$$\text{where } R := \sup_{\theta\in\mathbb{R}, \|\boldsymbol{v}\|=1} |g'_{\boldsymbol{v}}(\theta)|. \tag{6}$$

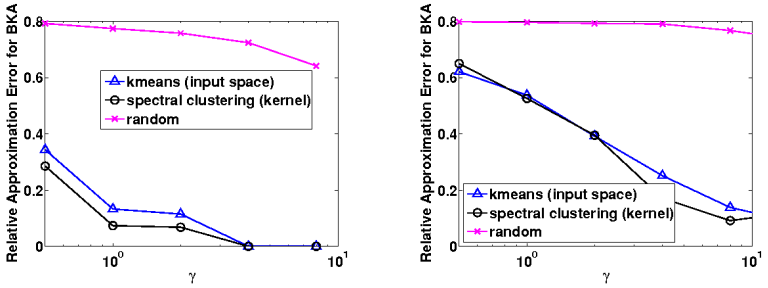
Squaring both sides of (5) we have

$$f(\boldsymbol{0})^2 \leq K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2 + \eta^2 R^2 \|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2 + 2K(\boldsymbol{x}_i, \boldsymbol{x}_j)(\eta R\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2).$$

From the classical arithmetic and geometric mean inequality, we can upper bound the last term by

$$2K(\boldsymbol{x}_i, \boldsymbol{x}_j)(\eta R\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2) \leq K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2 + \eta^2 R^2 \|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2,$$

therefore



$$\frac{f(\boldsymbol{0})^2}{2} \leq K(\boldsymbol{x}_i, \boldsymbol{x}_j)^2 + \eta^2 R^2 \|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2. \tag{7}$$

Plugging (7) into (3), we have

$$\begin{aligned} \mathcal{D}^{\text{kernel}}(\{\mathcal{V}_s\}_{s=1}^c) &\geq \sum_{s=1}^{c} \frac{1}{|\mathcal{V}_s|} \sum_{i,j\in\mathcal{V}_s} \left(\frac{f(\boldsymbol{0})^2}{2} - \eta^2 R^2 \|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2 \right) \\ &\geq \frac{nf(\boldsymbol{0})^2}{2} - \eta^2 R^2 \sum_{s=1}^{c} \frac{1}{|\mathcal{V}_s|} \sum_{i,j\in\mathcal{V}_s} \|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2, \end{aligned}$$

which can be manipulated to prove the desired bound (4). ■

Interestingly, the right hand side of (4) can be maximized when the k-means objective function D^{kmeans} is minimized. Therefore, although optimal solutions for k-means and ratio association might be different (consider the two circles data, when each circle forms a cluster), Theorem 1 shows that conducting k-means in the input space will provide a reasonably good way to exploit the clustering structure of shift-invariant kernels, especially when it is infeasible to perform spectral clustering on G which might need precomputation of the entire kernel matrix. Figure 2 shows that the partition from k-means can often work as well as spectral clustering on G, which directly optimizes D^{kernel}, and both of them are much better than random partitions. One advantage of conducting k-means is that the time complexity of each iteration is $O(ndc)$, which is much less than computing the kernel when the dimensionality $d \ll n$.

(a) covtype (b) cadata

Figure 2: The Gaussian kernel approximation error of BKA using different ways to generate five partitions on 500 samples from covtype and cadata; on these data sets k-means in the input space performs similarly to spectral clustering on the kernel matrix, but is more efficient.

4.2 Speeding up Kernel SVM with BKA

In this section we will show how to use block kernel approximation(BKA) to divide kernel SVM problem into subproblems and significantly speed up the computation. Given a set of instance-label pairs $(\boldsymbol{x}_i, y_i), i = 1, \ldots, n, \boldsymbol{x}_i \in \mathbb{R}^d$ and $y_i \in \{1, -1\}$, the main task in training the kernel SVM is to solve the following quadratic optimization problem:

$$\min_{\boldsymbol{\alpha}} f(\boldsymbol{\alpha}) = \frac{1}{2}\boldsymbol{\alpha}^T Q \boldsymbol{\alpha} - \boldsymbol{e}^T \boldsymbol{\alpha}, \text{ s.t. } 0 \le \boldsymbol{\alpha} \le C, \tag{8}$$

where $\boldsymbol{e}$ is the vector of all ones; C is the balancing parameter between loss and regularization in the SVM primal problem; $\boldsymbol{\alpha} \in \mathbb{R}^n$ is the vector of dual variables; and Q is an $n \times n$ matrix with $Q_{ij} = y_i y_j G_{ij}$, where $G_{ij} = K(\boldsymbol{x}_i, \boldsymbol{x}_j)$ is the kernel value between i-th and j-th sample. Letting $\boldsymbol{\alpha}^*$ denote the optimal solution of (8), the decision value for a test data $\boldsymbol{x}$ can be computed by

$$\sum_{i=1}^{n} \alpha_i^* y_i K(\boldsymbol{x}, \boldsymbol{x}_i). \tag{9}$$

Due to high computation cost of directly solving kernel SVM, we can approximate the kernel matrix G by BKA to divide whole kernel SVM problem into subproblems, where each subproblem can be handled efficiently and independently.

To do this, we first partition the dual variables into k subsets $\{\mathcal{V}_1, \ldots, \mathcal{V}_k\}$, where $\{\mathcal{V}_1, \ldots, \mathcal{V}_k\}$ are partitions generated by performing kmeans on the data points, and then solve the respective subproblems independently

$$\min_{\boldsymbol{\alpha}_{(c)}} \frac{1}{2}(\boldsymbol{\alpha}_{(c)})^T Q_{(c,c)} \boldsymbol{\alpha}_{(c)} - \boldsymbol{e}^T \boldsymbol{\alpha}_{(c)}, \text{ s.t. } 0 \le \boldsymbol{\alpha}_{(c)} \le C, \tag{10}$$

where $c = 1, \ldots, k$, $\boldsymbol{\alpha}_{(c)}$ denotes the subvector $\{\alpha_i \mid i \in \mathcal{V}_c\}$ and $Q_{(c,c)}$ is the submatrix of Q with row and column indexes $\mathcal{V}_c$.

dataset	Number of training samples	Number of testing samples	d
ijcnn1	49,990	91,701	22
census	159,619	39,904	409
covtype	464,810	116,202	54

Table 1: Dataset statistics

The quadratic programming problem (8) has n variables, and takes at least $O(n^2)$ time to solve in practice. By dividing it into k subproblems (10) with equal sizes, the time complexity for solving the subproblems can be reduced to $O(k \cdot (\frac{n}{k})^2) = O(n^2/k)$. Moreover, the space requirement is also reduced from $O(n^2)$ to $O(n^2/k^2)$.

After computing all the subproblem solutions, we concatenate them to form an approximate solution for the whole problem $\bar{\boldsymbol{\alpha}} = [\bar{\boldsymbol{\alpha}}_{(1)}, \ldots, \bar{\boldsymbol{\alpha}}_{(k)}]$, where $\bar{\boldsymbol{\alpha}}_{(c)}$ is the optimal solution for the c-th subproblem.

4.3 Comparing BKA-SVM with Low-rank Kernel SVM Solvers(BKA-SVM)

We now compare block structure based kernel SVM solver–BKA-SVM with low-rank structure based kernel SVM solvers. All the experiments are conducted on an Intel 2.66GHz CPU with 8G RAM. We use 3 benchmark datasets as shown in Table 1. The thee datasets can be downloaded from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets` or the UCI data repository. We use a random 80%-20% split for covtype, and the original training/testing split for other datasets.

4.3.1 Competing Methods

We include the following exact kernel SVM solvers (LIBSVM), approximate low-rank SVM solvers (LLSVM, FastFood) in our comparison:

1. LIBSVM: the implementation in the LIBSVM library (Chang and Lin, 2011) with a small modification to handle SVM without the bias term – we observe that LIBSVM has similar test accuracy with/without bias. We also include the results for using LIBSVM with random 1/5 subsamples on each dataset in Table 2.

2. LLSVM: improved Nyström method for nonlinear SVM by (Wang et al., 2011). We solve the resulting linear SVM problem by the dual coordinate descent solver in LIBLINEAR (Hsieh et al., 2008).

3. FastFood: use random Fourier features to approximate the kernel function (Le et al., 2013). We solve the resulting linear SVM problem by the dual coordinate descent solver in LIBLINEAR.

Both LLSVM and FastFood use low-rank representation to approximate kernel matrix so that to speed up solving kernel SVM.

LLSVM	38	98.23	1212	92.8	4451	84.21
FastFood	87	95.95	851	91.6	8550	80.1

Table 2: Comparison on real datasets using the RBF kernel.

4.3.2 Parameter Setting

We consider the RBF kernel $K(\boldsymbol{x}_i, \boldsymbol{x}_j) = \exp(-\gamma\|\boldsymbol{x}_i - \boldsymbol{x}_j\|_2^2)$. We use same kernel function for both training and test phases. We chose the balancing parameter C and kernel parameter γ by 5-fold cross validation on a grid of points: $C = [2^{-10}, 2^{-9}, \ldots, 2^{10}]$ and $\gamma = [2^{-10}, \ldots, 2^{10}]$ for ijcnn1, census, and covtype. For BKA-SVM, we set the number of clusters to be 64 for these three datasets. There is a tradeoff between the number of clusters and prediction accuracy. If we increase the number of clusters, BKA-SVM will become faster, but the prediction accuracy will mostly decrease. On the other hand, if the number of clusters is set smaller, BKA-SVM can achieve higher accuracy (in most cases), while takes more time to train. The following are parameter settings for other methods in Table 2: the rank is set to be 3000 in LLSVM; number of Fourier features is 3000 in Fastfood[1]; the tolerance in the stopping condition for LIBSVM is set to 10^{-3} (the default setting of LIBSVM).

Tables 2 present time taken and test accuracies. Experimental results show that the BKA-SVM achieves near-optimal test performance. Also we observe that BKA-SVM performs better than low-rank approximation based methods for kernel SVM problem showing the benefit of using block structure of kernel matrix.

We can see that BKA exploits the block structure of kernel matrix, and can speed up the training of kernel SVM. As shown in Tandon et al. (2016), BKA can also be used for speeding up kernel ridge regression problem. About the memory requirement, which is the main theme of this paper, BKA takes $O(\frac{n^2}{k})$ memory to approximate the kernel matrix, while popular low-rank based kernel approximation methods are more memory efficient, and only need linear memory to represent the kernel matrix.

5. Memory Efficient Kernel Approximation

There are two main drawbacks of the BKA approach: (i) it ignores all off-diagonal blocks, which results in large error when η is small (as seen in Figure 1(c)); (ii) for large-scale kernel approximation, it is too expensive to compute and store all the diagonal block entries. To

1. In Fastfood we control the number of blocks so that number of Fourier features is close to 3000 for each dataset.

overcome these two drawbacks, we propose to use low-rank representation for each block in the kernel matrix.

5.1 Low Rank Structure of Each Block

To motivate the use of low-rank representation in our proposed method, we first present the following bound:

Theorem 2 *Given data points $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n \in \mathbb{R}^d$, and a partition $\mathcal{V}_1, \ldots, \mathcal{V}_c$, and assume f is Lipschitz continuous, then for any s, t ($s = t$ or $s \neq t$)*

$$\|G^{(s,t)} - G_k^{(s,t)}\|_F \leq 4Ck^{-1/d}\sqrt{|\mathcal{V}_s||\mathcal{V}_t|}\min(r_s, r_t),$$

where $G_k^{(s,t)}$ is the best rank-k approximation to $G^{(s,t)}$; C is the Lipschitz constant of the shift-invariant function f; r_s is the radius of the s-th cluster.

Proof To prove this theorem, we use the ϵ-net theorem in (Cucker and Smale, 2001), which states that when all the data $\boldsymbol{x}_i \in \mathbb{R}^d$, $i = 1, \cdots, n$ are in a ball with radius r, there exist $T = (\frac{4r}{\bar{r}})^d$ balls of radius $\bar{r}$ that cover all the data points. If we set T to be k, then $\bar{r} = k^{-1/d}4r$.

Let $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{n_s}$ be the data points in the s-th cluster, and let $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_{n_t}$ be the data points in the t-th cluster, and $n_s = |\mathcal{V}_s|, n_t = |\mathcal{V}_t|$. Our goal is to show that $G^{(s,t)}$ is low-rank, where $G_{i,j}^{(s,t)} = K(\boldsymbol{x}_i, \boldsymbol{y}_j)$. Assume r_t is the radius of the t-th cluster, therefore we can find k balls with radius $\bar{r} = k^{-1/d}4r_t$ to cover $\{\boldsymbol{y}_j\}_{j=1}^{n_t}$.

Assume centers of the balls for t-th cluster are $\boldsymbol{m}_1, \boldsymbol{m}_2, \ldots, \boldsymbol{m}_k$, then we can form a low-rank matrix $\bar{G}^{(s,t)} = \bar{U}\bar{V}^T$, where for all $i = 1, \ldots, n_s, j = 1, \ldots, n_t$, and $q = 1, \ldots, k$,

$$\bar{U}_{i,q} = K(\boldsymbol{x}_i, \boldsymbol{m}_q) \text{ and } \bar{V}_{j,q} = \begin{cases} 1 & \text{if } \boldsymbol{y}_j \in Ball(\boldsymbol{m}_q), \\ 0 & \text{otherwise.} \end{cases}$$

Assume $\boldsymbol{y}_j$ is in ball q, then

$$\begin{aligned}(G_{ij}^{(s,t)} - \bar{G}_{ij}^{(s,t)})^2 &= (f(\boldsymbol{x}_i - \boldsymbol{y}_j) - f(\boldsymbol{x}_i - \boldsymbol{m}_q))^2 \\ &\leq C^2\|(\boldsymbol{x}_i - \boldsymbol{y}_j) - (\boldsymbol{x}_i - \boldsymbol{m}_q)\|^2 \\ &= C^2\|\boldsymbol{y}_j - \boldsymbol{m}_q\|_2^2 \\ &\leq C^2\bar{r}^2.\end{aligned}$$

Therefore, if $(G^{(s,t)})^*$ is the best rank-k approximation for $G^{(s,t)}$, then

$$\|G^{(s,t)} - (G^{(s,t)})^*\|_F \leq \|G^{(s,t)} - \bar{G}^{(s,t)}\|_F \leq Ck^{-1/d}4r_t\sqrt{n_s n_t}. \tag{11}$$

Similarly, by covering s-th cluster $\{\boldsymbol{x}_i\}_{i=1}^{n_s}$ with k balls we can get the following inequality:

$$\|G^{(s,t)} - (G^{(s,t)})^*\|_F \leq Ck^{-1/d}4r_s\sqrt{n_s n_t}. \tag{12}$$

Combining (11) and (12) gives the results. ■

(b) a random partition.

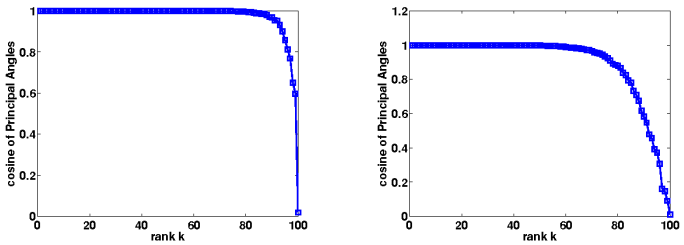

Table 3: Rank of each of the 5 blocks (from a subsampled ijcnn1 data set) using different partition strategies: (a) by k-means clustering; (b) by a random partition.

Theorem 2 suggests that each block(diagonal or off-diagonal block) of the kernel matrix will be low-rank if we find the partition by k-means in the input space and the radius of the cluster is small. In the following we present empirical confirmation of this result. In Table 3, we present the numerical rank of each block, where numerical rank for a m by n matrix A is defined as the number of singular values with magnitude larger than $\max(n,m)\|A\|_2\delta$ where δ is a small tolerance 10^{-6}. We sample 4000 data points from the ijcnn1 dataset and generate 5 clusters by k-means and random partition. Table 3a shows the numerical rank for each block using k-means, while Table 3b shows the numerical rank for each block when the partitions are random. We observe that by using k-means, the rank of each block is fairly small.

5.2 Memory Efficient Kernel Approximation (MEKA)

Based on the above observation, we propose a fast and memory efficient scheme to approximate shift-invariant kernel matrices. As suggested by Theorem 2, each block tends to be low-rank after k-means clustering; thus we can form a rank-k approximation for each of the c^2 blocks separately to achieve low error; however, this approach would require $O(cnk)$ memory, which can be prohibitive. Therefore, our proposed method first performs k-means clustering, and after rearranging the matrix according to clusters, it computes the low-rank basis only for diagonal blocks (which are more dominant than off-diagonal blocks) and uses them to approximate off-diagonal blocks. Empirically, we observe that the principal angles between the dominant singular subspaces of diagonal block and off-diagonal block are small (as shown in Figure 3). In Figure 3, we randomly sampled 1000 data points from the covtype and ijcnn1 datasets and generated 5 clusters by k-means for each dataset. The blue line shows the cosines of the principal angles between the dominant singular subspace of a diagonal block $G^{(s,s)}$ and that of an off-diagonal block $G^{(s,t)}$ for different ranks k, where s and t are randomly chosen. We can observe that most of the cosines are close to 1, showing that there is substantial overlap between the dominant singular subspaces of the diagonal and off-diagonal block.

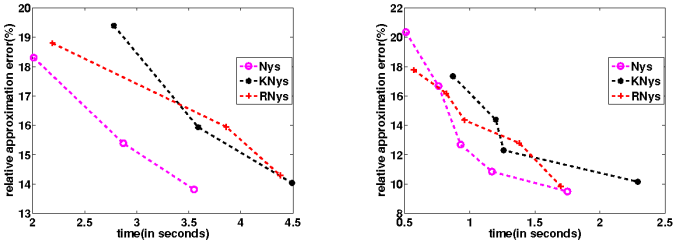
By using our proposed approach, we focus on diagonal blocks, and spend less effort on the off-diagonal blocks. Assume the rank-k_s approximation of the s^{th} diagonal block is

(a) covtype (b) ijcnn1

Figure 3: The cosines of the principal angles between the dominant singular subspaces of diagonal block and off-diagonal block of a Gaussian kernel ((a): $\gamma = 0.1$ and 1000 random samples from covtype; (b): $\gamma = 1$ and 1000 random samples from ijcnn1) with respect to different ranks. The cosines of the principal angles are close to 1 showing that two subspaces are similar.

$W^{(s)}L^{(s,s)}(W^{(s)})^T$, we form the following memory-efficient kernel approximation:

$$\tilde{G} = WLW^T, \tag{13}$$



where W is a diagonal matrix as

$$W \equiv \begin{bmatrix} W^{(1)} & 0 & \dots & 0 \\ 0 & W^{(2)} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & W^{(c)} \end{bmatrix}; \tag{14}$$

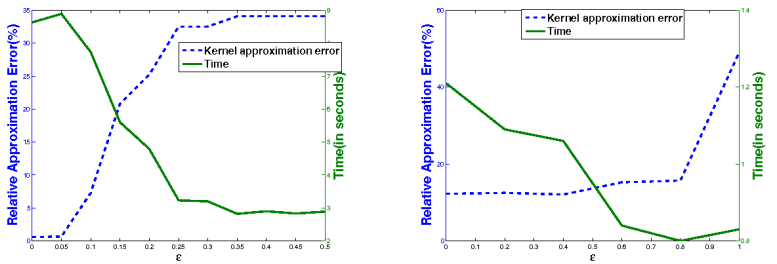
and L is a "link" matrix consisting of c^2 blocks, where each $k_s \times k_t$ block $L^{(s,t)}$ captures the interaction between the s^{th} and t^{th} clusters. For now, let us first assume $k_s = k\ \forall s$ (we will discuss different strategies to choose k_s later). Note that if we were to restrict L to be a block diagonal matrix, $\tilde{G}$ would still be a block diagonal approximation of G. However, we consider the more general case that L is dense. In this case, each off-diagonal block $G^{(s,t)}$ is approximated as $W^{(s)}L^{(s,t)}(W^{(t)})^T$, and this approximation is memory efficient as only $O(k^2)$ additional memory is required to represent the (s,t) off-diagonal block. If a rank-k approximation is used within each cluster, then the generated approximation has rank ck, but only needs a total of $O(nk + (ck)^2)$ storage.

Computing $W^{(s)}$. Since we aim to deal with dense kernel matrices of huge size, we use the standard Nyström approximation to compute low-rank "basis" for each diagonal block. When applying the standard Nyström method to a $n_s \times n_s$ block $G^{(s,s)}$, we sample m columns from $G^{(s,s)}$, evaluate their kernel values, compute the rank-k pseudo-inverse of an $m \times m$ matrix, and form $G^{(s,s)} \approx W^{(s)}L^{(s,s)}(W^{(s)})^T$. The time required per block is $O(n_s m(k+d) + m^3)$, and thus our method requires a total of $O(nm(k+d) + cm^3)$ time to form W. We can replace Nyström by any other low-rank approximation method discussed

in Section 2. In Figure 4 we compare using standard Nyström(Nys)(Williams and Seeger, 2001), k-means Nyström(KNys)(Zhang and Kwok, 2010), and Nyström with randomized SVD(RNys)(Li, Kwok, and Lu, 2010) to generate $W^{(s)}$ on both ijcnn1 and cadata datasets. As shown in Figure 4, we observe that the standard Nyström method combined with MEKA gives excellent performance.

(a) ijcnn1 (b) cadata

Figure 4: Comparison of using Nys, KNys, and RNys to obtain the basis $W^{(s)}$ for diagonal blocks in MEKA on ijcnn1 and cadata datasets. The x-axis shows the computation time and y-axis shows the relative kernel approximation error(%).



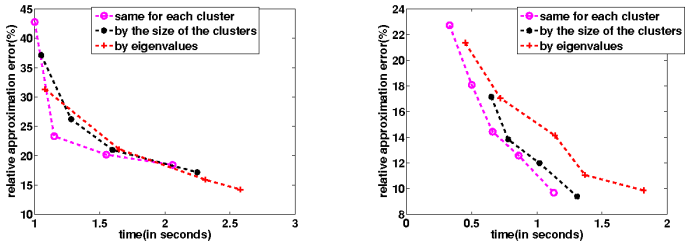
Computing $L^{(s,t)}$. The optimal least squares solution for $L^{(s,t)}(s \neq t)$ is the minimizer of the local approximation error $\|G^{(s,t)} - W^{(s)}L^{(s,t)}(W^{(t)})^T\|_F$. However, forming the entire $G^{(s,t)}$ block can be time consuming. For example, computing the whole kernel matrix for mnist2m with 2 million data points takes more than a week. Therefore, to compute $L^{(s,t)}$, we propose to randomly sample a $(1+\rho)k \times (1+\rho)k$ submatrix $\hat{G}^{(s,t)}$ from $G^{(s,t)}$, and then find $L^{(s,t)}$ that minimizes the error on this submatrix. If the row/column index set for the subsampled submatrix $\hat{G}^{(s,t)}$ in $G^{(s,t)}$ is v_s/v_t, then $L^{(s,t)}$ can be computed in closed form:

$$L^{(s,t)} = ((W^{(s)}_{v_s})^T W^{(s)}_{v_s})^{-1}(W^{(s)}_{v_s})^T \hat{G}^{(s,t)} W^{(t)}_{v_t}((W^{(t)}_{v_t})^T W^{(t)}_{v_t})^{-1},$$

where $W^{(s)}_{v_s}$ and $W^{(t)}_{v_t}$ are formed by the rows in $W^{(s)}$ and $W^{(t)}$ with row index sets v_s and v_t respectively.

Since there are only k^2 variables in $L^{(s,t)}$, we do not need too many samples for each block, and the time to compute $L^{(s,t)}$ is $O((1+\rho)^3k^3)$. In practice, we observe that setting ρ to be 2 or 3 is enough for a good approximation, so the time complexity is $O(k^3)$. Empirically, many values in the off-diagonal blocks are close to zero, and only a few of them have large values as shown in Figure 1. Based on this observation, we further propose a thresholding technique to reduce the time for storing and computing $L^{(s,t)}$. Since the distance between cluster centers is a good indicator for the values in an off-diagonal block, we can set the whole block $L^{(s,t)}$ to 0 if $K(\boldsymbol{m}_s, \boldsymbol{m}_t) \leq \epsilon$ for some thresholding parameter $\epsilon > 0$, where $\boldsymbol{m}_s$ and $\boldsymbol{m}_t$ are the k-means centroid for the s-th and t-th cluster respectively. Obviously, to choose ϵ, we need to achieve a balance between speed and accuracy. When ϵ is small, we will approximate more off-diagonal blocks; while when ϵ is large, we will set more off-diagonal blocks to be 0, but increase the approximation error. We test the influence

of thresholding parameter ϵ on the ijcnn1 and cadata data in Figure 5. When ϵ is large, although MEKA yields higher approximation error(because it omits more off-diagonal information), it is faster. On the other hand, for small ϵ, when more off-diagonal information is considered, we notice an increase in time and smaller in approximation error. In practice, we need to use cross-validation to select ϵ.



(a) ijcnn1 (b) cadata

Figure 5: Time (in seconds) and kernel approximation quality of MEKA when varying the thresholding parameter ϵ for setting off-diagonal blocks in L to be zero.

Choosing the rank k_s for each cluster. We need to decide the rank for the $s^{th}(s = 1, \cdots, c)$ cluster, k_s, which can be done in different ways: (i) the same k for all the clusters; (ii) k_s is proportional to the size of s^{th} cluster; (iii) eigenvalues based approach. For (iii), suppose $M^{(s)}$ is the $m_s \times m_s$ matrix consisting of the intersection of m_s sampled columns in $G^{(s,s)}$, and M is the $cm \times cm(\sum_{s=1}^{c} m_s = cm)$ block-diagonal matrix with $M^{(s)}$ as diagonal block. We can choose k_s such that the set of top-ck eigenvalues of M is the union of the eigenvalues of $M^{(s)}$ in each cluster, that is, $[\sigma_1(M), \ldots, \sigma_{ck}(M)] = \cup_{s=1}^{c}[\sigma_1(M^{(s)}), \ldots, \sigma_{k_s}(M^{(s)})]$. To use (iii), we can oversample points in each cluster, e.g., sample $2k$ points from each cluster, perform eigendecompostion of a $2k \times 2k$ kernel matrix, sort the eigenvalues from c clusters, and finally select the top-ck eigenvalues and their corresponding eigenvectors. Comparing these three strategies, (i) achieves lower memory usage and is fastest, and (ii) is more accurate than (i) with more memory usage, while (iii) is slowest but achieves lower error for diagonal blocks. In Figure 6, we compare these three sampling strategies to choose k_s on ijcnn1 and cadata datasets. It is shown that these three methods perform similarly well and choosing k_s to be same for each cluster performs sightly better than by the size of each cluster and singular values based approach. In the experiment, we set all the clusters to have the same rank k. We show that this simple choice of k_s already outperforms state-of-the-art kernel approximation methods.

We are now ready to present our main algorithm in Algorithm 1. In Table 4, we compare the time and space complexity for our method with SVD, standard Nyström, and RKS. We can see that MEKA is more memory efficient. For the time complexity, both T_L (time for computing off-diagonal L) and T_C (time for clustering) are small as (1) we use thresholding to force some $L^{(s,t)}$ blocks to be zero, and perform least squares on small blocks, which

(a) ijcnn1 (b) cadata

Method	Storage	Rank	Time Complexity
RKS (Rahimi and Recht, 2008)	$O(cnk)$	ck	$O(cnkd)$
Nyström(Williams and Seeger, 2001)	$O(cnk)$	ck	$O(cnm(ck+d)+(cm)^3)$
SVD	$O(cnk)$	ck	$O(n^3+n^2d)$
MEKA	$O(nk+(ck)^2)$	ck	$O(nm(k+d)+cm^3+T_L+T_C)$

Table 4: Memory and time analysis of various kernel approximation methods, where T_L is the time to compute the matrix L and T_C is the time for clustering in MEKA.

means T_L can at most be $O(\frac{1}{2}c^2k^3)$; (2)T_C is proportional to the number of samples. For a large dataset, we sample 20000 points for k-means, and thus the clustering is more efficient than working on the entire data set.

Algorithm 1 Memory Efficient Kernel Approximation (MEKA)

Input : Data points $\{(\boldsymbol{x}_i)\}_{i=1}^n$, scaling parameter γ, rank k, and no. of clusters c.

Output: The rank-ck approximation $\tilde{G} = WLW^T$ using $O(nk+(ck)^2)$ space

Generate the partition $\mathcal{V}_1, \ldots, \mathcal{V}_c$ by k-means;

for $s = 1, \ldots, c$ **do**

  Perform the rank-k approximation $G^{(s,s)} \approx W^{(s)}L^{(s,s)}(W^{(s)})^T$ by standard Nyström;

end

forall $(s,t)(s \neq t)$ **do**

  Sample a submatrix $\bar{G}^{(s,t)}$ from $G^{(s,t)}$ with row index set v_s and column index set v_t;

  Form $W_{v_s}^{(s)}$ by selecting the rows in $W^{(s)}$ according to index set v_s;

  Form $W_{v_t}^{(t)}$ by selecting the rows in $W^{(t)}$ according to index set v_t;

  Solve the least squares problem: $\bar{G}^{(s,t)} \approx W_{v_s}^{(s)}L^{(s,t)}(W_{v_t}^{(t)})^T$ to obtain $L^{(s,t)}$;

end

Dataset	T_C	T_W	T_L
pendigit	0.05	0.69	0.35
ijcnn1	0.15	1.27	0.84
covtype	1.83	9.82	12.23

Table 5: Time (in seconds) for each step of MEKA, where T_W is the time to compute low-rank approximation for the diagonal block matrices; T_L is the time to form the "link" matrix L; T_C is the time for performing k-means clustering.

In Table 5, we show the time cost for each step of MEKA on pendigit, ijcnn1, and covtype datasets. The execution time of our proposed algorithm mainly consists of three parts:(1) time for performing k-means clustering (T_C), (2) time for forming the "basis" W from the diagonal blocks (T_W), (3) time to compute the link matrix L from off-diagonal blocks (T_L). From Table 5, we observe that compared with T_W and T_L, T_C is fairly small and T_W dominates the whole process in most cases. For covtype data set, since we choose c to be large, T_L is sightly larger than T_W. We will analyze T_W, T_L, and T_C for different c in the experiment part.

5.3 Analysis

We now bound the approximation error for our proposed method. We show that when $\sigma_{k+1} - \sigma_{ck+1}$ is large, where σ_{k+1} and σ_{ck+1} are the $k+1^{st}$ and $ck+1^{st}$ singular values of G respectively, and entries in off-diagonal blocks are small, MEKA has a better approximation error bound compared to standard Nyström that uses similar storage.

Theorem 3 *Let Δ denote a matrix consisting of all off-diagonal blocks of G, so $\Delta^{(s,t)} = G^{(s,t)}$ for $s \neq t$ and all zeros when $s = t$. We sample cm points from the dataset uniformly at random without replacement and split them according to the partition from k-means, such that each cluster has m_s benchmark points and $\sum_{s=1}^c m_s = cm$. Let G_{ck} be the best rank-ck approximation of G, and $\tilde{G}$ be the rank-ck approximation from MEKA. Suppose we choose the rank k_s for each diagonal block using the eigenvalue based approach as mentioned in Section 5.1, then with probability at least $1-\delta$, the following inequalities hold for any sample of size cm:*

$$\|G-\tilde{G}\|_2 \leq \|G-G_{ck}\|_2 + \frac{1}{\sqrt{c}}\frac{2n}{\sqrt{m}}G_{\max}(1+\theta) + 2\|\Delta\|_2,$$

$$\|G-\tilde{G}\|_F \leq \|G-G_{ck}\|_F + \left(\frac{64k}{m}\right)^{\frac{1}{4}} nG_{\max}(1+\theta)^{\frac{1}{2}} + 2\|\Delta\|_F$$

where $\theta = \sqrt{\frac{n-m}{n-0.5}\frac{1}{\beta(m,n)}\log\frac{1}{\delta}}d_{\max}^G/G_{\max}^{\frac{1}{2}}$; $\beta(m,n) = 1 - \frac{1}{2\max\{m,n-m\}}$; $G_{\max} = \max_i G_{ii}$; *and* $d_{\max}^G$ *represents the distance* $\max_{ij}\sqrt{G_{ii}+G_{jj}-2G_{ij}}$.

Proof Let B denote the matrix formed by the diagonal block of G, that is,

$$B \equiv \begin{bmatrix} G^{(1)} & 0 & \dots & 0 \\ 0 & G^{(2)} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & G^{(c)} \end{bmatrix}. \tag{15}$$

According to the definition of Δ, $G = B + \Delta$. In MEKA, the error $\|\tilde{G} - G\|_2$ consists of two components,

$$\|\tilde{G} - G\|_2 = \|\tilde{B} - B + (\tilde{\Delta} - \Delta)\|_2 \leq \|\tilde{B} - B\|_2 + \|\tilde{\Delta} - \Delta\|_2 \tag{16}$$

where $\tilde{B}$ and $\tilde{\Delta}$ are the approximations for B and Δ in MEKA respectively.

Let us first consider the error in approximating the diagonal blocks $\|\tilde{B} - B\|_2$. Since we sample cm benchmark points from n data points uniformly at random without replacement and distribute them according to the partition coming from k-means, the s-th cluster now has m_s benchmark points with $\sum_{s=1}^{s=c} m_s = cm$. For the s-th diagonal block $G^{(s)}$, we will perform the rank-k_s approximation using standard Nyström, so we have $G^{(s)} \approx E^{(s)}(M_{k_s}^{(s)})^+ E^{(s)}$, where $E^{(s)}$ denotes the matrix formed by m_s sampled columns from $G^{(s)}$ and $M_{k_s}^{(s)}$ is a $m_s \times m_s$ matrix consisting of the intersection of sampled m_s columns.

Suppose we use the singular value based approach to choose k_s for s-th cluster as described in Section 5.1, and

$$M_{ck}^{+} equiv \begin{bmatrix} (M_{k_1}^{(1)})^+ & 0 & \dots & 0 \\ 0 & (M_{k_2}^{(2)})^+ & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & (M_{k_c}^{(c)})^+, \end{bmatrix} \tag{17}$$

where M is the $cm \times cm$ block diagonal matrix that consists of the intersection of the sampled cm columns. Then we can see that approximating the diagonal blocks B is equivalent to directly performing standard Nyström on B by sampling cm benchmark points uniformly at random without replacement to achieve the rank-ck approximation. The standard Nyström's norm-2 and Frobenius error bound are given in (Kumar et al., 2009), so $\|B - \tilde{B}\|_2$ can be bounded with probability at least $1 - \delta$ as

$$\|B - \tilde{B}\|_2 \leq \|B - B_{ck}\|_2 + \frac{2n}{\sqrt{cm}} B_{\max}[1 + \sqrt{\frac{n - cm}{n - 0.5} \frac{1}{\beta(cm, n)} \log \frac{1}{\delta}} d_{\max}^B / B_{\max}^{\frac{1}{2}}],$$

where B_{ck} denotes the best rank-ck approximation to B; $B_{\max} = \max_i B_{ii}$; $d_{\max}^B$ represents the distance $\max_{ij} \sqrt{B_{ii} + B_{jj} - 2B_{ij}}$.

To bound $\|\tilde{\Delta} - \Delta\|_2$, recall that some off-diagonal blocks in MEKA are set to 0 by thresholding and $\mathbf{0}$ is one special solution of least squares problem to compute $L^{(s,t)}$, we have $\|\tilde{\Delta} - \Delta\|_2 \leq \|\Delta\|_2$.

Furthermore, according to perturbation theory (Stewart and Ji-Guang, 1990), we have

$$\|B - B_{ck}\|_2 \leq \|G - G_{ck}\|_2 + \|\Delta\|_2. \tag{18}$$

The inequality in (16) combined with (18) gives a bound on $\|\tilde{G} - G\|_2$ as,

$$\begin{aligned} \|\tilde{G} - G\|_2 &\leq \|B - B_{ck}\|_2 + \|\Delta\|_2 + \frac{2n}{\sqrt{cm}} B_{\max}[1 + \sqrt{\frac{n - cm}{n - 0.5} \frac{1}{\beta(cm, n)} \log \frac{1}{\delta}} d_{\max}^B / B_{\max}^{\frac{1}{2}}] \\ &\leq \|G - G_{ck}\|_2 + 2\|\Delta\|_2 + \frac{2n}{\sqrt{cm}} B_{\max}[1 + \sqrt{\frac{n - cm}{n - 0.5} \frac{1}{\beta(cm, n)} \log \frac{1}{\delta}} d_{\max}^B / B_{\max}^{\frac{1}{2}}] \\ &\leq \|G - G_{ck}\|_2 + 2\|\Delta\|_2 + \frac{2n}{\sqrt{cm}} G_{\max}[1 + \sqrt{\frac{n - cm}{n - 0.5} \frac{1}{\beta(cm, n)} \log \frac{1}{\delta}} d_{\max}^G / G_{\max}^{\frac{1}{2}}] \\ &\leq \|G - G_{ck}\|_2 + 2\|\Delta\|_2 + \frac{1}{\sqrt{c}} \frac{2n}{\sqrt{m}} G_{\max}[1 + \sqrt{\frac{n - m}{n - 0.5} \frac{1}{\beta(m, n)} \log \frac{1}{\delta}} d_{\max}^G / G_{\max}^{\frac{1}{2}}], \end{aligned}$$

where G_{ck} denotes the best rank-ck approximation to G; $G_{\max} = \max_i G_{ii}$; $d_{\max}^G$ represents the distance $\max_{ij} \sqrt{G_{ii} + G_{jj} - 2G_{ij}}$. The third inequality is because $G = B + \Delta$, $B_{\max} \leq G_{\max}$ and $d_{\max}^B \leq d_{\max}^G$. The last inequality is because $n \gg m$ and $n \gg cm$.

Similarly by using perturbation theory and upper bounds for the Frobenius error of standard Nyström, the result follows. ■

When $k_s (s = 1, \cdots, c)$ is balanced (meaning k_s is approximately the same for each cluster) and n is large, MEKA provides a rank-ck approximation using roughly the same amount of storage as rank-k approximation by standard Nyström. Interestingly, from Theorem 3, if $\|G - G_k\|_2 - \|G - G_{ck}\|_2 \geq 2\|\Delta\|_2$, then

$$\|G - \tilde{G}\|_2 \leq \|G - G_k\|_2 + \frac{1}{\sqrt{c}} \frac{2n}{\sqrt{m}} G_{\max}(1 + \theta).$$

The second term in the right hand side of above inequality is only $\frac{1}{\sqrt{c}}$ of that in the spectral norm error bound for standard Nyström that uniformly samples m columns without replacement in G to obtain the rank-k approximation as shown in (Kumar, Mohri, and Talwalkar, 2009). Thus, if there is a large enough gap between σ_{k+1} and σ_{ck+1}, the error bound for our proposed method is better than standard Nyström that uses similar storage. Furthermore, when γ is large, G tends to have better clustering structure, suggesting in Theorem 3 that $\|\Delta\|$ is usually quite small. Note that when using the same rank k for all the clusters, the above bound can be worse because of some extreme cases, e.g., all the top-ck eigenvalues are in the same cluster. In practice we do not observe those extreme situations. We also want to mention that both $\|\Delta\|_F$ and $\|\Delta\|_2$ will be affected by the number of clusters c.

6. Experimental Results

In this section, we empirically demonstrate the benefits of our proposed method, MEKA on various data sets[2] that are listed in Table 6. Experiment results here are mainly based on

2. All the datasets are downloaded from `www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets` and UCI repository (Bache and Lichman, 2013). Note that the census datasets in Table 1 and Table 6 come from different sources.

Dataset	n	d	Dataset	n	d
wine	6,497	11	census	22,784	137
cpusmall	8,192	12	ijcnn1	49,990	22
pendigit	10,992	16	covtype	581,012	54
cadata	20,640	8	mnist2m	2,000,000	784

Table 6: Data set statistics (n: number of samples; d: dimension of samples).

the Gaussian kernel, but we observe similar behavior on other shift-invariant kernels (see Section 6.2). Note that the same kernel function is used in both training and test phases. We compare our method with six state-of-the-art kernel approximation methods:

1. The standard Nyström method (denoted by Nys)(Williams and Seeger, 2001). In the experiment, we uniformly sample $2k$ columns of G without replacement, and run Nyström for rank-k approximation.

2. Kmeans Nyström (denoted by KNys)(Zhang and Kwok, 2010), where the landmark points are the cluster centroids. As suggested in (Zhang et al., 2012), we sample 20000 points for clustering when the total number of data samples is larger than 20000.

3. Random Kitchen Sinks (denoted by RKS)(Rahimi and Recht, 2008), which approximates the shift-invariant kernel based on its Fourier transform.

4. Fastfood with "Hadamard features" (denoted by fastfood)(Le, Sarlos, and Smola, 2013).

5. Ensemble Nyström (denoted by ENys) (Kumar, Mohri, and Talwalkar, 2009). Due to concern for the computation cost, we set the number of "experts" in ENys 3.

6. Nyström using randomized SVD (denoted by RNys)(Li, Kwok, and Lu, 2010). We set the number of power iterations $q = 1$ and oversampling parameter $p = 10$.

We compare all the methods on two different tasks: kernel low-rank approximation and kernel ridge regression. We do not compare with BKA in this section, because (1) the approximation error of BKA is large when γ is small (as shown in Figure 1); (2) BKA is time consuming because it needs to compute all the diagonal blocks' kernel values, which needs $O(\frac{n^2 d}{c})$ time; (3) BKA is not memory efficient to approximate the kernel matrix, because it needs $O(\frac{n^2}{c})$ space to store the approximation. All the experiments are conducted on a machine with an Intel Xeon X5440 2.83GHz CPU and 32G RAM.

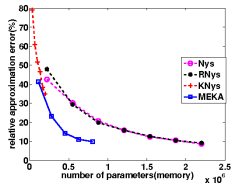
6.1 Kernel Approximation Quality

We now compare the kernel approximation quality for the above methods.

Main results. The kernel approximation results are shown in Figure 7 and Table 7. We use relative kernel approximation error $\|G - \tilde{G}\|_F / \|G\|_F$ to measure the quality. We randomly sampled 20000 rows of G to evaluate the relative approximation error for ijcnn1 and covtype. In Figure 7, we show the kernel approximation performance of different methods by varying k and γ. The rank (k) varies from 100 to 600 for ijcnn1 and covtype

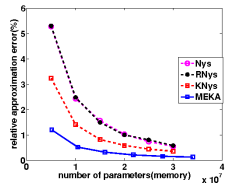
Dataset	k	γ	c	Nys	RNys	KNys	ENys	RKS	fastfood	MEKA
pendigit	128	2	5	0.1325	0.1361	0.0828	0.2881	0.4404	0.4726	**0.0811**
ijcnn1	128	1	10	0.0423	0.0385	0.0234	0.1113	0.2972	0.2975	**0.0082**
covtype	256	10	15	0.3700	0.3738	0.2752	0.5646	0.8825	0.8920	**0.1192**

Table 7: Comparison of approximation error of our proposed method with six other state-of-the-art kernel approximation methods on real datasets, where γ is the Gaussian scaling parameter; c is the number of clusters in MEKA; k is the rank of each diagonal-block in MEKA and the rank of the approximation for six other methods. Note that for a given k, every method has roughly the same amount of memory. All results show relative kernel approximation errors for each k.



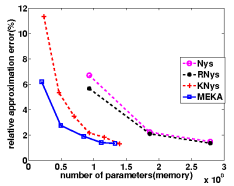
and from 20 to 200 for the pendigit data. Figure 7 shows that our proposed approximation scheme always achieves lower error with less time and memory. The main reason is that using similar amount of time and memory, our method aims to approximate the kernel matrix by a rank-ck approximation, while all other methods are only able to form a rank-k approximation.

In Table 7, we fix the rank k and γ, so that each method has the same memory usage of low-rank representation, and compare MEKA with them in terms of relative approximation error. As it can be seen, under the same amount of memory, our proposed method consistently yields lower approximation error than other methods.



Also as we can see from Table 7 and Figure 8, Nyström based methods perform much better than random features based methods (including RKS and Fastfood here) in terms of kernel approximation quality. Therefore we do not show their performance in Figure 7, so that we could see the difference between MEKA and other Nyström based methods.

Robustness to the Gaussian scaling parameter γ. To show the robustness of our proposed algorithm with different γ as explained in Section 3, we test its performance on the ijcnn1 (Figure 9a), cadata (Figure 9b) and sampled covtype datasets (Figure 1c). The relative approximation errors for different γ values are shown in the figures using a fixed amount of memory. For large γ, the kernel matrix tends to have a block structure, so our proposed method yields lower error than other methods. The gap becomes larger as γ increases. Interestingly, Figure 1c shows that the approximation error of MEKA is superior to even the exact SVD, as it is much more memory efficient. Even for small γ where the kernel exhibits low-rank structure, our proposed method performs better than Nyström based methods, suggesting that it can get the low-rank structure of the kernel matrix.



Robustness to the number of clusters c. Compared with Nyström, one main extra parameter for our method is the number of clusters c. In Figure 10, we test our method with different values of c on ijcnn1 dataset. In Figure 10a, we show how the approximation error changes when c is varied from 5 to 25 (with rank $k = 100$ in each cluster). The memory usage is $nk + (ck)^2$, so the storage increases as c increases. For a fair comparison, we increase the rank of other methods as c increases, so that all the methods use the same amount of memory. Figure 10a shows that the performance of our proposed method for varying choices of c. We can observe that under different c, MEKA always performs better than others. Furthermore, in Figure 10b we show the time cost for each step of MEKA on

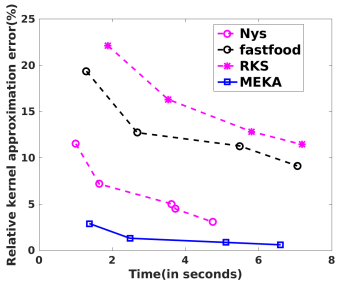

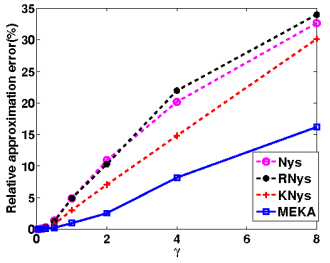

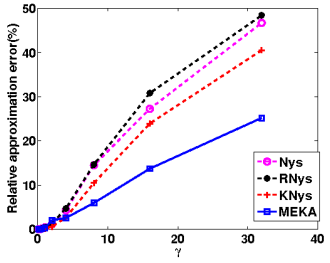

Figure 8: Comparison between Nyström based methods (MEKA and standard Nyström) and random feature based methods (RKS and fastfood). We can see that Nyström based methods perform much better than random feature based methods for kernel approximation.

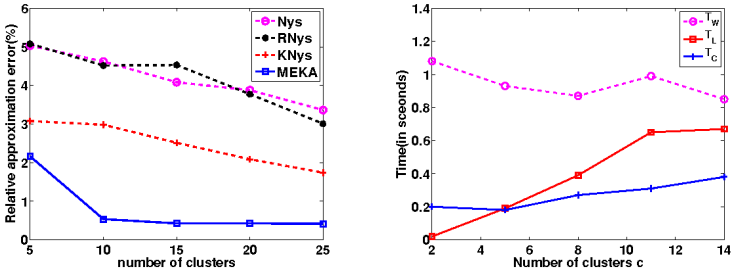
(a) ijcnn1.

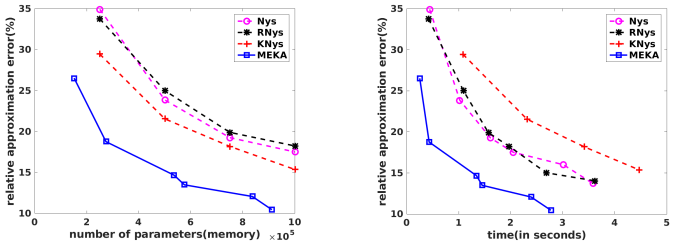


(b) cadata.

Figure 9: The kernel approximation errors for different Gaussian scaling parameter γ.

ijcnn1 dataset when varying the number of clusters c. Here the parameter γ is set to be 1. From Figure 10b, we observe that when the number of clusters c is small, T_W will dominate the whole process. As c increases, the time for computing the link matrix L, T_L, increases. This is because the number of off-diagonal blocks increases quadratically with c. Since the time complexity for k-means is $O(ncd)$, T_C increases linearly with c.

6.2 The Performance of MEKA for Approximating the Laplacian Kernel



As we mentioned in Section 5, our algorithm is suitable for approximating stationary kernels. Besides Gaussian kernel, we can apply MEKA to approximate other kernels, e.g., Laplacian kernel ($K(x, y) = e^{-\gamma\|x-y\|_1}$). Figure 11 compares our proposed method with the standard Nyström(Nys), Randomized Nyström(RNys), and Kmeans Nyström(KNys) for approximating the Laplacian kernel on ijcnn1 data. Similar to Gaussian kernel, we observe that MEKA is more memory efficient and faster than other methods for approximating the Laplacian kernel.

(a) kernel approximation under different numbers of clusters c in MEKA. For standard Nyström(Nys), Randomized Nyström(RNys), and Kmeans Nyström(KNys), we use the same memory with MEKA.

(b) Time for each step of MEKA when varying the number of clusters c. T_C is the time for performing k-means clustering; T_W is the time to form the "basis" W from the diagonal blocks; and T_L is the time to compute L from off-diagonal blocks.

Figure 10: The kernel approximation errors and time cost for each step of MEKA when varying c on ijcnn1 dataset.

(a) memory vs approximation error.

(b) time vs approximation error.

Figure 11: Low-rank Laplacian kernel approximation results for ijcnn1 dataset.

6.3 Kernel Ridge Regression

Next we compare the performance of various methods on kernel ridge regression (Saunders, Gammerman, and Vovk, 1998):

$$\max_{\boldsymbol{\alpha}} \quad \lambda \boldsymbol{\alpha}^T \boldsymbol{\alpha} + \boldsymbol{\alpha}^T G \boldsymbol{\alpha} - 2\boldsymbol{\alpha}^T \boldsymbol{y}, \tag{19}$$

where G is the kernel matrix formed by training samples $\{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_l\}$, and $\boldsymbol{y} \in \mathbb{R}^l$ are the targets. For each kernel approximation method, we first form the approximated kernel $\tilde{G}$, and then solve (19) by conjugate gradient (CG). The main computation in CG is the matrix vector product $\tilde{G}\boldsymbol{v}$. Using low-rank approximation, this can be computed using $O(nk)$ flops. For our proposed method, we compute $WLW^T\boldsymbol{v}$, where $W^T\boldsymbol{v} = \sum_{s=1}^{c} W^{(s)}\boldsymbol{v}^{(s)}$ requires

Dataset	k	γ	c	λ	Nys	RNys	KNys	ENys	RKS	fastfood	MEKA
wine	128	2^{-10}	3	2^{-4}	0.7514	0.7555	0.7568	0.7732	0.7459	0.7509	**0.7375**
cadata	128	2^{2}	5	2^{-3}	0.1504	0.1505	0.1386	0.1462	0.1334	0.1502	**0.1209**
cpusmall	256	2^{2}	5	2^{-4}	8.8747	8.6973	6.9638	9.2831	9.6795	10.2601	**6.1130**
census	256	2^{-4}	5	2^{-5}	0.0679	0.0653	0.0578	0.0697	0.0727	0.0732	**0.0490**
covtype	256	2^{2}	10	2^{-2}	0.8197	0.8216	0.8172	0.8454	0.8011	0.8026	**0.7106**
mnist2m	256	2^{-5}	40	2^{-5}	0.2985	0.2962	0.2725	0.3018	0.3834	na	**0.2667**

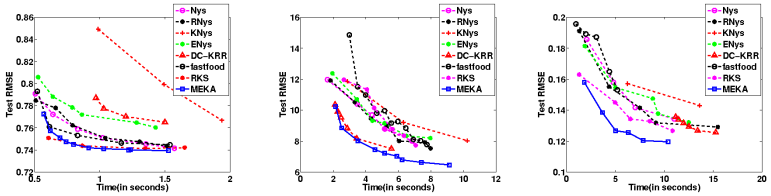


Table 8: Comparison of our proposed method with six other state-of-the-art kernel approximation methods on real datasets for kernel ridge regression, where λ is the regularization constant. All the parameters are chosen by cross validation, and every method has roughly the same amount of memory as in Table 7. All results show test RMSE for regression for each k. Note that k for fastfood needs to be larger than d, so we cannot test fastfood on mnist2m when $k = 256$.

