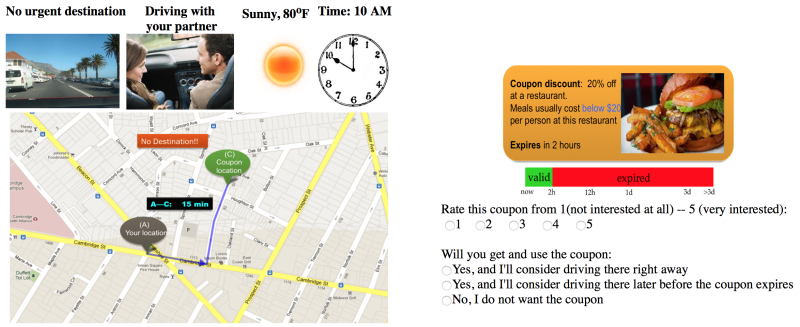

Figure 13: Example 2 of scenario in the survey

Abstract

In many applications, not all the features used to represent data samples are important. Often only a few features are relevant for the prediction task. The choice of dependence measures often affect the final result of many feature selection methods. To select features that have complex nonlinear relationships with the response variable, the dependence measure should be *equitable*, a concept proposed by Reshef et al. (2011); that is, the dependence measure treats linear and nonlinear relationships equally. Recently, Kinney and Atwal (2014) gave a mathematical definition of *self-equitability*. In this paper, we introduce a new concept of *robust-equitability* and identify a robust-equitable copula dependence measure, the *robust copula dependence* (RCD) measure. RCD is based on the L_1-distance of the copula density from uniform and we show that it is equitable under both equitability definitions. We also prove theoretically that RCD is much easier to estimate than mutual information. Because of these theoretical properties, the RCD measure has the following advantages compared to existing dependence measures: it is robust to different relationship forms and robust to unequal sample sizes of different features. Experiments on both synthetic and real-world data sets confirm the theoretical analysis, and illustrate the advantage of using the dependence measure RCD for feature selection.

Keywords: dependence measure, feature selection, copula, equitability, mutual information

1. Introduction

The performance of machine learning algorithms is dependent on the input features representing each data sample. Often not all of these features are useful: some may be irrelevant and some may be redundant. Feature selection is thus needed to help improve the performance of learning tasks. Moreover, feature selection can decrease the computational cost of algorithms, and provide domain experts with an increased understanding of which factors are important.

Feature selection algorithms can be categorized based on how the learning algorithms is incorporated into the selection algorithm: *filter*, *wrapper*, or *embedded* methods (Kohavi and John, 1997; Guyon and Elisseeff, 2003; Yu and Liu, 2004). Filter methods (Kira and Rendell, 1992; Yu and Liu, 2004; Peng et al., 2005; He et al., 2005; Song et al., 2007) pre-select features, without running the learning algorithm. Features are evaluated only through the intrinsic properties of the data. Wrapper methods (Kohavi and John, 1997; Guyon et al., 2002; Dy and Brodley, 2004) "wraps" the search around the learning algorithm and evaluate candidate feature subsets based on learning performance in each candidate feature subset. Embedded methods (Tibshirani, 1996; Vapnik and Vapnik, 1998) incorporate feature search and the learning algorithm into a single optimization problem formulation. Wrapper and embedded methods, contrary to filter methods, select features specific to the learning algorithm; thus, they are most likely to be more accurate than filter methods on a particular learning algorithm, but the features they choose may not be appropriate for other algorithms. Another limitation of wrapper methods is that they are computationally expensive because they need to train and test the learning algorithm for each feature subset candidate, which can be prohibitive when working with high-dimensional data.

Filter methods rely on measures based on intrinsic properties of the data. More specifically, they evaluate features based on some dependence measure criterion between features and the target variable and select the subset of features that optimizes this criterion. Let d be the number of original features. An exhaustive search, which involves 2^d possible feature subsets is computationally impractical. Thus, one commonly employs heuristic search strategies, such as greedy approaches (e.g., sequential forward/backward search (Pudil et al., 1994)). However, these strategies can lead to local optima. Random search methods, such as genetic algorithms, add some randomness to help escape from local optima. When the dimensionality is very high, one can only afford an individual search. Individual search methods (Guyon and Elisseeff, 2003; He et al., 2005) evaluate each feature individually according to a criterion and then select features, which either satisfies a condition or are top-ranked. The problem with individual search methods is that they ignore feature interaction and dependencies. To account for such interactions and dependencies, Yu and Liu (2004) selects relevant features individually and then add a separate redundancy removal step to account for linear correlation between features; Peng et al. (2005) suggests another way, by maximizing relevance and minimizing redundancy (mRMR) together.

In addition to search strategies, the performance of filter methods depend heavily on the choice of dependence measures. The ability to measure the dependence between random variables is a fundamental problem in statistics and machine learning. One of the simplest and most common dependence measure is the Pearson correlation coefficient (ρ_{lin}). However, this measure only captures linear relationships. Another popular measure is mutual information (MI). MI can capture nonlinear dependencies but is difficult to estimate (Fernandes and Gloor, 2010; Reshef et al., 2011) (see Theorem 3 in Section 4). Kernel-based dependence measures (Gretton et al., 2005a; Fukumizu et al., 2007) (e.g., the Hilbert-Schmidt Independence Criterion (HSIC)) have been introduced as an alternative to MI which does not require explicitly learning joint distributions. However, HSIC depends on the choice of kernels. Hilbert-Schmidt Normalized Information Criterion (HSNIC), also known as normalized conditional cross-covariance operator (NOCCO) (Fukumizu et al., 2007), is kernel-free, meaning it does not depend on the choice of kernels in the limit of infinite data. Even though HSNIC is kernel-free, both HSIC and HSNIC's values may vary when we use different

scales. Poczos et al. (2012) applied Maximum Mean Discrepancy (MMD) after empirical copula transformation to make the kernel-based dependence measure invariant to strictly monotone transformation of the marginal variables. The Copula-MMD (CMMD) can also be written in HSIC formulation after empirical copula transformation. Similarly, Reddi and Póczos (2013) applied HSNIC after empirical copula transformation (CHSNIC). Other dependence measures can also be applied after empirical copula transformation, resulting in measures that are also invariant to strictly monotone transformations. However, they (e.g., CMMD and CHSNIC) may fail to treat non-monotonic relations equally.

Reshef et al. (2011) proposed the concept of *equitability*, which states that a dependence measure should give equal importance to all relations: linear and nonlinear. For example, we expect a fair dependence measure to treat a perfectly linear relationship and a perfectly sinusoid relationship equally. Kinney and Atwal (2014) mathematically defined equitability by proposing *self-equitability*—under a nonlinear regression model with additive noise, a dependence measure should be invariant to any deterministic transformation of the marginal variables, under a nonlinear regression model with additive noise (a formal definition is provided in Definition 1, Section 2). A self-equitable dependence measure will treat all forms of relationships equally in the large data limit for the additive noise model. Kinney and Atwal (2014) proved that MI is self-equitable, and recommended its usage.

To choose among the many self-equitable dependence measures, we further propose a new *robust-equitability* concept such that the measure also treats all forms of relationships equally in the mixture noise model. That is, in a mixture distribution with p proportion of deterministic signal hidden in continuous independent background noise, the measure should reflect the signal strength p. The mixture noise model reflects real applications where measurements (features) are often corrupted with noise. For example, sensor data maybe corrupted by noise from hardware and environmental factors. Reshef et al. (2011, 2015b) considered equitability for a statistic. Our robust-equitability, as well as Kinney and Atwal (2014)'s self-equitability, is defined on the population quantity instead. Particularly, in the mixture distribution above, we define a dependence measure as *weakly-robust-equitable* if it is a monotone transformation of the proportion p, and is robust-equitable if it equals to p exactly.

In this paper, we show that among a class of self-equitable copula-based dependence measures, only *robust copula dependence* (RCD), defined as the total variational distance (the half of the L_1 distance) between copula density and uniform (independence) density, is also weakly-robust-equitable (and robust-equitable). Without referring to the copula density, RCD can be equivalently stated as the total variational distance between the probability distribution and the (independent) product of its marginal distributions, and is equivalent to the Silvey's Delta measure (Silvey, 1964). In the literature, the Silvey's Delta (RCD) was only cited as an abstract benchmark. Here, we propose a k-nearest-neighbor (KNN)-based estimator for RCD and prove its consistency. Besides the L_1 distance RCD, we also investigated properties of the L_2 distance between copula density and the uniform density (we call CD_2). CD_2 is the theoretical value of HSNIC in the large data limit (Fukumizu et al., 2007).

In addition, the robust-equitability study in this paper provides insights on the difficulty of estimating MI. Some authors studied the convergence of MI estimators by imposing the Hölder condition on the copula density. This Hölder condition, while being a standard condition for density estimations, does not hold for any commonly used copula (Omelka et al., 2009; Segers, 2012). Under a more realistic Hölder condition on the bounded region of copula density, we provide a theoretical proof that the mutual information (MI)'s minimax risk is infinite. This provides a theoretical explanation on the statistical difficulty of estimating MI observed by practitioners (Fernandes and Gloor, 2010; Reshef et al., 2011). Moreover, we prove that although both MI and CD_2 are self-equitable, they are not robust-equitable. Therefore, MI and CD_2 may not rank the features correctly by dependence strength in some cases, even in the large data limit. We confirm this phenomena on both synthetic and real-world data sets. In contrast, RCD is consistently estimable under the same condition. As for kernel-based dependence measures, HSIC and CMMD are neither self-equitable nor robust-equitable, HSNIC and CHSNIC are self-equitable but not robust-equitable and their estimators converge very slowly. Since RCD is the only measure that is both self-equitable and robust-equitable among these measures, it can be very useful for feature selection.

In summary, the contributions of this paper are: (1) the introduction of the concept of robust-equitability; (2) the identification of RCD as a dependence measure that is both self- and robust-equitable and the proposal of a practical consistent estimator for RCD; (3) theoretically proving that non-robust-equitable measures MI and CD_2 cannot be consistently estimated and showing that this can lead to incorrect selection of features when sample size is large or when sample sizes are unequal for different features; and finally, (4) demonstrating that the robust-equitable RCD is a better dependence measure for feature selection compared to existing dependence measures through experiments on synthetic and real-world data sets, in terms of robustness to function types, correctness in large sample size and correctness in unequal sample sizes. This paper is a substantially extended version of our conference version (Chang et al., 2016). In particular, this work includes the following additional materials: (1) a more complete treatment of the motivation and rationale of equitability definitions—we discuss the relationship of equitability to Renyi's theorems, to more copula-based dependence measures, and to independence tests; (2) a more complete theoretical treatment of the difficulty in estimation of mutual information (MI) versus RCD; in particular, we add a theorem showing that the difficulty of MI estimation is not due to the unboundedness of its definition, but is intrinsic due its being non-robust-equitable; and (3) more extensive empirical studies illustrating how equitability helps in feature selection.

The rest of this paper is organized as follows. In Section 2, we motivate the equitability concepts, discussing different equitability definitions and relationship to copula and Renyi's theorems. Particularly, we propose the concept of robust-equitability, and define a robust-equitable dependence measure called robust copula dependence. In Section 3, we prove MI and CD_2 are not consistently estimable. We also prove RCD can be consistently estimated and provide its estimators based on kernel density estimation (KDE) and k-nearest-neighbors (KNN). In Section 4, we provide feature selection experiments on synthetic and real data sets to demonstrate the advantage of RCD compared to existing dependence measures. We end with conclusions and discussions in Section 5.

2. A Robust-Equitable Dependence Measure

In this section, we investigate the theoretical properties of different dependence measures. In particular, we would like the dependence measures to have the following characteristics. We would like the dependence measures to rank a feature with less noise as having a stronger dependence with the response variable compared to features with more noise. We do not want measures that prefer a particular type of relationship (e.g., linear). Moreover, we do not want the measures to be too sensitive to sample size (i.e., when different features have unequal sample sizes, the dependence measure should not prefer a feature simply because it has more samples, but should still rank the features

based on the strength of the deterministic signal compared to noise). Note that it is becoming more common for databases to have features that have unequal sample sizes due to the prevalence of data collection from heterogeneous sources. For example, a clinical database may have more samples with clinical features compared to samples with genomic information. In such as setting, we would like to use all the data available to perform feature selection rather than to create equal sample sizes by throwing away samples from the larger set. In this paper, we formalize these ideas through the recently proposed equitability concept: We want to use dependence measures that reflect the noise level, regardless of relationship type.

2.1 Self-equitability, Rényi's Axioms and Copula-based Dependence Measures

Reshef et al. (2011) proposed that an equitable measure should "give similar scores to equally noisy relationships of different types." Kinney and Atwal (2014) mathematically defined self-equitability through invariance under all nonlinear relationships in the regression model

$$Y = f(X) + \epsilon, \tag{1}$$

where f is a deterministic function, ϵ is the random noise variable whose distribution may depend on $f(X)$ as long as ϵ has no additional dependence on X.

Definition 1 *A dependence measure $D[X;Y]$ is self-equitable if and only if $D[X;Y] = D[f(X);Y]$ whenever f is the function in model (1).*

Kinney and Atwal (2014) recommended usage of a self-equitable measure: mutual information (MI).

To understand self-equitability better, we notice that Definition 1 is very similar to Rényi's Sixth Axiom A6, both are defined through the invariance of the dependence measure under transformations. Rényi (1959) proposed seven axioms for dependence measures $D[X;Y]$. **(A1)** $D[X;Y]$ is defined for any random variables X and Y; **(A2)** symmetric $D[X;Y] = D[Y;X]$; **(A3)** $0 \leq D[X;Y] \leq 1$; **(A4)** $D(X;Y) = 0$ if and only if X and Y are statistically independent; **(A5)** $D(X;Y) = 1$ if either $X = f(Y)$ or $Y = g(X)$ for some Borel-measurable functions f and g; **(A6)** If f and g are Borel-measurable, one-one mappings of the real line into itself then $D[f(X);g(Y)] = D[X;Y]$; **(A7)** If the joint distribution of X and Y is bivariate Gaussian, with linear correlation coefficient ρ, then $D[X;Y] = |\rho|$.

For a symmetric dependence measure (satisfying Axiom A2), Axiom A6 can be rewritten as $D[f(X);Y] = D[X;Y]$ for all Borel-measurable f. Hence self-equitability is a weaker version requiring an extra assumption that f satisfies the model (1).

It is known that Rényi's maximum correlation coefficient is the only measure that satisfies all seven Rényi's Axioms. However, Rényi's maximum correlation coefficient has a number of major drawbacks, e.g., it equals 1 too often and is generally not effectively estimable (Schweizer and Wolff, 1981; Székely and Rizzo, 2009). Hence enforcing all seven axioms is often considered too strong a constraint on the dependence measure, while some axioms are often considered desirable. For example, HSIC is shown to satisfy the first four axioms by Gretton et al. (2005a) and Gretton et al. (2005b).

For comparison, another weakened version of Axiom A6 is to restrict the transformations to monotone functions (Schweizer and Wolff, 1981), but without imposing the regression model (1). We may call this version of Axiom (A6*) *weak-equitability*.

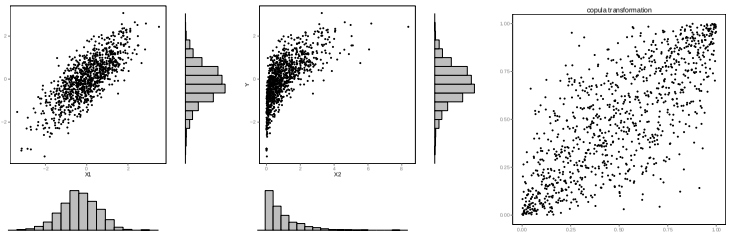

Figure 1: Left: Bivariate Gaussian with $\rho = 0.75$. Middle: Data with exponential marginal for X. Right: The Gaussian copula. The first two distributions have the same copula as in the right figure.

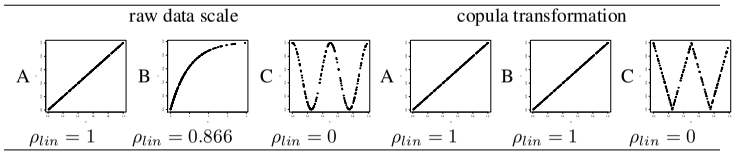

Table 1: Pearson correlation coefficient on three function relationships.

Definition 2 *A dependence measure $D[X;Y]$ is weak-equitable if and only if $D[X;Y] = D[f(X);Y]$ whenever f is a strictly monotone continuous deterministic function.*

The weak-equitable dependence measures treat all monotone (but not all nonlinear) relationships equally, and is a property shared by all copula-based dependence measures (e.g., CMMD and CHSNIC). Sklar's theorem ensures that, for any joint distribution function $F_{X,Y}(x,y) = Pr(X \leq x, Y \leq y)$, there exists a copula C—a probability distribution on the unit square $\mathcal{I}^2 = [0,1] \times [0,1]$—such that

$$F_{X,Y}(x,y) = C[F_X(x), F_Y(y)] \qquad \text{for all } x, y. \tag{2}$$

Here $F_X(x) = Pr(X \leq x)$ and $F_Y(y) = Pr(Y \leq y)$ are the marginal cumulative distribution functions (CDFs) of X and Y respectively. In other words, the copula C is the joint CDF of the two copula-transformed, uniformly distributed, variables $U = F_X(X)$ and $V = F_Y(Y)$. In this way, the copula decomposition separates the dependence from any marginal effects, and the copula C captures all the dependence between X and Y. Figure 1 shows the data from two distributions with different marginals but the same dependence structure.

Table 1 shows three simple examples and their respective copula transformations. We can see that the linear correlation ρ_{lin} prefers the linear relationship in (A). Applying on the copula-transformed variables on the right half of Table 1, ρ_{lin} (now equivalent to Spearman's ρ) becomes invariant to monotone transformation in (B), but still cannot capture the non-monotone nonlinear relationship in (C).

While copula-based dependence measures treats the monotone functions equally, equitability aims to also treat non-monotone functions equally. However, the original Rényi's Axiom A6 may be overly strong, and self-equitability aims to treat non-monotone functions equally only under the regression model (1).

We first consider some self-equitable copula-based dependence measures and further choose among these measures based on a new equitability definition in the next Subsection 2.2. Mutual information (MI), the recommended measure in Kinney and Atwal (2014), is self-equitable and is based on copula density $c(u, v)$,

$$\mathrm{MI} = \int_{I^2} \log[c(u, v)]c(u, v)dudv, \tag{3}$$

where I^2 is the unit square. We now consider a large class of self-equitable copula-based measures. Since the marginal variables X, Y are independent if and only if the corresponding copula distribution is uniform, we measure the dependence between X, Y through the distance between their copula distribution and the uniform distribution. Let the *Copula Distance* CD_α be the L_α distance between a copula density and the uniform copula density $\pi(u, v) = 1$.

$$\mathrm{CD}_\alpha = \int_{I^2} |c(u, v) - 1|^\alpha dudv, \quad \alpha > 0. \tag{4}$$

Combining Eq.4 in Fukumizu et al. (2007) and Eq.(4) here, CD_2 is the theoretical value of HSNIC in the large data limit. Our first result is that, the Copula Distance is self-equitable when $\alpha \geq 1$.

Lemma 1 *The Copula-Distance* CD_α *with* $\alpha \geq 1$ *is self-equitable.*

The proof follows from Theorems S3 and S4 of Kinney and Atwal (2014), since $g(x) = |x - 1|^\alpha$ is convex when $\alpha \geq 1$.

Remark: Schweizer and Wolff (1981) studied a class of dependence measures that are the L_α distance between a joint copula $C(u, v)$ and the uniform copula $\Pi(u, v) = uv$. The L_1, L_2 and L_∞ distance result in, the Wolf's σ, Hoeffding's Φ^2 and Wolf's κ respectively. Schweizer and Wolff (1981) showed that these measures satisfy a modified set of Rényi's Axioms, including Axiom (A6*) weak-equitability. In contrast to the Copula-Distance CD_α (L_α distance based on *copula densities*), these measures are based on the *cumulative distribution functions* and *are not self-equitable*. Since $C(u, v) = Pr(U \leq u, V \leq v)$ is the cumulative distribution function, such measures cumulate the deviation from independence from $u = 0$ to $u = 1$, and do not remain invariant for all nonlinear transformations f in model (1).

2.2 Robust Equitability

To select among the many self-equitable dependence measures, we want to consider additional equitability conditions. Some self-equitable dependence measures may not perform well in practice. For example, Rényi's maximum correlation coefficient (Rcor) satisfies the stronger Rényi's Axiom A6, thus it is also self-equitable. $Rcor(X; Y) = \sup_{f,g} \rho[f(X); g(Y)]$, where ρ is the linear correlation coefficient and the supremum is taken over all Borel-measurable functions f and g. Rcor has a number of major drawbacks, e.g., it equals 1 too often and is generally not effectively estimable (Schweizer and Wolff, 1981; Székely and Rizzo, 2009).

We observe the deficiencies more clearly in another self-equitable measure, the ideal dependence coefficient (IDC): $IDC(X; Y) = 0$ if X and Y are independent and $IDC(X; Y) = 1$ otherwise. IDC satisfies the first six Rényi's Axioms, and is self-equitable. It equals one for all dependent X and Y, providing no distinction of the dependence strength. IDC is only an abstract measure, the estimation of IDC is equivalent to *testing independence* between X and Y. However,

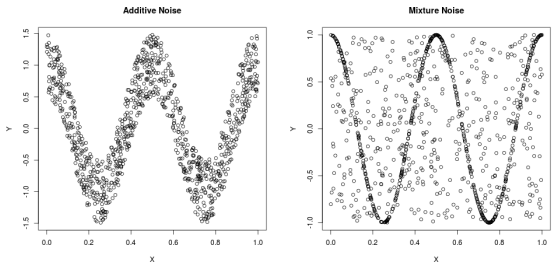

Figure 2: Left: Additive noise for self-equitability. Right: Mixture noise for robust-equitability.

for feature selection, IDC is not helpful at all because it provides no distinction of the dependence strength for different features. It is also hard to estimate. We wish for a new equitability criterion to exclude trivial dependence measures like IDC.

The self-equitability definition focuses on the regression $Y = f(X) + \epsilon$. However, in practice, this additive noise model does not capture all data types. In some cases, for example in sensor measurements, the deterministic signal is hidden in continuous background noise. Figure 2 illustrates these two types of noise. The Left subfigure shows additive noise on a deterministic sinusoidal function. The Right subfigure is the same deterministic signal on a uniform background noise. Mathematically, after the copula transformation, the second mixture noise model is described by a mixture copula: a continuous copula on the unit square I^2 is added to a deterministic signal C_s, which is a singular copula. Any copula can always be separated into a singular component and an absolutely continuous component (Nelsen, 2006, page 27). Independent background noise is represented by taking the absolutely continuous component as the independence copula $\Pi(u, v) = uv$ on I^2. Therefore, with p proportion of hidden deterministic relationship, the copula $C = pC_s + (1 - p)\Pi$. Here C_s is a singular copula representing the deterministic relationship, so that its support $\mathcal{S}$ has Lebesgue measure zero. The equitability in this mixture noise model means that the dependence measure should give the same value for all types of deterministic signal C_s.

Definition 3 *A dependence measure* $D[X; Y]$ *is robust-equitable if and only if* $D[X; Y] = p$ *whenever* (X, Y) *follows a distribution whose copula is* $C = pC_s + (1 - p)\Pi$*, for a singular copula* C_s*.*

Among the self-equitable Copula-Distances ($\alpha \geq 1$), L_1 distance is the special case that does reflect the proportion of deterministic relationship in the mixture copula.

$$CD_1 = p \int_{\mathcal{S}} C(du, dv) + \int_{\mathcal{I}^2 \setminus \mathcal{S}} |(1 - p) - 1|dudv = p(1) + p = 2p.$$

Therefore we define the scaled version of CD_1 as *robust copula dependence (RCD)*

$$RCD = \frac{1}{2}CD_1 = \frac{1}{2}\int_{\mathcal{I}^2} |c(u, v) - 1|dudv. \tag{5}$$

Lemma 2 *The robust copula dependence RCD is robust-equitable.*

Mathematically, RCD is the same as Silvey's Delta (Silvey, 1964):

$$\Delta = \int_{\phi>1} [p(x,y) - p_X(x)p_Y(y)]dxdy,$$

where p_X and p_Y are the marginal probability densities for X and Y, p is the joint probability density for X and Y, and $\phi(x,y) = p(x,y)/[p_X(x)p_Y(y)]$. We write equation (5) in terms of the absolutely continuous copula density for ease of understanding. When part of the copula is singular, the RCD in (5) can be defined as in Silvey (1964), interpreting ϕ as the Radon-Nikodym derivative of the joint distribution with respect to a dominating probability measure which does cover the possibility of singularity. Alternatively, for a mixture copula C, the RCD can be defined as the limit of $\lim_{m\to\infty} RCD(C_m)$ for equation (5) on any sequence of continuous copulas $\{C_1, C_2, ...\}$ that converges to C. The convergence means that $\lim_{m\to\infty} \|C_m - C\|_1 := 2 \lim_{m\to\infty} \sup_A |C_m(A) - C(A)| = 0$, where the supremum is taken over all Borel sets A. A second way of interpretation is helpful in thinking about why CD_α, when $\alpha > 1$, can not be made robust-equitable and why this leads to statistical difficulties in estimation which we will discuss in detail in the next section.

Roughly speaking, for the mixture copula $C = pC_s + (1-p)\Pi$, the copula density for the absolutely continuous component is $c_c(u,v) = 1-p$, while we can imagine $c_s(u,v)$ as an abstract copula density for the singular component such that $\int_{\mathcal{B}} c_s(u,v)dudv := \int_{\mathcal{B}} C(du,dv) = C_s(\mathcal{B})$ for any subset $\mathcal{B} \subset \mathcal{S}$. Since $\mathcal{S}$ has Lebesgue measure zero, $c_s(u,v) = \infty$ for $(u,v) \in \mathcal{S}$ so that c_s is not a proper density, but rather an abstract limit of the sequence $\lim_{m\to\infty} c_{m,s}$. Here for any convergent sequence of continuous copulas $\{C_1, C_2, ...\}$ above, $c_{m,s}(u,v) = c_m(u,v) - c_c(u,v)$ is the continuous copula density that approaches the abstract $c_s(u,v)$. For any open set $\mathcal{B}_\mathcal{O} \supset \mathcal{B}$, $C_s(\mathcal{B}_\mathcal{O}) = \int_{\mathcal{B}_\mathcal{O}} c_s(u,v)dudv := \lim_{m\to\infty} \int_{\mathcal{B}_\mathcal{O}} c_{m,s}(u,v)dudv$, and $C_s(\mathcal{B}) = \lim_{\mathcal{B}_\mathcal{O}\to\mathcal{B}} C_s(\mathcal{B}_\mathcal{O})$. Hence for any $\alpha > 1$, $\int_{\mathcal{B}}[c_s(u,v)]^\alpha dudv = \int_{\mathcal{S}}[c_s(u,v)]^{\alpha-1}c_s(u,v)dudv = \int_{\mathcal{S}} \infty c_s(u,v)dudv = \infty$. So that $CD_\alpha = \infty$ whenever $\alpha > 1$ and $p > 0$. Similarly, $MI = \infty$ for all $p > 0$. They do not distinguish the dependence strength in the mixture distribution according to the signal proportion p, and can not be transformed to be robust-equitable as they over-emphasize the singular component (high copula density region).

If the dependence measure does not equal p exactly but is a monotone function of p, then we can scale it to get a robust-equitable version, and call it weakly-robust-equitable.

Definition 4 *A dependence measure $D[X;Y]$ is weakly-robust-equitable if and only if $D[X;Y]$ is a strictly monotone function of p whenever (X,Y) follows a distribution whose copula is $C = pC_s + (1-p)\Pi$, for a singular copula C_s.*

Lemma 3 *The Copula-Distance CD_α is weakly-robust-equitable if and only if $\alpha \leq 1$.*

When $\alpha > 1$, since $CD_\alpha = \infty$ whenever $p > 0$, those are not weakly-robust-equitable. When $\alpha < 1$, $\int_{\mathcal{S}}[c_s(u,v)]^\alpha dudv = \int_{\mathcal{B}}[c_s(u,v)]^{\alpha-1}c_s(u,v)dudv = 0$ so that the contribution from the singular region $\mathcal{S}$ is zero. In these cases,

$$CD_\alpha = 0 + \int_{\mathcal{I}^2\setminus\mathcal{S}} |(1-p) - 1|^\alpha dudv = p^\alpha$$

is weakly-robust-equitable. And CD_1 is weakly-robust-equitable from Lemma 2.

The self-equitability for additive noise model requires that $\alpha \geq 1$, while the weakly-robust-equitablity in the mixture noise model requires that $\alpha \leq 1$. Hence only $\alpha = 1$ satisfies the equitability condition in both noise models, and resulting in the robust-equitable RCD.

2.2.1 RCD, OTHER EQUITABILITY DEFINITIONS AND RÉNYI'S AXIOM

Having introduced our measure, RCD, and the robust-equitability definition, we can further compare them to the other equitability definitions in the literature. Reshef et al. (2011) considers equitability as the ability of a statistic $\hat{D}$ to approximately reflect the nonlinear R^2 over different relationships. They proposed a statistic MIC and demonstrate numerically such equitability through simulated examples. Kinney and Atwal (2014) propose to formalize such concept for the population parameter $D[X;Y]$ such that an R^2-*equitable* measure equals $g(R^2[f(X),Y])$ in the additive noise model (1) $Y = f(X) + \epsilon$, and showed that no nontrivial dependence measure can satisfy this R^2-equitability. The self-equitability definition is proposed as an alternative. Murrell et al. (2014) pointed out that such impossibility results are due to the non-identifiability due to the specification of ϵ term, allowing ϵ to possibly depend on $f(X)$. Under such specification, for example, a noiseless parabola can be realized as a noisy version of a noiseless linear relationship (Murrell et al., 2014). Reshef et al. (2015b) propose another formal equitability framework through interpretable intervals of a statistic under additive homoscedastic noises for both X and Y.

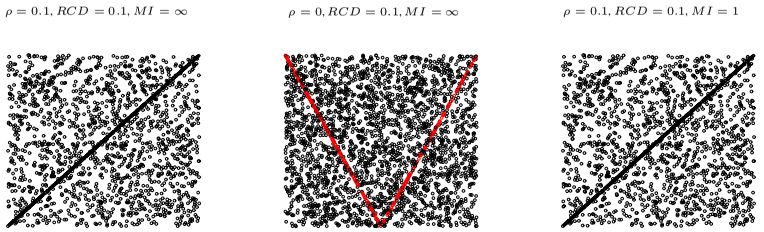
Our robust-equitability definition shares some common characteristics with both Kinney and Atwal (2014)'s and Reshef et al. (2015b)'s approach respectively. Similar to Kinney and Atwal (2014), our robust-equitability focuses on the population quantity $D[X;Y]$ instead of a statistic $\hat{D}[X;Y]$. This allows proof of theoretical equitability properties for specific dependence measures, as the statistical estimation error $\hat{D} - D$ can be kept as a separate issue. Robust-equitability does have implications on the statistical estimation error bounds which will be discussed in the next section. Self-equitability and robust-equitability focus on the invariance of $D[X;Y]$ as in Rényi's Axiom A6, but for different noise models. Reshef et al. (2015b) and our robust-equitability definition each focuses on a noise model to avoid the non-identifiability issue in Kinney and Atwal (2014)'s model: additive homoscedastic noise and mixture uniform noise respectively. Under each model, there is a clearly identifiable quantity of interest: the nonlinear R^2 and the mixture proportion p respectively.

Furthermore, our RCD satisfies the first five Rényi's Axioms. Particularly, $RCD = 0$ if and only if X and Y are statistically independent, $RCD = 1$ if X and Y are related through a deterministic relationship. And RCD is symmetric in that $RCD[X;Y] = RCD[Y;X]$. Notice that this symmetric property is an appropriate requirement for feature selection with the filtering method mRMR (Peng et al., 2005). Given a data set $\mathbf{X} \in \mathbb{R}^{n\times d}$, where n is the number of samples, d is the number of features, and target variable $Y \in \mathbb{R}^{n\times 1}$, let X_i denote the i-th feature, mRMR finds from the d-dimensional feature space, $\mathbb{R}^d$, a subspace of m features that optimally characterize Y, by solving the following optimization problem:

$$\max_S \frac{1}{|S|} \sum_{X_i\in S} D[X_i;Y] - \frac{1}{|S|^2} \sum_{X_i,X_j\in S} D[X_i;X_j], \tag{6}$$

where S is the optimal feature set, the first term maximizes relevance and the second term minimizes redundancy. Notice that this method only requires bivariate dependence between different features $D[X_i;X_j]$ in addition to the bivariate dependence between each feature and response variable $D[X_i;Y]$. The feature selection results of mRMR with an asymmetric dependence measure would depend on how the features are ordered, which is an undesirable characteristic.

RCD satisfies self-equitability, which is a weakened version of the sixth Rényi's Axiom. The Rényi's Axiom A7 requires the dependence measure to agree with the natural quantity of $|\rho|$ for bivariate Gaussian distributions (which corresponds to a linear regression model). Our RCD does not satisfy that, but instead agree with $|\rho|$ for the mixture noise setting with a linear deterministic relationship, since in that case $p = |\rho|$. Our robust-equitability definition requires the measure equals p exactly, which provides an easy interpretation in that it is an equitable extension of Pearson's correlation $|\rho|$ to all forms of hidden nonlinear deterministic relationships. It is not essential to require the exact equality to p, as equaling to a monotone function of p (weakly-robust-equitability) would enable a robust-equitable version of the measure through a transformation. However, precisely equaling to p is nice due to the above easier interpretation. Notice that $R^2 = \rho^2$ for the additive noise regression model with a linear relationship (bivariate Gaussian distribution). Hence the nonlinear R^2 can be similarly considered as an equitable extension of Pearson's correlation in the additive noise model to all forms of nonlinear regression relationships. However, unlike p, R^2 does not satisfy the symmetric property since regressing Y on X and regressing X on Y do not give the same value.



For discrete random variables, Equation (5) corresponds to the Kolmogorov dependence measure in the pattern recognition literature (Vilmansen, 1972, 1973; Ekdahl and Koski, 2006) and also known as the Mortara dependence index (Bagnato et al., 2013). In the discrete case, the measure has a maximum value less than 1. In contrast, $RCD = 1$ when X and Y are deterministically related. For continuous random variables X and Y, Silvey's Delta has been cited only as an abstract concept and no practical estimator was used in the literature for data analysis. The new name, *Robust Copula Dependence* (RCD), emphasizes the fact that it is a robust-equitable copula-based dependence measure.

2.3 Testing Independence Versus Estimation Errors of Dependence Measures

In practice, feature selection is based on an estimator $\hat{D}(X;Y)$ on the data set, since the exact value of the dependence measure $D(X;Y)$ is unknown to the user. Hence the feature selection results are affected by the estimation error $\hat{D} - D$. The estimation error also needs to be studied.

An estimator $\hat{D}[X;Y]$ is often used to test the independence between X and Y. Some studies compare different dependence measures $D[X;Y]$s by the power of independence testing using their corresponding estimators $\hat{D}[X;Y]$s (Reshef et al., 2011; Simon and Tibshirani, 2011; Reshef et al., 2015a). However, while independence testing is related to the estimation of dependence measures $D[X;Y]$, the power of the independence test is not a proper way of comparing dependence measures $D[X;Y]$. In fact, as mentioned in Section 2.2, the independence test corresponds to an estimation of the trivial measure IDC: $IDC(X;Y) = 0$ if X and Y are independent and $IDC(X;Y) = 1$ otherwise. Thus the power comparison is comparing the performance of $\hat{D}[X;Y]$ in estimating $IDC(X;Y)$ rather than estimating its corresponding parameter $D[X;Y]$. Also, good independence test statistics may not have corresponding interpretable dependence measures (Sun and Zhao, 2014).

As Reshef et al. (2015b) pointed out, the estimator $\hat{D}[X;Y]$ for equitable $D[X;Y]$ is most powerful at testing the hypothesis if the signal strength exceeding a threshold $D[X;Y] \geq D_0$, rather than being most powerful at testing independence $D[X;Y] = 0$. Besides simply testing for independence, dependence measures serve another important purpose: ranking the strength of the dependence relationships. For example, in the World Health Organization (WHO) data set in Reshef et al. (2011) the vast majority of the hundreds of the variables show dependence with other variables.

(a) (b) (c)

Figure 3: Hidden in background noise are 10% (red colored) data on a deterministic curve in (a) and (b), on a narrow strip around the line in (c).

So the independence tests do not provide much information there. To achieve sparse representation (feature selection), it is important to pick out the strongest dependence relationships. Equitable dependence measure ensures that the signal strength is reflected, rather than the functional form.

The robust-equitability definitions also have implications on the estimation errors. Some self-equitable measures can equal one too often, the extreme case being the IDC. When the dependence measure $D[X;Y]$ equals one for too many type of distributions, it does not distinguish dependence strength among them, and also makes its estimation difficult. Robust-equitability excludes such measures. In the next section, we theoretically show that robust-equitable RCD is intrinsically much easier to estimate than non-robust-equitable (but only self-equitable) MI and CD_2. This is due to the instability in the theoretical values of MI and CD_2. The following examples illustrate the difference between self-equitability (Figure 3: a versus b) and robust-equitability (Figure 3: a versus c). The self-equitable measures (RCD, MI), unlike ρ, have the same value in Figures 3(a) and 3(b) where each has 10% deterministic data on two different curves. In Figure 3(c), 10% of the data fall around (rather than exactly on) the line in a very small strip of area $0.1/exp(10) = 4.5 \times 10^{-6}$, which is very close to the distribution in Figure 3(a). The robust-equitable RCD values are very similar (differ only in 10^{-6} order) in Figures 3(a) and 3(c), but the MI values changes from ∞ to 1. Since these two almost indistinguishable distributions result in very different theoretical MI values (∞ and 1), no estimator can do well.

3. Statistical Estimation Errors

In this section, we study the estimation errors theoretically, and provide a practical estimator for RCD. In particular, we analyze the statistical estimation error $\hat{D} - D$.

3.1 The Inconsistency Results on Estimation of Mutual Information and CD_2

We theoretically show that MI and CD_2 are much harder to estimate compared to the robust-equitable RCD. We formally quantify the estimation difficulty through the minimax convergence rate over a family $\mathfrak{C}$.

Denote $\mathbf{z} = (u, v)$. Let $\mathfrak{C}$ be the family of continuous copulas with the density satisfying the following Hölder condition on the region where $c(\mathbf{z})$ is bounded above by some constant $M > 1$, denoted as A_M:

$$|c(\mathbf{z}_1) - c(\mathbf{z}_2)| \leq M_1 \|\mathbf{z}_1 - \mathbf{z}_2\|_{l_1}, \tag{7}$$

for a constant M_1 and for all $\mathbf{z}_1 \in A_M$, $\mathbf{z}_2 \in A_M$, and $\|\cdot\|_{l_1}$ denotes the l_1 norm.

The estimation of MI has been studied extensively in the literature. Over all distributions, even discrete ones, no uniform rate of convergence is possible for MI (Antos and Kontoyiannis, 2001; Paninski, 2003). On the other hand, many estimators were shown to converge to MI for every distribution. These results are not contradictory, but rather common phenomena for many parameters. The first result is about the uniform convergence over all distributions, while the second result is about the pointwise convergence for each distribution. The first restriction is too strong, while the second restriction is too weak. The difficulty of estimating a parameter needs to be studied for uniform convergence over a properly chosen family.