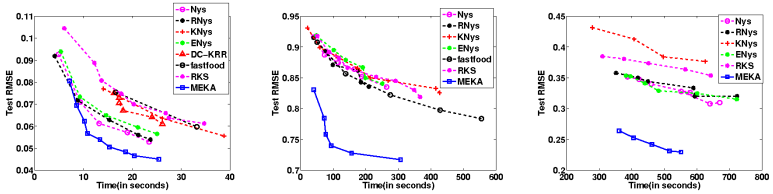
$O(nk)$ flops, $L(W\boldsymbol{v})$ requires $O(\|L\|_0)$ flops, and $W(LW^T\boldsymbol{v})$ requires $O(nk)$ flops. Therefore, the time complexity for computing the matrix vector product for both MEKA and low-rank approximation methods is proportional to the memory for storing the approximate kernel matrices. Besides kernel approximation algorithms, we compare our method with another divide-and-conquer based kernel ridge regression method (denoted DC-KRR)(Zhang et al., 2013). The basic idea in Zhang et al. (2013) is to randomly partition the data into c parts and then train a kernel ridge regression model in each partition. To test a new data point, it will be tested on each submodel and the final prediction is the average of c predictions.



The parameters are chosen by five fold cross-validation and shown in Table 8. The rank for these algorithms is varied from 100 to 1000. The test root mean square error (test RMSE) is defined as $\|\boldsymbol{y}^{te} - G^{te}\boldsymbol{\alpha}\|$, where $\boldsymbol{y}^{te} \in \mathbb{R}^u$ is testing labels and $G^{te} \in \mathbb{R}^{u \times l}$ is the approximate kernel values between testing and training data. The covtype and mnist2m data sets are not originally designed for regression, and here we set the target variables to be 0 and 1 for mnist2m and -1 and 1 for covtype. Table 8 compares the kernel ridge regression performance of our proposed scheme with six other methods given the same amount of memory or same k in terms of test RMSE. It shows that our proposed method consistently performs better than other methods. Figure 12 shows the time usage of different methods for regression by varying the memory or rank k. As we can see that using the same amount of time, our proposed algorithm always achieves the lowest test RMSE. The total running time consists of the time for obtaining the low-rank approximation and time for regression. The former depends on the time complexity for each method, and the latter depends on the memory requirement to store the low-rank matrices. As shown in the previous experiment, MEKA is faster than the other methods while achieving lower approximation error and using less memory. As a consequence, it achieves lower test RMSE in less time compared to other kernel approximation methods.

7. Conclusions and Discussions

In this paper, we have proposed a novel framework, Memory Efficient Kernel Approximation (MEKA) for approximating shift-invariant kernel matrices. We observe that the structure of the shift-invariant kernel matrix changes from low rank to block diagonal as the scale

(a) wine, time vs regression error. (b) cpusmall, time vs regression error. (c) cadata, time vs regression error.

(d) census, time vs regression error. (e) covtype, time vs regression error. (f) mnist2m, time vs regression error.

Figure 12: Kernel ridge regression results for various data sets. Methods with regression error above the top of y-axis are not shown. All results are averaged over five independent runs.

parameter is changed. Our method exploits both low-rank and block structure present in the kernel matrix, and thus performs better than previously proposed low-rank based methods in terms of approximation and regression error, speed and memory usage. The code for MEKA is available at `www.cs.utexas.edu/~ssi/meka/`. We will discuss next about some typical problems encountered when using MEKA and how to deal with them.

7.1 Dealing with the Non-PSD Issue

If for each off-diagonal block, we sample all the entries, the resulting approximate matrix in MEKA will be positive semidefinite(PSD). The reason is as follow: if we use all the all-diagonal blocks to compute the link matrix L, the approximation will be $G \approx WLW^T$ with $L = W^T G W$. Since G is PSD, so it is with L, which proves WLW^T will be PSD.

However, due to the sampling procedure in MEKA, the resulting approximate matrix might not be PSD, which will cause some problems when PSD is required for some applications, e.g., kernel SVM with hinge loss. There are two simple and effective ways to solve this issue: (1) The first method (MEKA-PSD) is to set negative eigenvalues to 0. The procedure is first to perform eigen-decomposition on the small $ck \times ck$ "link" matrix $L = USU^T$(where U and S are the eigenvector and eigenvalue matrices for L respectively) in the MEKA representation, and then shrink its negative eigenvalues to be 0, which forms the new eigenvalue matrix $\bar{S}$ for L. After that, the new MEKA approximation will become: $\bar{G} = WU\bar{S}U^TW^T$. Since $\bar{S}$ is now PSD, so it is with $WU\bar{S}U^TW^T$. Therefore, $\bar{G}$ will be PSD after above shrinking operation. Due to eigen-decomposition on L and the following

shrinking operation, both the kernel approximation error and computation time will increase slightly. We show the comparison of Nys, MEKA and MEKA-PSD on ijcnn1 dataset in Figure 13. We can see that to achieve similar approximation, MEKA-PSD is slightly slower than MEKA, but still performs better than Nys, which also generates PSD kernel approximation. (2) The second method is to directly add a small value ϵ to the diagonal of $\bar{G}$, which is equivalent to using regularization term when applying MEKA for kernel methods. We show the kernel ridge regression results in Table 8, where we add regularization term to MEKA. Note that to make sure the resulting MEKA approximation is PSD for the second method, ϵ should be equal or larger than the absolute value of the smallest negative eigenvalue of $\bar{G}$.

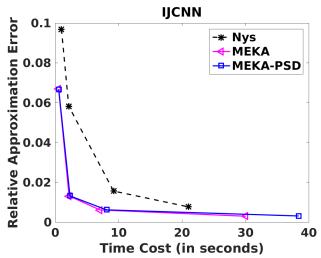


Figure 13: MEKA-PSD kernel approximation results for ijcnn1 dataset.

7.2 Dealing with the Instability Issue

There are two steps in Algorithm 1 that might cause the approximation unstable. One is due to the basis formed from each diagonal block– W_i. If the kernel matrix has strong block-diagonal structure, choosing columns from diagonal blocks to form W will perform well; on the contrary, if the kernel matrix does not have very strong block structure, other sampling strategies can be involved, for example, sampling columns from the rows corresponding to each partition to form the basis. Another step which might cause unstable result is due to insufficient entries sampled when forming the "link" matrix L. One way to solve this issue is to sample more entries from each off-diagonal block to form L when the computation time is not the main concern.

7.3 Other Applications using MEKA

In the experiment section, we apply MEKA for kernel approximation and kernel ridge regression, and besides that we could use our MEKA framework for many other machine learning applications: such as speeding up the computation of the inverse of the kernel matrix.

For many machine learning applications, e.g., Gaussian Process, we need to compute the matrix inverse $(G + \lambda I)^{-1}$, where computing the inverse of a dense matrix becomes the bottleneck for these applications. By approximating kernel matrix G in MEKA form

$G \approx WLW^T$, the inverse operation can be done in a faster fashion using Woodbury formula.

$$\begin{aligned}(\lambda I + G)^{-1} &\approx (\lambda I + WLW^T)^{-1} \\ &= \frac{1}{\lambda}(I - W(\lambda L^{-1} + W^T W)^{-1} W^T)\end{aligned}$$

We can see that after the approximation, we only need to inverse the $ck \times ck$ matrix which reduce the time complexity for inverse of the dense matrix from $O(n^3)$ to $O(n(ck)^2 + (ck)^3)$.

Besides speeding up the matrix inverse, MEKA can also be used to approximate the eigendecomposition of kernel matrix and used in various machine learning applications, for instance, manifold learning and kernelized dimensionality reduction.

Abstract

We show that kernel-based quadrature rules for computing integrals can be seen as a special case of random feature expansions for positive definite kernels, for a particular decomposition that always exists for such kernels. We provide a theoretical analysis of the number of required samples for a given approximation error, leading to both upper and lower bounds that are based solely on the eigenvalues of the associated integral operator and match up to logarithmic terms. In particular, we show that the upper bound may be obtained from independent and identically distributed samples from a specific non-uniform distribution, while the lower bound if valid for any set of points. Applying our results to kernel-based quadrature, while our results are fairly general, we recover known upper and lower bounds for the special cases of Sobolev spaces. Moreover, our results extend to the more general problem of full function approximations (beyond simply computing an integral), with results in L_2- and L_∞-norm that match known results for special cases. Applying our results to random features, we show an improvement of the number of random features needed to preserve the generalization guarantees for learning with Lipshitz-continuous losses.

Keywords: Quadrature, positive-definite kernels, integral operators.

1. Introduction

The numerical computation of high-dimensional integrals is one of the core computational tasks in many areas of machine learning, signal processing and more generally applied mathematics, in particular in the context of Bayesian inference (Gelman, 2004), or the study of complex systems (Robert and Casella, 2005). In this paper, we focus on *quadrature rules*, that aim at approximating the integral of a certain function from only the (potentially noisy) knowledge of the function values at as few as possible well-chosen points. Key situations that remain active areas of research are problems where the measurable space where the function is defined on is either high-dimensional or structured (e.g., presence of discrete structures, or graphs). For these problems, techniques based on *positive definite kernels* have emerged as having the potential to efficiently deal with these situations, and to improve over plain Monte-Carlo integration (O'Hagan, 1991; Rasmussen and Ghahramani, 2003; Huszár and Duvenaud, 2012; Oates and Girolami, 2015). In particular, the quadrature problem may be cast as the one of approximating a fixed element, the mean element (Smola et al., 2007), of a Hilbert space as a linear combination of well chosen elements, the goal being to minimize the number of these factors as it corresponds to the required number of function evaluations.

A seemingly unrelated problem on positive definite kernels have recently emerged, namely the representation of the corresponding infinite-dimensional feature space from *random sets of features*. If a certain positive definite kernel between two points may be represented as the expectation of the product of two random one-dimensional (typically non-linear) features computed on these two points, the full kernel (and hence its feature space) may be approximated by sufficiently many random samples, replacing the expectation by a sample average (Neal, 1995; Rahimi and Recht, 2007; Huang et al., 2006). When using these random features, the complexity of a regular kernel method such as the support vector machine or ridge regression goes from quadratic in the number of observations to linear in the number of observations, with a constant proportional to the number of random features, which thus drives the running time complexity of these methods.

In this paper, we make the following contributions:

- After describing the functional analysis framework our analysis is based on and presenting many examples in Section 2, we show in Section 3 that these two problems are strongly related; more precisely, optimizing weights in kernel-based quadrature rules can be seen as decomposing a certain function in a special class of random features for a particular decomposition that always exists for all positive definite kernels on a measurable space.
- We provide in Section 4 a theoretical analysis of the number of required samples for a given approximation error, leading to both upper and lower bounds that are based solely on the eigenvalues of the associated integral operator and match up to logarithmic terms. In particular, we show that the upper bound may be obtained as independent and identically distributed samples from a specific non-uniform distribution, while the lower bound if valid for any set of points.
- Applying our results to kernel quadrature, while our results are fairly general, we recover known upper and lower bounds for the special cases of Sobolev spaces (Section 4.4). Moreover, our results extend to the more general problem of full function approximations (beyond simply computing an integral), with results in L_2- and L_∞-norm that match known results for special cases (Section 5).
- Applying our results to random feature expansions, we show in Section 4.5 an improvement of the number of random features needed for preserving the generalization guarantees for learning with Lipshitz-continuous losses.

2. Random Feature Expansions of Positive Definite Kernels

Throughout this paper, we consider a topological space $\mathcal{X}$ equipped with a Borel probability measure $d\rho$, which we assume to have full support. This naturally defines the space of square-integrable functions[1].

1. For simplicity and following most of the literature on kernel methods, we identify functions and their equivalence classes for the equivalence relationship of being equal except for a zero-measure (for $d\rho$) subset of $\mathcal{X}$.

2.1 Reproducing Kernel Hilbert Spaces and Integral Operators

We consider a continuous positive definite kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, that is a symmetric function such that for all finite families of points in $\mathcal{X}$, the matrix of pairwise kernel evaluations is positive semi-definite. This thus defines a reproducing kernel Hilbert space (RKHS) $\mathcal{F}$ of functions from $\mathcal{X}$ to $\mathbb{R}$, which we also assume separable. This RKHS has two important characteristic properties (see, e.g., Berlinet and Thomas-Agnan, 2004):

(a) *Membership of kernel evaluations*: for any $x \in \mathcal{X}$, the function $k(\cdot, x) : y \mapsto k(y, x)$ is an element of $\mathcal{F}$.

(b) *Reproducing property*: for all $f \in \mathcal{F}$ and $x \in \mathcal{X}$, $f(x) = \langle f, k(\cdot, x)\rangle_{\mathcal{F}}$. In other words, function evaluations are equal to dot-products with a specific element of $\mathcal{F}$.

Moreover, throughout the paper, we assume that the function $x \mapsto k(x, x)$ is integrable with respect to $d\rho$ (which is weaker than $\sup_{x\in\mathcal{X}} k(x, x) < \infty$). This implies that $\mathcal{F}$ is a subset of $L_2(d\rho)$; that is, functions in the RKHS $\mathcal{F}$ are all square-integrable for $d\rho$. In general, $\mathcal{F}$ is strictly included in $L_2(d\rho)$, but, in this paper, we will always assume that it is *dense* in $L_2(d\rho)$, that is, any function in $L_2(d\rho)$ may be approximated arbitrarily closely by a function in $\mathcal{F}$. Finally, for simplicity of our notation (to make sure that the sequence of eigenvalues of integral operators is infinite) we will always assume that $L_2(d\rho)$ is infinite-dimensional, which excludes finite sets for $\mathcal{X}$. Note that the last two assumptions (denseness and infinite dimensionality) can easily be relaxed.

Integral operator. Reproducing kernel Hilbert spaces are often studied through a specific integral operator which leads to an isometry with $L_2(d\rho)$ (Smale and Cucker, 2001). Let $\Sigma : L_2(d\rho) \to L_2(d\rho)$ be defined as

$$(\Sigma f)(x) = \int_{\mathcal{X}} f(y)k(x, y)d\rho(y).$$

Since $\int_{\mathcal{X}} k(x, x)d\rho(x)$ is finite, Σ is self-adjoint, positive semi-definite and trace-class (Simon, 1979). Given that Σf is a linear combination of kernel functions $k(\cdot, y)$, it belongs to $\mathcal{F}$. More precisely, since we have assumed that $\mathcal{F}$ is dense in $L_2(d\rho)$, $\Sigma^{1/2}$, which is the unique positive self-adjoint square root of Σ, is a bijection from $L_2(d\rho)$ to our RKHS $\mathcal{F}$; that is, for any $f \in \mathcal{F}$, there exists a unique $g \in L_2(d\rho)$ such that $f = \Sigma^{1/2}g$ and $\|f\|_{\mathcal{H}} = \|g\|_{L_2(d\rho)}$ (Smale and Cucker, 2001). This justifies the notation $\Sigma^{-1/2}f$ for $f \in \mathcal{F}$ and means that $\Sigma^{1/2}$ is an isometry from $L_2(d\rho)$ to $\mathcal{F}$; in other words, for any functions f and g in $\mathcal{F}$, we have:

$$\langle f, g\rangle_{\mathcal{F}} = \langle \Sigma^{-1/2}f, \Sigma^{-1/2}g\rangle_{L_2(d\rho)}.$$

This justifies the view of $\mathcal{F}$ as the subspace of functions $f \in L_2(d\rho)$ such that $\|\Sigma^{-1/2}f\|^2_{L_2(d\rho)}$. This relationship is even more transparent when considering a spectral decomposition of Σ.

Mercer decomposition. From extensions of Mercer's theorem (König, 1986), there exists an orthonormal *basis* $(e_m)_{m\geqslant 1}$ of $L_2(d\rho)$ and a summable non-increasing sequence of strictly positive eigenvalues $(\mu_m)_{m\geqslant 1}$ such that $\Sigma e_m = \mu_m e_m$. Note that since we have assumed that $\mathcal{F}$ is dense in $L_2(d\rho)$, there are no zero eigenvalues.

Since $\Sigma^{1/2}$ is an isometry from $L_2(d\rho)$ to $\mathcal{F}$, $(\mu_m^{1/2}e_m)_{m\geqslant 1}$ is an orthonormal basis of $\mathcal{F}$. Moreover, we can use the eigendecomposition to characterize elements of $\mathcal{F}$ as the functions in $L_2(d\rho)$ such that

$$\|\Sigma^{-1/2}f\|^2_{L_2(d\rho)} = \sum_{m\geqslant 1} \mu_m^{-1}\langle f, e_m\rangle^2_{L_2(d\rho)}$$

is finite. In other words, once projected in the orthonormal basis $(e_m)_{m\geqslant 1}$, elements f of $\mathcal{F}$ correspond to a certain decay of its decomposition coefficients $(\langle f, e_m\rangle_{L_2(d\rho)})_{m\geqslant 1}$.

Finally, by decomposing the function $k(\cdot, y) : x \mapsto k(x, y)$, we obtain the Mercer decomposition:

$$k(x, y) = \sum_{m\geqslant 1} \mu_m e_m(x)e_m(y).$$

Properties of the spectrum. The sequence of eigenvalues $(\mu_m)_{m\geqslant 1}$ is an important quantity that appears in most of the analyses of kernel methods (Hastie and Tibshirani, 1990; Caponnetto and De Vito, 2007; Harchaoui et al., 2008; Bach, 2013). It depends both on the kernel k and the chosen distribution $d\rho$.

Some modifications of the kernel k or the distribution $d\rho$ lead to simple behaviors for the spectrum. For example, if we have a second distribution so that $\frac{d\rho'}{d\rho}$ is upper-bounded by a constant c, then, as a consequence of the Courant-Fischer minimax theorem (Horn and Johnson, 2012), the eigenvalues for $d\rho'$ are less than than c times that the ones for $d\rho$. Similarly, if the kernel k' is such that $ck - k'$ is a positive definite kernel, then we have a similar bound between eigenvalues.

In this paper, for any strictly positive λ, we will also consider the quantity $m^*(\lambda)$ equal to the number of eigenvalues μ_m that are greater than or equal to λ. Since we have assume that the sequence m is non-increasing, we have $m^*(\lambda) = \max\{m \geqslant 1,\ \mu_m \geqslant \lambda\}$. This is a left-continuous non-increasing function, that tends to $+\infty$ when λ tends to zero (since we have assumed that there are infinitely many strictly positive eigenvalues), and characterizes the sequence $(\mu_m)_{m\geqslant 1}$, as we can recover μ_m as $\mu_m = \sup\{\lambda \geqslant 0,\ m^*(\lambda) \geqslant m\}$.

Potential confusion with covariance operator. Note that the operator Σ is a self-adjoint operator on $L_2(d\rho)$. It should not be confused with the (non-centered) covariance operator C (Baker, 1973), which is a self-adjoint operator on a different space, namely the RKHS $\mathcal{F}$, defined by $\langle g, Cf\rangle_{\mathcal{F}} = \int_{\mathcal{X}} f(x)g(x)d\rho(x)$. Given that $\Sigma^{1/2}$ is an isometry from $L_2(d\rho)$ to $\mathcal{F}$, the operator C may also be used to define an operator on $L_2(d\rho)$, which happens to be exactly Σ. Thus, the two operators have the same eigenvalues. Moreover, we have, for any $y \in \mathcal{X}$:

$$(Cf)(y) = \langle k(\cdot, y), Cf\rangle_{\mathcal{F}} = \int_{\mathcal{X}} k(x, y)f(x)d\rho(x) = (\Sigma f)(y),$$

that is, C is equal to the restriction of Σ on $\mathcal{F}$.

2.2 Kernels as Expectations

On top of the generic assumptions made above, we assume that there is another measurable set $\mathcal{V}$ equipped with a probability measure $d\tau$. We consider a function $\varphi : \mathcal{V} \times \mathcal{X} \to \mathbb{R}$ which

is square-integrable (for the measure $d\tau \otimes d\rho$), and assume that the kernel k may be written as, for all $x, y \in \mathcal{X}$:

$$k(x,y) = \int_{\mathcal{V}} \varphi(v,x)\varphi(v,y)d\tau(v) = \langle \varphi(\cdot,x), \varphi(\cdot,y)\rangle_{L_2(d\tau)}. \quad (1)$$

In other words, the kernel between x and y is simply the expectation of $\varphi(v,x)\varphi(v,y)$ for v following the probability distribution $d\tau$. In this paper, we see $x \mapsto \varphi(v,x) \in \mathbb{R}$ as a one-dimensional random feature and $\varphi(v,x)\varphi(v,y)$ is the dot-product associated with this random feature. We could consider extensions where $\varphi(v,x)$ has values in a Hilbert space (and not simply $\mathbb{R}$), but this is outside the scope of this paper.

Square-root of integral operator. Such additional structure allows to give an explicit characterization of the RKHS $\mathcal{F}$ in terms of the features φ. In terms of operators, the function φ leads to a specific square-root of the integral operator Σ defined in Section 2.1 (which is not the positive self-adjoint square-root $\Sigma^{1/2}$).

We consider the bounded linear operator $T : L_2(d\tau) \to L_2(d\rho)$ defined as

$$(Tg)(x) = \int_{\mathcal{V}} g(v)\varphi(v,x)d\tau(v) = \langle g, \varphi(\cdot,x)\rangle_{L_2(d\tau)}. \quad (2)$$

Given $T : L_2(d\tau) \to L_2(d\rho)$, the adjoint operator $T^* : L_2(d\rho) \to L_2(d\tau)$ is the unique operator such that $\langle g, T^*f\rangle_{L_2(d\tau)} = \langle Tg, f\rangle_{L_2(d\rho)}$ for all f, g. Given the definition of T in Eq. (2), we simply inverse the role of $\mathcal{V}$ and $\mathcal{X}$ and have:

$$(T^*f)(v) = \int_{\mathcal{X}} f(x)\varphi(v,x)d\rho(x).$$

This implies by Fubini's theorem that

$$\begin{aligned}(TT^*f)(y) &= \int_{\mathcal{V}} \Big(\int_{\mathcal{X}} f(x)\varphi(v,y)d\rho(x)\Big)\varphi(v,x)d\tau(v) \\ &= \int_{\mathcal{X}} f(x)\Big(\int_{\mathcal{V}} \varphi(v,y)\varphi(v,x)d\tau(v)\Big)d\rho(x) = \int_{\mathcal{X}} f(x)k(x,y)d\rho(x) = (\Sigma f)(y),\end{aligned}$$

that is we have an expression of the integral operator Σ as $\Sigma = TT^*$. Thus, the decomposition of the kernel k as an expectation corresponds to a particular *square root* T of the integral operator—there are many possible choices for such square roots, and thus many possible expansions like Eq. (1). It turns out that the positive self-adjoint square root $\Sigma^{1/2}$ will correspond to the equivalence with quadrature rules (see Section 3.2).

Decomposition of functions in $\mathcal{F}$. Since $\Sigma = TT^*$ and $\Sigma^{1/2}$ is an isometry between $L_2(d\rho)$ and $\mathcal{F}$, we can naturally expressed any elements of $\mathcal{F}$ through the operator T and thus the features φ.

As a linear operator, T defines a bijection from the orthogonal of its null space $(\text{Ker } T)^\perp \subset L_2(d\tau)$ to its image $\text{Im}(T) \subset L_2(d\rho)$, and this allows to define uniquely $T^{-1}f \in (\text{Ker } T)^\perp$ for any $f \in \text{Im}(T)$, and a dot-product on $\text{Im}(T)$ as

$$\langle f, h\rangle_{\text{Im}(T)} = \langle T^{-1}f, T^{-1}g\rangle_{L_2(d\tau)}.$$

As shown by Bach (2017, App. A), $\text{Im}(T)$ turns out to be equal to our RKHS[2]. Thus, the norm $\|f\|_{\mathcal{F}}^2$ for $f \in \mathcal{F}$ is equal to the squared L_2-norm of $T^{-1}f \in (\text{Ker } T)^\perp$, which is itself equal to the minimum of $\|g\|_{L_2(d\tau)}^2$ over all g such that $Tg = f$. The resulting g may also be defined through pseudo-inverses.

In other words, a function $f \in L_2(d\rho)$ is in $\mathcal{F}$ if and only if it may be written as

$$\forall x \in \mathcal{X},\ f(x) = \int_{\mathcal{V}} g(v)\varphi(v,x)d\tau(v) = \langle g, \varphi(\cdot,x)\rangle_{L_2(d\tau)},$$

for a certain function $g : \mathcal{V} \to \mathbb{R}$ such that $\|g\|_{L_2(d\tau)}^2$ is finite, with a norm $\|f\|_{\mathcal{F}}^2$ equal to the minimum (which is always attained) of $\|g\|_{L_2(d\tau)}^2$, over all possible decompositions of f.

Singular value decomposition. The operator T is an Hilbert-Schmidt operator, to which the singular value decopomposition can be applied (Kato, 1995). That is, there exists an orthonormal basis $(f_m)_{m\geqslant 1}$ of $(\text{Ker } T)^\perp \subset L_2(d\tau)$, together with the orthonormal basis $(e_m)_{m\geqslant 1}$ of $L_2(d\rho)$ which we have from the eigenvalue decomposition of $\Sigma = TT^*$, such that $Tf_m = \mu_m^{1/2}e_m$. Moreover, we have:

$$\varphi(v,x) = \sum_{m\geqslant 1} \mu_m^{1/2} e_m(x)f_m(v), \quad (3)$$

with a convergence in $L_2(d\tau \otimes d\rho)$. This extends the Mercer decomposition of the kernel $k(x,y)$.

Integral operator as an expectation. Given the expansion of the kernel k in Eq. (1), we may express the integral operator Σ as follows, explicitly as an expectation:

$$\begin{aligned}\Sigma f &= \int_{\mathcal{X}} f(y)k(\cdot,y)d\rho(y) = \int_{\mathcal{X}}\int_{\mathcal{V}} f(y)\varphi(v,\cdot)\varphi(v,y)d\rho(y)d\tau(v) \\ &= \int_{\mathcal{V}} \varphi(v,\cdot)\langle \varphi(v,\cdot), f\rangle_{L_2(d\rho)}d\tau(v) = \Big(\int_{\mathcal{V}} \varphi(v,\cdot) \otimes_{L_2(d\rho)} \varphi(v,\cdot)d\tau(v)\Big)f, \quad (4)\end{aligned}$$

where $a \otimes_{L_2(d\rho)} b$ is the operator $L_2(d\rho) \to L_2(d\rho)$ so that $(a \otimes_{L_2(d\rho)} b)f = \langle b, f\rangle_{L_2(d\rho)}a$. This will be useful to define empirical versions, where the integral over $d\tau$ will be replaced by a finite average.

2.3 Examples

In this section, we provide examples of kernels and usual decompositions. We first start by decompositions that always exist, then focus on specific kernels based on Fourier components.

2. The proof goes as follows: (a) for any $y \in \mathcal{X}$, $k(\cdot,y)$ can be expressed as $\int_{\mathcal{V}} \varphi(v,y)\varphi(v,\cdot)d\tau(v) = T\varphi(\cdot,y)$ and thus belongs to $\text{Im}(T)$; (b) for any $f \in \text{Im}(T)$, and $y \in \mathcal{X}$, we have $\langle f, k(\cdot,y)\rangle_{\text{Im}(T)} = \langle T^{-1}f, \varphi(\cdot,y)\rangle_{L_2(d\tau)} = (TT^{-1}f)(y) = f(y)$, that is, the reproducing property is satisfied. These two properties are characteristic of $\mathcal{F}$.

Mercer decompositions. The Mercer decomposition provides an expansion for all kernels, as follows:

$$k(x,y) = \sum_{m \geqslant 1} \frac{\mu_m}{\operatorname{tr} \Sigma} \Big[\big(\operatorname{tr} \Sigma \big)^{1/2} e_m(x) \Big] \cdot \Big[\big(\operatorname{tr} \Sigma \big)^{1/2} e_m(x) \Big],$$

which can be transformed in to an expectation with $\mathcal{V} = \mathbb{N}^*$. In Section 3.2, we provide another generic decomposition with $\mathcal{V} = \mathcal{X}$. Note that this decomposition is typically impossible to compute (except for special cases below, i.e., special pairs of kernels k and distributions $d\rho$).

Periodic kernels on $[0,1]$. We consider $\mathcal{X} = [0,1]$ and translation-invariant kernels $k(x,y)$ of the form $k(x,y) = t(x-y)$, where t is a square-integrable 1-periodic function. These kernels are positive definite if and only if the Fourier series of t is non-negative (Wahba, 1990). An orthonormal basis of $L_2([0,1])$ is composed of the constant function $c_0 : x \mapsto 1$ and the functions $c_m : x \mapsto \sqrt{2} \cos 2\pi mx$ and $s_m : x \mapsto \sqrt{2} \sin 2\pi mx$. A kernel may thus be expressed as

$$k(x,y) = \nu_0 c_0(x) + \sum_{m>0} \nu_m \big[c_m(x) c_m(y) + s_m(x) s_m(y) \big] = \nu_0 + 2 \sum_{m>0} \nu_m \cos 2\pi m(x-y).$$

This can be put trivially as an expectation with $\mathcal{V} = \mathbb{Z}$ and leads to the usual Fourier features (Rahimi and Recht, 2007). This is also exactly a Mercer decomposition for k and the uniform distribution on $[0,1]$, with eigenvalues ν_0 and ν_m, $m > 0$ (each of these with multiplicity 2). The associated RKHS norm for a function f is then equal to

$$\|f\|_{\mathcal{F}}^2 = \nu_0^{-1} \Big(\int_0^1 f(x) dx \Big)^2 + 2 \sum_{m>0} \nu_m^{-1} \left[\Big(\int_0^1 f(x) \cos 2\pi mx dx \Big)^2 + \Big(\int_0^1 f(x) \sin 2\pi mx dx \Big)^2 \right].$$

A particularly interesting example is obtained through derivatives of f. If f is differentiable and has a derivative $f' \in L_2([0,1])$, then, on the Fourier series coefficients of f, taking the derivative corresponds to multiplying the two m-th coefficients by $2\pi m$ and swapping them. Sobolev spaces for periodic functions on $[0,1]$ (i.e., such that $f(0) = f(1)$) are defined through integrability of derivatives (Adams and Fournier, 2003). In the Hilbert space set-up, a function f belongs to the Sobolev space of order s if one can define a s-th order square-integrable derivative in L_2 (for the Lebesgue measure, which happens to be equal to $d\rho$), that is, $f^{(s)} \in L_2([0,1])$. The Sobolev squared norm is then defined as any positive linear combination of the quadratic forms $\int_0^1 f^{(t)}(x)^2 dx$, $t \in \{0, \dots, s\}$, with non-zero coefficients for $t = 0$ and $t = s$ (all of these norms are then equivalent). If only using $t = 0$ and $t = s$ with non-zero coefficients, we need $\nu_0^{-1} = 1$ and $\nu_m^{-1} = 1 + m^{2s}$. An equivalent (i.e, with upper and lower bounded ratios) sequence is obtained by replacing $\nu_m = (1 + m^{2s})^{-1}$ by $\nu_m = m^{-2s}$, leading to a closed-form formula:

$$k(x,y) = 1 + \frac{(-1)^{s-1} (2\pi)^{2s}}{(2s)!} B_{2s}(\{x-y\}),$$

where $\{x-y\}$ denotes the fractional part of $x-y$, and B_{2s} is the $2s$-th Bernoulli polynomial (Wahba, 1990). The RKHS $\mathcal{F}$ is then the Sobolev space of order s on $[0,1]$, with a norm equivalent to any of the family of Sobolev norms; it will be used as a running example throughout this paper.

Extensions to $[0,1]^d$. In order to extend to $d > 1$, we may consider several extensions as described by Oates and Girolami (2015), and compute the resulting eigenvalues of the integral operators. For simplicity, we consider the Sobolev space on $[0,1]$, with $\nu_0 = 1$ and $\nu_m^{-1} = m^{2s}$ for $m > 0$. The first possibility to extend to $[0,1]^d$ is to take a kernel which is simply the pointwise product of individual kernels on $[0,1]$. That is, if $k(x,y)$ is the kernel on $[0,1]$, define $K(X,Y) = \prod_{j=1}^d k(x_j, y_j)$ between X and Y in $[0,1]^d$. As shown in Appendix A, this leads to eigenvalue decays bounded by $(\log m)^{2s(d-1)} m^{-2s}$, and thus up to logarithmic terms at the same speed m^{-2s} as $d = 1$. While this sounds attractive in terms of generalization performance, it corresponds to a space a function which is not a Sobolev space in d dimensions. That is the associated squared norm on f would be equivalent to a linear combination of squared L_2-norm of partial derivatives

$$\int_{[0,1]^d} \Big(\frac{\partial^{t_1 + \cdots + t_d} f}{\partial x_1^{t_1} \cdots \partial x_d^{t_d}} \Big)^2 dx$$

for all $t_1, \dots, t_d$ in $\{0, \dots, s\}$. This corresponds to functions which have square-integrable partial derivatives with all *individual* orders less than s. All values of $s \geqslant 1$ are allowed and lead to an RKHS.

This is thus to be contrasted with the usual multi-dimensional Sobolev space which is composed of functions which have square-integrable partial derivatives with all orders $(t_1, \dots, t_d)$ with *sum* $t_1 + \cdots + t_d$ less than s. Only $s > d/2$ is then allowed to get an RKHS (see, e.g., Berlinet and Thomas-Agnan, 2004, Theorem 132, p. 348). The Sobolev norm is then of the form

$$\sum_{t_1 + \cdots + t_d \leqslant s} \int_{[0,1]^d} \Big(\frac{\partial^{t_1 + \cdots + t_d} f}{\partial x_1^{t_1} \cdots \partial x_d^{t_d}} \Big)^2 dx.$$

In the expansion on the d-th order tensor product of the Fourier basis, the norm above is equivalent to putting a weight on the element $(m_1, \dots, m_d)$ asymptotically equivalent to $\big(\sum_{j=1}^d m_j \big)^{2s}$, which thus represent the inverse of the eigenvalues of the corresponding kernel for the uniform distribution $d\rho$ (this is simply an explicit Mercer decomposition). Thus, the number of eigenvalues which are greater than λ grows as the number of $(m_1, \dots, m_d)$ such that their sum is less than $\lambda^{-1/(2s)}$, which itself is less than a constant times $\lambda^{-d/(2s)}$ (see a proof in Appendix A). This leads to an eigenvalue decay of $m^{-2s/d}$, which is much worse because of the term in $1/d$ in the exponent.

Translation invariant kernels on $\mathbb{R}^d$. We consider $\mathcal{X} = \mathbb{R}^d$ and translation-invariant kernels $k(x,y)$ of the form $k(x,y) = t(x-y)$, where t is an integrable function from $\mathbb{R}^d$ to $\mathbb{R}$. It is known that these kernels are positive definite if and only if the Fourier transform of t is always a non-negative real number. More precisely, if $\hat{t}(\omega) = \int_{\mathbb{R}^d} t(x) e^{-i\omega^\top x} dx \in \mathbb{R}_+$, then

$$k(x,y) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} \hat{t}(\omega) e^{i\omega^\top (x-y)} d\omega = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} \hat{t}(\omega) \big[\cos \omega^\top x \cos \omega^\top y + \sin \omega^\top x \sin \omega^\top y \big] d\omega.$$

Following Rahimi and Recht (2007), by sampling ω from a density proportional to $\hat{t}(\omega) \in \mathbb{R}_+$ and b uniformly in $[0,1]$ (and independently of ω), then by defining $\mathcal{V} = \mathbb{R}^d \times [0,1]$ and $\varphi(\omega, b, x) = \sqrt{2} \cos(\omega^\top x + 2\pi b)$, we obtain the kernel k.

For these kernels, the decay of eigenvalues has been well-studied by Widom (1963), who relates the decay of eigenvalues to the tails of the distribution $d\rho$ and the decay of the Fourier transform of t. For example, for the Gaussian kernel where $k(x,y) = \exp(-\alpha\|x-y\|_2^2)$, on sub-Gaussian distributions, the decay of eigenvalues is geometric, and for kernels leading to Sobolev spaces of order s, such as the Matern kernel (Furrer and Nychka, 2007), the decay is of the form $m^{-2s/d}$. See also examples by Birman and Solomyak (1977); Harchaoui et al. (2008).

Finally, note that in terms of computation, there are extensions to avoid linear complexity in d (Le et al., 2013).

Kernels on hyperspheres. If $\mathcal{X} \subset \mathbb{R}^{d+1}$ is the d-dimensional hypersphere defined as $\{x \in \mathbb{R}^{d+1}, \|x\|_2^2 = 1\}$, then specific kernels may be used, of the form $k(x,y) = t(x^\top y)$, where t has to have a positive Legendre expansion (Smola et al., 2001). Alternatively, kernels based on neural networks with random weights are directly in the form of random features (Cho and Saul, 2009; Bach, 2017): for example, the kernel $k(x,y) = \mathbb{E}(v^\top x)_+^s (v^\top x)_+^s$ for v uniformly distributed in the hypersphere corresponds to sampling weights in a one-hidden layer neural network with rectified linear units (Cho and Saul, 2009). It turns out that these kernels have a known decay for their spectrum.

As shown by Smola et al. (2001); Bach (2017), the equivalent of Fourier series (which corresponds to $d = 1$) is then the basis of spherical harmonics, which is organized by integer frequencies $k \geqslant 1$; instead of having 2 basis vectors (sine and cosine) per frequency, there are $O(k^{d-1})$ of them. As shown by Bach (2017, page 44), we have an explicit expansion of $k(x,y)$ in terms of spherical harmonics, leading to a sequence of eigenvalues equal to $k^{-d-2s-1}$ on the entire subspace associated with frequency k. Thus, by taking multiplicity into account, after $\sum_{j=1}^k j^{d-1} \approx k^d$ (up to constants) eigenvalues, we have an eigenvalue of $k^{-d-2s-1}$; this leads to an eigenvalue decay (where all eigenvalues are ordered in decreasing order and we consider the m-th one) as $(m^{1/d})^{-d-2s-1} = m^{-1-1/d-2s/d}$.

2.4 Approximation from Randomly Sampled Features

Given the formulation of k as an expectation in Eq. (1), it is natural to consider sampling n elements $v_1, \dots, v_n \in \mathcal{V}$ from the distribution $d\tau$ and define the kernel approximation

$$\hat{k}(x,y) = \frac{1}{n}\sum_{i=1}^n \varphi(v_i,x)\varphi(v_i,y), \tag{5}$$

which defines a finite-dimensional RKHS $\hat{\mathcal{F}}$.

From the strong law of large numbers—which can be applied because we have the finite expectation $\mathbb{E}|\varphi(v,x)\varphi(v,y)| \leqslant \big(\mathbb{E}|\varphi(v,x)|^2\mathbb{E}|\varphi(v,y)|^2\big)^{1/2}$, when n tends to infinity, $\hat{k}(x,y)$ tends to $k(x,y)$ almost surely, and thus we get as tight as desired approximations of the kernel k, for a given pair $(x,y) \in \mathcal{X}\times\mathcal{X}$. Rahimi and Recht (2007) show that for translation-invariant kernels on a Euclidean space, then the convergence is uniform over a compact subset of $\mathcal{X}$, with the traditional rate of convergence of $\sqrt{\frac{\log n}{n}}$.

In this paper, we rather consider *approximations of functions* in $\mathcal{F}$ by functions in $\hat{\mathcal{F}}$, the RKHS associated with $\hat{k}$. A key difficulty is that in general $\hat{\mathcal{F}}$ is not even included in $\mathcal{F}$,

and therefore, we cannot use the norm in $\mathcal{F}$ to characterize approximations. In this paper, we choose the L_2-norm associated with the probability measure $d\rho$ on $\mathcal{X}$ to characterize the approximation. Given $f \in \mathcal{F}$ with norm $\|f\|_{\mathcal{F}}$ less than one, we look for a function $\hat{f} \in \hat{\mathcal{F}}$ of the smallest possible norm and so that $\|f - \hat{f}\|_{L_2(d\rho)}$ is as small as possible.

Note that the measure $d\tau$ is associated to the kernel k and the random features φ, while the measure $d\rho$ is associated to the way we want to measure errors (and leads to a specific defintion of the integral operator Σ).

Computation of error. Given the definition of the Hilbert space $\mathcal{F}$ in terms of φ in Section 2.2, given $g \in L_2(d\tau)$ with $\|g\|_{L_2(d\tau)} \leqslant 1$ and $f(x) = \int_{\mathcal{V}} g(v)\varphi(v,x)d\tau(v)$, we aim at finding an element of $\hat{\mathcal{F}}$ close to f. We can also represent $\hat{\mathcal{F}}$ through a similar decomposition, now with a finite number of features, i.e., through $\alpha \in \mathbb{R}^n$ such that $\hat{f} = \sum_{i=1}^n \alpha_i \varphi(v_i,\cdot)$ with norm[3] $\|\hat{f}\|_{\hat{\mathcal{F}}}^2 \leqslant n\|\alpha\|_2^2$ as small as possible and so that the following approximation error is also small:

$$\|\hat{f} - f\|_{L_2(d\rho)} = \Big\| \sum_{i=1}^n \alpha_i \varphi(v_i,\cdot) - \int_{\mathcal{V}} g(v)\varphi(v,\cdot)d\tau(v)\Big\|_{L_2(d\rho)}. \tag{6}$$

Note that with $\alpha_i = \frac{1}{n}g(v_i)$ and v_i sampled from $d\tau$ (independently), then, we have $\mathbb{E}(\|\alpha\|_2^2) = \sum_{i=1}^n \mathbb{E}\alpha_i^2 = \frac{1}{n}\mathbb{E}g(v)^2 \leqslant \frac{1}{n}$ and an expected error equal to $\mathbb{E}(\|f-\hat{f}\|_{L_2(d\rho)}^2) = \frac{1}{n}\mathbb{E}\|g(v)\varphi(v,\cdot)\|_{L_2(d\rho)}^2 \leqslant \frac{1}{n}\sup_{v\in\mathcal{V}}\|\varphi(v,\cdot)\|_{L_2(d\rho)}^2$; our goal is to obtain an error rate with a better scaling in n, by (a) choosing a better distribution than $d\tau$ for the points $v_1,\dots,v_n$ and (b) by finding the best possible weights $\alpha \in \mathbb{R}^n$ (that should of course depend on the function g).

Goals. We thus aim at sampling n points $v_1,\dots,v_n \in \mathcal{V}$ from a distribution with density q with respect to $d\tau$. Then the kernel approximation using *importance weights* is equal to

$$\hat{k}(x,y) = \frac{1}{n}\sum_{i=1}^n \frac{1}{q(v_i)}\varphi(v_i,x)\varphi(v_i,y)$$

(so that the law of large numbers leads to an approximation converging to k), and we thus aim at minimizing $\Big\|\sum_{i=1}^n \frac{\beta_i}{q(v_i)^{1/2}}\varphi(v_i,\cdot) - \int_{\mathcal{V}} g(v)\varphi(v,\cdot)d\tau(v)\Big\|_{L_2(d\rho)}$, with $n\|\beta\|_2^2$ (which represents the norm of the approximation in $\hat{\mathcal{F}}$ because of our importance weights are taken into account) as small as possible.

3. Quadrature in RKHSs

Given a square-integrable (with respect to $d\rho$) function $g : \mathcal{X} \to \mathbb{R}$, the quadrature problem aims at approximating, for all $h \in \mathcal{F}$, integrals

$$\int_{\mathcal{X}} h(x)g(x)d\rho(x)$$

3. Note the factor n because our finite-dimensional kernel in Eq. (5) is an average of kernels and not a sum.

by linear combinations

$$\sum_{i=1}^n \alpha_i h(x_i)$$

of evaluations $h(x_1), \dots, h(x_n)$ of the function h at well-chosen points $x_1, \dots, x_n \in \mathcal{X}$. Of course, coefficients $\alpha \in \mathbb{R}^n$ are allowed to depend on g (they will in linear fashion in the next section), but not on h, as the so-called quadrature rule has to be applied to all functions in $\mathcal{F}$.

3.1 Approximation of the Mean Element

Following Smola et al. (2007), the error may be expressed using the reproducing property as:

$$\sum_{i=1}^n \alpha_i h(x_i) - \int_{\mathcal{X}} h(x) g(x) d\rho(x) = \left\langle h, \sum_{i=1}^n \alpha_i k(\cdot, x_i) - \int_{\mathcal{X}} k(\cdot, x) g(x) d\rho(x) \right\rangle_{\mathcal{F}},$$

and by Cauchy-Schwarz inequality its supremum over $\|h\|_{\mathcal{F}} \leqslant 1$ is equal to

$$\left\| \sum_{i=1}^n \alpha_i k(\cdot, x_i) - \int_{\mathcal{X}} k(\cdot, x) g(x) d\rho(x) \right\|_{\mathcal{F}}. \tag{7}$$

The goal of quadrature rules formulated in a RKHS is thus to find points $x_1, \dots, x_n \in \mathcal{X}$ and weights $\alpha \in \mathbb{R}^n$ so that the quantity in Eq. (7) is as small as possible (Smola et al., 2007). For $g = 1$, the function $\int_{\mathcal{X}} k(\cdot, x) d\rho(x)$ is usually referred to as the mean element of the distribution $d\rho$.

The standard Monte-Carlo solution is to consider $x_1, \dots, x_n$ sampled i.i.d. from $d\rho$ and the weights $\alpha_i = g(x_i)/n$, which leads to a decrease of the error in $1/\sqrt{n}$, with $\mathbb{E}\|\alpha\|_2^2 \leqslant \frac{1}{n}$ and an expected squared error which is equal to $\frac{1}{n}\mathbb{E}\|g(v)k(\cdot, x)\|_{\mathcal{F}}^2 \leqslant \frac{1}{n}\|g\|_{L_2(d\rho)}^2 \sup_{x \in \mathcal{X}} k(x, x)$ (Smola et al., 2007). Note that when $g = 1$, Eq. (7) corresponds to a particular metric between the distribution $d\rho$ and its corresponding empirical distribution (Sriperumbudur et al., 2010).

In this paper, we explore sampling points x_i from a probability distribution on $\mathcal{X}$ with density q with respect to $d\rho$. Note that when g is a constant function, it is sometimes required that the coefficients α are non-negative and sum to a fixed constant (so that constant functions are exactly integrated). We will not pursue this here as our theoretical results do not accommodate such constraints (see, e.g., Chen et al., 2010; Bach et al., 2012, and references therein).

Tolerance to noisy function values. In practice, independent (but not necessarily identically distributed) noise ε_i may be present with variance $\sigma^2(x_i)$. Then, the worst (with respect to $\|h\|_{\mathcal{F}} \leqslant 1$) expected (with respect to the noise) squared error is

$$\begin{aligned} &\inf_{\|h\|_{\mathcal{F}} \leqslant 1} \mathbb{E} \left| \sum_{i=1}^n \alpha_i (h(x_i) + \varepsilon_i) - \int_{\mathcal{X}} h(x) g(x) d\rho(x) \right|^2 \\ = \ & \left\| \sum_{i=1}^n \alpha_i k(\cdot, x_i) - \int_{\mathcal{X}} k(\cdot, x) g(x) d\rho(x) \right\|_{\mathcal{F}}^2 + \sum_{i=1}^n \alpha_i^2 \sigma^2(x_i), \end{aligned}$$

and thus in order to be robust to noise, having a small weighted ℓ_2-norm for the coefficients $\alpha \in \mathbb{R}^n$ is important.

3.2 Reformulation as Random Features

For any $x \in \mathcal{X}$, the function $k(\cdot, x)$ is in $\mathcal{F}$, and since we have assumed that $\Sigma^{1/2}$ is an isometry from $L_2(d\rho)$ to $\mathcal{F}$, there exists a unique element, which we denote $\psi(\cdot, x)$, of $L_2(d\rho)$ such that $\Sigma^{1/2}\psi(\cdot, x) = k(\cdot, x)$. Given the Mercer decomposition $k(\cdot, x) = \sum_{m \geqslant 1} \mu_m e_m(x) e_m$, we have the expansion $\psi(\cdot, x) = \sum_{m \geqslant 1} \mu_m^{1/2} e_m(x) e_m$ (with convergence in the L_2-norm for the measure $d\rho \otimes d\rho$; note that we do not assume that $\mu_m^{1/2}$ is summable), and thus we may consider ψ as a symmetric function. Note that ψ may not be easy to compute in many practical cases (except for some periodic kernels on $[0, 1]$).

We thus have for $(x, y) \in \mathcal{X} \times \mathcal{X}$:

$$\begin{aligned} k(x, y) &= \langle k(\cdot, x), k(\cdot, y) \rangle_{\mathcal{F}} = \langle \Sigma^{1/2}\psi(\cdot, x), \Sigma^{1/2}\psi(\cdot, y) \rangle_{\mathcal{F}} = \langle \psi(\cdot, x), \psi(\cdot, y) \rangle_{L_2(d\rho)} \\ &\qquad \text{because of the isometry property of } \Sigma^{1/2}, \\ &= \int_{\mathcal{X}} \psi(v, x)\psi(v, y) d\rho(v). \end{aligned} \tag{8}$$

That is, the kernel k may always be written as an expectation. Moreover, we have the quadrature error in Eq. (7) equal to (again using the isometry $\Sigma^{1/2}$ from $L_2(d\rho)$ to $\mathcal{F}$):

$$\begin{aligned} \left\| \sum_{i=1}^n \alpha_i k(\cdot, x_i) - \int_{\mathcal{X}} k(\cdot, x) g(x) d\rho(x) \right\|_{\mathcal{F}} &= \left\| \sum_{i=1}^n \alpha_i \Sigma^{1/2}\psi(x_i, \cdot) - \int_{\mathcal{X}} \Sigma^{1/2}\psi(x, \cdot) g(x) d\rho(x) \right\|_{\mathcal{F}} \\ &= \left\| \sum_{i=1}^n \alpha_i \psi(x_i, \cdot) - \int_{\mathcal{X}} \psi(x, \cdot) g(x) d\rho(x) \right\|_{L_2(d\rho)}, \end{aligned}$$

which is exactly an instance of the approximation result in Eq. (6) with $\mathcal{V} = \mathcal{X}$ and $\varphi = \psi$, that is the random feature is indexed by the same set $\mathcal{X}$ as the kernel. Thus, the quadrature problem, that is finding points x_i and weights (α_i) to get the best possible error over all functions of the unit ball of $\mathcal{F}$, is a *subcase* of the random feature problem for a specific expansion. Note that this random decomposition in terms of ψ is always possible (although not in closed form in general).

Interpretation through square-roots of intergral operators. As shown in Section 2.2, random feature expansions correspond to square-roots of the integral operator $\Sigma : L_2(d\rho) \to L_2(d\rho)$ as $\Sigma = TT^*$. Among the many possible square roots, the quadrature case corresponds exactly to the positive self-adjoint square root $T = \Sigma^{1/2}$. In this situation, the basis $(f_m)_{m \geqslant 1}$ of the singular value decomposition of $T = \Sigma^{1/2}$ is equal to $(e_m)_{m \geqslant 1}$, recovering the expansion $\psi(x, y) = \sum_{m \geqslant 1} \mu_m^{1/2} e_m(x) e_m(y)$ which we have seen above.

Translation-invariant kernels on $[0, 1]^d$ or $\mathcal{X} = \mathbb{R}^d$. In this important situation, we have two different expansions: the one based on Fourier features, where the random variable indexing the one-dimensional feature is a *frequency*, while for the one based on the square root ψ, the random variable is a *spatial variable* in $\mathcal{X}$. As we show in Section 4, our results are independent of the chosen expansions and thus apply to both. However, (a) when the

goal is to do quadrature, we need to use ψ, and (b) in general, the decomposition based on Fourier features can be easily computed once samples are obtained, while for most kernels, $\psi(x, y)$ does not have any closed-form simple expression. In Section 6, we provide a simple example with $\mathcal{X} = [0, 1]$ where the two decompositions are considered.

Goals. In order to be able to make the parallel with random feature approximations, we consider importance-weighted coefficients $\beta_i = \alpha_i q(x_i)^{1/2}$, and we thus aim at minimizing the approximation error

$$\Big\| \sum_{i=1}^n \beta_i q(x_i)^{-1/2} k(\cdot, x_i) - \int_{\mathcal{X}} k(\cdot, x) g(x) d\rho(x) \Big\|_{\mathcal{F}}.$$

We consider potential independent noise with variance $\sigma^2(x_i) \leqslant \tau^2 q(x_i)$ for all x_i, so that the tolerance to noise is characterized by the ℓ_2-norm $\|\beta\|_2$.

3.3 Relationship with Column Sampling

The problem of quadrature is related to the problem of column sampling. Given n observations $x_1, \dots, x_n \in \mathcal{X}$, the goal of column-sampling methods is to approximate the $n \times n$ matrix of pairwise kernel evalulations, the so-called *kernel matrix*, from a subset of its columns. It has appeared under many names: Nyström method (Williams and Seeger, 2001), sparse greedy approximations (Smola and Schölkopf, 2000), incomplete Cholesky decomposition (Fine and Scheinberg, 2001), Gram-Schmidt orthonormalization (see, e.g., Shawe-Taylor and Cristianini, 2004) or CUR matrix decompositions (Mahoney and Drineas, 2009).

While column sampling has typically been analyzed for a fixed kernel matrix, it has a natural extension which is related to quadrature problems: selecting n points $x_1, \dots, x_n$ from $\mathcal{X}$ such that the projection of any element of the RKHS $\mathcal{F}$ onto the subspace spanned by $k(\cdot, x_i)$, $i = 1, \dots, n$ is as small as possible. Natural functions from $\mathcal{F}$ are $k(\cdot, x)$, $x \in \mathcal{X}$, and thus the goal is to minimize, for such $x \in \mathcal{X}$,

$$\inf_{\alpha \in \mathbb{R}^n} \Big\| \sum_{i=1}^n \alpha_i k(\cdot, x_i) - k(\cdot, x) \Big\|_{\mathcal{F}}^2.$$

In the usual sampling approach, several points are considered for testing the projection error, and it is thus natural to consider the criterion averaged through the measure $d\rho$, that is:

$$\int_{\mathcal{X}} \inf_{\alpha \in \mathbb{R}^n} \Big\| \sum_{i=1}^n \alpha_i k(\cdot, x_i) - k(\cdot, x) \Big\|_{\mathcal{F}}^2 d\rho(x).$$

In fact, when $d\rho$ is supported on a finite set, this formulation is equivalent to minimizing the nuclear norm between the kernel matrix and its low-rank approximation. There are thus several differences and similarities between recent work on column sampling (Bach, 2013; El Alaoui and Mahoney, 2015) and the present paper on quadrature rules and random features:

- **Different error measures**: The column sampling approach corresponds to a function g in Eq. (7) which is a Dirac function at the point x, and is thus not in $L_2(d\rho)$. Thus the two frameworks are not equivalent.

- **Approximation vs. prediction**: The works by Bach (2013); El Alaoui and Mahoney (2015) aim at understanding when column sampling leads to no loss in predictive performance within a supervised learning framework, while the present paper looks at approximation properties, mostly regardless of any supervised learning problem, except in Section 4.5 for random features (but not for quadrature).
- **Lower bounds**: In Section 4.3, we provide explicit lower bounds of approximations, which are not available for column sampling.
- **Similar sampling issues**: In the two frameworks, points $x_1, \dots, x_n \in \mathcal{X}$ are sampled i.i.d. with a certain distribution q, and the best choice depends on the appropriate notion of leverage scores (Mahoney, 2011), while the standard uniform distribution leads to an inferior approximation result. Moreover, the proof techniques are similar and based on concentration inequalities for operators, here in Hilbert spaces rather in finite dimensions.

3.4 Related Work on Quadrature

Many methods have been designed for the computation of integrals of a function given evaluations at certain well-chosen points, in most cases when g is constant equal to one. We review some of these below.

Uni-dimensional integrals. When the underlying set $\mathcal{X}$ is a compact interval of the real line, several methods exists, such as the trapezoidal or Simpson's rules, which are based on interpolation between the sample points, and for which the error decays as $O(1/n^2)$ and $O(1/n^4)$ for functions with uniformly bounded second or fourth derivatives (Cruz-Uribe and Neugebauer, 2002).

Gaussian quadrature is another class of methods for one-dimensional integrals: it is based on a basis of orthogonal polynomials for $L_2(d\rho)$ where $d\rho$ is a probability measure supported in an interval, and their zeros (Hildebrand, 1987, Chap. 8). This leads to quadrature rules which are exact for polynomials of degree $2n - 1$ but error bounds for non-polynomials rely on high-order derivatives, although the empirical performance on functions of a Sobolev space in our experiments is as good as optimal quadrature schemes (see Section 6); depending on the orthogonal polynomials, we get various quadrature rules, such as Gauss-Legendre quadrature for the Lebesgue measure on $[0, 1]$.

Quasi Monte-carlo methods employ a sequence of points with low discrepancy with uniform weights (Morokoff and Caflisch, 1994), leading to approximation errors of $O(1/n)$ for univariate functions with bounded variation, but typically with no adaptation to smoother functions.

Higher-dimensional integrals. All of the methods above may be generalized for products of intervals $[0, 1]^d$, typically with d small. For larger problems, Bayes-Hermite quadrature (O'Hagan, 1991) is essentially equivalent to the quadrature rules we study in this paper.

Some of the quadrature rules are constrained to have positive weights with unit sum (so that the positivity properties of integrals are preserved and constants are exactly inegrated). The quadrature rules we present do not satisfy these constraints. If these constraints are required, kernel herding (Chen et al., 2010; Bach et al., 2012) provides a novel way to select

a sequence of points based on the conditional gradient algorithm, but with currently no convergence guarantees improving over $O(1/\sqrt{n})$ for infinite-dimensional spaces.

Theoretical results. The best possible error for a quadrature rule with n points has been well-studied in several settings; see Novak (1988) for a comprehensive review. For example, for $\mathcal{X} = [0, 1]$ and the space of Sobolev functions, which are RKHSs with eigenvalues of their integral operator decreasing as m^{-2s}, Novak (1988, Prop. 2 and 3, page 38) shows that the best possible quadrature rule for the uniform distribution and $g = 1$ leads to an error rate of n^{-s}, as well as for any squared-integrable function g. The proof of these results (both upper and lower bounds) relies on detailed properties of Sobolev spaces. In this paper, we recover these results using only the decay of eigenvalues of the associated integral operator Σ, thus allowing straightforward extensions to many situations, like Sobolev spaces on manifolds such as hyperspheres (Hesse, 2006), where we also recover existing results (up to logarithmic terms).

Moreover, Novak (1988, page 17) shows that adaptive quadrature rules where points are selected sequentially with the knowledge of the function values at previous points cannot improve the worst-case guarantees. Our results do not recover this lower bound result for adaptivity.

Finally, Langberg and Schulman (2010) consider multiplicative errors in computing integrals and mainly focuses on different function spaces, such as ones used in clustering functionals. Although sampling quadrature points from a well-chosen density is common in the two approaches, the analysis tools are different. It would be interesting to see if some of these tools can be transferred to our RKHS setting.

From quadrature to function approximation and optimization. The problem of quadrature, uniformly over all functions $g \in L_2(d\rho)$ that define the integral, is in fact equivalent to the full approximation of a function h given values at n points, where the approximation error is characterized in L_2-norm. Indeed, given the observations $h(x_i)$, $i = 1, \dots, n$, we build $\sum_{i=1}^n \alpha_i h(x_i)$ as an approximation of $\int_{\mathcal{X}} g(x)h(x)d\rho(x)$. It turns out that the coefficients α_i are linear in g, that is, there exists $a_i \in L_2(d\rho)$ such that $\alpha_i = \langle a_i, g\rangle_{L_2(d\rho)}$. This implies that $\sum_{i=1}^n h(x_i)\langle a_i, g\rangle_{L_2(d\rho)}$ is an approximation of $\langle h, g\rangle_{L_2(d\rho)}$. Thus, the worst case error with respect to g in the unit ball of $L_2(d\rho)$ is $\big\| \sum_{i=1}^n h(x_i)a_i - h\big\|_{L_2(d\rho)}$, that is, we have an approximation result of h through observations of its values at certain points.

Novak (1988) considers the approximation problem in L_∞-norm and shows that for Sobolev spaces, going from L_2- to L_∞-norms incurs a loss of performance of $\sqrt{n}$. We recover partially these results in Section 5 from a more general perspective. When optimizing the points at which the function is evaluated (adaptively or not), the approximation problem is often referred to as experimental design (Cochran and Cox, 1957; Chaloner and Verdinelli, 1995).

Finally, a third problem is of interest (and outside of the scope of this paper), namely the problem of finding the minimum of a function given (potentially noisy) function evaluations. For noiseless problems, Novak (1988, page 26) shows that the approximation and optimization problems have the same worst-case guarantees (with no influence of adaptivity); this optimization problem has also been studied in the bandit setting (Srinivas et al., 2012) and in the framework of "Bayesian optimization" (see, e.g. Bull, 2011).

4. Theoretical Analysis

In this section, we provide approximation bounds for the random feature problem outlined in Section 2.4 (and thus the quadrature problem in Section 3). In Section 4.1, we provide generic upper bounds, which depend on the eigenvalues of the integral operator Σ and present matching lower bounds (up to logarithmic terms) in Section 4.3. The upper-bound depends on specific distributions of samples that we discuss in Section 4.2. We then consider consequences of these results on quadrature (Section 4.4) and random feature expansions (Section 4.5).

4.1 Upper Bound

The following proposition (see proof in Appendix B.1) determines the minimal number of samples required for a given approximation accuracy:

Proposition 1 (Approximation of the unit ball of $\mathcal{F}$) *For $\lambda > 0$ and a distribution with positive density q with respect to $d\tau$, we consider*

$$d_{\max}(q, \lambda) = \sup_{v \in \mathcal{V}} \frac{1}{q(v)} \langle \varphi(v, \cdot), (\Sigma + \lambda I)^{-1} \varphi(v, \cdot)\rangle_{L_2(d\rho)}. \tag{9}$$

Let $v_1, \dots, v_n$ be sampled i.i.d. from the density q, then for any $\delta \in (0, 1)$, if

$$n \geqslant 5 d_{\max}(q, \lambda) \log \frac{16 d_{\max}(q, \lambda)}{\delta},$$

with probability greater than $1 - \delta$, we have $\frac{1}{n}\sum_{i=1}^n q(v_i)^{-1}\|\varphi(v_i, \cdot)\|^2_{L_2(d\rho)} \leqslant \frac{2 \operatorname{tr} \Sigma}{\delta}$ and

$$\sup_{\|f\|_{\mathcal{F}} \leqslant 1} \inf_{\|\beta\|_2^2 \leqslant \frac{4}{n}} \Big\| f - \sum_{i=1}^n \beta_i q(v_i)^{-1/2} \varphi(v_i, \cdot) \Big\|^2_{L_2(d\rho)} \leqslant 4\lambda.$$

We can interpret the proposition above as follows: given any squared error $4\lambda > 0$ and a distribution with density q, the number n of samples from q needed so that the unit ball of $\mathcal{F}$ is approximated by the ball of radius 2 of $\hat{\mathcal{F}}$ is, up to logarithmic terms, at most a constant times $d_{\max}(q, \lambda)$, defined in Eq. (9). The result above is a statement for a fixed q and λ and this number of samples n depends on these.

We could also invert the relationship between λ and n, that is, answer the following question: given a fixed number n of samples, what is the approximation error λ? This requires inverting the function $\lambda \mapsto d_{\max}(q, \lambda)$. This will be done in Section 4.2 for a specific distribution q where the expression simplifies, together with specific examples from Section 2.3.

Finally, note that we also have a bound on $\frac{1}{n}\sum_{i=1}^n q(v_i)^{-1}\|\varphi(v_i, \cdot)\|^2_{L_2(d\rho)}$, which shows that our random functions are not too large on average (this constraint will be needed in the lower bound as well in Section 4.3).

Sketch of proof. The proof technique relies on computing an explicit candidate $\beta \in \mathbb{R}^n$ obtained from minimizing a regularized least-squares formulation

$$\inf_{\beta \in \mathbb{R}^n} \Big\| \sum_{i=1}^n \beta_i q(v_i)^{-1/2} \varphi(v_i, \cdot) - f \Big\|^2_{L_2(d\rho)} + n\lambda \|\beta\|_2^2.$$

It turns out that the final bound on the squared error is exactly proportional to the regularization parameter λ. As shown in Appendix B.1, this leads to an approximation $\hat{f}$ which is a linear function of f, as $\hat{f} = (\hat{\Sigma} + \lambda I)^{-1}\hat{\Sigma} f$, where $\hat{\Sigma}$ is a properly defined empirical integral operator and $\lambda > 0$ is the regularization parameter. Then, Bernstein concentration inequalities for operators (Minsker, 2011) can be used in a way similar to the work of Bach (2013); El Alaoui and Mahoney (2015) on column sampling, to provide a bound on all desired quantities.

Result in expectation. In Section 4.5, we will need a result in expectation. As shown at the end of Appendix B.1, as soons as, $\lambda \leqslant (\operatorname{tr}\Sigma)/4$ and $n \geqslant 5 d_{\max}(\lambda)\log\frac{2(\operatorname{tr}\Sigma)d_{\max}(\lambda)}{\lambda}$, then

$$\mathbb{E}\left(\sup_{\|f\|_{\mathcal{F}}\leqslant 1}\ \inf_{\|\beta\|_2^2\leqslant\frac{4}{n}}\left\|f-\sum_{i=1}^{n}\beta_i q(v_i)^{-1/2}\varphi(v_i,\cdot)\right\|_{L_2(d\rho)}^2\right)\leqslant 8\lambda.$$

4.2 Optimized Distribution

We may now consider a specific distribution that depends on the kernel and on λ, namely

$$q_\lambda^*(v)=\frac{\langle\varphi(v,\cdot),(\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}}{\int_{\mathcal{V}}\langle\varphi(v,\cdot),(\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}d\tau(v)}=\frac{\langle\varphi(v,\cdot),(\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}}{\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}},\quad(10)$$

for which $d_{\max}(q_\lambda^*,\lambda)=d(\lambda)=\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}$. With this distribution, we thus need to have $n\geqslant 5d(\lambda)\log\frac{16d(\lambda)}{\delta}$ with $d(\lambda)=\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}$ is the *degrees of freedom*, a traditional quantity in the analysis of least-squares regression (Hastie and Tibshirani, 1990; Caponnetto and De Vito, 2007), which is always smaller than $d_{\max}(1,\lambda)$ and can be upper-bounded explicitly for many examples, as we now explain. The computation of $d_{\max}(1,\lambda)$ in the operator setting (for which we may use $q=1$), a quantity often referred to as the maximal *leverage score* (Mahoney, 2011), remains an open problem.

The quantity $d(\lambda)$ only depends on the integral operator Σ, that is, for all possible choices of square roots, i.e., all possible choices of feature expansions, the number of samples that our results guarantee is the same. This being said, some expansions may be more computationally practical than others, and when using the distribution with $q(v)=1$, the bounds will be different.

Expression in terms of singular value decomposition. Given the singular value decomposition of φ in Eq. (3), we have, for any $v\in\mathcal{V}$, $\varphi(v,\cdot)=\sum_{m\geqslant 1}\mu_m^{1/2}f_m(v)e_m$ and thus

$$q_\lambda^*(v)\propto\langle\varphi(v,\cdot),(\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}=\sum_{m\geqslant 1}\frac{\mu_m}{\mu_m+\lambda}f_m(v)^2,$$

which provides an explicit expression for the density q_λ^*.

For a given squared error value λ, the optimized distribution q_λ^*, while leading to the degrees of freedom that will happen to be optimal in terms of approximation, has two main drawbacks:

- **Dependence on** λ: this implies that if we want a reduced error (i.e., a smaller λ), then the samples obtained from a higher λ, may not be reused to provably obtain the desired bound; in other words, the sampling is not *anytime*. For specific examples, e.g., quadrature with periodic kernels on $[0,1]$ with the uniform distribution, then $q=1$ happens to be optimal for all λ, and thus, we may reuse samples for different values of the error.
- **Hard to compute in practice**: the optimal distribution depends on a *leverage score* $\langle\varphi(v,\cdot),(\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}$, which may be hard to use for several reasons; first, it requires access to the infinite-dimensional operator Σ, which may be difficult; moreover, even if it possible to invert $\Sigma+\lambda I$, the set $\mathcal{V}$ might be particularly large and impractical to sample from. At the end of Section 4.1, we propose a simple algorithm based on sampling.

Eigenvalues and degrees of freedom. In order to relate more directly to the eigenvalues of Σ, we notice that we may lower bound the degrees of freedom by a constant times the number $m^*(\lambda)$ of eigenvalues greater than λ:

$$d(\lambda)=\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}=\sum_{m\geqslant 1}\frac{\mu_m}{\mu_m+\lambda}\geqslant\sum_{\mu_m\geqslant\lambda}\frac{\mu_m}{\mu_m+\lambda}\geqslant\frac{1}{2}\max(\{m,\ \mu_m\geqslant\lambda\})=m^*(\lambda),$$

as defined in Section 2.1.

Moreover, we have the upper-bound:

$$d(\lambda)=\sum_{\mu_m\geqslant\lambda}\frac{\mu_m}{\mu_m+\lambda}+\sum_{\mu_m<\lambda}\frac{\mu_m}{\mu_m+\lambda}\leqslant\max(\{m,\ \mu_m\geqslant\lambda\})+\frac{1}{\lambda}\sum_{\mu_m<\lambda}\mu_m.$$

We now make the assumption that there exists a $\gamma>0$ independent of j such that

$$\forall j\geqslant 1,\quad\sum_{m=j}^{\infty}\mu_m\leqslant\gamma j\mu_j.\qquad(11)$$

This assumption essentially states that the eigenvalues decay sufficiently homogeneously and is satisfied by $\mu_m\propto m^{-2\alpha}$ with $\gamma=(2\alpha-1)^{-1}$, $\mu_m\propto r^m$ with $\gamma=(1-r)^{-1}$ and similar bounds also hold for all examples in Section 2.3. It allows us to relate the degrees of freedom directly to eigenvalue decays.

Indeed, this implies that $\frac{1}{\lambda}\sum_{\mu_m<\lambda}\mu_m\leqslant\gamma\max(\{m,\ \mu_m\geqslant\lambda\})=\gamma m^*(\lambda)$ for all $\lambda\leqslant\mu_1$ (the largest eigenvalue) and thus

$$\frac{1}{2}m^*(\lambda)\leqslant d\leqslant\big[1+\gamma\big]m^*(\lambda).$$

We can now restate the approximation result of Prop. 1 from Section 4.1 with the optimized distribution (see proof in Appendix B.2):

Proposition 2 (Approximation of the unit ball of $\mathcal{F}$ for optimized distribution) *For $\lambda>0$ and the distribution with density q_λ^* defined in Eq. (10) with respect to $d\tau$, with degrees of freedom $d(\lambda)$. Let $v_1,\dots,v_n$ be sampled i.i.d. from the density q_λ^*, defining the kernel (and its associated RKHS $\hat{\mathcal{F}}$) $\hat{k}(x,y)=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{q(v_i)}\varphi(v_i,x)\varphi(v_i,y)$. Then, for any $\delta\in(0,1)$, with probability $1-\delta$, we have:*

$$\sup_{\|f\|_{\mathcal{F}}\leqslant 1}\ \inf_{\|\hat{f}\|_{\hat{\mathcal{F}}}\leqslant 2}\left\|f-\hat{f}\right\|_{L_2(d\rho)}^2\leqslant 4\lambda,$$

under any of the following conditions:

(a) if $n \geqslant 5\ d(\lambda) \log\big[16 d(\lambda)/\delta\big]$,

(b) if Eq. (11) is satisfied, and, by choosing $m \leqslant \frac{n}{5(1+\gamma)\log\frac{16n}{5\delta}}$, *and* $\lambda = \mu_m$.

The statement (a) above, is a simple corollary of Prop. 1, and goes from level of error λ to minimum number n of samples. The statement (b) goes in the other direction, that is, from the number of samples n to the achieved approximation error. It depends on the eigenvalues μ_m of the integral operator taken at $m = O(n/\log(n))$. For example, for polynomial decays of eigenvalues of the form $\mu_m = O(m^{-2s})$, we get (non squared) errors proportional to $(\log n)^s n^{-s}$ for n samples, while for geometric decays, we get geometric errors as a function of the number n of samples.

Note however that for the statement (b) to hold, we need to sample the points $v_1, \dots, v_n$ from the distribution $q^*_{\mu_m}$, that is, for different numbers of samples n, the distribution is unfortunately different (except in special cases). It would be interesting to study the properties of independent but *not identically distributed* samples $v_1, \dots, v_n$ and the possibility of achieving the same rate adaptively.

Corollary for Sobolev spaces. For the sake of concreteness, we consider the special case of $\mathcal{X} = \mathbb{R}^d$ and translation-invariant kernels. We assume that the distribution $d\rho$ is sub-Gaussian. Then for Sobolev spaces of order s, the eigenvalue decay is proportional to $m^{-2s/d}$. Thus, if we can sample from the optimized distribution, after n random features, we obtain an approximation of the unit ball of $\mathcal{F}$ with error $n^{-s/d}$, independently of the chosen expansion, the spatial one used for quadrature or the spectral one used in random Fourier features. For kernels in $\mathbb{R}^d$, these distributions are not readily computed in closed form and need to computed through a dedicated algorithm such as the one we present below.

The same approximation results holds for translation-invariant kernels on $[0,1]^d$; but when $d\rho$ is the uniform distribution, as shown in Section 4.4, the optimized distribution for the quadrature case is still the uniform distribution, for all values of λ, and can thus be computed.

Algorithm to estimate the optimized distribution. We now consider a simple algorithm for estimating the optimized distribution q^*_λ. It is based on using a large number N of points $v_1, \dots, v_N$ from $d\tau$, and replacing $d\tau$ by a potentially weighted empirical distribution $d\hat{\tau}$ associated with these N points. Therefore, we may use any set of points and weights, which leads to a distribution close to $d\tau$. In full generality, only random samples from $d\tau$ are readily available (with weights $1/N$), but for special cases, such as $\mathcal{V} = [0,1]$ or $\mathcal{V} = \mathbb{N}^*$, we may use deterministic representations. See examples in Section 6.

We thus assume that we have N pairs $(v_i, \eta_i) \in \mathcal{V} \times \mathbb{R}_+$, $i = 1, \dots, N$, such that $\sum_{i=1}^n \eta_i = 1$. Since $d\hat{\tau}$ has a finite support with at most N elements, we may identify $L_2(d\hat{\tau})$ and $\mathbb{R}^N$ (with its canonical dot-product), and the operator T goes now from $\mathbb{R}^N$ to $L_2(d\rho)$, with $Tg = \sum_{i=1}^N \eta_i^{1/2} g_i \varphi(v_i, \cdot) \in L_2(d\rho)$, with $T\delta_i = \eta_i^{1/2} \varphi(v_i, \cdot) \in L_2(d\rho)$, for δ_i the i-th element of the canonical basis of $\mathbb{R}^N$. Then, we have:

$$\begin{aligned}
\langle \varphi(v_i, \cdot), (\Sigma + \lambda I)^{-1} \varphi(v_i, \cdot) \rangle_{L_2(d\rho)} &= \eta_i^{-1} \langle T\delta_i, (TT^* + \lambda I)^{-1} T\delta_i \rangle_{L_2(d\rho)} \\
&= \eta_i^{-1} \langle T\delta_i, T(T^*T + \lambda I)^{-1} \delta_i \rangle_{L_2(d\rho)} \\
&= \eta_i^{-1} \big(T^* T (T^*T + \lambda I)^{-1} \big)_{ii}.
\end{aligned}$$

This implies that the density of the optimized distribution with respect to the uniform measure on $\{v_1, \dots, v_N\}$ is proportional to $\big(T^*T(T^*T + \lambda I)^{-1}\big)_{ii}$. We can then sample any number n of points from resampling from $\{v_1, \dots, v_N\}$ from the density above. The computational complexity is $O(N^3)$. A detailed analysis of the approximation properties of this algorithm is outside the scope of this paper.

We have $(T^*T)_{ij} = \eta_i^{1/2} \eta_j^{1/2} \int_{\mathcal{X}} \varphi(v_i, x) \varphi(v_j, x) d\rho(x)$. In some cases, it can be computed in closed form—such as for quadrature where this is equal to $\eta_i^{1/2} \eta_j^{1/2} k(v_i, v_j)$. In some others, it requires i.i.d. samples $x_1, \dots, x_M$ from $d\rho$, and the following estimate: $\eta_i^{1/2} \eta_j^{1/2} M^{-1} \sum_{k=1}^M \varphi(v_i, x_k) \varphi(v_j, x_k)$.

4.3 Lower Bound

In this section, we aim at providing lower-bounds on the number of samples required for a given accuracy. We have the following result (see proof in Appendix B.3):

Proposition 3 (Lower approximation bound) *For* $\delta \in (0,1)$, *if we have a family of functions* $\psi_1, \dots, \psi_n \in L_2(d\rho)$ *such that*

$$\frac{1}{n} \sum_{i=1}^n \|\psi_i\|^2_{L_2(d\rho)} \leqslant 2 \operatorname{tr} \Sigma / \delta, \quad \text{and} \quad \sup_{\|f\|_{\mathcal{F}} \leqslant 1} \inf_{\|\beta\|_2^2 \leqslant \frac{4}{n}} \Big\| f - \sum_{i=1}^n \beta_i \psi_i \Big\|^2_{L_2(d\rho)} \leqslant 4\lambda,$$

then $n \geqslant \dfrac{\max\{m,\ \mu_m \geqslant 144\lambda\}}{4 \log \frac{10 \operatorname{tr} \Sigma}{\lambda \delta}}$.

We can make the following observations:

- The proof technique not surprisingly borrows tools from minimax estimation over ellipsoids, namely the Varshamov-Gilbert's lemma.
- We obtain matching upper and lower bounds up to logarithmic terms, using only the decay of eigenvalues $(\mu_m)_{m \geqslant 1}$ of the integral operator Σ (of course, if sampling from the optimized distribution q^*_λ is possible). Indeed in that case, as shown in Prop. 2, we have shown that we need at most $10\ d(\lambda) \log\big[2d(\lambda)\big]$, where $d(\lambda)$ is the degrees of freedom, which is upper and lower bounded by a constant times $m^*(\lambda) = \max\{m,\ \mu_m \geqslant \lambda\}$.
- In order to obtain such a bound, we need to constrain both $\|\beta\|_2$ and the norms of the vectors ψ_i, which correspond to bounded features for the random feature interpretation and tolerance to noise for the quadrature interpretation. We choose our scaling to match the constraints we have in Prop. 1, for which the parameter δ ends up entering the lower bound logarithmically.

4.4 Quadrature

We may specialize the results above to the quadrature case, namely give a formulation where the features φ do not appear (or equivalently using ψ defined in Section 3.2). This is a special case where $\mathcal{V} = \mathcal{X}$ and $\varphi = \psi$. In terms of operators T in Section 2.2, this corresponds to $T = \Sigma^{1/2}$.

Optimized distribution. Following Section 4.1, we have an expression for the optimized distribution, both in terms of operators, as follows,

$$q_\lambda^*(x) \propto \langle \psi(x,\cdot), (\Sigma+\lambda I)^{-1}\psi(x,\cdot)\rangle_{L_2(d\rho)} = \langle \Sigma^{-1/2}k(x,\cdot), (\Sigma+\lambda I)^{-1}\Sigma^{-1/2}k(x,\cdot)\rangle_{L_2(d\rho)},$$

and in terms of eigenvalues and eigenvectors of k, that is,

$$q(x) \propto \langle k(\cdot,x), \Sigma^{-1/2}(\Sigma+\lambda I)^{-1}\Sigma^{-1/2}k(\cdot,x)\rangle_{L_2(d\rho)} = \sum_{m\geqslant 1}\frac{\mu_m}{\mu_m+\lambda}e_m(x)^2. \qquad (12)$$

While this is uniform in some special cases (uniform distribution on $[0,1]$ and Sobolev kernels, as shown below), this is typically hard to compute and sample from. An algorithm for approximating it was presented at the end of Section 4.1.

A weakness of our result is that in general our optimized distribution $q_\lambda^*(x)$ depends on λ and thus on the number of samples. In some cases with symmetries (i.e., uniform distribution on $[0,1]$ or the hypersphere), q_λ^* happens to be constant for all λ. Note also that we have observed empirically that in some cases, q_λ^* converges to a certain distribution when λ tends to zero (see an example in Section 6).

Sobolev spaces. For Sobolev spaces with order s in $[0,1]^d$ or $\mathbb{R}^d$ (for which we assume $d<2s$), the decay of eigenvalues is of the form $m^{-2s/d}$ and thus the error after n samples is $n^{-s/d}$ (up to logarithmic terms), which recovers the upper and lower bounds of Novak (1988, pages 37 and 38) (also up to logarithmic terms).

For the special case of Sobolev spaces on $[0,1]^d$ with $d\rho$ the uniform distribution, the optimized distribution in Eq. (12) is also the uniform distribution. Indeed, the eigenfunctions of the integral operator Σ are d-th order tensor products of the uni-dimensional Fourier basis (the constant and all pairs of sine/cosine at a given frequency), with the *same eigenvalue* for the 2^d possibilities of sines/cosines for a given multi-dimensional frequency $(m_1,\dots,m_d)$. Therefore, when summing all squared values of the eigenfunctions corresponding to $(m_1,\dots,m_d)$, we get the sum $\sum_{a\in\{0,1\}^d}\prod_{i=1}^d \cos^{2a_i}(2\pi m_i x_i)\sin^{2(1-a_i)}(2\pi m_i x_i)$, which ends up being constant equal to one (and thus independent of x) because of the identity $\cos^2(2\pi m_i x_i)+\sin^2(2\pi m_i x_i)=1$.

Finally, we may consider Sobolev spaces on the hypersphere, with the kernels presented in Section 2.3. As shown by Bach (2017, Appendix D.3), the kernel $k(x,y) = \mathbb{E}(v^\top y)_+^s(v^\top y)_+^s$ for v uniform on the hypersphere, leads to a Sobolev space of order $t = s+\frac{d+1}{2}$, while the decay of eigenvalue of the integral operator was shown to be $m^{-1-1/d-2s/d}$ in Section 2.3. It is thus equal to $m^{-2t/d}$, and we recover the result from Hesse (2006).

Quadrature rule. We assume that points $x_1,\dots,x_n$ are sampled from the distribution with density q with respect to $d\rho$. The quadrature rule for a function $h\in\mathcal{F}$ is $\sum_{i=1}^n \frac{\beta_i h(x_i)}{q(x_i)^{1/2}}$. To compute β, we need to minimize with respect to β the error:

$$\Big\| \sum_{i=1}^n \frac{\beta_i}{q(x_i)^{1/2}}k(\cdot,x_i) - \int_{\mathcal{X}} k(\cdot,x)g(x)d\rho(x)\Big\|_{\mathcal{F}}^2 + n\lambda\|\beta\|_2^2,$$

which is the regularized worst case squared error in the estimation of the integral of h over $h\in\mathcal{F}$. The best error is obtained for $\lambda=0$, but our guarantees are valid for $\lambda>0$, with an explicit control over the norm $\|\beta\|_2^2$, which is important for robustness to noise.

Given the values of $\int_{\mathcal{X}} k(x_i,x)g(x)d\rho(x) = z_i$, for $i=1,\dots,n$, which can be computed in closed form for several triplet $(k,g,d\rho)$ (see, e.g., Smola et al., 2007; Oates and Girolami, 2015), then the problem above is equivalent to minimizing with respect to β:

$$\sum_{i=1}^n\sum_{j=1}^n \frac{\beta_i\beta_j}{q(x_i)^{1/2}q(x_j)^{1/2}}k(x_i,x_j) - \sum_{i=1}^n \frac{\beta_i}{q(x_i)^{1/2}}z_i + n\lambda\|\beta\|_2^2,$$

which leads to a $n\times n$ linear system with running time complexity $O(n^3)$. Note that when adding points sequentially (in particular for kernels for which the distribution q_λ^* is independent of λ, such as Sobolev spaces on $[0,1]$), one may update the solution so that after n steps, the overall complexity is $O(n^3)$.

Approximation of functions in $\mathcal{F}$. With the quadrature weights β estimated above and the quadrature rule $\sum_{i=1}^n \frac{\beta_i h(x_i)}{q(x_i)^{1/2}}$ for the estimation of $\int_{\mathcal{X}} g(x)f(x)d\rho(x)$, we may derive an expression which is explicitly linear in g. Following the proof of Prop. 1 in Appendix B.1, we have, when specialized to the quadrature case:

$$\hat\Sigma = \frac{1}{n}\sum_{i=1}^n \frac{1}{q(v_i)}\psi(x_i,\cdot)\otimes_{L_2(d\rho)}\psi(x_i,\cdot) = \Sigma^{-1/2}\bigg(\frac{1}{n}\sum_{i=1}^n\frac{1}{q(v_i)}k(x_i,\cdot)\otimes_{L_2(d\rho)}k(x_i,\cdot)\bigg)\Sigma^{-1/2},$$

Moreover, we have $\beta_i = \frac{1}{nq(x_i)^{1/2}}\langle k(\cdot,x_i), \Sigma^{-1/2}(\hat\Sigma+\lambda I)^{-1}\Sigma^{1/2}g\rangle_{L_2(d\rho)}$ from Eq. (15) in Appendix B.1, and the quadrature rule becomes:

$$\begin{aligned}\sum_{i=1}^n \frac{\beta_i h(x_i)}{q(x_i)^{1/2}} &= \sum_{i=1}^n \frac{\beta_i}{q(x_i)^{1/2}}\langle h, \Sigma^{-1}k(\cdot,x_i)\rangle_{L_2(d\rho)}\\ &= \bigg\langle h, \frac{1}{n}\sum_{i=1}^n \Sigma^{-1}\frac{1}{q(x_i)}\big[k(x_i,\cdot)\otimes_{L_2(d\rho)}k(x_i,\cdot)\big]\Sigma^{-1/2}(\hat\Sigma+\lambda I)^{-1}\Sigma^{1/2}g\bigg\rangle_{L_2(d\rho)}\\ &= \big\langle h, \Sigma^{-1/2}\hat\Sigma(\hat\Sigma+\lambda I)^{-1}\Sigma^{1/2}g\big\rangle_{L_2(d\rho)} = \big\langle g, \Sigma^{1/2}\hat\Sigma(\hat\Sigma+\lambda I)^{-1}\Sigma^{-1/2}h\big\rangle_{L_2(d\rho)},\end{aligned}$$

which can be put in the form $\langle \hat h, g\rangle_{L_2(d\rho)}$ with the approximation $\hat h = \Sigma^{1/2}\hat\Sigma(\hat\Sigma+\lambda I)^{-1}\Sigma^{-1/2}h$ of the function $h\in\mathcal{F}$. Having a bound for all functions g such that $\|g\|_{L_2(d\rho)}\leqslant 1$ is equivalent to having a bound on $\|h-\hat h\|_{L_2(d\rho)}$. In Section 5, we consider extensions, where we consider other norms than the L_2-norm for characterizing the approximation error $\hat h - h$. Moreover, we consider cases where h belongs to a strict subspace of $\mathcal{F}$ (with improved results).

4.5 Learning with Random Features

We consider supervised learning with m i.i.d. samples from a distribution on inputs/outputs (x,y), and a uniformly G-Lipschitz-continuous loss function $\ell(y,\cdot)$, which includes logistic regression and the support vector machine. We consider the empirical risk $\hat L(f) = \frac{1}{m}\sum_{i=1}^m \ell(y_i,f(x_i))$ and the expected risk $L(f)=\mathbb{E}\ell(y,f(x))$, with x having the marginal distribution $d\rho$ that we consider in earlier sections. We assume that $\mathbb{E}k(x,x) = \operatorname{tr}\Sigma = R^2$. We have the usual generalization bound for the minimizer $\hat f$ of $\hat L(f)$ with respect to

$\|f\|_{\mathcal{F}} \leqslant F$, based on Rademacher complexity (see, e.g., Shalev-Shwartz and Ben-David, 2014):

$$\mathbb{E}\big[L(\hat{f})\big] \leqslant \inf_{\|f\|_{\mathcal{F}} \leqslant F} L(f) + 2\mathbb{E}\Big[\sup_{\|f\|_{\mathcal{F}} \leqslant F} |L(f) - \hat{L}(f)|\Big] \leqslant \inf_{\|f\|_{\mathcal{F}} \leqslant F} L(f) + \frac{4FGR}{\sqrt{m}}. \qquad (13)$$

We now consider learning by sampling n features from the optimized distribution from Section 4.2, leading to a function parameterized by $\beta \in \mathbb{R}^n$, i.e., $\hat{g}_\beta = \sum_{i=1}^n \beta_i q(v_i)^{-1/2} \varphi(v_i, \cdot)$, an element of $L_2(d\rho)$. Applying results from Section 4.1, we assume that $\lambda \leqslant R^2/4$ and $n \geqslant 5d(\lambda) \log \frac{2(\operatorname{tr}\Sigma) d(\lambda)}{\lambda}$, where $d(\lambda)$ is equal to the degrees of freedom associated with the kernel k and distribution $d\rho$. Thus, the expected squared error for approximating the unit-ball of $\mathcal{F}$ by the ball of radius 2 of the approximation $\hat{\mathcal{F}}$ obtained from the approximated kernel is less than 8λ.

If we consider the estimator $\hat{\beta}$ obtained by minimizing the empirical risk of $\hat{g}_\beta$ subject to $\|\beta\|_2 \leqslant 2F/\sqrt{n}$. We have the following decomposition of the error for any $\gamma \in \mathbb{R}^n$ such that $\|\gamma\|_2 \leqslant 2F/\sqrt{n}$ and $f \in \mathcal{F}$ such that $\|f\|_{\mathcal{F}} \leqslant F$:

$$\begin{aligned}
& L(\hat{g}_{\hat{\beta}}) \\
= \;& L(\hat{g}_{\hat{\beta}}) - \hat{L}(\hat{g}_{\hat{\beta}}) + \hat{L}(\hat{g}_{\hat{\beta}}) - \hat{L}(\hat{g}_\gamma) + \hat{L}(\hat{g}_\gamma) - L(\hat{g}_\gamma) + L(\hat{g}_\gamma) - L(f) + L(f) \\
\leqslant \;& 2\Big[\sup_{\|\beta'\|_{\mathcal{F}} \leqslant 2F/\sqrt{n}} |L(\hat{g}_{\beta'}) - L(\hat{g}_{\beta'})|\Big] + \big[L(\hat{g}_\gamma) - L(f)\big] + L(f) \\
\leqslant \;& 2\Big[\sup_{\|\beta'\|_{\mathcal{F}} \leqslant 2F/\sqrt{n}} |L(\hat{g}_{\beta'}) - L(\hat{g}_{\beta'})|\Big] + \sup_{\|f'\|_{\mathcal{F}} \leqslant F} \inf_{\|\gamma\|_2 \leqslant 2F/\sqrt{n}} \big[L(\hat{g}_\gamma) - L(f')\big] + \inf_{\|f\|_{\mathcal{F}} \leqslant F} L(f).
\end{aligned}$$

We now take expectation with respect to the data and the random features. Following standard results for Rademacher complexities of ℓ_2-balls (Bartlett and Mendelson, 2003, Lemma 22), the first term is less than

$$\frac{4FG}{m\sqrt{n}} \mathbb{E}\Big(\sum_{i=1}^m \sum_{j=1}^n \frac{\varphi(v_i, x_j)^2}{q(v_i)}\Big)^{1/2} \leqslant \frac{4FG}{m\sqrt{n}} (nm \operatorname{tr}\Sigma)^{1/2} = \frac{4FGR}{\sqrt{m}}.$$

Because of the G-Lipschitz-continuity of the loss, we have $L(\hat{g}_\gamma) - L(f') \leqslant G\|\hat{g}_\gamma - f'\|_{L_2(d\rho)}$, and thus the second term is less than $\sqrt{8\lambda} GF \leqslant 3GF\sqrt{\lambda}$. Overall, we obtain

$$\mathbb{E}\big[L(\hat{g}_{\hat{\beta}})\big] \leqslant \inf_{\|f\|_{\mathcal{F}} \leqslant F} L(f) + 3GF\sqrt{\lambda} + \frac{4FGR}{\sqrt{m}}.$$

If we consider $\lambda = R^2/m$ in order to lose only a constant factor compared to Eq. (13), we have the constraint $n \geqslant 5d(R^2/m) \log\big[2md(R^2/m)\big]$.

We may now look at several situations. In the worst case, where the decay of eigenvalue is not fast, i.e., very close to $1/i$, then we may only use the bound $d(\lambda) = \operatorname{tr}\Sigma(\Sigma + \lambda I)^{-1} \leqslant \lambda^{-1} \operatorname{tr}\Sigma = R^2/\lambda$, and thus a sufficient condition $n \geqslant 10m \log 2m$, and we obtain the same result as Rahimi and Recht (2009).

However, when we have eigenvalue decays as $R^2 i^{-2s}$, we get (up to constants), following the same computation as Section 4.2, $d(\lambda) \leqslant (R^2/\lambda)^{1/(2s)}$, and thus $n \geqslant m^{1/(2s)} \log m$, which is a significant improvement (regardless of the value of F). Moreover, if the decay is geometric as r^i, then we get $d(\lambda) \leqslant \log(R^2/\lambda)$, and thus $n \geqslant (\log m)^2$, which is even more significant.

5. Quadrature-related Extensions

In Section 4.4, we have built an approximation $\hat{h} = \Sigma^{1/2}\hat{\Sigma}(\hat{\Sigma} + \lambda I)^{-1}\Sigma^{-1/2} h$ of a function $h \in \mathcal{F}$, which is based on n function evaluations $h(x_1), \dots, h(x_n)$. We have presented in Section 4.4 a convergence rate for the L_2-norm $\|\hat{h} - h\|_{L_2(d\rho)}$ for functions h with less than unit $\mathcal{F}$-norm $\|h\|_{\mathcal{F}} \leqslant 1$. Up to logarithmic terms, if using the optimal distribution for sampling $x_1, \dots, x_n$, then we get a squared error of μ_n where μ_n is the n-th largest eigenvalue of the integral operator Σ.

Robustness to noise. We have seen that if the noise in the function evaluations $h(x_i)$ has a variance less than $q(x_i)\tau^2$, then the error $\|h - \hat{h}\|^2_{L_2(d\rho)}$ has an additional term $\tau^2 \|\beta\|_2^2 \leqslant \frac{4\tau^2}{n}$. Hence, the amount of noise has to be less than $n\mu_n$ in order to incur no loss in performance (a bound which decreases with n).

Adaptivity to smoother functions. We assume that the function h happens to be smoother than what is sufficient to be an element of the RKHS $\mathcal{F}$, that is, if $\|\Sigma^{-s} h\|_{L_2(d\rho)} \leqslant 1$, where $s \geqslant 1/2$. The case $s = 1/2$ corresponds to being in the RKHS. In the proof of Prop. 1 in Appendix B.1, we have seen that with high-probability we have:

$$(\hat{\Sigma} + \lambda I)^{-1} \preccurlyeq 4(\Sigma + \lambda I)^{-1}. \qquad (14)$$

We now see that we can bound the error $\|\hat{h} - h\|_{L_2(d\rho)}$ as follows:

$$\begin{aligned}
\|\hat{h} - h\|_{L_2(d\rho)} &= \|\Sigma^{1/2}\hat{\Sigma}(\hat{\Sigma} + \lambda I)^{-1}\Sigma^{-1/2} h - h\|_{L_2(d\rho)} \\
&= \lambda \big\|\Sigma^{1/2}(\hat{\Sigma} + \lambda I)^{-1}\Sigma^{-1/2+s}\Sigma^{-s} h\big\|_{L_2(d\rho)} \\
&\leqslant \lambda \big\|\Sigma^{1/2}(\hat{\Sigma} + \lambda I)^{-1/2}\big\|_{\mathrm{op}} \big\|(\hat{\Sigma} + \lambda I)^{-1/2}\Sigma^{-1/2+s}\big\|_{\mathrm{op}} \|\Sigma^{-s} h\|_{L_2(d\rho)}.
\end{aligned}$$

We may now bound each term. The first one $\big\|\Sigma^{1/2}(\hat{\Sigma} + \lambda I)^{-1/2}\big\|_{\mathrm{op}}$ is less than 2, because of Eq. (14). The second one $\big\|(\hat{\Sigma} + \lambda I)^{-1/2}\Sigma^{-1/2+s}\big\|_{\mathrm{op}}$ is equal to $\big\|(\hat{\Sigma} + \lambda I)^{s-1}(\hat{\Sigma} + \lambda I)^{1/2-s}\Sigma^{-1/2+s}\big\|_{\mathrm{op}}$, and thus less than $\big\|(\hat{\Sigma}+\lambda I)^{s-1}\|_{\mathrm{op}} \cdot \big\|(\hat{\Sigma}+\lambda I)^{1/2-s}\Sigma^{-1/2+s}\big\|_{\mathrm{op}} \leqslant 2\lambda^{s-1}$. Overall we obtain

$$\|\hat{h} - h\|_{L_2(d\rho)} \leqslant 4\lambda^s.$$

The norm $h \mapsto \|\Sigma^{-s} h\|_{L_2(d\rho)}$ is an RKHS norm with kernel $\sum_{m \geqslant 0} \mu_m^{2s} e_m(x) e_m(y)$, with corresponding eigenvalues equal to $(\mu_m)^{2s}$. From Prop. 2 and 3, the optimal number of quadrature points to reach a squared error less than ε is proportional to the number $\max(\{m,\ \mu_m^{2s} \geqslant \varepsilon\})$, while using the quadrature points from $s = 1/2$, leads to a number $\max(\{m,\ \mu_m \geqslant \varepsilon^{1/(2s)}\})$, which is equal. Thus if the RKHS used to compute the quadrature weights is a bit too large (but not too large, see experiments in Section 6), then we still get the optimal rate. Note that this robustness is only shown for the regularized estimation of the quadrature coefficients (in our simulations, the non-regularized ones also exhibit the same behavior).

Approximation with stronger norms. We may consider characterizing the difference $\hat{h} - h$ with different norms than $\|\cdot\|_{L_2(d\rho)}$, in particular norms $\|\Sigma^{-r}(\hat{h} - h)\|_{L_2(d\rho)}$, with

$r \in [0, 1/2]$. For $r = 0$, this is our results in L_2-norm, while for $r = 1/2$, this is the RKHS norms. We have, using the same manipulations than above:

$$\begin{aligned}\|\Sigma^{-r}(\hat{h} - h)\|_{L_2(d\rho)} &= \lambda \big\|\Sigma^{1/2-r}(\hat{\Sigma} + \lambda I)^{-1}\Sigma^{-1/2}h\big\|_{L_2(d\rho)} \\ &\leqslant \lambda^{1/2-r}\big\|\Sigma^{1/2-r}(\hat{\Sigma} + \lambda I)^{r-1/2}\big\|_{\rm op}\|\Sigma^{-1/2}h\|_{L_2(d\rho)} \leqslant 2\lambda^{1/2-r}.\end{aligned}$$

When $r = 1/2$, we get a result in the RKHS norm, but with no decay to zero; the RKHS norm $\|\cdot\|_{\mathcal{F}}$ would allow a control in L_∞-norm, but as noticed by Steinwart et al. (2009); Mendelson and Neeman (2010), such a control may be obtained in practice with r much smaller. For example, when the eigenfunctions e_m are uniformly bounded in L_∞-norm by a constant C (as is the case for periodic kernels in $[0, 1]$ with the uniform distribution), then, for any $x \in \mathcal{X}$, we have for $t > 1$,

$$f(x)^2 = \sum_{m=1}^{\infty}(m+1)^t\langle f, e_m\rangle^2_{L_2(d\rho)}e_m(x)^2(m+1)^{-t} \leqslant \sum_{m=0}^{\infty}(m+1)^t\langle f, e_m\rangle^2_{L_2(d\rho)}\frac{C^2}{t-1}.$$

If for simplicity, we assume that $\mu_m = (m+1)^{-2s}$ (like for Sobolev spaces), we have $\|\Sigma^{-r}f\|^2_{L_2(d\rho)} = \sum_{m=1}^{\infty}\mu_m^{-2r}\langle f, e_m\rangle^2_{L_2(d\rho)} = \sum_{m=1}^{\infty}(m+1)^t\langle f, e_m\rangle^2_{L_2(d\rho)}$ with $r = t/4s$. If $\lambda \leqslant O(n^{-2s})$ (as suggested by Prop. 1), then we obtain a squared L_∞-error less than $\frac{1}{t-1}\lambda^{1-2r} = O\big(\frac{1}{t-1}n^{-2s(1-t/2s)}\big) = O\big(\frac{n^t}{t-1}n^{-2s}\big)$. With $t = 1 + \frac{1}{\log n}$, we get $O\big(\frac{n\log n}{n^{-2s}}\big)$, and thus a degradation compared to the squared L_2-loss of n (plus additional logarithmic terms), which corresponds to the (non-improvable) result of Novak (1988, page 36).

6. Simulations

In this section, we consider simple illustrative quadrature experiments[4] with $\mathcal{X} = [0, 1]$ and kernels $k(x, y) = 1 + \sum_{m=1}^{\infty}\frac{1}{m^{2s}}\cos 2\pi m(x - y)$, with various values of s and distributions $d\rho$ which are Beta random variable with the two parameters equal to $a = b$, hence symmetric around $1/2$.

Uniform distribution. For $b = 1$, we have the uniform distribution on $[0, 1]$ for which the cosine/sine basis is orthonormal, and the optimized distribution q^*_λ is also uniform. Moreover, we have $\int_0^1 k(x, y)d\rho(x) = 1$. We report results comparing different Sobolev spaces for testing functions to integrate (parameterized by s) and learning quadrature weights (parameterized by t) in Figure 1, where we compute errors averaged over 1000 draws. We did not use regularization to compute quadrature weights α. We can make the following observations:

- The exponents in the convergence rates for $s = t$ (matching RKHSs for learning quadrature weights and testing functions) are close to $2s$ as expected.
- When the functions to integrate are less smooth than the ones used for learning quadrature weights (that is $t > s$), then the quadrature performance does not necessarily decay with the number of samples.

4. Matlab code for all 5 figures may be downloaded from `http://www.di.ens.fr/~fbach/quadrature.html`.

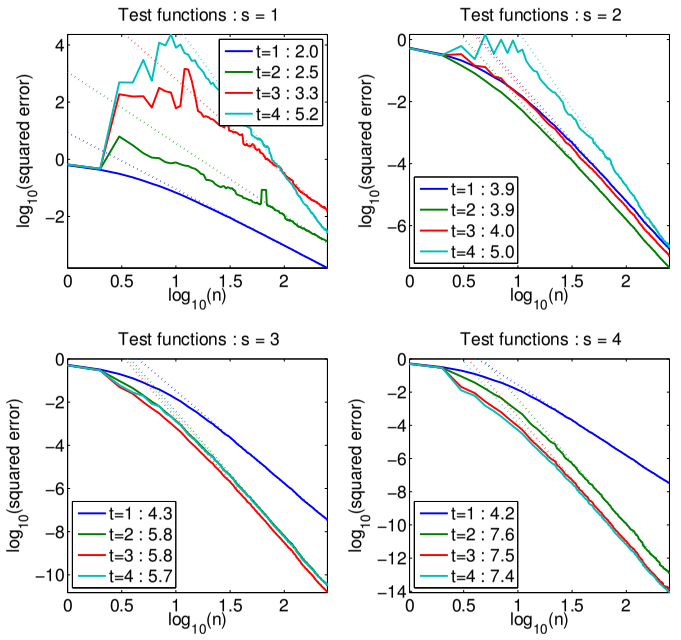

Figure 1: Quadrature for functions in a Sobolev space with parameter s (four possible values) for the uniform distribution on $[0, 1]$, with quadrature rules obtained from different Sobolev spaces with parameters t (same four possible values). We compute affine fits in log-log-space (in dotted) to estimate convergence rates of the form C/n^u and report the value of u. Best seen in color.

- On the contrary, when $s > t$, then we have convergence and the rate is potentially worse than the optimal one (attained for $s = t$), and equal when $t \geqslant s/2$, as shown in Section 5.

In Figure 2, we compare several quadrature rules on $[0, 1]$, namely Simpson's rule with uniformly spread points, Gauss-Legendre quadrature and the Sobol sequence with uniform weights. For $s = 1$, as expected, all squared errors decay as n^{-2} with a worse constant for our kernel-based rule, while for $s = 2$ (smoother test functions), the Sobol sequence is not adaptive, while all others are adaptive and get convergence rates around n^{-4}.

Non-uniform distribution. We consider the case $a = b = 1/2$, which is the distribution $d\rho$ with density $\pi^{-1}x^{-1/2}(1 - x)^{-1/2}$ with respect to the Lebesgue measure, and with cumulative distribution function $F(x) = \pi^{-1}\arccos(1 - 2x)$. We may use an approximation

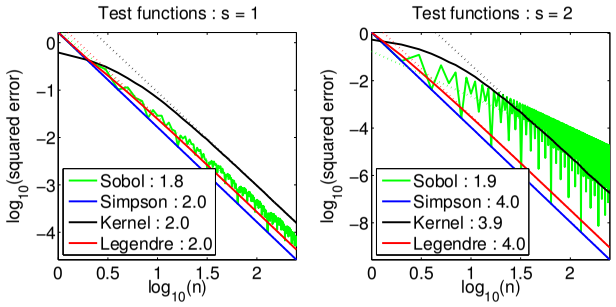

Figure 2: Quadrature for functions in a Sobolev space with parameters $s = 1$ (left) and $s = 2$ (right), for the uniform distribution on $[0, 1]$, with various quadrature rules. We compute affine fits in log-log-space (in dotted) to estimate convergence rates of the form C/n^u and report the value of u. Best seen in color.

of $d\tau$ with N unweighted points $F^{-1}(k/N) = \big(1 - \cos\frac{k\pi}{N}\big)/2$, for $k \in \{1, \dots, N\}$ and the algorithms from the end of Section 4.2. We consider the Sobolev kernel with $s = 1$.