As MI is defined through the copula density, it is natural to consider the families generally used in density estimation literature. Starting from Farrell (1972), it is standard to study the minimax rate of convergence for density estimation over the class of functions whose m-th derivatives satisfy the Hölder condition. Since the minimax convergence rate usually is achieved by the kernel density estimator, it is also the optimal convergence rate of density estimation under those Hölder classes. Generally, with the Hölder condition imposed on the m-th derivatives, the optimal rate of convergence for two-dimensional kernel density estimator is $n^{-(m+1)/(2m+4)}$ (Silverman, 1986; Scott, 1992).

Therefore, when studying the convergence of MI estimators, it is very tempting to impose the Hölder condition on the copula density. In fact, imposing the Hölder condition (7) on the whole I^2, Liu et al. (2012) showed that the kernel density estimation (KDE) based MI estimator converges at the parametric rate of $n^{-1/2}$. Pál et al. (2010) also considered similar Hölder condition when they studied the convergence of k-nearest-neighbor (KNN) based MI estimator. However, such a condition is usually too strong for copula density, thus these results cannot fully reflect the true difficulty of MI estimation. When $c(u, v)$ is unbounded, the Hölder condition (7) cannot hold for the region where $c(u, v)$ is big. Hence imposing this Hölder condition (7) on the whole I^2 would exclude many commonly used continuous copula densities (e.g., Gaussian, student-T, etc.) since their densities are unbounded (Omelka et al., 2009; Segers, 2012). Therefore, we impose it only on the region where the copula density is small. Specifically, we assume that the Hölder condition holds only on the region $A_M = \{(u, v) : c(u, v) < M\}$ for a constant $M > 1$. Then this condition is satisfied by all common continuous copulas in the book by Nelsen (2006). For example, all Gaussian copulas satisfy the Hölder condition (7) on A_M for some constants $M > 1$ and $M_1 > 0$. But no Gaussian copulas, except the independence copula Π, satisfy the Hölder condition (7) over the whole $\mathcal{I}^2$.

Theorem 4 *Let $\widehat{MI}$ be any estimator of the mutual information* MI *based on the observations $\mathbf{Z}_1 = (U_1, V_1)$, ..., $\mathbf{Z}_n = (U_n, V_n)$ from a copula distribution $C \in \mathfrak{C}$. And let $\widehat{CD}_\alpha$ be any estimator of the CD_α in equation (4). Then*

$$\begin{aligned} \sup_{C \in \mathfrak{C}} E[|\widehat{MI}(C) - \mathrm{MI}(C)|] &= \infty, \text{ and} \\ \sup_{C \in \mathfrak{C}} E[|\widehat{CD}_\alpha(C) - CD_\alpha(C)|] &= \infty, \text{ for any } \alpha > 1. \end{aligned} \tag{8}$$

The detailed proof is provided in AppendixA. This theorem states that MI and CD_2 cannot be consistently estimated over the family $\mathfrak{C}$. This result does not depend on the estimation method used, as it reflects the theoretical instability of these quantities. There are many estimators for MI: kernel density estimation (KDE) (Moon et al., 1995), the k-nearest-neighbor (KNN) (Kraskov et al., 2004), maximum likelihood estimation of density ratio (Suzuki et al., 2009). However, practitioners are often frustrated by the unreliability of these estimation (Fernandes and Gloor, 2010; Reshef et al., 2011). This theorem provides a theoretical explanation.

Notice that the inconsistency results over this family $\mathfrak{C}$ is not due to the unboundedness of MI and CD_2. They can be transformed into correlation measures with values between 0 and 1 (Joe, 1989): $MIcor = \sqrt{1 - e^{-2MI}}$ and $\phi cor = \sqrt{CD_2/(1 + CD_2)}$. The $MIcor$ is known as the Linfoot correlation in the literature (Speed, 2011). We use the name $MIcor$ to indicate it as the scaled version of MI. The next theorem showed that $MIcor$ cannot be consistently estimated over the family $\mathfrak{C}$ also.

Theorem 5 *Let $\widehat{MIcor}$ be any estimator of $MIcor$ based on the observations $\mathbf{Z}_1 = (U_1, V_1)$, ..., $\mathbf{Z}_n = (U_n, V_n)$ from a copula distribution $C \in \mathfrak{C}$. Then*

$$\sup_{C \in \mathfrak{C}} E[|\widehat{MIcor}(C) - MIcor(C)|] \quge \quad a_2 > 0, \tag{9}$$

for a positive constant a_2.

The detailed proof is provided in Appendix B.

The estimation difficulty of these dependence measures is due to their lack of smoothness related to being not weakly-robust-equitable. Reshef et al. (2015a, Section 4) proved a similar lack of smoothness of MI and $MIcor$, while their proposed statistic MIC may be considered a smoothed version which shows equitable behavior under their framework. Our results are stronger in that: (a) our results establish the statistical difficulty of estimation via minimax rate, and (b) our results apply to a broader class of dependence measures.

3.2 The Consistent Estimation of RCD

The equitability definitions and error analysis above assume a bivariate dependence measure. In this section, we will state the estimation results for a general d-dimensional RCD in equation (5): $RCD = \frac{1}{2}\int_{\mathcal{I}^d} |c(\mathbf{z}) - 1| d\mathbf{z}$ for d-dimensional $\mathbf{z}$. That is, for $\mathbf{z} = (z_1, ..., z_d)$, the copula transformation changes each dimension to uniformly distributed variables $u_j = F_u^{-1}(z_j)$, $j = 1, ..., d$. Then $\int |c(\mathbf{z}) - 1| d\mathbf{z} := \int ... \int |c(u_1, ..., u_d) - 1| du_1 ... du_d$. The robust-equitability definition can be easily changed to the d-dimensional mixture copula with a singular component and the d-dimensional uniform distribution. And, in the d-dimensional case, the calculation above equation (5) still holds so that RCD is robust-equitable. Notice that other equitability definitions such as self-equitability is only defined for the bivariate case, and the filtering feature selection method mRMR also uses only the bivariate dependence.

Mathematically, MI (and $MIcor$) is unstable because it overweighs the region with large density $c(\mathbf{z})$ values. From equation (3), MI is the expectation of $\log[c(\mathbf{z})]$ under the true copula distribution $c(\mathbf{z})$. In contrast, RCD in (5) takes the expectation at the independence case Π instead. Even if $c(\mathbf{z})$ cannot be consistently estimated in the region A_M^c (the complement of A_M), its error contribution to $\widehat{RCD}$ can be bounded. The following theorem, which is proved in Appendix C, shows the result for the KDE estimator for RCD.

Theorem 6 *Let the KDE estimator of the d-dimensional copula density based on observations* $\mathbf{Z}_1, \cdots, \mathbf{Z}_n$ *be*

$$\hat{c}_{kde}(\mathbf{Z}) = \frac{1}{nh^d} \sum_{i=1}^{n} K(\frac{\mathbf{Z}_i - \mathbf{Z}}{h}). \tag{10}$$

We assume the following conditions:

- *The bandwidth* $h \to 0$ *and* $nh^d \to \infty$.
- *The kernel* K *is non-negative and has a compact support in,* $\mathbb{B}_0 = \{\mathbf{Z} : \|\mathbf{Z}\|_{l_2} \leq 1\}$, *the d-dimensional unit ball centered at* 0.
- *The kernel* K *is bounded.* $M_K = \max_{s \in \mathbb{B}_0} K(s)$, $\int_{\mathbb{B}_0} K(s)ds = 1$, $\mu_2^2 = \int_{\mathbb{B}_0} K^2(s)ds < \infty$

Then the plugged-in estimator $\widehat{RCD} = RCD(\hat{c}_{kde})$ *has a risk bound*

$$\sup_{C \in \mathfrak{C}} E[|\widehat{RCD} - RCD|] \leq M_1 h + \frac{\sqrt{2}\mu_2}{\sqrt{n}h^{\frac{d}{2}}} + O(\frac{1}{nh^d}). \tag{11}$$

In addition to the KDE based RCD estimator, we can estimate RCD consistently by plugging in the KNN estimator (Loftsgaarden and Quesenberry, 1965) of the copula density: $\hat{c}(\mathbf{z}) = k/n/A_{r(k,n)}$ using copula based observations $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$. Here $r(k,n)$ is the distance from (d-dimensional) $\mathbf{z}$ to the k-th closest of $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$, and A_r is the volume of the d-dimensional hyper-ball with radius r. Then $\widehat{RCD} = RCD(\hat{c}) = \sum_{\hat{c}(\mathbf{Z}_i)>1}[1 - 1/\hat{c}(\mathbf{Z}_i)]/n$.

Theorem 7 *Assuming* c *in* $\mathfrak{C}$ *has bounded continuous second order derivative in* A_M, $k \to \infty$ *and* $(k/n) \to 0$ *when* $n \to \infty$. *Then the plugged-in KNN estimator* $\widehat{RCD} = RCD(\hat{c})$ *has a risk bound*

$$\sup_{C \in \mathfrak{C}} E[|\widehat{RCD} - RCD|] \leq \tilde{c_1}(\frac{k}{n\epsilon})^{\frac{2}{d}} + \frac{\tilde{c_2}}{\sqrt{k}} + 2\epsilon, \tag{12}$$

for some finite constants $\tilde{c_1}$ *and* $\tilde{c_2}$, *and* $\epsilon = \epsilon(n)$ *is any sequence converging to* 0 *slower than* k/n.

Here, the extra technical assumption on the second order derivative allows a simpler proof (provided in Appendix D) by citing formulas in Mack and Rosenblatt (1979). Without it, RCD can still be estimated consistently as in Theorem 6. The error bound (12) is minimized by $\epsilon = (k/n)^{2/(d+2)}$ and $k = n^{4/(d+6)}$. Hence, in the bivariate ($d = 2$) case, we have $k = O(\sqrt{n})$. Simulations in Appendix E suggests a practical estimator with $k = 0.25\sqrt{n}$.

When RCD is estimated well under a sample size, further increasing the sample size does not change its estimation value much. In contrast, the estimated MI and CD_2 values can continuously change by a large margin as sample size increases, altering the ranking of features, sometimes to the wrong order.

Computational Complexity of KNN-based RCD Estimator The computation of KNN-based RCD is dominated by empirical ranking for each dimension and k-nearest neigbhor search for each sample. The ranking can be solved by mergesort, which costs $\mathcal{O}(dn \log n)$ for d dimensions (Cormen, 2009). The k-nearest neighbor search can be solved using k-d tree construction, which has $\mathcal{O}(kdn \log n)$ complexity when d is small (no larger than 20) (Bentley, 1975). However, the complexity can increase to $\mathcal{O}(kdn^2)$ if d becomes large. Therefore, the overall complexity is $\mathcal{O}(kdn \log n)$ for low dimension data and $\mathcal{O}(kdn^2)$ for high dimension data.

4. Experimental Results

In this section, we empirically verify the properties of RCD in our theoretical analysis.

We first check the estimation errors for RCD in synthetic experiments with additive noise and mixture noise respectively. For each type of noise, we simulate data with several different relationships so as to show the effect of self-equitability and robust-equitability respectively. In particular, we compare the RCD estimator with an MI estimator based on the same density estimation. Due to the non-robust-equitability of MI, in the mixture noise cases, the MI estimator varies widely with the sample sizes. In contrast, RCD converges as sample sizes increases. Therefore, MI may provide misleading ranking of features with unequal sample sizes. Also, the ranking between relationships with the two different noise types are greatly affected by the sample sizes under MI, while ranking under RCD remains relatively stable.

We then conduct several synthetic experiments to illustrate the properties in feature selection, and then show that similar patterns exist on real-world data sets. In Section 4.3, we show that: (1) Non-self-equitable dependence measures may provide misleading ranking under additive noise; (2) Non-robust-equitable dependence measures may provide misleading ranking under mixture noise when features have unequal sample sizes; (3) The ranking by non-robust-equitable dependence measures between the two types of noises are sensitive to sample size. Section 4.4 shows that similar behavior occurs in three real data examples. This confirms that the advantages of self-equitable and robust-equitable dependence measures are not just theoretical, but are real in some practical situations.

Furthermore, we compare the performance of feature selection by the filter method mRMR (Peng et al., 2005) as a feature search strategy and using various dependence measures as measures of relevance and redundancy (refer to Equation (6)). We conducted the mRMR method first on synthetic examples in Section 4.5, to illustrate why non-self-equitability or non-robust-equitability could lead to misleading results. We then perform mRMR on nine benchmark data sets from the UCI Data Repository (Lichman, 2013) in Section 4.6. Notice that the feature selection performance on a particular data set is affected by the type of existing relationships and the type of predictors used. For example, Pearson's correlation with a linear regression predictor should perform best if linear relationship is dominant in a data set. For a fair comparison, we measure performance by 10-fold cross-validated MSE of spline regression, a general nonlinear predictor (Friedman, 1991), using the selected features. Self-equitability and robust-equitability lead to equitable and robust feature selection. Hence RCD should provide stable performance across different types of data, not necessarily best in each situation. However, over many data sets with different types of nonlinear relationships, robust-equitable RCD would provide best average performance as confirmed on these nine benchmark data sets.

There are some parameters to be set for computing various dependence measures. For kernel based measures, we follow the settings used by Fukumizu et al. (2007). For HSNIC, we set the regularization parameter $\epsilon_n = 10^{-5}n^{-3.1}$ to satisfy the convergence guarantee given by Theorem 5 from Fukumizu et al. (2007). As discussed in the previous section, we set $k = 0.25\sqrt{n}$ for the k-NN estimator of MI, RCD and CD_2.

4.1 Estimation Errors and Equitability

In this section, we study the estimation errors of our RCD estimates through synthetic experiments, and examine the equitability effect in ranking features. We first generate data from four different

type	level	Linear		Square Root		Cubic		Quadratic

	0.8	0.80(0.02)	0.80(0.01)	0.73(0.02)	0.72(0.01)	0.69(0.03)	0.69(0.01)	0.00(0.04)	0.00(0.01)

Table 3: The expected values of ρ estimates (with standard deviation in parenthesis) based on 100 simulations.

functional types: linear, square root, cubic, and quadratic (cases A, C, D, F in Table 11 of Appendix E) with two sample sizes of $n = 1000$ and $n = 10000$ respectively. Also, data with two different noise paradigms and three noise levels are tested with three measures, RCD, (non-self-equitable) ρ and (non-robust-equitable) CD_2.

As we can see from Table 2, the standard deviation of the RCD estimates are small, and the expected value of RCD converges to the true values as sample size increases. The expected values of RCD was similar for the different functional relationships. They are closer to the true values under the mixture noise than under the additive noise. For either noise type, the estimates are very accurate for sample size $n = 10,000$. Although there are some random estimation errors, the RCD estimates would not miss-rank features with moderate difference in true RCD values. That is, it never ranks features with real RCD = 0.2 as more dependent than features with real RCD = 0.4, under samples $n = 1000$ or $n = 10,000$. So the RCD estimates can be used to provide reliable dependence ranking that do not change dramatically under sample sizes $n = 1000$ versus $n = 10,000$.

In contrast, the non-self-equitable Pearson's ρ values depend on the functional relationship. Under the mixture noise, the estimated ρ values are close to the mixture proportion only for the linear relationship. Hence its ranking of features is heavily influenced by the functional relationships. Particularly, it fails to detect the quadratic relationship in the last column of Table-3. Even when 80% of data follows the deterministic quadratic relationship, it is still ranked as less dependent than the features with other functional relationships (even if the other features has only 40% deterministic mixture proportion).

For the non-robust-equitable CD_2 in Table 4, its value changes dramatically under sample sizes $n = 1000$ versus $n = 10,000$, especially under mixture noise. This demonstrates that sample size affects the ranking by CD_2 in contrast to the ranking by the robust-equitable RCD. If the

	0.8	4.75(0.15)	10.24(0.11)	4.79(0.17)	10.34(0.11)	4.75(0.16)	10.24(0.11)	2.87(0.08)	6.27(0.07)

Table 4: The expected values of CD_2 estimates (with standard deviation in parenthesis) based on 100 simulations.

two features have unequal sample sizes, then the feature with larger sample size has a built-in preference by CD_2. For each of the functional types, CD_2 ranks a feature with mixture proportion (of deterministic data) 0.6 but large sample size $n = 10000$ as more dependent than a strongly dependent feature with mixture proportion 0.8 but smaller sample size $n = 1000$. Also, for features with different noise types, their ranking are inconsistent when sample size changes. For example, for the linear relationship under sample size $n = 1000$, CD_2 ranks the feature with RCD = 0.6 mixture noise as less dependent than the feature with RCD = 0.8 additive noise. But when sample size is increased to $n = 10000$, the ranking between these two features reverses. While it is not necessary for other dependence measures to rank features across different noise types in the same order as RCD, the stability of the ranking under different sample sizes is desirable. The non-robust-equitable dependence measures may not provide consistent ranking.

In summary, we observe three advantages of RCD for feature selection, in comparison to other dependence measures. (1) Non-equitable measures such as ρ may prefer certain functional relationships (say, linear), while RCD treat them equitably. (2) Self-equitable but non-robust-equitable measure such as CD_2 prefer features with larger sample size. (3) Self-equitable but non-robust-equitable measure such as CD_2 does not provide stable ranking among features when sample size changes.

4.2 Multivariate Equitability Analysis

We now perform equitability analysis on simulated multivariate data. Following the framework of Reshef et al. (2014); Murrell et al. (2016), we generate noisy data from various functional forms, and plot the estimated dependence measure values against the signal level in Figure 4. Our robust-equitability definition extends the natural signal level to higher dimensional case in the mixture noise model. Here we study three dimensional ($d = 3$) cases of six different nonlinear function relationships, generated with different portion of uniform noise from 0 to 0.9 (with signal portion from 0.1 to 1). The sample size $n = 1000$ is used in this experiment. Figure 5 plots the six three dimensional different nonlinear function relationships at signal level 0.8 (0.2 proportion of uniform noise).

According to Reshef et al. (2014), a measure is more equitable if the length of a band, when cutting each plot in Figure 4 with a horizontal line, is smaller. That is, the measure with smaller bandwidth could capture the dependence purely based on the noise level, and is robust to different (linear and nonlinear) relationships. On the other hand, if the band is very wide, it will give the same score for data with a wide range of noise levels, and hence could not identify strong relationships correctly. Figure 4 shows that RCD is the most equitable, since it has the narrowest bandwidth and

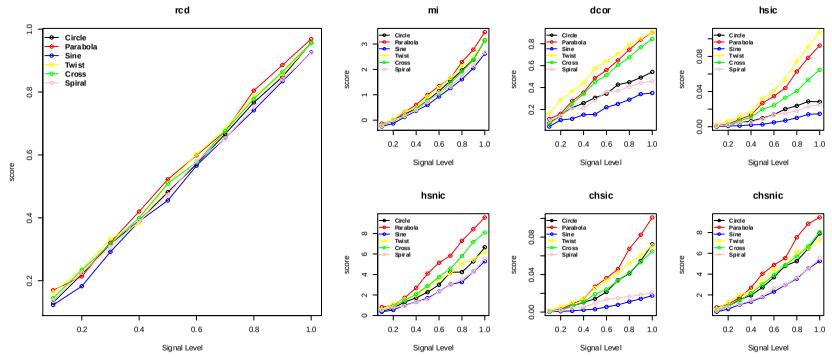

Figure 4: Seven dependence measure values versus signal levels.

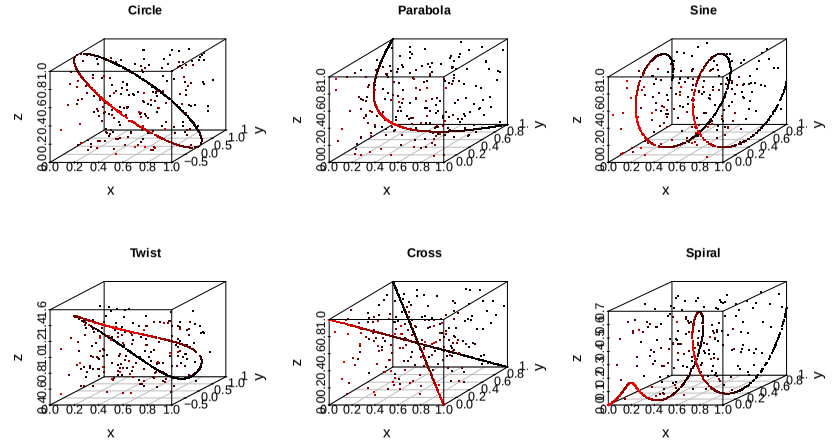

Figure 5: Six function types, circle, parabola, sine/cosine, twisted curve, two cross lines, and a spiral curve, with 20% uniform noise from 0 to 0.9 (with signal portion from 0.1 to 1). The examples in this figure is of signal level 0.8.

lies on the signal level line. The self-equitable mutual information is second best, has relatively narrower bandwidth compared to other measures except RCD.

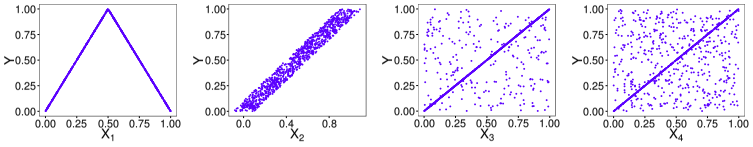

Figure 6: (X_1, Y) has a nonmonotonic relationship with deterministic signal. (X_2, Y) has linear relationship with uniform additive noise with width $d = 0.2$. (X_3, Y) has background noise with a 0.75 linear signal portion. (X_4, Y) is similar to (X_3, Y) but with a 0.5 signal portion.

Table 5: Dependence measure values for synthetic data. Sample sizes $n = 300$ and $n = 10,000$ are considered. Each row corresponds to one type of measure. The MSE is presented in the last row.

4.3 Synthetic Data Sets I: Ranking Features

To compare the performance of each dependence measure in feature selection, we consider four features X_1, X_2, X_3, X_4 and target variable Y as shown in Figure 6. Y has a nonmonotonic but deterministic relationship with X_1 and a linear relationship with X_2 plus some additive noise. In addition, Y has linear relationships with both X_3 and X_4 corrupted by increasing level of continuous background noise. For each feature X_i, we calculate its dependence measure with Y for different sample sizes $n = 300$ and $10,000$. Results are presented in Table 5.

Since X_1 has a deterministic relationship with Y, it should be ranked as more dependent than the other features. X_3 and X_4 has mixture noise with the mixture proportions of 0.75 and 0.5 respectively. We can see that the values learned by RCD are close to those values and correctly ranks X_3 as more dependent than X_4. The last row of Table 5 reports the 10-fold cross-validated mean-squared-error (MSE) of a nonlinear predictor using each feature. Here RCD results are consistent with the MSE results, providing higher scores for those with lower MSE values (more predictive of Y). Now, we inspect the other dependence measures and observe the three issues mentioned in Section 4.1.

Self-equitability. We expect the self-equitable measures to treat linear and nonlinear models equally (i.e., they should prefer X_1 over X_2 because X_1 is purely deterministic while X_2 has some noise). As we can see from Table 5, Pearson correlation coefficient ρ_{lin}, and kernel-based measures prefer

X_2 more than X_1. On the other hand, self-equitable measures MI, CD_2 and RCD were able to rank the features correctly. Although HSNIC and CHSNIC have the same value as CD_2 in the large data limit, empirically they behave similarly to other non-self-equitable kernel-based measures due to slow convergence of their estimators (Reddi and Póczos, 2013).

Selection Correctness in Unequal Sample Sizes. In real applications, some features may have some missing measurements, resulting in unequal number of samples among the various features. In this setting, we still want to compare feature relevance. An ideal dependence measure should not be influenced greatly by unequal sample sizes. Let us take a closer look at MI and CD_2 and on how they rank features X_3 and X_4. Note that X_3 has a stronger signal-to-noise proportion than X_4 ($p = 0.5$ versus $p = 0.75$); thus, ideally, one would like the measure to rank X_3 higher than X_4 as empirically confirmed by the MSE results. The ranking provided by MI and CD_2 is correct when both features have the same sample size, $n = 10,000$. However, if the stronger feature X_3 has missing measurements so that $n = 300$ for X_3, then X_3 is ranked lower than X_4 by CD_2, which would mislead feature selection algorithms. MI will make the same mistake if the sample size for X_4 further increases.

Selection Stability in Different Sample Sizes. Ideally, a measure should not vary too much as the sample size changes. However, we observe that MI, CD_2, and HSNIC's ranking of features X_2, X_3 and X_4 is affected when the sample size is increased. With fixed sample size $n = 300$, MI ranks X_2 as having higher deterministic relationship with Y compared to X_4. However, when the sample size is increased to $n = 10,000$, it reverses the ranking of these features. This is due to its non-robust-equitability and resulting estimation difficulty, as proved in Theorems 4 and 5. Additionally, similar phenomenon appears for CHSNIC and HSNIC on features X_2 and X_3. We observe that when $n = 300$, they rank X_2 as having higher dependence with Y compared to X_3. However, when $n = 10,000$, these rankings are reversed. These inconsistencies may mislead feature selection algorithms.

4.4 Real Data Sets I: Ranking Features

In this subsection, we verify that the equitability properties in Subsection 4.3 are also observed on real data.

Self-equitability. Consider the stock data set from StatLib[1]. This data set provides daily stock prices for ten aerospace companies. Our task is to determine the relative relevance of the stock price of the first two companies (X_1, X_2) in predicting that of the fifth company (Y). The scatter plots of Y against X_1, X_2 are presented in Figure 7. Ideally, self-equitable measures should prefer X_1 over X_2 because the MSE associated with X_1 is lower even though it has a more complex function form. As we can see from Table 8, self-equitable measures MI, CD_2, and RCD all correctly select X_1. While measures that are not self-equitable fail to select the right feature.

Selection Correctness in Unequal Sample Sizes. Consider the KEGG metabolic reaction network data set (Lichman, 2013). Our task is to select the most relevant features in predicting target variable 'Characteristic path length' (Y). The 'Average shortest path' (X_1), 'Eccentricity' (X_2) and 'Closeness centrality' (X_3) are used as candidate features. Observe the ranking of X_1 and X_3 from Table 6, when they have equal sample sizes (either 1000 or 20,000), MI, CD_2 and RCD all rank X_1 as being more relevant than X_3. The MSE values also confirmed that X_1 is more predictive of Y than X_3. However, if there are missing measurements of X_1, then we may need to compare X_1

with 1000 samples and X_3 with 20,000 samples. The feature X_3 with less signal strength but larger sample size is given higher ranking by MI and CD_2, degrading the performance of feature selection algorithms. In contrast, RCD correctly identifies X_1 as being more relevant than X_3 even with the unequal sample size.

Selection Stability in Different Sample Sizes. Ideally, a measure should not vary too much as the sample size changes. However, in Table 6, CD_2's ranking of features X_2 and X_3 is affected by the increase in sample size. If we fix sample size $n = 1000$, CD_2 ranks X_2 as more relevant than X_3 in predicting Y, agreeing with the MSE ranking. However, when the sample size increases to $n = 20,000$, CD_2 will prefer X_3. CD_2 will select the feature X_3 when the sample size is large even though it is less relevant to Y. RCD has the same ranking under both sample sizes.

4.5 Synthetic Data Sets II: mRMR Feature Selection

In this part, we investigate the performance of feature selection for each dependence measure with mRMR (Peng et al., 2005). We generate data from the following additive regression model $Y = 1.5\cos(3\pi X_1) + (1 - 2|2X_2 - 1|)^2 + \epsilon$, where X_1 and X_2 are uniformly distributed on $[0, 1]$, and $\epsilon \sim N(0, 0.05)$. We consider feature selection from twenty features. The first two features are X_1 and X_2. The next six features are noisy versions of X_1 and X_2, with some as mixtures. They are also related to Y. A good feature selection method should select X_1 and X_2 before these more

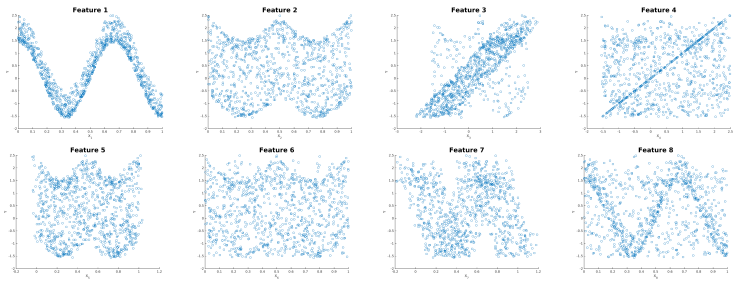

Figure 9: Scatter plots of the features $X_1, \cdots, X_8$ versus Y.

Feature X_1	X_1
Feature X_2	X_2
Feature X_3	25% X_2 and 75% Y with additive noise $U(-0.75, 0.75)$
Feature X_4	20% X_2, 20% Y and 60% background noise
Feature X_5	X_2 with additive noise $U(-0.05, 0.05)$
Feature X_6	50% X_2 and 50% background noise
Feature X_7	X_1 with additive noise $U(-0.2, 0.2)$
Feature X_8	50% X_1 and 50% background noise
Feature X_9,...,X_{20}	pure random noise

Table 7: Features that are used in the additive regression model.

noisy features X_3 to X_8. The rest 12 features X_9 to X_{20} are simply random noise not related to X_1, X_2 or Y. The features are listed in Table 7. And we plot the first eight features versus Y in one simulation run in Figure 9.

We generate data sets with size $n = 1000$, and select the features with mRMR based on the eight dependence measures. We repeat this experiment fifty times and record the order of each feature being selected in each data sets. We then apply spline regression model using the top one to ten selected features and report their respective cross-validated mean square error (MSE). The cross-validated MSE averaged over 50 runs are plotted in Figure 10.

In this synthetic example, RCD yields the lowest MSE. We can see why by looking at the feature selection result in more details. Table 8 reports the features that are most frequently selected as the top one to five features using mRMR. Inversely, Table 9 shows the median order of being selected for each relevant feature X_1, ..., X_8.

From the tables, RCD correctly selects the two true features X_1 and X_2 as the top two features, thus resulting in the lowest MSE curve in Figure 10. The non-self-equitable measures, for this data distribution, incorrectly ranks first the feature X_3 which has linear relationship with Y in parts of the data (75% mixture). Then Pearson's correlation ρ does not rank X_1 and X_2 high because the relationships are nonlinear. Some nonlinear non-self-equitable measures (HSNIC, CMMD, CHSNIC) are able to rank the feature X_1 second, but cannot select feature X_2 which has a nonlinear relationship with Y. That is due to X_2, which also has some dependence with X_3, was penalized when X_3 was selected first. The self-equitable measures MI, CD_2 and RCD, in contrast, correctly rank X_1 first. However, only the robust-equitable RCD ranks X_2 second. The non-robust-equitable MI and CD_2 incorrectly ranks the noisy X_4 second, instead of X_2, due to mishandling of the mixture noise.

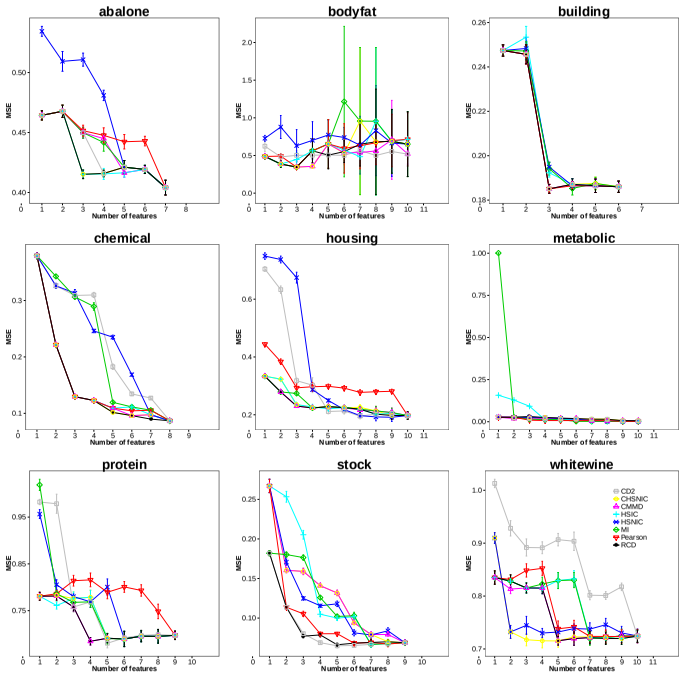

Figure 11: MSE of mRMR-based Feature Selection on nine real-world data sets

4.6 Real Data Sets II: mRMR Feature Selection

Here we used the various dependence measures as measures of relevance and redundancy in the mRMR-based search strategy, and compare the feature selection results on nine real-world data sets. Due to the cubic computational cost of kernel-based measures (HSNIC, CHSNIC), up to 1000 samples are used for each data set. We compare the results of RCD versus other dependence measures by showing plots of 10-fold cross-validated MSE using spline regressor with the features selected by these measures versus the number of selected features in Figure 11.

We used the Kruskal-Wallis test to compare the MSE between different measures. Table 10 lists the top dependence measures in order of their MSE. For each data set, we only include the dependence measures resulting in MSE equivalent to the best MSE (p-value > 0.05 for Kruskal-Wallis test) in the table. We can see that RCD performs as one of the best in 8 out of 9 data sets. Most other measures are worse off in more than half of the data sets. Only CHSNIC and CMMD are close in performance. In particular, CMMD is among the best measures in 5 data sets. CHSNIC performs as one of the best in 6 data sets and actually beats RCD in one data set, *whitewine*. RCD in fact find the best top feature in every data set including *whitewine*. However, the best second feature

in *whitewine* was not selected by RCD. Overall, RCD has the best performance in mRMR-based feature selection compared to competing dependence measures.

5. Conclusions and Discussions

As the data size explodes, researchers are studying increasingly complex relationships among features. Restricting the focus on simple linear relationship can miss very informative features. Therefore, how to measure the dependence strength equitably for various functional relationships has attracted recent interest from researchers (Reshef et al., 2011; Kinney and Atwal, 2014; Murrell et al., 2014; Reshef et al., 2015b). This paper provides a theoretical treatment of various equitability definitions, including our proposal of the robust-equitability concept. The robust copula dependence (RCD) is proven to be both self-equitable and robust-equitable. Theoretically we show that RCD is intrinsically easier to estimate than some other self-equitable dependence measures (such as MI and CD_2). Particularly, through minimax rate of convergence, we provide a theoretical explanation for the difficulty of accurately estimating MI which is noted by practitioners. A practical estimator is provided for RCD, which enables its usage in feature selection.

Through theoretical and empirical studies, we have shown that RCD does better in ranking the features according to deterministic signal strengths compared to other dependence measures. The non-self-equitable measures may prefer noisy features with certain types of relationships (e.g., monotonic) over less noisy features with more complex relationships. Self-equitable but non-robust-equitable measures (such as MI and CD_2) overcome this deficiency but have estimation problems, leading to non-robust feature selection particularly when comparing features with unequal sample sizes. RCD can be used in feature selection to overcome these limitations.

Using nonlinear dependence measures, rather than the Pearson's correlation, in high-dimensional data analysis (e.g. independent component analysis) is becoming more popular to deal with possibly non-Gaussian noises. The equitability properties of RCD make it an ideal choice of dependence measure in such applications. Replacing measures such as MI by RCD may lead to more robust results as shown in the examples of Section 4. RCD estimation in high-dimensional case however, similar to MI, may be inaccurate as it involves high-dimensional density estimation. The improvement on nonparametric RCD estimation remains an ongoing research effort, and can lead to wider applications.

Appendix A. Proof of Theorem 4

For simplicity, we focus on the bivariate case (X and Y are each one-dimensional variables). The extension of the proof to the multivariate case is straight forward. We first work on mutual information, then show the similar arguments on the copula distances. To prove the theorem, we use Le Cam (1973)'s method to find the lower bound on the minimax risk of the estimating mutual information MI. To do this, we will use a more convenient form of Le Cam's method developed by Donoho and Liu (1991). Define the module of continuity of a functional T over the class $\mathbf{F}$ with respect to Hellinger distance as in equation (1.1) of Donoho and Liu (1991):

$$w(\varepsilon) = \sup\{|T(F_1) - T(F_2)| : H(F_1, F_2) \le \varepsilon, F_i \in \mathbf{F}\}. \tag{13}$$

Here $H(F_1, F_2)$ denotes the Hellinger distance between F_1 and F_2. Then the minimax rate of convergence for estimating $T(F)$ over the class $\mathbf{F}$ is bounded below by $w(n^{-1/2})$.

We now look for a pair of density functions $c_1(u, v)$ and $c_2(u, v)$ on the unit square for distributions that are close in Hellinger distance but far away in their mutual information. This provides a lower bound on the module of continuity for mutual information MI over the class $\mathfrak{C}$, and hence leads to a lower bound on the minimax risk. We outline the proof next.

We first divide the unit square into three disjoint regions R_1, R_2 and R_3 with $R_1 \cup R_2 \cup R_3 = [0,1]\times[0,1]$. The first density function $c_1(u, v)$ puts probability masses δ, a and $1-a-\delta$ respectively on the regions R_1, R_2 and R_3 each uniformly. The a is an arbitrary small fixed value, for example, $a = 0.01$. For now, we take δ to be another small fixed value. The area of the region is chosen so that $c_1(u, v) = M$ on region R_2 and $c_1(u, v) = M^*$ on region R_1 for a very big M^*. The second density function $c_2(u, v)$, compared to $c_1(u, v)$, moves a small probability mass ε from R_1 to R_2. We will see that the Hellinger distance between c_1 and c_2 is of the same order as ε, but the change in MI is unbounded for big M^*. Hence module of continuity $w(\varepsilon)$ is unbounded for mutual information MI. Therefore the MI can not be consistently estimated over the class $\mathfrak{C}$.

Specifically, the region R_1 is chosen to be a narrow strip immediately above the diagonal, $R_1 = \{(u, v) : -\delta_1 < u - v < 0\}$; and R_2 is chosen to be a narrow strip immediately below the diagonal, $R_2 = \{(u, v) : 0 \le u - v < \delta_2\}$. The remaining region is $R_3 = [0,1]\times[0,1]\setminus(R_1 \cup R_2)$. The values of δ_1 and δ_2 are chosen so that the areas of regions R_1 and R_2 are δ/M^* and a/M respectively. Then clearly $c_1(u, v) = M^*$ on R_1; $c_1(u, v) = M$ on R_2; $c_1(u, v) = (1-a-\delta)/(1-a/M-\delta/M^*)$ on R_3. And $c_2(u, v) = M^* - \varepsilon(M^*/\delta)$ on R_1; $c_2(u, v) = M + \varepsilon(M/a)$ on R_2; $c_2(u, v) = c_1(u, v)$ on R_3. See the Figure 12.

Then we have

$$\begin{aligned} 2H^2(c_1, c_2) &= \int (\sqrt{c_2(u,v)} - \sqrt{c_1(u,v)})^2 du dv \\ &= (\sqrt{M^* - \varepsilon(M^*/\delta)} - \sqrt{M^*})^2 \delta/M^* + (\sqrt{M + \varepsilon(M/a)} - \sqrt{M})^2 a/M \\ &= \delta(\sqrt{1 - \varepsilon/\delta} - 1)^2 + a(\sqrt{1 + \varepsilon/a} - 1)^2 \\ &= \delta(\varepsilon/2\delta)^2 + a(\varepsilon/2a)^2 + o(\varepsilon^2) \\ &= \varepsilon^2(\tfrac{1}{4\delta} + \tfrac{1}{4a}) + o(\varepsilon^2). \end{aligned}$$

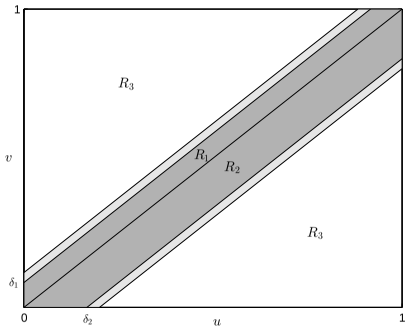

Figure 12: The plot shows the regions R_1, R_2 and R_3. The other two narrow strips neighboring R_1 and R_2 are for the continuity correction mentioned at the end of the proof.

Hence the Hellinger distance is of the same order as ε:

$$H(c_1, c_2) = \varepsilon\sqrt{\frac{1}{8\delta} + \frac{1}{8a}} + o(\varepsilon).$$

On the other hand, the difference in the mutual information is

$$\begin{aligned} &\mathrm{MI}(c_1) - \mathrm{MI}(c_2) \\ =\ & \delta\log(M^*) + a\log(M) - (\delta - \varepsilon)\log[M^* - \varepsilon(M^*/\delta)] - (a + \varepsilon)\log[M + \varepsilon(M/a)] \\ =\ & \varepsilon\log(M^*) - \varepsilon\log(M) - (\delta - \varepsilon)\log(1 - \varepsilon/\delta) - (a + \varepsilon)\log(1 + \varepsilon/a). \end{aligned} \tag{14}$$

Here M, δ and a are fixed constants. Hence when $M^* \to \infty$, this difference in MI also goes to ∞. For example, if we let $M^* = e^{1/(\varepsilon)^2}$, then the module of continuity $w(\varepsilon) \ge O(1/\varepsilon)$. That means, the rate of convergence is at least $O(w(n^{-1/2})) = O(n^{1/2}) \to \infty$. In other words, MI can not be consistently estimated.

Now, let us consider the $\mathrm{CD}_\alpha = \int_{I^2} |c(u, v) - 1|^\alpha du dv$, for $\alpha > 1$, where I^2 is the unit square.

$$\begin{aligned} &\mathrm{CD}_\alpha(c_1) - \mathrm{CD}_\alpha(c_2) \\ =\ & |M^* - 1|^\alpha \delta/M^* + |M^- 1|^\alpha a/M - |M^* - 1 - \varepsilon(M^*/\delta)|^\alpha \delta/M^* + |M - 1 + \varepsilon(M/a)|^\alpha a/M \\ =\ & [|M^* - 1|^\alpha - |M^* - 1 - \varepsilon(M^*/\delta)|^\alpha]\delta/M^* + [|M^- 1|^\alpha - |M - 1 + \varepsilon(M/a)|^\alpha]a/M \\ =\ & \alpha[(M^* - 1)^{\alpha-1} M^*/\delta - (M - 1)^{\alpha-1} M/\alpha]\varepsilon + o(\varepsilon^2). \end{aligned} \tag{15}$$

Again, M, δ and a are fixed constants. Hence when $M^* \to \infty$, this difference in $\mathrm{CD}_\alpha, \alpha > 1$ also goes to ∞. For example, if we let $M^* = (\varepsilon^{-2} + M^\alpha)^{\frac{1}{\alpha-1}} + 1$, then the module of continuity $w(\varepsilon) \ge O(1/\varepsilon)$. Note that $\alpha > 1$ is essential here. That means, the rate of convergence is at least $O(w(n^{-1/2})) = O(n^{1/2}) \to \infty$. In other words, $\mathrm{CD}_\alpha, \alpha > 1$ can not be consistently estimated.

The above outlines the main idea of the proof, ignoring some mathematical subtleties. One is that the example densities c_1 and c_2 are only piecewise continuous on the three regions, but not truly continuous as required for the class $\mathfrak{C}$. This can be easily remedied by connecting the three pieces linearly. Specifically we set the densities $c_i(u,v) = M$, $i = 1, 2$, on the boundary between R_1 and R_3, $\{(u,v) : u - v = -\delta_1\}$, and on the boundary between R_2 and R_3, $\{(u,v) : u - v = \delta_2\}$. Then we use two narrow strips within R_3, $\{(u,v) : -\delta_3 \le u-v \le -\delta_1\}$ and $\{(u,v) : \delta_2 \le u-v \le \delta_4\}$ to connect the constant $c_i(u,v)$ values on the rest of region R_3 with the boundary value $c_i(u,v) = M$ continuously through linear (in $u - v$) $c_i(u,v)$'s on the two strips that satisfies the Hölder condition (7) of the main text. By the Hölder condition, the connection can be made with strips of width at most $(M - 1 + a + \delta)/M_1$. This continuity modification does not affect the calculation of the difference $\text{MI}(c_1) - \text{MI}(c_2)$ or $\text{CD}_\alpha(c_1) - \text{CD}_\alpha(c_2)$ above as c_1 and c_2 only differ on regions R_1 and R_2. Within regions R_1 and R_2, the densities c_1 and c_2 can be further similarly connected continuously linearly in $u - v$. As there is no Hölder condition on A_M^c, the connection within R_1 and R_2 can be as steep as we want. Clearly the order obtained through above calculations will not change if we make these connections very steep so that their effect is negligible.

Another technical subtlety is that the c_1 and c_2 defined above are only densities on the unit square but not copula densities which require uniform marginal distributions. However, it is clear that the marginal densities for c_is are uniform over the interval $(\delta_3, 1 - \delta_4)$ and linear in the rest of interval near the two end points 0 and 1. The copulas densities c_i^*'s corresponding to c_i's can be calculated directly through Sklar's decomposition (1) in the main text. It is easy to see that the order for the module of continuity $w(\varepsilon)$ remains the same for using the corresponding copula densities c_i^*'s.

Appendix B. Proof of Theorem 5

The proof is almost the same as the proof for MI, but need some modification of the pair of least favorable c_1 and c_2 above. The small difference in Hellinger distance of c_1 and c_2 can lead to unbounded difference in $MI(c_1)$ and $MI(c_2)$ since MI is unbounded. After the transformation $MIcor = \sqrt{1 - e^{-2MI}}$ is bounded. The difference between $MIcor(c_1)$ and $MIcor(c_2)$ in the above example is actually small since the MI are big for both c_1 and c_2 (leading to corresponding $MIcor$s close to zero). However, $MIcor$ is also very hard to estimate over the class $\mathfrak{C}$. To see this, we follow the same reasoning above but modify the example of c_1 and c_2. First, we notice that for any pair of densities c_1 and c_2,

$$\begin{aligned} |MIcor(c_1) - MIcor(c_2)| &= |\sqrt{1 - e^{-2MI(c_1)}} - \sqrt{1 - e^{-2MI(c_2)}}| \\ &= |\tfrac{[1-e^{-2MI(c_1)}]-[1-e^{-2MI(c_2)}]}{\sqrt{1-e^{-2MI(c_1)}}+\sqrt{1-e^{-2MI(c_2)}}}| \\ &\ge \tfrac{1}{2}|e^{-2MI(c_1)} - e^{-2MI(c_2)}| \\ &= \tfrac{1}{2}e^{-2MI(c_1)}|1 - e^{-2[MI(c_1)-MI(c_2)]}|. \end{aligned}$$

For the difference $MIcor(c_1) - MIcor(c_2)$ to be the same order of the difference $MI(c_1) - MI(c_2)$, we need to set $MI(c_1)$ at constant order when $\varepsilon \to 0$.

Therefore, we modify the above c_1 to have probability mass $\delta = 2\varepsilon$ in region R_1, varying with the ε value instead of fixed as before. And we set $M^* = e^{1/\varepsilon}$, leading to

$$\begin{aligned} & MI(c_1) \\ = \;& \delta \log(M^*) + a\log(M) + (1 - a - \delta)\log[(1 - a - \delta)/(1 - a/M - \delta/M^*)] \\ = \;& 2 + a\log(M) + (1 - a - 2\varepsilon)\log[(1 - a - 2\varepsilon)/(1 - a/M - 2\varepsilon e^{-1/\varepsilon})], \end{aligned}$$

which converges to a fixed constant $a_1 = 2 + a\log(M) + (1-a)\log[(1-a)/(1-a/M)]$ as $\varepsilon \to 0$. Using (14), recall that $\delta = 2\varepsilon$ and $M^* = e^{1/\varepsilon}$, we have

$$\begin{aligned} & MI(c_1) - MI(c_2) \\ = \;& \varepsilon\log(M^*) - \varepsilon\log(M) - (\delta - \varepsilon)\log(1 - \varepsilon/\delta) - (a + \varepsilon)\log(1 + \varepsilon/a) \\ = \;& 1 - \varepsilon\log(M) - \varepsilon\log(1/2) - (a + \varepsilon)\log(1 + \varepsilon/a), \end{aligned}$$

which converges to 1 as $\varepsilon \to 0$. Hence we have

$$\lim_{\varepsilon\to 0} w(\varepsilon) \ge \lim_{\varepsilon\to 0} \frac{1}{2}e^{-2MI(c_1)}|1 - e^{-2[MI(c_1)-MI(c_2)]}| = \frac{1}{2}e^{-2a_1}(1 - e^{-2(1)}),$$

a positive constant $a_2 = e^{-2a_1}(1 - e^{-2})/2$. Therefore, $MIcor$ can not be estimated consistently over the class $\mathfrak{C}$ either.

Appendix C. Proof of Theorem 6

The first two terms in (11) corresponds to bias and standard deviation of kernel density estimation when the copula density is bounded. When the copula density is unbounded, the kernel density estimation $\hat{c}(\mathbf{Z})$ is not consistent. However, a smaller order $O(\frac{1}{nh^d})$ term bounds the overall error contribution to $\widehat{RCD}$ resulting from $\hat{c}(\mathbf{Z})$ in the unbounded copula density region.

Let $M_2 = \frac{M+1}{2}$, $A_{M_2} = \{\mathbf{Z}|c(\mathbf{Z}) \le M_2\}$, $T_1(c) = \int_{A_{M_2}}(1 - c(\mathbf{Z}))_+ d\mathbf{Z}$, $T_2(c) = \int_{A_{M_2}^c}(1 - c(\mathbf{Z}))_+ d\mathbf{Z}$, $RCD = T_1(c) + T_2(c)$, and $\widehat{RCD} = T_1(\hat{c}) + T_2(\hat{c})$

Firstly, we consider the region A_{M_2} with bounded copula density. Here we calculate the bias and variance of the kernel density estimator using standard methods first.

$$\bar{c}_n(\mathbf{Z}) = E[\hat{c}_{kde}(\mathbf{Z})] = \frac{1}{h^d}\int K(\frac{\mathbf{z} - \mathbf{Z}}{h})c(\mathbf{z})d\mathbf{z} = \int K(s)c(\mathbf{Z} + sh)ds.$$

Hence

$$\begin{aligned} |Bias(\mathbf{Z})| = |\textstyle\int K(s)c(\mathbf{Z} + sh)ds - c(\mathbf{Z})| &\le \textstyle\int_{\mathbb{B}_0} K(s)|c(\mathbf{Z} + sh) - c(\mathbf{Z})|ds \\ &\le \textstyle\int_{\mathbb{B}_0} K(s)M_1 h ds \\ &= M_1 h. \end{aligned} \tag{16}$$

$$\begin{aligned} |Var(\mathbf{Z})| &= \tfrac{1}{n}Var[\tfrac{1}{h^d}K(\tfrac{\mathbf{Z}_1 - \mathbf{Z}}{h})] \le \tfrac{1}{n}E[\tfrac{1}{h^{2d}}K^2(\tfrac{\mathbf{Z}_1 - \mathbf{Z}}{h})] \\ &= \tfrac{1}{nh^d}\textstyle\int_{\mathbb{B}_0} K^2(s)c(\mathbf{Z} + sh)ds \\ &\le \tfrac{1}{nh^d}\textstyle\int_{\mathbb{B}_0} K^2(s)[c(\mathbf{Z}) + M_1 h]ds \\ &= \tfrac{\mu_2^2}{nh^d}[c(\mathbf{Z}) + M_1 h]. \end{aligned} \tag{17}$$

Hence the integrated mean square error of the density estimator $\hat{c}_n(\mathbf{Z})$ over regions A_{M_2} is

$$\begin{aligned} IMSE(\mathbf{Z}) &= \int_{A_{M_2}} [Bias^2(\mathbf{Z}) + Var(\mathbf{Z})] d\mathbf{Z} \\ &\le \int_{A_{M_2}} [M_1^2 h^2 + \tfrac{\mu_2^2}{nh^d}[c(\mathbf{Z}) + M_1 h] d\mathbf{Z} \ \le M_1^2 h^2 + \tfrac{\mu_2^2}{nh^d}[1 + M_1 h] \\ &\le M_1^2 h^2 + \tfrac{2\mu_2^2}{nh^d} \end{aligned} \tag{18}$$

Hence the error of $\widehat{RCD}$ on A_{M_2} is bounded by

$$\begin{aligned} E|T_1(\hat{c}) - T_1(c)| &\le E \int_{A_{M_2}} |(1 - \hat{c}_n(\mathbf{Z}))_+ - (1 - c(\mathbf{Z}))_+| d\mathbf{Z} \\ &\le E \int_{A_{M_2}} |\hat{c}_n(\mathbf{Z}) - c(\mathbf{Z})| d\mathbf{Z} \\ &\le \sqrt{E \int_{A_{M_2}} (\hat{c}_n(\mathbf{Z}) - c(\mathbf{Z}))^2 d\mathbf{Z}} \\ &\le \sqrt{d^2 M_1^2 h^2 + \tfrac{2\mu_2^2}{nh^d}} \\ &\le dM_1 h + \sqrt{2}\mu_2 (\tfrac{1}{nh^d})^{1/2}. \end{aligned}$$

Now we consider the region $A^c_{M_2}$ with unbounded copula density. For $\mathbf{Z} \in A^c_{M_2}$, $\hat{c}(\mathbf{Z})$ does not have a finite variance bound in (17). But we can bound the variance by the expectation $\bar{c}_n(\mathbf{Z}) = E[\hat{c}_n(\mathbf{Z})]$. Let $M_3 = \frac{M_2+1}{2}$, when h small, $\mathbf{Z} \in A^c_{M_2}$ implies $\mathbf{Z} + sh \in A^c_{M_3}$. Hence

$$|Var(\mathbf{Z})| \le \frac{1}{nh^d} \int_{\mathbb{B}_0} K^2(s) c(\mathbf{Z} + sh) ds \le \frac{M_K}{nh^d} \int_{\mathbb{B}_0} K(s) c(\mathbf{Z} + sh) ds = \frac{M_K}{nh^d} \bar{c}_n(\mathbf{Z})$$

Using Chebyshev's inequality,

$$\begin{aligned} E[1_{\{\hat{c}_n(\mathbf{Z}) < 1\}}] = P(\hat{c}_n(\mathbf{Z}) < 1) &\le P(|\bar{c}_n(\mathbf{Z}) - \hat{c}_n(\mathbf{Z})| > \bar{c}_n(\mathbf{Z}) - 1) \\ &\le \frac{Var[\hat{c}_n(\mathbf{Z})]}{[\bar{c}_n(\mathbf{Z}) - 1]^2} \\ &\le \frac{M_K}{nh^d} \frac{\bar{c}_n(\mathbf{Z})}{[\bar{c}_n(\mathbf{Z}) - 1]^2} \ \le \frac{M_K M_4}{nh^d} \end{aligned}$$

where $M_4 = \frac{M_3}{(M_3 - 1)^2}$.

Hence the error of $\widehat{RCD}$ on $A^c_{M_2}$ is bounded by

$$E|T_2(\hat{c}) - T_2(c)| = E[T_2(\hat{c})] \le \int_{A^c_{M_2}} E[1_{\{\hat{c}_n(\mathbf{Z}) < 1\}}] d\mathbf{Z} \le \frac{M_K M_4}{nh^d}$$

Combining the above results:

$$E[|\widehat{RCD} - RCD|] \le M_1 h + \frac{\sqrt{2}\mu_2}{\sqrt{n} h^{d/2}} + \frac{M_K M_4}{nh^d}. \tag{19}$$

This finishes the proof.

Note that we can use any L_p norm ($1 \le p \le \infty$) in the Hölder condition: equation (7). The kernel K is then assumed to have support in the unit ball $\mathbb{B}_0$ corresponding to that L_p norm. The proof remains exactly the same. We in fact will use L_∞ norm in our estimator for computational simplicity. In that case, the unit ball $\mathbb{B}_0 = \{\mathbf{Z} : \|\mathbf{Z}\|_{l_\infty} \le 1\}$ is in fact the d-dimensional cube.

Appendix D. Proof of Theorem 7

Here for $\widehat{RCD} = RCD(\hat{c})$ we use the k-NN estimator (Loftsgaarden and Quesenberry, 1965) of the copula density

$$\hat{c}_{knn}(\mathbf{Z}) = \frac{\frac{k(n)}{n}}{A_{r(k(n),n),\mathbf{Z}}}, \tag{20}$$

where $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$ are the copula based observations, $r(k(n), n)$ is the distance from $\mathbf{Z}$ to the k^{th} closest of $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$ and $A_{r(k(n),n),\mathbf{Z}}$ is the volume of the d-dimensional hyper-ball with radius $r(k(n), n)$.

In the following, without ambiguity, we denote $r(k(n), n)$ by r, and $k(n)$ by k. Hence the volume $A_{r,\mathbf{Z}}$ is $v_d \cdot r^d$, where v_d is the volume of the d-dimensional unit ball $\mathbb{B}_0$. And $\hat{c}_{knn}(\mathbf{Z}) = k/(v_d n r^d)$. For l_2 norm, $v_d = \pi^{d/2}/\Gamma[(d+2)/2]$ where $\Gamma(\cdot)$ denotes the Gamma function.

Moore and Yackel (1977a) showed that, for bounded densities, there is equivalence between the consistency of the KDE density estimator and the consistency of the k-NN estimator. To cite the results of (Moore and Yackel, 1977a), we assume a slightly stronger version of the Hölder condition than (7). That is, we assume that c also has bounded continuous *second order* derivative in A_M. Let $Q(\mathbf{Z}) = tr[\frac{\partial^2 c(\mathbf{Z})}{\partial \mathbf{Z}^2}]$ denote the trace of the Hessian matrix of copula density $c(\mathbf{Z})$. For the d-dimensional vector $\mathbf{Z} = (z_1, ..., z_d)$, the Hessian matrix $\partial^2 c(\mathbf{Z})/\partial \mathbf{Z}^2$ has entries

$$[\frac{\partial^2 c(\mathbf{Z})}{\partial \mathbf{Z}^2}]_{ij} = \frac{\partial^2 c(\mathbf{Z})}{\partial z_i \partial z_j}.$$

Then we rewrite the error bound in Theorem 7 explicitly as

$$\sup_{C \in \mathfrak{C}} E[|\widehat{RCD} - RCD|] \le 2\bar{Q}(\frac{k}{n\epsilon})^{\frac{2}{d}} + \frac{2M}{\sqrt{k}} + 2\epsilon,$$

where $\bar{Q} = \frac{1}{2(d+2)\pi} \Gamma^{2/d}(\frac{d+2}{2}) \sup_{\mathbf{Z} \in A_M} Q(\mathbf{Z})$, and $\epsilon = \epsilon(n)$ is any sequence converging to 0 slower than k/n. We suppress the n from the notation in ϵ without ambiguity as in k and r above.

We shall use the following asymptotic results on k-NN density estimator in Mack and Rosenblatt (1979). Denote $\tilde{Q}(\mathbf{Z}) = \frac{1}{2(d+2)\pi} \Gamma^{2/d}(\frac{d+2}{2}) Q(\mathbf{Z})$. Then

$$\begin{aligned} Bias[\hat{c}_{knn}(\mathbf{Z})] &= \tfrac{\tilde{Q}(\mathbf{Z})}{c(\mathbf{Z})^{2/d}} (\tfrac{k}{n})^{2/d} + O(\tfrac{c(\mathbf{Z})}{k}) + o((\tfrac{k}{n})^{2/d}), \\ Var[\hat{c}_{knn}(\mathbf{Z})] &= \tfrac{c^2(\mathbf{Z})}{k} + o(\tfrac{1}{k}). \end{aligned} \tag{21}$$

These expressions provide control on the error contribution of $\hat{c}(\mathbf{Z})$ to $\widehat{RCD}$ when $c(\mathbf{Z})$ is bounded both from above and from below. Similar to the proof of KDE-based $\widehat{RCD}$, we prove that the error contribution to $\widehat{RCD}$ from the big copula density region is of a smaller order $O(1/k)$. Different from the KDE, the k-NN density estimator also does not have finite bias bound in (21) when the copula density $c(\mathbf{Z})$ is not bounded below. Therefore, we also need to control the error contribution to $\widehat{RCD}$ from the small ($< \epsilon$) copula density region separately.

As before, let M_2 be a constant between 1 and M, say, $M_2 = \frac{M+1}{2}$. We now separate the three regions by copula density: $A^c_{M_2} = \{\mathbf{Z} : c(\mathbf{Z}) > M_2\}$ (big), $A_{M_2,\epsilon} = \{\mathbf{Z} : \epsilon \le c(\mathbf{Z}) \le M_2\}$ (middle) and $A_\epsilon = \{\mathbf{Z} : c(\mathbf{Z}) < \epsilon\}$ (small). Then we can separate RCD into three components

$RCD = T_1(c) + T_2(c) + T_3(c)$: $T_1(c) = \int_{A_{M_2^c}} [1 - c(\mathbf{Z})]_+ d\mathbf{Z}$, $T_2(c) = \int_{A_{M_2,\epsilon}} [1 - c(\mathbf{Z})]_+ d\mathbf{Z}$ and $T_3(c) = \int_{A_\epsilon} [1 - c(\mathbf{Z})]_+ d\mathbf{Z}$.

Firstly, we look at the error bound on $A^c_{M_2}$, the region of big copula density. Similar to the KDE, the error in $\hat{c}_{knn}(\mathbf{Z})$ can be arbitrarily large for $\mathbf{Z} \in A^c_{M_2}$. However, the error only leads to the error in $\widehat{RCD}$ if $\hat{c}_{knn}(\mathbf{Z}) < 1$. From equation (20), $\hat{c}_{knn}(\mathbf{Z}) < 1$ if and only if

$$r > (\frac{k}{nv_d})^{1/d} \stackrel{\text{def}}{=} \bar{r}.$$

This occurs when at most $k-1$ of observations $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$ fall into the ball $\mathbb{B}(\mathbf{Z}; \bar{r})$ which is centered at $\mathbf{Z}$ with radius $\bar{r}$.

Let $\bar{N}(\mathbf{Z})$ denotes the number of observations falling into $\mathbb{B}(\mathbf{Z}; \bar{r})$. Then $\bar{N}(\mathbf{Z})$ follows a binomial distribution with mean $n\bar{p}$, where $\bar{p} = \int_{\mathbb{B}(\mathbf{Z};\bar{r})} c(\mathbf{z}) d\mathbf{z}$. Since $k/n \to 0$, $\bar{r} \to 0$. Hence $M_1 \bar{r} < (M_2 - 1)/2$ when n is large enough. Then the whole ball $\mathbb{B}(\mathbf{Z}; \bar{r})$ is contained in $A^c_{M_3}$ with $M_3 = (M_2 + 1)/2$ as before. Hence $\bar{p} = \int_{\mathbb{B}(\mathbf{Z};\bar{r})} c(\mathbf{z}) d\mathbf{z} \geq M_3 v_d \bar{r}^d = M_3 k/n$. Using Chebyshev's inequality,

$$\begin{aligned} Pr[\hat{c}_{knn}(\mathbf{Z}) < 1] &= E[\mathbb{1}\{\bar{N}(\mathbf{Z}) < k\}] \leq \tfrac{Var[\bar{N}(\mathbf{Z})]}{\{E[\bar{N}(\mathbf{Z})] - k\}^2} = \tfrac{n\bar{p}(1-\bar{p})}{(n\bar{p}-k)^2} \\ &\leq \tfrac{1}{n\bar{p}[1-k/(n\bar{p})]^2} \leq \tfrac{1}{M_3 k[1-1/M_3]^2} \\ &= O(\tfrac{1}{k}). \end{aligned}$$

Hence

$$E|T_1(c) - T_1(\hat{c}_{knn})| = \int_{A^c_{M_2}} E[1_{\{\hat{c}_{knn}(\mathbf{Z}) < 1\}}] d\mathbf{Z} \leq \frac{1}{M_3 k[1 - 1/M_3]^2} = O(\frac{1}{k}).$$

Secondly, we look at the error bound on $A_{M_2,\epsilon}$, the region of middle copula density. Using (21), for $\mathbf{Z} \in A_{M_2,\epsilon}$, the mean squared error of $\hat{c}_{knn}(\mathbf{Z})$ is

$$\begin{aligned} E[(\hat{c}_n(\mathbf{Z}) - c(\mathbf{Z}))^2] &= bias^2(\mathbf{Z}) + Var(\mathbf{Z}) \\ &= [\frac{\tilde{Q}(\mathbf{Z})}{c(\mathbf{Z})^{2/d}} (\frac{k}{n})^{2/d}]^2 + \frac{c^2(\mathbf{Z})}{k} + o((\frac{k}{n})^{4/d} + \frac{1}{k}) \\ &\leq (\frac{\bar{Q}^2}{\epsilon^{4/d}})(\frac{k}{n})^{4/d} + \frac{M_2^2}{k} + o((\frac{k}{n})^{4/d} + \frac{1}{k}). \end{aligned}$$

Hence

$$E|\hat{c}_{knn}(\mathbf{Z}) - c(\mathbf{Z})| \leq \sqrt{E[(\hat{c}_n(\mathbf{Z}) - c(\mathbf{Z}))^2]} \leq \sqrt{2}[\bar{Q}(\frac{k}{n\epsilon})^{2/d} + \frac{M_2}{\sqrt{k}}][1 + o(1)].$$

We get

$$E[T_2(\hat{c}_{knn}) - T_2(c)] \leq E[\int_{A_{M_2,\epsilon}} |\hat{c}_{knn}(\mathbf{Z}) - c(\mathbf{Z})| d\mathbf{Z}] \leq \sqrt{2}[\bar{Q}(\frac{k}{n\epsilon})^{2/d} + \frac{M_2}{\sqrt{k}}][1 + o(1)]. \quad (22)$$

Thirdly, we look at the error bound on A_ϵ, the region of small copula density. From equation (20), $\hat{c}_{knn}(\mathbf{Z}) \geq 2\epsilon$ if and only if

$$r \leq (\frac{k}{n 2\epsilon v_d})^{1/d} \stackrel{\text{def}}{=} r^*.$$

This occurs when at least k of observations $\mathbf{Z}_1, \mathbf{Z}_2, \cdots, \mathbf{Z}_n$ fall into the ball $\mathbb{B}(\mathbf{Z}; r^*)$. Since $k/(n\epsilon) \to 0$, $r^* \to 0$.

Let $N^*(\mathbf{Z})$ denotes the number of observations falling into $\mathbb{B}(\mathbf{Z}; r^*)$. Then $\bar{N}(\mathbf{Z})$ follows a binomial distribution with mean np^*, where $p^* = \int_{\mathbb{B}(\mathbf{Z};r^*)} c(\mathbf{z}) d\mathbf{z}$.

Using Taylor expansion, we have (from last line page 228 in Biau et al. (2011))

$$\int_{\mathbb{B}(\mathbf{Z};r)} c(\mathbf{z}) d\mathbf{z} = c(\mathbf{Z}) v_d r^d + \tilde{Q}(\mathbf{Z}) v_d r^{d+2} + o(r^{d+2}).$$

Therefore, using $r^* \to 0$, we have $p^* = c(\mathbf{Z}) v_d (r^*)^d [1 + o(1)] \leq \epsilon v_d (r^*)^d [1 + o(1)]$ which converges to $k/(2n)$. Hence for n big, $p^* < 0.6k/n$. Using Chebyshev's inequality,

$$\begin{aligned} Pr[\hat{c}_{knn}(\mathbf{Z}) > 2\epsilon] &= E[\mathbb{1}\{N^*(\mathbf{Z}) < k\}] \leq \tfrac{Var[N^*(\mathbf{Z})]}{[k - E(N^*(\mathbf{Z}))]^2} = \tfrac{np^*(1-p^*)}{(k-np^*)^2} \\ &\leq \tfrac{0.6k}{(0.4k)^2} < \tfrac{3}{k} \\ &= O(\tfrac{1}{k}). \end{aligned}$$

Since $c(\mathbf{Z}) \leq \epsilon$, if $\hat{c}_{knn}(\mathbf{Z}) \leq 2\epsilon$, then $|\hat{c}_{knn}(\mathbf{Z}) - c(\mathbf{Z})| \leq 2\epsilon$. Hence

$$\begin{aligned} E|T_3(c) - T_3(\hat{c}_{knn})| &\leq \textstyle\int_{A_\epsilon} E|\hat{c}_{knn}(\mathbf{Z}) - c(\mathbf{Z})| d\mathbf{Z} \leq \int_{A_\epsilon} \{2\epsilon + Pr[\hat{c}_{knn}(\mathbf{Z}) > 2\epsilon]\} d\mathbf{Z} \\ &< 2\epsilon + \tfrac{3}{k} = O(\epsilon + \tfrac{1}{k}). \end{aligned}$$

Finally, when combining the three parts, the terms $O(1/k) = o(1/\sqrt{k}) < (2 - \sqrt{2})/\sqrt{k}$. Hence we arrive at

$$\sup_{C \in \mathfrak{C}} E[|\widehat{RCD} - RCD|] \leq 2[\bar{Q}(\frac{k}{n\epsilon})^{2/d} + \frac{M_2}{\sqrt{k}} + \epsilon], \quad (23)$$

which finished the proof.

Note that we can use other l_p norms, which changes the v_d in the proof to the volume of the unit ball under the corresponding norm. The rate does not change.

We can also prove the consistency under Hölder condition without assuming continuous second derivatives. However, that involve tedious derivation of bias and variance bounds similar to (21) for k-NN density estimators. We provide the simple proof here by citing (21) from Mack and Rosenblatt (1979).

To minimize the error bound in (12), we get $\epsilon = (k/n)^{2/(d+2)}$ and $k = n^{4/(d+6)}$. So in bivariate ($d = 2$) case, we take $k = O(n^{1/2})$. Taking k below the $n^{4/(d+6)}$ rate will make the $O(1/\sqrt{k})$ term dominant in the error bound. In that case, the asymptotic results on the k-NN density estimation states that $\sqrt{k}[\hat{c}(\mathbf{Z}) - c(\mathbf{Z})]/c(\mathbf{Z})$ converge to a standard Gaussian distribution. Then $\sqrt{k}[\widehat{RCD} - RCD]$ converges to an integral of a Gaussian process.

Appendix E. Selection of Tuning Parameter in the Practical Estimator

For a practical estimator for $\widehat{RCD}$, we need to decide the bandwidth in KDE-based estimator or the number of neighbors k in KNN-based estimator. Theorem 4 and Theorem 5 provides the rates. For bivariate case, $h = O(n^{-1/4})$ and $k = O(\sqrt{n})$. To decide the constant coefficient, we used empirical simulations.

First, for KDE estimators, we tested $\widehat{RCD}$ on nine functions (listed in Table 11) with various levels of additive noises. Four sample sizes of $n = 10^2$, 10^3, 10^4 and 10^5 are used.Figure 13 plots

the simulation results using $h = 0.25n^{-1/4}$. We can see that the performance of $\widehat{RCD}$ improves as sample size increases, and gives very accurate estimates for RCD under big sample sizes. For illustration, we showed the plots with bandwidth $h = 0.1n^{-1/4}$ and $h = 0.5n^{-1/4}$ in Figure 14 and Figure 15 respectively. Those bandwidth choices are clearly either too small ($h = 0.1n^{-1/4}$ estimator overshoot in several cases when RCD is small) or too big ($h = 0.5n^{-1/4}$ estimator converges slowly when RCD is large). Hence the bandwidth $h = 0.25n^{-1/4}$ is a good choice.

A	Linear	$y = x$
B	Quadratic	$y = x^2$
C	Square Root	$y = \sqrt{x}$
D	Cubic	$y = x^3$
E	Centered Cubic	$y = 4(x - 1/2)^3$
F	Centered Quadratic	$y = 4x(1 - x)$
G	Cosine (Period 1)	$y = [\cos(2\pi x) + 1]/2$
H	Circle	$(x - 1/2)^2 + y^2 = 1/4$
I	Cross	$y = \pm(x - 1/2)$

Table 11: The function relationships used in Figures 13 - 18.

According to the equivalence results between the KDE and the KNN estimator by (Moore and Yackel, 1977b), the k in the KNN density estimation corresponds to the bandwidth in KDE estimator as $c(\mathbf{z})(2h)^2 = k/n$. As the mean of copula density $c(\alpha)$ is one, $h = 0.25n^{-1/4}$ corresponds to $k = n(2h)^2 = 0.25\sqrt{n}$. The simulation results for KNN-based $\widehat{RCD}$ with $k = 0.25\sqrt{n}$, $k = 0.1\sqrt{n}$ and $k = 0.5\sqrt{n}$ are plotted in Figures 16 - 18. Similar pattern as in KDE-based estimator are observed. Hence we propose the practical KNN-based $\widehat{RCD}$ to use $k = 0.25\sqrt{n}$.

Furthermore, we also checked the KNN-based $\widehat{RCD}$ on the mixture noise setting used in definition 2: a proportion (p) of deterministic function is hidden in independent continuous noise. Six types of deterministic function are used, as listed in Table 12. When $n = 5000$, the $\widehat{RCD}$ is close to the true value p in the simulations. And compared to the two choices of $k = 0.1\sqrt{n}$ and $k = 0.5\sqrt{n}$, $k = 0.25\sqrt{n}$ provide a good balance of approximating the true values when RCD is small or large.

A	Linear	$y = x$
B	Centered Quadratic	$y = 4(x - 1/2)^2$
C	Cosine	$y = \cos(4\pi x)$
D	Cross	$y = \pm x 1_{\{0 \le x \le 1\}}$
E	Circle	$(2x - 1)^2 + y^2 = 1$
F	Cross 2	$y = \pm(x - 1/2)1_{\{0 \le x \le 1\}}$

Editor: Nikos Vlassis

Abstract

This paper presents a multiscale approach to efficiently compute approximate optimal transport plans between point sets. It is particularly well-suited for point sets that are in high-dimensions, but are close to being intrinsically low-dimensional. The approach is based on an adaptive multiscale decomposition of the point sets. The multiscale decomposition yields a sequence of optimal transport problems, that are solved in a top-to-bottom fashion from the coarsest to the finest scale. We provide numerical evidence that this multiscale approach scales approximately linearly, in time and memory, in the number of nodes, instead of quadratically or worse for a direct solution. Empirically, the multiscale approach results in less than one percent relative error in the objective function. Furthermore, the multiscale plans constructed are of interest by themselves as they may be used to introduce novel features and notions of distances between point sets. An analysis of sets of brain MRI based on optimal transport distances illustrates the effectiveness of the proposed method on a real world data set. The application demonstrates that multiscale optimal transport distances have the potential to improve on state-of-the-art metrics currently used in computational anatomy.

1. Introduction

The study of maps between shapes, manifolds and point clouds is of great interest in a wide variety of applications. There are many data types, e.g. shapes (modeled as surfaces), images, sounds, and many more, where a similarity between a pair of data points involves computing a map between the points, and the similarity is a functional of that map. The map between a pair of data points however contains much more information than the similarity measure alone, and the study of networks of such maps have been successfully used to organize, extract functional information and abstractions, and help regularize estimators in large collections of shapes (M. Ovsjanikov and Guibas, 2010; Qixing Huang, 2014; Huang and Guibas, 2013). The family of maps to be considered depends on the type of shape, manifold or point cloud, as well as on the choice of geometric features to be preserved in a particular application. These considerations are not restricted to data sets where each point is naturally a geometric object: high-dimensional data sets of non-geometric nature, from musical pieces to text documents to trajectories of high-dimensional stochastic dynamical systems, are often mapped, via feature sets, to geometric objects. The considerations above therefore apply to a very wide class of data types.

In this paper we are interested in the problem where each object is a point cloud – a set of points in $\mathbb{R}^D$ – and will develop techniques for computing maps from one point cloud to another, in particular in the situation where D is very large, but the point clouds are close to being low-dimensional, for example they may be samples from a d-dimensional smooth manifold $\mathcal{M}$ ($d \ll D$). The two point clouds may have a different number of points, and they may arise from a sample of a low-dimensional manifold $\mathcal{M}$ perturbed by high-dimensional noise (for more general models see the works by Little et al. (2012), Maggioni et al. (2016) and Liao and Maggioni (2016)). In this setting we have to be particularly careful in both the choice of maps and in their estimation since sampling and noise have the potential to cause significant perturbations.

We find optimal transport maps rather well-suited for these purposes. They automatically handle the situation where the two point clouds have different cardinality, they handle in a robust fashion noise, and even changes in dimensionality, which is typically ill-defined, for point clouds arising from real-world data (Little et al., 2012). Optimal transport has a very long history in a variety of disciplines and arises naturally in a wide variety of contexts, from optimization problems in economics and resource allocation, to mathematics and physics, to computer science (e.g. network flow algorithms). Thus, applications of optimal transport range from logistics and economics (Beckmann, 1952; Carlier et al., 2008), geophysical models (Cullen, 2006), image analysis (Rubner et al., 1998; Haker et al., 2004) to machine learning (Cuturi and Doucet, 2014; Cuturi and Avis, 2014). Despite these widespread applications, the efficient computation of optimal transport plans remains challenging, especially in complex geometries and in high dimensions.

For point sets the optimal transport problem can be solved by a specialized linear program, the minimum network flow problem (Ahuja et al., 1993; Tarjan, 1997). The minimum network flow problem has been extensively studied in the operations research community and several fast algorithms exist. However, these algorithms, at least on desktop hardware, do not scale beyond a few thousand source and target points. Our framework extends the applications of these algorithms to problem instances several orders of magnitude larger, under suitable assumptions on the geometry of the data. We exploit a multiscale representation of the source and target sets to reduce the number of variables in the linear program and quickly find good initial solutions, as illustrated in Figure 1. The optimal transport problem is solved (with existing algorithms) at the coarsest scale and the solution is propagated to the next scale and refined. This process is repeated until the finest scale is reached. This strategy, discussed in detail in Section 3, is adaptable to memory limitations and speed versus accuracy trade-offs. For some of the refinement strategies, it is guaranteed to converge to the optimal solution.

Our approach draws from a varied set of work that is briefly summarized in Section 2. The proposed approach generalizes and builds on previous and concurrently developed hierarchical methods (Glimm and Henscheid, 2013; Schmitzer and Schnörr, 2013; Schmitzer, 2015; Oberman and Ruan, 2015). The work in this paper adds the following contributions:

- The description of a general multiscale framework for discrete optimal transport that can be applied in conjunction with a wide range of optimal transport algorithms.
- A set of propagation and refinement heuristics, including approaches that are similar and/or refine existing ones (Glimm and Henscheid, 2013; Oberman and Ruan, 2015; Schmitzer, 2015) as well as novel ones. In particular we propose a novel propagation

strategy based on capacity restrictions of the network flow problem at each scale. This new approach proves to be very efficient and accurate in practice. Overall, the heuristics result empirically in a linear increase in computation time with respect to data set size.