In Figure 3, we plot all densities q_λ^* as a function of λ. When λ is large, we unsuprisingly obtain the uniform density, while, more surprisingly, when λ tends to zero, the density tends to a density, which happens here to be proportional to $x^{1/4}(1-x)^{1/4}$ (leading to a Beta distribution with parameters $a = b = .25$).

We may also consider the same kernel but with the Fourier expansion on $\mathbb{N}$. This is done by representing $d\tau \propto \delta_0 + \sum_{k \in \mathbb{Z}^*} \frac{1}{k^2}\delta_k$ by truncating to all $|k| \leqslant K$, with $K = 50$, which is a weighted representation. We plot in Figure 4 the optimal density over the set of integers, both with respect to the input density (which decays as $1/n^2$) and the counting measure. When λ is large, we recover the input density, while when λ tends to zero, q_λ^* tends to be uniform (and thus, does not converge to a finite measure).

7. Conclusion

In this paper, we have shown that kernel-based quadrature rules are a special case of random feature expansions for positive definite kernels, and derived upper and lower bounds on approximations, that match up to logarithmic terms. For quadrature, this leads to widely applicable results while for random features this allows a significantly improved guarantee within a supervised learning framework.

The present work could be extended in a variety of ways, for example towards bandit optimization rather than quadrature (Srinivas et al., 2012), the use of quasi-random sampling within our framework in the spirit of Yang et al. (2014); Oates and Girolami (2015), a similar analysis for kernel herding (Chen et al., 2010; Bach et al., 2012), an extension to fast rates for non-parametric least-squares regression (Hsu et al., 2014) but with an improved computational complexity, and a study of the consequences of our improved approximation

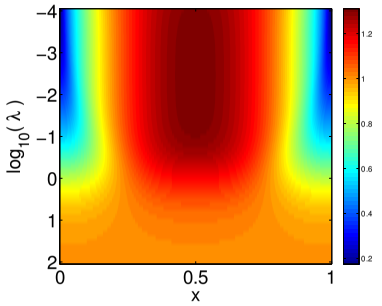

Figure 3: Optimal log-densities $q_\lambda^*(x)$ (with respect to the input distribution) for several values of λ, for the expansion used for quadrature. Best seen in color.

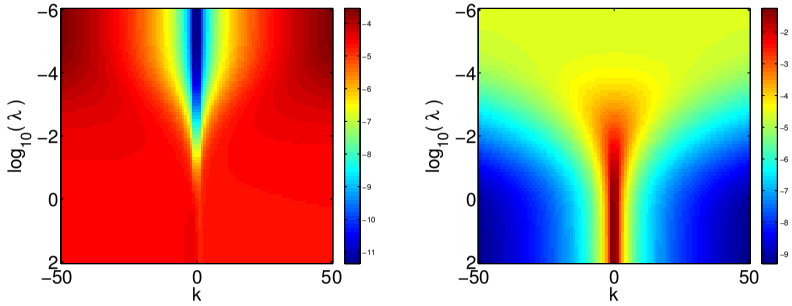

Figure 4: Optimal densities $q_\lambda^*(k)$ for several values of λ, for Fourier feature expansions. Left: with respect to the input distribution (which itself has distribution proportional to $1/k^2$ with respect to the counting measure); right: with respect to the counting measure. Best seen in color.

result for online learning and stochastic approximation, in the spirit of Dai et al. (2014); Dieuleveut and Bach (2015).

Comments of the reviewers were greatly appreciated and helped improve the presentation significantly. The author would like to thank the STVI for the opportunity of writing a single-handed paper.

Appendix A. Kernels on Product Spaces

In this appendix, we consider sets $\mathcal{X}$ which are products of several simple sets $\mathcal{X}_1, \dots, \mathcal{X}_d$, with known kernels $k_1, \dots, k_d$, each with RKHS $\mathcal{F}_1, \dots, \mathcal{F}_d$. We also assume that we have d measures $d\rho_1, \dots, d\rho_d$, leading to sequences of eigenvalues $(\mu_{jm_j})_{m_j \geqslant 1}$ and eigenfunctions $(e_{jm_j})_{m_j \geqslant 1}$.

Our aim is to define a kernel k on $\mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_d$ with the product measure $d\rho = d\rho_1 \cdots d\rho_d$. For illustration purposes, we consider decays of the form $\mu_m \propto m^{-2s}$ for the d kernels, that will be useful for Sobolev spaces. We also consider the case where $\mu_m \propto \exp(-\rho m)$. For some combinations, eigenvalue decay is the most natural, in others, the number of eigenvalues $m^*(\lambda)$ greater than a given $\lambda > 0$ is more natural.

A.1 Sum of Kernels: $k(x,y) = \sum_{j=1}^d k_j(x_j, y_j)$

In this situation, the RKHS for k is isomorphic to $\mathcal{F}_1 \times \cdots \times \mathcal{F}_d$, composed of functions g such that there exists $f_1, \dots, f_d$ in $\mathcal{F}_1, \dots, \mathcal{F}_d$ such that $g(x) = \sum_{j=1}^d f_j(x_j)$, that is we obtain separable functions, which are sometimes used in the context of generalized additive models (Hastie and Tibshirani, 1990). The corresponding integral operator is then block-diagonal with j-th block equal to the integral operator for k_j and $d\rho_j$. This implies that that its eigenvalues are the concatenation of all sequences $(\mu_{jm_j})_{m_j \geqslant 0}$. Thus the function $m^*(\lambda)$ is the sum of functions $m_1^*(\lambda) + \cdots + m_d^*(\lambda)$.

In terms of norms of functions, we have a norm equal to $\|g\|_{\mathcal{F}}^2 = \sum_{j=1}^d \|f_j\|_{\mathcal{F}_j}^2$.

In the particular case where $\mu_{jm_j} \propto m_j^{-2s}$ for all j, or equivalently, a number of eigenvalues of k_j greater than λ proportional to $\lambda^{-1/(2s)}$, we have a number of eigenvalues of k greater than λ equivalent to $d\lambda^{-1/(2s)}$, that is a decay for the eigenvalues proportional to $(m/d)^{-2s}$. Similarly, when the decay is exponential as $\exp(-\rho m)$, we get a decay of $\exp(-\rho m/d)$.

A.2 Product of Kernels: $k(x,y) = \prod_{j=1}^d k_j(x_j, y_j)$

In this situation, the RKHS for K is exactly the tensor product of $\mathcal{F}_1, \dots, \mathcal{F}_d$, i.e., the span of all functions $\prod_{j=1}^d f_j(x_j)$, for $f_1, \dots, f_d$ in $\mathcal{F}_1, \dots, \mathcal{F}_d$ (Berlinet and Thomas-Agnan, 2004). Moreover, the integral operator for k is a tensor product of the d integral operator for $k_1, \dots, k_d$. This implies that its eigenvalues are $\mu_{1m_1} \times \cdots \times \mu_{dm_d}$, $m_1, \dots, m_d \geqslant 0$. In terms of norms of functions defined on $\mathcal{X}_1 \times \cdots \times \mathcal{X}_d$, this thus corresponds to

$$\sum_{m_1, \dots, m_d \geqslant 0} \Big(\prod_{j=1}^d \mu_{jm_j} \Big)^{-1} \Big\langle f, \prod_{j=1}^d e_{jm_j}(x_j) \Big\rangle_{L_2(d\rho^{\otimes d})}^2 .$$

Special cases. In the particular case where $\mu_{jm_j} \propto m_j^{-2s}$ for all j, we have a number of eigenvalues of k greater than λ equivalent to the number of multi-indices such that $m_1 \times \cdots \times m_d$ is less than $\lambda^{-1/(2s)}$. By counting first the index m_1, this can be upper-bounded by the sum of $\frac{\lambda^{-1/(2s)}}{m_2 \cdots m_d}$ over all indices $m_2, \dots, m_d$ less than $\lambda^{-1/(2s)}$, which is less than $\lambda^{-1/(2s)} \big(\sum_{m=1}^{\lambda^{-1/(2s)}} \frac{1}{m} \big)^{d-1} = O\Big(\lambda^{-1/(2s)} \big(s \log \frac{1}{\lambda} \big)^{d-1} \Big)$. This results in a decay of eigenvalues bounded by $(\log m)^{2s(d-1)} m^{-2s}$ (this can be obtained by inverting approximately the function of λ).

When the decay is exponential as $\exp(-\rho\lambda)$, then we get that $m^*(\lambda)$ is the number of multi-indices $(m_1, \dots, m_d)$ such that their sum is less than $c = \frac{\log \frac{1}{\lambda}}{\rho}$; when c is large, this is equivalent to c^d times the volume of the d-dimensional simplex, and thus less than $\frac{c^d}{d!} = \big(\frac{\log \frac{1}{\lambda}}{\rho} \big)^d \frac{1}{d!}$. This leads to a decay of eigenvalues as $\exp(-\rho d! ^{1/d} m^{1/d})$ or, by using Stirling formula, less than $\exp(-\rho d m^{1/d})$.

Appendix B. Proofs

B.1 Proof of Prop. 1

As shown in Section 2.2, any $f \in \mathcal{F}$ with $\mathcal{F}$-norm less than one may be represented as $f = \int_{\mathcal{V}} g(v) \varphi(v, \cdot) d\tau(v)$, for a certain $g \in L_2(d\tau)$ with $L_2(d\tau)$-norm less than one. We do not solve the problem in β exactly, but use a properly chosen Lagrange multiplier λ and consider the following minimization problem:

$$\Big\| \sum_{i=1}^n \beta_i q(v_i)^{-1/2} \varphi(v_i, \cdot) - \int_{\mathcal{X}} \varphi(v, \cdot) g(v) d\tau(v) \Big\|_{L_2(d\rho)}^2 + n\lambda \|\beta\|_2^2.$$

We consider the operator $\Phi : \mathbb{R}^n \to L_2(d\rho)$ such that

$$\Phi\beta = \sum_{i=1}^n \beta_i q(v_i)^{-1/2} \varphi(v_i, \cdot).$$

We then need to minimize the familiar least-squares problem:

$$\big\| f - \Phi\beta \big\|_{L_2(d\rho)}^2 + n\lambda \|\beta\|_2^2,$$

with solution from the usual normal equations and the matrix inversion lemma for operators (Ogawa, 1988):

$$\beta = (\Phi^*\Phi + n\lambda I)^{-1} \Phi^* f = \frac{1}{n} \Phi^* (\frac{1}{n} \Phi\Phi^* + \lambda I)^{-1} f. \tag{15}$$

We consider the empirical integral operator $\hat{\Sigma} : L_2(d\rho) \to L_2(d\rho)$, defined as

$$\hat{\Sigma} = \frac{1}{n}\Phi\Phi^* = \frac{1}{n}\sum_{i=1}^n \frac{1}{q(v_i)}\varphi(v_i,\cdot) \otimes_{L_2(d\rho)} \varphi(v_i,\cdot),$$

that is, for $a, b \in L_2(d\rho)$, $\langle a, \hat{\Sigma} b\rangle_{L_2(d\rho)} = \sum_{i=1}^n \frac{\langle a, \varphi(v_i,\cdot)\rangle_{L_2(d\rho)}\langle b, \varphi(v_i,\cdot)\rangle_{L_2(d\rho)}}{q(v_i)}$. By construction, and following the end of Section 2.2, we have $\mathbb{E}\hat{\Sigma} = \Sigma$.

The value of $\|f - \Phi\beta\|^2_{L_2(d\rho)}$ is equal to

$$\begin{aligned}\|f - \Phi\beta\|^2_{L_2(d\rho)} &= \|f - \hat{\Sigma}(\hat{\Sigma}+\lambda I)^{-1}f\|^2_{L_2(d\rho)} = \|\lambda(\hat{\Sigma}+\lambda I)^{-1}f\|^2_{L_2(d\rho)} \\ &= \lambda^2\big\langle f, (\hat{\Sigma}+\lambda I)^{-2}f\big\rangle_{L_2(d\rho)} \leqslant \lambda\big\langle f, (\hat{\Sigma}+\lambda I)^{-1}f\big\rangle_{L_2(d\rho)}, \qquad (16)\end{aligned}$$

because $(\hat{\Sigma}+\lambda I)^{-2} \preccurlyeq \lambda^{-1}(\hat{\Sigma}+\lambda I)^{-1}$ (with the classical partial order between self-adjoint operators).

Finally, we have, with $\beta = \frac{1}{n}\Phi^*(\hat{\Sigma}+\lambda I)^{-1}f$:

$$n\|\beta\|_2^2 = \big\langle (\hat{\Sigma}+\lambda I)^{-1}f, \hat{\Sigma}(\hat{\Sigma}+\lambda I)^{-1}f\big\rangle_{L_2(d\rho)} \leqslant \big\langle f, (\hat{\Sigma}+\lambda I)^{-1}f\big\rangle_{L_2(d\rho)}, \qquad (17)$$

using $(\hat{\Sigma}+\lambda I)^{-2}\hat{\Sigma} \preccurlyeq (\hat{\Sigma}+\lambda I)^{-1}$.

By construction, we have $\mathbb{E}(\hat{\Sigma}) = \Sigma$. Moreover, we have, by Cauchy-Schwarz inequality:

$$\begin{aligned}\langle a, (f \otimes_{L_2(d\rho)} f)a\rangle_{L_2(d\rho)} &= \bigg(\int_{\mathcal{X}} a(x)f(x)d\rho(x)\bigg)^2 = \bigg(\int_{\mathcal{X}}\int_{\mathcal{V}} a(x)g(v)\varphi(v,x)d\tau(v)d\rho(x)\bigg)^2 \\ &\leqslant \bigg(\int_{\mathcal{V}} g(v)^2 d\tau(v)\bigg)\int_{\mathcal{V}}\bigg(\int_{\mathcal{X}} a(x)\varphi(v,x)d\rho(x)\bigg)^2 d\tau(v) \\ &= \|g\|^2_{L_2(d\rho)}\langle a, \Sigma a\rangle_{L_2(d\rho)} \leqslant \langle a, \Sigma a\rangle_{L_2(d\rho)}.\end{aligned}$$

Thus $f \otimes_{L_2(d\rho)} f \preccurlyeq \Sigma$, and we may thus define $\langle f, \Sigma^{-1}f\rangle_{L_2(d\rho)}$, which is less than one.

Overall we aim to study $\langle f, (\hat{\Sigma}+\lambda I)^{-1}f\rangle_{L_2(d\rho)}$, for $\langle f, \Sigma^{-1}f\rangle_{L_2(d\rho)} \leqslant 1$, to control both the norm $\|\beta\|_2^2$ in Eq. (17) and the approximation error $\|f - \Phi\beta\|^2_{L_2(d\rho)}$ in Eq. (16). We have, following a similar argument than the one of Bach (2013); El Alaoui and Mahoney (2015) for column sampling, i.e., by a formulation using $\Sigma - \hat{\Sigma}$ in terms of operators in an appropriate way:

$$\begin{aligned}&\langle f, (\hat{\Sigma}+\lambda I)^{-1}f\rangle_{L_2(d\rho)} \\ =\ &\langle f, (\Sigma+\lambda I+\hat{\Sigma}-\Sigma)^{-1}f\rangle_{L_2(d\rho)} \\ =\ &\big\langle (\Sigma+\lambda I)^{-1/2}f, \big[I + (\Sigma+\lambda I)^{-1/2}(\hat{\Sigma}-\Sigma)(\Sigma+\lambda I)^{-1/2}\big]^{-1}(\Sigma+\lambda I)^{-1/2}f\big\rangle_{L_2(d\rho)}.\end{aligned}$$

Thus, if $(\Sigma+\lambda I)^{-1/2}(\hat{\Sigma}-\Sigma)(\Sigma+\lambda I)^{-1/2} \succcurlyeq -tI$, with $t \in (0,1)$, we have

$$\begin{aligned}\langle f, (\hat{\Sigma}+\lambda I)^{-1}f\rangle_{L_2(d\rho)} &\leqslant \langle (\Sigma+\lambda I)^{-1/2}f, (1-t)^{-1}(\Sigma+\lambda I)^{-1/2}f\rangle_{L_2(d\rho)} \\ &= (1-t)^{-1}\langle f, (\Sigma+\lambda I)^{-1}f\rangle_{L_2(d\rho)} \\ &\leqslant (1-t)^{-1}\langle f, \Sigma^{-1}f\rangle_{L_2(d\rho)} \leqslant (1-t)^{-1}.\end{aligned}$$

Moreover, we have shown $(\hat{\Sigma}+\lambda I)^{-1} \preccurlyeq \frac{1}{1-t}(\Sigma+\lambda I)^{-1}$.

Thus, the performance depends on having $(\Sigma+\lambda I)^{-1/2}(\Sigma-\hat{\Sigma})(\Sigma+\lambda I)^{-1/2} \preccurlyeq tI$.

We consider the self-adjoint operators X_i, for $i = 1, \dots, n$, which are independent and identically distributed:

$$X_i = \frac{1}{n}(\Sigma+\lambda I)^{-1}\Sigma - \frac{1}{n}\frac{1}{q(v_i)}\big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big],$$

so that our goal is to provide an upperbound on the probability that $\|\sum_{i=1}^n X_i\|_{\rm op} > t$, where $\|\cdot\|_{\rm op}$ is the operator norm (largest singular values). We use the notation

$$d = \operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1} = \int_{\mathcal{V}} \frac{\langle \varphi(v,\cdot), (\Sigma+\lambda I)^{-1}\varphi(v,\cdot)\rangle_{L_2(d\rho)}}{q(v)} q(v)d\tau(v) \leqslant d_{\max}.$$

We have

$$\begin{aligned}\mathbb{E}X_i &= 0, \text{ by construction of } X_i, \\ X_i &\preccurlyeq \frac{1}{n}(\Sigma+\lambda I)^{-1}\Sigma \preccurlyeq \frac{1}{n}\operatorname{tr}\big[(\Sigma+\lambda I)^{-1}\Sigma\big]I \preccurlyeq \frac{d_{\max}}{n}I, \\ X_i &\succcurlyeq -\frac{1}{n}\frac{1}{q(v_i)}\big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \\ &\succcurlyeq -\frac{1}{n}\frac{1}{q(v_i)}\big\|(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big\|^2_{L_2(d\rho)} I \succcurlyeq -\frac{d_{\max}}{n}I, \\ \|X_i\|_{\rm op} &\leqslant \frac{d_{\max}}{n} \text{ as a consequence of the two previous inequalities.}\end{aligned}$$

Moreover,

$$\begin{aligned}&\mathbb{E}(X_i^2) \\ =\ &\mathbb{E}\bigg[\frac{1}{n}\frac{1}{q(v_i)}\big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big]\bigg]^2 - \big[\frac{1}{n}(\Sigma+\lambda I)^{-1}\Sigma\big]^2 \\ \preccurlyeq\ &\mathbb{E}\bigg[\frac{1}{n}\frac{1}{q(v_i)}\big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big]\bigg]^2 \\ =\ &\mathbb{E}\frac{\langle \varphi(v_i,\cdot), (\Sigma+\lambda I)^{-1}\varphi(v_i,\cdot)\rangle_{L_2(d\rho)}}{n^2 q(v_i)^2}\big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \\ \preccurlyeq\ &\frac{d_{\max}}{n^2}\mathbb{E}\bigg(\big[\frac{1}{q(v_i)}(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big] \otimes_{L_2(d\rho)} \big[(\Sigma+\lambda I)^{-1/2}\varphi(v_i,\cdot)\big]\bigg) = \frac{d_{\max}}{n^2}\Sigma(\Sigma+\lambda I)^{-1}.\end{aligned}$$

This leads to

$$\sum_{i=1}^n \mathbb{E}(X_i^2) \preccurlyeq \frac{d_{\max}}{n}(\Sigma+\lambda I)^{-1}\Sigma,$$

with a maximal eigenvalue less than $\frac{d_{\max}}{n}$ and a trace less than $\frac{d_{\max}}{n}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1} = \frac{d\, d_{\max}}{n}$.

Following Hsu et al. (2014), we use a matrix Bernstein inequality which is independent of the underlying dimension (which is here infinite). We consider the bound of Minsker (2011, Theorem 2.1), which improves on the earlier result of Hsu et al. (2012, Theorem 4), that is:

$$\mathbb{P}\Big(\Big\|\sum_{i=1}^n X_i\Big\|_{\rm op} > t\Big) \leqslant 2d\Big(1+\frac{6}{t^2\log^2(1+nt/d_{\max})}\Big)\exp\Big(-\frac{t^2/2}{d_{\max}/n(1+t/3)}\Big)$$

We now consider $t=\frac{3}{4}$, $\delta\in(0,1)$, and $n\geqslant Bd_{\max}\log\frac{Cd_{\max}}{\delta}$, with appropriate constants $B,C>0$. This implies that

$$\exp\Big(-\frac{t^2/2}{d_{\max}/n(1+t/3)}\Big)\leqslant\exp\Big(-\frac{(3/4)^2/2}{5/4}B\log\frac{Cd_{\max}}{\delta}\Big)\leqslant\big(\frac{\delta}{Cd_{\max}}\big)^{\frac{(3/4)^2B/2}{5/4}},$$

which is less then $\big(\frac{\delta}{Cd}\big)^{\frac{(3/4)^2B/2}{5/4}}$, and, if $d_{\max}\geqslant D$, using $n\geqslant Bd_{\max}\log CD$,

$$1+\frac{6}{t^2\log^2(1+nt/d_{\max})}\leqslant 1+\frac{6\cdot 16/9}{\log^2\big(1+(3B/4)\log(CD)\big)},$$

while if $d_{\max}\leqslant D$ and $n\geqslant 1$,

$$1+\frac{6}{t^2\log^2(1+nt/d_{\max})}\leqslant 1+\frac{6\cdot 16/9}{\log^2\big(1+(3/4D)\big)}.$$

In order to get a bound, we need $\frac{(3/4)^2B/2}{5/4}\geqslant 1$, and we can take $B=5$. If we take $C=8$, then in order to have $1+\frac{6}{t^2\log^2(1+nt/d_{\max})}\leqslant 4$, we can take $D=3/8$. Thus the probability is less than δ.

Finally, in order to get the extra bound on $\frac{1}{n}\sum_{i=1}^n q(v_i)^{-1}\|\varphi(v_i,\cdot)\|^2_{L_2(d\rho)}$, we consider $\mathbb{E}\operatorname{tr}\hat\Sigma=\operatorname{tr}\Sigma=\int_{\mathcal{X}}k(x,x)d\rho(x)$, and thus, by Markov's inequality, with probability $1-\delta$,

$$\frac{1}{n}\sum_{i=1}^n q(v_i)^{-1}\|\varphi(v_i,\cdot)\|^2_{L_2(d\rho)}=\operatorname{tr}\hat\Sigma\leqslant\frac{1}{\delta}\operatorname{tr}\Sigma. \tag{18}$$

By taking $\delta/2$ instead of δ in the control of $\|\sum_{i=1}^n X_i\|_{\rm op}>t$ and in the Markov inequality above, we have a control over $\|\beta\|_2^2$, $\operatorname{tr}\hat\Sigma$ and the approximation error, which leads to the desired result in Prop 1. This will be useful for the lower bound of Prop. 3.

We can make the following extra observations regarding the proof:

- It may be possible to derive a similar result with a thresholding of eigenvalues in the spirit of Zwald et al. (2004), but this would require Bernstein-type concentration inequalities for the projections on principal subspaces.
- We have seen that with high-probability, we have $(\hat\Sigma+\lambda I)^{-1}\preccurlyeq 4(\Sigma+\lambda I)^{-1}$. Note that $A\preccurlyeq B$ does not imply in $A^2\preccurlyeq B^2$ (Bhatia, 2009, page 9) and that in general we do not have $(\hat\Sigma+\lambda I)^{-2}\preccurlyeq C(\Sigma+\lambda I)^{-2}$ for any constant C (which would allow an improvement in the error by replacing λ by λ^2, and violate the lower bound of Prop. 3).
- We may also obtain a result in expectation, by using $\delta=4\lambda/\operatorname{tr}\Sigma$ (which is assumed to be less than 1), leading to a squared error with expectation less than 8λ as soon as $n\geqslant 5d_{\max}(\lambda)\log\frac{2(\operatorname{tr}\Sigma)d_{\max}(\lambda)}{\lambda}$. Indeed, we can use the bound 4λ with probability $1-\delta$ and $\|f\|^2_{L_2(d\rho)}\leqslant\operatorname{tr}\Sigma$ with probability δ, leading to a bound of $4\lambda(1-\delta)+\delta\operatorname{tr}\Sigma\leqslant 8\lambda$. We use this result in Section 4.5.

B.2 Proof of Prop. 2

We start from the bound above, with the constraint $n\geqslant 5d(\lambda)\log\frac{16d(\lambda)}{\delta}$. Statement (a) is a simple reformulation of Prop. 1. For statement (b), if we assume $m\leqslant\frac{n}{5(1+\gamma)\log\frac{16n}{5\delta}}$, and $\lambda=\mu_m$, then we have $d(\lambda)\leqslant(1+\gamma)m$, which implies $n\geqslant 5d(\lambda)\log\frac{16d(\lambda)}{\delta}$, and (b) is a consequence of (a).

B.3 Proof of Prop. 3

We first use the Varshamov-Gilbert's lemma (see, e.g., Massart, 2003, Lemma 4.7). That is, for any integer s, there exists a family $(\theta_j)_{j\in J}$ of at least $|J|\geqslant e^{s/8}$ distinct elements of $\{0,1\}^s$, such that for $j\neq j'\in J$, $\|\theta_j-\theta_{j'}\|_2^2\geqslant\frac{s}{4}$.

For each $\theta\in\{0,1\}^s$, we define an element of $\mathcal{F}$ with norm less than one, as $f(\theta)=\frac{\sqrt{\mu_s}}{\sqrt{s}}\sum_{i=1}^s\theta_i e_i\in\mathcal{F}$, where (e_i,μ_i), $i=1,\dots,s$ are the eigenvector/eigenvalue pairs associated with the s largest eigenvalues of Σ. We have, since $\mu_i\geqslant\mu_s$ for $i\in\{1,\dots,s\}$ and $\|\theta\|_2^2\leqslant 1$:

$$\|f(\theta)\|_{\mathcal{F}}^2=\frac{\mu_s}{s}\sum_{i=1}^s\theta_i^2\mu_i^{-1}\leqslant\frac{\mu_s}{s}\sum_{i=1}^s\theta_i^2\mu_s^{-1}\leqslant\frac{1}{s}\sum_{i=1}^s\theta_i^2\leqslant 1.$$

Moreover, for any $j\neq j'\in J$, we have $\|f(\theta_j)-f(\theta_{j'})\|^2_{L_2(d\rho)}=\frac{\mu_s}{s}\|\theta_j-\theta_{j'}\|_2^2\geqslant\frac{\mu_s}{4}$.

We now assume that s is selected so that $\sqrt{4\lambda}\leqslant\sqrt{\frac{\mu_s}{4}}/3$. By applying the existence results to all functions f_j, $j\in J$, then there exists a family $(\beta_j)_{j\in J}$ of elements of $\mathbb{R}^n$, with squared ℓ_2-norm less than $\frac{4}{n}$, and for which, for all j,

$$\Big\|f_j-\sum_{i=1}^n(\beta_j)_i\psi_i\Big\|_{L_2(d\rho)}\leqslant\sqrt{4\lambda}.$$

This leads to, for any $j\neq j'\in J$,

$$\begin{aligned}\Big\|\sum_{i=1}^n(\beta_j-\beta_{j'})_i\psi_i\Big\|_{L_2(d\rho)}&\geqslant\big\|f_j-f_{j'}\big\|_{L_2(d\rho)}-\Big\|\sum_{i=1}^n(\beta_j)_i\psi_i-f_j\Big\|_{L_2(d\rho)}-\Big\|\sum_{i=1}^n(\beta_{j'})_i\psi_i-f_{j'}\Big\|_{L_2(d\rho)}\\&\geqslant\sqrt{\mu_s/4}-2\sqrt{\frac{\mu_s}{4}}/3=\sqrt{\frac{\mu_s}{4}}/3.\end{aligned}$$

Moreover, we have the bound

$$\Big\|\sum_{i=1}^n(\beta_j-\beta_{j'})_i\psi_i\Big\|^2_{L_2(d\rho)}\leqslant\Big(\sum_{i=1}^n(\beta_j-\beta_{j'})_i^2\Big)\sum_{i=1}^n\|\psi_i\|^2_{L_2(d\rho)}\leqslant\|\beta_j-\beta_{j'}\|_2^2\cdot n(2\delta^{-1}\operatorname{tr}\Sigma).$$

Combining the last two inequalities, we get $\|\beta_j - \beta_{j'}\|_2 \geqslant \sqrt{\frac{\delta\mu_s}{72n\operatorname{tr}\Sigma}} = \Delta$. Thus, $e^{s/8}$ is less than the Δ-packing number of the ball of radius $r = 2/\sqrt{n}$, which is itself less than $(r/\Delta)^n(2+\Delta/r)^n$ (see, e.g., Massart, 2003, Lemma 4.14). Since $\Delta/r = \sqrt{\frac{\delta\mu_s}{4\cdot 72\operatorname{tr}\Sigma}} \leqslant \frac{1}{12\sqrt{2}}$, we have

$$\frac{s}{8} \leqslant n\left(\frac{1}{2}\log\frac{4\cdot 72\operatorname{tr}\Sigma}{\delta\mu_s} + \log(2+\frac{1}{12\sqrt{2}})\right).$$

This implies $n \geqslant \frac{s}{4\log\frac{\operatorname{tr}\Sigma}{\delta\mu_s}+29}$. Given that we have to choose $\mu_s \geqslant 144\lambda$ for the result to hold, this implies the desired result, since $4\log(1440) \geqslant 29$.

Abstract

We present a novel analysis of the dynamics of tensor power iterations in the overcomplete regime where the tensor CP rank is larger than the input dimension. Finding the CP decomposition of an overcomplete tensor is NP-hard in general. We consider the case where the tensor components are randomly drawn, and show that the simple power iteration recovers the components with bounded error under mild initialization conditions. We apply our analysis to unsupervised learning of latent variable models, such as multi-view mixture models and spherical Gaussian mixtures. Given the third order moment tensor, we learn the parameters using tensor power iterations. We prove it can correctly learn the model parameters when the number of hidden components k is much larger than the data dimension d, up to $k = o(d^{1.5})$. We initialize the power iterations with data samples and prove its success under mild conditions on the signal-to-noise ratio of the samples. Our analysis significantly expands the class of latent variable models where spectral methods are applicable. Our analysis also deals with noise in the input tensor leading to sample complexity result in the application to learning latent variable models.

Keywords: tensor decomposition, tensor power iteration, overcomplete representation, unsupervised learning, latent variable models

1. Introduction

CANDECOMP/PARAFAC (CP) decomposition of a symmetric tensor $T \in \mathbb{R}^{d\times d\times d}$ is the process of decomposing it into a succinct sum of rank-one tensors, given by

$$T = \sum_{j\in[k]} \lambda_j a_j \otimes a_j \otimes a_j, \quad \lambda_j \in \mathbb{R},\ a_j \in \mathbb{R}^d, \tag{1}$$

where $\otimes$ denotes the outer product. The minimum k for which the tensor can be decomposed in the above form is called the (symmetric) tensor rank. *Tensor power iteration* is a simple, popular and efficient method for recovering the tensor rank-one components a_j's. The tensor power iteration is given by

$$x \leftarrow \frac{T(I,x,x)}{\|T(I,x,x)\|}, \tag{2}$$

where

$$T(I,x,x) := \sum_{j,l\in[d]} x_j x_l T(:,j,l) \in \mathbb{R}^d$$

is a *multilinear* combination of tensor *fibers*, and $\|\cdot\|$ is the ℓ_2 norm operator. See Section 1.3 for an overview of tensor notations and preliminaries.

The tensor power iteration is a generalization of matrix power iteration: for matrix $M \in \mathbb{R}^{d\times d}$, the power iteration is given by $x \leftarrow Mx/\|Mx\|$. Dynamics and convergence properties of matrix power iterations are well understood (Horn and Johnson, 2012). On the other hand, a theoretical understanding of tensor power iterations is much more limited. Tensor power iteration can be viewed as a *gradient descent* step (with infinite step size), corresponding to the problem of finding the best rank-1 approximation of the input tensor T (Anandkumar et al., 2014c). This optimization problem is non-convex. Unlike the matrix case, where the number of isolated stationary points of power iteration is at most the dimension (given by eigenvectors corresponding to unique eigenvalues), in the tensor case, the number of stationary points is, in fact, exponential in the input dimension (Cartwright and Sturmfels, 2013). This makes the analysis of tensor power iteration far more challenging.

Despite the above challenges, many advances have been made in understanding the tensor power iterations in specific regimes. When the components a_j's are orthogonal to one another, it is known that there are no spurious local optima for tensor power iterations, and the only stable fixed points correspond to the true a_j's (Zhang and Golub, 2001; Anandkumar et al., 2014c). Any tensor with linearly independent components a_j's can be orthogonalized, via an invertible transformation (whitening) and thus, its components can be recovered efficiently. A careful perturbation analysis in this setting was carried out in Anandkumar et al. (2014c).

The framework in Anandkumar et al. (2014c) is however not applicable in the overcomplete setting, where the tensor rank k exceeds the dimension d. Such overcomplete tensors cannot be orthogonalized and finding guaranteed decomposition is a challenging open problem. It is known that finding CP tensor decomposition is NP-hard (Hillar and Lim, 2013). In this paper, we make significant headway in showing that the simple power iterations can recover the components in the overcomplete regime under a set of mild conditions on the components a_j's.

Overcomplete tensors also arise in many machine learning applications such as moments of many latent variable models, e.g., multiview mixtures, independent component Analysis (ICA), and sparse coding models, where the number of hidden variables exceeds the input dimensions (Anandkumar et al., 2015). Overcomplete models often have impressive empirical performance (Coates et al., 2011), and can provide greater flexibility in modeling, and are more robust to noise (Lewicki and Sejnowski, 2000). By studying algorithms for overcomplete tensor decomposition, we expand the class of models that can be learnt efficiently using simple spectral methods such as tensor power iterations. Note there are other algorithms for decomposing overcomplete tensors (De Lathauwer et al., 2007; Goyal et al., 2013; Bhaskara et al., 2013), but they all require tensors of at least 4-th order and require large computational complexity. Ge and Ma (2015) works for 3rd order tensor but requires quasi-polynomial time. The main contribution of this paper is an analysis for the practical power method in the overcomplete regime.

1.1 Summary of Results

We analyze the dynamics of third order tensor power iterations in the overcomplete regime. We assume that the tensor components a_j's are randomly drawn from the unit sphere. Since general tensor decomposition is challenging in the overcomplete regime, we argue that this is a natural first step to consider for tractable recovery.

We characterize the basin of attraction for the local optima near the rank-one components a_j's. We show that under mild initialization condition, there is fast convergence to these local optima in $O(\log\log d)$ iterations. This result is the core technical analysis of this paper stated in the following theorem.

Theorem 1 (Dynamics of tensor power iteration) *Consider tensor $\hat{T} = T + E$ such that exact tensor T has rank-k decomposition in (1) with rank-one components $a_j \in \mathbb{R}^d, j \in [k]$ being uniformly i.i.d. drawn from the unit d-dimensional sphere, and the ratio of maximum and minimum (in absolute value) weights λ_j's being constant. In addition, suppose the perturbation tensor E has bounded spectral norm as*

$$\|E\| \leq \epsilon \frac{\sqrt{k}}{d}, \quad \text{where} \quad \epsilon < o\left(\frac{\sqrt{k}}{d}\right). \tag{3}$$

Let tensor rank $k = o(d^{1.5})$, and the unit-norm initial vector $x^{(1)}$ satisfy the correlation bound

$$|\langle x^{(1)}, a_j\rangle| \geq d^{\beta}\frac{\sqrt{k}}{d}, \tag{4}$$

w.r.t. some true component $a_j, j \in [k]$, for some $\beta > (\log d)^{-c}$ for some universal constant $c > 0$. After $N = \Theta(\log\log d)$ iterations, the tensor power iteration in (2) outputs a vector having w.h.p. a constant correlation with the true component a_j as $|\langle x^{(N+1)}, a_j\rangle| \geq 1 - \gamma$, for any fixed constant $\gamma > 0$.

As a corollary, this result can be used for learning latent variable models such as multiview mixtures. We show that the above initialization condition is satisfied using a sample with mild signal-to-noise ratio; see Section 2 for more details on this.

The above result is a significant improvement over the recent analysis by Anandkumar et al. (2015, 2014a,b) for overcomplete tensor decomposition. In these works, it is required for the initialization vectors to have a constant amount of correlation with the true a_j's. However, obtaining such strong initializations is usually not realistic in practice. On the other hand, the initialization condition in (4) is mild, and decaying even when the rank k is significantly larger than dimension d; up to $k = o(d^{1.5})$. In learning the mixture model, such initialization vectors can be obtained as samples from the mixture model, even when there is a large amount of noise. Given this improvement, we combine our analysis in Theorem 1, and the guarantees in Anandkumar et al. (2015, 2014a), proving that the model parameters can be recovered consistently.

A detailed proof outline for Theorem 1 is provided in Section 3.1. Under the random assumption, it is not hard to show that the first iteration of tensor power update makes progress. However, after the first iteration, the input vector and the tensor components are no longer *independent* of each other. Therefore, we cannot directly repeat the same argument for the second step.

How do we analyze the second step even though the vector and tensor components are correlated? The main intuition is to characterize the dependency between the vector and the tensor components, and show that there is still enough randomness left for us to repeat the argument. This idea was inspired by the analysis of Approximate Message Passing (AMP) algorithms (Bayati and Montanari, 2010). However, our analysis here is very different in several key aspects: 1) In approximate message passing, typically the analysis works in the *large system limit*, where the number of iterations is fixed and the dimension goes to infinity. Here we can handle a superconstant number of iterations $O(\log\log d)$, even for finite d; 2) Usually k is assumed to be a constant factor times d in the AMP-like analysis, while here we allow them to be polynomially related.

1.2 Related Work

Tensor decomposition for learning latent variable models: In the introduction, some related works are mentioned which study the theoretical and practical aspects of spectral techniques for learning latent variable models. Among them, Anandkumar et al. (2014c) provide the analysis of tensor power iteration for learning several latent variable models in the undercomplete regime. Anandkumar et al. (2014a) provide the analysis in the overcomplete regime and Anandkumar et al. (2014b) provide tensor concentration bounds and apply the analysis in (Anandkumar et al., 2014a) to learning LVMs proposing tight sample complexity guarantees.

Learning mixture of Gaussians: Here, we provide a subset of related works studying learning mixture of Gaussians which are more comparable with our result. For a more detailed list of these works, see Anandkumar et al. (2014c); Hsu and Kakade (2013). The problem of learning mixture of Gaussians dates back to the work by Pearson (1895). They propose a moment-based technique that involves solving systems of multivariate polynomials which is in general challenging in both computational and statistical sense. Recently, lots of studies on learning Gaussian mixture models have been done improving both aspects which can be divided to two main classes: distance-based and spectral methods.

Distance-based methods impose separation condition on the mean vectors showing that under enough separation the parameters can be estimated. Among such approaches, we can mention Dasgupta (1999); Vempala and Wang (2002); Arora and Kannan (2005). As discussed in the summary of results, these results work even if $k > d^{1.5}$ as long as the separation condition between means is satisfied, but our work can tolerate higher level of noise in the regime of $k = o(d^{1.5})$ with polynomial computational complexity. The guarantees in (Vempala and Wang, 2002) also work in the high noise regime but need higher computational complexity as polynomial in $k^{O(k)}$ and d.

In the spectral approaches, the observed moments are constructed and the spectral decomposition of the observed moments are performed to recover the parameters (Kalai et al., 2010; Anandkumar et al., 2012, 2014b). Kalai et al. (2010) analyze the problem of learning mixture of two general Gaussians and provide algorithm with high order polynomial sample and computational complexity. Note that in general, the complexity of such methods grows exponentially with the number of components without further assumptions (Moitra and Valiant, 2010). Hsu and Kakade (2013) provide a spectral algorithm under non-degeneracy conditions on the mean vectors and propose guarantees with polynomial sample complexity depending on the condition number of the moment matrices. Anandkumar et al. (2014b) perform tensor power iteration on the third order moment tensor to recover the mean vectors in the overcomplete regime as long as $k = o(d^{1.5})$, but need very good initialization vector having constant correlation with the true mean vector. Here, we improve the correlation level required for convergence.

1.3 Notation and Tensor Preliminaries

Let $[k] := \{1, 2, \ldots, k\}$, and $\|v\|$ denote the ℓ_2 norm of vector v. We use $\tilde{O}$ and $\tilde{\Omega}$ to hide polylog factors in asymptotic notations O and Ω, respectively.

Tensor preliminaries: A real *p-th order tensor* $T \in \bigotimes^p \mathbb{R}^d$ is a member of the outer product of Euclidean spaces $\mathbb{R}^d$. The different dimensions of the tensor are referred to as *modes*. For instance, for a matrix, the first mode refers to columns and the second mode refers to rows. In addition, *fibers* are higher order analogues of matrix rows and columns. A fiber is obtained by fixing all but one of the indices of the tensor (and is arranged as a column vector). For example, for a third order tensor $T \in \mathbb{R}^{d\times d\times d}$, the mode-1 fiber is given by $T(:, j, l)$. Similarly, *slices* are obtained by fixing all but two of the indices of the tensor. For example, for the third order tensor T, the slices along 3rd mode are given by $T(:, :, l)$.

We view a tensor $T \in \mathbb{R}^{d\times d\times d}$ as a multilinear form. In particular, for vectors $u, v, w \in \mathbb{R}^d$, we have [1]

$$T(I, v, w) := \sum_{j,l\in[d]} v_j w_l T(:, j, l) \ \in \mathbb{R}^d, \tag{5}$$

which is a multilinear combination of the tensor mode-1 fibers. Similarly $T(u, v, w) \in \mathbb{R}$ is a multilinear combination of the tensor entries, and $T(I, I, w) \in \mathbb{R}^{d\times d}$ is a linear combination of the tensor slices.

A 3rd order tensor $T \in \mathbb{R}^{d\times d\times d}$ is said to be rank-1 if it can be written in the form

$$T = \lambda \cdot a \otimes b \otimes c \Leftrightarrow T(i, j, l) = \lambda \cdot a(i) \cdot b(j) \cdot c(l), \tag{6}$$

1. Compare with the matrix case where for $M \in \mathbb{R}^{d\times d}$, we have $M(I, u) = Mu := \sum_{j\in[d]} u_j M(:, j)$.

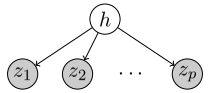

Figure 1: Multiview mixture model.

where notation $\otimes$ represents the *outer product* and $a, b, c \in \mathbb{R}^d$ are unit vectors. A tensor $T \in \mathbb{R}^{d\times d\times d}$ is said to have a CP *rank* at most k if it can be written as the sum of k rank-1 tensors as

$$T = \sum_{i\in[k]} \lambda_i a_i \otimes b_i \otimes c_i, \quad \lambda_i \in \mathbb{R}, \ a_i, b_i, c_i \in \mathbb{R}^d. \tag{7}$$

For third order tensor $T \in \mathbb{R}^{d\times d\times d}$, the spectral (operator) norm is defined as

$$\|T\| := \sup_{\|u\|=\|v\|=\|w\|=1} |T(u, v, w)|.$$

In the rest of the paper, Section 2 describes how to apply our tensor results to learning multiview mixture models. Section 3 illustrates the proof ideas, with more details in the Appendix. Finally we conclude in Section 4.

2. Learning Multiview Mixture Model through Tensor Methods

We proposed our main technical result in Section 1.1 providing convergence guarantees for the tensor power iterations given mild initialization conditions in the overcomplete regime; see Theorem 1. Along this result we provide the application to learning multiview mixtures model in Theorem 2. In this section, we briefly introduce the tensor decomposition framework as the learning algorithm and then state the learning guarantees with more details and remarks.

2.1 Multiview Mixture Model

Consider an exchangeable multiview mixture model with k components and $p \geq 3$ views; see Figure 1. Suppose that hidden variable h is a discrete categorical random variable taking one of the k states. It is convenient to represent it by basis vectors such that

$$h = e_j \in \mathbb{R}^k \quad \text{if and only if} \quad \text{it takes the } j\text{-th state.}$$

Note that $e_j \in \mathbb{R}^k$ denotes the j-the basis vector in the k-dimensional space. The prior probability for each hidden state is $\Pr[h = e_j] = \lambda_j, j \in [k]$. For simplicity, in this paper we assume all the λ_i's are the same. However, similar argument works even when the ratio of maximum and minimum prior probabilities $\lambda_{\max}/\lambda_{\min}$ is bounded by some constant.

The variables (views) $z_l \in \mathbb{R}^d$ are related to the hidden state through *factor matrix* $A \in \mathbb{R}^{d\times k}$ such that

$$z_l = Ah + \eta_l, \quad l \in [p],$$

Algorithm 1 Learning multiview mixture model via tensor power iterations

Require: 1) Third order moment tensor $T \in \mathbb{R}^{d\times d\times d}$ in (8), 2) n samples of z_1 in multiview mixture model as $z_1^{(\tau)}, \tau \in [n]$, and 3) number of iterations N.

1: **for** $\tau = 1$ **to** n **do**
2: **Initialize** unit vectors $x_\tau^{(1)} \leftarrow z_1^{(\tau)} / \left\| z_1^{(\tau)} \right\|$.
3: **for** $t = 1$ **to** N **do**
4: Tensor power updates (see (5) for the definition of the multilinear form):

$$x_\tau^{(t+1)} = \frac{T\left(I, x_\tau^{(t)}, x_\tau^{(t)}\right)}{\left\| T\left(I, x_\tau^{(t)}, x_\tau^{(t)}\right)\right\|}, \tag{9}$$

5: **end for**
6: **end for**
7: **return** the output of Procedure 2 with input $\left\{x_\tau^{(N+1)} : \tau \in [n]\right\}$ as estimates x_j.

where zero-mean noise vectors $\eta_l \in \mathbb{R}^d$ are independent of each other and the hidden state h. Given this, the variables (views) $z_l \in \mathbb{R}^d$ are conditionally independent given the latent variable h, and the conditional means are $\mathbb{E}[z_l|h = e_j] = a_j$, where $a_j \in \mathbb{R}^d$ denotes the j-th column of factor matrix $A = [a_1 \cdots a_k] \in \mathbb{R}^{d\times k}$. In addition, the above properties imply that the order of observations z_l do not matter and the model is *exchangeable*. The goal of the learning problem is to recover the parameters of the model (factor matrix) A given observations.

For this model, the third order[2] observed moment has the form (Anandkumar et al., 2014c)

$$\mathbb{E}[z_1 \otimes z_2 \otimes z_3] = \sum_{j\in[k]} \lambda_j a_j \otimes a_j \otimes a_j. \tag{8}$$

Hence, given third order observed moment, the unsupervised learning problem (recovering factor matrix A) reduces to computing a tensor decomposition as in (8).

2.2 Tensor Decomposition Algorithm

The algorithm for unsupervised learning of multiview mixture model is based on tensor decomposition techniques provided in Algorithm 1. The main step in (9) performs *tensor power iteration*;[3] see (5) for the multilinear form definition. After running the algorithm for all different initialization vectors, the clustering process from Anandkumar et al. (2015) ensures that the best converged vectors are returned as the estimation of true components a_j.

2. It is enough to form the third order moment for our learning purpose.
3. This is the generalization of matrix power iteration to 3rd order tensors.

Procedure 2 Clustering process (Anandkumar et al., 2015)

Require: Tensor $T \in \mathbb{R}^{d\times d\times d}$, set $S := \left\{x_\tau^{(N+1)} : \tau \in [n]\right\}$, parameter ν.

1: **while** S is not empty **do**
2: Choose $x \in S$ which maximizes $|T(x, x, x)|$.
3: Do N more iterations of (9) starting from x.
4: **Output** the result of iterations denoted by $\hat{x}$.
5: Remove all the $x \in S$ with $|\langle x, \hat{x}\rangle| > \nu/2$.
6: **end while**

2.3 Learning Guarantees

We assume a Gaussian prior on the mean vectors, i.e., the vectors $a_j \sim \mathcal{N}(0, I_d/d)$, $j \in [k]$ are i.i.d. drawn from a standard multivariate Gaussian distribution with unit expected square norm. Note that in the high dimension (growing d), this assumption is the same as uniformly drawing from unit sphere since the norm of vector concentrates in the high dimension and there is no need for normalization. Even though we impose a prior distribution, we do not use a MAP estimator, since the corresponding optimization is NP-hard. Instead, we learn the model parameters through decomposition of the third order moments through tensor power iterations. The assumption of a Gaussian prior is standard in machine learning applications. We impose it here for tractable analysis of power iteration dynamics. Such Gaussian assumptions have been used before for analysis of other iterative methods such as approximate message passing algorithms, and there are evidences that similar results hold for more general distributions; see (Bayati and Montanari, 2010) and references there.

As explained in the previous sections, we use tensor power method to learn the components a_j's, and the method is initialized with observed samples z_i. Intuitively, this initialization is useful since $z_i = Ah + \eta_i$ is a perturbed version of desired parameter a_j (when $h = e_j$). Thus, we present the result in terms of the signal-to-noise (SNR) ratio which is the expected norm of signal a_j (which is one here) divided by the expected norm of noise η_i, i.e., the SNR in the i-th sample $z_i = a_j + \eta_i$ (assumed $h = e_j$) is defined as $\text{SNR} := \mathbb{E}[\|a_j\|]/\mathbb{E}[\|\eta_i\|]$. This specifies how much noise the initialization vector z_i can tolerate in order to ensure the convergence of tensor power iteration to a desired local optimum. We now propose the conditions required for recovery guarantees, and state a brief explanation of them.

Conditions for Theorems 2 and 3:

- Rank condition: $k \le o(d^{1.5})$.
- The columns of A are uniformly i.i.d. drawn from unit d-dimensional sphere.
- The noise vectors $\eta_l, l \in [3]$, are independent of matrix A and each other. In addition, the signal-to-noise ratio (SNR) is w.h.p. bounded as

$$\text{SNR} \ge \Omega\left(\frac{\sqrt{\max\{k, d\}}}{d^{1-\beta}}\right),$$

for some $\beta \ge (\log d)^{-c}$ for universal constant $c > 0$.

The rank condition bounds the level of overcompleteness for which the recovery guarantees are satisfied. The random assumption on the columns of A are crucial for analyzing the dynamics of tensor power iteration. We use it to argue there exists enough randomness left in the components after conditioning on the previous iterations; see Section 3.1 for the details. The bound on the SNR is required to make sure the given sample used for initialization is close enough to the corresponding mean vector. This ensures that the initial vector is inside the basin-of-attraction of the corresponding component, and hence, the convergence to the mean vector can be guaranteed. Under these assumptions we have the following theorem.

Theorem 2 (Learning multiview mixture model: closeness to single columuns) *Consider a multiview mixture model (or a spherical Gaussian mixture) in the above settings with k components in d dimensions. If the above conditions hold, then the tensor power iteration converges to a vector close to one of the true mean vectors a_j's (having constant correlation).*

In particular, for mildly overcomplete models, where $k = \alpha d$ for some constant $\alpha > 1$, the signal-to-noise ratio (SNR) is as low as $\Omega(d^{-1/2+\epsilon})$, for any $\epsilon > 0$. Thus, we can learn mixture models with a high level of noise. In general, we establish how the required noise level scales with the number of hidden components k, as long as $k = o(d^{1.5})$.

The above theorem states convergence to desired local optima which are close to true components a_j's. In Theorem 3, we show that we can sharpen the above result, by jointly iterating over the recovered vectors, and consistently recover the components a_j's. This result also uses the analysis from Anandkumar et al. (2015).

Theorem 3 (Learning multiview mixture model: recovering the factor matrix) *Assume the above conditions hold. The initialization of power iteration is performed by samples of z_1 in multiview mixture model. Suppose the tensor power iterations are at least initialized once for each $a_j, j \in [k]$ such that $z_1 = a_j + \eta_1$.[4] Then by using the exact 3rd order moment tensor in (8) as input, the tensor decomposition algorithm outputs an estimate $\hat{A}$ (up to permutation of its columns) satisfying w.h.p. (over the randomness of the components a_j's)*

$$\left\| \hat{A} - A \right\|_F \leq \epsilon,$$

where the number of iterations of the algorithm is $N = \Theta\left(\log\left(\frac{1}{\epsilon}\right) + \log\log d\right)$.

See Section 3 for the proof.

The above theorems assume the exact third order tensor is given to the algorithm. We provide the results given empirical tensor in Section 2.3.1.

Learning spherical Gaussian mixtures: Consider a mixture of k different Gaussian vectors with spherical covariance. Let $a_j \in \mathbb{R}^d, j \in [k]$ denote the mean vectors and the covariance matrices are $\sigma^2 I$. Assuming the parameter σ is known, the modified third order observed moment

$$M_3 := \mathbb{E}[z \otimes z \otimes z] - \sigma^2 \sum_{i \in [d]} \left(\mathbb{E}[z] \otimes e_i \otimes e_i + e_i \otimes \mathbb{E}[z] \otimes e_i + e_i \otimes e_i \otimes \mathbb{E}[z] \right)$$

4. Note that this happens for component j with high probability when the number of initializations is proportional to inverse prior probability corresponding to that mixture.

has the tensor decomposition form (Hsu and Kakade, 2012)

$$M_3 = \sum_{j \in [k]} \lambda_j a_j \otimes a_j \otimes a_j,$$

where λ_j is the probability of drawing j-th Gaussian mixture. The above guarantees can be applied to learning mean vectors a_j in this model with the additional property that the noise is spherical Gaussian.

Learning multiview mixture model with distinct factor matrices: Consider the multiview mixture model with different factor matrices where the first three views are related to the hidden state as

$$z_1 = Ah + \eta_1, \quad z_2 = Bh + \eta_2, \quad z_3 = Ch + \eta_3.$$

Then, the guarantees in the above theorem can be extended to recovering the columns of all three factor matrices A, B, and C with appropriate modifications in the power iteration algorithm as follows. First the update formula (9) is changed as

$$x_{1,\tau}^{(t+1)} = \frac{T\left(I, x_{2,\tau}^{(t)}, x_{3,\tau}^{(t)}\right)}{\left\| T\left(I, x_{2,\tau}^{(t)}, x_{3,\tau}^{(t)}\right) \right\|}, \quad x_{2,\tau}^{(t+1)} = \frac{T\left(x_{1,\tau}^{(t)}, I, x_{3,\tau}^{(t)}\right)}{\left\| T\left(x_{1,\tau}^{(t)}, I, x_{3,\tau}^{(t)}\right) \right\|}, \quad x_{3,\tau}^{(t+1)} = \frac{T\left(x_{1,\tau}^{(t)}, x_{2,\tau}^{(t)}, I\right)}{\left\| T\left(x_{1,\tau}^{(t)}, x_{2,\tau}^{(t)}, I\right) \right\|},$$

which is the alternating asymmetric version of symmetric power iteration in (9). Here, we alternate among different modes of the tensor. In addition, the initialization for each mode of the tensor is appropriately performed with the samples corresponding to that mode. Note that the analysis still works in the asymmetric version since there exists even more independence relationships through the iterations of the power update because of introducing new random matrices B and C.

2.3.1 Sample Complexity Analysis

In the previous section, we assumed the exact third order tensor in (8) is given to the tensor decomposition Algorithm 1. We now estimate the tensor given n samples $z_1^{(i)}, z_2^{(i)}, z_3^{(i)}, i \in [n]$, as

$$\hat{T} = \frac{1}{n} \sum_{i \in [n]} z_1^{(i)} \otimes z_2^{(i)} \otimes z_3^{(i)}. \tag{10}$$

For the multiview mixture model introduced in Section 2.1, let the noise vector η_l be spherical, and ζ^2 denote the variance of each entry of noise vector. We now provide the following recovery guarantees.

Additional conditions for Theorem 4:

- Let $E_1 := [\eta_1^{(1)}, \eta_1^{(2)}, \ldots, \eta_1^{(n)}] \in \mathbb{R}^{d \times n}$, where $\eta_1^{(i)} \in \mathbb{R}^d$ is the i-th sample of noise vector η_1. These noise matrices satisfy the following *RIP property* which is adapted from Candes and Tao (2006). Matrix $E_1 \in \mathbb{R}^{d \times n}$ satisfies a weak RIP condition such that for any subset of $O\left(\frac{d}{\log^2 d}\right)$ number of columns, the spectral norm of E_1 restricted to those columns is bounded by 2. The same condition is satisfied for similarly defined noise matrices E_2 and E_3.

- The number of samples n satisfies lower bound such that

$$\zeta\left(\frac{\sqrt{d}}{n}+\sqrt{\lambda_{\max}\frac{d}{n}}\right)+\zeta^2\left(\frac{d}{n}+\sqrt{\lambda_{\max}\frac{d^{1.5}}{n}}\right)+\zeta^3\left(\frac{d^{1.5}}{n}+\sqrt{\frac{d}{n}}\right)\leq\min\left\{\epsilon\frac{\sqrt{k}}{d},\tilde{O}(\lambda_{\min})\right\},\qquad(11)$$

where $\epsilon<o\left(\sqrt{k}/d\right)$.

Theorem 4 (Learning multiview mixture model) *Consider the empirical tensor in* (10) *as the input to tensor decomposition Algorithm 1. Suppose the above additional conditions are also satisfied. Then, the same guarantees as in Theorem 2 hold. In addition, the same guarantees as in Theorem 3 also hold with the recovery bound (up to permutation of columns of $\hat{A}$) changed as*

$$\left\|\hat{A}-A\right\|_F\leq\tilde{O}\left(\frac{\sqrt{k}\cdot\|E\|}{\lambda_{\min}}\right),$$

where E denotes the perturbation tensor originated from empirical estimation in (10)*, and its spectral norm $\|E\|$ is bounded by the LHS of* (11)*.*

See Section 3 for the proof.

3. Proof Outline

Our main technical result is the analysis of third order tensor power iteration provided in Theorem 1 which also allows to tolerate some amount of noise in the input tensor. We analyze the noiseless and noisy settings in different ways. We basically first prove the result for the noiseless setting where the input tensor has an exact rank-k decomposition in (1). When the noise is also considered, we show that the contribution of noise in the analysis is dominated by the main signal, and thus, the same result still holds. For the rest of this section we focus on the noiseless setting, while we discuss the proof ideas for the noisy case in Section 3.2.

We first discuss the proof of Theorem 3 which involves two phases. In the first phase, we show that under certain small amount of correlation (see (13)) between the initial vector and the true component, the power iteration in (2) converges to some vector which has constant correlation with the true component. This result is the core technical analysis of this paper which is provided in Lemma 5. In the second phase, we incorporate the result of Anandkumar et al. (2015, 2014a) which guarantees the convergence of power iteration (followed by a coordinate descent iteration) given initial vectors having constant correlation with the true components. This is stated in Lemma 6.

To simplify the notation, we consider the tensor[5]

$$T=\sum_{j\in[k]}a_j\otimes a_j\otimes a_j,\quad a_j\sim\mathcal{N}(0,\frac{1}{d}I_d).\qquad(12)$$

5. In the analysis, we assume that all the weights are equal to one which can be generalized to the case when the ratio of maximum and minimum weights (in absolute value) are constant.

Notice that this is exactly proportional to the 3rd order moment tensor of the multiview mixture model in (8).

The following lemma is restatement of Theorem 1 in the noiseless setting.

Lemma 5 (Dynamics of tensor power iteration, phase 1) *Consider the rank-k tensor T of the form in* (12)*. Let tensor rank $k=o(d^{1.5})$, and the unit-norm initial vector $x^{(1)}$ satisfies the correlation bound*

$$|\langle x^{(1)},a_j\rangle|\geq d^{\beta}\frac{\sqrt{k}}{d},\qquad(13)$$

w.r.t. some true component $a_j, j\in[k]$, for some $\beta>(\log d)^{-c}$ for some universal constant $c>0$. After $N=\Theta(\log\log d)$ iterations, the tensor power iteration in (2) *outputs a vector having w.h.p. a constant correlation with the true component a_j as*

$$|\langle x^{(N+1)},a_j\rangle|\geq 1-\gamma,$$

for any fixed constant $\gamma>0$.

The proof outline of above lemma is provided in Section 3.1. Next, we provide the following lemma from Anandkumar et al. (2015) which provides the dynamics of tensor power iteration when the initialization satisfies the constant correlation bound stated below.

Lemma 6 (Dynamics of tensor power iteration, phase 2) *Consider the rank-k tensor T of the form in* (12) *with rank condition $k\leq o(d^{1.5})$. Let the initial vectors $x_j^{(1)}$ satisfy the constant correlation bound*

$$|\langle x_j^{(1)},a_j\rangle|\geq 1-\gamma_j,$$

w.r.t. true components $a_j, j\in[k]$, for some constants $\gamma_j>0$. Let the output of the tensor power updates[6] in (2) *applied to all these different initialization vectors after $N=\Theta\left(\log\frac{1}{\epsilon}\right)$ iterations be stacked as columns of matrix $\hat{A}$. Then, we have w.h.p.[7]*

$$\left\|\hat{A}-A\right\|_F\leq\epsilon,$$

where the recovery error is up to permutation of columns of $\hat{A}$.

See Anandkumar et al. (2015) for the proof of above lemma. Given the above two lemmas, the learning result in Theorem 3 is directly proved.

Proof of Theorem 3 The result is proved by combining Lemma 5 and Lemma 6. Note that the initialization condition in (4) is w.h.p. satisfied given the SNR bound assumed. ■

Proof of Theorem 4 In Theorem 3, we provided the result given exact tensor by combining Lemmas 5 and 6. The only difference here is we are given an empirical estimate of the tensor and we need to incorporate the effect of noise in the empirical input. We now use

6. This result also needs an additional step of coordinate descent iterations since the true components are not the fixed points of power iteration; see Anandkumar et al. (2015, 2014a) for the details.
7. Anandkumar et al. (2015, 2014a) recover the vector up to sign since they work in the asymmetric case. In symmetric case it is easy to resolve sign ambiguity issue.

Theorem 1 that characterizes the effect of noise in first step (adapting Lemma 5 to noisy setting), and Anandkumar et al. (2015) that provide the result of Lemma 6 in noisy setting. In addition, the tensor concentration bound for multiview mixture model is analyzed in Theorem 1 of Anandkumar et al. (2014b) (Lemma 56 in Anandkumar et al. (2015)) that shows the error between empirical and exact tensors is bounded as

$$\|\hat{T}-T\| \leq \zeta\left(\frac{\sqrt{d}}{n}+\sqrt{\lambda_{\max}\frac{d}{n}}\right)+\zeta^2\left(\frac{d}{n}+\sqrt{\lambda_{\max}\frac{d^{1.5}}{n}}\right)+\zeta^3\left(\frac{d^{1.5}}{n}+\sqrt{\frac{d}{n}}\right).$$

The sample complexity requirement in (11) is then derived by imposing the error requirements in our noisy analysis of tensor power dynamics in Theorem 1 (see Equation (3)) and the noisy analysis of Lemma 6 (see Theorem 1 of Anandkumar et al. (2015) where the perturbation tensor E needs to be bounded as $\|E\| \leq \tilde{O}(\lambda_{\min})$). The final recovery error on $\left\|\hat{A}-A\right\|_F$ is also from Theorem 1 of Anandkumar et al. (2015). ■

3.1 Proof Outline of Lemma 5 (Noiseless Case of Theorem 1)

First step: We first intuitively show the first step of the algorithm makes progress. Suppose the tensor is $T=\sum_{j\in[k]} a_j\otimes a_j\otimes a_j$, and the initial vector x has correlation $|\langle x,a_1\rangle| \geq d^{\beta}\frac{\sqrt{k}}{d}$ with the first component. The result of the first iteration is the normalized version of the following vector:

$$\tilde{x}=\sum_{j\in[k]}\langle a_j,x\rangle^2 a_j.$$

Intuitively, this vector should have roughly $\langle a_1,\tilde{x}\rangle = d^{2\beta}\frac{k}{d^2}$ correlation with a_1 (as the other terms are random they don't contribute much). On the other hand, the norm of this vector is roughly $O(\sqrt{k}/d)$: this is because $\langle a_j,x\rangle^2$ for $j\neq 1$ is roughly[8] $1/d$, and the sum of k random vectors with length $1/d$ will have length roughly $O(\sqrt{k}/d)$. These arguments can be made precise showing the normalized version $\tilde{x}/\|\tilde{x}\|$ has correlation $d^{2\beta}\frac{\sqrt{k}}{d}$ with a_1 ensuring progress in the first step.

Going forward: As we explained, the basic idea behind proving Lemma 5 is to characterize the conditional distribution of random Gaussian tensor components a_j's given previous iterations. In particular, we show that the residual independent randomness left in these conditional distributions is large enough and we can exploit it to obtain tighter concentration bounds throughout the analysis of the iterations. The Gaussian assumption on the components, and small enough number of iterations are crucial in this argument.

Notations: For two vectors $u,v\in\mathbb{R}^k$, the Hadamard product denoted by $*$ is defined as the entry-wise multiplication of vectors, i.e., $(u*v)_j := u_jv_j$ for $j\in[k]$. For a matrix A, let $P_{\perp_A}$ denote the projection operator to the subspace orthogonal to column span of A. For a subspace R, let $R^{\perp}$ denote the space orthogonal to it. Therefore, for a subspace R, the projection operator on the subspace orthogonal to R is equivalently denoted by $P_{R^{\perp}}$ or $P_{\perp_R}$. For a random matrix D, let $D|\{u=Dv\}$ denote the conditional distribution of D given linear constraints $u=Dv$. We also use equality notation $\overset{(d)}{=}$ to denote the equivalence in distribution.

Lemma 5 involves analyzing the dynamics of power iteration in (2) for 3rd order rank-k tensors. For the rank-k tensor in (12), the power iterative form $x\leftarrow\frac{T(I,x,x)}{\|T(I,x,x)\|}$ can be written as

$$x^{(t+1)}=\frac{A\left(A^\top x^{(t)}\right)^{*2}}{\left\|A\left(A^\top x^{(t)}\right)^{*2}\right\|}, \tag{14}$$

where the multilinear form in (5) is used. Here, $A=[a_1\cdots a_k]\in\mathbb{R}^{d\times k}$ denotes the factor matrix, and for vector $y\in\mathbb{R}^k$, $y^{*2}:=y*y\in\mathbb{R}^k$ represents the element-wise square of entries of y.

We consider the case where $a_i\sim\mathcal{N}(0,\frac{1}{d}I)$ are i.i.d. drawn and we analyze the evolution of the dynamics of the power update. As explained earlier, for a given initialization $x^{(1)}$, the update in the first step can be analyzed easily since A is independent of $x^{(1)}$. However, in subsequent steps, the updates $x^{(t)}$ are dependent on A, and it is no longer clear how to provide a tight bound on the evolution of $x^{(t)}$. In this work, we provide a careful analysis by controlling the amount of "correlation build-up" by exploiting the structure of Gaussian matrices under linear constraints. This enables us to provide better guarantees for matrix A with Gaussian entries compared to general matrices A.

*Intermediate update steps and variables:*Before we proceed, we need to break down power update in (2) and introduce some intermediate update steps and variables as follows. Recall that $x^{(1)}\in\mathbb{R}^d$ denotes the initialization vector. Without loss of generality, let us analyze the convergence of power update to first component of rank-k tensor T denoted by a_1. Hence, let the first entry of $x^{(1)}$ denoted by $x_1^{(1)}$ be the maximum entry (in absolute value) of $x^{(1)}$, i.e., $x_1^{(1)}=\|x^{(1)}\|_\infty$. Let $B:=[a_2\ a_3\ \cdots\ a_k]\in\mathbb{R}^{d\times(k-1)}$, and therefore $A=[a_1|B]$. We break the power update formula in (2) into a few steps by introducing intermediate variables $y^{(t)}\in\mathbb{R}^k$ and $\tilde{x}^{(t+1)}\in\mathbb{R}^d$ as

$$y^{(t)}:=A^\top x^{(t)},\quad \tilde{x}^{(t+1)}:=A(y^{(t)})^{*2}.$$

Note that $\tilde{x}^{(t+1)}$ is the unnormalized version of $x^{(t+1)}:=\tilde{x}^{(t+1)}/\|\tilde{x}^{(t+1)}\|$, i.e., $\tilde{x}^{(t+1)}:=T(I,x^{(t)},x^{(t)})$. Thus, we need to jointly analyze the dynamics of all variables $x^{(t)}$, $y^{(t)}$ and $(y^{(t)})^{*2}$. Define

$$X^{[t]}:=\left[x^{(1)}|\ldots|x^{(t)}\right],\quad Y^{[t]}:=\left[y^{(1)}|\ldots|y^{(t)}\right].$$

Matrix B is randomly drawn with i.i.d. Gaussian entries $B_{ij}\sim\mathcal{N}(0,\frac{1}{d})$. As the iterations proceed, we consider the following conditional distributions

$$B^{(t,1)}:=B|\{X^{[t]},Y^{[t]}\},\quad B^{(t,2)}:=B|\{X^{[t+1]},Y^{[t]}\}. \tag{15}$$

Thus, $B^{(t,1)}$ is the conditional distribution of B at the middle of t^{th} iteration (before update step $\tilde{x}^{(t+1)}=A(y^{(t)})^{*2}$) and $B^{(t,2)}$ is the conditional distribution at the end of t^{th} iteration (after update step $\tilde{x}^{(t+1)}=A(y^{(t)})^{*2}$). By analyzing the above conditional distributions, we can characterize the left independent randomness in B.

8. The correlation between two unit Gaussian vectors in d dimensions is roughly $1/\sqrt{d}$.

3.1.1 Conditional Distributions

In order to characterize the conditional distribution of B under evolution of $x^{(t)}$ and $y^{(t)}$ in (15), we exploit the following basic fact (see (Bayati and Montanari, 2010) for proof).

Lemma 7 (Conditional distribution of Normal matrices under linear condition) *Consider random matrix D with i.i.d. Gaussian entries $D_{ij} \sim \mathcal{N}(0,\sigma^2)$. Conditioned on $u = Dv$ with known vectors u and v, the matrix D is distributed as*

$$D|\{u = Dv\} \overset{(\mathrm{d})}{=} \frac{1}{\|v\|^2} uv^\top + \tilde{D}P_{\perp_v},$$

where random matrix $\tilde{D}$ is an independent copy of D with i.i.d. Gaussian entries $\tilde{D}_{ij} \sim \mathcal{N}(0,\sigma^2)$, and $P_{\perp_v}$ is the projection operator on to the subspace orthogonal to v.

We refer to $\tilde{D}P_{\perp_v}$ as the *residual* random matrix since it represents the remaining *randomness* left after conditioning. It is a random matrix whose rows are independent random vectors that are orthogonal to v, and the variance in each direction orthogonal to v is equal to σ^2.

The above Lemma can be exploited to characterize the conditional distribution of B introduced in (15). However, a naive direct application using the constraint $Y^{[t]} = A^\top X^{[t]}$ is not transparent for analysis. The reason is the evolution of $x^{(t)}$ and $y^{(t)}$ are themselves governed by the conditional distribution of B given previous iterations. Therefore, we need the following recursive version of Lemma 7 which can be immediately argued by induction.

Corollary 8 (Iterative conditioning) *Consider random matrix D with i.i.d. Gaussian entries $D_{ij} \sim \mathcal{N}(0,\sigma^2)$, and let $F \overset{(\mathrm{d})}{=} P_{\perp_C} D P_{\perp_R}$ be the random Gaussian matrix whose columns are orthogonal to space C and rows are orthogonal to space R. Conditioned on the linear constraint $u = Dv$, where[9] $u \in C^\perp$, the matrix F is distributed as*

$$F|\{u = Dv\} \overset{(\mathrm{d})}{=} \frac{1}{\|(P_{\perp_R} v)\|^2} u(P_{\perp_R} v)^\top + P_{\perp_C} \tilde{D} P_{\perp_{\{R,v\}}},$$

where random matrix $\tilde{D}$ is an independent copy of D with i.i.d. Gaussian entries $\tilde{D}_{ij} \sim \mathcal{N}(0,\sigma^2)$.

Thus, the *residual* random matrix $P_{\perp_C}\tilde{D}P_{\perp_{\{R,v\}}}$ is a random Gaussian matrix whose columns are orthogonal to C and rows are orthogonal to $\mathrm{span}\{R, v\}$. The variance in any remaining dimension is equal to σ^2.

3.1.2 Form of Iterative Updates

Now we exploit the conditional distribution arguments proposed in the previous section to characterize the conditional distribution of B given the update variables x and y up to the current iteration; recall (15) where $B^{(t,1)}$ is the conditional distribution of B at the middle of t^{th} iteration and $B^{(t,2)}$ at the end of t^{th} iteration. Before that, we need to introduce some more intermediate variables.

9. We need that $u \in C^\perp$, otherwise the event $u = Dv$ is impossible.

Intermediate variables: We separate the first entry of y and $(y)^{*2}$ from the rest, i.e., we have

$$y_1^{(t)} = a_1^\top x^{(t)}, \quad y_{-1}^{(t)} = B^\top x^{(t)} \sim (B^{(t-1,2)})^\top x^{(t)},$$

where $y_{-1}^{(t)} \in \mathbb{R}^{k-1}$ denotes $y^{(t)} \in \mathbb{R}^k$ with the first entry removed. The update formula for $\tilde{x}^{(t+1)}$ can be also decomposed as

$$\tilde{x}^{(t+1)} = (y_1^{(t)})^2 a_1 + Bw^{(t)} \sim (y_1^{(t)})^2 a_1 + B^{(t,1)} w^{(t)},$$

where

$$w^{(t)} := (y_{-1}^{(t)})^{*2} \in \mathbb{R}^{k-1},$$

is the new intermediate variable in the power iterations. Let $B_{\text{res.}}^{(t,1)}$ and $B_{\text{res.}}^{(t,2)}$ denote the *residual* random matrices corresponding to $B^{(t,1)}$ and $B^{(t,2)}$ respectively, and

$$u^{(t+1)} := B_{\text{res.}}^{(t,1)} w^{(t)}, \quad v^{(t)} := (B_{\text{res.}}^{(t-1,2)})^\top x^{(t)},$$

where $u^{(t)} \in \mathbb{R}^d$ and $v^{(t)} \in \mathbb{R}^{k-1}$ are respectively the part of $x^{(t)}$ and $y_{-1}^{(t)}$ representing the residual randomness after conditioning on the previous iterations. We also summarize all variables and notations in Table 1 in the Appendix which can be used as a reference throughout the paper.

Finally we make the following observations.

Lemma 9 (Form of iterative updates) *The conditional distribution of B at the middle of t^{th} iteration denoted by $B^{(t,1)}$ satisfies*

$$B^{(t,1)} \overset{(\mathrm{d})}{=} \sum_{i\in[t-1]} \frac{u^{(i+1)}(P_{\perp_{W^{[i-1]}}} w^{(i)})^\top}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} + \sum_{i\in[t]} \frac{P_{\perp_{X^{[i-1]}}} x^{(i)} (v^{(i)})^\top}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|^2} + B_{\text{res.}}^{(t,1)}, \tag{16}$$

$$B_{\text{res.}}^{(t,1)} \overset{(\mathrm{d})}{=} P_{\perp_{X^{[t]}}} \tilde{B} P_{\perp_{W^{[t-1]}}}, \tag{17}$$

where random matrix $\tilde{B}$ is an independent copy of B with i.i.d. Gaussian entries $\tilde{B}_{ij} \sim \mathcal{N}(0, \frac{1}{d})$. Similarly, the conditional distribution of B at the end of t^{th} iteration denoted by $B^{(t,2)}$ satisfies

$$B^{(t,2)} \overset{(\mathrm{d})}{=} \sum_{i\in[t]} \left(\frac{u^{(i+1)}(P_{\perp_{W^{[i-1]}}} w^{(i)})^\top}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} + \frac{P_{\perp_{X^{[i-1]}}} x^{(i)} (v^{(i)})^\top}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|^2} \right) + B_{\text{res.}}^{(t,2)}, \tag{18}$$

$$B_{\text{res.}}^{(t,2)} \overset{(\mathrm{d})}{=} P_{\perp_{X^{[t]}}} B' P_{\perp_{W^{[t]}}}, \tag{19}$$

where random matrix B' is an independent copy of B with i.i.d. Gaussian entries $B'_{ij} \sim \mathcal{N}(0, \frac{1}{d})$.

The lemma can be directly proved by applying the iterative conditioning argument in Corollary 8. See the detailed proof in the appendix.

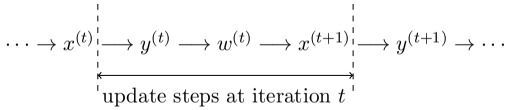

Figure 2: Flow of the power update algorithm stating intermediate steps. Iteration t for which the inductive step should be argued is also indicated.

3.1.3 Analysis of Iterative Updates

Lemma 9 characterizes the conditional distribution of B given the update variables x and y up to the current iteration; see (15) for the definition of conditional forms of B denoted by $B^{(t,1)}$ and $B^{(t,2)}$. Intuitively, when the number of iterations $t \ll d$, then the residual independent randomness left in $B^{(t,1)}$ and $B^{(t,2)}$ (respectively denoted by $B^{(t,1)}_{\text{res.}}$ and $B^{(t,2)}_{\text{res.}}$) characterized in Lemma 9 is large enough and we can exploit it to obtain tighter concentration bounds throughout the analysis of the iterations.

Note that the goal is to show that under $t \ll d$, the iterations $x^{(t)}$ converge to the true component with constant error, i.e., $|\langle x^{(t)}, a_1\rangle| \geq 1-\gamma$ for some constant $\gamma > 0$. If this already holds before iteration t we are done, and if it does not hold, next iteration is analyzed to finally achieve the goal. This analysis is done via *induction argument*. During the iterations, we maintain several invariants to analyze the dynamics of power update. The goal is to ensure progress in each iteration as in (20).

Induction hypothesis: The following are assumed at the beginning of the iteration t as induction hypothesis; see Figure 2 for the scope of inductive step.

1. *Length of Projection on x:*

$$\delta_t \leq \|P_{\perp_{X^{[t-1]}}} x^{(t)}\| \leq 1,$$

where δ_t is of order $1/\operatorname{polylog} d$, and the value of δ_t only depends on t and $\log d$.

2. *Length of Projection on w:*

$$\delta'_{t-1}\frac{\sqrt{k}}{d} \leq \|P_{\perp_{W^{[t-2]}}} w^{(t-1)}\| \leq \Delta'_{t-1}\frac{\sqrt{k}}{d},$$
$$\|P_{\perp_{W^{[t-2]}}} w^{(t-1)}\|_\infty \leq \Delta'_{t-1}\frac{1}{d},$$

where δ'_t is of order $1/\operatorname{polylog} d$ and Δ'_t is of order $\operatorname{polylog} d$. Both δ'_t and Δ'_t only depend on t and $\log d$.

3. *Progress:*[10]

$$|\langle a_1, x^{(t)}\rangle| \in [\delta^*_t, \Delta^*_t] d^{\beta 2^{t-1}}\frac{\sqrt{k}}{d}, \tag{20}$$
$$|\langle a_1, P_{\perp_{X^{[t-1]}}} x^{(t)}\rangle| \leq \Delta^*_t d^{\beta 2^{t-1}}\frac{\sqrt{k}}{d}.$$

4. *Norm of u,v:*

$$\frac{\delta_{t-1}}{2}\sqrt{\frac{k}{d}} \leq \|v^{(t-1)}\| \leq 2\sqrt{\frac{k}{d}},$$
$$\frac{\delta'_{t-1}}{2}\frac{\sqrt{k}}{d} \leq \|u^{(t)}\| \leq 2\Delta'_{t-1}\frac{\sqrt{k}}{d}.$$

The analysis for basis of induction and inductive step are provided in Appendix B.

3.2 Effect of Noise in Theorem 1

Given rank-k random tensor T in (12), and a starting point $x^{(1)}$, our analysis in the noiseless setting shows that the tensor power iteration in (2) outputs a vector which will be close to a_j if $x^{(1)}$ has a large enough correlation with a_j.

Now suppose we are given noisy tensor $\hat{T} = T + E$ where E has some small norm. In this case where the noise is also present, we get a sequence $\hat{x}^{(t)} = x^{(t)} + \xi^{(t)}$ where $x^{(t)}$ is the component not incorporating any noise (as in previous section[11]), while $\xi^{(t)}$ represents the contribution of noise tensor E in the power iteration; see (21) below. We prove that $\xi^{(t)}$ is a very small noise that does not change our calculations stated in the following lemma.

Lemma 10 (Bounding norm of error) *Suppose the spectral norm of the error tensor E is bounded as*

$$\|E\| \leq \epsilon\sqrt{k}/d, \quad \text{where} \quad \epsilon < o(\sqrt{k}/d).$$

Then the noise vector $\xi^{(t)}$ at iteration t satisfies the ℓ_2 norm bound

$$\|\xi^{(t)}\| \leq \tilde{O}(d^{\beta 2^{t-1}}\epsilon).$$

Note that when t is the first number such that $d^{\beta 2^{t-1}} \geq d/\sqrt{k}$, we have $\|\xi^{(t)}\| = o(1)$.

Notice that since when $d^{\beta 2^{t-1}} \geq d/\sqrt{k}$, the main induction is already over and we know $x^{(t)}$ is constant close to the true component, and thus, the noise is always small.

Proof idea: We now provide an overview of ideas for proving the above lemma; see Appendix D for the complete proof which is based on an induction argument. We first

10. Note that although the bounds on $y^{(t)}_{-1}$ are argued at iteration t, the bound on the first entry of $y^{(t)}$ denoted by $y^{(t)}_1 = \langle a_1, x^{(t)}\rangle$ is assumed here in the induction hypothesis at the end of iteration $t-1$.

11. Note that there is a subtle difference between notation $x^{(t)}$ in the noiseless and noisy settings. In the noiseless setting, this vector is normalized, while in the noisy setting the whole vector $\hat{x}^{(t)} = x^{(t)} + \xi^{(t)}$ is normalized.

write the following recursion expanding the contribution of main signal and noise terms in the tensor power iteration as

$$\begin{aligned} x^{(t+1)} + \xi^{(t+1)} &= \text{Norm}\left(\hat{T}(x^{(t)} + \xi^{(t)}, x^{(t)} + \xi^{(t)}, I)\right) \\ &= \text{Norm}\left(T(x^{(t)}, x^{(t)}, I) + 2T(x^{(t)}, \xi^{(t)}, I) + T(\xi^{(t)}, \xi^{(t)}, I) + E(\hat{x}^{(t)}, \hat{x}^{(t)}, I)\right), \end{aligned} \tag{21}$$

where for vector v, we have $\text{Norm}(v) := v/\|v\|$, i.e., it normalizes the vector. The first term is the desired main signal and should have the largest norm, and the rest of the terms are the noise terms. The third term is of order $\|\xi^{(t)}\|^2$, and hence, it should be fine whenever we choose $\|E\|$ to be small enough. The last term is $O(\|E\|)$ and is the same for all iterations so that is also fine. The problematic term is the second term, whose norm if we bound naively is $2\|\xi^{(t)}\|$. However the normalization factor also contributes a factor of roughly $d/\sqrt{k}$, and thus, this term grows exponentially; it is still fine if we just do a constant number of iterations, but the exponent will depend on the number of iterations.

In order to solve this problem, and make sure that the amount of noise we can tolerate is independent of the number of iterations, we need a better way to bound the noise term $\xi^{(t)}$. The main problem here is we bound the norm of $\|T(x^{(t)}, \xi^{(t)}, I)\|$ by $\|T\|\|\xi^{(t)}\| \leq O(\xi^{(t)})$, by doing this we ignored the fact that $x^{(t)}$ is uncorrelated with the components in T. In order to get a tighter bound, we introduce another norm $\|\cdot\|_*$; see Definition 21 for the exact form. Intuitively, the norm $\|\cdot\|_*$ captures the fact that x does not have a high correlation with the components (except for the first component that x will converge to), and gives a better bound. In particular we have $\|T(x^{(t)}, \xi^{(t)}, I)\| \approx \frac{\sqrt{k}}{d}\|\xi^{(t)}\|_2$. Therefore, the normalization factor is compensated by the additional term $\frac{\sqrt{k}}{d}$.

4. Conclusion

In this paper, we provide a novel analysis for the dynamics of third order tensor power iteration showing convergence guarantees to vectors having constant correlation with the tensor component. This enables us to prove unsupervised learning of latent variable models in the challenging overcomplete regime where the hidden dimensionality is larger than the observed dimension. The main technical observation is that under random Gaussian tensor components and small number of iterations, the residual randomness in the components (which are involved in the iterative steps) are sufficiently large. This enables us to show progress in the next iteration of the update step. As future work, it is very interesting to generalize this analysis to higher order tensor power iteration, and more generally to other kinds of iterative updates.

Table 1: Table of parameters and variables. Superscript (t) denotes the variable at t-th iteration.

Appendix A. Proof of Lemma 9

Proof of Lemma 9 Recall that we have updates of the form

$$\tilde{x}^{(t+1)} = A(y^{(t)})^{*2}, \quad w^{(t)} := (y_{-1}^{(t)})^{*2}, \quad y^{(t)} = A^\top x^{(t)}.$$

Let

$$X^{[t]\setminus 1} := \left[x^{(2)}|\dots|x^{(t)}\right],$$

and let the rows of $Y^{[t]}$ are partitioned as the first and the rest of rows as

$$Y^{[t]} = \left[Y_1^{[t]\top} \middle| Y_{-1}^{[t]\top}\right]^\top.$$

We now make the following simple observations

$$\begin{aligned} B^{(t,1)} &\overset{(d)}{=} B|\{Y^{[t]} = A^\top X^{[t]},\ \tilde{X}^{[t]\setminus 1} = A(Y^{[t-1]})^{*2}\} \\ &\overset{(d)}{=} B|\{Y_{-1}^{[t]} = B^\top X^{[t]},\ \tilde{X}^{[t]\setminus 1} = a_1(Y_1^{[t-1]})^{*2} + BW^{[t-1]}\} \\ &\overset{(d)}{=} B|\{v^{(1)} = B^\top x^{(1)}, \dots, v^{(t)} = (B_{\text{res.}}^{(t-1,2)})^\top x^{(t)}, \\ &\qquad u^{(2)} = B_{\text{res.}}^{(1,1)} w^{(1)}, \dots, u^{(t)} = B_{\text{res.}}^{(t-1,1)} w^{(t-1)}\}, \end{aligned}$$

where the second equivalence comes from the fact that B is matrix A with first column removed. Now applying Corollary 8, we have the result. The distribution of $B^{(t,2)}$ follow similarly. ■

Appendix B. Analysis of Induction Argument

In this section, we analyze the basis of induction and inductive step for the induction argument proposed in Section 3.1.3 for the proof of Lemma 5.

B.1 Basis of Induction

We first show that the hypothesis holds for initialization vector $x^{(1)}$ as the basis of induction.

Claim 1 (Basis of induction) *The induction hypothesis is true for $t = 1$.*

Proof Notice that induction hypothesis for $t = 1$ only involves the bounds on $\|x^{(1)}\|$ and $\langle a_1, x^{(1)}\rangle$ as in Hypotheses 1 and 3, respectively. These bounds are directly argued by the correlation assumption on the initial vector $x^{(1)}$ stated in (13) where $\delta_1 = \delta_1^* = \Delta_1^* = 1$. ■

B.2 Inductive Step

Assuming the induction hypothesis holds for all the values till the end of iteration $t-1$ (stated in Section 3.1.3), we analyze the t-th iteration of the algorithm, and prove that induction hypothesis also holds for the values at the end of iteration t. See Figure 2 where the scope of iteration t and the flow of the algorithm is shown. In the rest of this section, we pursue the flow of the algorithm at iteration t starting from computing $y^{(t)}$ and ending up with computing $x^{(t+1)}$ to prove the desired induction hypothesis at iteration t.

B.2.1 Hypothesis 4

We start by showing that the induction Hypothesis 4 holds at iteration t using the induction Hypotheses 1 and 2 in the previous iteration.

Claim 2 *We have*

$$\begin{aligned} &\frac{\delta_t}{2}\sqrt{\frac{k}{d}} \le \|v^{(t)}\| \le 2\sqrt{\frac{k}{d}}, \\ &\frac{\delta_t'}{2}\frac{\sqrt{k}}{d} \le \|u^{(t+1)}\| \le 2\Delta_t'\frac{\sqrt{k}}{d}. \end{aligned}$$

Proof Recall that $v^{(t)} := (B_{\text{res.}}^{(t-1,2)})^\top x^{(t)}$, and by applying the form of $B_{\text{res.}}^{(t-1,2)}$ in (19), we have

$$v^{(t)} \overset{(d)}{=} P_{\perp_{W^{[t-1]}}} B'^\top P_{\perp_{X^{[t-1]}}} x^{(t)}. \tag{22}$$

Since random matrix $B' \in \mathbb{R}^{d\times(k-1)}$ is an independent copy of B with i.i.d. Gaussian entries $B'_{ij} \sim \mathcal{N}(0, \frac{1}{d})$, we know $v^{(t)}$ is a random Gaussian vector in the subspace orthogonal to $W^{[t-1]}$. On the other hand, for any vector $z \in \mathbb{R}^d$, we have

$$\mathbb{E}\left[\|B'^\top z\|^2\right] = z^\top \mathbb{E}\left[B'B'^\top\right] z = \frac{k-1}{d}\|z\|^2,$$

where $\mathbb{E}\left[B'B'^\top\right] = \frac{k-1}{d} I$ is exploited. Let $z = P_{\perp_{X^{[t-1]}}} x^{(t)}$. Then, by applying the above equality to the expansion of $v^{(t)}$ in (22), we have

$$\mathbb{E}\left[\|v^{(t)}\|^2\right] = \frac{k-t}{k-1}\cdot\frac{k-1}{d}\cdot\|P_{\perp_{X^{[t-1]}}} x^{(t)}\|^2 = \frac{k-t}{d}\cdot\|P_{\perp_{X^{[t-1]}}} x^{(t)}\|^2 \in \left[\delta_t^2\frac{k}{d}\left(1-\frac{t}{k}\right), \frac{k}{d}\right],$$

where $\dim(W^{[t-1]}) = t-1$ is also used in the first step, and the last step is concluded from Hypothesis 1. Finally, by concentration property of random Gaussian vectors, when $t \ll d$ we have with high probability

$$\|v^{(t)}\| \in \left[\frac{\delta_t}{2}\sqrt{\frac{k}{d}}, 2\sqrt{\frac{k}{d}}\right].$$

Similarly, for $u^{(t+1)} := B_{\text{res.}}^{(t,1)} w^{(t)}$, and by applying the form of $B_{\text{res.}}^{(t,1)}$ in (17), we have

$$u^{(t+1)} \overset{(d)}{=} P_{\perp_{X^{[t]}}} \tilde{B} P_{\perp_{W^{[t-1]}}} w^{(t)}. \tag{23}$$

Since random matrix $\tilde{B} \in \mathbb{R}^{d\times(k-1)}$ is an independent copy of B with i.i.d. Gaussian entries $\tilde{B}_{ij} \sim \mathcal{N}(0, \frac{1}{d})$, we know $u^{(t+1)}$ is a random Gaussian vector in the subspace orthogonal to $X^{[t]}$. On the other hand, for any vector $z \in \mathbb{R}^{k-1}$, we have

$$\mathbb{E}\left[\|\tilde{B}z\|^2\right] = z^\top \mathbb{E}\left[\tilde{B}^\top \tilde{B}\right] z = \|z\|^2,$$

where $\mathbb{E}\left[\tilde{B}^\top \tilde{B}\right] = I$ is exploited. Let $z = P_{\perp_{W^{[t-1]}}} w^{(t)}$. Then, by applying the above equality to the expansion of $u^{(t+1)}$ in (23), we have

$$\mathbb{E}\left[\|u^{(t+1)}\|^2\right] = \frac{d-t}{d} \cdot \|P_{\perp_{W^{[t-1]}}} w^{(t)}\|^2 \in \left[(\delta_t')^2 \frac{k}{d^2}\left(1 - \frac{t}{d}\right), (\Delta_t')^2 \frac{k}{d^2}\right],$$

where $\dim(X^{[t]}) = t$ is also used in the first step, and the last step is concluded from Hypothesis 2. Finally, by concentration property of random Gaussian vectors, when $t \ll d$ we have with high probability

$$\|u^{(t+1)}\| \in \left[\frac{\delta_t'}{2}\frac{\sqrt{k}}{d}, 2\Delta_t'\frac{\sqrt{k}}{d}\right].$$

■

B.2.2 Hypothesis 2

Computing $y^{(t)}$: In the first step of iteration t, the algorithm computes $y^{(t)}$. By induction Hypothesis 3, we know $|y_1^{(t)}| = \tilde{\Theta}(d^{\beta 2^{t-1}}\sqrt{k}/d)$. The other coordinates of $y^{(t)} := A^\top x^{(t)}$ are $y_{-1}^{(t)} = B^\top x^{(t)}$ which conditioning on the previous iterations are equivalent (in distribution) to

$$\begin{aligned} y_{-1}^{(t)} &\overset{(d)}{=} \left(B^{(t-1,2)}\right)^\top x^{(t)} \\ &= \left(\sum_{i\in[t-1]} \left(\frac{u^{(i+1)}(P_{\perp_{W^{[i-1]}}} w^{(i)})^\top}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} + \frac{P_{\perp_{X^{[i-1]}}} x^{(i)}(v^{(i)})^\top}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|^2}\right) + B_{\text{res.}}^{(t-1,2)}\right)^\top x^{(t)} \\ &= \sum_{i\in[t-1]} \left(\tilde{\Theta}\left(\frac{d^2}{k}\right) P_{\perp_{W^{[i-1]}}} w^{(i)} \langle u^{(i+1)}, x^{(t)}\rangle + \tilde{\Theta}(1) v^{(i)} \langle P_{\perp_{X^{[i-1]}}} x^{(i)}, x^{(t)}\rangle\right) + v^{(t)}, \quad (24) \end{aligned}$$

where form of $B^{(t-1,2)}$ in (18) is used in the second equality. The bounds on the norms come from Hypotheses 1 and 2. The last term is by definition $v^{(t)} := (B_{\text{res.}}^{(t-1,2)})^\top x^{(t)}$. Note that differences in polylog factors in the (upper and lower) bounds in Hypotheses 1 and 2 are represented by notation $\tilde{\Theta}(\cdot)$.

We will establish subsequently that if $k > d$, the terms involving $v^{(i)}$'s in the above expansion dominate, and the terms involving $P_{\perp_{W^{[i-1]}}} w^{(i)}$'s have norm of a smaller order; see Claim 3.

Computing $w^{(t)}$: In the next step of the algorithm at iteration t, $w^{(t)}$ is computed for which we now argue if the induction hypothesis holds up to iteration t, both lower and upper bounds at iteration t as $\|P_{\perp_{W^{[t-1]}}} w^{(t)}\| \in [\delta_t', \Delta_t']\frac{\sqrt{k}}{d}$ (see induction Hypothesis 2) also hold.

Lower bound: For the lower bound, intuitively the *fresh* random vector $v^{(t)}$ should bring enough randomness into $w^{(t)}$. We formulate that in the following lemma.

Lemma 11 *Suppose R and R' are two subspaces in $\mathbb{R}^k$ with dimension at most $t \le \frac{k}{16(\log k)^2}$. Let $p \in \mathbb{R}^k$ be an arbitrary vector, $z \in \mathbb{R}^k$ be a uniformly random Gaussian vector in the space orthogonal to R, and finally $w = (p+z)*(p+z)$. Then with high probability, we have*

$$\|P_{\perp_{R'}} w\| \ge \frac{\mathbb{E}[\|z\|^2]}{40\sqrt{k}}.$$

Recall that $w^{(t)} := y_{-1}^{(t)} * y_{-1}^{(t)}$, and $y_{-1}^{(t)}$ is expanded in (24) as sum of an arbitrary vector and a random Gaussian vector. Applying above lemma with $R = R' = \text{span}(W^{[t-1]})$, we have with high probability

$$\|P_{\perp_{W^{[t-1]}}} w^{(t)}\| \ge \frac{\mathbb{E}[\|v^{(t)}\|^2]}{40\sqrt{k}} \ge \frac{\delta_t^2}{160}\sqrt{k}/d,$$

where Hypothesis 4 gives lower bound $\|v^{(t)}\| \ge \delta_t/2\sqrt{k/d}$ (used in the second inequality). By choosing $\delta_t' = \delta_t^2/160$ the lower bound in Hypothesis 2 is proved.

Upper bound: In order to prove the upper bounds in Hypothesis 2, we follow the sequence of arguments below:

Claim 3: $\|y_{-1}^{(t)}\|_\infty \overset{(\cdot)^2}{\Longrightarrow} \|w^{(t)}\|_\infty \overset{\text{Lemma 12}}{\Longrightarrow} \|P_{\perp_{W^{[t-1]}}} w^{(t)}\|_\infty \Rightarrow \|P_{\perp_{W^{[t-1]}}} w^{(t)}\|$

First we prove a bound on the infinity norm of $y_{-1}^{(t)}$:

Claim 3 (Upper bound on $\|y_{-1}^{(t)}\|_\infty$) *We have*

$$\|y_{-1}^{(t)}\|_\infty \le \frac{t}{\delta_t}\frac{\log d}{\sqrt{d}} + (t-1)\left(\frac{\Delta_{t-1}'}{\delta_{t-1}'}\right)^2 \frac{1}{\sqrt{k}} = \tilde{O}\left(\frac{1}{\sqrt{d}}\right).$$

Proof We exploit the induction hypothesis to bound the ℓ_∞ norm of all the terms in the expansion of $y_{-1}^{(t)}$ in (24).

For the terms involving $v^{(i)}$, since they are random Gaussian vectors with expected square norm at most k/d, by Lemma 19 we know $\|v^{(i)}\|_\infty \le \frac{\log d}{\sqrt{d}}$ with high probability. In addition, for $v^{(i)}$, $i < t$, the coefficient is bounded as

$$\frac{\langle P_{\perp_{X^{[i-1]}}} x^{(i)}, x^{(t)}\rangle}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|^2} \le \frac{1}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|} \le \frac{1}{\delta_i}, \quad (25)$$

where the last step uses Hypothesis 1. Therefore, the total contribution from terms involving $v^{(i)}$ in $\|y_{-1}^{(t)}\|_\infty$ is bounded by $\frac{t}{\delta_t}\frac{\log d}{\sqrt{d}}$.

For the terms involving $P_{\perp_{W^{[i-1]}}} w^{(i)}, i \in [t-1]$, we have from Hypothesis 2 that the ℓ_∞ norm is bounded as $\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|_\infty \le \Delta_i' \frac{1}{d}$. In addition, the corresponding coefficient is bounded by

$$\frac{\langle u^{(i+1)}, x^{(t)}\rangle}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} \le \frac{\|u^{(i+1)}\| \cdot \|x^{(t)}\|}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} \le \frac{2\Delta_i'}{\delta_i'^2}\frac{d}{\sqrt{k}}. \tag{26}$$

Again bounds in Hypotheses 2 and 4 are exploited in the last inequality. Hence, the total contribution from terms involving $P_{\perp_{W^{[i-1]}}} w^{(i)}, i \in [t-1]$ in $\|y_{-1}^{(t)}\|_\infty$ is bounded by $(t-1)\left(\frac{\Delta_{t-1}'}{\delta_{t-1}'}\right)^2 \frac{1}{\sqrt{k}}$.

Combining the above bounds finishes the proof. ■

Since $w^{(t)} := y_{-1}^{(t)} * y_{-1}^{(t)}$, the above claim immediately implies that

$$\|w^{(t)}\|_\infty \le \tilde{O}\left(\frac{1}{d}\right). \tag{27}$$

Now we have the ℓ_∞ norm on w, however we need to bound the ℓ_∞ norm of the projected vector $P_{\perp_{W^{[t-1]}}} w^{(t)}$. Intuitively this is clear as the vectors in the space $W^{[t-1]}$ all have small ℓ_∞ as guaranteed by induction hypothesis. We formalize this intuition using the following lemma.

Lemma 12 *Suppose R is a subspace in $\mathbb{R}^k$ of dimension t', such that there is a basis $\{r_1, \ldots, r_{t'}\}$ with $\|r_i\|_\infty \le \frac{\Delta}{\sqrt{k}}$ and $\|r_i\| = 1$. Let $p \in \mathbb{R}^k$ be an arbitrary vector, then*

$$\|P_{\perp_R} p\|_\infty \le \|p\|_\infty + \|p\|\Delta\frac{\sqrt{t'}}{\sqrt{k}}.$$

Let $R = \mathrm{span}(W^{[t-1]})$. Then the vectors $P_{\perp_{W^{[i-1]}}} w^{(i)} / \|P_{\perp_{W^{[i-1]}}} w^{(i)}\|$, $i \in [t-1]$ form a basis for subspace R, and we know from Hypothesis 2 that the ℓ_∞ norm of each of these basis vectors is bounded by $\frac{\Delta}{\sqrt{k}}$ for $\Delta := \frac{\Delta_{t-1}'}{\delta_{t-1}'}$ which is of order polylog d. Applying above lemma, we have

$$\|P_{\perp_{W^{[t-1]}}} w^{(t)}\|_\infty \le \|w^{(t)}\|_\infty(1 + \Delta\sqrt{t-1}) \le \frac{\Delta_t'}{d},$$

where the last inequality uses bound (27), and appropriate choosing for Δ_t' which is of order polylog d and only depends on t and $\log d$. This concludes the upper bound on the ℓ_∞ norm in Hypothesis 2. The upper bound on the ℓ_2 norm is also immediately argued using this ℓ_∞ norm bound where an additional $\sqrt{k}$ factor shows up.

B.2.3 Hypothesis 1

Computing $x^{(t+1)}$:

In the next step of iteration t, the algorithm computes $x^{(t+1)}$. Conditioning on the previous iterations, the unnormalized version $\tilde{x}^{(t+1)}$ is equivalent (in distribution) to

$$\begin{aligned}
\tilde{x}^{(t+1)} &\overset{(d)}{=} B^{(t,1)} w^{(t)} + (y_1^{(t)})^2 a_1 \\
&= \sum_{i\in[t-1]} \frac{u^{(i+1)}(P_{\perp_{W^{[i-1]}}} w^{(i)})^\top}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} w^{(t)} + \sum_{i\in[t]} \frac{P_{\perp_{X^{[i-1]}}} x^{(i)}(v^{(i)})^\top}{\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|^2} w^{(t)} \\
&\quad + B_{\text{res.}}^{(t,1)} w^{(t)} + (y_1^{(t)})^2 a_1 \\
&= \sum_{i\in[t-1]} \tilde{\Theta}\left(\frac{d^2}{k}\right) u^{(i+1)} \langle P_{\perp_{W^{[i-1]}}} w^{(i)}, w^{(t)}\rangle + \sum_{i\in[t]} \tilde{\Theta}(1) P_{\perp_{X^{[i-1]}}} x^{(i)} \langle v^{(i)}, w^{(t)}\rangle \\
&\quad + u^{(t+1)} + (y_1^{(t)})^2 a_1,
\end{aligned} \tag{28}$$

where form of $B^{(t,1)}$ in (16) is used in the second equality. The bounds on the norms come from Hypotheses 1 and 2. The last term is the definition of $u^{(t+1)} := B_{\text{res.}}^{(t,1)} w^{(t)}$. Note that differences in polylog factors in the (upper and lower) bounds in Hypotheses 1 and 2 are represented by notation $\tilde{\Theta}(\cdot)$.

The goal is to prove Hypothesis 1 holds at t-th iteration (which is to show the desired lower and upper bounds on $\|P_{\perp_{X^{[t]}}} x^{(t+1)}\|$) assuming induction hypothesis holds for earlier iterations. Given the normalization $x^{(t+1)} := \tilde{x}^{(t+1)}/\|\tilde{x}^{(t+1)}\|$ in each iteration, we have

$$\|P_{\perp_{X^{[t]}}} x^{(t+1)}\| = \frac{1}{\|\tilde{x}^{(t+1)}\|}\|P_{\perp_{X^{[t]}}} \tilde{x}^{(t+1)}\|. \tag{29}$$

Therefore, we first bound the norm of $\tilde{x}^{(t+1)}$ which turns out to be $\|\tilde{x}^{(t+1)}\| = \tilde{\Theta}\left(\frac{\sqrt{k}}{d}\right)$ as argued in the following.

Lower bound: The lower bound on $\|\tilde{x}^{(t+1)}\|$ simply follows from the term $u^{(t+1)}$, which is an independent random Gaussian.