- An implementation in the R package *mop* that allows the combination of multiple heuristics to tailor speed and accuracy to the requirements of particular applications.

Compared to other linear programming based approaches, the multiscale approach results in a speedup of up to multiple orders of magnitude in large problems and permits to solve approximately transportation problems of several orders of magnitudes larger than previously possible. Comparing to PDE based approaches is difficult and PDE based methods are limited to low-dimensional domains and specific cost metrics. The proposed framework is demonstrated on several numerical examples and compared to the state-of-the-art approximation algorithm by Cuturi (2013).

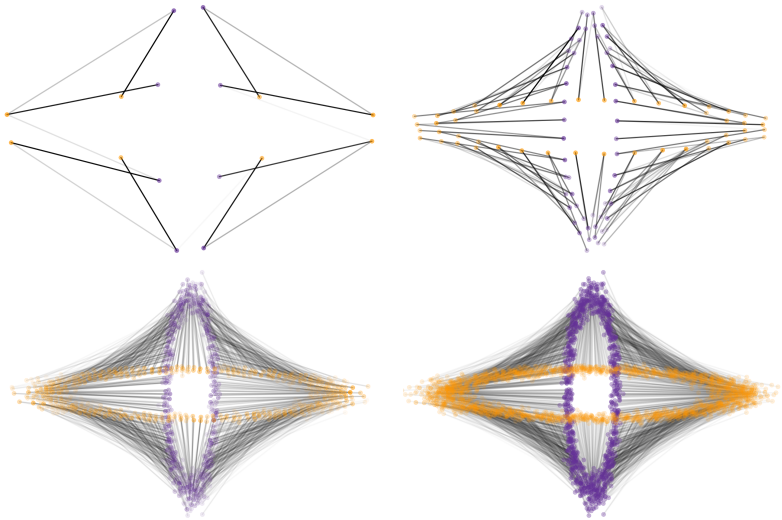

Figure 1: Optimal transport between two noisy elliptical shapes in 2-D. We visualize coarse-to-fine approximations to the source (purple dots) and target (yellow dots) point clouds, together with the optimal transportation plan at each scale (gray edges). The intensity of the points is proportional to mass – at coarser scales each point represents an agglomerate of points at finer scales, and its mass is the sum of the masses of the points it represents. Similarly the intensity of the lines is proportional to the amount of mass transported along the line. Notice that the optimal transport formulation permits multiple lines exiting a source point or entering a target point.

2. Background

Optimal transport is the problem of minimizing the cost of moving a source probability distribution to a target probability distribution given a function that assigns costs to moving mass from source to target locations. The classical formulation by Monge (1781) considers the minimization over mass preserving mappings. Later Kantorovitch (1958) considered the same problem but as a minimization over couplings between the two probability measures, which permits to split mass from a single source across multiple target locations. More precisely, for two probability measures μ and ν on probability spaces $\mathbf{X}$ and $\mathbf{Y}$ respectively, a coupling of μ and ν is a measure π on $\mathbf{X} \times \mathbf{Y}$ such that the marginals of π are μ and ν, i.e. $\pi(A \times \mathbf{Y}) = \mu(A)$ for all (μ-measurable) sets $A \subseteq \mathbf{X}$ and $\pi(\mathbf{X} \times B) = \nu(B)$ for all (ν-measurable) sets $B \subseteq \mathbf{Y}$. We denote by $\mathcal{C}(\mu, \nu)$ the set of couplings between μ and ν. Informally, we may think of $d\pi(x, y)$ as the amount of infinitesimal mass to be transported from source x to destination y, with the condition that π is a coupling guaranteeing that the source mass is distributed according to μ and the destination mass is distributed according to ν. Such couplings always exist: we always have the trivial coupling $\pi = \mu \times \nu$. The trivial coupling is uninformative, every source mass $d\mu(x)$ is transported to the same target distribution ν. In Monge's formulation the coupling is restricted to the special form $\pi(x, y) = \delta_{T(x)}$ where δ_y is the Dirac-δ measure with mass at $y \in \mathbf{Y}$, and T is a function $\mathbf{X} \to \mathbf{Y}$: in this case the coupling is "maximally informative" in the sense that there is a function mapping each source x to a single destination y; in particular the mass $d\mu(x)$ at x is not split into multiple portions that are shipped to different target y's.

To define optimal transport and optimal couplings, we need a cost function $\mathsf{c}(x, y)$ on $\mathbf{X} \times \mathbf{Y}$ representing the work or cost needed to move a unit of mass from x to y. Then for every coupling π we may define the cost of π to be

$$\mathbb{E}_{(X,Y)\sim\pi}[\mathsf{c}(X, Y)]\,, \tag{1}$$

with (X, Y) being a pair of random variables distributed according to π. An optimal coupling π minimizes this cost over all choices of couplings. When seeking an optimal transportation plan, the above becomes

$$\mathbb{E}_{X\sim\mu}[\mathsf{c}(X, T(X))] = \int_{\mathbf{X}} \mathsf{c}(x, T(x)) d\mu(x)\,,$$

and one minimizes over all (measurable) functions $T : \mathbf{X} \to \mathbf{Y}$. One often designs the cost function c in an application-dependent fashion, and the above framework is extremely general. When $\mathbf{X} = \mathbf{Y}$ is a metric space with respect to a distance ρ (with suitable technical conditions relating the metrics and the measures μ, ν that we will not delve into, referring the reader to Villani (2009)), then distinguished choices for the cost are those that are related to the metric structure. The natural choice of $\mathsf{c}(x, y) = \rho(x, y)^p$, for some $p > 0$ leads to the definition of the Wasserstein-Kantorovich-Rubinstein metric on the space of probability measures on $\mathbf{X}$:

$$W_p(\mu, \nu) := \min_{\pi\in\mathcal{C}(\mu,\nu)} \left(\int_{\mathbf{X}} \int_{\mathbf{X}} \rho(x, y)^p d\pi(x, y) \right)^{\frac{1}{p}}. \tag{2}$$

Computational solutions to optimal transport split roughly in two settings: Approaches based on the solution of partial differential equations derived from the continuous optimal

transport formulation, briefly discussed in Section 2.1 and, more relevant to this paper, combinatorial optimization methods to directly solve for a discrete optimal transport plan discussed in Section 2.2.

2.1 Continuous Optimal Transport

In case that at least the source distribution admits a density, and when the cost function is the squared Euclidean distance, the optimal coupling is deterministic, i.e. there exists a transport map, and the optimal solution is the gradient of a convex function (Brenier, 1991). This has been exploited to solve the optimal transport problem by numerical partial differential equation approaches (Benamou and Brenier, 2000; Angenent et al., 2003; Haker et al., 2004; Iollo and Lombardi, 2011; Papadakis et al., 2013; Benamou et al., 2014).

An alternative formulation proposed by Aurenhammer et al. (1998) shows that the optimal transport from a source density to a target distribution of a set of weighted Dirac delta's can be solved through a finite dimensional unconstrained convex optimization. Mérigot (2011) proposes a multiscale approach for the formulation of Aurenhammer et al. (1998).

Both the numerical PDE based approaches as well as the unconstrained convex optimization require a discretization of the full domain which is generally not feasible for higher dimensional domains. For arbitrary cost functions and distributions the optimal transport problem does typically not result in a deterministic coupling and can not be solved through PDE based approaches.

2.2 Discrete Optimal Transport and Linear Programming

For two discrete distributions $\mu = \sum_1^n w(x_i)\delta(x_i)$ and $\nu = \sum_1^m v(y_i)\delta(y_i)$ with $\sum w(x_i) = \sum v(y_i) = 1$ the optimal transport problem is equivalent to the linear program

$$\min_{\pi} \sum_{\substack{i=1,\dots,n \\ j=1,\dots,m}} \mathtt{c}(x_i, y_j)\pi(x_i, y_j) \quad \text{s.t.} \quad \begin{cases} \sum_j \pi(x_i, y_j) = \mu(\{x_i\}) = w(x_i) \\ \sum_i \pi(x_i, y_j) = \nu(\{y_j\}) = v(y_j) \\ \pi(x_i, y_j) \geq 0 \end{cases} . \tag{3}$$

The solution is called an optimal coupling π^*, and the minimum value attained at π^*, is called the cost of π^*, or the optimal cost of the transport problem, and is denoted by $\mathtt{cost}(\pi^*) = \sum_{i,j} \mathtt{c}(x_i, y_j)\pi^*(x_i, y_j)$. The constraints enforce that π is a coupling. The variables $\pi(x_i, y_j)$ correspond to the amount of mass transported from source x_i to target y_j, at cost $\mathtt{c}(x_i, y_j)$. The linear constraints are of rank $n + m - 1$: when $n + m - 1$ of the constraints are satisfied, either the n constraints of the source density or the m constraints of the target density are satisfied. Since the sum of outgoing mass is equal to the sum of incoming mass, i.e. $\mu(\mathbf{X}) = \nu(\mathbf{Y})$, it follows that all constraints must be satisfied. The optimal solution lies, barring degeneracies, on a corner of the polytope defined by the constraints, i.e. is a basic feasible solution. This implies that exactly $n + m - 1$ entries of the optimal coupling π are non-zero, i.e. π is a sparse matrix. The optimal coupling is a Monge transport map if and only if all the mass of a source x_i is transported to exactly one target location. A Monge solution does not exist for every optimal transport problem, in fact a small perturbation of μ will always suffice to make a Monge solution impossible.

For source and target data sets with the same cardinality and equally weighted δ-functions, Kantorovich's optimal transport problem reduces to an assignment problem, whose solution is a Monge optimal transport map. In this special case, the optimal transport problem can be efficiently solved by the Hungarian algorithm (Kuhn, 1955). The assignment problem results in a degenerate linear program since only n entries are non-zero (instead of $2n - 1$). We can therefore think of optimal transport as a robust version of assignments. This can also be seen from the point of view of convexity: in the assignment problem, π is a permutation matrix deciding to which y_j each x_i is transported. The convex hull of permutation matrices is exactly the set of doubly-stochastic matrices, to which a coupling π belongs as a consequence of the constraints in (3).

For point sets with different cardinalities and/or points with different masses the optimal transport problem can be solved by a linear program and is a special case of the minimum cost network flow problem. The minimum cost flow problem is well studied and a number of algorithms (Ford and Fulkerson, 1956; Klein, 1967; Cunningham, 1976; Goldberg and Tarjan, 1987; Bertsekas and Tseng, 1988; Orlin, 1997) exist for its solution. This discrete solution approach is not constrained to specific cost functions and can work with arbitrary cost functions.

However, the linear programming approach neglects possibly useful geometric properties of the measures and the cost function. Our work makes assumptions about the underlying geometry of the measure spaces and the associated cost function, and in this way is a mixing of the low-dimensional "geometric PDE" approaches with the discrete non-geometric optimization approaches. It exploits the geometric assumptions to relieve the shortcomings of either approach, namely it scales to high-dimensional data, provided that the intrinsic dimension is low in a suitable sense, and does not require a mesh data structure. At the same time we use the geometry of the data to speed up the linear program, which per–se does not leverage geometric structures.

The refinement strategies of the proposed multiscale approach add subsets of paths among all pairwise paths at each subsequent scale to improve the optimal transport plan. This strategy of adding paths, is akin to column generation approaches (Desrosiers and Lübbecke, 2005). Column generation, first developed by Dantzig and Wolfe (1960) and Ford and Fulkerson (1956), reduces the number of variables in a linear program by solving a smaller linear program on a subset of the original variables and introducing new variables on demand. However, the proposed approach exploits the geometry of the problem instead of relying on an auxiliary linear program (Dantzig and Wolfe, 1960) or shortest path computations (Ford and Fulkerson, 1956) to detect the entering variables.

2.3 Approximation Strategies

In the computer vision literature, the Earth Movers distance or equivalently the Wasserstein-1 distance, which is simply the cost of the optimal coupling, is a successful similarity measure for image retrieval (Rubner et al., 1998). In this application the transport plan is not of interest but only the final transport cost. For this purpose Indyk and Thaper (2003), Shirdhonkar and Jacobs (2008) and Andoni et al. (2008) developed algorithms that compute an approximate cost but do not yield a transport plan. Some of these approaches are based on the dual formulation of optimal transport, which involves testing against Lipschitz func-

tions, and observing that Lipschitz functions may be characterized by decay properties of their wavelet coefficients. In this sense these approaches are multiscale as well.

To speed up computations in machine learning applications Cuturi (2013) proposes to *smooth* transport plans by adding a maximum entropy penalty to the optimal transport formulation. The resulting optimization problem is efficiently solved through matrix scaling with Sinkhorn fixed-point iterations. Because of the added regularization term, the solution will in general be different from the optimal transportation. It may however be the case that these particular (or perhaps other) regularized solutions are better suited for certain applications.

2.4 Related Work

Very recently a number of approaches have been proposed to solve the optimal transport in a multiscale fashion (Glimm and Henscheid, 2013; Schmitzer and Schnörr, 2013; Schmitzer, 2015; Oberman and Ruan, 2015). Glimm and Henscheid (2013) design an iterative scheme to solve a discrete optimal transport problem in reflector design and propose a heuristic for the iterative refinements based on linear programming duality. This iterative scheme can be interpreted as a multiscale decomposition of the transport problem based on geometry of the source and target sets. The proposed potential refinement strategy extends the heuristic proposed by Glimm and Henscheid (2013) to guarantee optimal solutions and adds a more efficient computation strategy: Their approach requires to check all possible variables at the next scale. In Section 3.4.1 we introduce a variation of the approach by Glimm and Henscheid (2013) by adding a branch and bound strategy to avoid checking all variables, and an iterative procedure that guarantees optimal solutions.

Schmitzer and Schnörr (2013) propose a multiscale approach on grids that uses a refinement strategy based on spatial neighborhoods, akin to the neighborhood refinement described in Section 3.4.2. Schmitzer (2015) uses a multiscale approach to develop a modified auction algorithm with guaranteed worst case complexity and optimal solutions. We use data structures that enable us to quickly construct neighborhoods, even for point clouds that live in high-dimensions, but have low-intrinsic dimension; we also exploit these structures to not compute all the pairwise possible costs, as well as the candidate neighborhoods in our propagation steps. This can result in substantial savings in the scaling of the algorithm, from $|\mathbf{X}|^3$ to just $|\mathbf{X}|\log|\mathbf{X}|$. We are therefore able to scale to larger problem, solving on a laptop problems an order of magnitude larger than those in Oberman and Ruan (2015) for example, and showing linear scaling on a large range of scales. Schmitzer (2015) use the c–cyclical monotonicity property of optimal transport plans (Villani, 2009, Chapter 5) to construct "shielding neighborhoods" that permit to exclude paths from further consideration. The idea of shielding neighborhoods is combined with a multiscale strategy that permits to quickly refine initial neighborhood estimates.

Finally, in our work we emphasize that the multiscale construction is not only motivated by its computational advantage, but also as a way of revealing possibly important features of the optimal transportation map. As we show in Section 5, features collected from the multiscale optimal transportation maps leads to improved predictors for brain conditions. More generally, we expect multiscale properties of optimal transportation maps to be useful

in a variety of learning tasks; the connections between learning and optimal transportation are still a very open field, to be explored and exploited.

3. Multiscale Optimal Transport

Solving the optimal transport problem for two point sets $\mathbf{X}$ and $\mathbf{Y}$ directly requires $|\mathbf{X}||\mathbf{Y}|$ variables, or paths to consider. In other words, the number of paths along which mass can be transported grows quadratically in the number of points and quickly yields exceedingly large problems. The basic premise of the multiscale strategy is to solve a sequence of transport problems based on increasingly accurate approximations of the source and target point set. The multiscale strategy helps to reduce the problem size at each scale by using the solution from the previous scale to inform which paths to include in the optimization at the next finer scale. Additionally, the solution at the previous scale helps to find a good initialization for the current scale which results in fewer iterations to solve the reduced size linear program.

The multiscale algorithm (see Algorithm 1 and Figure 2 for a visual illustration) comprises of three key elements:

(I) A way of ***coarsening*** *the sets* of source points $\mathbf{X}$ and measure μ in a multiscale fashion, yielding a chain

$$(\mathbf{X},\mu) =: (\mathbf{X}_J,\mu_J) \to (\mathbf{X}_{J-1},\mu_{J-1}) \to \cdots \to (\mathbf{X}_j,\mu_j) \to \cdots \to (\mathbf{X}_0,\mu_0) \qquad (4)$$

connecting the scales from fine to coarse, with $\mathbf{X}_j$ of decreasing cardinality as the scale decreases, and the discrete measure μ_j "representing" a coarsification of μ at scale j, with $\mathrm{supp}(\mu_j) = \mathbf{X}_j$ (the support of μ_j is the set of points with positive measure). Similarly for $\mathbf{Y}$ and ν we obtain the chain

$$(\mathbf{Y},\mu) =: (\mathbf{Y}_J,\nu_J) \to (\mathbf{Y}_{J-1},\nu_{J-1}) \to \cdots \to (\mathbf{Y}_j,\nu_j) \to \cdots \to (\mathbf{Y}_0,\nu_0) \qquad (5)$$

This coarsening step is described in Section 3.1 and the resulting multiscale family of transport problems is discussed in Section 3.2.

(II) A way of ***propagating*** *a coupling* π_j solving the transport problem $\mu_j \rightarrowtail \nu_j$ at scale j to a coupling π_{j+1} at scale $j+1$. This is described in Section 3.3.

(III) A way of ***refining*** *the propagated solution* to the optimal coupling at scale j. This is described in Section 3.4.

3.1 The Coarsening Step: Multiscale Approximations to X, μ and c

To derive approximation bounds for the error of the multiscale transport problem at each scale we rely on the notion of a regular family of multiscale partitions formally described in Section 3.1.1. The multiscale partition is used to define approximations to μ and $\mathtt{c}$ at all scales. An integral part of the definitions is that the constructions can be interpreted as a tree, with all nodes at a fixed height corresponding to one scale of the multiscale partitioning.

Algorithm 1: Multiscale Discrete Optimal Transport

Input: Two discrete measures μ and ν, and a stopping scale $J_0 \leq J$
Output: Multiscale family of transport plans $(\pi_j : \mu_j \rightarrowtail \nu_j)_{j=0}^{J_0}$
Construct multiscale structures $\{\{\mathbf{X}_j, \mu_j)\}_{j=0}^{J}$ and $\{\{\mathbf{Y}_j, \nu_j)\}_{j=0}^{J}$.
Let $\tilde{\pi}_0$ be an arbitrary coupling $\mu_0 \rightarrowtail \nu_0$.
for $j = 0 \dots J_0 - 1$ **do**
  Refine initial guess $\tilde{\pi}_j$ to the optimal coupling $\pi_j : \mu_j \rightarrowtail \nu_j$.
  Propagate π_j from scale j to scale $j+1$, obtaining a coupling $\tilde{\pi}_{j+1}$

We start with some notation needed for the definition of the multiscale partitions. Let $(\mathbf{X}, \rho, \mu)$ be a measure metric space with metric ρ and finite measure μ. Without loss of generality assume that $\mu(\mathbf{X}) = 1$. The metric ball of center z and radius r is $B_z(r) = \{x \in \mathbf{X} : \rho(x, z) < r\}$. We say that $\mathbf{X}$ has doubling dimension d if every ball $B_z(r)$ can be covered by at most 2^d balls of radius $r/2$ (Assouad, 1983). Furthermore, a space has a doubling measure if $\mu(B_z(r)) \asymp r^d$, i.e. if there exist a constant c_1 such that for every $z \in \mathbf{X}$ and $r > 0$ we have $c_1^{-1} r^d \leq \mu(B_z(r)) \leq c_1 r^d$. Here and in what follows, we say that $f \asymp g$ if there are two constants $c_1, c_2 > 0$ such that for every z in the domain of both functions f, g we have $c_1 f(z) \leq g(z) \leq c_2 f(z)$ (and therefore a similar set of inequalities holds with the roles of f and g swapped), and we say that f and g have the same order of magnitude. Having a doubling measure implies having a doubling metric, and up to changing the metric to an equivalent one, one may choose the same d in the doubling condition for the metric and in that for the measure: we assume this has been done from now on. This family of spaces is rather general, it includes regular domains in $\mathbb{R}^D$, as well as smooth compact manifolds $\mathcal{M}$ endowed with volume measures.

3.1.1 Multiscale Approximations to $\mathbf{X}$ and μ

A regular family of multiscale partitions, with scaling parameter $\theta > 1$, is a family of sets $\{\{C_{j,k}\}_{k=1}^{K_j}\}_{j=0}^{J}$, where j denotes the scale and k indexes the sets at scale j, such that:

(i) the sets $\{C_{j,k}\}_{k=1}^{K_j}$ form a partition of $\mathbf{X}$, i.e. they are disjoint and $\cup_{k=1}^{K_j} C_{j,k} = \mathbf{X}$;

(ii) either $C_{j+1,k'}$ does not intersect a $C_{j,k}$, or it is completely contained in it;

(iii) there exists a constant $A > 0$ such that for all j, k we have the diameter $\mathrm{diam}(C_{j,k}) \leq A\theta^{-j}$;

(iv) each $C_{j,k}$ contains a "center" point $c_{j,k}$ such that $B_{c_{j,k}}(\theta^{-j}) \subseteq C_{j,k}$.

To ease the notation we will fix $\theta = 2$ in what follows, but the constructions and results hold, mutatis mutandis, for general $\theta > 1$. The properties (i) and (ii) above imply that there exists a tree $\mathcal{T}$, with nodes at scale j (i.e. at distance j from the root) in bijection with $\{C_{j,k}\}_{k=1}^{K_j}$, such that $(j+1, k')$ is a child of (j, k) if and only if $C_{j+1,k'}$ is contained in $C_{j,k}$. Moreover properties (iii) and (iv), together with the properties of spaces with a doubling measure, imply that $\mu(C_{j,k}) \asymp 2^{-jd}$ and $K_j \asymp 2^{jd}$. These partitions are classical in harmonic analysis, mimicking dyadic cubes in Euclidean space, and they have recently

been used to construct multiscale decompositions of data sets in high-dimensions (Little et al., 2012; Allard et al., 2012; Iwen and Maggioni, 2013; Chen et al., 2012). We say that $C_{j+1,k'}$, or even $(j+1, k')$, is a child of $C_{j,k}$ (respectively, of (j,k)) if $C_{j+1,k'} \subseteq C_{j,k}$, and that such $C_{j,k}$ (respectively (j,k)) is a parent of $C_{j+1,k'}$ (resp. $(j+1, k')$).

Given two discrete sets $\mathbf{X}$ and $\mathbf{Y}$ in a doubling metric space of homogeneous type with dimension d, we construct the corresponding families of multiscale partitions $\{\{C_{j,k}^{\mathbf{X}}\}_{k=1}^{K_j^{\mathbf{X}}}\}_{j=0}^{J}$ and $\{\{C_{j,k}^{\mathbf{Y}}\}_{k=1}^{K_j^{\mathbf{Y}}}\}_{j=0}^{J}$ (we assume the same range of scales to keep the notation simple). The construction of the multiscale approximations is illustrated in Figure 2.

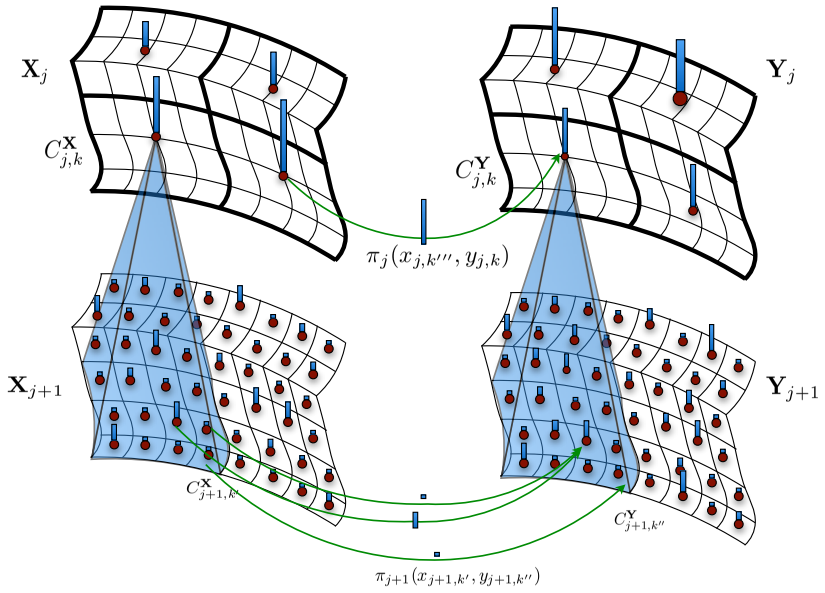

Figure 2: An illustration of the multiscale framework. The coarsening step constructs from a set of weighted points $\mathbf{X}_{j+1}$ at scale $j+1$ a smaller set of weighted points at scale j (blue bars). An equivalent coarsening is performed on the target point set $\mathbf{Y}_{j+1}$ Neighboring points at scale $j+1$ are combined into a single representative at scale j with mass equivalent to the weights of the combined points. The optimal transport plan (green arrows) is solved at the coarser scale j, then propagated to scale $j+1$ and refined.

The space $\mathbf{X}_j$ will be the partition at scale j, namely the set $\{C_{j,k}^{\mathbf{X}}\}_{k=1}^{K_j^{\mathbf{X}}}$, of cardinality $K_j^{\mathbf{X}}$. The measures μ and ν may be coarsened in the natural way, by letting μ_j be defined

recursively on $\mathbf{X}_j$ by

$$\mu_j(C^{\mathbf{X}}_{j,k}) = \sum_{(j+1,k') \text{ child of } (j,k)} \mu_{j+1}(C^{\mathbf{X}}_{j+1,k'}) \,, \tag{6}$$

and similarly for ν_j. These are in fact projections of these measures, and may also be interpreted as conditional expectations with respect to the σ-algebra generated by the multiscale partitions. We can associate a point $\overline{c}^{\mathbf{X}}_{j,k}$ to each $C^{\mathbf{X}}_{j,k}$ in various ways, by "averaging" the points in $C^{\mathbf{X}}_{j+1,k'}$, for $(j+1,k')$ a child of (j,k). At the finest scale we may let $\overline{c}^{\mathbf{X}}_{J,k} = c^{\mathbf{X}}_{J,k}$ (this being a "center" for $C_{J,k}$ as in item (iv) in the definition of multiscale partitions), and then recursively we defined the coarser centers step from scale $j+1$ to scale j in one of the following ways:

(i) If the metric space is also a vector space a natural definition of $x_{j,k} := \overline{c}^{\mathbf{X}}_{j,k}$ is a weighted average of the $\overline{c}^{\mathbf{X}}_{j+1,k'}$ corresponding to children:

$$\overline{c}^{\mathbf{X}}_{j,k} = \sum_{(j+1,k') \text{ child of } (j,k)} \mu_{j+1}(\{\overline{c}^{\mathbf{X}}_{j+1,k'}\}) \overline{c}^{\mathbf{X}}_{j+1,k'} \,.$$

(ii) In general we can define $x_{j,k} := \overline{c}^{\mathbf{X}}_{j,k}$ as the point

$$\overline{c}^{\mathbf{X}}_{j,k} = \mathrm{argmin}_{c \in \mathbf{X}} \sum_{(j+1,k') \text{ child of } (j,k)} \rho^p(c, \overline{c}^{\mathbf{X}}_{j+1,k'}) \,,$$

for some $p \geq 1$, typically $p = 1$ (median) or $p = 2$ (Fréchet mean).

Of course similar constructions apply to the space $\mathbf{Y}_j$, yielding points $y_{j,k} := \overline{c}^{\mathbf{Y}}_{j,k}$. We discuss algorithms for these constructions in Section 4.1.1.

3.1.2 Coarsening the cost function $\mathtt{c}$

The multiscale partition provides several ways to coarsen the cost function: for every $x_{j,k}$ and $y_{j,k'}$ we consider

($\mathtt{c}$-i) the pointwise value

$$\mathtt{c}_j(c^{\mathbf{X}}_{j,k}, c^{\mathbf{Y}}_{j,k'}) := \mathtt{c}(x^{\mathbf{X}}_{j,k}, y^{\mathbf{Y}}_{j,k'}) \,, \tag{7}$$

where $x_{j,k}$ and $y_{j,k'}$ are defined in any of the ways above;

($\mathtt{c}$-ii) the local average

$$\mathtt{c}_j(c^{\mathbf{X}}_{j,k}, c^{\mathbf{Y}}_{j,k'}) := \operatorname*{argmin}_{\alpha} \sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} (\alpha - \mathtt{c}(x,y))^2 = \frac{\sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} \mathtt{c}(x,y)}{|C^{\mathbf{X}}_{j,k}||C^{\mathbf{Y}}_{j,k'}|} \,; \tag{8}$$

($\mathtt{c}$-iii) the local weighted average

$$\begin{aligned} \mathtt{c}_j(c^{\mathbf{X}}_{j,k}, c^{\mathbf{Y}}_{j,k'}) &:= \operatorname*{argmin}_{\alpha} \sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} (\alpha - \mathtt{c}(x,y))^2 \, \pi^*_{j-1}(x_{j-1,k_1}, y_{j-1,k'_1}) \\ &= \frac{\sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} \mathtt{c}(x,y) \pi^*_{j-1}(x_{j-1,k_1}, y_{j-1,k'_1})}{\sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} \pi^*_{j-1}(x_{j-1,k_1}, y_{j-1,k'_1})} \,, \end{aligned}$$

where π^*_{j-1} is the optimal or approximate transportation plan at scale $j-1$, defined in (9); k_1 is the unique index for which $C^{\mathbf{X}}_{j,k} \subseteq C^{\mathbf{X}}_{j-1,k_1}$ and k'_1 is the unique index for which $C^{\mathbf{Y}}_{j,k} \subseteq C^{\mathbf{Y}}_{j-1,k'_1}$.

3.2 Multiscale Family of Optimal Transport Problems

With the definitions of the multiscale family of coarser spaces $\mathbf{X}_j$ and $\mathbf{Y}_j$, corresponding measures μ_j and ν_j, and corresponding cost $\mathtt{c}_j$, we may consider, for each scale j, the following optimal transport problem:

$$\pi^*_j := \operatorname*{argmin}_{\pi} \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \mathtt{c}_j(x_{j,k}, y_{j,k'}) \pi(x_{j,k}, y_{j,k'}) \text{ s.t. } \begin{cases} \sum_{k'} \pi(x_{j,k}, y_{j,k'}) = \mu_j(\{x_{j,k}\}) & \forall k \in K^{\mathbf{X}}_j \\ \sum_{k} \pi(x_{j,k}, y_{j,k'}) = \nu_j(\{y_{j,k'}\}) & \forall k' \in K^{\mathbf{Y}}_j \\ \pi(x_{j,k}, y_{j,k'}) \geq 0 \end{cases} \tag{9}$$

The problems in this family are related to each other, and to the optimal transportation problem in the original spaces. We define the cost of a coupling as

$$\mathtt{cost}(\pi_j) = \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \mathtt{c}_j(x_{j,k}, y_{j,k'}) \pi_j(x_{j,k}, y_{j,k'}) \,. \tag{10}$$

The cost of the optimal coupling π^*_j at scale j is provably an approximation to the cost of the optimal coupling π^* (which is equal to π^*_J):

Proposition 1 *Let π^* be the optimal coupling, i.e. the solution to (3), and π^*_j the optimal coupling at scale j, i.e. the solution to (9). Define*

$$E_j(\pi^*) := \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \sum_{\substack{x \in C^{\mathbf{X}}_{j,k} \\ y \in C^{\mathbf{Y}}_{j,k'}}} \left(\mathtt{c}_j(x_{j,k}, y_{j,k'}) - \mathtt{c}(x,y)\right) \pi^*(x,y) \,. \tag{11}$$

Then

$$\mathtt{cost}(\pi^*_j) \leq \mathtt{cost}(\pi^*) + E_j(\pi^*) \,, \tag{12}$$

and if $\mathtt{c}_j = \mathtt{c}$ and $\mathtt{c}$ is Lipschitz with constant $||\nabla \mathtt{c}||_\infty$, we have

$$\mathtt{cost}(\pi^*_j) \leq \mathtt{cost}(\pi^*) + 2^{-j} A ||\nabla \mathtt{c}||_\infty \,, \tag{13}$$

where A is such that $\max_{k,k'} \{\mathrm{diam}(C^{\mathbf{X}}_{j,k}), \mathrm{diam}(C^{\mathbf{Y}}_{j,k'})\} \leq A \cdot 2^{-j}$.

Proof Consider the coupling π_j induced at scale j by the optimal coupling π^*, defined by

$$\pi_j(x_{j,k}, y_{j,k'}) = \sum_{x \in C^{\mathbf{X}}_{j,k}, y \in C^{\mathbf{Y}}_{j,k'}} \pi^*(x,y) \,.$$

First of all, since $\{C^{\mathbf{X}}_{j,k}\}_k$ and $\{C^{\mathbf{Y}}_{j,k'}\}_{k'}$ are partitions, it is immediately verified that π_j is a coupling. Secondly, observe that

$$\begin{aligned}
\mathtt{cost}(\pi_j) &= \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \mathtt{c}_j(x_{j,k}, y_{j,k'})\pi_j(x_{j,k}, y_{j,k'}) = \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \sum_{\substack{x\in C^{\mathbf{X}}_{j,k} \\ y\in C^{\mathbf{Y}}_{j,k'}}} \mathtt{c}_j(x_{j,k}, y_{j,k'})\pi^*(x,y) \\
&= \sum_{\substack{x\in\mathbf{X} \\ y\in\mathbf{Y}}} \mathtt{c}(x,y)\pi^*(x,y) + \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \sum_{\substack{x\in C^{\mathbf{X}}_{j,k} \\ y\in C^{\mathbf{Y}}_{j,k'}}} \big(\mathtt{c}_j(x_{j,k}, y_{j,k'}) - \mathtt{c}(x,y)\big)\,\pi^*(x,y) \\
&= \mathtt{cost}(\pi^*) + \underbrace{\sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} \sum_{\substack{x\in C^{\mathbf{X}}_{j,k} \\ y\in C^{\mathbf{Y}}_{j,k'}}} \big(\mathtt{c}_j(x_{j,k}, y_{j,k'}) - \mathtt{c}(x,y)\big)\,\pi^*(x,y)}_{=:E_j(\pi^*)} .
\end{aligned}$$

Since $\mathtt{cost}(\pi^*_j) \le \mathtt{cost}(\pi_j)$ (since π^*_j is optimal), we obtain (12). When $\mathtt{c}_j = \mathtt{c}$ and $\mathtt{c}$ is Lipschitz with constant $||\nabla \mathtt{c}||_\infty$, we have

$$\begin{aligned}
E_j(\pi^*) &\le \sum_{\substack{k\,:\,x\in C^{\mathbf{X}}_{j,k} \\ k'\,:\,y\in C^{\mathbf{Y}}_{j,k'}}} \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} ||\nabla \mathtt{c}||_\infty \cdot ||(x_{j,k}, y_{j,k'}) - (x,y)||\pi^*(x,y) \\
&\le \sum_{\substack{k\,:\,x\in C^{\mathbf{X}}_{j,k} \\ k'\,:\,y\in C^{\mathbf{Y}}_{j,k'}}} \sum_{\substack{k=1,\dots,K^{\mathbf{X}}_j \\ k'=1,\dots,K^{\mathbf{Y}}_j}} ||\nabla \mathtt{c}||_\infty 2^{-j} A\pi^*(x,y) \\
&\le 2^{-j} A||\nabla \mathtt{c}||_\infty ,
\end{aligned}$$

with A as in the claim. ∎

In the discrete, finite case that we are considering, $\mu_j \to \mu$ and $\nu_j \to \nu$ trivially since $\mu_J = \mu$ and $\nu_J = \nu$ by construction. If μ and ν were continuous, and at least when $\mathtt{c}(x,y) = \rho(x,y)^p$ for some $p \ge 1$, then if μ and ν have finite p-moment (i.e. $\int_{\mathbf{X}} \rho(x,x_0)^p d\mu$ and similarly for ν), we would obtain convergence of a subsequence of $\mathtt{c}(\pi^*_j)$ to $\mathtt{c}(\pi^*)$ by general results (e.g. as a simple consequence of Lemma 4.4. in (Villani, 2009)).

Note that the approximations do not guarantee that the transport plans are close in any other sense but their cost. Consider the arrangement in Figure 3, the transport plans are ϵ-close in cost but the distances between the target locations of the sources are far no matter how small ϵ gets.

3.3 Propagation Strategies

The approximation bounds in Section 3.2 show that the optimal solution π_j at scale j is $|E_{j+1} - E_j|$ close to optimal solution π^*_{j+1} at scale $j+1$. This suggests that the solution at scale j can provide a reasonably close to optimal initialization for scale $j+1$.

As proposed by Glimm and Henscheid (2013) the solution at a given scale can be interpolated at the next scale (or finer discretization). The most direct approach to initialize the

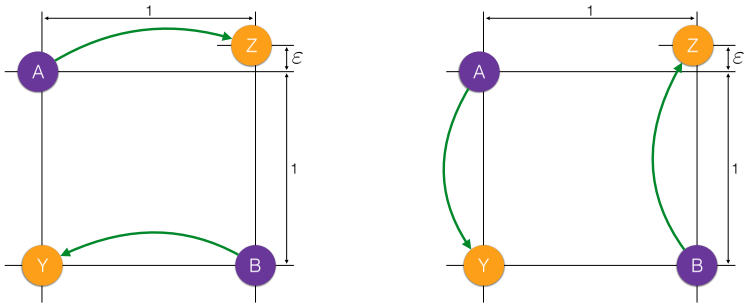

Figure 3: An example that illustrates that closeness in cost does not indicate closeness of the transport plan. The transport plans (green arrows) between the sources A and B (purple) and the targets Y and Z (orange) in (a) and (b) are ϵ-close but their respective target locations are very far.

transport problem at scale $j+1$ given the solution π^*_j at scale j is to distribute the mass $\pi^*_j(x_k, y_{k'})$ equally to all combinations of paths between children(x_k) and children$(y_{k'})$.

This propagation strategy results in a reduction in the number of iterations required to find an optimal solution at the subsequent scale. This warm-starting alone is often not sufficient, however. At the finest scale the problems still requires the solution of a problem of size $O(n^2)$. This quickly reaches memory constraints with $\Omega(10^4)$ points, and a single iteration of Newton's method or a pivot step of a linear program becomes prohibitively slow. Thus, we consider reducing the number of variables, which substantially speeds up the algorithm, albeit we may lose guarantees on its computational complexity and/or its ability to achieve arbitrary accuracy, so that only numerical experiments will support our constructions. These reductions are achieved by considering only a subset $\mathbf{R}_{j+1}$ of all possible paths $\mathbf{A}_{j+1}$ at scale $j+1$.