Claim 4 *If $t \le \frac{d}{10}$, then we have whp*

$$\|\tilde{x}^{(t+1)}\| \ge \frac{\delta_t'}{4}\frac{\sqrt{k}}{d}.$$

Proof We have

$$\|\tilde{x}^{(t+1)}\| \ge \|P_{\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp} \tilde{x}^{(t+1)}\| = \|P_{\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp} u^{(t+1)}\|.$$

Note that the equality is concluded from expansion of $\tilde{x}^{(t+1)}$ in (28) where all the components of $\tilde{x}^{(t+1)}$ in the subspace $\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp$ is represented by $u^{(t+1)}$. The vector $P_{\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp} u^{(t+1)}$ is the projection of a random Gaussian vector $u^{(t+1)}$ in to a subspace of dimention $d - o(d)$. Hence it is still a random Gaussian vector with expected square norm larger than $\frac{\delta_t'^2}{2}\frac{k}{d^2}$. By Lemma 18, with high probability the desired bound holds. ■

Upper bound: The upper bound is argued in the following claim.

Claim 5 *We have either*

$$\langle x^{(t+1)}, a_1\rangle \geq 1-\gamma,$$

for some constant $\gamma > 0$ or

$$\|\tilde{x}^{(t+1)}\| \leq \tilde{O}\left(\frac{\sqrt{k}}{d}\right).$$

Proof Let $\tilde{x}^{(t+1)}$ in (28) be written as $\tilde{x}^{(t+1)} = z + (y_1^{(t)})^2 a_1$ where vector $z \in \mathbb{R}^d$ represents all the other terms in the expansion. The analysis is done under two cases 1) $(y_1^{(t)})^2 \geq \frac{2}{\gamma}\|z\|$ and 2) $(y_1^{(t)})^2 < \frac{2}{\gamma}\|z\|$ for some constant $\gamma > 0$. Note that the left hand side is the norm of $(y_1^{(t)})^2 a_1$ since $\|a_1\| = 1$, and in addition $(y_1^{(t)})^2 = \langle x^{(t)}, a_1\rangle^2$.

Case 1 $\left((y_1^{(t)})^2 \geq \frac{2}{\gamma}\|z\|\right)$: For the $x^{(t+1)} := \tilde{x}^{(t+1)}/\|\tilde{x}^{(t+1)}\|$, we have

$$\begin{aligned}\langle x^{(t+1)}, a_1\rangle &= \frac{1}{\|z + (y_1^{(t)})^2 a_1\|}\langle z + (y_1^{(t)})^2 a_1, a_1\rangle \\ &\geq \frac{1}{\|z\| + (y_1^{(t)})^2}\left[(y_1^{(t)})^2 - \|z\|\right] \\ &\geq \frac{1-\frac{\gamma}{2}}{1+\frac{\gamma}{2}} \geq 1-\gamma,\end{aligned}$$

where triangle and Cauchy-Schwartz inequality are used in the first bound, and the second inequality is concluded from assumption $(y_1^{(t)})^2 \geq \frac{2}{\gamma}\|z\|$.

Case 2 $\left((y_1^{(t)})^2 < \frac{2}{\gamma}\|z\|\right)$: We exploit the induction hypothesis to bound the norm of all the terms in the expansion of $\tilde{x}^{(t+1)}$ in (28).

For the terms involving $u^{(i+1)}, i \in [t]$, we have $\|u^{(i+1)}\| \leq 2\Delta_i'\frac{\sqrt{k}}{d}$ from Hypothesis 4 and the argument for $\|u^{(t+1)}\|$. In addition, for $u^{(i+1)}$, $i \in [t-1]$, the coefficient is bounded as

$$\frac{\langle P_{\perp_{W^{[i-1]}}} w^{(i)}, w^{(t)}\rangle}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|^2} \leq \frac{\|w^{(t)}\|}{\|P_{\perp_{W^{[i-1]}}} w^{(i)}\|} \leq \frac{\Delta_t'}{\delta_i'}, \tag{30}$$

where Cauchy-Schwartz inequality is used in the first bound, and the bound in Hypothesis 2 and (27) are exploited in the last inequality. Therefore, the total contribution from terms involving $u^{(i+1)}$ in $\|\tilde{x}^{(t+1)}\|$ is bounded by $\frac{2(t-1)\Delta_t'^2}{\delta_t'}\frac{\sqrt{k}}{d}$.

For the terms involving $P_{\perp_{X^{[i-1]}}} x^{(i)}, i \in [t]$, we have $\|P_{\perp_{X^{[i-1]}}} x^{(i)}\| \leq 1$, but the coefficient $\langle v^{(i)}, w^{(t)}\rangle$ needs further analysis to be bounded which is done in Lemma 13 saying $|\langle v^{(i)}, w^{(t)}\rangle| \leq \tilde{O}\left(\frac{\sqrt{k}}{d}\right)$. This implies that the total contribution from terms involving $P_{\perp_{X^{[i-1]}}} x^{(i)}$ in $\|\tilde{x}^{(t+1)}\|$ is bounded by $\tilde{O}\left(\frac{\sqrt{k}}{d}\right)$.

Combining the above bounds and considering the assumption that the norm of $(y_1^{(t)})^2 a_1$ in the expansion of $\tilde{x}^{(t+1)}$ is dominated by the norm of other terms argued above, the proof is complete concluding that $\|\tilde{x}^{(t+1)}\| \leq \tilde{O}\left(\frac{\sqrt{k}}{d}\right)$. ■

Lemma 13 *Under the induction hypothesis (up to update step $\tilde{x}^{(t+1)} := A(y^{(t)})^{*2}$ at iteration t), we have for $i \in [t]$,*

$$|\langle v^{(i)}, w^{(t)}\rangle| \leq O\left(t^3\frac{(\Delta_{t-1}')^4}{(\delta_{t-1}')^4\delta_t^2}(\log d)\frac{\sqrt{k}}{d}\right) = \tilde{O}\left(\frac{\sqrt{k}}{d}\right).$$

Using (29) and the fact that $\|\tilde{x}^{(t+1)}\| = \tilde{\Theta}\left(\frac{\sqrt{k}}{d}\right)$, we have

$$\|P_{\perp_{X^{[t]}}} x^{(t+1)}\| \geq \tilde{\Theta}\left(\frac{d}{\sqrt{k}}\right)\|P_{\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp} u^{(t+1)}\| \geq \frac{\delta_t'}{4},$$

where the bound $\|P_{\mathrm{span}(X^{[t]}, U^{[t]}, a_1)^\perp} u^{(t+1)}\| \geq \frac{\delta_t'}{4}\frac{\sqrt{k}}{d}$ is also used. This finishes the proof that Hypothesis 1 holds.

B.2.4 Hypothesis 3

Finally we prove Hypothesis 3 at iteration t given earlier induction hypothesis. The first part of the hypothesis is proved in the following claim.

Claim 6 *We have*

$$|\langle a_1, x^{(t+1)}\rangle| \in [\delta_{t+1}^*, \Delta_{t+1}^*]d^{\beta 2^t}\frac{\sqrt{k}}{d}.$$

Proof We first show the correlation bound on the unnormalized version as $\langle a_1, \tilde{x}^{(t+1)}\rangle$. Looking at the expansion of $\tilde{x}^{(t+1)}$ in (28), the correlation $\langle a_1, \tilde{x}^{(t+1)}\rangle$ involves three types of terms emerging from $(y_1^{(t)})^2 a_1$, $u^{(i+1)}$ and $P_{\perp_{X^{(i-1)}}} x^{(i)}$. In the following, we argue the correlation from each of these terms where we observe that the correlation is dominated by the term $(y_1^{(t)})^2 a_1$, and the rest of terms contribute much smaller amount.

For the term $(y_1^{(t)})^2 a_1$, we have

$$\langle a_1, (y_1^{(t)})^2 a_1\rangle = (y_1^{(t)})^2 \in [(\delta_t^*)^2, (\Delta_t^*)^2]d^{\beta 2^t}\frac{k}{d^2},$$

where the last part exploits induction Hypothesis 3 in the previous iteration.

For the terms involving $u^{(i+1)}$, these vectors are random Gaussian vectors in a subspace (with dimension $\Omega(d)$), and therefore, we have with high probability

$$\langle a_1, u^{(i+1)}\rangle \leq \mathbb{E}[\|u^{(i+1)}\|]\cdot O\left(\frac{\log d}{\sqrt{d}}\right) \leq \tilde{O}\left(\frac{\sqrt{k}}{d\sqrt{d}}\right) \leq \tilde{O}\left(\frac{k}{d^2}\right),$$

where the correlation bound between two independent random Gaussian vectors in $\Omega(d)$-dimension is used in the first inequality,[12] Hypothesis 4 is exploited in the second inequality, and finally last inequality is from assumption $k > d$. In addition, the coefficient associated

12. For two independent random Gaussian vectors $p, q \in \mathbb{R}^d$, we have with high probability $\langle p, q\rangle \leq \mathbb{E}[\|p\|]\cdot\mathbb{E}[\|q\|]\cdot O\left(\frac{\log d}{\sqrt{d}}\right)$.

with $u^{(i+1)}$ is bounded by Δ_t'/δ_i' argued in (30). Hence, the total contribution from terms involving $u^{(i+1)}$ in $\langle \tilde{x}^{(t+1)}, a_1\rangle$ is bounded by $\tilde{O}\left(\frac{k}{d^2}\right)$.

For the terms involving $P_{\perp_{X^{[i-1]}}} x^{(i)}$, by Hypothesis 3 we have

$$\langle a_1, P_{\perp_{X^{[i-1]}}} x^{(i)}\rangle \leq \Delta_i^* d^{\beta 2^{i-1}} \frac{\sqrt{k}}{d}.$$

In addition, the associated coefficient is bounded by $\tilde{O}\left(\frac{\sqrt{k}}{d}\right)$ from Lemma 13. Hence, the total contribution from terms involving $P_{\perp_{X^{[i-1]}}} x^{(i)}$ in $\langle \tilde{x}^{(t+1)}, a_1\rangle$ is bounded by $\tilde{O}\left(d^{\beta 2^{t-1}} \frac{k}{d^2}\right)$.

Combining the above bounds implies

$$|\langle a_1, \tilde{x}^{(t+1)}\rangle| \leq \tilde{O}\left(d^{\beta 2^t} \frac{k}{d^2}\right).$$

Finally, using the bound on the norm of $\tilde{x}^{(t+1)}$ argued as $\|\tilde{x}^{(t+1)}\| = \tilde{\Theta}\left(\frac{\sqrt{k}}{d}\right)$ finishes the proof. ■

To prove the last part of Hypothesis 3, we use the following lemma which is very similar to Lemma 12.

Lemma 14 *Suppose R is a subspace in $\mathbb{R}^d$ of dimension t', such that there is a basis $\{r_1, \ldots, r_{t'}\}$ with $|\langle r_i, a_1\rangle| \leq \Delta$ and $\|r_i\| = 1$. Let $p \in \mathbb{R}^d$ be an arbitrary vector, then*

$$|\langle P_{\perp_R} p, a_1\rangle| \leq |\langle p, a_1\rangle| + \|p\|\Delta\sqrt{t'}.$$

We apply this lemma with $R = \text{span}(X^{[t]})$, and the basis is $P_{\perp X^{[i-1]}} X^{(i)}/\|P_{\perp X^{[i-1]}} X^{(i)}\|$. By induction hypothesis Δ in the lemma is at most $\Delta_*^t d^{\beta 2^t}\sqrt{k}/d$, let $v = x^{(t+1)}$ then this gives the desired bound.

Let $R = \text{span}(X^{[t]})$. Then the vectors $P_{\perp_{X^{[i-1]}}} x^{(i)}/\|P_{\perp_{X^{[i-1]}}} x^{(i)}\|$, $i \in [t]$ form a basis for subspace R, and we know from Hypotheses 1 and 3 that the correlation between these basis vectors and a_1 is bounded by $\Delta := \Delta_t^* d^{\beta 2^{t-1}} \frac{\sqrt{k}}{d}$. Applying above lemma, we have

$$|\langle P_{\perp_{X^{[t]}}} x^{(t+1)}, a_1\rangle| \leq |\langle x^{(t+1)}, a_1\rangle| + \Delta\sqrt{t} \leq \Delta_{t+1}^* d^{\beta 2^t} \frac{\sqrt{k}}{d},$$

where the last inequality uses the first part of Hypothesis 3 proved earlier in this section. Note that Δ_{t+1}^* is a new polylog factor here.

B.3 Growth Rate of δ_t, δ_t', Δ_t', δ_t^*, Δ_t^*

We know that if the number of iterations t is a constant, then the δ and Δ parameters (i.e., δ_t, δ_t', Δ_t', δ_t^*, Δ_t^*) in the induction hypothesis are bounded by polylog factors of d. Here, we show that these parameters can be still bounded even when the number of steps is slightly larger than a constant. Let

$$R_t := \max\{1/\delta_t, \Delta_{t-1}'/\delta_{t-1}', \Delta_t^*/\delta_t^*\}.$$

We know $R_1 = 1$, and by the inductive step analysis we have the following polynomial recursion property.

Claim 7 $R_{t+1} = \text{poly}(R_t, t, \log d)$.

This claim follows from the proof of inductive step, where in every step the δ and Δ parameters are bounded by polynomial functions of previous δ's (Δ's), t, and $\log d$.

We now solve this recursion as follows.

Lemma 15 *Suppose $R_{t+1} \leq c_0 R_t^{c_1} t^{c_2} (\log d)^{c_3}$ where c_0, c_1, c_2, c_3 are positive constants, and we know $R_1 = 1$. Then*

$$R_t \leq (\log d)^{2^{c_4 t}},$$

for some constant $c_4 > 0$ depending on c_0, c_1, c_2, c_3.

Proof Without loss of generality assume $c_0 \geq 1$, $c_2 \geq 1$, $c_3 \geq 1$, and $R_1 \geq \log d$. Given these assumptions, we have $R_t \geq \max\{c_0, t, \log d\}$, for $t \geq 1$. Applying this to the assumption $R_{t+1} \leq c_0 R_t^{c_1} t^{c_2} (\log d)^{c_3}$, we have

$$R_{t+1} \leq R_t^{1+c_1+c_2+c_3}. \tag{31}$$

Pick some $q > 0$ such that $R_1 \leq (\log d)^{2^q}$, and pick some

$$c_4 \geq \max\{q, \log_2(1 + c_1 + c_2 + c_3)\}.$$

Now we prove the result by the induction argument. Since $c_4 \geq q$, the basis of induction holds for R_1. As the inductive step, suppose $R_t \leq (\log d)^{2^{c_4 t}}$. Applying this to (31), we have

$$R_{t+1} \leq (\log d)^{(1+c_1+c_2+c_3)2^{c_4 t}} \leq (\log d)^{2^{c_4(t+1)}},$$

where $2^{c_4} \geq (1 + c_1 + c_2 + c_3)$ is used in the last inequality. This finishes the inductive step and the result is proved. ■

Using the above bound, we show in the following corollary that the δ and Δ parameters in the induction hypothesis are bounded by polylog factors of d even if the number of steps t goes up to $c \log\log d$ for small enough constant c. In addition, we show that if $\beta \geq (\log d)^{-c_5}$ for some constant $c_5 > 0$, then the power method converges to a point $x^{(t)}$ which is constant close to the true component.

Corollary 16 *There exists a universal constant $c_5 > 0$ such that if*

$$\beta \geq (\log d)^{-c_5},$$

and the initial correlation is lower bounded by $d^\beta \frac{\sqrt{k}}{d}$ (see (13)), then with high probability the power method gets to a point that is constant close to the true component in $\Theta(\log\log d)$ number of steps.

Proof Pick the number of steps to be $t = (\log\log d)/2c_4$, where c_4 is the constant in Lemma 15. Then, from Lemma 15 we have

$$R_t \leq (\log d)^{\sqrt{\log d}} \leq o(d),$$

where the last inequality can be shown by taking the log of both sides. This says that the analysis of inductive step still holds after such number of iterations.

Finally, by progress bound in (20), we can see that if $\beta \geq (\log d)^{-c_5}$, then the power method converges to a point $x^{(t)}$ which is constant close to the true component. ■

Appendix C. Auxiliary Lemmas for Induction Argument

In this section we prove the lemmas used in arguing inductive step in Appendix B.2.

We first introduce the following lemma proposing a lower bound on the singular value of product of matrices.

Lemma 17 (Merikoski and Kumar 2004) *Let C and D be $k \times k$ matrices. If $1 \leq i \leq k$ and $1 \leq l \leq k - i + 1$, then*

$$\sigma_i(CD) \geq \sigma_{i+l-1}(C) \cdot \sigma_{k-l+1}(D),$$

where $\sigma_j(C)$ denotes the j-th singular value (in decreasing order) of matrix C.

C.1 Properties of Random Gaussian Vectors

We start with some basic properties of random Gaussian vectors. First as a simple fact, the norm of a random Gaussian vector is concentrated as follows which is proved via simple concentration inequalities.

Lemma 18 *Let $z \in \mathbb{R}^d$ be a random Gaussian vector with $\mathbb{E}[zz^\top] = \frac{1}{d} I$. Then we have with high probability $\frac{1}{2} \leq \|z\| \leq 2$.*

Next we show the ℓ_∞ norm of a Gaussian vector is small, even if it is projected on some subspace.

Lemma 19 *Let R be any linear subspace in $\mathbb{R}^d$ and $z \in \mathbb{R}^d$ be a random Gaussian vector with $\mathbb{E}[zz^T] = \frac{1}{d} I$. Then we have with high probability $\|P_{\perp_R} z\|_\infty \leq \frac{\log d}{\sqrt{d}}$.*

Proof Since $P_{\perp_R}$ is a projection matrix, in particular the norm of its columns is bounded by 1. Hence, each entry of $P_{\perp_R} z$ is a Gaussian random variable with variance bounded by $\frac{1}{d}$ implying that with high probability the absolute value of each coordinate is smaller than $\frac{\log d}{\sqrt{d}}$. Finally, the desired ℓ_∞ norm bound is argued by applying union bound. ■

We can also show that most of the entries are of size at least $\frac{1}{\sqrt{d}}$.

Lemma 20 *Let R be any linear subspace in $\mathbb{R}^d$ with dimension $t \leq \frac{d}{16(\log d)^2}$ and $z \in \mathbb{R}^d$ be a random Gaussian vector with $\mathbb{E}[zz^T] = \frac{1}{d} I$. Then we have with high probability at least $1/2$ of the entries $i \in [d]$ satisfy $|(P_{\perp_R} z)_i| \geq \frac{1}{4\sqrt{d}}$.*

Proof Since the entries of z are independent Gaussian random variables with standard deviation $\frac{1}{\sqrt{d}}$, we know with high probability at least $1/2$ of the entries have absolute value larger than $\frac{1}{2\sqrt{d}}$. On the other hand, $P_R z$ is also a random Gaussian vector with expected square norm bounded by

$$\mathbb{E}[\|P_R z\|^2] \leq \frac{\mathbb{E}[\|z\|^2]}{16(\log d)^2} = \frac{1}{16(\log d)^2},$$

where the assumption on the dimension of subspace R is used in the inequality. By Lemma 19 we know with high probability entries of $P_R z$ are bounded by $1/4\sqrt{d}$. Now $P_{\perp_R} z = z - P_R z$ must have at least $1/2$ of the entries with absolute value larger than $1/4\sqrt{d}$. ■

Using the above lemmas, we can prove Lemma 11.

Proof of Lemma 11 Let z, z' be two independent samples of z, and w, w' be the corresponding w vectors. We have

$$w - w' = (p + z) * (p + z) - (p + z') * (p + z') = (2p + z + z') * (z - z'). \tag{32}$$

By properties of Gaussian vectors, $z + z'$, $z - z'$ are two *independent* random Gaussian vectors in the subspace orthogonal to R each with expected square norm $2\mathbb{E}[\|z\|^2]$. We use $z_1 := z + z'$ and $z_2 := z - z'$ to denote these two random Gaussian vectors.

Next, we show that with high probability

$$\|P_{\perp_{R'}}(w - w')\| \geq \frac{\mathbb{E}[\|z\|^2]}{20\sqrt{k}}.$$

Note that this implies the result of lemma as follows. Suppose $\|P_{\perp_{R'}} w\| < \frac{1}{40}\mathbb{E}[\|z\|^2]/\sqrt{k}$ with probability δ. Since w' is an independent sample, with probability δ^2 this bound holds for both w and w'. When this happens, we have $\|P_{\perp_{R'}}(w - w')\| < \frac{1}{20}\mathbb{E}[\|z\|^2]/\sqrt{k}$ by triangle inequality. Since we showed δ^2 is negligible, δ is also negligible.

First we sample z_2. Let $R'' = \mathrm{span}(R', p * z_2)$. Then by expansion of $w - w'$ in (32), we have

$$\|P_{\perp_{R'}}(w - w')\| = \|P_{\perp_{R'}}\big(2(p * z_2) + (z_1 * z_2)\big)\| \geq \|P_{\perp_{R''}}(z_1 * z_2)\| = \|P_{\perp_{R''}} \mathrm{Diag}(z_2) P_{\perp_R} z_1\|, \tag{33}$$

where the inequality is concluded by ignoring the component along $p * z_2$ direction. The last equality is from[13] $u * v = \mathrm{Diag}(u) \cdot v$ (for two vectors u and v), and the assumption that $z_1 = z + z'$ is in the subspace orthogonal to R. For the matrix $P_{\perp_{R''}} \mathrm{Diag}(z_2) P_{\perp_R}$, we have[14]

$$\sigma_{k/4}\left(P_{\perp_{R''}} \mathrm{Diag}(z_2) P_{\perp_R}\right) \geq \sigma_{k/2}\left(\mathrm{Diag}(z_2)\right) \cdot \sigma_{7k/8}\left(P_{\perp_R}\right) \cdot \sigma_{7k/8}\left(P_{\perp_{R''}}\right) \geq \frac{\sqrt{\mathbb{E}[\|z\|^2]}}{4\sqrt{k}},$$

where the first inequality is from Lemma 17, and the last step is argued as follows. By Lemma 18, with high probability z_2 has square norm at least $\mathbb{E}[\|z_2\|^2]/2 = \mathbb{E}[\|z\|^2]$, and

13. For vector u, $\mathrm{Diag}(u)$ denotes the diagonal matrix with u as its main diagonal.
14. Recall that $\sigma_l(A)$ denotes the l-th singular value (in decreasing order) of matrix A.

therefore, by Lemma 20 at least $k/2$ of its entries have absolute value larger than $\frac{\sqrt{\mathbb{E}[\|z\|^2]}}{4\sqrt{k}}$. Therefore, we can restrict attention to the space spanned by the $k/4$ top singular vectors. In addition, within this subspace we have with high probability $\|z_1\|^2 \geq \mathbb{E}[\|z\|^2]/8$, and hence,

$$\|P_{\perp_{R''}}\mathrm{Diag}(z_2)P_{\perp_R}z_1\| \geq \frac{\mathbb{E}[\|z\|^2]}{20\sqrt{k}},$$

which finishes the proof by applying (33). ■

C.2 Properties of Projections

In this part we prove some basic properties of projections. Intuitively, if the whole subspace has small inner-product with some vector, then the projection of an arbitrary vector to the orthogonal subspace should not change the inner-product with that particular vector by too much. This is what we stated in Lemma 14 and prove it here.

Proof of Lemma 14 We have $P_{\perp_R}p = p - \sum_{i=1}^{t'}\langle p, r_i\rangle r_i$, and therefore

$$\begin{aligned}
|\langle P_{\perp_R}p, a_1\rangle| &\leq |\langle p, a_1\rangle| + \sum_{i=1}^{t'}|\langle p, r_i\rangle\langle a_1, r_i\rangle| \\
&\leq |\langle p, a_1\rangle| + \Delta\sum_{i=1}^{t'}|\langle p, r_i\rangle| \\
&\leq |\langle p, a_1\rangle| + \Delta\sqrt{t'\sum_{i=1}^{t'}\langle p, r_i\rangle^2} \\
&\leq |\langle p, a_1\rangle| + \Delta\|p\|\sqrt{t'}.
\end{aligned}$$

The first step is triangle inequality and the third is Cauchy-Schwartz. ■

Lemma 12 is very similar.

Proof of Lemma 12 This lemma essentially follows from Lemma 14, because ℓ_∞ norm is just the maximum inner-product to a basis vector. More specifically, the above lemma is applied for all $a_1 = e_j, j \in [k]$, where e_j denotes the j-th basis vector in $\mathbb{R}^k$. ■

C.3 Bounding Correlation Between v and w

We are only left with Lemma 13. The main difficulty in proving this lemma is that the later steps are dependent on the previous steps. In the proof we show the dependency is bounded and in fact we can treat them as independent.

Proof of Lemma 13 Recall $w^{(t)} = y_{-1}^{(t)} * y_{-1}^{(t)}$, and $y_{-1}^{(t)}$ is specified in (24). We now expand the Hadamard product in $w^{(t)}$ and bound all the resulting $O(t^2)$ terms.

The first type of terms has the form $\langle v^{(i)}, P_{\perp_{W^{[i_1-1]}}}w^{(i_1)} * P_{\perp_{W^{[i_2-1]}}}w^{(i_2)}\rangle$, which can be bounded as

$$\begin{aligned}
\langle v^{(i)}, P_{\perp_{W^{[i_1-1]}}}w^{(i_1)} * P_{\perp_{W^{[i_2-1]}}}w^{(i_2)}\rangle &\leq k\cdot\|v^{(i)}\|_\infty\cdot\|P_{\perp_{W^{[i_1-1]}}}w^{(i_1)} * P_{\perp_{W^{[i_2-1]}}}w^{(i_2)}\|_\infty \\
&\leq 2k\frac{\log d}{\sqrt{d}}\frac{(\Delta'_{t-1})^2}{d^2},
\end{aligned}$$

where $\|v^{(i)}\|_\infty$ is bounded by Lemma 19, and ℓ_∞ norm of other vector is bounded by induction Hypothesis 2. In addition, the corresponding coefficient is bounded by (see (26), and note that both $i_1, i_2 < t$)

$$\frac{4(\Delta'_{t-1})^2}{(\delta'_{t-1})^4}\frac{d^2}{k}.$$

Hence, the total contribution from such terms is bounded by

$$8t^2\frac{(\Delta'_{t-1})^4}{(\delta'_{t-1})^4}\frac{\log d}{\sqrt{d}}. \tag{34a}$$

The second type of terms has the form

$$\langle v^{(i)}, P_{\perp_{W^{[i_1-1]}}}w^{(i_1)} * v^{(i_2)}\rangle = \langle v^{(i)} * v^{(i_2)}, P_{\perp_{W^{[i_1-1]}}}w^{(i_1)}\rangle,$$

which can be bounded as

$$\|P_{\perp_{W^{[i_1-1]}}}w^{(i_1)}\|_\infty\cdot\|v^{(i)} * v^{(i_2)}\|_1 \leq \|P_{\perp_{W^{[i_1-1]}}}w^{(i_1)}\|_\infty\cdot\frac{\|v^{(i)}\|^2 + \|v^{(i_2)}\|^2}{2} \leq 4\Delta'_{t-1}\frac{k}{d^2},$$

where the last inequality is concluded from Hypotheses 2 and 4. In addition, the corresponding coefficient is bounded by (see (25) and (26), and note that both $i_1, i_2 < t$)

$$\frac{2\Delta'_{t-1}}{(\delta'_{t-1})^2\delta_{t-1}}\frac{d}{\sqrt{k}}.$$

Hence, the total contribution from such terms is bounded by

$$8t^2\frac{(\Delta'_{t-1})^2}{\delta_{t-1}(\delta'_{t-1})^2}\frac{\sqrt{k}}{d}. \tag{34b}$$

The third type of terms has the form $\langle v^{(i)}, v^{(i_1)} * v^{(i_2)}\rangle$, with coefficient bounded by $1/\delta_{t-1}^2$ (see (25)). For bounding these inner products, we need to use the fact that they are random Gaussian vectors, however the main difficulty is that they are correlated (if $i > j$, then the subspace that $v^{(i)}$ is in that depends on $v^{(j)}$). To resolve this difficulty, we treat $v^{(i)} \in \mathbb{R}^{k-1}$ as projection of $n^{(i)} \in \mathbb{R}^{k-1}$ into subspace orthogonal to $W^{[t-1]}$, where $n^{(i)}$'s are *independent* Gaussian vectors in the full $k-1$ dimensional space. Independent of the ordering of i, i_1, i_2, we have with high probability

$$\langle n^{(i)}, n^{(i_1)} * n^{(i_2)}\rangle \leq O\left(\frac{\sqrt{k}}{d\sqrt{d}}\right),$$

since it is a sum of $k-1$ independent mean-0 entries each with variance $\frac{1}{d^3}$. On the other hand, from Hypothesis 4, we have $\mathbb{E}[\|v^{(i)}\|^2] \le 4\frac{k}{d}$, and since vector $n^{(i)} - v^{(i)}$ is in the subspace $W^{[t-1]}$ with dimension t, we have

$$\mathbb{E}[\|n^{(i)} - v^{(i)}\|^2] \le O\left(\frac{t}{k}\right) \cdot \frac{4k}{d} = O\left(\frac{t}{d}\right),$$

and therefore, we have with high probability $\|n^{(i)} - v^{(i)}\| \le O(\sqrt{t/d})$ for all $i \in [t-1]$. Using this, the difference between $\langle n^{(i)}, n^{(i_1)} * n^{(i_2)}\rangle$ and $\langle v^{(i)}, v^{(i_1)} * v^{(i_2)}\rangle$ can be bounded as

$$|\langle n^{(i)}, n^{(i_1)} * n^{(i_2)}\rangle - \langle v^{(i)}, v^{(i_1)} * v^{(i_2)}\rangle| \le O\left((\log k) t \frac{\sqrt{k}}{d\sqrt{d}}\right),$$

where the right hand side is the bound on the dominant term in the expansion of difference as

$$\begin{aligned}|\langle n^{(i)}, (n^{(i_1)} - v^{(i_1)}) * (n^{(i_2)} - v^{(i_2)})\rangle| &\le \|n^{(i)}\| \cdot \|(n^{(i_1)} - v^{(i_1)}) * (n^{(i_2)} - v^{(i_2)})\| \\ &\le O\left((\log k)\sqrt{\frac{k}{d}}\right) \cdot O\left(\frac{t}{d}\right) \\ &= O\left((\log k) t \frac{\sqrt{k}}{d\sqrt{d}}\right).\end{aligned}$$

Here, the first inequality is the Cauchy-Schwartz, and the second inequality is from bound on the norm of random Gaussian vector $n^{(i)}$, and the bound on the norm of difference vectors $n^{(i_1)} - v^{(i_1)}$ stated earlier. Hence, the total contribution from such terms is bounded by

$$O\left(t^3 \frac{\log k}{\delta_{t-1}^2} \frac{\sqrt{k}}{d\sqrt{d}}\right). \tag{34c}$$

Taking the sum of all the terms in (34a)-(34c) gives the desired bound. ■

Appendix D. Additional Arguments for Noise Analysis

We first formally define norm $\|\cdot\|_*$ which was discussed in proof outline in Section 3.2.

Definition 21 (Norm $\|\cdot\|_*$) *Given a matrix $A = [a_1\ a_2\ \cdots\ a_k] \in \mathbb{R}^{d\times k}$, for any vector $u \in \mathbb{R}^d$, the norm $\|u\|_{A^*}$ is defined as*

$$\|u\|_{A^*} = \max_{i\in[k]} |\langle a_i, u\rangle|.$$

This norm satisfies a property shown in Lemma 22 which enables us to argue that $\xi^{(t)}$ is small enough as stated in Lemma 10.

We now provide the proof of main lemma for noise analysis.

Proof of Lemma 10 We prove this by an induction argument.

Basis of induction: For $t = 1$, $x^{(1)}$ is the initialization vector and thus, $\xi^{(1)} = 0$. Hence, the proposed bound holds for the basis of induction $t = 1$.

Inductive step: Assuming the inductive hypothesis holds for step t, we prove it also holds for step $t+1$. We have

$$\begin{aligned}x^{(t+1)} + \xi^{(t+1)} &= \text{Norm}\left(\hat{T}(x^{(t)} + \xi^{(t)}, x^{(t)} + \xi^{(t)}, I)\right) \\ &= \text{Norm}\left(T(x^{(t)}, x^{(t)}, I) + 2T(x^{(t)}, \xi^{(t)}, I) + T(\xi^{(t)}, \xi^{(t)}, I) + E(\hat{x}^{(t)}, \hat{x}^{(t)}, I)\right).\end{aligned} \tag{35}$$

The first term $T(x^{(t)}, x^{(t)}, I)$ corresponds to main signal; recall that $x^{(t+1)} = \text{Norm}(T(x^{(t)}, x^{(t)}, I))$ in the noiseless setting, where the unnormalized version $\tilde{x}^{(t+1)} := T(x^{(t)}, x^{(t)}, I)$ has norm at least $\tilde{\Omega}(\sqrt{k}/d)$ which is argued in the induction argument for Hypothesis 1. We now bound the desired property of noise terms in the above expansion.

For the second term, we break it into two terms as

$$2T(x^{(t)}, \xi^{(t)}, I) = 2\langle x^{(t)}, a_1\rangle\langle \xi^{(t)}, a_1\rangle a_1 + 2T'(x^{(t)}, \xi^{(t)}, I) =: p + q,$$

where $T' := \sum_{j>1} a_j \otimes a_j \otimes a_j$. Here $p := 2\langle x^{(t)}, a_1\rangle\langle \xi^{(t)}, a_1\rangle a_1$ corresponds to the multilinear form from first component of T, and $q := 2T'(x^{(t)}, \xi^{(t)}, I)$ corresponds to the multilinear form from the rest of components.

For q, we apply Lemma 22. Note that since $\|x^{(t)}\|_{B^*} \le \tilde{O}(1/\sqrt{d})$, we get an extra $1/\sqrt{d}$ factor in the bound provided by Lemma 22, and therefore we have

$$\|q\|_2 \le \tilde{O}(\epsilon d^{\beta 2^{t-1}} \sqrt{k}/d),$$

where we also used the induction hypothesis $\|\xi^{(t)}\| \le \tilde{O}(\epsilon d^{\beta 2^{t-1}})$.

For p, we have

$$\|p\| = 2|\langle x^{(t)}, a_1\rangle| \cdot |\langle \xi^{(t)}, a_1\rangle| \le \tilde{O}\left(\epsilon d^{\beta 2^t} \sqrt{k}/d\right),$$

where the inequality is from the signal and noise induction hypotheses; see Equation (20) for the signal induction hypothesis.

The third term $T(\xi^{(t)}, \xi^{(t)}, I)$ has ℓ_2 norm bounded as

$$\|T(\xi^{(t)}, \xi^{(t)}, I)\| \le \|T\|\|\xi^{(t)}\|^2 \le \tilde{O}(d^{\beta 2^t}\epsilon^2) \le \tilde{O}(\epsilon d^{\beta 2^t}\sqrt{k}/d),$$

where the first inequality uses the sub-multiplicative property, and the second inequality exploits the bounded norm of random tensor T as $\|T\| \le O(1)$, and the induction hypothesis in t-th step. The final inequality uses the assumption $\epsilon < o(\sqrt{k}/d)$ in the lemma.

The fourth term $E(\hat{x}^{(t)}, \hat{x}^{(t)}, I)$ has ℓ_2 norm bounded by

$$\|E(\hat{x}^{(t)}, \hat{x}^{(t)}, I)\| \le \|E\|\|\hat{x}^{(t)}\|^2 \le \epsilon\sqrt{k}/d,$$

where we use the sub-multiplicative property in the first inequality, and the assumption on the norm of error tensor E in the lemma, and the fact that $\|\hat{x}^{(t)}\| = 1$ are exploited in the second inequality.

Summarizing the above calculations on different terms of the update in (35), the signal plus noise vector before normalization is

$$T(x^{(t)}, x^{(t)}, I) + 2T(x^{(t)}, \xi^{(t)}, I) + T(\xi^{(t)}, \xi^{(t)}, I) + E(\hat{x}^{(t)}, \hat{x}^{(t)}, I) =: \alpha x^{(t+1)} + z,$$

where α is a coefficient which is lower bounded as $\alpha \geq \tilde{\Omega}(\sqrt{k}/d)$. The vector z also satisfies

$$\|z\| \leq \tilde{O}(\epsilon d^{\beta 2^t} \sqrt{k}/d), \tag{36}$$

which is derived by combining the bounds we argued on the second, third and fourth terms.

Note that until the very last step we always have $d^{\beta 2^t} \leq o(d/\sqrt{k})$ (otherwise we are constantly close to the true component, and we are done). In this case the norm of z is negligible compared to α since $\|z\| \leq o(\alpha)$, and thus, the normalization factor is equal to $\|\alpha x^{(t+1)} + z\| = \alpha(1 \pm o(1))$. Therefore, after the normalization, we have the noise vector $\xi^{(t+1)} = \alpha' x^{(t+1)} + \beta z$, where $|\alpha'| \leq \|z\|/\alpha \leq o(1)$ and $|\beta| \leq 2/\alpha \leq \tilde{O}(d/\sqrt{k})$, hence we know $\|\xi^{(t+1)}\| \leq \tilde{O}(\epsilon d^{\beta 2^t})$.

For the last step of the induction, the norm of $T(x^{(t)}, x^{(t)}, I)$ is also larger (it has norm $d^{\beta 2^t} k/d^2$, which is larger than $\sqrt{k}/d$ for the last step). Since $\epsilon < o(\sqrt{k}/d)$ we still know the noise is negligible.

■

Lemma on the property of $\|\cdot\|_*$ norm defined in Definition 21:

Lemma 22 *Consider a random tensor $T = \sum_{j\in[k]} a_j \otimes a_j \otimes a_j$ where a_j's are zero-mean random Gaussian with expected unit norm. Let $T' = \sum_{j>1} a_j \otimes a_j \otimes a_j$ and $B := [a_2, a_3, \ldots, a_k] \in \mathbb{R}^{d\times(k-1)}$. Then with high probability, for any vectors u, v such that $\|u\|_{B^*} \leq 1$ and $\|v\|_2 \leq 1$, we have*

$$\|T'(u, v, I)\|_2 \leq \tilde{O}\left(\sqrt{k/d}\right).$$

Proof We prove this lemma along similar ideas provided in the proof of Anandkumar et al. (2015, Claim 5) (Anandkumar et al. (2014b, Claim 1)). Let $A := [a_1, \ldots, a_k] \in \mathbb{R}^{d\times k}$, and η_j's be independent random ± 1 variables with $\Pr[\eta_j = 1] = 1/2$. We rewrite tensor T' as

$$T' = \sum_{j>1} \eta_j a_j \otimes a_j \otimes a_j. \tag{37}$$

Since a_j's are zero-mean random Gaussian vectors, we have $\eta_j a_j \sim a_j$, and thus, the new T' has the same distribution as the original one. We now first sample vectors a_j's, and this already makes the norm $\|\cdot\|_{B*}$ well-defined. In addition, the value of η_j's does not change the singular values of A or B. Also note that since a_j's are zero-mean random Gaussian vectors with expected norm 1, they also satisfy with high probability the incoherence condition such that $|\langle a_i, a_j\rangle| \leq \tilde{O}(1/\sqrt{d})$ for all $i \neq j$. Thus, we condition on all these fixed events, and the only remaining random variables are just the η_j's.

The proposed statement in the lemma is equivalent to bounding

$$\sup_{\|u\|_{B^*}=1, \|v\|=\|w\|=1} \left|T'(u, v, w)\right|.$$

In order to bound it, we provide an ϵ-net argument. We construct an ϵ-net such that for any vector $u \in \mathbb{R}^d$ with unit $\|\cdot\|_{B^*}$ norm, there is a vector u' in the net such that $\|B^\top(u - u')\| \leq 1/k^2$. We also construct standard ε-net for vectors $u, w \in \mathbb{R}^d$ with unit ℓ_2 norm. By standard construction, this ε-net has size $\exp(O(d \log d))$. We now show that for all u in ϵ-net with unit $\|\cdot\|_{B*}$ norm, and all v, w in ϵ-net with unit ℓ_2 norm, the desired bound $|T'(u, v, w)| \leq \tilde{O}\left(\sqrt{k/d}\right)$ holds with high probability. Then for the other vectors (u, v, w) not in the ε-net, the result follows from their closest points in the net.

Now for a fixed triple (u, v, w) in the ε-net, we have

$$T'(u, v, w) = \sum_{j>1} \eta_j \langle u, a_j\rangle\langle v, a_j\rangle\langle w, a_j\rangle,$$

which is a sum of independent random variables; recall that the randomness is from η_j's, and a_j's are already sampled and thus they are fixed here. We partition the above sum into *large* and *small* terms as $T'(u, v, w) = S_L + S_{L^c}$ such that the summation S_L is the sum of large terms including terms in set

$$L := \left\{j \in \{2, 3, \ldots, k\} : |\langle v, a_j\rangle| \geq \log d/\sqrt{d} \vee |\langle w, a_j\rangle| \geq \log d/\sqrt{d}\right\},$$

and the rest are the small terms forming S_{L^c}. Note that $|\langle u, a_j\rangle| \leq 1$ since $\|u\|_{B*} = 1$.

Bounding $|S_{L^c}|$: Since the variables are bounded in this summation corresponding to small terms, we use Bernstein's inequality, and thus with probability at least $1 - \delta$, we have $|S_{L^c}| \leq \frac{\sqrt{k \log 1/\delta}\cdot \text{polylog}\, d}{d}$ for the fixed point in the ε-net. By choosing small enough $\delta = \exp(-Cd \log d)$ (where C is large enough constant), we can apply the union bound on the ε-net, and conclude that for all the vectors in the net, $|S_{L^c}|$ is smaller than $\tilde{O}(\sqrt{k/d})$ with high probability.

Bounding $|S_L|$: Since the columns of matrix B are random Gaussian vectors, it satisfies the RIP property with high probability (see Remark 3 in Anandkumar et al. (2014b) for the precise definition of RIP), and thus by the definition of RIP and Lemma 3 in Anandkumar et al. (2014b), we have $\|B_L\| \leq 2$ where B_L is the sub-columns of matrix B specified by set L.

We now have

$$|S_L| \leq \sum_{j\in L} |\langle u, a_j\rangle| \cdot |\langle v, a_j\rangle| \cdot |\langle w, a_j\rangle| \leq \sum_{j\in L} |\langle v, a_j\rangle| \cdot |\langle w, a_j\rangle| \leq \left\|B_L^\top v\right\| \cdot \left\|B_L^\top w\right\| \leq 4,$$

where the second step uses the fact that $|\langle u, a_j\rangle| \leq 1$, the third step exploits Cauchy-Schwartz inequality, and the last step uses bound $\|B_L\| \leq 2$. Notice that matrix B is already sampled before we do the ε-net argument, and therefore, we do not need to do union bound over all u, v, w for this event.

Since we assume the overcomplete regime $k \geq d$, the bound on $|S_{L^c}|$ is dominant which finishes the proof.

JSAT: Java Statistical Analysis Tool, a Library for Machine Learning

Edward Raff raff.edward@gmail.com
Department of Computer Science and Electrical Engineering
University of Maryland, Baltimore County

Editor: Geoff Holmes

Abstract

Java **S**tatistical **A**nalysis **T**ool (JSAT) is a Machine Learning library written in pure Java. It works to fill a void in the Java ecosystem for a general purpose library that is relatively high performance and flexible, which is not adequately fulfilled by Weka (Hall et al., 2009) and Java-ML (Abeel et al., 2009). Almost all of the algorithms are independently implemented using an Object-Oriented framework. JSAT is made available under the GNU GPL license here: `https://github.com/EdwardRaff/JSAT`.

Keywords: java, machine learning, open source, java library, machine learning software.

1. Introduction

There exist relatively few general purpose Machine Learning libraries for use in the Java ecosystem. Weka is one of the only such libraries in this domain, and one of the oldest and most used in general. It seems that more modern and efficient libraries, such as Scikit-learn (Pedregosa et al., 2011), have been developed in every language but Java. While a number of distributed libraries, such as MLlib (Meng et al., 2016), exist in the Java ecosystem, their focus precludes the inclusion of many algorithms that do not scale out. These tools may add needless overhead and complexity for datasets and tasks that can be solved with a single machine. This leaves a void in the Java ecosystem for a tool that is both easy for developers, relatively fast, and allows more flexibility for researchers to develop and compare new algorithms.

JSAT attempts to fill this void. It is written in Java 6 and has no dependencies, making it easy to integrate into any Java project without conflict. Many common "bread and butter" algorithms, such as k-means, Random Forest, and SVMs are implemented with multiple different solvers. In every case one or more classical implementations is included, such as Platt's SMO algorithm for SVMs, that can be used as a baseline for correctness and comparison for researchers developing new solutions and to ensure performance is respectable compared to common baselines. Popular and more efficient algorithms, such as the algorithms for Linear-SVM and L1 regularized Logistic-Regression used in LIBLINEAR (Fan et al., 2008) are provided—as well as less common but advantageous solutions, such as accelerated k-means algorithms. JSAT is not limited to exact solvers like SMO, and includes many faster approximations such as the Projectron and BSGD.

Collectively, JSAT includes numerous algorithms for classification and regression (over 70), clustering (18), feature selection and engineering (over 20), visualization (5), and the tools for implementing them. These counts do not include cases where many algorithms are covered by a single class. For example, the `NNChainHAC` class provides $O(n^2)$ hierarchical clustering for any Lance Williams dissimilarity. This also includes a number of algorithms that are useful but not widely available—be it in Java or any other language. Some examples include a multi-class generalization of the popular Passive Aggressive classifier and the Adaptive Multi-Hyperplane Machine (AMM). Almost all code in JSAT has been implemented independently by the author based on the original papers, rather than porting other implementations. The three primary interfaces in JSAT are `Classifier`, `Regressor`, and `Clusterer` for the three primary tasks JSAT supports. Each interface defines the API for learning and inference, with extension interfaces for specializes abilities, such as an `UpdateableClassifier` for online learning. JSAT also has interfaces related to warm starting, change detection, text processing, building/querying metric spaces, loss functions, and optimization. JSAT comes out to about 202k lines of code, compared to 707k for Weka and just under 190k lines for Scikit-learn.[1]

2. Features

JSAT has a number of features in its implementation and design to try and balance ease of use for users, and the development of new algorithms by researchers. Both of these tasks benefit from a certain level of performance in terms of run-time, which JSAT strives to achieve for all algorithms. A small benchmark on MNIST is given in Table 1, where JSAT is compared against the same algorithm in other libraries, with JSAT adjusted to match the default parameters used by others. Error rate was measured from one run on the standard training and testing split of MNIST. JSAT's performance is generally better than Weka and BudgetedSVM (Djuric et al., 2013), and more mixed when compared to LIBLINEAR. That the latter two are written in C/C++ is important to demonstrate that Java code can perform on a similar level while offering the benefits of the Java platform and ecosystem. JSAT's large collection of algorithms also allows for better efficiency by selecting the most appropriate algorithm. For example, when using the accelerated k-means algorithm from Elkan (2003), JSAT becomes 170 times faster with respect to Weka's implementation. All of these numbers are for single-threaded executions, and JSAT supports multi-threaded execution of many algorithms, more so than Weka and many other libraries.

2.1 For Researchers

JSAT includes a wide breadth of algorithms, allowing for comparison against many other approaches in a unified framework. Comparisons also become more meaningful as all al-

gorithms are on an equal footing of speed, avoiding the need for alternative comparison metrics when using multiple libraries. Compared to Python, developing in Java can be a benefit for any algorithm that is not easy to implement in a vectorized approach, which is necessary for performance in most interpreted languages.

For high level implementations, JSAT includes the L-BFGS and OWL-QN solvers, requiring only the implementation of the desired objective function and its gradient to be used. It's also common to implement one's algorithm via SGD for efficiency, and JSAT provides common variants such as Nestrov Momentum SGD, Adam, and RMSprop.

When using lower level linear algebra constructs, JSAT continues to use an Object-Oriented approach. This allows for simple and common tricks to be added to an implementation by changing only the initialization of the object. For example the `ScaledVector` object allows one to implement the common trick for updating a vector by a scalar in constant time presented in Shalev-Shwartz et al. (2007). This works with both sparse and dense vectors. Similar objects exist for a vector shifted by a constant, keeping track of the 2-norm of a vector, or implicitly constructing the degree-2 polynomial expansion of the vector.

We also borrow the concept of the `kcentroid` from Dlib (King, 2009), called `KernelPoint` in JSAT. This object represents the result of performing math in the space induced by using the kernel trick. The object itself approximates the result with a compact solution by projecting new vectors to a basis set. JSAT extends it to support multiple strategies, such as the specialized merged result for the RBF kernel from Wang et al. (2010). This allows for a single piece of code to switch between multiple different approximation methods for implementing a kernelized algorithm. A `KernelPoints` further extends the concept to multiple kernelized weight vectors backed by a single set of basis vectors, which is useful for multi-class algorithms.

At the lowest level, JSAT includes interfaces for continuous and discrete probability distributions, and implementations of more specialized math functions such as the digamma function. Faster, but less accurate, implementations of common math functions are provided as well so authors may optimize their algorithms further. Useful tools are included at this level, such as a generic object for implementing functions via continued fractions.

2.2 For Developers / Users

Building Machine Learning-based solutions often revolves around parameter tuning and trying multiple different algorithms to see which obtains the best performance. Based on this fact, JSAT attempts to make this process simpler for both novices as well as experts. All data in JSAT is represented with a `DataSet` class, of which specialized instances exist for label-less, classification, and regression datasets—making the goal explicit by the type system. The creation of test and validation sets are simply one function call, for example `List<DataSet> splits = dataset.randomSplit(0.7, 0.2, 0.1)` will split a dataset into 3 subsets, with 70% for training, 20% for validation, and 10% for testing. Any number of ratios could be given, and it would return as many sets. It can also be used for selecting a random subset by passing in just one value less than 1.

Explicit classification and regression model evaluation objects exist to either use preselected test sets or perform cross validation. Each support the use of an arbitrary number of evaluation metrics for their respective types, which can be passed in as objects. This includes common metrics such as AUC, F_β score, Precision, Recall, and others. These metrics, as well as many of the algorithms in JSAT, support weighted data instances.

```
ClassificationDataSet dataset = LIBSVMLoader.loadC(new
    File("diabetes.libsvm"));
List<ClassificationDataSet> splits = dataset.randomSplit(0.75, 0.25);
ClassificationDataSet train = splits.get(0), test = splits.get(1);
PlattSMO model = new PlattSMO(new RBFKernel());//have data, now pick model
RandomSearch search = new RandomSearch((Classifier)model, 3);
search.autoAddParameters(train); //automatically find parameters to tune
search.trainC(train);//build model & tune parameters
ClassificationModelEvaluation cme = new
    ClassificationModelEvaluation(search.getTrainedClassifier(), train);
cme.evaluateTestSet(test);//evaluate tuned model
System.out.println("Tuned Error rate: " + cme.getErrorRate());
```

Listing 1: Loading a dataset and performing a parameter search in JSAT

Built upon these is a framework for model evaluation, currently supporting the classic Grid-Search approach and the Random-Search method (Bergstra and Bengio, 2012). Setting the search parameters and their ranges is both cumbersome from a coding standpoint, and difficult for novice users. To alleviate this issue, every object with tunable parameters in JSAT may specify a distribution for each parameter it wants included in the search. This is done with respect to an input dataset, and the methods are discovered through Java's reflection mechanism. This allows JSAT to automatically populate the search parameters with reasonable values, even when the user may not have properly normalized their data. An abridged example of this is provided in Listing 1. In this example, the RBF kernel will automatically be searched over a wider space since the data has not been normalized into the $[-1, 1]$ range, a common issue overlooked by beginners (Hsu et al., 2003). It also has the benefit of being concise, and does not need to be changed when the algorithm used changes. When desired, the user can manually specify the searched parameters and values.

The GridSearch object also has additional logic for models that can be warm-started in their training. The warm-start interface indicates the main parameter that warm-starts should be based off of—automatically making use of this functionality for faster training. This is also helpful for building regularization paths, as is common with L_1 regularized models (Schmidt et al., 2009). This is an improvement over many packages that support warm-starting for some models, but require explicit cross validation objects for each algorithm.

3. Conclusion and Future Plans

JSAT has a wide breadth in the algorithms and tools it makes available to users and researchers, and fills a vital performance need while maintaining a relatively small code base. Future development goals are to further refine the API for consistency and ease of use. A move to Java 8 is planned, and will be used to perform more significant refactoring.

Editor: Nicolai Meinshausen

Abstract

Model selection consistency in the high–dimensional regression setting can be achieved only if strong assumptions are fulfilled. We therefore suggest to pursue a different goal, which we call a minimal class of models. The minimal class of models includes models that are similar in their prediction accuracy but not necessarily in their elements. We suggest a random search algorithm to reveal candidate models. The algorithm implements simulated annealing while using a score for each predictor that we suggest to derive using a combination of the lasso and the elastic net. The utility of using a minimal class of models is demonstrated in the analysis of two data sets.

Keywords. Model Selection; High–dimensional Data; Lasso; Elastic Net; Simulated Annealing

1. Introduction

High–dimensional statistical problems have been arising as a result of the vast amount of data gathered today. A more specific problem is that estimation of the usual linear regression coefficients vector cannot be performed when the number of predictors exceeds the number of observations. Therefore, a sparsity assumption is often added. For example, the number of regression coefficients that are not equal to zero is assumed to be small. If it was known in advance which predictors have non zero coefficients, the classical linear regression estimator could have been used. Unfortunately, it is not known. Even worse, the natural relevant discrete optimization problem is usually not computationally feasible.

The lasso estimator (Tibshirani, 1996), which solves the problem of minimizing prediction error together with an ℓ_1–norm penalty, is possibly the most popular method to address this problem, since it results in a sparse estimator. Various algorithms are available to compute this estimator (e.g., Friedman et al., 2010). The theoretical properties of the lasso have been thoroughly researched in the past 15 years. For the high–dimensional problem, prediction rates were established in various manners (Greenshtein and Ritov, 2004; Bunea et al., 2006; Bickel et al., 2009; Bunea et al., 2007; Meinshausen and Yu, 2009). The capability of the lasso to choose the correct model depends on the true coefficient vector and the matrix of the predictors (Meinshausen and Bühlmann, 2006; Zhao and Yu, 2006; Zhang and Huang, 2008). However, the underlying assumptions are typically rather restrictive, and cannot be checked in practice.

In the high–dimensional setting, the task of finding the true model might be too ambitious, if meaningful at all. Only in certain situations, which could not be identified in practice, model selection consistency is guaranteed. Even in the classical setup, with more observations than predictors, there is no model selection consistent estimator unless further assumptions are fulfilled. This leads us to present a different objective. Instead of searching for a single "true" model, we aim to present a number of possible models a researcher should look at. Our goal, therefore, is to find potentially good prediction models. In short, we suggest to find the best models for each small model size. Then, by looking at these models one may reach interesting conclusions regarding the underlying problem. Some of these, as we demonstrate in applications, can be concluded using statistical reasoning, but most of these should be reasoned by a subject matter expert.

In order to find these models, we implement a search algorithm that uses simulated annealing (Kirkpatrick et al., 1983). The suggested algorithm is provided with a "score" for each predictor. We suggest to get these scores using a multi–step procedure that implements both the lasso and the elastic net (Zou and Hastie, 2005) (and then the lasso again). Multi–step procedures in the high–dimensional setting have drawn some attention and were demonstrated to be better than the standard lasso (Zou, 2006; Bickel et al., 2010).

The rest of the paper is organized as follows. Section 2 presents the concept of minimal class of models and the notations. Section 3 describes a search algorithm for relevant models, and gives motivation for the sequential use of the lasso and the elastic net when calculating scores for the predictors. Section 4 investigates the performance of the suggested search algorithm in simulation studies and then Section 5 illustrates data analysis using a minimal class of models in two examples. Section 6 suggests a short discussion. Technical proofs and supplementary data are provided in the appendix.

2. Description of the problem

We start with notations. First, denote $||v||_q := (\sum v_j^q)^{1/q}$, $q > 0$ for the ℓ_q (*pseudo*) norm of any vector v and $\|v\|_0 = \lim_{q\to 0} ||v||_q$ for its cardinality. The data consist of a matrix of predictors $X_{n\times p} = (X^{(1)}\ X^{(2)}\ ...\ X^{(p)})$ and a response vector $Y_{n\times 1}$. WLOG, X is centered and scaled and Y is centered as well. We are mainly interested in the case $p > n$. The

underling model is $Y = X\beta^0 + \epsilon$ where $\epsilon_{n\times 1}$ is a random error, $E(\epsilon) = 0$, $V(\epsilon) = \sigma^2 I$, I is the identity matrix.

Denote $S \subseteq \{1, ..., p\}$ for a set of indices of X. We call S *a model*. We use $s = |S|$ to denote the cardinality of the set S. Denote also $S_0 := \{j : \beta^0 \neq 0\}$ and $s_0 = |S_0|$ for the true model, and its size, respectively. For any model S, we define X_S to be the submatrix of X which includes only the columns specified by S. Let $\hat{\beta}_S^{LS}$ be the usual least squares (LS) estimator corresponding to a model S, that is,

$$\hat{\beta}_S^{LS} = (X_S^T X_S)^{-1} X_S^T Y,$$

provided $X_S^T X_S$ is non singular.

Now, the straightforward approach to estimate S_0 given a model size κ is to consider the following optimization problem:

$$\min_{\beta} \frac{1}{n}||Y - X\beta||_2^2, \qquad \text{s.t} \quad ||\beta||_0 = \kappa. \tag{1}$$

Unfortunately, typically, solving (1) is computationally infeasible. Therefore, other methods were developed and are commonly used. These methods produce sparse estimators and can be implemented relatively fast. We first present here the lasso (Tibshirani, 1996), defined as

$$\hat{\beta}^L = \underset{\beta}{\operatorname{argmin}}\Big(\frac{1}{n}||Y - X\beta||_2^2 + \lambda||\beta||_1\Big)$$

where $\lambda > 0$ is a tuning constant. For some applications, a different amount of regularization is applied for each predictor. This is done using the weighted lasso, defined by

$$\hat{\beta}_w^L = \underset{\beta}{\operatorname{argmin}}\Big(\frac{1}{n}||Y - X\beta||_2^2 + \lambda||w \cdot \beta||_1\Big) \tag{2}$$

where w is a vector of p weights, $w_j \geq 0$ for all j, and $a \cdot b$ is the Hadamard (Schur, entrywise) product of two vectors a and b. Next is the elastic net estimator

$$\hat{\beta}^{EN} = \underset{\beta}{\operatorname{argmin}}\Big(\frac{1}{n}||Y - X\beta||_2^2 + \lambda_1||\beta||_1 + \lambda_2||\beta||_2^2\Big). \tag{3}$$

This estimator is often described as a compromise between the lasso and the well known Ridge regression (Hoerl and Kennard, 1970) since it could be rewritten as

$$\hat{\beta}^{EN} = \underset{\beta}{\operatorname{argmin}}\Big(\frac{1}{n}||Y - X\beta||_2^2 + \lambda\big(\alpha||\beta||_1 + (1-\alpha)||\beta||_2^2\big)\Big). \tag{4}$$

Let $\hat{\beta}_n$ be a sequence of estimators for β^0 and let $\hat{S}_n$ be the sequence of corresponding models. Model selection consistency is commonly defined as

$$\lim_{n\to\infty} P(\hat{S}_n = S_0) = 1. \tag{5}$$

If $p \ll n$ and small, then criteria based methods (e.g., BIC, Schwarz, 1978) are model selection consistent if p is fixed or if suitable conditions are fulfilled, see Wang et al. (2009)

and references therein. However, these methods are rarely computationally feasible for large p. For $p > n$, it turns out that practically strong and unverifiable conditions are needed to achieve (5) for popular regularization based estimators (Zhao and Yu, 2006; Meinshausen and Bühlmann, 2006; Huang et al., 2008; Jia and Yu, 2010; Tropp, 2004; Zhang, 2009).

In light of these established results, we suggest to pursue a different goal. Instead of finding a single model, we suggest to look for a group of models. Each of these models should include low number of predictors, but it should also be capable of predicting Y well enough. Therefore, $\mathcal{G}_0^n = \mathcal{G}_0^n(\kappa, \eta)$ is called a minimal class of models of size κ and efficiency η if

$$\mathcal{G}_0^n = \Big\{S : |S| = \kappa \;\&\; E||Y - X_S\beta_S^{0\star}||_2^2 \leq \min_{|S'|=\kappa} E||Y - X_{S'}\beta_{S'}^{0\star}||_2^2\} + \eta\Big\}.$$

where $\beta_S^{0\star}$ minimizes $E||Y - X_S\beta_S||_2^2$. Note that $\mathcal{G}_0^n$ depends on n, similarly to the way the true model has been considered previously (Greenshtein and Ritov, 2004; Meinshausen and Bühlmann, 2006; Zhao and Yu, 2006). In fact, if $p > n$ then, necessarily, p grows with n and, at the least, new potential predictors are added; the size of $\mathcal{G}_0^n$ may also change. Clearly, $\mathcal{G}_0^n$ is unknown. However, at a first sight, it is unclear how to refer to this set. Even when carrying out model selection, one hardly treats the true model as a parameter, even though it can be looked as such. In terms of inference, in simple, low dimensional, models, likelihood ratio tests can be used in some frequentist cases, or posterior probabilities for the Bayesians. More generally, model selection criteria, such as AIC (Akaike, 1974) or BIC, are typically used, without assigning formal statistical tools to address uncertainty. In this sense, the true minimal class of models is some type of a weak equivalence class, with respect to the true model S_0. Given η, it answers the following question. Are there additional models, other than S_0, that can be considered satisfactory? If the answer is yes, which are these models? Existence of alternative models may help researchers to question the strength of certain conclusions. Furthermore, when high–dimensional regression is used as part of a pilot study to determine which predictors should be measured regularly, alternative models may be compared in terms of cost. On the other hand, if there are multiple models explaining the data in a satisfactory manner, is there such a thing as the true model? If not, then conceptual concerns may arise. We further discuss these and related important issues in Section 6.

From a practical point of view, it would be useful to consider instead a sample version of $\mathcal{G}_0^n$, $\mathcal{G}^n(\kappa, \eta)$, defined as

$$\mathcal{G}^n(\kappa, \eta) = \Big\{S : |S| = \kappa \;\&\; \frac{1}{n}||Y - X_S\hat{\beta}_S^{LS}||_2^2 \leq \min_{|S'|=\kappa}\{\frac{1}{n}||Y - X_{S'}\hat{\beta}_{S'}^{LS}||_2^2\} + \eta\Big\}. \tag{6}$$

One could control how similar the models in $\mathcal{G} = \mathcal{G}^n$ are to each other in terms of prediction, using the tuning parameter η. A reasonable choice is $\eta = c\sigma^2$ with some $c > 0$. If σ^2 is unknown, it could be replaced with an estimate, e.g., using the scaled lasso (Sun and Zhang, 2012). An alternative to $\mathcal{G}$ is to generate the set of models by simply choosing for each κ the M models having the lowest sample mean square error (MSE), for some number M. The LS estimator, $\hat{\beta}_S^{LS}$, minimizes the sample prediction error for any model S with size $s \leq n$. Thus, this estimator is used for each of the considered models.

In practice, one may find $\mathcal{G}$ for a few values of κ, e.g., $\kappa = 1, ..., 10$, and then examines the pooled results, $\bigcup_{j=1}^{k} \mathcal{G}(j, \eta)$. Alternatively, the empirical MSE $n^{-1}||Y - X_S\hat{\beta}_S^{LS}||_2^2$ in the

definition of $\mathcal{G}$ can be replaced with one of the available model selection criteria, e.g., AIC, BIC or lasso. Then, models of varying size can be included in the class. Note that we are interested in situations where there is a fair number of models with a relatively very small number of variables (predictors) out of the available p.

At this point, a natural question is how can we benefit from using a minimal class of models. Examining the models in $\mathcal{G}$ may allow us to derive conclusions regarding the importance of different explanatory variables. We demonstrate this kind of analysis in Section 5 using two real data examples.

A minimal class of models could be also used in conjunction with the available models aggregation procedures. Aggregation of estimates obtained by different models was suggested both for the frequentist (Hjort and Claeskens, 2003), and for the Bayesian, (Hoeting et al., 1999). The well–known "Bagging" (Breiman, 1996) is also a technique to combine results from various models. Averaging across estimates obtained by multiple models is usually carried out to account for the uncertainty in the model selection process. We, however, are not interested in improving prediction per se, but in identifying good models. Nor are we interested in identifying the best model, since this is not possible or even meaningful in our setup, but in identifying predictors (and models) that are potentially relevant and important.

2.1 Relation to other work

A similar point of view on the relevance of a predictor was given by Bickel and Cai (2012). They considered a predictor to be important if its relative contribution to the predictive power of a set of predictors is high enough. Their next step was to consider only specific type of sets, such that their prediction error is low, yet they do not contain too many variables.

Rigollet and Tsybakov (2012) investigated the question of prediction under minimal conditions. They showed that linear aggregation of estimators is beneficial for high–dimensional regression when assuming sparsity of the number of estimators included in the aggregation. They also showed that choosing exponential weights for the aggregation corresponds to minimizing a specific, yet relevant, penalized problem. Their estimator, however, is computationally impossible and they have little interest in predictors and model identification.

As we describe in Section 3, our suggested search algorithm for candidate models travels through the model space. We choose to use simulated annealing to prevent the algorithm from getting stuck in a local minimum. Some Bayesian model selection procedures move along the model space, usually using a relevant posterior distribution, cf. O'Hara and Sillanpää (2009). We, however, do not assume any prior distribution for the coefficient values. Our use of the algorithm is only as a search mechanism, simply to find as many as possible models included in $\mathcal{G}$. Convergence properties of the classical simulated annealing algorithm are not of interest to our use of it. We are interested in the path generated by the algorithm and not in its final state.

3. A search algorithm

In this section, we suggest an algorithm to find $\mathcal{G}$ for a given κ and η. The problem is that $||Y - X_S\hat{\beta}_S^{LS}||_2^2$ is unknown for all S, and since p is large, even for a relatively small κ,

the number of possible models is huge (e.g., for $p = 200, k = 4$ there are almost 65 million possible models). We therefore suggest to focus our attention on smaller set of models, denoted by $\mathcal{M}(\kappa)$. $\mathcal{M}$ is a large set of models, but not too large so we can calculate MSEs for all the models within $\mathcal{M}$ in a reasonable computer running time. Once we have $\mathcal{M}$ and the corresponding MSEs, we can form $\mathcal{G}$ by choosing the relevant models out of $\mathcal{M}$.

The remaining question is how to assemble $\mathcal{M}$ for a given κ. Any greedy algorithm is bound to find models that are all very similar. Our purpose is to find models that are similar in their predictive power, but heterogeneous in their structure. For this we propose a simulated annealing algorithm (Kirkpatrick et al., 1983) which we now describe.

3.1 Simulated annealing algorithm

Our approach therefore is to implement a search algorithm which travels between potentially attractive models. We use a simulated annealing algorithm (Kirkpatrick et al., 1983), originally suggested for function optimization. The maximizer of a function $f(\theta)$ is of interest. Let $T = (t_1, t_2, ..., t_R)$ be a decreasing set of positive "temperatures". For every temperature level $t \in T$, iterative steps are carried out, before moving to the next, lower, temperature level. In each step, a random move from the current θ to another $\theta' \neq \theta$ is suggested. The move is then accepted with a probability that depends on $\exp\big[\big(f(\theta') - f(\theta)\big)/t\big]$. Typically, although not necessarily, a Metroplis–Hastings criterion (Metropolis et al., 1953; Hastings, 1970) is used to decide whether to accept the suggested move θ' or to stay at θ. After a predetermined number ,N_t, of such iterations, the algorithm moves to the next $t' < t$ in T, taking the final state in temperature t as the initial state for t'. The motivation for using this algorithm is that for high "temperatures", moves that do not improve the target function are possible, so the algorithm does not get stuck in a small area of the parameter space. However, as we lower the temperature, the decision to move to a suggested point is based almost solely on the criterion of improvement in the target function value. The name of the algorithm and its motivation come from annealing in metallurgy (or glass processing), where a strained piece of metal is heated, so that a reorganization of its atoms is possible, and then it colds off slowly so the atoms can settle down in low energy position. See Brooks and Morgan (1995) for a general review of simulated annealing in the context of statistical problems.

In our case, the parameter of interest is the model S and the objective function is

$$f(S) = -\frac{1}{n}||Y - X_S\hat{\beta}_S^{LS}||_2^2.$$

We now describe the proposed algorithm in more detail. We use simulated annealing with Metropolis–Hastings acceptance criterion as a search mechanism for good models. That is, we are not looking for the settling point of the algorithm; instead, we are following its path, hoping that much of it will be in neighborhood of good models.

We say the algorithm is in step (t, i) if the current temperature is $t \in T$ and the current iteration in this temperature is $i \in \{1, ..., N_t\}$. For simplicity, we describe here the algorithm for $N_t = N$ for all t. Let S_t^i and $\hat{\beta}_t^i$ be the model and the corresponding LS estimator in the beginning of the state (t, i), respectively. An iteration includes a suggested model S_t^{i+}, a LS estimator for this model, $\hat{\beta}_t^{i+}$, and a decision whether to move to S_t^{i+} and $\hat{\beta}_t^{i+}$ or to stay

at S_t^i and $\hat{\beta}_t^i$. We now define how S_t^{i+} is suggested and what is the probability of accepting this move.

For each S_t^i, we suggest S_t^{i+} by a minor change, i.e., we take one predictor out and we add another instead, and then obtain $\hat{\beta}_t^{i+}$ by standard linear regression. Assume that for every variable $j \in (1, ..., p)$, we have a score γ_j, such that higher value of γ_j reflects that the variable j should be included in a model, comparing with other possible variables. WLOG, assume $0 \leq \gamma_j \leq 1$ for all j. We choose a variable $r^* \in S_t^i$ and take it out with the probability function

$$p_{i,r}^{out} = \frac{{\gamma_r}^{-1}}{\sum\limits_{u \in S_t^i} {\gamma_u}^{-1}}, \quad \forall r \in S_t^i. \tag{7}$$

Next, we choose a variable $\ell^* \notin S_t^i$ and add it to the model with the probability function

$$p_{i,\ell}^{in} = \frac{\gamma_\ell}{\sum\limits_{u \notin S_t^i} \gamma_u}, \quad \forall \ell \notin S_t^i. \tag{8}$$

Thus,

$$S_t^{i+} = \{S_t^i \setminus r^*\} \cup \{\ell^*\}$$

and we may calculate the LS solution $\hat{\beta}_t^{i+}$ for the model S_t^{i+}. The first part of our iteration is over; a potential candidate was chosen. The second part is the decision whether to move to the new model or to stay at the current one. Following the scheme of simulated annealing algorithm with Metropolis–Hastings criterion, we calculate

$$q = \exp\Big(\frac{1}{nt}\big(||Y - X_{S_t^i}\hat{\beta}_t^i||_2^2 - ||Y - X_{S_t^{i+}}\hat{\beta}_t^{i+}||_2^2\big)\Big)\frac{Pr(S_t^{i+} \to S_t^i)}{Pr(S_t^i \to S_t^{i+})}$$

where

$$\begin{aligned} Pr(S_t^i \to S_t^{i+}) &= p_{i,r^*}^{out}\ p_{i,\ell^*}^{in} \\ Pr(S_t^{i+} \to S_t^i) &= p_{i^+,\ell^*}^{out}\ p_{i^+,r^*}^{in}. \end{aligned} \tag{9}$$

We are now ready for the next iteration $i+1$ by setting

$$(S_t^{i+1}, \hat{\beta}_t^{i+1}) = \begin{cases} (S_t^{i+}, \hat{\beta}_t^{i+}) & w.p \quad \min(1, q) \\ (S_t^i, \hat{\beta}_t^i) & w.p \quad \max(0, 1-q). \end{cases}$$

Along the run of the algorithm, the suggested models and their corresponding MSEs are kept. These models are used to form $\mathcal{M}(\kappa)$, and $\mathcal{G}$ can be then identified for a given value of η.

We now point out several issues for the practical application of the algorithm. First, the algorithm was described above for one single value of κ. In practice, one may run the algorithm separately for different values of κ. Another consideration is the tuning parameters of the algorithm that are provided by the user: The temperatures T; the number of iterations N; the starting point $S_{t_1}^1$; and the vector $\gamma = (\gamma_1, ..., \gamma_p)$. Our empirical experience is that the first three can be managed without too many concerns. In particular, the algorithm should be started from more than one initial point, and the results from

each run should be kept and compared; see Sections 4 and 5. Regarding the vector γ, a wise choice of this vector should improve the chance of the algorithm to move in desired directions. We deal with this question in Section 3.2. However, in what follows we show that, under suitable conditions, the algorithm can work well even with a general choice of γ.

Define S_0, s_0 and β^0 as before and let $\mu = X\beta^0$. That is, $Y = \mu + \epsilon$. We first introduce a few simple and common assumptions:

(A1) $||\mu||_2^2 = O(n)$

(A2) s_0 is small, i.e., $s_0 = O(1)$.

(A3) $p = n^a, a > 1$

(A4) $\epsilon \sim N_n(0, \sigma^2 I)$

Denote A_γ for the set of positive entries in γ. That is, $A_\gamma \subseteq \{1, .2, ...p\}$ is a (potentially) smaller group of predictors than all the p variables. Denote also $h_\gamma = |A_\gamma|$ for the cardinality of A_γ and $\gamma_{min} := \min\limits_{i \in A_\gamma} \gamma_i$ for the lowest positive entry in γ.

To motivate our next assumption, we note that, informally, the algorithm is expected to preform reasonably well if:

1. The true model is relatively small (e.g., with 10 active variables).
2. A variable in the true model is adding to the prediction of a set of variables if a very few (e.g., 2) other variables are in the set.

Our next assumption is more restrictive. Let $\bar{S}$ be an interesting model of size s_0–a model with not too many predictors and with a low MSE. The models we are looking for are of this nature. We facilitate the idea of $\bar{S}$ being an interesting model by assuming that $X_{\bar{S}}\hat{\beta}_{\bar{S}}$ is close to μ (in the asymptotic sense). We virtually assume that for every model of size $|\bar{S}|$, which is not $\bar{S}$, if we take out a predictor that is not part of $\bar{S}$, and replace it with a predictor from $\bar{S}$, the subspace spanned by the new model is not much further from μ, comparing with the subspace spanned by the original model. Formally, denote $\mathcal{P}_{\mathcal{S}}$ for the projection matrix onto the subspace spanned by the columns of the submatrix X_S.

(B1) There exist $t_0 > 0$ and a constant $c > 0$, such that for all S, $|S| = s_0 - 1$, for all $j \in \bar{S} \cap S^c$, $j' \in \bar{S}^c \cap S^c$, and for a large enough n

$$\frac{1}{n}\left[||\mathcal{P}_{S_j^\star}\mu||_2^2 - ||\mathcal{P}_{S_{j'}^\star}\mu||_2^2\right] > 4t_0 \log c, \tag{10}$$

where $S_r^\star \equiv S \cup \{r\}$.

We note that since c could be lower than one, the right hand side of (10) can be negative. The following theorem gives conditions under which the simulated annealing algorithm is passing through an interesting model $\bar{S}$. More accurately, the theorem states that there is always strictly positive probability to pass through $\bar{S}$ in the next few moves. This result covers all models that Assumption (B1) holds for. Note however, that we do not claim that

the algorithm finds all the models in a minimal class. Proving such a result would probably require complicated assumptions on models with larger size than s_0, and their relation to $\bar{S}$ and other interesting models.

Let $P_t^m(S'|S)$ be the probability of passing through model S' in the next m iterations of the algorithm, given the current temperature is t, and the current state of the algorithm is the model S.

Theorem 1 *Consider the simulated annealing algorithm with $\kappa = s_0$ and with a vector γ such that $\gamma_{min} \geq c_\gamma$. Let Assumptions (A1)–(A4) hold and let Assumption (B1) hold for some temperature t_0 and with $c = c_\gamma$. If $\bar{S} \subseteq A_\gamma$ then for all $S \subseteq A_\gamma$ with $s = s_0$, for all $m \geq s_0 - |\bar{S} \cap S|$ and for large enough n,*

$$P_{t_0}^m(\bar{S}|S) > \left[\frac{c_\gamma^2}{s_0(h_\gamma - s_0)}\right]^{s_0}. \tag{11}$$

A proof is given in the appendix. Theorem 1 states that for any specification of the vector γ, such that the entries in γ are positive for all the predictors in $\bar{S}$, the probability that the algorithm would visit $\bar{S}$ in the next m moves is always positive, provided the temperature is high enough, and provided it is possible to move from the current model to $\bar{S}$ in m moves.

For the classical model selection setting with $p < n$, a similar method was suggested by Brooks et al. (2003). Their motivation is as follows. When searching for the most appropriate model, likelihood based criteria are often used. However, maximizing the likelihood to get parameters estimates for each model becomes infeasible as the number of possible models increases. They therefore suggest to simplify the process by maximizing simultaneously over the parameter space and the model space. They suggest a simulated annealing type algorithm to implement this optimization. This algorithm is essentially an automatic model selection procedure.

3.2 Choosing γ

The simulated annealing algorithm described above is provided with the vector γ. The values $\gamma_1, ..., \gamma_p$ should represent the knowledge regarding the importance of the predictors, although we do not assume that any prior knowledge is available. As it can be seen in equations (7)–(8), predictors with high γ values have larger probability to enter the model if they are not part of the current model, and lower probability to be suggested for replacement if they are already part of it. Since p is large, we may also benefit if γ includes many zeros.

One simple choice of γ is to take the absolute values of the univariate correlations of the different predictors with Y. We could also threshold the correlations in order to keep only predictors having large enough correlation (in absolute value) with Y. However, using univariate correlations is clearly problematic since it overlooks the covariance structure of the predictors in X.

Another possibility is to first use the lasso with a relatively low penalty, and then to set $\gamma_j = |\hat{\beta}_j^L|/||\hat{\beta}^L||_1$. The idea behind this suggestion is that predictors with large coefficient value may be more important for prediction of Y.

However, as discussed in Section 2, the lasso might miss some potentially good predictors. It is well known that the elastic net may add these predictors to the solution, although

it might also add unnecessary predictors. Moreover, it is not clear how to choose γ_j using solely the elastic net. The lasso and the elastic net estimators are not model selection consistent in many situations. However, for our purpose, combining both methods together may help us get a reservoir of promising predictors.

Zou and Hastie (2005) provided motivation and results that justify the common knowledge that the elastic net is better to use with correlated predictors. Since we intend to exploit this property of the elastic net, this paper offers an additional theoretical background. We present a more general result later on this section, but for now, the following proposition demonstrates why the elastic net tends to include correlated predictors in its model.

Proposition 2 *Define X and Y as before, and define $\hat{\beta}^{EN}$ by (3). Let $X^{(1)}$ and $X^{(2)}$ be two columns of X and denote $\rho = n^{-1}(X^{(1)})^T X^{(2)}$. Assume $|\hat{\beta}_1^{EN}| \geq c_\beta$ for some $c_\beta > 0$. If $|\rho| > 1 - \lambda_2^2 c_\beta^2/||Y||_2^2$ then $|\hat{\beta}_2^{EN}| > 0$.*

A proof is given in the appendix. Proposition 2 gives motivation for why $\hat{\beta}^{EN}$ has typically a larger model than $\hat{\beta}^L$. It also quantifies how much correlated two predictors need to be so the elastic net would either include both predictors or none of them.

Going back to our γ vector, the next question is how to use the lasso and the elastic net in order to assign a "score" to each predictor. Let S_L and S_{EN} be the models that correspond to $\hat{\beta}^L$ and $\hat{\beta}^{EN}$, respectively. Define S_+ for the group of predictors that were part of the elastic net model but not part of the lasso model and S_{out} for the predictors that were not included in any of them. Note that $S_L \cap S_+ = S_L \cap S_{out} = S_+ \cap S_{out} = \emptyset$ and $S_L \cup S_+ \cup S_{out}$ is $\{1, ..., p\}$. Define

$$\hat{\beta}_+^L(\delta) = \arg\min_\beta \Big(\frac{1}{n}||Y - X\beta||_2^2 + \lambda \sum_{j=1}^p \delta^{\mathbf{1}\{j \in S_+\}}|\beta_j|\Big), \qquad \delta \in [0, 1],$$

and let $S_+^L(\delta)$ be the appropriate model. In this procedure, a reduced penalty is given for predictors that $\hat{\beta}^L$ might have missed. Thus, these predictors are encouraged to enter the model, and since they may take the place of others, predictors in S_L that their explanation power is not high enough are pushed out of the model. Note that $\hat{\beta}_+^L(\delta)$ is a special case of $\hat{\beta}_w^L$, as defined in (2), with $w_j = \delta^{\mathbf{1}\{j \in S_+\}}$.

We demonstrate how the reduced–penalty procedure works using a toy example. A data set with $n = 30$ and $p = 50$ is simulated. We take the coefficient vector to be $\beta^0 = (0.5\ 0.5\ 1\ 1\ 1\ 0\ 0\ ...\ 0)^T$ and σ^2 is taken to be one. The predictors are independent normal variables with the exception of 0.8 correlation between $X^{(1)}$ and $X^{(2)}$. Predictor 1 is included in the lasso model, however predictor 2 is not. Figure 1 presents the coefficients' estimates of $X^{(1)}, X^{(2)}$ and $X^{(3)}$ when lowering the penalty of $X^{(2)}$. Note how $X^{(2)}$ enters the model for low enough penalty while $X^{(1)}$ leaves the model for low enough penalty (on $X^{(2)}$).

We suggest to measure the importance of a predictor $j \in S_+$ by the highest δ such that $j \in S_+^L(\delta)$. On the other hand, the importance of a predictor $j' \in S_L$ can be measured by the highest δ such that $j' \notin S_+^L(\delta)$ (now, smaller δ reflects j' is more important). With this in our mind, we continue to the derivation of γ.

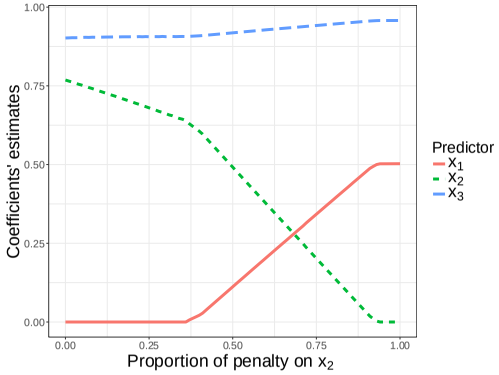

Figure 1: Toy example: coefficients' estimates for predictors $X^{(1)}, X^{(2)}$ and $X^{(3)}$ when lowering the lasso penalty for $X^{(2)}$ only. The rightmost point corresponds to a lasso procedure with equal penalties for all predictors

Let $\Delta = (\delta_0 < \delta_1 < ... < \delta_h)$ be a grid of $[0, 1]$, with $\delta_0 = 0$ and $\delta_h = 1$. For each $\delta \in \Delta$, we obtain $\hat{\beta}^L_+(\delta)$. Define

$$i^\star_j = \begin{cases} \underset{i}{\text{argmax}}\{i : \hat{\beta}^L_{+j}(\delta_i) \neq 0\} & j \notin S_L \\ \underset{i}{\text{argmax}}\{i : \hat{\beta}^L_{+j}(\delta_i) = 0\} & j \in S_L \end{cases}$$

and if the argmax is over an empty set, define $i^\star_j = 0$. We suggest to choose γ_j as follows:

$$\gamma_j = \begin{cases} 0 & j \in S_{out} \\ \delta_{i^\star_j}/2 & j \in S_+ \\ \\ 1 - \delta_{i^\star_j}/2 & j \in S_L, \end{cases}$$

for all $j \in \{1, ..., p\}$. This choice of γ has the following nice properties.

- A predictor $j \notin S_L$ with $i^\star_j = 0$ is excluded from consideration.
- On the other hand, for a predictor $j \in S_L$, if $i^\star_j = 0$ than $\gamma_j = 1$, which is the maximal possible value. Even when the penalty for other predictors is dramatically reduced, leading to their entrance to the model, j remains part of the solution and hence it is essential for prediction of Y.
- Since predictors in S_L were picked when equal penalties were assigned to all predictors, they get priority over predictors in S_+.

- However, for two identical predictors, $X^{(j)} = X^{(j')}$ (or highly correlated predictors) such that $j \in S_L$ and $j' \notin S_L$, we get a desirable result. By Proposition 2, we know that $X'_j \in S_+$. Now, for $\delta_{h-1} < 1$ it is clear that $j' \in S^L_+(\delta_{h-1})$ and $j \notin S^L_+(\delta_{h-1})$. Therefore. $i^\star_j = i^\star_{j'} = h-1$ hence if δ_{h-1} is taken to be close to one, then $\gamma_j \simeq \gamma_{j'} \simeq 0.5$ as one might want.

Proposition 2 concerns two correlated predictors. In practice, the covariance structure of X may be much more complicated. Therefore the question arises: can we say something more general on the elastic net in the presence of competing models? Apparently we can. Let M_1 and M_2 be two models, that is, two sets of predictors, that possibly intersect. Assume that the elastic net solution chose all the predictors in M_1. What can we say about the predictors in M_2? Are there conditions on X_{M_2}, X_{M_1} and Y such that all the predictors in M_2 are also chosen? If the answer is yes (and it is, as Theorem 3 states), it justifies our use of the elastic net to reveal more relevant predictors. In our case, the relevant predictors are the building blocks of models in $\mathcal{G}$.

In order to reveal this property of the elastic net, we analyze $\hat{\beta}^{EN}$, the solution of (3), when assuming all the predictors in M_1 have non-zero values. Denote $M^{(-)}$ for $(M_1 \cup M_2)^c$, the set of predictors that are not included in M_1 or M_2 and $\tilde{X} = X_{M^{(-)}}$ for the appropriate submatrix of X. Let $\hat{\beta}^{EN}_{M_1}$, $\hat{\beta}^{EN}_{M_2}$ and $\hat{\beta}^{EN}_{M^-}$ be the coordinates of $\hat{\beta}^{EN}$ that correspond to M_1, M_2 and $(M_1 \cup M_2)^c$, respectively. Let $\tilde{Y} = Y - \tilde{X}\hat{\beta}^{EN}_{M^-}$ be the unexplained residual of Y, after taking into account $\tilde{X}$. Finally, we show that both M_1 and M_2 are chosen by the elastic net if the prediction of $\tilde{Y}$ using M_1, namely $X_{M_1}\hat{\beta}^{EN}_{M_1}$, projected onto the subspace spanned by the columns of M_2 is correlated enough with $\tilde{Y}$. Formally,

Theorem 3 *Define $\hat{\beta}^{EN}$ as before. Let M_1 and M_2 be two models with the appropriate submatrices X_{M_1} and X_{M_2}. Define $\tilde{X}$ and $\tilde{Y}$ as before. Define $\hat{\beta}^{EN}_{M_1}$ and $\hat{\beta}^{EN}_{M_2}$ as before. Denote $\mathcal{P}_{M_2}$ for the projection matrix onto the subspace spanned by the columns of X_{M_2}. WLOG, assume $|M_2| \leq |M_1|$ and that all the coordinates of $\hat{\beta}^{EN}_{M_1}$ are different than zero. Finally, if*

$$\tilde{Y}^T \mathcal{P}_{M_2} X_{M_1} \hat{\beta}^{EN}_{M_1} > c_1(\lambda_1, \lambda_2, X_{M_1}, \tilde{Y}, \hat{\beta}^{EN}_{M_1}), \tag{12}$$

then all the coordinates of $\hat{\beta}^{EN}_{M_2}$ are different than zero.

A proof and a discussion on the technical aspects of condition (12) and the constant c_1 are given in the appendix. Theorem 3 states that under a suitable condition, predictors belonging to at least one of two competing models are chosen by the elastic net. In our context, when we have a model M_1 with a good prediction accuracy, i.e., $X_{M_1}\hat{\beta}^{EN}_{M_1}$ is close to $\tilde{Y}$, then predictors in any another model M_2 which has similar prediction, that is $\mathcal{P}_{M_2} X_{M_1}\hat{\beta}^{EN}_{M_1}$ is also close to $\tilde{Y}$, would be chosen by the elastic net. Hence, these predictors are expected to have a positive value in γ, and our simulated annealing algorithm would pass through these models, provided the conditions in Theorem 1 are met. Therefore, these models are expected to appear in $\mathcal{G}$.

4. Simulation Studies

In order to examine the performance of the suggested search algorithm, we present in this section results from two simulation studies. The first investigates whether models similar in

their capability to describe the underlying population can be found by the algorithm. The second simulation study examines the out–of–sample prediction error of models included in the minimal class of models.

We present below a scenario in which, other then the model used to create the data, there are three more models, that are not nested within the underlying model, with population prediction error close to the underlying model. In practice, all of these four models are of interest.

We consider $Y = X\beta^0 + \epsilon$, $\epsilon \sim N(0, I)$ with β_j^0 equals to C for $j = 1, 2, ..., 6$ and zero for $j > 6$. C is a constant chosen to get a desired signal to noise ratio (SNR) $||X\beta^0||_2$. The predictors in X are all i.i.d. $N(0, I)$ with the exception of $X^{(7)}$ and $X^{(8)}$, which are defined by

$$X^{(7)} = \frac{2}{3}[X^{(1)} + X^{(2)}] + \xi_1, \qquad \xi_1 \sim N_n\left(0, \frac{1}{9}I\right)$$
$$X^{(8)} = \frac{2}{3}[X^{(3)} + X^{(4)}] + \xi_2, \qquad \xi_2 \sim N_n\left(0, \frac{1}{9}I\right)$$

where ξ_1 and ξ_2 are independent. In this scenario, there are 4 models we would like to find: (I) {1,2,3,4,5,6}; (II) {5,6,7,8}; (III) {3,4,5,6,7}; and (IV) {1,2,5,6,8}. In particular, each of these models minimizes the population prediction error $E||Y - X_S\beta_S||_2^2\}$ for models with its size. That is, Model (I) minimizes the population prediction error for models of size $k = 6$, Model (II) minimizes the prediction error for models of size $k = 4$, and both models (III) and (IV) minimize the prediction error for models of size $k = 5$. Furthermore, it can be shown, for example, that the population prediction error of Model (III) is just 3.7% larger than the error of true model for $SNR = 1$, 14.8% for $SNR = 2$, and larger values for $SNR \geq 4$

Note that while models (II)–(IV) do not describe the data as well as Model (I), they contain less predictors. Furthermore, in an hypothetical real-life situation where future measurements were to be made on the predictors and the outcome, and, for the sake of the example, $X^{(1)}$ or $X^{(2)}$ were more expensive to measure, models (II)–(IV) could have provided a frugal alternative, while preserving a reasonable prediction error.

As part of this simulation study, for each simulated data set, we do the following:

1. Obtain γ as explained in Section 3.2. The tuning parameter of the lasso is taken to be the minimizer of the cross–validation MSE. For the elastic net, α in (4) is taken to be 0.4.

2. Run the simulated annealing algorithm for $\kappa = 4, 5, 6$. The tuning parameters of the algorithm are chosen quite arbitrarily: $T = (10 \times 0.7^1, 10 \times 0.7^2, ..., 10 \times 0.7^{20})$; $\Delta = (0, 0.02, 0.04, ..., 0.98, 1)$; $N_t = N = 100$ for all $t \in T$.

3. Then, for each model (I)–(IV), we check whether the model is the best model obtained (as measured by MSE) among models with the same size. For example, we check if Model (II) is the best model out of all models that were found with $\kappa = 4$. We also check whether the model is one of the top five models among models with the same size.

SNR	Model	$p = 200$ Best	$p = 200$ Top 5	$p = 500$ Best	$p = 500$ Top 5	$p = 1000$ Best	$p = 1000$ Top 5

Table 1: Proportion that each model is chosen as best model or as one of top five models for different number of potential predictors (p) and various SNR values.

A 1000 simulated data sets were generated for each different scenario: For $n = 100$, $p = 200, 500, 1000$ and for SNR $= 1, 2, 4, 8, 12, 16$. Table 1 displays the proportion of times each model was chosen, either as the best one, or as one of the top five models. The results are as one might expect. For large SNR, the models are chosen more frequently. However, models (III) and (IV) are competing, in the sense that they both include five predictors. Even for large SNR, each of the models, (III) and (IV), is chosen in about 50% of the cases. Therefore, as recommended in Section 3.1, we repeat the simulations while starting the algorithm from different initial points, that is, different initial models.

Figure 2 presents comparison between running the algorithm from one and three starting points. When we initiated the algorithm from three different models, the results improved for all models, and in particular for models (III) and (IV). The results described in this section are quite similar to the results we obtained when forming $\mathcal{G}(\kappa, \eta)$ as defined in (6), for each $\kappa = 4, 5, 6$ separately and using arbitrary small values of η.

We now turn to describe the second simulation study, that concerns out–of–sample prediction of the models found by the algorithm. Here we consider three scenarios. The true model consisting 20 predictors for all scenarios. In Scenario 1, X consists p iid normally distributed predictors with mean zero and variance one. The 20 first entries in β^0 are created from iid normal distribution, and then rescaled to achieve the desired SNR. In Scenario 2,

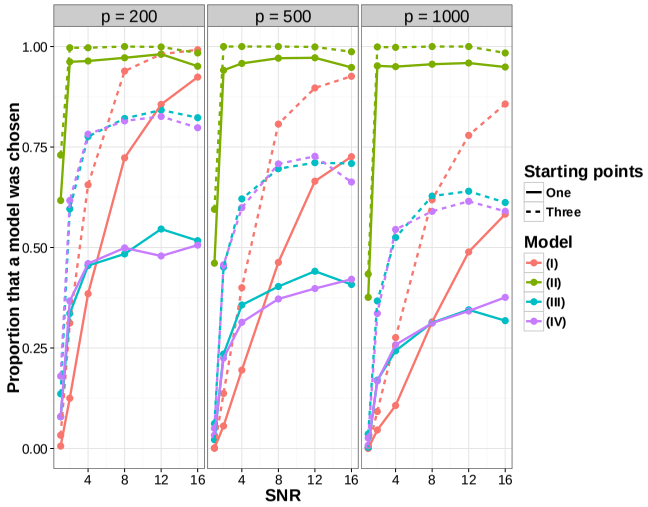

Figure 2: Proportion that each model is chosen as one of top five models for different number of potential predictors (p) and various SNR values. There is an apparent improvement when running the algorithm from three starting points.

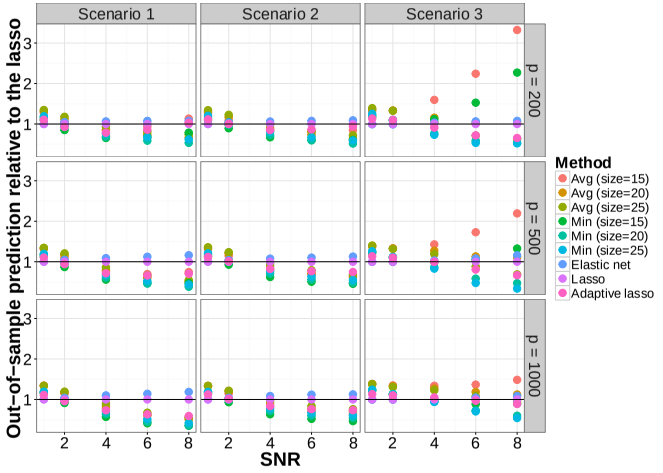
β^0 is created in the same as in Scenario 1, but a more complex correlation structure is considered for X. First, define $\Sigma^{(m)}$ to be an $m \times m$ covariance matrix defined so for all $i = 1, ..., m$ and $j = 1, ., m$, $\Sigma_{ij}^{(m)} = 0.75^{|i-j|}$. The subvector containing the first 5 predictors, $(X^{(1)}, X^{(2)}, ..., X^{(5)})$ is created with the covariance matrix $\Sigma^{(5)}$. Then, each of the next 10 predictors $X^{(j)}, j = 6, 7..., 15$ is correlated with two predictors that are not part of the true model. For example, $(X^{(6)}, X^{(21)}, X^{(22)})$ is simulated from $N_3(0, \Sigma^{(3)})$ and $(X^{(7)}, X^{(23)}, X^{(24)})$ is simulated from $N_3(0, \Sigma^{(3)})$. The remaining predictors are simulated as iid $N(0, 1)$. In Scenario 3, X is created as in Scenario 2, but the coefficients in the true model are now all equal. That is, $\beta_j^0 = C, j = 1, 2, ..., 20$, with C being a constant chosen to get a desired SNR.

As in the previous study, $Var(\epsilon) = I, n = 100$ and we consider $p = 200, 500, 1000$. We report the results for SNR=1,2,4,6,8. For each synthetic data set, the simulated annealing is used for $\kappa = 15, 20, 25$. The algorithm is initiated three times per κ value, and the best five models per run are kept, and then combined to have a minimal class of models containing up to 15 models (per κ value). Other tuning parameters are chosen as in the first simulation study. Figure 3 compares mean (over the synthetic data sets) out–of–sample prediction error for the best model (in terms of prediction error) within the minimal class of models, the average of out–of–sample prediction error among the models in the minimal class, as well as the errors of the lasso, elastic net and adaptive lasso. Results are presented



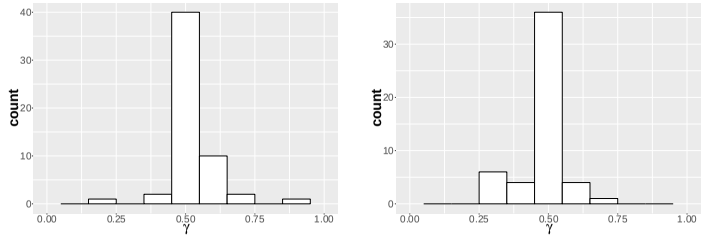


Figure 3: Out–of–sample prediction error for different scenarios, different number of potential predictors (p) and various SNR values. Methods compared are lasso, elastic net and adaptive lasso, as well as the average (avg) and minimal (min) error in the minimal class of models, with model size of 15,20 and 25 predictors. The classes were built by combining 5 best models obtained from three runs of the simulated annealing search algorithm.

relative to the out–of–sample prediction error of the lasso. For SNR=1, the lasso performs the best, for all three scenarios considered, although the other methods show comparable performance. Under Scenarios 1 and 2, when the non–zero parameters are created from a normal distribution, so some predictors are stronger and others are weaker, the best model identified by the minimal class, for either $\kappa = 20$ or $\kappa = 25$, outperforms other methods for SNR>1. Under Scenario 3, where all coefficients (in the true model) are equal, the same pattern is observed for SNR>4. For large SNR values, under Scenario 3, the models in the minimal class of size 15 are underperforming. While under Scenarios 1 and 2, the predictors missed by the minimal class with $\kappa = 15$ are likely to be those with small effect, under Scenario 3 all predictors have an equal effect. We also considered scenarios with X simulated from $N_p(0, \Sigma^{(p)})$. The results are similar to those observed for Scenario 1 and hence are omitted.

5. Real data sets

We demonstrate the utility of using a minimal class of models in the analysis of two real data sets. The tuning parameters of the lasso and the elastic net were taken to be the same as in Section 4. The tuning parameters of the simulated annealing algorithm were

(a) Riboflavin data (b) Air pollution data

Figure 4: Histograms of the values of γ for positive entries only in the two data set analysis examples.

$T = 10 \times (0.7^1, 0.7^2, ..., 0.7^{20})$, $\Delta = (0, 0.01, 0.02, ..., 0.98, 0.99, 1)$, and $N_t = N = 100$ for all $t \in T$.

5.1 Riboflavin

We use a high–dimensional data about the production of riboflavin (vitamin B2) in Bacillus subtilis that were recently published (Bühlmann et al., 2014). The data consist $p = 4088$ predictors. These are measures of log expression levels of genes in $n = 71$ observations. The target variable is the (log) riboflavin production rate.

The lasso model S_L includes 40 predictors (and intercept), and the elastic net model S_{EN} includes 59 predictors. In total, we get 61 different predictors (i.e., genes). Panel (a) of Figure 4 presents the histogram of the positive values in γ.

We run the algorithm from three random starting points for each model size between 1 and 10. We keep the five best models for each size and starting point, to get, after removal of duplicates, a total of 112 models. See Table 2 for the number of unique models as a function of the model size. Following a referee comment, we note here that in practice models with low model size may have unacceptably low R^2, and this can be checked in practice. In our analysis here we keep these models since the R^2 values are all larger than 0.35 and to ease the exposition, so we would be able to compare the search results to models obtained by other methods. The models found by other methods, for the riboflavin data, are of a relatively small size; see Bühlmann et al. (2014)

The following insights are drawn from examining more carefully the models we obtained (see Table 1 in the online appendix):

- In total, the models include 53 different predictors. Out of these, 35 predictors appear in less than 10% of the models, meaning they are probably less important as predictors of riboflavin production rate.

- Gene number 2564 appears in all models of size larger than 3 and in 5 out of 8 models of size 3. However, this gene is not included in any of the smaller models. This gene is the only one that appears in more than half of our models. We can infer that while

Model size	1	2	3	4	5	6	7	8	9	10
Number of models	5	5	8	6	13	15	15	15	15	15

Table 2: Riboflavin data: Number of unique models for each model size after running the algorithm from 3 different starting points

this gene does not hold an effect strong enough comparing to other genes in order to stand out, it has a unique relation with the outcome predictor that could not be mimicked using other combination of genes.

- At least one gene from the group $\{4002, 4003, 4004, 4006\}$ is contained in all models of size larger than one, although never more than one of these genes. Genes number 4003 and 4004 appear more frequently than genes number 4002 and 4006. Looking at the correlation matrix of these genes only, we see they are all highly correlated (pairwise correlations > 0.97). Future research could take this finding into account by using, e.g., the group lasso (Yuan and Lin, 2006).

- Similarly, either gene number 1278 or gene number 1279 appear in about half of the models. They are also strongly correlated (0.984). The same statement holds for genes number 69 and 73 (correlation of 0.945) as well.

- The importance of genes number 792,1131, and possibly others, should be also examined since each of them appears in a variety of different models.

We now compare our results to models obtained using other methods, as reported in Bühlmann et al. (2014). The multiple sample splitting method to get p–values (Meinshausen et al., 2009) yields only one significant predictor. Indeed, a model that includes only this predictor is part of our models. If one constructs his model using the stability selection (Meinshausen and Bühlmann, 2010) as a screening process for the predictors, he would get a model consisting three genes, which correspond to columns number $625, 2565$ and 4004 in our X matrix. However, this model is not included in our top models. In fact, the highest MSE for a model in our 8 models of size 3 is 0.2047 while the MSE of the model suggested using the stability selection is 0.2703, more than 30% difference!

5.2 Air pollution

We now demonstrate how the proposed procedure can be used for traditional, purportedly simpler, problem. The air pollution data set (McDonald and Schwing, 1973) includes 58 Standard Metropolitan Statistical Areas (SMSAs) of the US (after removal of outliers). The outcome variable is age-adjusted mortality rate. There are 15 potential predictors including air pollution, environmental, demographic and socioeconomic predictors. Description of the predictors is given in Table 4 in the appendix.

There is no guarantee that the relationship between the predictors and the outcome variable has a linear form. We therefore include commonly used transformations of each

variable, namely natural logarithm, square root and power of two transformations. Considering also all possible two way interactions, we have a total of 165 predictors.

High–dimensional regression model that includes transformations and interactions has been dealt with in the literature. For example, by using two step procedures (Bickel et al., 2010) or by solving a relevant optimization problem (Bien et al., 2013). Our procedure has a different goal, since we are not looking for the best predictive model, but rather for meaningful insights about the data.

Following the lasso and elastic net step, we are left with 51 predictors with positive γ_j (6 untransformed predictors, 4 log transformations, 6 square root transformations, 9 power of two transformations and the rest are interactions). Panel (b) of Figure 4 presents the histogram of the positive values in γ.

We modify the search algorithm to make it produce results typical to an analysis involving interaction terms. In particular, we search for models such that an interaction term is included only if at least one of the corresponding main terms is included in the model. In order to do so, the definitions in (7) and (8) are modified such that the probability of proposing an interaction term is zero if none of the corresponding main effects is in this model (excluding the variable chosen to be taken out). On the other hand, main effects are "protected" of being suggested to be excluded from the model, if any interaction involving them is part of the current model. We achieve this by setting to zero the probability of suggesting a predictor when an interaction term involving this predictor is included.

Following our earlier comment on considering satisfactory models, and since we are looking for more complex models in this example, considering the option of transformations and interactions, we run the algorithm for $\kappa = 5, 6, ..., 15$, for each κ, from three starting points, and then we keep the 5 best models. In total, we get 164 unique models. Table 3 summarizes the results for prominent main effect predictors, that is, predictors that appear in at least third of the models we obtained. The table presents a matrix of the joint frequency of each two predictors. Each cell in the table is the number of models including both the predictor listed in the row and the predictor listed in the column. The diagonal is simply the number of models that a predictor appears in. Considering Table 3, the nitric oxide pollution is invaluable for prediction of mortality rate. This predictor (in a log shape) appears in a large majority of the models. The percentage of non–white population also appears in most models. In almost half of them, it appears untransformed, but the same could be said about this predictor after square root transformation. However, in less than 10% of the models, this predictor appears in both forms. We conclude that this predictor should be used for prediction of the mortality rate, but the question of transformation remains unsolved. Similar comments can be made about hydrocarbon pollution.