To distinguish the optimal solution on the reduced set of paths at scale j from the optimal solution over all paths we introduce some notation. Let $\mathbf{A}_{j+1}$ be the set of all possible paths between sources and targets at scale $j+1$. Let $\mathbf{R}_{j+1} \subseteq \mathbf{A}_{j+1}$ be the set of paths propagated from the previous solution (e.g. children of mass-bearing paths found at scale j). Let $\pi^*_{j+1}|_{\mathbf{P}}$ be the optimal solution to the transport problem restricted to a set of paths $\mathbf{P} \subset \mathbf{A}_{j+1}$. With this notation, $\pi^*_{j+1}|_{\mathbf{A}_{j+1}} = \pi^*_{j+1}$. The optimal coupling $\pi^*_{j+1}|_{\mathbf{R}_{j+1}}$ on the reduced set of paths problem does not need to match the optimal coupling π^*_{j+1} on all paths. However $\pi^*_{j+1}|_{\mathbf{R}_{j+1}}$ does provide a starting point for further refinements discussed in Section 3.4.

3.3.1 Simple Propagation

The most direct approach to reduce the number of paths considered at subsequent scales is to include only paths at scale $j+1$ whose endpoints are children of endpoints of mass-

bearing paths at scale j. The optimal solution at scale j has exactly $K_j^{\mathbf{X}} + K_j^{\mathbf{Y}} - 1$ paths with non-zero weight. Thus, the number of paths at scale $j+1$ reduces to $O(C^2(K_j^{\mathbf{X}}+K_j^{\mathbf{Y}}))$, where C is the maximal number of children of any node at scale j. In particular, $C \asymp 2^d$ for a doubling space of dimension d. This reduces the number of variables from "quadratic", $O(K_j^{\mathbf{X}} K_j^{\mathbf{Y}})$, to linear, $O(K_j^{\mathbf{X}} + K_j^{\mathbf{Y}})$. This propagation strategy by itself, however, often leads to a dramatic loss of accuracy in both the cost the transportation plan, and the transportation plan itself.

3.3.2 Capacity Constraint Propagation

This propagation strategy solves a modified minimum flow problem at scale j in order to include additional paths at scale $j+1$ that are likely to be included in the optimal solution π^*_{j+1}. This is achieved by adding a capacity constraint to the mass bearing paths at scale j in the optimal coupling $\pi^*_j|_{\mathbf{R}_j}$: The amount of mass of a mass bearing path $\pi^*_j|_{\mathbf{R}_j}(x_{j,k}, y_{j,k'})$ is constrained to $\lambda \min\left(\mu_j(x_{j,k}), \nu_j(y_{j,k'})\right)$ with λ random uniform on $[0.1, 0.9]$. The randomness is introduced to avoid degenerate constraints. The solution of this modified minimum–flow problem forces the inclusion of n_c additional paths, where n_c is the number of constraints added. There are various options for adding capacity constraints, we propose to constrain all mass bearing paths of the optimal solution at scale $\pi^*_j|_{\mathbf{R}_j}$. The capacity constrained problem thus results in a solution with twice the number of paths as in the coupling $\pi^*_j|_{\mathbf{R}_j}$. The solution of the capacity constrained minimum flow problem is propagated as before to the next scale.

To increase the likelihood of including paths required to find an optimal solution at the next scale, the capacity constrained procedure can be iterated multiple times. Each time the mass bearing paths in the modified solution are constrained and a new solution is computed. Each iteration doubles the number of mass bearing paths and the number of iterations controls how many paths are propagated to the next scale. Thus, the capacity constraint propagation strategy bounds the number of paths considered in the linear program. The optimal transport plan on a source set $\mathbf{X}$ and $\mathbf{Y}$ results in a linear program with $|\mathbf{X}| + |\mathbf{Y}|$ constraints and $|\mathbf{X}||\mathbf{Y}|$ variables and the optimal transport plan has $|\mathbf{X}| + |\mathbf{Y}| - 1$ mass bearing paths. It follows that the capacity constraint propagation strategy considers linear programs with at most $O\left(2^i(|\mathbf{X}| + |\mathbf{Y}|)\right)$ constraints, where i is the number of iterations of the capacity propagation scheme. This results in a significant reduction in problem size, since at each scale we only consider a number of paths scaling as $O(|\mathbf{X}| + |\mathbf{Y}|)$ instead of $O(|\mathbf{X}||\mathbf{Y}|)$.

3.4 Refinement Strategies

Solving the reduced transport problem at scale $j+1$, propagated from scale j, can not guarantee an optimal solution at scale $j+1$. Propagating a sub-optimal solution further may lead to an accumulation of errors. This section describes strategies to refine the reduced transport problem to find closer approximations or even optimal transport plans at each scale. These refinement strategies are essentially batch column generation methods (Desaulniers et al., 2002), that take advantage of the multiscale structure.

3.4.1 Potential Refinement

This refinement strategy exploits the potential functions, or dual solution, to determine additional paths to include given the currently optimal solution on the reduced set of paths from the propagation. The dual formulation of the optimal transport can be written as:

$$\max_{\phi,\psi} \sum_{i=1,..,n} \mu(\{x_i\})\phi(x_i) - \sum_{j=1,..,m} \nu(\{y_j\})\psi(y_j) \quad \text{s.t.} \quad \phi(x_i) - \psi(y_j) \leq \mathsf{c}(x_i, y_j)\,. \tag{14}$$

The functions ϕ and ψ are called dual variables or potential functions. From the dual formulation it follows that at an optimal solution the *reduced cost* $\mathsf{c}(x,y) - \phi(x) + \psi(y)$ is larger or equal to zero. This also follows from the Kantorovich duality of optimal transport (Villani, 2009, Chapter 5).

The potential refinement strategy uses the potential functions ϕ and ψ from the solution of the reduced problem to determine which additional paths to include. If the solution on the reduced problem is not optimal on all paths, then there exist paths with negative reduced cost. Thus, we check the reduced cost between all paths and include the ones negative reduced cost. A direct implementation of this strategy would require to check all possible paths between the source and target points. To avoid checking all pairwise paths between source and target point sets at the current scale, we introduce a branch and bound procedure on the multiscale structure that efficiently determines all paths with negative reduced cost.

Let $\phi^*_j|_{\mathbf{P}}$ and $\psi^*_j|_{\mathbf{P}}$ the dual variables, i.e., the potential functions, at the optimal solution $\pi^*_j|_{\mathbf{P}}$ on the set of paths $\mathbf{P}$ for the source and target points, respectively. Define $\mathbf{V}_j(\pi^*_j|_{\mathbf{P}})$ as the set of paths with non-positive reduced cost with respect to $\phi^*_j|_{\mathbf{P}}$ and $\psi^*_j|_{\mathbf{P}}$

$$\mathbf{V}_j(\pi^*_j|_{\mathbf{P}}) = \left\{\pi_j(x_k, y_{k'}) \in \mathbf{A}_j : \mathsf{c}(x_k, y_{k'}) - \phi^*_j|_{\mathbf{P}}(x_k) - \psi^*_j|_{\mathbf{P}}(y_{k'}) \leq 0\right\}\,.$$

The *potential* refinement strategy now refines the propagated solution $\pi^*_j|_{\mathbf{R}_j}$ by including all negative reduced cost paths $\mathbf{Q}^0_j = \mathbf{V}_j(\pi^*_j|_{\mathbf{R}_j})$. Let $\pi^*_j|_{\mathbf{Q}^0_j}$ be the associated optimal transport. This new solution changes the potential functions which in turn may require to include additional paths. Thus the potential refinement strategy can be iterated with $\mathbf{Q}^i_j = \mathbf{V}_j(\pi^*_j|_{\mathbf{Q}^{i-1}_j})$ leading to monotonically decreasing optimal transport plans $\pi^*_j|_{Q^i_j}$. Since a solution is optimal if and only if all reduced cost are ≥ 0 this iterative strategy converges to the optimal solution.

The set of paths with negative reduced cost given $\phi^*_j|_{\mathbf{P}}$ and $\psi^*_j|_{\mathbf{P}}$ are determined by descending the tree and excluding nodes that can not contain any negative reduced cost paths. This requires bounds on the potential functions for any node at scale smaller than j. The bound is achieved by storing at each target node of the multiscale decomposition the maximal $\psi^*_j|_{\mathbf{P}}$ of any of its descendants at scale j. Now for each source node x_k the target multiscale decomposition is descended, but only towards nodes at which a potential negative reduced cost can exist.

Depending on the properties of $\phi^*_j|_{\mathbf{P}}$ and $\psi^*_j|_{\mathbf{P}}$, this refinement strategy may reduce the number of required cost function evaluations drastically. In empirical experiments the total number of paths considered in the iterative potential refinement was typically reduced to $O(2^d(K_j^{\mathbf{X}} + K_i^{\mathbf{X}}))$, with d being the doubling dimension of the data set.

The potential refinement strategy is also employed by Glimm and Henscheid (2013) without the branch and bound procedure. The shielding neighborhoods proposed by Schmitzer (2015) similarly uses the potentials to define which variables are needed to define a sparse optimal transport problem and also suggests to iterate the neighborhood shields in order to arrive at an optimal solution.

3.4.2 Neighborhood Refinement

This section presents a refinement strategy that takes advantage of the geometry of the data. The approach is based on the heuristic that most paths at the next scale are suboptimal due to boundary effects when moving from one scale to the next, induced by the sharp partitioning of the space at scale j. Such artifacts from the multiscale structure are mitigated by including paths between spatial neighbors in the source and target locations of the optimal solution on the propagated paths. This refinement strategy is also employed by Oberman and Ruan (2015).

Let $\mathbf{N}_j(\pi_j, r)$ be the set of paths such that the source and target of any path are within radius r of the source and target of a path with non-zero mass transfer in π_j. The neighborhood refinement strategy is to expand the reduced set of paths using the union of paths in the current reduced set and its neighbors:

$$\mathbf{E}_j = \mathbf{R}_j \cup \mathbf{N}_j\left(\pi_j^*|_{\mathbf{R}_j}, r\right)$$

When moving from one scale to the next the cost of any path can change at most two times the radius r of the parent node which suggests to set the radius of the neighborhood in consideration as two times the node radius.

This heuristics does not guarantee an optimal solution, but does reduce the number of paths to consider at scale j to $O(q_r^2(K_j^{\mathbf{X}} + K_j^{\mathbf{Y}}))$ with q_r being the number of neighbors within radius $2^{-j}r$, for a doubling space with dimension d, $q_r \asymp r^d$.

The neighborhood strategy requires to efficiently compute the set of points within a ball of a given radius and location. Depending on the multiscale structure there are different ways to compute the set of neighbors. A generic approach that does not depend on any specific multiscale structure is to use a branch and bound strategy. For this approach, each node requires an upper bound $u(c_i)$ on the maximal distance from the representative of node c_i to any of its descendants. Using these upper bounds the tree is searched, starting from the root node, while excluding any child nodes for which $\mathtt{c}(x, c_i) - u(c_i) > r$ from further consideration. For multiscale structures such as regular grids more efficient direct computations are possible. For this paper we implemented the generic branch and bound strategy that works with any multiscale structure.

3.5 Remark on Errors

The error induced by this multiscale framework stems from two sources. First, if $J_0 < J$, i.e., the optimal transport problem is only solved up to scale J_0, the solution at scale J_0 has a bounded approximation error, as detailed in Section 3.2. By solving the transport problem only up to a certain scale permits to trade-off computation time versus precision with guaranteed approximation bounds. However, to speed up computation we rely on heuristics that, depending on the refinement strategy, yield solutions at each scale that might not be optimal. This second type error is difficult to quantify; however, for the potential refinement strategy that we introduce Section 3.4.1, an optimal solution can be guaranteed. The propagation and refinement strategies introduced in Sections 3.3 and 3.4 permit trade-offs between accuracy and computational cost.

4. Numerical Results and Comparisons

We tested the performance of the proposed multiscale transport framework with respect to computational speed as well as accuracy for different propagation and refinement strategies on various source and target point sets with different properties.

The multiscale approach is implemented in C++ with an R front end in the package *mop*[1]. For comparisons, we also implemented the Sinkhorn distance approach (Cuturi, 2013) in C++ with an R front end in the package *sinkhorn*[1]. Our C++ implementation uses the Eigen linear algebra library (Guennebaud et al., 2010), which resulted in faster runtimes than the MATLAB implementation by Cuturi (2013).

4.1 Implementation Details

The R package *mop* provides a flexible implementation of the multiscale framework and is adaptable to any multiscale decomposition that can be represented by a tree. The package permits to use different optimization algorithms to solve the individual transport problem. Currently the multiscale framework implementation supports the open source library GLPK (Makhorin, 2013) and the commercial packages MOSEK (Andersen and Andersen, 2013) and CPLEX (IBM, 2013) (both free for academic use). MOSEK and CPLEX support a specialized network simplex implementation that runs 10-100 times faster than a typical primal simplex implementation. Both the MOSEK and CPLEX network simplex run at comparable times, with CPLEX slightly faster in our experiments. Furthermore CPLEX supports starting from an advanced initial basis for the network simplex algorithm which improves the multiscale run-times significantly. Thus, the numerical test are all run using the CPLEX network simplex algorithm.

4.1.1 Algorithms for Constructing Multiscale Point Set Representations

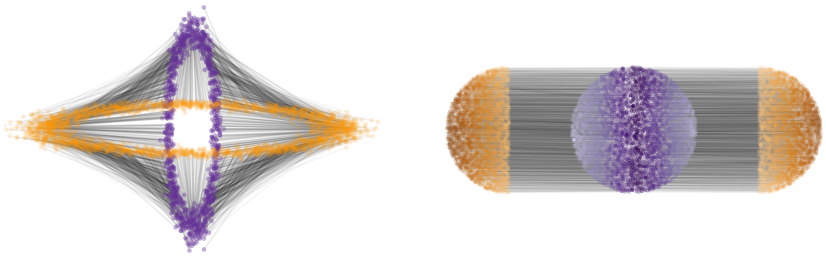
Various approaches exist to build the multiscale structures described in Section 3.1, such as hierarchical clustering type algorithms (Ward Jr, 1963), or in low dimensions constructions such as quad and oct-trees (Finkel and Bentley, 1974; Jackins and Tanimoto, 1980) or kd-trees (Bentley, 1975) are feasible. Data structures developed for fast nearest neighbor queries, such as navigating nets (Krauthgamer and Lee, 2004) and cover trees (Beygelzimer et al., 2006) induce a hierarchical structure on the data sets with guarantees on partition size and geometric regularity of the elements of the partition at each scale, under rather general assumptions on the distribution of the points. The complexity of cover trees (Beygelzimer et al., 2006) is $O(C^d Dn \log n)$, for some constant C, where $n = |\mathbf{X}|$, d is the doubling dimension of $\mathbf{X}$, and D is the cost of computing a distance between a pair of points. Therefore the algorithm is practical only when the intrinsic dimension is small, in which case they are provably adaptive to such intrinsic dimension. The optimal transport approach

1. available on `https://bitbucket.org/suppechasper/optimaltransport`

does not rest on a specific multiscale structure and can be adapted to application-dependent considerations. However, the properties of the multiscale structure, i.e., depth and partition sizes, do affect run-time and approximation bounds.

In our experiments we use an iterative K-means strategy to recursively split the data into subsets. The tree is initialized using the mean of the complete data set as the root node. Then K-means is run resulting in K children. This procedure is recursively applied for each leaf node, in a breadth first fashion, until a desired number of of leaf nodes, a maximal leaf radius or the leaf node contains only a single point. For the examples shown we select $K = 2^d$ with d the dimensionality of the data set. For high-dimensional data K could be set to an estimate of the intrinsic dimensionality. Since in all experiments we are equipped with a metric structure we use the pointwise coarsening of the cost function as in Equation (7). The reported results include the computation time for building the hierarchical decomposition, which is, however, negligible compared to solving the transport problem at all scales.

4.1.2 Multiscale Transport Implementation for Point Sets



Algorithm 2 details the steps for computing multiscale optimal transport plans using the newtork simplex for solving the optimization problems at each scale and iterated K–means to construct the multiscale structures.

Algorithm 2: Point Set based Multiscale Optimal Transport Implementation

Input: Source point set $\mathbf{X} = \{x\}_{i=0}^{N}$.
Target point set $\mathbf{Y} = \{y\}_{i=0}^{M}$.
A propagation strategy p.
A refinement strategy r.
Output: Multiscale family of transport plans $(\pi_j : \mathbf{X}_j \rightarrowtail \mathbf{Y}_j)_{j=0}^{J}$
Construct multiscale point sets $\{\mathbf{X}_j\}_{j=0}^{N}$ and $\{\mathbf{Y}_j\}_{j=0}^{M}$ using iterated K–means.
if $N < M$ **then**
  Add scales $\{\mathbf{X}_j\}_{j=N+1}^{J}$ by repeating the last scale.
if $N > M$ **then**
  Add scales $\{\mathbf{Y}_j\}_{j=M+1}^{J}$ by repeating the last scale.
Set $J = \max(N, M)$
Form the measures μ_j and ν_j as in equation (6).
Compute optimal transport π_0 at coarsest scale with the network simplex.
for $j = 1 \dots J$ **do**
  Propagate the π_{j-1} from scale $j-1$ to scale j using the propagation strategy p, obtaining a set of paths $\mathbf{S}_j = p(\pi_{j-1}$ at scale j
  Use the network simplex algorithm to solve for optimal transport on the set of paths $\mathbf{S}_j$ yielding a coupling $\tilde{\pi}_j$
  Create the refined set of paths $\mathbf{R}_j = r(\tilde{\pi}_j)$ using the refinement strategy r.
  Use the network simplex algorithm to solve for optimal transport on the set of paths $\mathbf{R}_j$ yielding the optimal coupling π_j on the paths $\mathbf{R}_j$.

4.2 Propagation and Refinement Strategy Performance

Figure 5 illustrates the behaviour of the different propagation and refinement strategies on two examples: The ellipses example in Figure 1 and Caffarelli's smoothness counter example described in Villani (2009, Chapter 12) and illustrated in Figure 4. The ellipse example consists of two uniform samples (source and target data set) of size n from the unit circle with normal distributed noise added with zero mean and standard deviation 0.1. The source data sample is then scaled in the x-Axis by 1.3 and in the y-Axis by 0.9, while the target data set is scaled in the x-Axis by 0.9 and in the y-Axis by 1.1. Caffarelli's example consists of two uniform samples on $[-1, 1]^2$ of size n. Any points outside the unit circle are then discarded. Additionally, the target data sample is split along the x-Axis at 0 and shifted by $+2$ and -2 for points with positive and negative x-Axis values, respectively. We tested 7

(a) (b)

Figure 4: Optimal transport plans on the (a) ellipse and (b) Caffarelli data sets with 5000 points for the source and target point set each. The optimal transport plans are indicated by black lines with transparency indicating the amount of mass being transported from source to target.

different strategies of different combinations of propagation strategies from Section 3.3 with refinement strategies from Section 3.4:

1. (ICP) Iterated capacity propagation (Section 3.3.2) with 0 to 5 iterations with no refinements. Note iterated capacity with 0 iterations is equivalent to simple propagation (Section 3.3.1).
2. (NR) Simple propagation (Section 3.3.1) with neighborhood refinement (Section 3.4.2) with radius factor ranging from 0.5 to 2.5 in 0.5 increments.
3. (ICP + NR) Iterated capacity propagation with 1 to 5 iterations combined with neighborhood refinement with radius factor fixed to 1.
4. (CP + NR) A single iteration of capacity propagation combined with neighborhood refinement with radius factor from 0.5 to 2.5 with 0.5 increments.
5. (IPR) Simple propagation with iterated potential refinement (Section 3.4.1) with 1 to 5 iterations.
6. (ICP + PR) Iterated capacity propagation with 1 to 5 iterations combined with a single potential refinement step.
7. (CP + IPR) A single iteration of capacity propagation combined with 1 to 5 iterations of potential refinement.

Figure 5 shows that almost all strategies have less than one percent relative error. The exception is the simple propagation with no refinements applied (i.e. iterated capacity propagation with no iterations). The randomness of the iterated capacity constrained algorithm can results in worse results despite a larger number of iterations. However, it will always perform better than using the simple propagation strategy. The neighborhood refinement strategy improves the results significantly, but after a radius factor of one the improvements start to level out. The potential refinement strategy finds the optimal solution when iterated a few times. Combining the refinement strategy with capacity propagation reduces relative error and computation time. The computation time is reduced because the capacity propagation yields a closer initialization to the optimal solution. The combination of potential refinement strategy and capacity propagation has the additional benefit that the branch and bound strategy is more efficient since fewer comparisons need to be made when checking for paths and smaller linear programs have to be solved in each refinement step.

For very small relative error ($< 10^{-11}$) the optimal solution is sometimes not achieved.

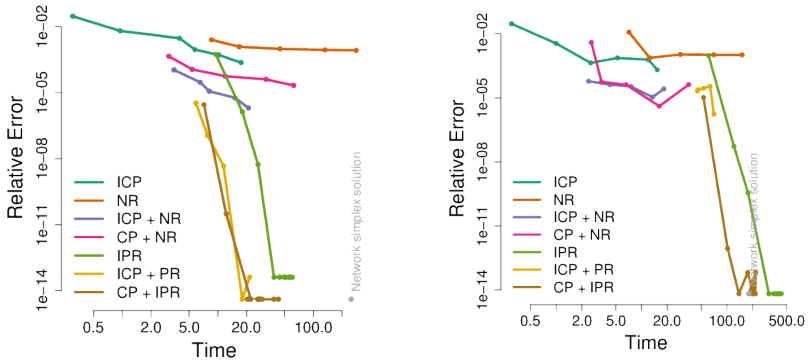


Figure 5: A comparison of different multiscale propagation and refinement strategies on the (a) ellipse and (b) Caffarelli data sets with 5000 points for the source and target point set each. For a description of the different strategies see text, the lines in the relative error graphs indicate increasing number of iterations or radius factor for the different strategies. Both the time and accuracy axes are in logarithmic scale. All strategies, except capacity propagation with 0 iterations (ICP) and neighborhood refinement (NR) with radius factor 0.5, find solution with relative error less than one percent. The capacity propagation strategies can find optimal solutions up to numerical precision.

This is due to tolerance settings in the network simplex algorithm which are on the order of 10^{-11}. Thus, depending how the network simplex approaches the optimum it might stop at different basic feasible solutions.

Figure 5 shows that the computation time and relative error for problem of equal sizes depends on the type of problem. An important aspect of the problem type is the ratio of

the transport distance to the diameters of the source and target point sets. To illustrate this effect we computed optimal transport plans for two data sets with source and target distributions uniform on $[0,1]^2$. In the first case the distributions are perfectly overlapping and in the second case the target distributions shifted by 2 units in the x direction. Figure 6 shows that for large ratios the relative error is typically much smaller. This is expected since variations in the transport plan only change the cost marginally. For small ratios, i.e. source and target distributions that are almost identical, a small variation in the transport plan leads to a large relative error. Another observation is the following: the potential strategy

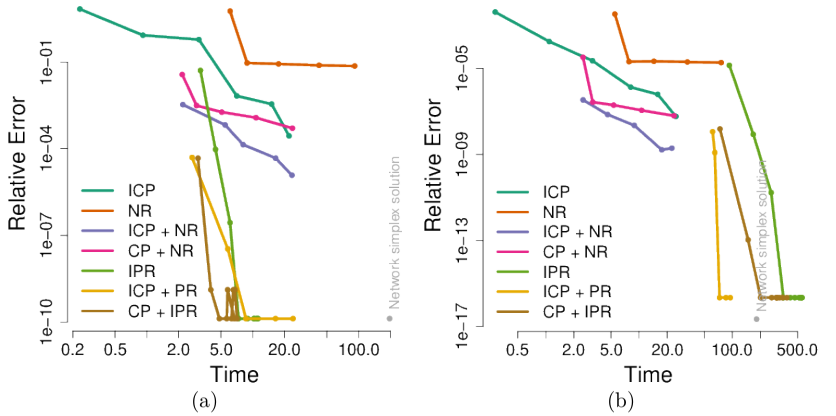

Figure 6: The effect of distance to support size ratio on computation time and relative error for the different multiscale propagation and refinement strategies source and target point sets of 5000 points each sampled uniformly from a square of side length one and ground truth transport distance (a) 0 and (b) 2. Both the time and accuracy axes are in logarithmic scale.

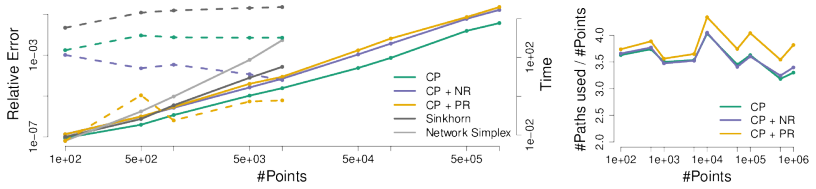


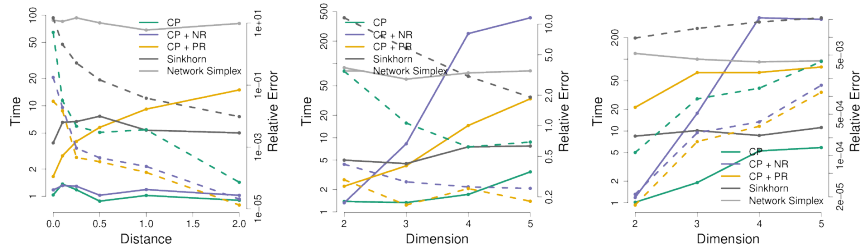
is less effective for transport problems where most mass is transported very far, relative to the distances within source and target point set. This is because a small change in the length of a path can include many possible source and target locations and the transport polytope has many suboptimal solutions with similar cost. If on the other hand most mass is transported on the order of the nearest neighbor distances within the source and target point set, there are many fewer possible paths within a small change in path length and the transport polytope is "steep" in the direction of the cost function.

4.3 Comparison to Network Simplex and Sinkhorn Transport

In this section we compare the CPLEX network simplex algorithm (IBM, 2013) and the Sinkhorn approach (Cuturi, 2013) to three different multiscale strategies:

1. (CP) Capacity propagation strategy using a single iteration with no further refinements.

2. (CP + NR) Capacity propagation combined with neighborhood refinement with radius factor fixed to one and a single capacity constraint iteration.
3. (CP + PR) Capacity propagation combined with potential refinement with a single iteration each.



(a) (b)

Figure 7: (a) A comparison of computation time (solid) and relative error (dashed) with respect to the network simplex solution for the CPLEX network simplex, Sinkhorn distance and the proposed multiscale strategy with increasing number of points. (b) The number of total paths considered is roughly constant with four times the number of points in the problem, i.e., the multiscale approach results in only a linear increase in problem size instead of quadratic for a direct approach. The number of points on the x-axis denotes the number of source points $|\mathbf{X}|$ which is approximately equal to the number of target points $|\mathbf{Y}|$. The Sinkhorn approach is competitive in computation time for smaller problems. For larger problems only the multiscale strategies outperform the Sinkhorn approach quickly, and are the only algorithms that remain viable.

Figure 7 shows computation time, relative error and problem size for increasing sample size on the ellipse data set. The Sinkhorn transport employs a regularization term and is thus not expected to converge to the actual transport distance. The comparison of the relative error provides an indication of how far the regularization strays from the true transport distance. For small size problems the Sinkhorn transport is as comparable in speed to the multiscale approach.. The multiscale approach outperforms both competitors for moderate data sizes of a few thousand source and target points. The multiscale approach scales roughly linear in the problem size while both the Sinkhorn and network simplex scale approximately quadratically. The capacity propagation without refinement runs an order of magnitude faster than including refinements and results in relative errors less than one percent for more than a few hundred points. The network simplex and Sinkhorn approach run out of memory on a 16GB computer for problems larger than around $2 \cdot 10^4$ constraints and about 10^8 variables. The proposed multiscale framework results in a linear increase in problem size for the propagation and refinement strategies tested and, on the same 16GB computer, can solve instances with $2 \cdot 10^6$ constraints (source and target points) in a few hours, which would result in about 10^{12} variables (paths) for the full optimal transport problem. The computation times are comparable to the results reported by Oberman and Ruan (2015); Schmitzer (2015) on examples on regular grids that result in similar sized problems.

The relative error and computation time depend again on the type of problem. Figure 8(a) shows computation time and relative error on transport problems on source and target data sets sampled uniformly from $[0,1]^2$ with different shifts in the target distribution. If required, the relative error can be reduced using multiple capacity propagation and potential refinement iterations as illustrated in Figure 6. In these experiments we set the tolerance parameter for Sinkhorn to $1e^{-5}$, and tried also $1e^{-2}$ to see if this would result in significant speed ups, with minimal accuracy loss, but it resulted in only approximately a 10% speedup, and no fundamental change in the behavior for large problem sizes. The tolerance parameter for CPLEX is set to $1e^{-8}$. The approach by Schmitzer (2015) is similar to the refinement property strategy, we expect that computation time grows similarly as for the potential strategy for problems with large transport distances compared to the source and target support size.

The final experiment tests the performance with respect to the dimensionality of the source and target distributions. We used two uniform distributions $[0,1]^d$ with d varying from 2 to 5 and the target shifted such that the actual transport distance is 0 and 2.

(a) (b) (c)

Figure 8: Computation time (solid) and relative error (dashed) with respect to (a) changes transport distance to support size ratio in two dimensions and (b,c) dimensionality with ground truth transport distance (b) 0 and (c) 2. The source and target distributions are uniform on a square of side length 1 with approximately 5000 points each. The potential refinement increases proportional to the transport distance to support ratio. The neighborhood strategy is less effective in higher dimensions, due to the curse of dimensionality, but performs better than the Sinkhorn approach. The capacity propagation strategy is less affected by the dimensionality of the problem.

5. Application to Brain MR Images

An important building block for the analysis of brain MRI populations is the definition of a metric that measures how different two brain MRI are. A mathematically well motivated and popular approach for distance computations between brain images is based on large deformation diffeomorphic metric mappings (LDDMM (Miller et al., 2002)). Here we explore optimal transport distance as an alternative metric for comparing brain images.

To solve for the optimal transport map between two 3D brain images we extract for each image a point cloud from the intensity volumes. Each point represents a voxel as a point in 3-dimensional space, the location of the voxel. The mass of the point is equal to the intensity value of the voxel, normalized to sum to one over all points. For illustration, Figure 9 shows a single slice extracted from the original volumes and optimal transport maps between the two slices. This 2D problem resulted in point set of approximately $20,000$ points.

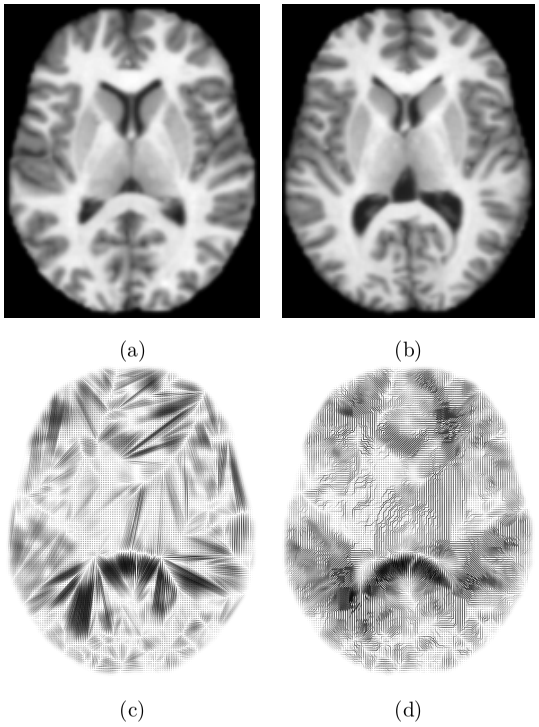


Figure 9: Slice of (a) source and (b) target brain image and optimal transport map for (c) Euclidean and (d) squared Euclidean cost function. For the squared Euclidean cost the optimal transport solutions typically prefer to move many locations small distances, i.e. shift mass among nearest neighbors. For images the neighborhoods are on regular grids resulting in a staircase appearance of the transport plan.

To compare the optimal transport distance to the LDDMM distance we compare how well the distances can be used to predict clinical parameters. Using the pairwise distances, we employ classical multidimensional scaling (MDS) to embed the pairwise distances into

Table 1: Optimal linear regression models from the OASIS data set, for age, mini mental state examination (MMSE) and clinical dementia rating (CDR). The PCA coordinates from the Euclidean distances are denoted with l_i, the diffeomorphic manifold coordinates with x_i, the transport coordinates by z_i and the multiscale transport coordinates with z_i^j from coarsest $j = 1$ to finest $j = 6$ scale. An entry with "$< \epsilon$" denotes quantities smaller than machine precision. The best results are indicated in bold.

Euclidean space. In this embedding each point corresponds to a 3D brain image and thus provides a coordinate system for the relative locations between the brain MRI's. The Euclidean structure of the embedding permits to use standard statistical tools to form prediction models, in our case linear regression.

Within this framework we compare Euclidean, LDDMM and optimal transport distances as the input to the multidimensional scaling step. Note, for the Euclidean distance, i.e. treating each brain MRI as a point in Euclidean space, classical multidimensional scaling is equivalent to a principal component analysis. For the comparisons we used the OASIS brain database (HHMI et al.). The OASIS database consists of T1 weighted MRI of 416 subjects aged 18 to 96. One hundred of the subjects over the age of 60 are diagnosed with mild to moderate dementia. The images in the OASIS data set are already skull-stripped, gain-field corrected and registered to the atlas space of Talairach and Tournoux (1988) with a 12-parameter affine transform. Associated with the data are several clinical parameters. For the linear regression from the MDS embeddings we restrict our attention to the prediction of age, mini mental state examination (MMSE) and clinical dementia rating (CDR).

The MDS computation requires pairwise distances. To speed up computations we reduce the number of points by downsampling the volumes to size $44 \times 52 \times 44$. This results, discarding zero intensity voxels, in point clouds of approximately $40,000$ points for each brain MRI. A single distance computation with capacity propagation takes on the order of 10 seconds resulting in a total computation time of around 2 weeks for all pairwise distances. For embedding the optimal transport distance we consider two approaches:

1. A five dimensional MDS embedding based on the transport cost at the finest scale.

2. A multiscale embedding using multiple five dimensional MDS embeddings, one for the transport cost at each scale.

From the embeddings we build linear regression models, using the embedding coordinates as independent variables and the clinical variables as dependent variables. As in Gerber et al. (2010) we use the Bayesian information criterion (BIC) on all regression subsets to extract a models that trade-off complexity, i.e. number of independent variables, with the quality of fit. Table 1 shows the results of the optimal transport, with squared Euclidean cost, distances compared to the results reported in Gerber et al. (2010). The transport based approach shows some interesting behaviours. The single scale model performs worse on age while performing similar on MMSE and CDR. The multiscale transport models perform similar to the LDDMM approach except for MMSE where it almost doubles the explained variance R^2. This suggests that the multiscale approach captures information about MMSE not contained in a single scale and prompts further research of multiscale based models to predict clinical parameters.

6. Conclusion

The multiscale framework extends the size of transport problems that can be solved by linear programming by one to two orders of magnitude in the size of the point sets.

The framework is flexible, the linear program at each scale can be solved by any method. Depending on the refinement strategy a dual solution would need to be constructed as well. The method can also be applied to solve the linear assignment problem. The solution at the finest scale will be binary if $n = m$, however, at intermediate steps a binary solution is not guaranteed unless at each scale the source and target sets have the same number of points. This could be enforced during the construction of the multiscale structures. As currently defined the method requires point set inputs for the multiscale constructing of the transport problems. However, one could design methods that construct such a multiscale structure from a cost matrix only. However, for large problems pairwise computations of all costs is typically prohibitively expensive.

The multiscale transport framework provides several options for further research. The framework can be combined with various regularizations, e.g. depending on scale and location and induces a natural multiscale decomposition of the transport map. This decomposition can be used to extract information about relevant scales in a wide variety of application domains. We are currently investigating the use of such multiscale decompositions for representation and analysis of sets of brain MRI.

The capacity constraint propagation approach suggests a different venue for further exploration. The capacity propagation strategy does not hinge on a geometrical notion of neighborhoods and is a suitable candidate to extend the multiscale framework to non-geometric problems. Studying the interdependency between the cost function, hierarchical decomposition of the transport problem (or possibly more generic linear programs) and the efficiency of the capacity constraint propagation is a challenging but interesting problem.

Abstract

Learning complex control policies from non-linear and redundant sensory input is an important challenge for reinforcement learning algorithms. Non-parametric methods that approximate values functions or transition models can address this problem, by adapting to the complexity of the data set. Yet, many current non-parametric approaches rely on unstable greedy maximization of approximate value functions, which might lead to poor convergence or oscillations in the policy update. A more robust policy update can be obtained by limiting the information loss between successive state-action distributions. In this paper, we develop a policy search algorithm with policy updates that are both robust and non-parametric. Our method can learn non-parametric control policies for infinite horizon continuous Markov decision processes with non-linear and redundant sensory representations. We investigate how we can use approximations of the kernel function to reduce the time requirements of the demanding non-parametric computations. In our experiments, we show the strong performance of the proposed method, and how it can be approximated efficiently. Finally, we show that our algorithm can learn a real-robot under-powered swing-up task directly from image data.

Keywords: Reinforcement Learning, Kernel Methods, Policy Search, Robotics

1. Introduction

Learning continuous valued control policies directly from sensory input presents a major obstacle to applying reinforcement learning (RL) methods effectively in realistic settings. In such settings, there exist two major problems. First, the dimensionality of sensory inputs often makes discretization of the state space infeasible. Secondly, in such settings, the amount of data that can be used to learn policies is often severely limited, increasing the bias in policy updates which can lead to oscillations or divergence (Mannor et al., 2007; Peters et al., 2008).

For the first problem, algorithms have been developed that rely on human-designed features for value function approximations or specialized parametric policies (Kaelbling et al., 1996; Kober et al., 2013; Bartlett, 2003). However, the applicability of such methods is limited in non-linear, redundant sensory domains where defining good features to linearly approximate value functions or policies is non-trivial. Alternative methods use deep neural networks to represent value functions or policies non-linearly (Mnih et al., 2015; Schulman et al., 2015; Lillicrap et al., 2016; Mnih et al., 2016). These representations have many parameters, and thus tend to require sampling many data points.

Recently, there has been a lot of progress towards avoiding the dependence on engineered features by using non-parametric techniques. Such techniques often use kernel functions to implicitly define a (possibly infinite) features space, replacing the manual definition of features. In contrast to task-specific hand-tuned feature spaces, many popular kernels are applicable to a large number of problems as the resulting representation can adapt to the complexity of the data. Non-parametric techniques have successfully been used in value-function methods, for example by Grünewälder et al. (2012b), Nishiyama et al. (2012), and Kroemer and Peters (2011). An overview of related work on non-parametric methods is given in Section 4.3 on page 32. Such methods generally require the inversion of matrices that grow with the number of data points, which limits their applicability. Another shortcoming is that these methods are still susceptible to the problem of data scarcity.

The problem of data scarcity is aggravated by the lack of a notion of the sampled data or sampling policy in many reinforcement learning approaches. At any point in the learning process, knowledge about the learning problem tends to be represented in two ways. First, the outcomes of recently sampled state-action pairs are stored in memory. Secondly, the current sampling policy implicitly represents the state-action pairs sampled longer ago (as well as the initial policy). Any policy update that causes the policy to represent new samples better might cause the policy to represent older samples less well, thus losing information. Many methods update policies or value functions without regard to the sampling policy. Since the recently sampled state-action pairs stored in, e.g., a mini-batch or replay memory are usually not sufficient to completely characterize the learning problem, such updates can result in a critical loss of essential information.

As a result, choosing an improved policy purely based on sampled returns often yields fast but premature convergence to a sub-optimal policy. Such updates favor biased solutions that eliminate states in which, by chance, only bad actions have been tried out. This problem is known as *optimization bias* (Mannor et al., 2007). Optimization biases may appear in both on- and off-policy reinforcement learning methods due to under-sampling (e.g., if we cannot sample sufficiently many of the state-action pairs prescribed by a policy, we will over-fit), model errors or even the policy update step itself.

In an on-line setting, many methods address this problem implicitly by staying close to the previous policy. For example, policy gradient methods allow only small incremental policy changes. The Fisher information metric—that occurs in policy updates using the natural policy gradients (Kakade, 2002; Peters and Schaal, 2008)—can be seen as a Taylor expansion of the loss of information or *relative entropy* between the path distributions generated by the original and the updated policy (Bagnell and Schneider, 2003a). Instead of bounding this Taylor approximation, we can explicitly bound the relative entropy between successive state-action distributions, leading to our Relative Entropy Policy Search (REPS) algorithm.[1] We discuss related policy search methods that limit the information loss in Section 4.1 on page 29.

In this paper, we propose a method based on this insight, that allows us to compute new policies given a data distribution for both off-policy and on-policy reinforcement learning. We start from the optimal control problem statement subject to the constraint that the loss of information is bounded. For continuous domains, where a suitable set of features is often not available, we develop a non-parametric version of this algorithm. This algorithm uses general kernels to define (possibly infinite) feature spaces implicitly, and considers ways to efficiently approximate this method to make it applicable to large data sets.

In our experiments, we show that our method outperforms other non-parametric methods on a reaching task and an under-powered swing-up task. We also show that our method performs well compared to neural-network based methods on a variant of the puddle world task with a 400-dimensional redundant input representation. Furthermore, we evaluate different approximations to process larger data sets efficiently. Finally, we show that using such an approximation, a real-robot pendulum swing-up task can be learned from vision data.

1.1 Problem Statement and Notation

In a Markov decision process (MDP), an agent in state $\mathbf{s}$ selects an action $\mathbf{a} \sim \pi(\mathbf{a}|\mathbf{s})$ according to a (possibly stochastic) policy π and receives a reward $\mathcal{R}_\mathbf{s}^\mathbf{a} \in \mathbb{R}$. We will assume continuous state-action spaces: $\mathbf{s} \in \mathcal{S} = \mathbb{R}^{D_\mathrm{s}}$, $\mathbf{a} \in \mathcal{A} = \mathbb{R}^{D_\mathrm{a}}$. If the Markov decision process is ergodic, for each policy π, there exists a stationary distribution $\mu_\pi(\mathbf{s})$ such that $\int_\mathcal{S}\int_\mathcal{A} \mathcal{P}_{\mathbf{ss}'}^\mathbf{a}\pi(\mathbf{a}|\mathbf{s})\mu_\pi(s)\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} = \mu_\pi(\mathbf{s}')$, where $\mathcal{P}_{\mathbf{ss}'}^\mathbf{a} = p(\mathbf{s}'|\mathbf{a},\mathbf{s})$. The goal of a reinforcement learning agent is to choose a policy such that the joint state-action distribution $p_\pi(\mathbf{s},\mathbf{a}) = \mu_\pi(\mathbf{s})\pi(\mathbf{a}|\mathbf{s})$ maximizes the average reward $J(\pi) = \int_\mathcal{S}\int_\mathcal{A} \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})\mathcal{R}_\mathbf{s}^\mathbf{a}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s}$.

The goal of relative entropy policy search is to obtain policies that maximize the expected reward $J(\pi)$ while bounding the information loss with respect to reference distribution $q(\mathbf{s},\mathbf{a})$, i.e.,

$$\max_{\pi,\mu_\pi} \quad \iint_{\mathcal{S}\times\mathcal{A}} \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})\mathcal{R}_\mathbf{s}^\mathbf{a}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s}, \tag{1}$$

$$\text{s. t.} \quad \iint_{\mathcal{S}\times\mathcal{A}} \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} \quad = 1, \tag{2}$$

$$\forall s' \quad \iint_{\mathcal{S}\times\mathcal{A}} \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})\mathcal{P}_{\mathbf{ss}'}^\mathbf{a}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} = \mu_\pi(\mathbf{s}'), \tag{3}$$

$$\mathrm{KL}(\pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})||q(\mathbf{s},\mathbf{a})) \ \leq \epsilon, \tag{4}$$

where Eqs. (1)–(3) specify the general reinforcement learning objective (Eq. 1) with the constraints that $\pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})$ is a distribution (Eq. 2) and μ_π is the stationary distribution under policy π (Eq. 3). Equation (4) specifies the additional bound on the KL divergence, where

$$\mathrm{KL}(p(x)||q(x)) = \int p(x)\log(p(x)/q(x))\mathrm{d}x.$$

The reference distribution q is usually set to the state-action distribution induced by previous policies, where the initial explorative policy is a wide, uninformed distribution such as a zero-centered Gaussian with a larger variance. In each iteration, the policy is adapted

to maximize the expected reward while respecting the constraint on the KL divergence. Thus, as learning progresses, the policy typically slowly converges towards a deterministic reward-maximizing policy.

In this paper, we aim at developing a reinforcement learning algorithm for continuous state-action MDPs with non-linear and redundant state representations. We assume the transition and reward models of the MDP are unknown. Furthermore, we will concentrate on infinite-horizon problems.

2. Stable Policy Updates for Stochastic Continuous MDPs

The relative entropy policy search optimization problem in Eqs. (1)–(4) defines controller updates that maximize the expected average reward under a bound on the information loss. However, for continuous systems with stochastic dynamics and non-parametric controllers, it is not straightforward to solve the optimization problem directly. In this section, we explain the steps to obtain a practical algorithm. First, we show how to find the dual of the optimization problem. Subsequently, we discuss how this problem can be solved for stochastic systems that are continuous and non-linear. After that, we discuss how to relax the assumption of ergodicity of the MDP by transforming the average reward MDP into a discounted reward MDP. Solving the optimization problem results in a new optimal policy that is, however, only defined on the current set of samples. Therefore, we discuss how the sample-based optimal policy can be generalized to the entire state space. Finally, we discuss how to set the hyper-parameters of the different steps of our method with minimal manual tuning.

2.1 Finding the Dual Problem

To find the dual to the optimization problem in Eqs. (1)–(4), first, we formulate the Lagrangian. For every constraint, we introduce a Lagrangian multiplier. Because Eq. (3) represents a continuum of constraints, we introduce a corresponding continuous state-dependent Lagrangian multiplier $V(\mathbf{s})$. Instead of summing the contributions for each constraint in the Lagrangian, here, we have to integrate instead. Analogously to the sampling distribution $q(\mathbf{s},\mathbf{a})$, we will write $p_\pi(\mathbf{s},\mathbf{a}) = \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})$ for the proposed state-action distribution to keep the exposition brief. Therefore, the Lagrangian

$$\begin{aligned} L(p,\eta,V,\lambda) = &\iint_{\mathcal{A}\times\mathcal{S}} p_\pi(\mathbf{s},\mathbf{a})\mathcal{R}_\mathbf{s}^\mathbf{a}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} + \int_\mathcal{S} V(\mathbf{s}')\left(\iint_{\mathcal{A}\times\mathcal{S}} p_\pi(\mathbf{s},\mathbf{a})\mathcal{P}_{\mathbf{ss}'}^\mathbf{a}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} - \mu_\pi(\mathbf{s}')\right)\mathrm{d}\mathbf{s}' \\ &+ \lambda\left(1 - \iint_{\mathcal{A}\times\mathcal{S}} p_\pi(\mathbf{s},\mathbf{a})\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s}\right) + \eta\left(\epsilon - \iint_{\mathcal{A}\times\mathcal{S}} p_\pi(\mathbf{s},\mathbf{a})\log\frac{p_\pi(\mathbf{s},\mathbf{a})}{q(\mathbf{s},\mathbf{a})}\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s}\right). \end{aligned}$$

Using the identity $\mu_\pi(\mathbf{s}) = \int_A p_\pi(\mathbf{s},\mathbf{a})\mathrm{d}\mathbf{a}$, the Lagrangian can be re-shaped in the more convenient form

$$L(p,\eta,V,\lambda) = \lambda - \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[V(\mathbf{s})\right] + \eta\epsilon + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[\mathcal{R}_\mathbf{s}^\mathbf{a} - \lambda + \int_\mathcal{S} V(\mathbf{s}')\mathcal{P}_{\mathbf{ss}'}^\mathbf{a}\mathrm{d}\mathbf{s}' - \eta\log\frac{p_\pi(\mathbf{s},\mathbf{a})}{q(\mathbf{s},\mathbf{a})}\right].$$

To find the optimal p, we take the derivative of L with respect to p and set it to zero

$$\frac{\partial L}{\partial p_\pi(\mathbf{s},\mathbf{a})} = \mathcal{R}_\mathbf{s}^\mathbf{a} - \lambda + \int_\mathcal{S} V(\mathbf{s}')\mathcal{P}_{\mathbf{ss}'}^\mathbf{a} \mathrm{d}\mathbf{s}' - \eta \log \frac{p_\pi(\mathbf{s},\mathbf{a})}{q(\mathbf{s},\mathbf{a})} - \eta - V(\mathbf{s}) = 0.$$

Therefore, we obtain the new state-action distribution

$$p_\pi(\mathbf{s},\mathbf{a}) = q(\mathbf{s},\mathbf{a}) \exp\left(\frac{\mathcal{R}_\mathbf{s}^\mathbf{a} + \int_\mathcal{S} V(\mathbf{s}')\mathcal{P}_{\mathbf{ss}'}^\mathbf{a} \mathrm{d}\mathbf{s}' - V(\mathbf{s})}{\eta}\right) \exp\left(\frac{-\lambda-\eta}{\eta}\right). \tag{5}$$

The function $V(\mathbf{s})$ resembles a value function, such that $\delta(\mathbf{s},\mathbf{a},V) = \mathcal{R}_\mathbf{s}^\mathbf{a} + \int_\mathcal{S} V(\mathbf{s}')\mathcal{P}_{\mathbf{ss}'}^\mathbf{a} \mathrm{d}\mathbf{s}' - V(\mathbf{s})$ can be identified as a Bellman error. Since $p_\pi(\mathbf{s},\mathbf{a})$ is a probability distribution, we can identify $\exp(-\lambda/\eta - 1)$ to be a normalization factor

$$\exp(-\lambda/\eta - 1) = \frac{1}{\iint_{\mathcal{A}\times\mathcal{S}} q(\mathbf{s},\mathbf{a}) \exp(\delta(\mathbf{s},\mathbf{a},V)/\eta) \,\mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s}} = \frac{1}{\mathbb{E}_{q(\mathbf{s},\mathbf{a})} \exp(\delta(\mathbf{s},\mathbf{a},V)/\eta)},$$

which yields the policy

$$\pi(\mathbf{a}|\mathbf{s}) \propto q(\mathbf{s},\mathbf{a}) \exp\left(\frac{\delta(\mathbf{s},\mathbf{a},V)}{\eta}\right). \tag{6}$$

To obtain the dual function, we re-insert the state-action distribution $p_\pi(\mathbf{s},\mathbf{a})$ in the Lagrangian[2]

$$\begin{aligned} g(\eta,V,\lambda) =& \lambda + \eta\epsilon + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[\delta(\mathbf{s},\mathbf{a},V) - \lambda - \eta \log \frac{p_\pi(\mathbf{s},\mathbf{a})}{q(\mathbf{s},\mathbf{a})}\right] \\ =& \eta\epsilon + \eta \log\left(\mathbb{E}_{q(\mathbf{s},\mathbf{a})} \exp(\delta(\mathbf{s},\mathbf{a},V)/\eta)\right). \end{aligned}$$

We typically do not know the sampling distribution q, as it depends on the unknown system dynamics. However, the expected value over q can be approximated straightforwardly by taking the average of samples $1,\ldots,n$ taken from q. Note that λ and q do not appear in the final expression of the dual function

$$g(\eta,V) = \eta\epsilon + \eta \log\left(\frac{1}{n}\sum_{i=1}^n \exp(\delta(\mathbf{s}_i,\mathbf{a}_i,V)/\eta)\right). \tag{7}$$

To compute the Bellman error δ, the transition distribution is required. As this distribution is generally not known, δ needs to be approximated. The dual function (7) depends implicitly on reference distribution q through the samples.

2.2 Solving the Dual Problem

To solve Eqs. (1)–(4), we need to find the Lagrangian parameters that minimize the dual function in Eq. (7), i.e., $(\eta^*,V^*) = \arg\min g(\eta,V)$. V is a function with domain $\mathcal{S}$, hence, for continuous domains, we will surely over-fit without additional assumptions. One possibility would be to assume V a function linear in designed features, but good features are task-specific and often hard to define. We will therefore make the more general assumption that V^* is of the form

$$V^* = \sum_{\tilde{\mathbf{s}}\in\tilde{\mathcal{S}}} \alpha_{\tilde{\mathbf{s}}} k_\mathrm{s}(\tilde{\mathbf{s}},\cdot), \tag{8}$$

for some set of states $\tilde{\mathcal{S}}$ and scalars α, and a chosen reproducing kernel k_s. In other words, we assume $V^* \in \mathcal{F}$ for a reproducing kernel Hilbert space (RKHS) $\mathcal{F}$ with kernel k_s. The kernel k_s implicitly defines a (possibly infinite dimensional) feature map $\boldsymbol{\phi}(\mathbf{s}) = k_\mathrm{s}(\mathbf{s},\cdot)$ (Schölkopf et al., 1999). Such an implicit definition has the advantage that we do not need to explicitly compute a feature basis for V^* (Hofmann et al., 2008). Kernels are in most cases easier to choose than feature vectors as the complexity of V^* can grow with the amount of training data. In the final algorithm, we will only work with inner product of implicit features that can be computed using the kernel function, $\boldsymbol{\phi}(\mathbf{s})^T\boldsymbol{\phi}(\mathbf{s}') = k_\mathrm{s}(\mathbf{s},\mathbf{s}')$. Therefore, we do not need to explicitly represent the (possibly infinite dimensional) feature maps (Hofmann et al., 2008; Schölkopf et al., 1999).

2.2.1 Embedding the Transition Model.

Since the transition model $\mathcal{P}_{\mathbf{ss}'}^\mathbf{a}$ in Eq. (5) is unknown, we need to approximate $\mathbb{E}_{\mathbf{s}'}[V(\mathbf{s}')|\mathbf{s},\mathbf{a}]$. One way to do so would be to estimate the joint density $p(\mathbf{s},\mathbf{a},\mathbf{s}')$ using, e.g., kernel density estimation, and solving the integral $\int_\mathcal{S} V(\mathbf{s}')p(\mathbf{s},\mathbf{a},\mathbf{s}')d\mathbf{s}'$. However, kernel density estimation in $\mathcal{S}\times\mathcal{A}\times\mathcal{S}$ requires many training samples, and solving the integral generally requires a time-consuming numerical procedure. Instead, as suggested by Song et al. (2009), we can directly estimate a conditional operator $\mathbf{C}_{S'|S,A}$ that maps features $\boldsymbol{\psi}(\mathbf{s},\mathbf{a})$ of state-action pairs to the expected value of implicit features $\boldsymbol{\phi}(\mathbf{s}') = k_\mathrm{s}(\mathbf{s}',\cdot)$. The resulting embedding $\boldsymbol{\mu}_{\mathbf{s}'|\mathbf{s},\mathbf{a}} = \mathbb{E}_{\mathbf{s}'}[\boldsymbol{\phi}(\mathbf{s}')|\mathbf{s},\mathbf{a}]$ can subsequently be used to approximate functions in $\mathcal{F}$, such as V. Using such embeddings avoids estimating the joint density and leads to good results even for high-dimensional data, and renders calculations of expected values over a function in $\mathcal{F}$ straightforward without numerical integration (Song et al., 2013).

In order to learn the conditional operator, we will use a kernel over the state-action space to implicitly define state-action features $\boldsymbol{\psi}(\mathbf{s},\mathbf{a}) = k_\mathrm{s}(\mathbf{s},\cdot)k_\mathrm{a}(\mathbf{a},\cdot)$. Given a sample $\{(\mathbf{s}_1,\mathbf{a}_1,\mathbf{s}_1'),\ldots,(\mathbf{s}_n,\mathbf{a}_n,\mathbf{s}_n')\}$, the empirical conditional embedding is defined as

$$\hat{\boldsymbol{\mu}}_{S'|s,a} = \hat{\mathbf{C}}_{S'|S,A}\boldsymbol{\psi}(\mathbf{s},\mathbf{a}) = \boldsymbol{\Phi}\boldsymbol{\beta}(\mathbf{s},\mathbf{a}), \tag{9}$$

$$\hat{\mathbf{C}}_{S'|S,A} = \boldsymbol{\Phi}(\mathbf{K}_\mathrm{sa} + l_C\mathbf{I})^{-1}\boldsymbol{\Psi}^T, \tag{10}$$

where $\hat{\mathbf{C}}_{S'|S,A}$ is a learned conditional operator that allows the computation of embedding strengths $\boldsymbol{\beta}(\mathbf{s},\mathbf{a}) = (\mathbf{K}_\mathrm{sa} + l_C\mathbf{I})^{-1}\mathbf{k}_\mathrm{sa}(\mathbf{s},\mathbf{a})$, as suggested by Grünewälder et al. (2012a,b). In this equation, l_C is a regularization coefficient, the matrices $\boldsymbol{\Psi} = [\boldsymbol{\psi}(\mathbf{s}_1,\mathbf{a}_1),\ldots,\boldsymbol{\psi}(\mathbf{s}_n,\mathbf{a}_n)]$ and $\boldsymbol{\Phi} = [\boldsymbol{\phi}(\mathbf{s}_1'),\ldots,\boldsymbol{\phi}(\mathbf{s}_n')]$ consist of implicit feature factors, whereas matrix $\mathbf{K}_\mathrm{sa} = \boldsymbol{\Psi}^T\boldsymbol{\Psi}$ and vector $\mathbf{k}_\mathrm{sa}(\mathbf{s},\mathbf{a}) = \boldsymbol{\Psi}^T\boldsymbol{\psi}(\mathbf{s},\mathbf{a})$ contain kernel function evaluations between pairs of data points.[3] The mean embedding $\hat{\boldsymbol{\mu}}_{S'|s,a}$ can be seen as a vector-valued kernel ridge regressor that maps $\mathbf{s},\mathbf{a}$ pairs to the expected function $k_\mathrm{s}(\mathbf{s}',\cdot)$ (Grünewälder et al., 2012a).

2. A detailed derivation is given in Appendix A.

3. This means $[\mathbf{K}_\mathrm{sa}]_{ij} = k_\mathrm{s}(\mathbf{s}_i,\mathbf{s}_j)k_\mathrm{a}(\mathbf{a}_i,\mathbf{a}_j)$, $[\mathbf{k}_\mathrm{sa}(\mathbf{s},\mathbf{a})]_i = k_\mathrm{s}(\mathbf{s}_i,\mathbf{s})k_\mathrm{a}(\mathbf{a}_i,\mathbf{a})$.

2.2.2 Evaluation of V.

In the next step, we want to use the conditional embedding to evaluate V. Conditional embeddings in reproducing kernel Hilbert spaces have the property that conditional expectations of functions in $\mathcal{F}$ can be calculated as inner product in the Hilbert space (Song et al., 2009). Since $V \in \mathcal{F}$, i.e., is of the form (8), the expected value of V can be approximated using the embedded distribution (Song et al., 2009; Grünewälder et al., 2012a,b), i.e.,

$$\mathbb{E}_{\mathbf{s}'}[V(\mathbf{s}')|\mathbf{s},\mathbf{a}] = \left\langle V, \hat{\boldsymbol{\mu}}_{S'|s,a} \right\rangle_{\mathcal{F}} = \sum_{i=1}^{n} \beta_i(\mathbf{s},\mathbf{a}) V(\mathbf{s}'_i).$$

In the dual function g from Eq. (7), V is now only evaluated at sampled states $\mathbf{s}_i$ and $\mathbf{s}'_i$. As we assumed $V \in \mathcal{F}$, the generalized representer theorem (Schölkopf et al., 2001) tells us that there is at least one optimum of the form (8) with $\tilde{\mathcal{S}}$ the set of all sampled states.[4] Consequently, $\mathbb{E}_{\mathbf{s}'}[V(\mathbf{s}')|\mathbf{s},\mathbf{a}] - V(\mathbf{s}) = \boldsymbol{\alpha}^T \tilde{\mathbf{K}}_{\mathrm{s}} \boldsymbol{\beta}(\mathbf{s},\mathbf{a}) - \boldsymbol{\alpha}^T \mathbf{k}_{\mathrm{s}}(\mathbf{s})$, where $\tilde{\mathbf{K}}_{\mathrm{s}}$ is the Gram matrix with entries $[\tilde{\mathbf{K}}_{\mathrm{s}}]_{ji} = k_{\mathrm{s}}(\tilde{\mathbf{s}}_j, \mathbf{s}'_i)$, and $[\mathbf{k}_s(\mathbf{s})]_j = k_{\mathrm{s}}(\tilde{\mathbf{s}}_j, \mathbf{s})$.

2.2.3 Finding a Numerical Solution.

The dual problem can now be restated in terms of η and $\boldsymbol{\alpha}$, as

$$\min_{\eta,\boldsymbol{\alpha}} g(\eta,\boldsymbol{\alpha}) = \eta\epsilon + \eta \log\left(\sum_{i=1}^{n} \frac{1}{n} \exp\left(\frac{\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha})}{\eta}\right)\right), \quad \text{s.t. } \eta \geq 0, \tag{11}$$

$$\delta(\mathbf{s},\mathbf{a},\boldsymbol{\alpha}) = \mathcal{R}^{\mathbf{a}}_{\mathbf{s}} + \boldsymbol{\alpha}^T \left(\tilde{\mathbf{K}}_{\mathrm{s}} \boldsymbol{\beta}(\mathbf{s},\mathbf{a}) - \mathbf{k}_{\mathrm{s}}(\mathbf{s})\right). \tag{12}$$

This objective is convex, and since the analytic gradient and Hessian for this objective are straightforward to obtain[5], we employ second order optimization methods to find the optimal η and $\boldsymbol{\alpha}$. Jointly optimizing for η and $\boldsymbol{\alpha}$ is rather slow because of the need of a constrained optimization method. As proposed by Lioutikov et al. (2014), we use a coordinate-descent-like approach where, iteratively, η and $\boldsymbol{\alpha}$ are minimized separately, keeping the value of the other variable fixed. Thus, a fast unconstrained convex optimization algorithm can be used to minimize $\boldsymbol{\alpha}$, whereas a more expensive constrained minimizer can be used for η. Minimizations are run for a fixed number of updates (instead of until convergence), and every iteration is initialized at the result of the last optimization, to speed up the optimization. Iterations continue until the constraints are fulfilled within an acceptable tolerance.

If we choose kernels $\mathbf{k}_{\mathrm{s}}(\mathbf{s}_i,\mathbf{s}_j) = \tilde{\phi}(\mathbf{s}_i)^T \tilde{\phi}(\mathbf{s}_j)$ and $\mathbf{k}_{\mathrm{sa}}((\mathbf{s}_i,\mathbf{a}_i),(\mathbf{s}_j,\mathbf{a}_j)) = \mathbb{1}_{\{(\mathbf{s}_i,\mathbf{a}_i)\}}((\mathbf{s}_j,\mathbf{a}_j))$, we obtain the original REPS formulation (Peters et al., 2010) as a special case, with corresponding Bellman error

$$\delta(\mathbf{s},\mathbf{a},\boldsymbol{\alpha}) = \mathcal{R}^{\mathbf{a}}_{\mathbf{s}} + \boldsymbol{\alpha}^T(\tilde{\phi}(\mathbf{s}') - \tilde{\phi}(\mathbf{s})). \tag{13}$$

In these equations, $\mathbb{1}$ is the indicator function, $\tilde{\phi}$ is a set of hand-crafted features, and $\mathbf{s}'$ is the observed outcome of applying action $\mathbf{a}$ in state $\mathbf{s}$. Our generalization allows the selection of widely applicable kernels that do not depend on hand-crafted features. Furthermore, avoiding the identity kernel function over the state-action space allows efficient learning in stochastic systems.

4. A sketch of the proof following Schölkopf et al. (2001) is given in Appendix B.
5. The dual and its partial derivatives and Hessians are given in Appendix A, together with a proof of convexity of the dual function.

2.3 Ensuring a Stationary Distribution

The REPS formulation (Eqs. 1–4) assumes the existence of a stationary distribution. However, not all MDPs have a stationary distribution for every policy π. For systems that do have a stationary distribution, steady-state behavior might not be realizable for real systems that need to be started and stopped. Furthermore, transient behavior, such as the swing-up of a pendulum, might be of greater interest than steady-state behavior.

We can ensure the system has a stationary distribution that includes such transients by resetting the system with a probability $1-\gamma$ at each time step. The system is subsequently set to a state from the initial state distribution $p_1(\mathbf{s})$. In this case, the expected value of V at the next time step is given by

$$\begin{aligned}\mathbb{E}[V(\mathbf{s}')|\mathbf{s},\mathbf{a}] &= \int_{\mathcal{S}} \gamma \mathcal{P}^{\mathbf{a}}_{\mathbf{ss}'} V(\mathbf{s}') + (1-\gamma) p_1(\mathbf{s}') V(\mathbf{s}') \mathrm{d}\mathbf{s}', \\ &= \gamma \boldsymbol{\alpha}^T \tilde{\mathbf{K}}_{\mathrm{s}} \boldsymbol{\beta}(\mathbf{s},\mathbf{a}) + (1-\gamma) \boldsymbol{\alpha}^T \hat{\boldsymbol{\mu}}_{S1}, \end{aligned} \tag{14}$$

where $\hat{\boldsymbol{\mu}}_{S1}$ is the empirical (observed) embedding of the initial state distribution and $\mathcal{P}^{\mathbf{a}}_{\mathbf{ss}'}$ are the transition probabilities of the original MDP. Such a reset procedure enables learning by removing the impracticable requirement of infinite roll-out length. In this way, we obtain a discounted setting similar to that used in RL methods that optimize the accumulated discounted reward.

2.4 Generalization of the Sample-Based Policy

The parameters resulting from the optimization, η and $\boldsymbol{\alpha}$, can be inserted back in Eqs. (12) and (6) to yield the desired probabilities $\{p_\pi(\mathbf{s}_1,\mathbf{a}_1),\ldots,p_\pi(\mathbf{s}_n,\mathbf{a}_n)\}$ at the sampled $(\mathbf{s},\mathbf{a})$ pairs (where $p_\pi(\mathbf{s},\mathbf{a}) = \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})$ as before). Conditioning on the current state yields the policy to be followed in the next iteration. However, since states and actions are continuous, we need to generalize from these weighted samples to nearby data points. To this end, we want to find a generalizing stochastic policy $\tilde{\pi}(\mathbf{a}|\mathbf{s})$ conditioned on the observed policy samples.

We first consider parametric policies $\tilde{\pi}(\mathbf{a}|\mathbf{s};\boldsymbol{\theta})$ linear in features $\boldsymbol{\phi}(s)$ with parameters $\boldsymbol{\theta}$. Later, we will generalize our results to non-parametric policies. We place a Gaussian prior over the unknown policy parameters, and choose a Gaussian noise model for the conditional over actions. Consequently, a Bayesian model is specified that will allow us to find a posterior over parameters $\boldsymbol{\theta}$

$$\begin{aligned} p(\boldsymbol{\theta}) &= \mathcal{N}(0, \alpha^{-1}\mathbf{I}), \\ \tilde{\pi}(\mathbf{a}|\mathbf{s};\boldsymbol{\theta}) &= \mathcal{N}(\boldsymbol{\theta}^T\boldsymbol{\phi}(\mathbf{s}), \beta^{-1}\mathbf{I}). \end{aligned}$$

By conditioning on the sampled state-action pairs, we obtain the familiar update equation

$$p(\boldsymbol{\theta}|\mathbf{a}_1,\ldots,\mathbf{a}_n,\mathbf{s}_1,\ldots,\mathbf{s}_n) = z^{-1} p(\boldsymbol{\theta}) \prod_{i=1}^{n} \tilde{\pi}(\mathbf{a}_i|\mathbf{s}_i;\boldsymbol{\theta}) \quad (\mathbf{s}_i,\mathbf{a}_i) \sim p_\pi(\mathbf{a},\mathbf{s}).$$

Algorithm 1 Policy iteration with relative entropy policy search (REPS)

repeat
- generate roll-outs according to $\tilde{\pi}_{i-1}$
- minimize dual — $\eta^*, \boldsymbol{\alpha}^* \leftarrow \arg\min g(\eta, \boldsymbol{\alpha})$ — Eq. 11
- calculate Bellman errors for each sample — $\delta_j \leftarrow \mathcal{R}_j + \boldsymbol{\alpha}^{*T}\left(\tilde{\phi}(\mathbf{s}'_j) - \tilde{\phi}(\mathbf{s}_j)\right)$ — Eq. 13
- calculate the sample weights — $w_j \leftarrow \exp(\delta_j/\eta^*)$ — Sec. 2.4
- fit a generalizing policy — $\tilde{\pi}_i(\mathbf{a}|\mathbf{s}) = \mathcal{N}(\mu(\mathbf{s}), \sigma^2(\mathbf{s}))$ — Sec. 2.4

until convergence

Here, z^{-1} is a normalization factor. However, our samples are drawn from $q(\mathbf{a}, \mathbf{s})$ and not $p_\pi(\mathbf{a}, \mathbf{s})$. From a log transformation of the update equation, we see that we can use importance sampling to estimate $\boldsymbol{\theta}$ using the approximation

$$\begin{aligned}
\log p(\boldsymbol{\theta}|\mathbf{a}_1, \mathbf{s}_1, \ldots, \mathbf{a}_n, \mathbf{s}_n) &= \log p(\boldsymbol{\theta}) + \sum_{i=1}^{n} \log \tilde{\pi}(\mathbf{a}|\mathbf{s}; \boldsymbol{\theta}) + \text{const.} && (\mathbf{s}_i, \mathbf{a}_i) \sim p_\pi(\mathbf{a}, \mathbf{s}), \\
&\approx \log p(\boldsymbol{\theta}) + \sum_{i=1}^{n} \frac{p_\pi(\mathbf{a}, \mathbf{s})}{q(\mathbf{a}, \mathbf{s})} \log \tilde{\pi}(\mathbf{a}|\mathbf{s}; \boldsymbol{\theta}) + \text{const.} && (\mathbf{s}_i, \mathbf{a}_i) \sim q(\mathbf{a}, \mathbf{s}), \\
&= \log p(\boldsymbol{\theta}) + \sum_{i=1}^{n} \log \tilde{\pi}(\mathbf{a}|\mathbf{s}; \boldsymbol{\theta})^{\frac{p_\pi(\mathbf{a}, \mathbf{s})}{q(\mathbf{a}, \mathbf{s})}} + \text{const.} && (\mathbf{s}_i, \mathbf{a}_i) \sim q(\mathbf{a}, \mathbf{s}),
\end{aligned}$$

As the new state-action distribution p_π is of the form given in (6), we can write the importance weights

$$w_i = \frac{p_\pi(\mathbf{s}_i, \mathbf{a}_i)}{q(\mathbf{s}_i, \mathbf{a}_i)} = \exp\left(\frac{\delta(\mathbf{s}_i, \mathbf{a}_i, V^*)}{\eta^*}\right).$$

Since $\tilde{\pi}(\mathbf{a}|\mathbf{s}; \boldsymbol{\theta})$ is Gaussian in our model, raising to the power of w_i simply scales the variance by $1/w_i$. By exponentiating both sides again, and using the familiar procedure for weighted Bayesian linear regression (Gelman et al., 2004), we find the predictive distribution

$$\tilde{\pi}(\mathbf{a}|\mathbf{s}) = \mathcal{N}(\beta \boldsymbol{\phi}(\mathbf{s})^T \mathbf{S}_n \boldsymbol{\Phi}^T \mathbf{D}^{-1} \mathbf{A}, \boldsymbol{\phi}(\mathbf{s})^T \mathbf{S}_n \boldsymbol{\phi}(\mathbf{s}) + \beta^{-1}), \quad S_n = (\beta \boldsymbol{\Phi}^T \mathbf{D}^{-1} \boldsymbol{\Phi} + \alpha \mathbf{I})^{-1}, \quad (15)$$

where $\mathbf{D}$ is a diagonal weighting matrix with $\mathbf{D}_{ii} = 1/w_i$ and $\mathbf{A} = [\mathbf{a}_1, \ldots, \mathbf{a}_n]^T$.

The policy mean is of the form of the lower bound introduced by Dayan and Hinton (1997), and the policy that maximizes this lower bound can be found through a weighted linear regression (Peters and Schaal, 2007), although that framework does not employ a Bayesian formulation and therefore cannot represent uncertainty in the parameters. Note that instead of basing the weights on a transformation of the reward function, our approach uses a transformation of the Bellman error, which takes the long-term expected rewards into account. The critical step of choosing the transformation was done by manual design in earlier work (Peters and Schaal, 2007; Dayan and Hinton, 1997)), while here the transformation directly results from the optimization problem (1)–(4). Algorithm 1 shows how the different steps of our approach fit together in the special case of linear value functions and policy, when sampled outcomes are used to approximate the Bellman error. This form of the algorithm was introduced in our earlier work (Peters et al., 2010).

Algorithm 2 Policy iteration with non-parametric REPS (NP-REPS)

repeat
- generate roll-outs according to $\tilde{\pi}_{i-1}$
- calculate kernel embedding strengths — $\boldsymbol{\beta}_j \leftarrow (\mathbf{K}_{\text{sa}} + l_C \mathbf{I})^{-1} \mathbf{k}_{\text{sa}}(\mathbf{s}_j, \mathbf{a}_j)$ — Sec. 2.2
- minimize kernel-based dual — $\eta^*, \boldsymbol{\alpha}^* \leftarrow \arg\min g(\eta, \boldsymbol{\alpha})$ — Eq. 11
- calculate kernel-based Bellman errors — $\delta_j \leftarrow \mathcal{R}_j + \boldsymbol{\alpha}^{*T}\left(\tilde{\mathbf{K}}_{\text{s}} \boldsymbol{\beta}_j - \mathbf{k}_{\text{s}}(\mathbf{s}_j)\right)$ — Eq. 12
- calculate the sample weights — $w_j \leftarrow \exp(\delta_j/\eta^*)$ — Sec. 2.4
- fit a generalizing non-parametric policy — $\tilde{\pi}_i(\mathbf{a}|\mathbf{s}) = \mathcal{N}(\mu(\mathbf{s}), \sigma^2(\mathbf{s}))$ — Sec. 2.5

until convergence

2.5 Non-Parametric Generalizing Policies

For non-parametric policies, Eq. (15) can be kernelized straightforwardly, to yield

$$\tilde{\pi}(\mathbf{a}|\mathbf{s}) = \mathcal{N}(\mu(\mathbf{s}), \sigma^2(\mathbf{s})), \;\; \mu(s) = \mathbf{k}_{\text{s}}(\mathbf{s})^T (\mathbf{K}_{\text{s}} + l\mathbf{D})^{-1} \mathbf{A}, \quad (16)$$

$$\sigma^2(\mathbf{s}) = k(\mathbf{s}, \mathbf{s}) + l - \mathbf{k}_{\text{s}}(\mathbf{s})^T (\mathbf{K}_{\text{s}} + l\mathbf{D})^{-1} \mathbf{k}_{\text{s}}(\mathbf{s}), \quad (17)$$

where kernel vector $\mathbf{k}_{\text{s}}(\mathbf{s}) = \boldsymbol{\phi}(\mathbf{s})^T \boldsymbol{\Phi}$, kernel matrix $\mathbf{K}_{\text{s}} = \boldsymbol{\Phi}^T \boldsymbol{\Phi}$, and l is a free regularization hyper-parameter. Together with other hyper-parameters, such as the kernel bandwidth, l can be set by performing cross-validation on a maximum marginal likelihood objective.

Kober et al. (2011) derived an EM-based policy search approach that uses similar cost-sensitive Gaussian processes (GPs). The regularization term in these GPs is modulated with the inverse of the weight at each data point. However, there are some notable differences. First of all, in our case the weights w are found by transforming the advantage function rather than the reward function, allowing decision making in longer-horizon problems. Furthermore, that approach used a maximum likelihood perspective which allows derivation of the mean, but not the variance. In contrast, we derive our policy update using importance sampling from a Bayesian perspective that allows a principled derivation of the covariance update. Algorithm 2 shows how the different steps of our approach, non-parametric relative entropy policy search (NP-REPS), fit together.

2.6 Hyper-parameter Optimization

The conditional operator has open hyper-parameters, namely, the hyper-parameters of the kernels over $\mathbf{s}$ and $\mathbf{a}$ as well as the regularization parameter l_C. We set l_C and the hyper-parameters of kernel k_{a} through two-fold cross-validation on the objective

$$\sum_{i=1}^{n} \left\| \boldsymbol{\phi}(\tilde{\mathbf{s}}_i)^T \boldsymbol{\phi}(\mathbf{s}'_i) - \boldsymbol{\phi}(\tilde{\mathbf{s}}_i)^T \hat{\mathbf{C}}_{S'|S,A} \boldsymbol{\psi}(\mathbf{s}_i, \mathbf{a}_i) \right\|^2,$$

which minimizes the difference between actual embedding strength and the embedding strength predicted using the conditional operator $\hat{\mathbf{C}}_{S'|S,A}$ introduced in Eq. (10). This objective is based on the cross-validation objective proposed by Grünewälder et al. (2012a), but exploits the fact that the embedding will only be evaluated at known functions $\boldsymbol{\phi}(\tilde{\mathbf{s}})$.

The hyper-parameters of k_s, the kernel for the predicted variable $\mathbf{s}'$, cannot be tuned this way as trivial solutions exist. For example, essentially constant features $\boldsymbol{\phi}(\mathbf{s}')$ with very high bandwidth minimize the prediction error. Instead, we set the hyper-parameters of k_s through minimization of the mean squared TD error in a two-fold cross-validation procedure. We choose this objective since the (residual) TD error is a common objective for feature selection (Parr et al., 2008) in reinforcement learning.

We optimize the hyper-parameters of the Gaussian process policy separately from finding the hyper-parameters of the conditional operator. The employed optimization objective is the weighted marginal likelihood, with weights w_i as discussed in Section 2.5. This objective is maximized in a cross-validation procedure where every roll-out is used as separate fold.

2.7 Efficient Approximations for Large Data Sets

The proposed algorithm requires inverting several $n \times n$ matrices, where n is the number of samples. If open hyper-parameters (such as regularization parameters or kernel bandwidths) need to be optimized, this inversion happens inside the optimization loop. As a consequence, learning becomes slow if more than approximately 5000 samples are used (on current computing hardware). Especially for complex problems and problems requiring a high control frequency, such a soft limit can be prohibitive. In order to scale our method to larger problems, approximate methods with high time efficiency have to be considered. In this section, we will discuss two families of such approximation methods: sparsification of the kernel matrix, and approximation of the kernel function using stochastic features. Related work on efficient calculations for non-parametric reinforcement learning are discussed in Section 4.4 on page 33.

2.7.1 Sparsification Approaches.

One way of scaling up kernel methods is to consider sparsifications, where a small number of pseudo-inputs are used rather than the full data set. Multiple sparsification schemes have been proposed in the context of supervised learning, notably the likelihood approximation used in the projected latent variables (PLV) approach (Seeger et al., 2003) and the Bayesian derivation of sparse pseudo-input Gaussian processes (SPGPs) by Snelson and Ghahramani (2006).

Such sparsifications have been used in a number of RL algorithms (Engel et al., 2003; Xu et al., 2014; Jung and Polani, 2007; Xu et al., 2007; Lever and Stafford, 2015). In many of these algorithms, a quadratic program is optimized to learn the embedding strength of the data points in the active set m. This approach typically results in an approximation $k(\mathbf{x}, \mathbf{x}') \approx \mathbf{k}_m(\mathbf{x})^T \mathbf{K}_{mm}^{-1} \mathbf{k}_m(\mathbf{x}')$. In this equation, $\mathbf{k}_m(\mathbf{x})$ and $\mathbf{K}_{mm}$ are a vector and a matrix, respectively, of similarities to the active set of m data-points (Jung and Polani, 2007; Xu et al., 2007). The same effective kernel is used in the PLV approach (Seeger et al., 2003). Note that, effectively, a non-stationary kernel is obtained, that is parametrized by the data points in the active set m (Jung and Polani, 2007; Xu et al., 2007).

The SPGP approach uses a very similar kernel, but includes a state-dependent regularization term. This term proves to be helpful in gradient-based hyper-parameter optimization (Snelson and Ghahramani, 2006). The covariance of output points is then given by $\mathbf{K}_{nm}\mathbf{K}_{mm}^{-1}\mathbf{K}_{mn} + l\mathbf{I} + \boldsymbol{\Lambda}$. In this equation, the n^{th} element on the diagonal of $\boldsymbol{\Lambda}$ is given by

$k(\mathbf{x}_n, \mathbf{x}_n) - \mathbf{k}_m(\mathbf{x}_n)^T \mathbf{K}_{mm}^{-1} \mathbf{k}_m(\mathbf{x}_n)$. The matrix $\mathbf{K}_{nm}$ denotes a Gram matrix between all n input points and the active subset of m data points, while k_m and $\mathbf{k}_m$ denote a scalar and vector of corresponding kernel values.

To derive a sparsification with the same type of effective kernel using the reward-dependent regularization terms introduced in Section 2.5, we can consider the regular update equation for the non-parametric policy mean in Eq. (16),

$$\mu(\mathbf{x}) = \mathbf{k}_n(\mathbf{x})^T (\mathbf{K}_{nn} + l\mathbf{D})^{-1} \mathbf{y},$$

where $\mathbf{y}$ is the vector of all training outputs. We replace the occurrences of the kernel with the effective kernel

$$\mu(\mathbf{x}) = \mathbf{k}_m(\mathbf{x})^T \mathbf{K}_{mm}^{-1} \mathbf{K}_{mn} (\mathbf{K}_{nm}\mathbf{K}_{mm}^{-1}\mathbf{K}_{mn} + l\mathbf{D} + \boldsymbol{\Lambda})^{-1} \mathbf{y}.$$

Now, we can apply the Woodbury identity to obtain the update equation

$$\mu(\mathbf{x}) = \mathbf{k}_m(\mathbf{x})^T (\mathbf{K}_{mm} + \mathbf{K}_{mn}(l\mathbf{D} + \boldsymbol{\Lambda})^{-1}\mathbf{K}_{nm})^{-1} \mathbf{K}_{mn} (l\mathbf{D} + \boldsymbol{\Lambda})^{-1} \mathbf{y}.$$

The empirical conditional embedding (Eq. 10) can similarly be approximated using this effective kernel. Considering the regular update equation for the non-parametric policy covariance in Eq. (17), in similar a fashion we can derive the predictive variance

$$\sigma^2(\mathbf{x}) = k(\mathbf{x}, \mathbf{x}) - \mathbf{k}_m(\mathbf{x})^T (\mathbf{K}_{mm}^{-1} + (\mathbf{K}_{mm} + \mathbf{K}_{mn}(l\mathbf{D} + \boldsymbol{\Lambda})^{-1}\mathbf{K}_{nm})^{-1}) \mathbf{k}_m(\mathbf{x}) + l.$$

Analogously, a cost-regularized version of the PLV approach can be obtained in a similar form, but omitting the $\boldsymbol{\Lambda}$ terms. As the proposed sparsification scheme depends on the inverse of $\mathbf{K}_{mm}$, numerical problems can potentially ensue if the active subset m is poorly chosen (such that two almost-equal data points are present). To address this issue, we regularize $\mathbf{K}_{mm}$ where necessary.

Alternatively, we consider fitting a regular Gaussian process to a set of M inducing inputs, with pseudo-targets given by weighted linear regression. For pseudo-outputs $\tilde{\mathbf{y}}$ of M sparse inputs, a Gaussian process would predict $\hat{\mathbf{y}} = \mathbf{K}_{nm}(\mathbf{K}_{mm} + l\mathbf{I})^{-1}\tilde{\mathbf{y}}$ at all (active and passive) inputs. Since we know the true outputs $\mathbf{y}$ for the training data, a maximum likelihood solution can be found using weighted linear regression, considering $\mathbf{K}_{nm}(\mathbf{K}_{mm} + l\mathbf{I})^{-1}$ as design matrix. This approach yields the update equations for the mean

$$\mu(\mathbf{x}) = \mathbf{k}_m \tilde{\mathbf{K}}_{mm}^{-1} \tilde{\mathbf{y}},$$

where $\tilde{\mathbf{K}}_{mm}^{-1}$ is the regularized inverse $(\mathbf{K}_{mm} + l\mathbf{I})^{-1}$. The inducing output values $\tilde{\mathbf{y}}$ are

$$\tilde{\mathbf{y}} = (\tilde{\mathbf{K}}_{mm}^{-1}\mathbf{K}_{mn}\mathbf{D}\mathbf{K}_{nm}\tilde{\mathbf{K}}_{mm}^{-1} + l_2\mathbf{I})^{-1} \tilde{\mathbf{K}}_{mm}^{-1}\mathbf{K}_{mn}\mathbf{D}\mathbf{y},$$

where l_2 is an additional regularization parameter. As the covariance does not depend on the inducing output at the training points, the standard update equation for Gaussian processes can be used in this case. The update equation for the mean corresponds to that of a Gaussian process with an effective kernel $k(x, x') = \mathbf{k}_m(x)^T \tilde{\mathbf{K}}_{mm}^{-1} \tilde{\mathbf{K}}_{mm}^{-1} \mathbf{k}_m(x')$.

2.7.2 Random Fourier Features.

Instead of sparsification, where the exact kernel function is used at a subset of data points, we might instead use an approximation of the kernel function at all data points. One such approach is proposed by Rahimi and Recht (2007). They define a distribution $p(z)$ over mapping functions z such that the inner products in sampled feature spaces are unbiased estimates of the kernel evaluation $k(\mathbf{x},\mathbf{y}) = \mathbb{E}[z(\mathbf{x})^T z(\mathbf{y})] \approx \mathbf{z}(\mathbf{x})^T\mathbf{z}(\mathbf{y})$, where $\mathbf{z}_i(\cdot) \sim p(z)$. They propose two kinds of random features that obey this criterion: Fourier features and binning features. As the binning features are suitable only for kernels that solely rely on the L1 norm between data points, we will focus on the Fourier features in this section. These features have been used successfully in various classification and regression tasks (Rahimi and Recht, 2007; Hernández-Lobato et al., 2014; Lu et al., 2016).

For the Fourier features, we require the Fourier transform $\alpha p(\boldsymbol{\omega})$ of a stationary (shift-invariant) kernel $k(\mathbf{x},\mathbf{y})$, where α is a normalization factor that ensures $p(\boldsymbol{\omega})$ is a probability distribution. The inverse Fourier transform is thus

$$k(\mathbf{x},\mathbf{y}) = \alpha \int_{\mathcal{R}^d} p(\boldsymbol{\omega}) e^{i\boldsymbol{\omega}^T(\mathbf{x}-\mathbf{y})} \mathrm{d}\boldsymbol{\omega} = 2\alpha \mathbb{E}[\cos(\boldsymbol{\omega}^T\mathbf{x} + b)\cos(\boldsymbol{\omega}^T\mathbf{y} + b)], \quad b \sim \mathcal{U}(0, 2\pi).$$

We can approximate this integral using samples $(\boldsymbol{\omega}_i, b_i)$ with $i = 1, \ldots, L$ and obtain

$$k(\mathbf{x},\mathbf{y}) \approx 2\alpha \frac{1}{L} \sum_{i=1}^{L} \cos(\boldsymbol{\omega}_i^T\mathbf{x} + b_i)\cos(\boldsymbol{\omega}_i^T\mathbf{y} + b_i) = \mathbf{z}(\mathbf{x})^T\mathbf{z}(\mathbf{y}),$$

with $\mathbf{z}_i(\mathbf{x}) = \sqrt{2\alpha L^{-1}}\cos(\boldsymbol{\omega}_i^T\mathbf{x} + b_i)$. As the chosen number of samples L gets smaller, the approximation gets coarser but computations will get faster, as we will need to invert $L \times L$ covariance matrices.

In this article, we will use the squared-exponential (or Gaussian) kernel $k_{\mathrm{es}}(\mathbf{x},\mathbf{y}) = \alpha \exp(-0.5||\mathbf{x}-\mathbf{y}||_{\Sigma^{-1}})$ with diagonal covariance Σ. This kernel has a corresponding Fourier transform $p_{\mathrm{es}}(\boldsymbol{\omega}) = \mathcal{N}(0,\Sigma)$. Furthermore, for periodic data we will use a periodic kernel $k_{\mathrm{p}}(\mathbf{x},\mathbf{y}) = \alpha \exp(-2\sin^2(0.5|\mathbf{x}-\mathbf{x}'|)/\sigma^2)$. This kernel is equivalent to the Gaussian kernel on periodic features

$$k_{\mathrm{p}}(\mathbf{x},\mathbf{y}) = k_{\mathrm{es}}([\cos(\mathbf{x}), \sin(\mathbf{x})]^T, [\cos(\mathbf{y}), \sin(\mathbf{y})]^T).$$

Therefore, suitable random features can be generated as

$$\mathbf{z}_i(x) = \sqrt{2\alpha L^{-1}}\cos([\cos(\mathbf{x}), \sin(\mathbf{x})]\boldsymbol{\omega}_i + b_i).$$

Products of Gaussian and periodic kernels can likewise be written as a single multivariate Gaussian kernel on appropriate features of the inputs and handled in a similar way. As a result, all matrix inversions are now performed on $L \times L$ rather than $n \times n$ matrices.

3. Experiments

We first evaluate our method first on a reaching task, and the under-powered pendulum swing-up task. Then, we will consider two tasks with redundant inputs: we compare different methods on a variant of the puddle-world task with a 400-dimensional input representation, and show the ability of the proposed method to learn a variant of the swing-up task on a real robot that has access only to camera images rather than joint angles. In this section, we will first discuss elements of our set-up that are the same across tasks. Subsequently, we discuss implementation specifics and results for each task separately.

3.1 Experimental Set-up

We assume a realistic exploration setup in which the agent cannot choose arbitrary state-action pairs. Instead, as shown in Alg. 2, from an initial state distribution our agent explores using its stochastic policy. After every 10 roll-outs, the model learner and the policy of the agents are updated. To bootstrap the model and the policy, the agent is given 30 roll-outs using a random exploratory policy initially. To avoid excessive computations, we include a simple forgetting mechanism that only keeps the latest 30 roll-outs at any time.[6] As each roll-out contains 49 time steps on average in the larger tasks (as episodes are reset with a constant probability after each step), most computations are performed on approximately 1500×1500 matrices.

After each update, in simulated runs, the learning progress is evaluated by running the learned policy on 100 roll-outs with a fixed random seed. This data is not used for learning. For every method, we performed 10 trials, each consisting of 20 iterations so that 220 roll-outs were performed per trial (30 initial roll-outs plus 10 per iteration). In real-robot runs we evaluate the learned policy on the training samples, and performed 6 trials of 10 iterations each. The model and policy are refined incrementally in every iteration.

3.2 Compared Methods

We compared learning progress of the proposed approach to that of various other approaches. On the one hand, we consider the non-parametric value-function based methods introduced by Grünewälder et al. (2012b) and Pazis and Parr (2011). On the other hand, we will compare to the performance of neural-network based methods introduced by Lillicrap et al. (2016) and Schulman et al. (2015) that are well-suited for redundant input data. We also compare to versions of REPS with the sample-based model approximation used by Peters et al. (2010) and Daniel et al. (2016), and one that uses a fixed feature set. The relationship of the proposed approach to earlier non-parametric reinforcement learning methods will be discussed in Section 4.3 on page 32.

3.2.1 Sample Based Model.

REPS only needs $\mathbb{E}_{\mathbf{s}'}[V(\mathbf{s}')|\mathbf{s},\mathbf{a}]$ at observed state-action pairs $(\mathbf{s}_i,\mathbf{a}_i)$. Therefore, if the system is deterministic, this expectation is simply $V(\mathbf{s}_i')$ at the observed values for $(\mathbf{s}_i,\mathbf{a}_i)$. In stochastic systems, this sample-based method is used as approximation.

3.2.2 Feature Based REPS with Fixed Basis Functions.

Instead of the non-parametric form of V assumed in this paper, we can follow earlier work and define a fixed feature basis (Peters et al., 2010; Daniel et al., 2016). We choose to use a

6. As a consequence, the reference distribution q is a mixture of the previous three state-action distributions in our experiments.

similar number of the same radial basis functions used in the non-parametric method, but distribute these according to a regular grid over the state-action space.

3.2.3 Approximate Value Iteration.

In this approach by Grünewälder et al. (2012b), the value function is assumed to be an element of the chosen RKHS. The maximization of the Q function requires discretizing $\mathbf{a}$, for which we choose 25 uniform bins in the allowable range. A deterministic policy selects $\mathbf{a}^* = \arg\max Q(\mathbf{s}_i, \cdot)$, but this policy does not explore, yielding bad performance in on-policy learning. To obtain an exploration-exploitation trade-off we replace the maximum by the soft-max operator $a^* \propto \exp(Q(\mathbf{s}_i, \cdot)c/\text{stdev}(Q(\mathbf{s}_i, \cdot)))$. The free parameter c specifies the greediness of the exploration/exploitation trade-off on normalized Q values. In an **on-policy** scheme, the new policy is used to obtain samples for the next iteration.

As a comparison to this on-policy scheme, we also compare using a **grid** of state-action pairs as training data. For a dense grid, this method has a richer input than all other methods, as those other methods start with uninformed roll-outs from the initial-state distribution. In a real system, obtaining such a grid is often unrealistic as the state cannot be set arbitrarily.

3.2.4 Non-parametric Approximate Linear Programming.

Pazis and Parr (2011) introduced a non-parametric method, NPALP, that assumes the value function is Lipschitz. This assumption allows the RL problem to be formalized as a linear program. This method assumes the dynamics are deterministic. A greedy policy is obtained that is optimal if all state-action pairs have been visited. Since visiting all state-action pairs is infeasible in continuous systems, we include exploration by adding Gaussian distributed noise to the action in a fraction ϵ of the selected actions.

3.2.5 Trust Region Policy Optimization.

This method, introduced by Schulman et al. (2015), uses a bound on the expected Kullback-Leibler divergence between successive policies, inspired by a theoretical policy iteration algorithm that guarantees non-decreasing expected returns. The method, TRPO, requires a parametric policy to be defined, but has been shown to work well with deep neural-network policies that can be used in many different tasks, thanks to their flexibility. We use the reference implementation provided in the RLlab framework (Duan et al., 2016). This TRPO implementation requires a fixed time horizon, so we evaluate this model on a modified version of the tasks where the episodes are of fixed length, equal to the expected episode length used for other methods.

3.2.6 Deep Deterministic Policy Gradients.

Lillicrap et al. (2016) introduced a policy gradient algorithm, DDPG, that works with deterministic policies. DDPG is an actor-critic method that uses neural networks for both the Q function and the policy. After each time step, the new experience sample is stored in an 'experience replay' buffer, a randomly sampled batch from this buffer is then used to calculate the policy gradient. This technique diminishes the problem that successive

samples tend to be highly correlated. We again use the RLlab implementation (Duan et al., 2016) with fixed episode length.

3.2.7 Linear Least Squares Policy Iteration

As an example of a linear method, we use LSPI (Lagoudakis and Parr, 2003). This method learns a Q function by minimizing temporal differences. We only include this method to show that linear methods in general do not suffice on our task with pixel inputs. As suggested by Lagoudakis and Parr (2003), we use this method off-line, in contrast to the other methods. Thus, all data used in this method has been gathered using the initial exploration policy.

3.3 Approximation Methods

We compare the approximation methods described in Section 2.7 to each other, as well as to a naive baseline. This comparison evaluates the trade-off between a better approximation quality and a faster computation time across a range of different numbers of features and inducing inputs.

3.3.1 Sub-sampling as Baseline.

For the sub-sampling baseline, we simply train the method as described in Section 2.2 with a subset of the data points, ignoring the points that are not in the random subset.

3.3.2 Sparse Pseudo-input Gaussian Processes (SPGP).

We use the method proposed by Snelson and Ghahramani (2006) to approximate the Gaussian process policy. To incorporate the desirability of data points, we use the modifications proposed in Section 2.7. There is no straightforward extension of this method to learn the Bellman error terms (Eq. 12). Therefore, in these steps of the algorithm we interpret the matrix $\mathbf{K}_{nm}$ introduced in Section 2.7 as a feature matrix. Subsequently, we calculate the Bellman error terms using the feature-based formulation introduced by Peters et al. (2010). In contrast to that work, we do not use single sample roll-outs, but calculate the embedding strengths $\boldsymbol{\beta}$ (Section 2.2) using a linear kernel with the pseudo-features as input. Snelson and Ghahramani (2006) suggest choosing the active subset by maximizing the marginal likelihood. However, this maximization is a computationally intensive process, and for the value function approximation, there is no criterion available equivalent to the maximum likelihood criterion for the supervised learning set-up. Therefore, we choose random subsets when applying this method.

3.3.3 Projected Latent Variables (LPV).

Additionally, we compare to the sparsification method proposed by Seeger et al. (2003). As in the previous method, we interpret the $\mathbf{K}_{nm}$ matrix as features and use these to calculate embedding strengths and Bellman error terms.

3.3.4 Regression-based Sparse GPs.

We also consider the regression-based sparse Gaussian Processes proposed in Section 2.7. Again, the $\mathbf{K}_{nm}$ matrix is interpreted as design matrix for calculation of the embedding strengths and Bellman error terms.

3.3.5 Fourier Transform Based Approximation

The last method we consider is based on the work of Rahimi and Recht (2007), with the extension to desirability-weighted samples as described in Section 2.7. As this method approximates the policy using features, we can use these features to calculate embedding strengths and Bellman error terms in the feature-based formulation introduced by Peters et al. (2010).

3.4 Reaching Task Experiment

In the reaching task, we simulate a simple two-link planar robot. In this task, the agent's actions directly set the accelerations of the two joints. Each link is of unit length and mass, and the system is completely deterministic. The agent gets negative reinforcement $r(\mathbf{s}, \mathbf{a}) = -10^{-4}||\mathbf{a}||_2^2 - ||\mathbf{x} - \mathbf{x}_{\text{des}}||_2^2$ according to the square of the applied action and of the distance of its end-effector to the Cartesian position $\mathbf{x}_{\text{des}} = [0.5,\ 0]$. Note that actions are two dimensional and states are four dimensional (joint positions and velocities). The robot starts stretched-out with the end-effector at $\mathbf{x} = [0,\ 2]$. The maximum applied acceleration is 50ms^2. We use $\gamma = 0.96$, which resets roll-outs after 24 samples, on average.

We use the commonly used squared-exponential (or Gaussian) kernel for angular velocities $\dot{\boldsymbol{\theta}}$ and actions. This kernel is defined as $k_{\text{se}}(\mathbf{x}_i, \mathbf{x}_j) = \exp(-(\mathbf{x}_i - \mathbf{x}_j)^T \mathbf{D}(\mathbf{x}_i - \mathbf{x}_j))$ (with $\mathbf{D}$ a diagonal matrix containing free bandwidth parameters). However, for the angles $\boldsymbol{\theta}$ we need a kernel that represents its periodicity. We use the kernel $k_{\text{p}}(x_i, x_j) = \exp(-\sum_d \sin((x_i^{(d)} - x_j^{(d)})/(2\pi))^2/\mathbf{l}_d^2)$, where $\mathbf{l}$ is a vector of free bandwidth parameters. Consequently, we obtain a complete kernel

$$k((\boldsymbol{\theta}_i, \dot{\boldsymbol{\theta}}_i, a_i), (\boldsymbol{\theta}_j, \dot{\boldsymbol{\theta}}_j, a_j)) = k_{\text{p}}(\boldsymbol{\theta}_i, \boldsymbol{\theta}_j) k_{\text{se}}(\dot{\boldsymbol{\theta}}_i, \dot{\boldsymbol{\theta}}_j) k_{\text{se}}(\mathbf{a}_i, \mathbf{a}_j),$$

composed of three simpler kernel functions.

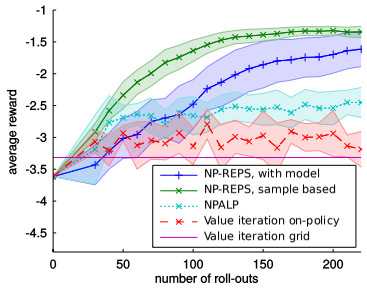
Feature-based REPS needs a grid over the complete state-action space. Due to difficulties with the six-dimensional state-action space, we omitted this method. The exploration parameter ϵ of the NPALP method was set to 0.1, with the standard deviation of Gaussian noise set to 30Nm^2. The Lipschitz constant was set to 1 with the velocity dimensions scaled by 1/5 for calculating distances. The exploration parameter c of the approximate value iteration method was set to 1.5. These values were manually tuned to yield fast and consistent learning progress. For REPS, we use a KL bound ϵ of 0.5 in our experiments, as this value empirically yielded acceptably fast learning progress while keeping updates smooth enough on a range of learning problems.

3.4.1 Results of the Reaching Task.

The results of the reaching task are shown in Figure 1. As this task is deterministic, the sample-based model is optimal and provides an upper bound to the performance we can

expect to get. Since non-parametric REPS with model learning needs to iteratively learn the transition distribution, its convergence is slower. After inspection of individual trials, the wide variance seems to be caused by occasional failures to find good hyper-parameters for the state-action kernel.

The baseline methods NPALP and value iteration using RKHS embeddings obtain good performance after the couple of iterations. However, if we iterate performing roll-outs and policy updates after those first steps, these methods fail to improve the policy consistently. The grid based value iteration scheme fails in this case: due to memory limitations the maximum grid size we could use was $[5 \times 5 \times 5 \times 5 \times 2 \times 2]$ in the 6-dimensional space, which appears to be insufficient to learn the task.



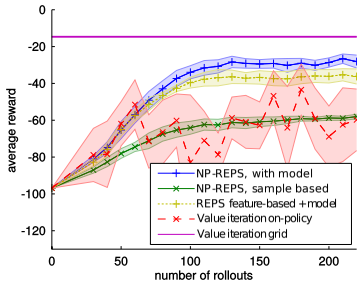


Figure 1: Comparison of learning progress of different methods on the reaching task. As this environment is deterministic, sample-based approximations of the transition functions are optimal. Error bars show twice the standard error of the mean. The value-iteration method does not depend on roll-outs, its performance is shown for comparison.

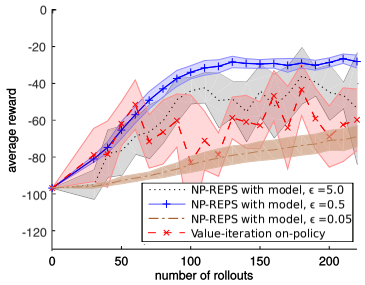

3.5 Low-Dimensional Swing-up Experiment

In this experiment, we simulate a pendulum with a length $l = 0.5\text{m}$ and a mass $m = 10\text{kg}$ distributed along its length. A torque a can be applied at the pivot. The pendulum is modeled by the dynamics equation $\ddot{\theta} = (glm\sin\theta + a - k\dot{\theta})/(ml^2/3)$, where $k = 0.25\text{Ns}$ is a friction coefficient and $g = 9.81$ is the gravitational constant. The controller's sampling frequency is 20 Hz, i.e., every 0.05s the agent gets a reward and chooses a new action. The maximum admissible torque is 30Nm, which prevents a direct swing-up from the downwards position. Additive noise with a variance of $1/dt$ disturbs the controls, resulting in a standard deviation of about 4.5Nm per time step. The reward function was set to $r(s, a) = -10\theta^2 - 0.1\dot{\theta}^2 - 10^{-3}a^2$, where θ is mapped to $[-0.5\pi, 1.5\pi)$ to differentiate the rewards of clockwise and counter-clockwise swing-ups. We use a reset probability of 0.02 ($\gamma = 0.98$).

The algorithms directly access the state variable encoding the angle θ and the angular velocity $\dot{\theta}$, i.e., the state is defined as $\mathbf{s} = [\theta, \dot{\theta}]^T$. The same kernels are used as in the reaching task experiment (Section 3.4). The NPALP method was not designed for stochastic systems and is consequently omitted. We set the grid size for feature-based REPS to $[10 \times 10 \times 10]$ and for the value-iteration method to $[19 \times 11 \times 11]$. The greediness parameter c for on-policy value-iteration was set to 2 after manual tuning. We compare the KL bound ϵ used in the previous experiment, 0.5, to two extreme settings $\epsilon = 5$ and $\epsilon = 0.05$ to illustrate the effect of this bound.

(a) Comparison of learning progress of different methods on the swing-up task.

(b) Comparison of learning progress under different bounds ϵ on the KL-divergence.

Figure 2: Results of the low-dimensional swing-up experiment. Our non-parametric relative entropy method outperforms the other on-policy learners. Error bars show twice the standard error of the mean.

3.5.1 Results of the Low-Dimensional Swing-up.

We show a comparison of the discussed methods in Figure 2a. The value iteration method starts out competitively, but fails to keep improving the policy. Large variance indicates the learning process is unstable. The bounded policy update in REPS makes the learning progress smooth by limiting information loss, limiting exploitation to retain more exploration in early stages of the learning process.

The sample-based baseline model performs considerably worse in this experiment, as it cannot account for stochastic transitions. The variant with fixed features performs well initially, but in later iterations, the non-parametric method is able to focus its representative power on frequently visited parts of the state space, resulting in an improved performance.

We show a comparison for different values of the KL bound ϵ in Figure 2b. We plotted two rather extreme values for ϵ. For a large value of $\epsilon = 5$, we observe behavior that is similar to the greedy value iteration scheme. Initially, performance increases, but learning progress has a high variance and is not smooth. Sub-optimal performance to both the proposed value $\epsilon = 0.5$ and the greedy value-iteration is caused by

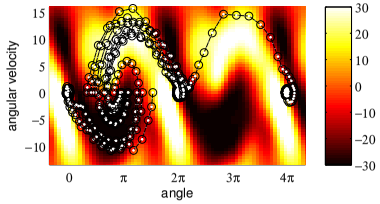

Figure 3: Mean of the learned stochastic policy. Superimposed are 15 trajectories starting at the x-axis between 0 and 2π. Most roll-outs reach the desired inverted pose, possibly after one swing back and forth. One roll-out overshoots and makes a full rotation before stabilizing the pendulum.

instability of the policy fitting described in Section 2.5 when the sample weights span several orders of magnitude. For a low value of $\epsilon = 0.05$, learning progress is very stable but slow. We found that setting $\epsilon = 0.5$ yielded good performance in all tasks we tried.

In contrast to the previous experiment, here, the grid-based value iteration method worked well, as shown in Figure 2a. The policy learned by NP-REPS, shown in Figure 3, sometimes overshoots the inverted position, which the grid based value iteration avoids. However, to reach this performance, a grid of training samples covering the full state-action space was needed. Providing such a grid is only feasible in simulation, as without an existing controller, it is generally not possible to start the dynamical system with arbitrary position and velocity. Furthermore, on higher-dimensional tasks, a grid of sufficient resolution would require impracticably many samples.

3.6 Image-based Puddle World Experiment

In this experiment, we investigated a modified version of the classical puddle-world task with a 400-dimensional redundant representation. In the puddle world task, the agent has to navigate to one corner of a two-dimensional world while avoiding high-cost areas ('puddles'). The aim of this experiment is to confirm the ability of our proposed method to handle such representation, and to compare our method to other method that have been shown to work well with raw sensory representations. We mostly follow the description for the puddle world by Sutton (1996). As size of the goal region we use the area above the line $x + y = 1.8$. We represent the state by a simple rendered pixel image, where the agent is represented by a circle of 8% of the image size (the agent does not 'see' the puddles, but has to learn where they are from experience). We found that for the policy search methods we studied, a relatively low discount factor ($\gamma = 0.96$) or corresponding reset probability (0.04) provided lower-variance results. Such a discount factor makes long-term rewards less salient, thus we modified the per time step reward to -10. To make the task sensible in an average-reward setting, we do not restart when the goal area is reached, rather requiring the agent to learn to maintain this desired position.

A Gaussian kernel directly on pixel images would be very sensitive to even small shifts. A better choice is a kernel exponential in the squared difference between low-pass filtered images. To this end, we convolve the image with a Gaussian kernel of 20% of the image size. The same representation is also used for the other methods. Note, that methods based on neural networks would be able to learn this and other invariances, but this additional expressive power comes at the cost of many parameters that have to be learned. The image is finally down-scaled to 20×20 pixels to be able to reduce the size of a batch of images in working memory. This does not change much for non-parametric methods (as relative distance between images should stay roughly constant), and reduces the number of weights in neural network based methods. We again performed 10 separate trials for each method, using 15 iterations for REPS and an equivalent amount of training experiments for the other methods. In each iteration, 20 roll-outs were performed, retaining the roll-outs from the last 3 iterations in memory as before.

The methods under comparison were tuned as follows. For NP-REPS, we set the bandwidth of the value function to half the maximal pixel intensity and added a $l2$ regularizer $10^{-9}\boldsymbol{\alpha}^T\boldsymbol{\alpha}$ to Eq. (11) to avoid over-fitting as this yielded good empirical performance.

Other hyper-parameters were optimized as explained previously, with the bandwidth of all pixels for the model and policy tied together to speed up optimization. The KL-bound ϵ was again set to 0.5. For LSPI, we discretized the actions in horizontal and vertical directions to three values: the maximum in either direction or 0.

For the neural-network based methods, we started from the default values in the RLlab implementation (Duan et al., 2016). We adapted the batch size / epoch length to the 20 roll-outs performed per iteration. We manually tuned other parameters to maximize empirical performance. This procedure resulted in a KL bound of 0.05 for TRPO (much higher than the default, which is tuned for situations where a lot of data is available but the task is harder). For DDPG, we obtained a learning rate of 10^{-4} for both the Q function and policy, a minimum replay memory size of 1500 and a maximum memory size of 5000 and a batch size of 64 (the relatively high batch size made the method more sample efficient). For DDPG, we used a Gaussian exploration strategy with a decay period of 5000, as well as multi-layer perceptron for the Q function. We tried several convolutional and three-layer feed-forward architectures, and got best performance for two layers with 4 hidden units each for TRPO and two layers with 8 hidden units for DDPG.

3.6.1 Results of the Image-based Puddle World Experiment.

The performance of the compared methods is shown in Figure 4. The poor performance of the LSPI method directly on raw pixels indicates that the problem is non-linear. TRPO with a neural network policy learns relatively slowly (we tried higher learning rates, however, these made learning more unstable but did not yield higher average returns). In our experiments, TRPO needed at least 1000 roll-outs to converge to a good solution. DDPG with a neural network policy and Q function learns about as fast as NP-REPS, but yields high-variance results that tend to be slightly worse by the end of the experiment.

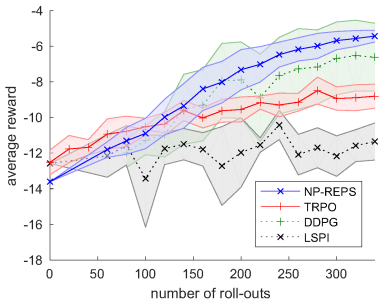

Figure 4: Results of the image-based puddle-world experiment. The RLlab version of DDPG only reports performance once the replay memory is initialized, so this graph starts after 80 roll-outs. Error bars show twice the standard error of the mean.

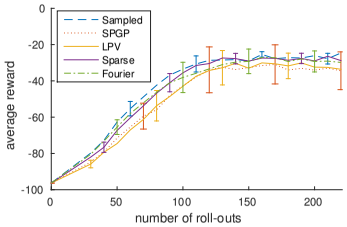
We want to stress two potential limitations of this experiment. First, difference between the compared methods might be due to either the representation of the policy and/or value function or the algorithm itself. Where NP-REPS uses kernel methods to represent the V function and the policy, TRPO and DDPG use neural networks. LSPI used a value function linear in the raw pixels with a greedy policy. Where in this experiment a non-parametric representation seems beneficial, in domains with visual distractors neural networks might do better. Secondly, this experiment evaluates how well TRPO and DDPG do in a situation with a low number of training roll-outs, whereas these methods are commonly used to work with a much higher number of roll-outs where they tend to do well.

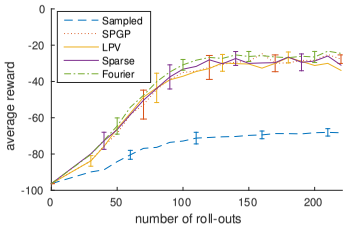
3.7 Approximation Experiment on the Swing-up Task

We evaluated different schemes for approximating the kernel matrix on the pendulum swing-up task described in Section 3.5. We do this by training policies using the various methods discussed in Section 3.3. The trade-off between accuracy and computational speed is defined by the number of inducing inputs for the sparse kernel methods, or by the number of random features used for the Fourier-transform based approximation. The number of features (respectively, inducing inputs) was varied to investigate the trade-off between approximation accuracy and computation speed. We measured the learning progress using the average reward, and additionally logged the time needed per iteration for each condition. We report the average time needed over 10 trials of 10 iterations.



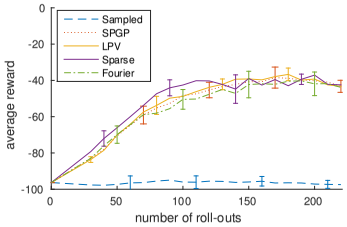
3.7.1 Results and Discussion of the Approximation Experiment.

A comparison of our results using different numbers of features is shown in Figure 5. In Figure 5a, all available inputs were used, and hence no approximation is needed. Thus, the sub-sampling method reduces to the original methods, and performs best. However, if the number of available bases is reduced to 500 (about one third of the available training points), just training on a sampled subset performs very badly, as shown in Figure 5b. In this set-up, the approximation based on a Fourier transform of the kernel seems the most suitable, both in terms of sample efficiency and of asymptotic average reward.

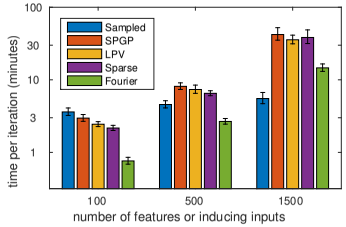


In Figure 5c, the available number of bases is reduced even more, to about 7% of the available training data. In this case, the regression-based sparsification method allows faster learning than the Fourier-based methods and both other sparsification methods, possibly because we used induced inputs $\tilde{y}$ that were optimal in a least-square sense. Considering that only 7% of the basis is available, the drop in performance relative to the full availability is modest.

Overall, the SPGP and LPV sparsification methods perform very similarly and yield similar asymptotic values as the regression-based sparsification methods. The main difference between these methods is the additional regularization term based on the approximation accuracy that Snelson and Ghahramani (2006) introduced. One of the main benefits of this additional regularization is a better behavior of the marginal likelihood for the purpose of optimizing the inducing input points (Snelson and Ghahramani, 2006). As we did not optimize for these points (as that would be too computationally costly to do inside the reinforcement-learning loop), our results seems plausible in this respect.



An indication of the time requirement of the different methods is given in Figure 5d. The implementations of the algorithms are not directly comparable, so drawing hard conclusions about the algorithms is not possible on the basis of this data. For example, cross-validation can be implemented using a fast decremental update of the matrix inverse only for the sub-sampled and Fourier-based methods. For the other sparsification methods, there is no straightforward way to implement this speed-up so these were trained using a 2-fold cross-validation setup (rather than using one fold for each trajectory, which would have been



(a) Different approximation methods using 1500 features or all available (on average 1500) inducing inputs.

(b) Different approximation methods using 500 features or inducing inputs.

(c) Different approximation methods using 100 features or inducing inputs.

(d) Time requirement of different approximation methods on a 2.7 GHz processor running in single threads, log scale.

Figure 5: Results of the evaluation of different approximation methods using different numbers of features. In all graphs, error bars indicate twice the standard error of the mean. The learning curves show error bars only for every fifth iteration to keep the figures interpretable. At a medium number of features (b), the Fourier-based random features deliver performance that is almost equal to the original algorithm, while requiring fewer computational resources (d). More computational resources can be saved by using only 100 features or inducing inputs, at the cost of a larger performance gap to the original algorithm (c).

even more expensive computationally). Therefore, these three methods ('SPGP', 'LPV', and 'Sparse') are slowest in cases with many available inducing inputs.

When all data is available, applying any approximation takes more time than the baseline 'sampling' method. However, the 'Fourier' method tends to be much faster when the number of features is reduced—one of the reasons for this effect is that in our implementation, calculated features are cached. This caching benefits feature-based approximations, but not kernel-based ones. Compared to using all available bases without approximating, the 'Fourier' method with 500 bases is about twice as fast at a similar level of performance.

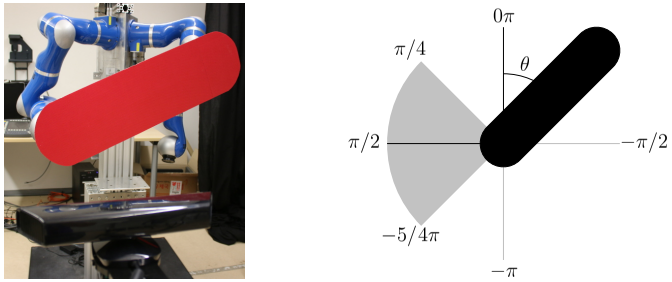
3.8 Real-Robot Swing-up Experiment from Vision Data

In this last experiment, we aim to validate our method on a real-robot task. We consider two scenarios: the learner either has access to the joint angles and velocity, or only to a redundant image-based representations of the state obtained through a camera pointed at the robot. Considering the time it takes to perform robot evaluations, and the wear to the robotic system, we provide a proof-of-concept of the proposed method without comparing to other methods.

3.8.1 Robot Set-up and System Dynamics.

To the end-effector of a Kuka light-weight robot arm, we attached a wooden rod with a mass of roughly 1kg and a length of roughly 80 cm. Red cardboard was used to make the pendulum visually salient. We aim to swing this rod up using the last degree-of-freedom, and limit the torque of the corresponding motor such that the pendulum cannot be swung up directly from the downwards position. This set-up is shown in Figure 6a.

A couple of characteristics of the robot system make the task different from the simulated pendulum swing-up task in the previous section. The robot link is limited in its range of motion to less than 2π and in its velocity to less than about $4.2/s$, whereas the simulation had no such limitation. To prevent the robot from moving hard into these limits, we add a feedback signal that stops the robot if it gets close to those limits for safety.[7] The joint limits are illustrated in Figure 6b.



To perform exploration on the real robot, another issue to address is that high jerk motions might damage the gearboxes. Therefore, instead of controlling the torque as in the previous experiments, we will control an increment to the torque. This increment will smoothly be added to the previous torque over the course of one time step. Controlling the increment, rather than directly controlling the torque, has the additional benefit that the applied torque tends to be more consistent over time, preventing 'washing out' of high-frequency control signals on the robot system. To preserve Markov properties, the previous torque has to be appended to the state vector. To provide comparable results over the different robot trials, instead of resetting the system randomly, we reset the system every 50 time steps to a set of ten different starting angles. The starting velocity and acceleration are set to zero.

3.8.2 Camera Set-up and Image Processing.

The camera provides video frames at a rate of about 30Hz, but this rate can fluctuate slightly during the experiments. To prevent synchronization issues between the camera and the control system, we let the arrival of camera images govern the time step length. Since we want to control the robot at about ten Hertz, we choose a new action whenever every third camera image is received. Consequently, not all torques are applied for the same duration, providing a source of transition noise.

To keep the amount of storage space and processing time limited, we down-sample the images to 15×20 pixels and reduce the image to a single channel (by subtracting the average brightness from the red channel value, since the color of the pendulum is red). The

7. The exact feedback signals used are given in Appendix C.

(a) (b)

Figure 6: The set-up of the real-robot swing-up experiment with redundant representation. (a) The robot set-up. One of the robot arms holds a pendulum which has a mass of about 1 kg and a length of about 80 cm. The Kinect camera in the foreground is used to provide feedback to the robot (proprioceptive joint information is not available to the robot). (b) An illustration of the set-up that illustrates the coordinate system used. As the image is shown from the camera's point of view, the coordinate system is inverted (clockwise θ). In the shaded area, an additional torque is applied to keep the robot from running into the joint limit at $\pi/2$.

image is blurred slightly with a low-pass filter to smooth out sensor noise, using a Gaussian kernel with a bandwidth of 6% of the image width. To provide the learner with a notion of velocity, the 15×20 pixel image and the 15×20 difference image to the previous time step were given to the robot as a concatenated 600-dimensional feature vector, as shown in Figure 7.

3.8.3 Employed Reward Function and Kernel.

In contrast to the earlier experiment, the real robot system is not periodic as it cannot turn the joint more than 2π. Consequently, we need a reward function that punishes the robot for getting too close to the joint limit. We use the reward function

$$r(\mathbf{s}, a) = \exp\left(-(1.5\theta)^2\right) - 2(\theta - 0.25)\,\mathbb{1}_{\{x \in \mathbb{R}: x > 0.25\}}(\theta) - 0.0005a^2,$$

where the first term rewards the robot for being close to the upright position and the second term penalizes the robot for being too close to the joint limit. All else being equal, we prefer solutions that do not needlessly change the torque, as jerky motion can damage the robots. Therefore, the third term penalizes large control actions.

As kernel on the state variables, we used a Gaussian kernel with three separate bandwidth parameters: one for all pixels of the current image, one for all pixels of the difference image, and one for the previously applied torque. The bandwidth parameters for all pixels of each image were tied together in this way to keep the hyper-parameter optimization manageable. For the learned transition model, the kernel on the action (torque increment) is again a squared exponential.

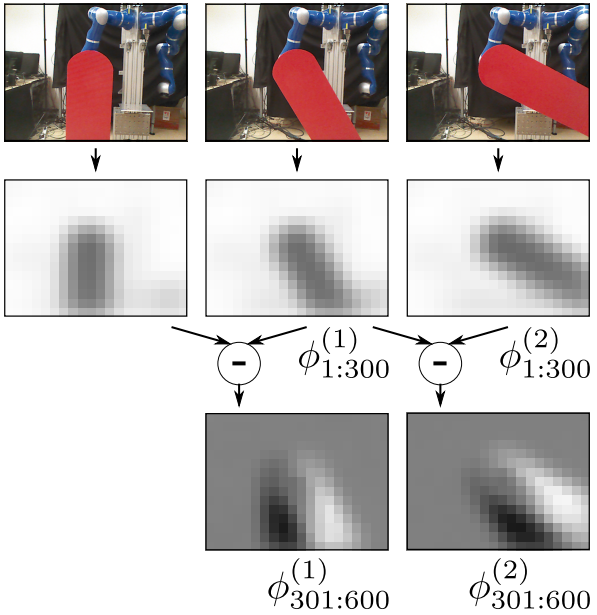


Figure 7: Sensor representation used by the robot. The Kinect camera image is downsampled into 15 by 20 pixels and converted to a single-channel image by subtracting the average intensity from the red channel values. From the resulting sequence of images, the current image and the difference between the current image and the previous image are concatenated with the previously applied torque, yielding a 601-dimensional feature vector.

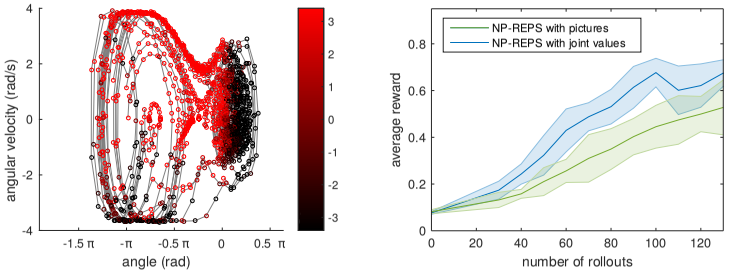
In this experiment, the heuristic for setting the bandwidth for the value function approximation according to the TD-error did not always work. Therefore, these three bandwidth parameters were set by hand to 0.5, 1.4, and 4.0, respectively, as these values allowed good prediction performance while being able to represent the value function with enough accuracy. The bandwidth parameters and other kernel parameters for the learned transition model and the policy were set automatically by maximizing the same cross-validation objectives used in the previous experiments. The bound on the KL divergence was set to $\epsilon = 0.8$.

We used the Fourier feature approximation to the full kernel matrix, as the simulation experiments showed these features to yield good performance with an intermediate number of bases while also requiring relatively little computation time. Furthermore, computing the features and evaluating the linear Bayesian policy is straightforward to implement on a robotic system and can run in real-time as it has relatively low computational demands. We used 1000 random basis features, as the system is intrinsically higher dimensional compared to the simulated pendulum swing-up experiment (as we appended the previously applied torque to the state vector).



Sometimes, a feasible solution to the dual optimization problem could not be found. We considered this effect could be due to over-fitting to the sensor noise in the camera that made the system partially observable. We addressed this issue by projecting the 1000-dimensional feature vectors on all principal components with principal values at least 5% of the maximum principal value for purpose of optimization of the dual function (Eq. 11) only. This procedure yielded between 100 and 200 components on our data set and addressed the problem satisfactorily. The dimension reduction also sped up the optimization of the dual function. Models and policies were still learned in the original 1000-dimensional spaces, as these steps contain regularization terms that make them robust to such over-fitting.

3.8.4 Results for the Real-robot Swing-up from Vision Data.

The results of the robot swing-up task are shown in Figure 8.[8] Of the six trials we performed, five resulted in policies that successfully swing-up and balance the pendulum. An example of the phase-space is shown in Figure 8a. It is apparent that the pendulum oscillates near the target position which occasionally causes the pendulum to drop. The pendulum-camera system has some system delay which could cause such oscillations, and which also prevents a finer time discretization.

Figure 8b shows the average learning progress for the task. The system learns from an initial uninformed policy that hardly obtains high rewards. Our result shows that non-parametric methods are a promising approach to dealing with redundant state representations such as images, since the task is successfully learned. Nevertheless, knowing a good representation, such as joint values, still resulted in better learning performance. Generally, many different representations could be used as long as a kernel yields appropriate similarity values can be defined that. In the end, the algorithm only performs operations based on those similarity values. Some pixels will never change their value. Such pixels are not problematic, as stationary kernels such as the squared exponential are not influenced by them.

8. A video illustrating the experiment and the results is available at `http://youtu.be/y00HJu2qcO0`.

(a) Phase-space trajectories with torque. (b) Learning progress over six trials.

Figure 8: Results of the real-robot experiment from vision data. (a) Phase-space trajectories of one of the learned policies. Color indicates the applied torque (Nm). In most trajectories, the robot manages to swing up the pendulum and balance it around the upright position ($\theta = 0$). Near this position, the pendulum tends to oscillate as a consequence of time discretization and system delays. (b) Learning progress with input from either joint angles or pictures only. The REPS algorithm would converge to a locally optimum solution regardless of input modality, but seems to need more training time to reach such a local optimum using visual input. The graph shows the average reward over six independent trials. Error bars show twice the standard error.

4. Related Work

Over the years, many different reinforcement learning (RL) algorithms have been proposed, as reviewed by, among others, Bertsekas and Tsitsiklis (1996); Szepesvári (2010); Sutton and Barto (1998); Busoniu et al. (2010); Powell (2007); Bartlett (2003); Kaelbling et al. (1996); Wiering and Otterlo (2012); and Deisenroth et al. (2013). Many of the most well-known algorithms are value-function methods. However, there is no notion of the sampled data or sampling policy in the value function, making it impossible to limit the loss of information as the policy is updated (Peters et al., 2010). Furthermore, in continuous state-action spaces, such methods need to be approximated, which means that policy iteration does not necessarily improve the policy (Kakade and Langford, 2002; Bartlett, 2003).

Policy search methods are a complementary class of reinforcement learning approaches, which explicitly represent the sampling policy (Deisenroth et al., 2013). Such methods might additionally represent a value function, e.g. (Williams, 1992; Peters and Schaal, 2008; Sutton and Barto, 1998), in which case they are referred to as actor-critic algorithms. Policy search methods allow the learning agent to take the sampled data or the sampling policy into account. Policy search methods offer other advantages: policies might be easier to represent than value functions and convergent algorithms for policy search are known (Bagnell and Schneider, 2003a). Furthermore, for certain policy parameterizations, stability guarantees can be given (Deisenroth et al., 2013). If prior knowledge or task demonstrations are available, these can usually be integrated straightforwardly in policy search methods (Deisenroth et al., 2013; Peters and Schaal, 2006). For these reasons, policy search methods have in practice proven to work well on real (e.g. robotic) systems (Deisenroth et al., 2013).

In high-dimensional domains, both value-function and policy search methods have often relied on hand-crafted feature representations (Kaelbling et al., 1996; Kober et al., 2013; Bartlett, 2003). This hand-tuning can largely be avoided by learning a suitable representation (Jonschkowski and Brock, 2015; Böhmer et al., 2013). Such an approach, however, often requires a lot of training data and usually relies on non-convex optimization. Defining a representation can also be side-stepped by using non-parametric methods (Ormoneit and Sen, 2002; Rasmussen and Kuss, 2003), that implicitly use very rich representations that can adapt to the complexity of the data. Such methods, however, have the disadvantage that they usually rely on inverting matrices that grow with the data set. As a solution, efficient approximations can be used (Seeger et al., 2003; Snelson and Ghahramani, 2006; Rahimi and Recht, 2007).

We discuss these issues in more detail in the remainder of this section. First, we discuss various RL methods that provide stable policy updates. Subsequently, we give an overview of different studies addressing RL with high-dimensional states, followed by a discussion of non-parametric RL techniques. Finally, we discuss various methods for efficiently approximating non-parametric methods that allow such methods to be applied to large data sets.

4.1 Policy Updates with Limited Information Loss.

Perhaps the most straightforward way to limit the information loss of a policy is to stay close to a previous policy. Policy gradient methods (Williams, 1992; Sutton et al., 1999), for example, limit the policy update $\delta\boldsymbol{\theta}$ to a step in the gradient direction of fixed Euclidean

length $\delta\boldsymbol{\theta}^T\delta\boldsymbol{\theta} = \epsilon$. However, this metric is not invariant to re-parametrization of the policy. This problem can be addressed by instead using the Fisher information metric $\mathbf{F}$ in the constraint $\delta\boldsymbol{\theta}^T\mathbf{F}(\boldsymbol{\theta})\delta\boldsymbol{\theta} = \varepsilon$, as suggested by Kakade (2002). This constraint can be interpreted as the second-order Taylor expansion of the loss of information (relative entropy) between the path distributions of the original and the updated policy (Bagnell and Schneider, 2003a).

There are two main approaches to specifying such an information constraint. As suggested by Bagnell and Schneider (2003a), the loss of information between successive path distributions might be bounded. Such a formulation is equivalent to bounding the expected loss of information between successive policies, since the transition dynamics are the same under both path distributions. In our previous work (Peters et al., 2010), we instead proposed to bound the information loss between successive state-action distributions.

The first formulation has led to various algorithms that provide stable policy updates. For example, the dynamic policy programming algorithm (Azar et al., 2011) uses the relative entropy between successive policies as an additional cost term in the value function. Similar update equations have been derived from two points of view. Firstly, from the point of view of maximizing the cumulative reward under constraints on the communication bandwidth or data processing capacity (Tishby and Polani, 2011), or, equivalently, minimizing the policy complexity under a constraint on the policy's value (Still and Precup, 2012). Another derivation minimizes the relative entropy from the trajectory distribution conditioned on obtaining maximal rewards to the proposed policy (Rawlik et al., 2013b). In these approaches, the trade-off between greedy exploitation and maintaining stable updates—analogous to the (inverse) temperature of a Boltzmann distribution—is a free parameter. To obtain convergence, an update schedule that decays the temperature over time has to be designed. In contrast to adding the relative entropy as a cost-term, Levine and Abbeel (2014) employ a bound on the relative entropy between successive policies.

Another line of work, that is related to bounding the divergence between successive policies, has focused on guaranteeing improvement of the policy by limiting the policy update. In conservative policy iteration (Kakade and Langford, 2002) and safe policy iteration (Pirotta et al., 2013), the updated policy is a mixture of the old policy and a greedy policy that maximized a lower bound on the policy improvement. Trust region policy optimization (Schulman et al., 2015) similarly guarantees policy improvement, using the relative entropy between successive policies in the lower bound.

Kober et al. (2013) observed that "in practice, reinforcement learning algorithms tend to work best for real systems when they are constrained to make modest changes to the distribution over states while learning". However, depending on the system dynamics, a small change in the policy might cause a large change in the distribution of states visited by the policy. Thus, it may be advantageous to limit the relative entropy between successive state-action distributions rather than between successive policies or trajectory distributions. Empirically, a bound on the state-action distribution has been shown to outperform a bound on the policy for relatively large step-sizes (Lioutikov et al., 2014). Moreover, bounding the information loss between subsequent state-action distributions has been shown to have optimal regret in an adversarial Markov decision process (MDP) settings for discrete finite horizon problems (Zimin and Neu, 2013).

In our previous work (Peters et al., 2010), the Relative Entropy Policy Search (REPS) algorithm was derived based on such a bound on the relative entropy between successive state-action distributions. Policies learned using REPS re-weight the previous state-action distribution using a soft-max of the advantage function. This soft-max policy is reminiscent of the common ad-hoc exploration-exploitation trade-off using Boltzmann exploration (Kaelbling et al., 1996; Sutton, 1990; Lin, 1993), expectation-maximization based updates (Peters and Schaal, 2007; Kober et al., 2011), and the previously discussed algorithms by Azar et al. (2011) and Rawlik et al. (2013b). The advantage of REPS is, that the 'temperature' parameter that governs exploration is set directly by the algorithm. As a result, the algorithm is invariant to re-scaling of the reward function, and the temperature automatically decreases as the policy converges.

Alternative techniques search an optimal policy within the space of policies of similar exponential form (Lever and Stafford, 2015; Bagnell and Schneider, 2003b). In REPS, the exponential form does not result from an imposed search-space of the policy, but is a direct consequence of solving the bounded optimization problem. Under specific assumptions on the environment and the reward functions, exponential transformations of the value functions are also used in the definition of the optimal policy in the non-parametric method by Rawlik et al. (2013a). The embedding of the exponentiated value function, however, suffers from numerical problems where the value function is low.

Earlier approaches based on the REPS formulation (Lioutikov et al., 2014; Kupcsik et al., 2013; Peters et al., 2010; Daniel et al., 2016) have shown to be successful on a variety of problems. In all these approaches, a function-valued Lagrangian multiplier V emerges from the resulting optimization problem, which can be seen as a value function (Peters et al., 2010). However, these approaches assume the Lagrangian multiplier V is linear in manually-defined features, making it hard to apply the algorithm to domains with high-dimensional non-linear sensor representations. We relaxed this assumption, by requiring V to be a member of a non-linear RKHS, allowing implicit infinite feature representations. In contrast to earlier approaches based on the REPS optimization problem, our method can naturally handle non-parametric policies, such as Gaussian process policies.

REPS requires the estimation of the Bellman error. This estimation can, for example, be performed using a learned transition model. Thus far, work on learned transition models for REPS has been limited. The transition dynamics have been approximated by deterministic single-sample outcomes (Daniel et al., 2016; Peters et al., 2010) which only works well for deterministic environments, or by time-dependent linear models (Lioutikov et al., 2014). Gaussian process models have been used in the bandit setting (Kupcsik et al., 2013) to learn a simulator that predicts the outcome of new roll-outs. Instead, similar to previous value function methods (Grünewälder et al., 2012b; Boots et al., 2013; Nishiyama et al., 2012), we will employ empirical conditional RKHS embeddings to obtain non-linear models for step-based reinforcement learning.

4.2 Reinforcement Learning for High-dimensional State Representations.

Recently, several researchers have started to address the problem of reinforcement learning with high-dimensional state representations such as camera images. In many of these works, learning consists of two fully separate steps: learning a representation and, subsequently,

learning a policy or value function. One possible approach is to view the problem as reducing the dimensionality of the high-dimensional states while losing as little information as possible. For such a purpose, deep neural networks such as deep auto-encoders have become popular. For example, Lange et al. (2012) and Mattner et al. (2012) used such networks to learn state representations that were subsequently exploited to learn visual tasks using fitted Q-iteration or non-parametric approximate dynamic programming, respectively. Finn et al. (2016) used spatial auto-encoders, that exploit the spatial coherence of images, to learn visual pushing tasks using guided policy search.

The discussed methods do not explicitly make use of the structure of reinforcement learning problems. In domains where salient sensory distractors occur, taking such structure into account can help avoid representing those distractors. Jonschkowski and Brock (2015) proposed a method that takes observed transitions and rewards into account using a set of robotic priors, to learn representations for, among others, a visual navigation task. Another way to take the dynamics into account is to use slow-feature analysis, which encodes diffusion distances based on the transition kernel (Böhmer et al., 2013). The learned representations were used in an LSPI approach to learn visual navigation. A visual navigation task was also addressed by Boots et al. (2011), who select features based on their ability to predict characteristics of possible future events. Forcing the dynamics to be linear in the latent space is another way of enforcing a task-relevant representation. Watter et al. (2015) showed this principle to be successful at learning representations for model-predictive control of several dynamical systems in an off-policy setting.

The goal of finding a state representation that takes the task structure into account can also be reached by directly learning neural network policies that map from high-dimensional sensory information to control actions (Levine et al., 2016). In this approach, the hidden neurons act as feature representation. As the network is trained to reproduce correct actions, those neurons are optimized to provide a representation that helps the learning agent succeed at its task. This method requires having a low-dimensional task representation available at train time. It guides the neural network training using locally optimized trajectories. Mnih et al. (2015) instead directly used a neural network as an approximate Q function, as such an approach is able to scale to large networks and data sets. Their method obtained superb performance on playing Atari games, but is limited to problems with a discrete set of actions. Other methods have used neural networks that represent policies and have achieved impressive results on simulated dynamical systems, including bipedal locomotion and a driving simulator (Schulman et al., 2015; Mnih et al., 2016; Lillicrap et al., 2016). These methods, however, tend to require data sets with a million transitions or more to achieve these results. Such large data sets are impractical to obtain for real physical systems, e.g., robots. Furthermore, all neural-network based learning methods rely on non-convex optimization of all the network weights.

4.3 Non-parametric Reinforcement Learning Methods.

Non-parametric kernel methods use an implicit representation of the data, and therefore avoid the explicit choice of a feature representation. Many different approaches in reinforcement learning have been re-formulated to use non-parametric methods. For example, non-parametric value iteration methods have been proposed for (partially observable) MDPs

(Grünewälder et al., 2012b; Nishiyama et al., 2012), and non-parametric approximate dynamic programming method have been proposed by Ormoneit and Sen (2002), Taylor and Parr (2009), Deisenroth et al. (2009), Kroemer and Peters (2011) and Xu et al. (2014). Engel et al. (2003) proposed a Gaussian process (GP) temporal difference algorithm, and furthermore, there are examples of non-parametric policy iteration schemes such as kernelized least-squares policy evaluation (Jung and Polani, 2007) and least-squares policy iteration (Xu et al., 2007; Rasmussen and Kuss, 2003). The approximate linear programming algorithm, proposed by Pazis and Parr (2011), does not use kernels. Instead, this model-free method assumes the value function is Lipschitz, and assumes deterministic dynamics. Such value function methods use greedy maximization with respect to approximated value functions. Consequentially, these methods use deterministic actions. If exploration of the state space is required, heuristics such as an ϵ-greedy or a soft-max policy can be used. Furthermore, Grünewälder et al. (2012b) and Nishiyama et al. (2012) consider only discrete action sets and assume the state-action space can be sampled uniformly. For robotic systems, this can generally only be done in simulation.

Policy-search methods can be applied to address these shortcomings, by iteratively improving a policy. Kober et al. (2011) introduced cost-regularized kernel regression, which finds non-parametric policies for contextual bandits. In contrast, other approaches have focused on step-based decision making. For example, Bagnell and Schneider (2003b) developed a policy gradient method embedding a desirability function that defines a policy in a RKHS. However, their approach is restricted to discrete actions, and as a model-free method, cannot exploit learnable system dynamics. More recently, Lever and Stafford (2015) introduced another policy gradient approach, which searches for the mean function of a Gaussian process policy within a RKHS. Although this method cannot represent non-Gaussian policies, unlike the method of Bagnell and Schneider (2003b), it can represent policies that are close to deterministic more easily. A disadvantage of this method is that a schedule to decay the co-variance of the Gaussian towards zero has to be manually defined. Vien et al. (2016) introduced a non-parametric variant of the natural policy gradient, together with a natural actor-critic algorithm and expectation-maximization based updates.

Alternative non-parametric methods were proposed by Rawlik et al. (2013a) and Deisenroth and Rasmussen (2011). The method by Rawlik et al. (2013a) considers continuous-time systems with continuous actions. This method assumes the environments injects observable control noise and that the system is control-affine. Deisenroth and Rasmussen (2011) describe a model-based iterative method. They explicitly marginalize the uncertain non-parametric model to avoid over-greedy optimization. However, their method requires the reward function to be known and to be of squared exponential form. Additionally, it selects actions greedily and so it does not address the exploration problem.

4.4 Efficient Approximation for Non-parametric RL Methods.

Kernel-based non-parametric methods usually require inverting Gram matrices, which are of dimension $n \times n$, where n is the number of data points. This step is a bottleneck for scaling up these methods to large data sets (1000 - 10000 samples being the upper limit where most of these methods start to be prohibitively slow). Therefore, non-parametric approaches benefit from efficient approximations for large data sets.

Multiple non-parametric RL algorithms handle large data sets by selecting a subset of data points, and then finding coefficients for each of the kernels using a quadratic programming problem (Engel et al., 2003; Xu et al., 2014; Jung and Polani, 2007; Xu et al., 2007; Lever and Stafford, 2015). In most cases, this sparsification approach results in an approximation of the kernel function by a non-stationary kernel function parametrized by a subset of active data-points, as pointed out by Jung and Polani (2007) and Xu et al. (2007). If all data-points were chosen to be active, this approximation would be exact.

A sparsification approach for the method of Ormoneit and Sen (2002) has been proposed by Barreto et al. (2011). The proposed stochastic factorization approach, however, works only on stochastic kernel matrices, such as used in Nadaraya-Watson kernel regression. Another approach for applying cost-regularized kernel regression to large data sets is to apply a learning algorithm to separate subsets of the data and combine the results (Macedo et al., 2014). However, as the authors state, this approximation is not mathematically equivalent to the original problem, and if, as suggested, data from multiple iterations is combined, the on-policy assumption of the algorithm would be violated.

Yet another method takes an approach complimentary to sparsification approaches. Whereas sparse Gaussian process approaches essentially find coefficients for the true kernel matrix at a subset of data points, Rahimi and Recht (2007) propose an approach that evaluates an approximation to the kernel function at all training data points. To the best of our knowledge, this type of approximations has, so far, not been explored in the context of reinforcement learning. This approach approximates the kernel function as an inner product of random Fourier features. As such, it is reminiscent of the work by Fard et al. (2013) and Ghavamzadeh et al. (2010), who use random projections for parametric value function methods. However, these studies aim at reducing the dimensionality of sparse or redundant features using random projections, the method of Rahimi and Recht (2007) is used to project low-dimensional vectors into high-dimensional feature spaces so that the function approximation problems become linear. Konidaris et al. (2011) employ Fourier basis features for value function approximation. The parameters of the basis features were predetermined whereas in our approach the parameters are drawn from a distribution based on the kernel bandwidth, which can be optimized using standard techniques.

5. Conclusion and Future Work

In this paper, we have developed a policy search method with smooth, robust updates to solve continuous MDPs. Our method uses learned non-parametric models and allows the use of non-parametric policies, avoiding hand-crafted features. By taking the sampling distribution into account during policy updates, stable learning progress was obtained even with relatively small batches of data. By embedding the conditional transition distribution, expectations over functions of the next state can be computed without density estimation. The resulting predictions are robust even with state representations with hundreds of dimensions.

We show that the resulting algorithm is able to outperform other non-parametric algorithms on a reaching task and a pendulum swing-up task with control noise in on-policy settings. We also show good performance of the proposed algorithm relative to neural-

network based methods on a variant of the puddle-world task with a redundant input representation.

A limiting factor in applying the method to larger problems is the computational cost of inverting the Gram matrix. To address this issue, we evaluated different approaches to approximate this matrix that allow the inverse to be calculated efficiently. We found the approximation of the kernel function using random Fourier features to have desirable properties: they are computationally fast, easy to implement, and yielded good performance for moderate numbers of basis features. Sparsification yielded better performance on a smaller set of basis functions.

We evaluated the applicability of the algorithm to a real-robot under-powered swing-up task, with 600-dimensional visual representations of the pendulum's state. Here, we found that our method could successfully learn policies that swing up and balance the pendulum, from high-dimensional data.

Many tasks concerning sensory data are similar to the real-robot under-powered swing-up task, in that they have a high extrinsic dimensionality, but are intrinsically low-dimensional. Kernel-based algorithms perform all operations on kernel values, so they are invariant to the extrinsic dimensionality. Our kernel-based RL algorithm can, thus, be applied to such tasks without a separate dimension reduction. However, underlying distractor dimensions would negatively impact kernel-based algorithms unless the kernel parameters would be set (by design or using learning techniques) to ignore those effects.

The proposed algorithm is designed with data scarcity in mind, and shows good empirical performance in such cases. However, even with the proposed approximation of the Gram matrix, the run-time of the algorithm can still be a limiting factor. As the complexity of learning problems grows, we need more data and more approximating features, increasing the computational requirements. Thus, the proposed algorithm is likely to be a good choice when obtaining samples is costly or restricted, but might not be the best choice when samples are cheap relative to computation time.

In future work, we want to investigate synergies between the optimization problem and the generalizing policy. We will also address hyper-parameter optimization in systems with multi-dimensional controls, as our current objective does not always yield suitable hyper-parameters. We plan to apply our algorithm on real-world robotic tasks, including tasks with high-dimensional visual or tactile sensors, and investigate how to exploit structural knowledge about dynamical systems in such tasks. To avoid the need to enhance visual salience, learning task-relevant kernels will be essential.

Acknowledgments

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007–2013) under grant agreements #610967 (TACMAN) and #270327 (CompLACS). Additionally, this project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement #645582 (RoMaNS). Part of this research has been made possible by the provision of compute time on the Lichtenberg cluster of the TU Darmstadt.

Appendix A. The Dual and its Derivatives

To obtain the dual function, we re-insert the state-action probabilities $p_\pi = \pi(\mathbf{a}|\mathbf{s})\mu_\pi(\mathbf{s})$ in the Lagrangian to obtain the dual

$$\begin{aligned}
g(\eta, V, \lambda) =& \lambda + \eta\epsilon + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[\delta(\mathbf{s},\mathbf{a},V) - \lambda - \eta \log \frac{p_\pi(\mathbf{s},\mathbf{a})}{q(\mathbf{s},\mathbf{a})}\right], \\
=& \lambda + \eta\epsilon + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[-\lambda + \lambda\right] + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\left[\delta(\mathbf{s},\mathbf{a},V) - \delta(\mathbf{s},\mathbf{a},V) + \eta\right], \\
=& \lambda + \eta\epsilon + \mathbb{E}_{p_\pi(\mathbf{s},\mathbf{a})}\eta \; \mathrm{d}\mathbf{a}\mathrm{d}\mathbf{s} = \lambda + \eta\epsilon + \eta = \eta\epsilon + \eta\log(Z), \\
=& \eta\epsilon + \eta \log\left(\mathbb{E}_{q(\mathbf{s},\mathbf{a})} \exp\left(\delta(\mathbf{s},\mathbf{a},V)/\eta\right)\right),
\end{aligned}$$

where we used that $\exp\left(-\lambda/\eta - 1\right) = Z^{-1}$, so $\lambda + \eta = \eta\log(Z)$. The expected value over q can straightforwardly be approximated by taking the average of samples $1, \ldots, n$ taken from q. Note that λ and q do not appear in the final expression.

$$g(\eta, V) = \eta\epsilon + \eta \log\left(\frac{1}{n}\sum_{i=1}^{n} \exp\left(\delta(\mathbf{s}_i,\mathbf{a}_i,V)/\eta\right)\right).$$

When employing the kernel embedding, the Bellman error is written as

$$\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) = \mathcal{R}_{\mathbf{s}_i}^{\mathbf{a}_i} + \boldsymbol{\alpha}^T(\mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)).$$

We define

$$w_i = \frac{\exp\left(\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha})/\eta\right)}{\sum_{i=j}^{n} \exp\left(\delta(\mathbf{s}_j,\mathbf{a}_j,\boldsymbol{\alpha})/\eta\right)}$$

to keep equations brief and readable. The partial derivatives can be written as:

$$\begin{aligned}
\frac{\partial g(\eta,\boldsymbol{\alpha})}{\partial \eta} =& -\frac{1}{\eta}\sum_{i=1}^{n} w_i\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) + \epsilon + \log\left(\frac{1}{n}\sum_{i=1}^{n}\exp\left(\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha})/\eta\right)\right), \\
\frac{\partial g(\eta,\boldsymbol{\alpha})}{\partial \boldsymbol{\alpha}} =& \sum_{i=1}^{n} w_i\left(\mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\right),
\end{aligned}$$

and furthermore, we obtain the Hessian:

$$\begin{aligned}
\mathbf{H}(g(\eta,\boldsymbol{\theta}) =& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\begin{bmatrix} -\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) \\ \mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\end{bmatrix}\begin{bmatrix} -\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) \\ \mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\end{bmatrix}^T\right) \\
& - \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\begin{bmatrix} -\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) \\ \mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\end{bmatrix}\right)\sum_{i=1}^{n}\left(w_i\begin{bmatrix} -\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) \\ \mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\end{bmatrix}\right)^T.
\end{aligned}$$

The Hessian of a function is positive semi-definite on a set if and only if the function is convex on that set. Since η is the Lagrange multiplier for an inequality constraint, we have $\eta \geq 0$.To show that $\mathbf{H}(g(\eta,\boldsymbol{\theta}))$ is positive semi-definite on $(\eta,\theta) \in [0,+\infty) \times \mathbb{R}^n$ we introduce the following abbreviation:

$$\mathbf{u}_i = \begin{bmatrix} -\delta(\mathbf{s}_i,\mathbf{a}_i,\boldsymbol{\alpha}) \\ \mathbf{K}\beta(\mathbf{s}_i,\mathbf{a}_i) - \mathbf{k}_\mathrm{s}(\mathbf{s}_i)\end{bmatrix}^T.$$

Now, we can re-write the Hessian

$$\begin{aligned}
\mathbf{H}(g(\eta,\boldsymbol{\alpha})) =& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\mathbf{u}_i\mathbf{u}_i^T\right) - \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\mathbf{u}_i\right)\sum_{i=1}^{n}\left(w_i\mathbf{u}_i\right)^T \\
=& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\mathbf{u}_i\mathbf{u}_i^T\right) - \frac{2}{\eta}\sum_{i=1}^{n}\left(w_i\mathbf{u}_i\right)\sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)^T \\
&+ \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\right)\sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)\sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)^T \\
=& \frac{1}{\eta}\sum_{i=1}^{n} w_i\left(\mathbf{u}_i\mathbf{u}_i^T - 2\mathbf{u}_i\sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)^T + \sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)\sum_{j=1}^{n}\left(w_j\mathbf{u}_j\right)^T\right) \\
=& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)^T\right).
\end{aligned}$$

Note that we have used the property that $\sum_{i=1}^{n} w_i = 1$. $\mathbf{H}$ is positive semi-definite if $\mathbf{a}^T\mathbf{H}\mathbf{a} \geq 0$ for any $\mathbf{a}$.

$$\begin{aligned}
\mathbf{a}^T\mathbf{H}\mathbf{a} =& \mathbf{a}^T\left(\frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)^T\right)\right)\mathbf{a} \\
=& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\mathbf{a}^T\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)\left(\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{u}_j\right)^T\mathbf{a}\right) \\
=& \frac{1}{\eta}\sum_{i=1}^{n}\left(w_i\left(\mathbf{a}^T\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{a}^T\mathbf{u}_j\right)^2\right).
\end{aligned}$$

The factors $\left(\mathbf{a}^T\mathbf{u}_i - \sum_{j=1}^{n} w_j\mathbf{a}^T\mathbf{u}_j\right)^2$ are squares of real numbers and thus non-negative. Since the w_i are the result of a soft-max operation and thus non-negative, this holds for the weighted sum, too. Thus, for any $\eta \geq 0$, $\mathbf{a}^T\mathbf{H}\mathbf{a} \geq 0$ and g is convex.

Appendix B. Optimization with Respect to V

We want to show that at least one of the functions V minimizing the dual functional g can be represented using a weighted sum of kernel functions centered at the sample states, i.e., that

$$V^* = \sum_{\tilde{\mathbf{s}}\in\tilde{\mathcal{S}}} \alpha_{\tilde{\mathbf{s}}} k_{\mathrm{s}}(\tilde{\mathbf{s}},\cdot), \tag{18}$$

where $\tilde{\mathcal{S}}$ is the set of states samples during the roll-outs. We follow some steps in the proof of Schölkopf et al. (2001). They consider arbitrary objective functions c mapping to $\mathbb{R}\cup\{\infty\}$ of the form

$$c((\mathbf{s}_1, y_1, V(\mathbf{s}_1)), \ldots, (\mathbf{s}_m, y_m, V(\mathbf{s}_m))), \tag{19}$$

which can represent an error function between the value of a function $V(\mathbf{s})$ at the samples $\mathbf{s}_i$ and the corresponding desired outputs y_i. In our case, we do not have desired output values y_i for our objective function. This is inconsequential as c can be arbitrary, and so can be independent of all y values.

Any function V can be written as $V = \sum_{\tilde{\mathbf{s}}\in\tilde{\mathcal{S}}} \alpha_{\tilde{\mathbf{s}}} k_{\mathrm{s}}(\tilde{\mathbf{s}},\cdot) + v(\mathbf{s})$, where $v(\mathbf{s})$ is an additional bias term. If V is constrained to be in the Hilbert space defined by k, Schölkopf et al. [2001] show that c is independent of the bias term $v(\mathbf{s})$. This means that for any optimal V' that is not of the proposed form, there is a V^* of the proposed form that has the same objective value which is obtained by subtracting $v(\mathbf{s})$ from V'.

As the dual function g satisfies the conditions to cost function c, for us this means that there is at least one V^* optimizing g of the proposed form. Note that it is inconsequential that the dual g also depends on Lagrangian parameter η. For any optimum $(\eta^*, V^{*\prime})$, if $V^{*\prime}$ is not of the proposed form, projecting $V^{*\prime}$ on the proposed basis yields another function V^* that satisfies $g(\eta^*, V^{*\prime}) = g(\eta^*, V^*)$, so (η^*, V^*) must be an optimum as well.

Therefore, there is always at least one minimum of any such function c of the proposed form.

Appendix C. Feedback signals to avoid joint angle and velocity limits

In our real robot set-up, the control action selected by the algorithm is the increment in the torque to be applied. However, to avoid running into joint angle and velocity limits, the resulting torque is modified when these limits are approached. Therefore, the torque applied at time step t

$$\tau^{(t+1)} = \max\left(\min\left(\tau_t + u + \tau_{\mathrm{s}}^{(t)} + \tau_{\mathrm{d}}^{(t)}, \tau_{\max}^{(t)}\right), \tau_{\min}^{(t)}\right),$$

where $\tau_{\mathrm{s}}^{(t)}$ and $\tau_{\mathrm{s}}^{(d)}$ terms that act as spring and damper when the robot gets close to the joint limit, and $\tau_{\max}^{(t)}$ and $\tau_{\min}^{(t)}$ are the maximum and minimum torque, respectively, that can be applied without breaking the velocity limit. The definition of θ, as well as the joint limit and the area where the feedback terms are applied, are illustrated in Figure 6b.

The feedback terms are defined as follows. The spring-like term

$$\tau_{\mathrm{s}}^{(t)} = \begin{cases} 0 & \text{if } -5/4\pi < \theta < 1/4\pi, \\ 15(-5/4\pi - \theta) & \text{if } \theta < -5/4\pi, \\ 15(1/4\pi - \theta) & \text{if } 1/4\pi < \theta, \end{cases}$$

is applied whenever the joint gets close to the joint limit at $1/2\pi = -3/2\pi$. The damper-like term

$$\tau_{\mathrm{d}}^{(t)} = \begin{cases} 0.3(-5/4\pi - \theta)\dot{\theta} & \text{if } \theta < -5/4\pi \text{ and } \dot{\theta} > 0, \\ 0.3(1/4\pi - \theta)\dot{\theta} & \text{if } 1/4\pi < \theta \text{ and } \dot{\theta} < 0, \\ 0 & \text{otherwise}, \end{cases}$$

is applied in the same region, as the feedback has to be higher when the pendulum has a high velocity. To prevent the velocity from exceeding the velocity limit, additionally, the minimum and maximum torques

$$\tau_{\max}^{(t)} = \min\left(\tau_{\max}^{(t-1)} + 0.05, 20(3.85 - \dot{\theta}) + 4.5\cos(\theta)\right),$$

$$\tau_{\min}^{(t)} = \max\left(\tau_{\min}^{(t-1)} - 0.05, 20(-3.7 - \dot{\theta}) + 4.5\cos(\theta)\right),$$

are applied. The cosine term is a rough compensation for the torque induced by gravity. The term linear in $\dot{\theta}$ is a linear damping term. Furthermore, the system has some delays which tended to induce oscillations close to the maximum torque. Therefore, the maximum (respectively minimum) can only be increased (decreased) by a small amount relative to the previous value.