We turn to the interactions. Because of the way we searched for interactions, it becomes "harder" for an interaction term to enter a model, and we therefore analyze them separately. Out of the 26 interactions considered, none clearly stood out above the rest. Five of the interaction terms appear in about 15% of the models. Two of those involve the percentage of non–white population, one with the prevalence of low–income, and the other with percentage of housing units with all facilities. Another of those five interaction terms is the interaction between percentage of elderly population and the average temperature in January. The latter main effect appears in about 50 models, and hence did not make the cutoff for Table 3. The percentage of elderly population was not included in either the lasso or elastic net

preliminary steps. However, the absence of age related effect is not so surprising since the outcome variable, the mortality rate, is age corrected. Nevertheless, since the interaction term appeared in about half of the models that included January temperature as a predictor, it can be considered if the main effect is also considered.

6. Discussion

Model selection consistency is an ambitious goal to achieve when dealing with high–dimensional data. A "minimal class of models" was defined to be a set of models that should be considered as candidates for prediction of the outcome variable. A search algorithm to identify these models was developed using a simulated annealing method. Under suitable conditions, that are outlined in Theorem 1, the algorithm passes through models of interest.

A score for each predictor is given using the lasso, the elastic net and a reduced–penalty lasso. These scores are used by the search algorithm. They are not necessarily optimal but we claim that they are sensible. Other scoring methods may achieve better results. On the other hand, the scores we use here may be used for other purposes. Theoretical justification for using the elastic net to unveil predictors the lasso might have missed was also presented. A simulation study demonstrated the capability of the search algorithm to detect relevant models.

One possible limitation of the proposed algorithm is the number of tuning parameters to be chosen. In our simulation studies and data analyses, we have found the algorithm to be quite robust to the parameters' specification. For ease of applications, we now list suggested default values for some of the parameters. The tuning parameter of the lasso λ, can be chosen by cross validation. Since the subsequent use of the elastic net is to bring into surface potential predictors, relatively low value for α in (4) can be taken, say $\alpha \in (0.2, 0.5)$. A possible choice for Δ is $(0, 0.01, 0.02, ..., 1)$. As always when using simulated annealing, T and N_t may be more complicated to choose. We used for all simulations and data analyses the sequence $T = (10 \times 0.7^1, 10 \times 0.7^2, ..., 10 \times 0.7^{20})$ and $N_t = 100$. This leaves us with the decision of which models sizes κ to consider. A preliminary run with, say $\kappa = 1, 2, ..., 10$

and, for example, comparing the MSEs for $\kappa = 5$ and $\kappa = 10$, may imply if there is a substantial benefit when adding variables, before moving to larger models. Similarly to many algorithms, the proposed simulated annealing algorithm should be initiated from multiple points.

As illustrated using real data examples, a class of minimal models can be used to derive conclusions regarding the problem at hand. This is rarely the case that a researcher believes a one true model exists, especially in the $p > n$ regime. Therefore, we suggest to abandon the search for this "holy grail", and to analyze the class of minimal models instead. While retreating from the choice of a single model, and instead analyzing group of models, offers advantages, it may complicate standard data analysis in at least two ways, even when putting computational issues aside. The first is a practical one and concerns the question of which analyses should be carried out once a minimal class of models, or at least its sample version, is obtained. Model averaging can be used to estimate association parameters. Similarly, predictions from multiple models can be averaged. More precise predictions or estimates may be obtained by coupling the obtained models with weights, possibly using the empirical MSEs. More robust aggregation can be obtained by using medians instead of averages, to deal with the fact that each model consists of a different number of predictors. Another, less formal, data analysis strategy is to combine subject matter knowledge with wealth of many models. We have demonstrated such exploratory analyses in Section 5, by comparing the proportion of models each predictor, or multiple predictors, are included.

The second issue is a conceptual one. If we indeed quit from searching for a single model, i.e., a single group of predictors, what are our assumptions about the underlying mechanism that the data came from. Do we believe such a mechanism exists? One answer is that we do not need to think about how the data was created, but how can we describe the data. This, however, offers only a partial answer because we are focused on exploratory analysis, while model selection is of interest from inferential perspective as well. If more than one model describes the data adequately, which one is the true one? Does it matter? While most data are not created following one's computer program, disbelieving in the existence of a true model certainly gives rise to further questions.

It is well known that achieving good prediction and successful model selection simultaneously, in a reasonable computation time, is impossible, especially in the high–dimensional setting. We therefore suggested here to make a compromise. Our approach is not necessarily optimal for prediction, nor for model selection. However, it offers a data analysis method that takes into account the uncertainty in model selection, but ensures reasonable prediction accuracy. This method can be used for either prediction, parameter estimation or model selection.

Appendix

Appendix A. Proofs

A.1 Proof of Theorem 1

We start with the following lemma.

Lemma 4 *Assume $Y = \mu + \epsilon$ and assume also (A1)–(A4). Let $\mathcal{S}_k = \{S : |S| = k, \hat{\beta}_S = (X_S^T X_S)^{-1} X_S^T Y\}$ be the set of all models with k variables, such that $\hat{\beta}_S$, the LS estimate, is unique. Denote $S_j^\star = S \cup \{j\}, j \notin S$ for a model that includes S and additional variable j not in S. We have*

$$\max_{\substack{S \in \mathcal{S}_k \\ 1 \le j \le p}} \epsilon^T (X_{S_j^\star} \hat{\beta}_{S_j^\star} - X_S \hat{\beta}_S) = o_p(n)$$

Let ξ_j be the vector of coefficients obtained by regressing $X^{(j)}$, the j^{th} column in X, on X_S and let $\mathcal{P}_j$ be the projection operator on the subspace spanned by the part of $X^{(j)}$ which is orthogonal to the subspace spanned by X_S. That is,

$$\mathcal{P}_j = \frac{(X^{(j)} - X_S \xi_j)(X^{(j)} - X_S \xi_j)^T}{||X^{(j)} - X_S \xi_j||_2^2}.$$

Let $\hat{\beta}^j_{S_j^\star}$ be the coefficient estimate of $X^{(j)}$ in model $S_j^\star$, and let $\hat{\beta}^{-j}_{S_j^\star}$ be the coefficient estimates of the variables in S but for the model $S_j^\star$. Since $(X^{(j)} - X_S \xi_j)$ is orthogonal to the subspace spanned by the columns of X_S we have

$$\begin{aligned} X_{S_j^\star} \hat{\beta}_{S_j^\star} &= X^{(j)} \hat{\beta}^j_{S_j^\star} + X_S \hat{\beta}^{-j}_{S_j^\star} \\ &= (X^{(j)} - X_S \xi_j) \hat{\beta}^j_{S_j^\star} + X_S (\hat{\beta}^{-j}_{S_j^\star} + \xi_j \hat{\beta}^j_{S_j^\star}) \\ &= (X^{(j)} - X_S \xi_j) \hat{\beta}^j_{S_j^\star} + X_S \hat{\beta}_S \\ &= \mathcal{P}_j y + X_S \hat{\beta}_S. \end{aligned}$$

Therefore,

$$\epsilon^T (X_{S_j^\star} \hat{\beta}_{S_j^\star} - X_S \hat{\beta}_S) = \epsilon^T \mathcal{P}_j \mu + \epsilon^T \mathcal{P}_j \epsilon.$$

Now, since $||\mathcal{P}_j \mu||_2^2 \le ||\mu||_2^2 = O(n)$, we get that for all j, $\epsilon^T \mathcal{P}_j \mu = O_p(\sqrt{n})$. Next, let $Z_1, ..., Z_{p^{k+1}}$ be $N(0, \sigma^2)$ random variables and observe that the approximate size of the set $\{S_k\} \times \{1, ..., p\}$ is p^{k+1}. We have for any $a > 0$

$$P\left(\max_{\substack{S \in \mathcal{S}_k \\ 1 \le j \le p}} \frac{1}{n} \epsilon^T \mathcal{P}_j \epsilon \ge a \right) \le P\left(\max_{1 \le j \le p^{k+1}} |Z_j| \ge \sqrt{\frac{an}{\sigma^2}} \right) \le \sigma \sqrt{\frac{2(k+1)\log p + o(1)}{an}}.$$

Now, since $p = n^\alpha$ and $k = o(n/\log n)$ we get that

$$P\left(\max_{\substack{S \in \mathcal{S}_k \\ 1 \le j \le p}} \frac{1}{n} \epsilon^T \mathcal{P}_j \epsilon \ge a \right) = o(1)$$

and we are done. □

We can now move to the proof of Theorem 1. For simplicity, the notation of i as the iteration number for the current temperature t is suppressed. Note that it is enough to only consider models such that $S \cap \bar{S} = \emptyset$ and to consider $m = s_0$. Denote $Q_t(S, g, j)$ for the probability of a move in the direction of $\bar{S}$ in the next iteration, that is, the probability of choosing a variable $j \in S \cap \bar{S}^c$ and replace it with a variable $g \in S^c \cap \bar{S}$. Denote $S' = \{S/\{j\}\} \cup \{g\}$ for this new model. We have

$$\begin{aligned} &Q_t(S,g,j) \\ &\quad = Pr(S \to S') \min\left[1, \exp\left(\frac{||Y - X_S\hat{\beta}_S||_2^2 - ||Y - X_{S'}\hat{\beta}_{S'}||_2^2}{t}\right)\frac{Pr(S' \to S)}{Pr(S \to S')}\right] \end{aligned} \tag{13}$$

where $Pr(S \to S')$ is the probability of suggesting S', given current model is S. Now, since $\gamma_{min} \geq c_\gamma$ and since the maximal value in γ equals to one by definition, we have for all $S \subseteq A_\gamma$,

$$\begin{aligned} c_\gamma(h_\gamma - s_0) &\leq \sum_{u \notin S} \gamma_u \leq h_\gamma - s_0 \\ s_0 &\leq \sum_{v \in S} \frac{1}{\gamma_v} \leq \frac{s_0}{c_\gamma}. \end{aligned} \tag{14}$$

Now, by substituting (14) into (7)–(9) we get

$$\begin{aligned} Pr(S \to S') &= \frac{\gamma_g}{\sum_{u \notin S}\gamma_u}\frac{1/\gamma_j}{\sum_{v \in S}\frac{1}{\gamma_v}} \geq \frac{c_\gamma^2}{s_0(h_\gamma - s_0)}, \\ \frac{Pr(S' \to S)}{Pr(S \to S')} &= \frac{\gamma_j^2}{\gamma_g^2}\frac{\sum_{u \notin S}\gamma_u \sum_{v \in S}\frac{1}{\gamma_v}}{\sum_{u \notin S'}\gamma_u \sum_{v \in S'}\frac{1}{\gamma_v}} \geq c_\gamma^4. \end{aligned} \tag{15}$$

Next, we have

$$\begin{aligned} &\frac{1}{n}||Y - X_S\hat{\beta}_S||_2^2 - \frac{1}{n}||Y - X_{S'}\hat{\beta}_{S'}||_2^2 \\ &\quad = \frac{1}{n}\left[(Y - X_{S'}\hat{\beta}_{S'}) + (Y - X_S\hat{\beta}_S)\right]^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) \\ &\quad = \frac{1}{n}Y^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) \\ &\quad = \frac{1}{n}\mu^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) + \frac{1}{n}\epsilon^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) \\ &\quad = \frac{1}{n}\mu^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) + \Delta_n(S, S') \end{aligned} \tag{16}$$

where the second equality is due to $\hat{\beta}_S$ and $\hat{\beta}_{S'}$ being LS estimators. We get that an estimator in linear model achieves better (lower) sample MSE, if the correlation of the prediction using this estimator with Y is larger. Now, denote $S'' = S' \cup S$. We have

$$\Delta_n(S, S') = \frac{1}{n}\epsilon^T\left[(X_{S''}\hat{\beta}_{S''} - X_S\hat{\beta}_S) - (X_{S''}\hat{\beta}_{S''} - X_{S'}\hat{\beta}_{S'})\right]$$

and if we apply Lemma 4 twice we get that $\Delta_n(S, S') = o_p(1)$. Now, regarding the first term in (16),

$$\begin{aligned} \frac{1}{n}\mu^T\left(X_{S'}\hat{\beta}_{S'} - X_S\hat{\beta}_S\right) &= \frac{1}{n}\mu^T\left(\mathcal{P}_{\mathcal{S}'}y - \mathcal{P}_{\mathcal{S}}y\right) \\ &= \frac{1}{n}\left(||\mathcal{P}_{\mathcal{S}'}\mu||_2^2 - ||\mathcal{P}_{\mathcal{S}}\mu||_2^2\right) + \Delta_n'(S, S') \end{aligned} \tag{17}$$

where $\Delta_n'(S, S') = \frac{1}{n}\mu^T\left[\mathcal{P}_{\mathcal{S}'}\epsilon - \mathcal{P}_{\mathcal{S}}\epsilon\right]$. The content of the proof of Lemma 4 implies that $\Delta_n'(S, S') = o_p(1)$. Now, by (16) and (17) and since Assumption (B1) holds for t_0 we get that for large enough n

$$\frac{1}{n}\left(||Y - X_S\hat{\beta}_S||_2^2 - ||Y - X_{S'}\hat{\beta}_{S'}||_2^2\right) \geq 4t\log c_\gamma. \tag{18}$$

Now, by substituting (15) and (18) into (13) we get that for large enough n,

$$Q_{t_0}(S, g, j) \geq \frac{c_\gamma^2}{s_0(h_\gamma - s_0)}$$

for all $S \neq \bar{S}$, $j \in S \cap \bar{S}^c$ and $g \in S^c \cap \bar{S}$. (11) follows from this immediately since for any integer m and for all $S \neq \bar{S}$,

$$P_{t_0}^m(S'|S) \geq \min_{\substack{\{S: S\cap\bar{S}=\emptyset\} \\ j \in S\cap\bar{S}^c \\ g \in S^c\cap\bar{S}}}[Q_t(S, g, j)]^{s_0} \geq \left[\frac{c_\gamma^2}{s_0(h_\gamma - s_0)}\right]^{s_0}.$$

A.2 Proof of Proposition 2

Recall that the elastic net estimator $\hat{\beta}^{EN}$ minimizes

$$||Y - X\beta||_2^2 + \lambda_1|\beta| + \lambda_2||\beta||_2^2 \tag{19}$$

Now, WLOG assume that $\hat{\beta}^{EN}$ is a solution such that $\hat{\beta}_1^{EN} > 0$. For convenience, we omit the "EN" superscript from now on (i.e., $\hat{\beta} = \hat{\beta}^{EN}$). Define the subspace

$$\mathcal{B} := \{\beta : \forall i \neq 1, 2 \;\; \beta_i = \hat{\beta}_i, \;\; \beta_1 = \tau\hat{\beta}_1, \;\; \beta_2 = (1 - \tau)\hat{\beta}_1\}. \tag{20}$$

If the minimum of (19) over $\mathcal{B}$ is obtained for $\tau \neq 1$, then given that $X^{(1)}$ is part of the elastic net model, predictor $X^{(2)}$ is also part of this model.

WLOG, write down X as $X = (X_{(12)} \quad X_{-(12)})$ where $X_{(12)} = (X^{(1)} \quad X^{(2)})$ are the first two columns of X and $X_{-(12)}$ are the rest of its columns. Similarly, we have $\beta^T = (\beta_{(12)}^T \quad \beta_{-(12)}^T)$ where $\beta_{(12)}$ is the first two entries in the vector β and $\beta_{-(12)}$ is the rest of the vector. Define $\tilde{Y} = Y - X_{-(12)}\beta_{-(12)}$. We can rewrite (19) as

$$||\tilde{Y} - X_{(12)}\beta_{(12)}||_2^2 + \lambda_1(|\beta_{-(12)}| + |\beta_{(12)}|) + \lambda_2(||\beta_{-(12)}||_2^2 + ||\beta_{(12)}||_2^2) \tag{21}$$

If the minimum of (21), on $\mathcal{B}$, is achieved at $0 < \tau^* < 1$ then $\hat{\beta}_2$ must be non zero. Minimizing (21) on $\mathcal{B}$ is essentially minimizing

$$-2\tilde{Y}^T X_{(12)}\beta_{(12)} + ||X_{(12)}\beta_{(12)}||_2^2 + \lambda_2||\beta_{(12)}||_2^2 \tag{22}$$

on $\mathcal{B}$. Now, by the definition of $\mathcal{B}$ in (20) and using simple algebra we get that (22) equals to

$$2\left[\hat{\beta}_1\tilde{Y}^T\left(\tau(X^{(2)}-X^{(1)})-X^{(2)}\right)-\hat{\beta}_1^2\tau(1-\tau)(1-\rho)+\lambda_2\hat{\beta}_1^2\left(\frac{1}{2}-\tau(1-\tau)\right)\right].$$

This is a quadratic function of τ, and by equating its derivative to zero we get that

$$\tau^*=\frac{1}{2}-\frac{\tilde{Y}^T(X^{(2)}-X^{(1)})}{2\hat{\beta}_1(\lambda_2+1-\rho)}$$

is the minimizer of (19) (the coefficient of the quadratic term is positive). Note that for $X^{(2)}=X^{(1)}$ we get the expected $\tau^*=\frac{1}{2}$ solution. Note also that this reveals no information regarding the lasso where $\lambda_2=0$. Next, we get that $0<\tau^*<1$ if

$$\left|\frac{\tilde{Y}^T(X^{(2)}-X^{(1)})}{\hat{\beta}_1(\lambda_2+1-\rho)}\right|<1. \tag{23}$$

Since $||X^{(2)}-X^{(1)}||_2^2=2(1-\rho)$ we have

$$|\tilde{Y}^T(X^{(2)}-X^{(1)})|\leq\sum_{i=1}^{n}|\tilde{Y}_i||X_i^{(2)}-X_i^{(1)}|\leq||\tilde{Y}||_2\sqrt{2(1-\rho)},$$

using the triangle inequality and then Cauchy–Schwartz inequality. It is assumed that $\hat{\beta}_1\geq c_\beta>0$ and it is known that $||\tilde{Y}||_2\leq||Y||_2$. Therefore, we may rewrite (23) as

$$\frac{\sqrt{2}||Y||_2\sqrt{1-\rho}}{c_\beta(\lambda_2+1-\rho)}<1.$$

Now, Denote $t=\sqrt{1-\rho}, u=\frac{||Y||_2}{c_\beta}$, we have

$$t^2-\sqrt{2}ut+\lambda_2>0.$$

For $\lambda_2>\frac{1}{2}u^2$, we get the result we want for all ρ's. For $\lambda_2<\frac{u^2}{2}$ we have

$$\sqrt{1-\rho}>\frac{1}{\sqrt{2}}(u+\sqrt{u^2-2\lambda_2}), \tag{24}$$

$$\sqrt{1-\rho}<\frac{1}{\sqrt{2}}(u-\sqrt{u^2-2\lambda_2}). \tag{25}$$

The RHS of (24) is larger than 1 if $\lambda_2<\sqrt{2}u-1$. That is, there is no suitable ρ for this case. The RHS of (25) is always positive, and for the same condition $\lambda_2<\sqrt{2}u-1$, it also meaningful, i.e., $(u-\sqrt{u^2-2\lambda_2})<\sqrt{2}$ and in terms of ρ,

$$\rho>1-\frac{1}{2}(u-\sqrt{u^2-2\lambda_2})^2$$

or alternatively,

$$\rho>1-\frac{u^2}{2}\left(1-\sqrt{1-\frac{2\lambda_2}{u}}\right)^2$$

and by Taylor expansion for $2\lambda_2/u$ we get

$$\rho>1-\frac{\lambda_2^2}{2u^2}$$

■

A.3 Proof of Theorem 3

The proof is similar to the proof of Proposition 2. Let $\hat{\beta}=\hat{\beta}^{EN}$ be the elastic net estimator and denote $\hat{\beta}_M$ for the values in $\hat{\beta}$ corresponding to the set of predictors M. We can partition the set of potential predictors $\{1,2,...,p\}$ to four disjoint subsets: $M^{(-)}$; $M_1\cap M_2^c$; $M_1^c\cap M_2$ and $M_1\cap M_2$. We replace (20) with

$$\mathcal{B}:=\{\beta:\beta_{M^{(-)}}=\hat{\beta}_{M^{(-)}}\ \ \beta_{M_1\cap M_2}=\hat{\beta}_{M_1\cap M_2}, \tag{26}$$

$$\beta_{M_1\cap M_2^c}=\tau\hat{\beta}_{M_1\cap M_2^c},\ \ \beta_{M_1^c\cap M_2}=(1-\tau)\Theta'\hat{\beta}_{M_1\cap M_2^c}\}. \tag{27}$$

where β_M is defined as the values in $\hat{\beta}$ corresponding to the set M and Θ' is the matrix of coefficients obtained from regressing $X_{M_1\cap M_2^c}$ on $X_{M_1^c\cap M_2}$. We define Θ to be an augmented version of Θ', which we obtain by regressing X_{M_1} on X_{M_2}. That is,

$$X_{M_2}\Theta=\mathcal{P}_{M_2}X_{M_1} \tag{28}$$

Note that on $\mathcal{B}$,

$$X\beta=\tilde{X}\hat{\beta}_{M^{(-)}}+\tau X_{M_1}\hat{\beta}_{M_1}+(1-\tau)X_{M_2}\Theta\hat{\beta}_{M_1}$$

Recalling that $\tilde{Y}=Y-\tilde{X}\hat{\beta}_{M^{(-)}}$, minimizing (3) on $\mathcal{B}$ is equivalent to minimize

$$\begin{aligned}||\tilde{Y}-\tau X_{M_1}\hat{\beta}_{M_1}-(1-\tau)X_{M_2}\Theta\hat{\beta}_{M_1}||_2^2+\lambda_1[\tau||\hat{\beta}_{M_1}||_1+(1-\tau)||\Theta\hat{\beta}_{M_1}||_1]\\+\lambda_2[\tau^2||\hat{\beta}_{M_1}||_2^2+(1-\tau)^2||\Theta\hat{\beta}_{M_1}||_2^2]\end{aligned} \tag{29}$$

as a function of τ. Using a first–order condition and substituting (28) we find that (29) is minimized for

$$\tau^*=\frac{-(\tilde{Y}-\mathcal{P}_{M_2}X_{M_1}\hat{\beta}_{M_1})^T(I-\mathcal{P}_{M_2})X_{M_1}\hat{\beta}_{M_1}+\frac{\lambda_1}{2}(||\hat{\beta}_{M_1}||_1-||\Theta\hat{\beta}_{M_1}||_1)-\lambda_2||\Theta\hat{\beta}_{M_1}||_2^2}{||(I-\mathcal{P}_{M_2})X_{M_1}\hat{\beta}_{M_1}||_2^2-\lambda_2||\hat{\beta}_{M_1}||_2^2-\lambda_2||\Theta\hat{\beta}_{M_1}||_2^2}. \tag{30}$$

Before we continue, note that if $X_2=X_1$ then Θ is the identity matrix and $\mathcal{P}_{M_2}X_{M_1}=X_1$. Substituting these facts into (30), we get that $\tau^*=\frac{1}{2}$ as one might expect. Same result is obtained for the case $M_2\subseteq M_1$.

As it can be seen in (26), the coordinates of $\hat{\beta}_{M_2}$ are all different than zero if $\tau^*<1$. Now, since $\mathcal{P}_{M_2}(I-\mathcal{P}_{M_2})=0$ we get that $\tau^*<1$ if

$$\begin{aligned}-\tilde{Y}^T(I-\mathcal{P}_{M_2})X_{M_1}\hat{\beta}_{M_1}+||(I-\mathcal{P}_{M_2})X_{M_1}\hat{\beta}_{M_1}||_2^2-\frac{\lambda_1}{2}||\Theta\hat{\beta}_{M_1}||_1\\>-\frac{\lambda_1}{2}||\hat{\beta}_{M_1}||_1-\lambda_2||\hat{\beta}_{M_1}||_2^2\end{aligned}$$

which is certainly true if

$$\tilde{Y}^T\mathcal{P}_{M_2}X_{M_1}\hat{\beta}_{M_1}-\frac{\lambda_1}{2}||\Theta\hat{\beta}_{M_1}||_1>-\frac{\lambda_1}{2}||\hat{\beta}_{M_1}||_1-\lambda_2||\hat{\beta}_{M_1}||_2^2+\tilde{Y}^TX_{M_1}\hat{\beta}_{M_1} \tag{31}$$

which is true if the condition in (12) is fulfilled for the appropriate c_1. ■

Appendix B. Supplementary table for Section 5.2

Predictor	Description
prec	Mean annual precipitation in inches
jant	Mean January temperature in degrees F
jult	Mean July temperature in degrees F
age65	Percentage of population aged 65 or older
pphs	Population per household
educ	Median school years completed by those over 22
h **facl**	Percentage of housing units which are sound and with all facilities
dens	Population per square mile in urbanized areas
nwht	Percentage of non–white population in urbanized areas
wtcl	Percentage of employed in white collar occupations
linc	Percentage of families with income $<$ 3,000 dollars in urbanized areas
HC	Relative pollution potential of hydrocarbon
NOx	Relative pollution potential of nitric oxides
SUL	Relative pollution potential of sulfur dioxide
hum	Annual average percentage of relative humidity at 1pm

Editor: Geoff Holmes

Abstract

WEKA is a widely used, open-source machine learning platform. Due to its intuitive interface, it is particularly popular with novice users. However, such users often find it hard to identify the best approach for their particular dataset among the many available. We describe the new version of *Auto-WEKA*, a system designed to help such users by automatically searching through the joint space of WEKA's learning algorithms and their respective hyperparameter settings to maximize performance, using a state-of-the-art Bayesian optimization method. Our new package is tightly integrated with WEKA, making it just as accessible to end users as any other learning algorithm.

Keywords: Hyperparameter Optimization, Model Selection, Feature Selection

1. The Principles Behind Auto-WEKA

The WEKA machine learning software (Hall et al., 2009) puts state-of-the-art machine learning techniques at the disposal of even novice users. However, such users do not typically know how to choose among the dozens of machine learning procedures implemented in WEKA and each procedure's hyperparameter settings to achieve good performance.

Auto-WEKA[1] addresses this problem by treating all of WEKA as a single, highly parametric machine learning framework, and using Bayesian optimization to find a strong instantiation for a given dataset. Specifically, it considers the combined space of WEKA's learning algorithms $\mathcal{A} = \{A^{(1)}, \ldots, A^{(k)}\}$ and their associated hyperparameter spaces $\Lambda^{(1)}, \ldots, \Lambda^{(k)}$ and aims to identify the combination of algorithm $A^{(j)} \in \mathcal{A}$ and hyperparameters $\lambda \in \Lambda^{(j)}$ that minimizes cross-validation loss,

$$A^*_{\lambda^*} \in \operatorname*{argmin}_{A^{(j)} \in \mathcal{A}, \lambda \in \Lambda^{(j)}} \frac{1}{k} \sum_{i=1}^{k} \mathcal{L}\left(A^{(j)}_{\lambda}, \mathcal{D}^{(i)}_{\text{train}}, \mathcal{D}^{(i)}_{\text{test}}\right),$$

where $\mathcal{L}(A_\lambda, \mathcal{D}^{(i)}_{\text{train}}, \mathcal{D}^{(i)}_{\text{test}})$ denotes the loss achieved by algorithm A with hyperparameters λ when trained on $\mathcal{D}^{(i)}_{\text{train}}$ and evaluated on $\mathcal{D}^{(i)}_{\text{test}}$. We call this the *combined algorithm selection and hyperparameter optimization (CASH)* problem. CASH can be seen as a blackbox function optimization problem: determining $\operatorname{argmin}_{\boldsymbol{\theta} \in \boldsymbol{\Theta}} f(\boldsymbol{\theta})$, where each configuration $\boldsymbol{\theta} \in \boldsymbol{\Theta}$ comprises the choice of algorithm $A^{(j)} \in \mathcal{A}$ and its hyperparameter settings $\lambda \in \Lambda^{(j)}$. In this formulation, the hyperparameters of algorithm $A^{(j)}$ are *conditional* on $A^{(j)}$ being selected. For a given $\boldsymbol{\theta}$ representing algorithm $A^{(j)} \in \mathcal{A}$ and hyperparameter settings $\lambda \in \Lambda^{(j)}$, $f(\boldsymbol{\theta})$ is then defined as the cross-validation loss $\frac{1}{k} \sum_{i=1}^{k} \mathcal{L}(A^{(j)}_{\lambda}, \mathcal{D}^{(i)}_{\text{train}}, \mathcal{D}^{(i)}_{\text{test}})$.[2]

Bayesian optimization (see, e.g., Brochu et al., 2010), also known as sequential model-based optimization, is an iterative method for solving such blackbox optimization problems. In its n-th iteration, it fits a probabilistic model based on the first $n-1$ function evaluations $\langle \boldsymbol{\theta}_i, f(\boldsymbol{\theta}_i) \rangle_{i=1}^{n-1}$, uses this model to select the next $\boldsymbol{\theta}_n$ to evaluate (trading off exploration of new parts of the space *vs* exploitation of regions known to be good) and evaluates $f(\boldsymbol{\theta}_n)$. While Bayesian optimization based on Gaussian process models is known to perform well for low-dimensional problems with numerical hyperparameters (see, e.g., Snoek et al., 2012), tree-based models have been shown to be more effective for high-dimensional, structured, and partly discrete problems (Eggensperger et al., 2013), such as the highly conditional space of WEKA's learning algorithms and their corresponding hyperparameters we face here.[3] Thornton et al. (2013) showed that tree-based Bayesian optimization methods yielded the best performance in Auto-WEKA, with the random-forest-based SMAC (Hutter et al., 2011) performing better than the tree-structured Parzen estimator, TPE (Bergstra et al., 2011). Auto-WEKA uses SMAC to determine the classifier with the best performance on the given data.

2. Auto-WEKA 2.0

Since the initial release of a usable research prototype in 2013, we have made substantial improvements to the Auto-WEKA package described by Thornton et al. (2013). At a prosaic level, we have fixed bugs, improved tests and documentation, and updated the software to work with the latest versions of WEKA and Java. We have also added four major features.

First, we now support regression algorithms, expanding Auto-WEKA beyond its previous focus on classification (starred entries in Fig. 1). Second, we now support the optimization of all performance metrics WEKA supports. Third, we now natively support parallel runs (on a single machine) to find good configurations faster and save the N best configurations of each run instead of just the single best. Fourth, Auto-WEKA 2.0 is now fully integrated with WEKA. This is important, because the crux of Auto-WEKA lies in its simplicity: providing a push-button interface that requires no knowledge about the available learning algorithms or their hyperparameters, asking the user to provide, in addition to the dataset to be processed, only a memory bound (1 GB by default) and the overall time

1. Thornton et al. (2013) first introduced Auto-WEKA and empirically demonstrated state-of-the-art performance. Here we describe an improved and more broadly accessible implementation of Auto-WEKA, focussing on usability and software design.

2. In fact, on top of machine learning algorithms and their respective hyperparameters, we also include attribute selection methods and their respective hyperparameters in the configurations $\boldsymbol{\theta}$, thereby jointly optimizing over their choice and the choice of algorithms.

3. Conditional dependencies can also be accommodated in the Gaussian process framework (Hutter and Osborne, 2013; Swersky et al., 2013), but currently, tree-based methods achieve better performance.

Figure 1: Learners and methods supported by Auto-WEKA 2.0, along with number of hyperparameters $|\Lambda|$. Every learner supports classification; starred learners also support regression.

budget available for the entire learning process.[4] The overall budget is set to 15 minutes by default to accommodate impatient users; longer runs allow the Bayesian optimizer to search the space more thoroughly; we recommend at least several hours for production runs.

The usability of the earlier research prototype was hampered by the fact that users had to download Auto-WEKA manually and run it separately from WEKA. In contrast, Auto-WEKA 2.0 is now available through WEKA's package manager. Users do not need to install software separately; everything is included in the package and installed automatically upon request. After installation, Auto-WEKA 2.0 can be used in two different ways:

1. *As a meta-classifier:* Auto-WEKA can be run like any other machine learning algorithm in WEKA: via the GUI, the command-line interface, or the public API. Figure 2 shows how to run it from the command line.
2. *Through the Auto-WEKA tab:* This provides a customized interface that hides some of the complexity. Figure 3 shows the output of an example run.

Source code for Auto-WEKA is hosted on GitHub (`https://github.com/automl/autoweka`) and is available under the GPL license (version 3). Releases are published to the WEKA package repository and available both through the WEKA package manager and from the Auto-WEKA project website (`http://automl.org/autoweka`). A manual describes how to use the WEKA package and gives a high-level overview for developers; we also provide lower-level Javadoc documentation. An issue tracker on GitHub, JUnit tests and the continuous integration system Travis facilitate bug tracking and correctness of the code. Since its release on March 1, 2016, Auto-WEKA 2.0 has been downloaded more than 15 000 times, with an average of about 400 downloads per week.

4. Internally, to avoid using all its budget for executing a single slow learner, Auto-WEKA limits individual runs of any learner to 1/12 of the overall budget; it further limits feature search to 1/60 of the budget.

```
java -cp autoweka.jar weka.classifiers.meta.AutoWEKAClassifier
    -timeLimit 5 -t iris.arff -no-cv
```

Figure 2: Command-line call for running Auto-WEKA with a time limit of 5 minutes on training dataset `iris.arff`. Auto-WEKA performs cross-validation internally, so we disable WEKA's cross-validation (`-no-cv`). Running with `-h` lists the available options.

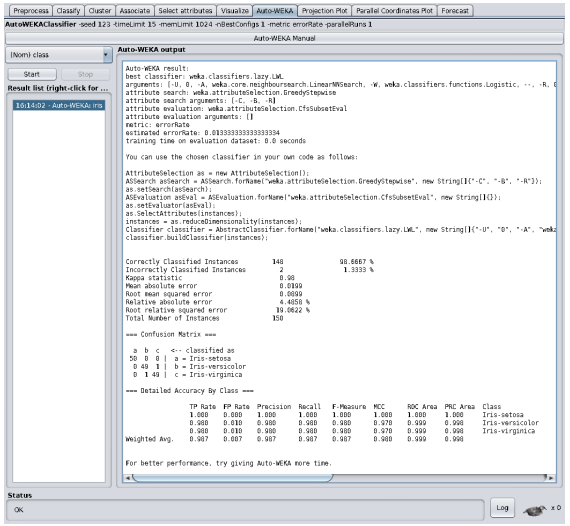

Figure 3: Example Auto-WEKA run on the iris dataset. The resulting best classifier along with its parameter settings is printed first, followed by its performance. While Auto-WEKA runs, it logs to the status bar how many configurations it has evaluated so far.

3. Related Implementations

Auto-WEKA was the first method to use Bayesian optimization to automatically instantiate a highly parametric machine learning framework at the push of a button. This *automated machine learning (AutoML)* approach has recently also been applied to Python and scikit-learn (Pedregosa et al., 2011) in Auto-WEKA's sister package, *Auto-sklearn* (Feurer et al., 2015). Auto-sklearn uses the same Bayesian optimizer as Auto-WEKA, but comprises a smaller space of models and hyperparameters, since scikit-learn does not implement as many different machine learning techniques as WEKA; however, Auto-sklearn includes additional meta-learning techniques.

It is also possible to optimize hyperparameters using WEKA's own grid search and MultiSearch packages. However, these packages only permit tuning one learner and one filtering method at a time. Grid search handles only one hyperparameter. Furthermore, hyperparameter names and possible values have to be specified by the user.

Abstract

POMDPs.jl is an open-source framework for solving Markov decision processes (MDPs) and partially observable MDPs (POMDPs). POMDPs.jl allows users to specify sequential decision making problems with minimal effort without sacrificing the expressive nature of POMDPs, making this framework viable for both educational and research purposes. It is written in the Julia language to allow flexible prototyping and large-scale computation that leverages the high-performance nature of the language. The associated JuliaPOMDP community also provides a number of state-of-the-art MDP and POMDP solvers and a rich library of support tools to help with implementing new solvers and evaluating the solution results. The most recent version of POMDPs.jl, the related packages, and documentation can be found at `https://github.com/JuliaPOMDP/POMDPs.jl`.

Keywords: POMDP, MDP, sequential decision making, Julia, open-source

1. Introduction

Recent advances in algorithms and hardware make partially observable Markov decision processes (POMDPs) a viable model for a variety of applications ranging from aircraft collision avoidance (Wolf and Kochenderfer, 2011) to spoken dialog systems (Young et al., 2013). In general, POMDPs can be applied to a wide variety of problems that include state and dynamic uncertainties as well as continuous and discrete domains (Kochenderfer, 2015). State-of-the-art algorithms like POMCP (Silver and Veness, 2010) and MCVI (Bai et al., 2010) can solve problems with millions of states and with continuous state spaces. However, working with POMDPs is challenging due to their probabilistic nature and the complexity of the algorithms used to solve them.

POMDPs.jl is an interface for solving POMDPs written in the Julia programming language (Bezanson et al., 2012). It is designed to support users in three different roles: 1) defining problems, 2) creating solvers, and 3) running experiments. The goals of POMDPs.jl are to allow users in these roles to easily build on code written by others through a single unified interface, simplify the process of benchmarking algorithms against one another, and encourage growth of the software ecosystem through open-source contributions. This ecosystem is organized as an online community, JuliaPOMDP. The centerpiece of the community is the POMDPs.jl package — a unified, implementation-free interface providing access to a growing collection of state-of-the-art solvers, benchmark problems, and libraries of support tools. An outline of the POMDPs.jl architecture and its core concepts are shown in Fig. 1. POMDPs.jl provides abstract types corresponding to each of the core concepts and a list of functions that defines a standard interface. Users implement concrete types that represent problems or solvers and specify their behavior by defining methods.

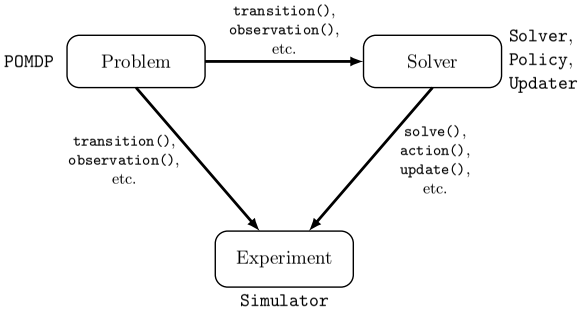

Figure 1: POMDPs.jl framework architecture. The three main concepts in the architecture: problem, solver and experiment are supported by abstract types in the framework as well as necessary function implementations.

2. Existing Frameworks and Related Work

There are a number of frameworks that are capable of solving decision making problems in fully observable settings, but few accommodate partially observable domains. The most closely related frameworks to POMDPs.jl are APPL (Kurniawati et al.), AI-Toolbox (Bargiacchi), and ZMDP (Smith) in that they can handle problems with partial observability. However, these frameworks either support only a generative model problem definition (APPL for MCVI) or explicit problem definitions using probability tables (APPL for SARSOP, AI-Toolbox and ZMDP), but not both. This limits the flexibility of the frameworks to handle both discrete and continuous domains. While the fact that these frameworks are all written in C++ leads to performant code, it makes prototyping slow and challenging for new users. It is also comparatively more difficult to extend these frameworks to new domains and implement new algorithms due to their complicated hierarchies and lack of modularity in the source code. A number of reinforcement learning frameworks exist that are designed to be easily extendable such as BURLAP (Diuk et al., 2008), RLPy (Geramifard et al., 2015), and rllab (Duan et al., 2016). However, these frameworks primarily cater to problems that are fully observable.

3. Why POMDPs.jl?

POMDPs.jl aims to simplify the task of writing problems, implementing solvers, and running experiments in the context of POMDPs. The advantages of POMDPs.jl are as follows:
Simplicity: The POMDPs.jl interface provides a minimal set of types and functions necessary to define a problem, a solver, and experiments in a partially observable setting. The POMDPs.jl interface contains 10 abstract types and 37 functions, of which, each user will define a subset for their problem. For example, if a user wants to solve an MDP rather than a POMDP, they do not need to implement functions involving observations. Examples of function requirements for the MCTS and SARSOP solvers are shown in Table 1.

Table 1: A section of the function table for two solvers that use POMDPs.jl

functions	`states`	`actions`	`observations`	`transition`	`observation`	`reward`	⋯
MCTS	n/a	✓	n/a	✓	n/a	✓	⋯
SARSOP	✓	✓	✓	✓	✓	✓	
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮

Expressiveness: The POMDPs.jl interface provides flexibility to handle problems that are fully or partially observable, problems that are continuous or discrete, and problems with infinite and finite horizons. Solvers may leverage explicitly-defined distributions, if they are available, or only use samples from a generative model. Moreover, all POMDPs.jl problems can be defined in code. Julia makes it easy to prototype new code, removing the need for problem specification or solver configuration files written in another format.
Extensibility: The interface allows new algorithms to be implemented with minimal effort. By providing an expressive interface to a POMDP model, POMDPs.jl allows algorithm writers to access any component of the model with simple function calls. Since all solvers are implemented within a unified framework, POMDPs.jl also allows for standardized benchmarking across algorithms. It is also simple to call programs written in other languages from Julia, such as Python and C, allowing existing solvers to be wrapped using POMDPs.jl.
Usability: A number of ready-to-use solvers supporting the POMDPs.jl interface are available from the JuliaPOMDP community. To install the SARSOP solver, for example, the user only needs to run `POMDPs.add("SARSOP")`, and the package manager will download and compile any dependencies on all three major platforms — Linux, Windows, and OS X.

4. Concepts and Use Case Examples

This section describes the three main concepts outlined in Fig. 1, namely the problem, the solver, and the experiment. The POMDPs.jl interface consists of several abstract types and a set of functions that support these concepts.
Problem: The problem defines the MDP or POMDP model to be solved. Below is a definition for the Tiger POMDP (Kaelbling et al., 1998).

```
immutable TigerPOMDP <: POMDP{Bool, Int64, Bool}
    p_correct::Float64      # probability of hearing the tiger correctly
    discount::Float64       # discount factor
end
```

The `TigerPOMDP` type inherits from the abstract `POMDP` type (part of the POMDPs.jl interface), which is parametrized by the state, action, and observation types. In this case, the state is represented by the native `Bool` type, but, in general, these types may be user-defined. The same flexibility is available for the other components of the problem, giving the user the flexibility to define their problem in the form of their choosing.
Solver: A solver implementation typically requires three type definitions: a `Solver` that contains the parameters that define solver behavior, a `Policy` that defines a mapping from beliefs to actions, and an `Updater` that defines how the belief is updated with new observations. An example of a QMDP (Littman et al., 1995) policy type is shown below.

```
type QMDPPolicy{Action} <: Policy
    alphas::Matrix{Float64}     # policy alpha vectors
    action_map::Vector{Action} # indices to actions
    pomdp::POMDP                # POMDP model
end
```

A solver implementation usually includes three top-level functions: `solve`, that creates a policy for the problem given the solver, `action`, that emits an action for a belief based on the policy, and `update`, that updates the belief based on the action taken and the observation received, given the updater.
Experiment: Experiments combine problems and solvers to evaluate the quality of a solver policy. For example, the experimenter might create a simulator type, `Sim`, and a corresponding `simulate` function (an important part of the main loop is shown below).

```
function simulate(sim::Sim, pomdp, policy, updater, initial_dist)
   ...
   for t in 1:sim.max_steps
       a = action(policy, b)
       sp = rand(sim.rng, transition(pomdp, s, a))
       r_total += discount(pomdp)^t*reward(pomdp, s, a, sp)
       o = rand(sim.rng, observation(pomdp, s, a, sp))
       b = update(updater, b, a, o)
       ...
```

A simulation can then be run as follows:

```
using QMDP, POMDPModels, POMDPToolbox # import JuliaPOMDP packages
pomdp = TigerPOMDP()                  # initialize the tiger problem
solver = QMDPSolver()                 # initialize QMDP solver
policy = solve(solver, pomdp)         # compute a policy
r = simulate(Sim(), pomdp, policy, updater(policy), DiscreteBelief(2))
```

5. Conclusion

POMDPs.jl is a high level interface for working with POMDPs that allows users to easily define their problems, create new solvers, and run experiments. This manuscript provides a brief overview of the framework and its features; extensive documentation and examples for this software package can be found at `https://github.com/JuliaPOMDP/POMDPs.jl`. Future work includes integrating Julia's shared memory parallelism into sampling based solvers to improve computational efficiency, as well as introducing support for reinforcement learning algorithms.

Abstract

This article introduces a class of first-order stationary time-varying Pitman-Yor processes. Subsuming our construction of time-varying Dirichlet processes presented in (Caron et al., 2007), these models can be used for time-dynamic density estimation and clustering. Our intuitive and simple construction relies on a generalized Pólya urn scheme. Significantly, this construction yields marginal distributions at each time point that can be explicitly characterized and easily controlled. Inference is performed using Markov chain Monte Carlo and sequential Monte Carlo methods. We demonstrate our models and algorithms on epidemiological and video tracking data.

1. Introduction

This paper introduces a class of dependent Pitman-Yor processes[1] that can be used for time-varying density estimation and classification in a variety of settings. The construction of this class of dependent Pitman-Yor processes is in terms of a generalised Pólya urn scheme where dependencies between distributions that evolve over time, for instance, are induced by simple urn-like operations on counts and the parameters to which they are associated.

Our Pólya urn for time-varying Pitman-Yor processes is expressive per dependent slice, as each is represented by a Pitman-Yor process (infinite) mixture distribution of which the component densities may as usual take any form. The dependency-inducing mechanism is also flexible and easy to control, a claim supported by an applied literature (see Gasthaus et al. (2008); Ji and West (2009); Ozkan et al. (2009); Bartlett et al. (2010); Neiswanger et al. (2014); Jaoua et al. (2014) among others) that has grown around the subsumed version of this work (Caron et al., 2007). The generalised Pólya urn dependent Dirichlet process can be recovered by a specific settings of the parameters in this generalized model.

Most of the emphasis of this paper is on defining the model and describing its statistical characteristics. While additional model complexity does not automatically beget useful expressivity, in the case of this model and others like it (see Lin et al. (2010) for example), we assert that it does. For example, in applications like fully unsupervised visual object detection and tracking there is an increasing need for top-down models that introduce coherence through bias towards physical plausibility. While dependent density estimation techniques abound in the literature, there are few that possess the right combination of interpretability and flexibility to fill the role of top-down priors for such complex applications. We illustrate experimentally that this model succeeds at filling this role.

The remainder of the paper is organized as follows: In Section 2 we review Pitman Yor processes and stationarity. In Section 3, we present our main contribution, first-order stationary Pitman-Yor mixture models. Section 4 describes sequential Monte Carlo (SMC) and Markov chain Monte Carlo (MCMC) algorithms for inference. We demonstrate the models and algorithms in Section 5 on various applications. Finally we discuss some potential extensions of this class of models in Section 6 and Appendix A.

2. Background

Pitman-Yor processes include a wide class of distributions on random measures such as the popular Dirichlet process (Ferguson, 1973) and the finite symmetric Dirichlet-multinomial prior (Green and Richardson, 2001); see for example (Pitman and Yor, 1997). In particular, Dirichlet process mixtures can be interpreted as a generalization of finite mixture models to infinite mixture models and have become very popular over the past few years in statistics and related areas to perform clustering and density estimation (Escobar and West, 1995; Müller and Quintana, 2004; Teh and Jordan, 2010). More general Pitman-Yor processes enjoy greater flexibility and have been shown to provide a better fit to text or image data due to their ability to capture power-law properties of such data (Teh, 2006).

However, there are many situations where we cannot assume that the distribution of the observations is fixed and instead this latter evolves over time. For example, in a clustering

1. A preliminary version of this work has been presented as a conference paper (Caron et al., 2007)

application, the number of clusters and the locations of these clusters may vary over time. This situation also occurs in spatial statistics where the spatial distribution of localized events such as diseases or earthquakes changes over time (Hall et al., 2006). To address such problems, this article introduces a novel class of time-varying first-order stationary Pitman-Yor process mixtures; that is processes which have marginals following the same Pitman-Yor process mixture.

We first briefly recall here standard results about Pitman-Yor process mixtures. Let $t = 1, 2, ...$ denote a discrete-time index. Note that this index is not needed in this section but will become essential in what is to come. For any generic sequence $\{x_m\}$, we define $x_{k:l} = (x_k, x_{k+1}, \ldots, x_l)$. For ease of presentation, we assume that we receive a fixed number n of observations at each time t denoted $\mathbf{z}_t = \mathbf{z}_{1:n,t}$ which are independent and identically distributed samples from

$$F_t(\cdot) = \int_{\mathcal{Y}} f(\cdot|\mathbf{y}) d\mathbb{G}_t(\mathbf{y}) \tag{1}$$

where $f(\cdot|\mathbf{y})$ is the mixed probability density function and $\mathbb{G}_t$ is the mixing distribution distributed according to a Pitman-Yor process

$$\mathbb{G}_t \sim \mathcal{PY}(\alpha, \theta, \mathbb{H}). \tag{2}$$

Here $\mathbb{H}$ is a base probability measure and the real parameters α and θ satisfy either

$$0 \leq \alpha < 1 \text{ and } \theta > -\alpha \tag{3}$$
$$\text{or } \alpha < 0 \text{ and } \theta = -m\alpha \text{ for } m \in \mathbb{N}. \tag{4}$$

The case $\alpha = 0$ and $\theta > 0$ corresponds to the Dirichlet process denoted $DP(\theta, \mathbb{H})$. The random measure $\mathbb{G}_t$ satisfies the following *stick-breaking* representation (Sethuraman, 1994; Pitman, 1996)

$$\mathbb{G}_t = \sum_{j=1}^{\infty} V_{j,t} \delta_{U_{j,t}} \tag{5}$$

with $V_{j,t} = \beta_{j,t} \prod_{i=1}^{j-1}(1 - \beta_{i,t})$, $\beta_{j,t} \overset{\text{ind}}{\sim} \mathcal{B}(1 - \alpha, \theta + j\alpha)$, $U_{j,t} \overset{\text{iid}}{\sim} \mathbb{H}$ where $\mathcal{B}$ denotes the Beta distribution. From (1), we have equivalently, for $k = 1, \ldots, n$, the following hierarchical model

$$\mathbf{y}_{k,t}|\mathbb{G}_t \overset{\text{iid}}{\sim} \mathbb{G}_t, \tag{6}$$
$$\mathbf{z}_{k,t}|\mathbf{y}_{k,t} \overset{\text{iid}}{\sim} f(\cdot|\mathbf{y}_{k,t}). \tag{7}$$

We can also reformulate the Pitman-Yor process mixture by integrating out the mixing measure $\mathbb{G}_t$ and introducing allocation variables $\mathbf{c}_t = c_{1:n,t}$. For any $j \in \mathcal{J}(\mathbf{c}_t)$, where $\mathcal{J}(\mathbf{c}_t)$ is the set of unique values in $\mathbf{c}_t$, we have

$$U_{j,t} \overset{\text{iid}}{\sim} \mathbb{H}, \tag{8}$$
$$\mathbf{z}_{k,t}|U_{c_{k,t},t} \sim f(\cdot|U_{c_{k,t},t}).$$

For convenience, we label here the clusters by their order of appearance. We set $c_{1,1} = 1$, $K_1 = 1$ and $\mathbf{m}_1^1 = m_{1:K_1,1}^1$ a vector of size K_1. Then, at time $t = 1$, for $k = 2, \ldots, n$ the

following Pólya urn model describes the predictive distribution of a new allocation variable (Blackwell and MacQueen, 1973; Pitman, 1996)

w.p. $\frac{m_{i,1}^1 - \alpha}{k - 1 + \theta}$, $i \in \{1, \ldots, K_1\}$ set $c_{k,1}^1 = i$, $m_{i,1}^1 = m_{i,1}^1 + 1$,
w.p. $\frac{K_1\alpha + \theta}{k - 1 + \theta}$, set $K_1 = K_1 + 1$, $c_{k,1}^1 = K_1$, $m_{K_1,1}^1 = 1$,

where the abbreviation 'w.p.' stands for 'with probability'.

The sequence associated with $c_{1,t}, \ldots, c_{n,t}$ is exchangeable and induces a random partition of n, that is an unordered collection of $k \leq n$ positive integers with sum n or, equivalently, a random allocation of n unlabeled points into some random number of unlabeled clusters (materialized by a color for example); each cluster containing at least one point. A common way to represent a partition of n is by the number of terms of various sizes; that is the vector of counts $(a_1, \ldots, a_n)$ where $\sum_{j=1}^n a_j = k$ and $\sum_{j=1}^n j a_j = n$. Here a_1 is the number of terms of size 1, a_2 is the number of terms of size 2, etc. Following (Antoniak, 1974), we say that $\mathbf{c}_t \in C(a_{1:n})$ if there are a_1 distinct values of $\mathbf{c}_t$ that occur only once, a_2 that occur twice, etc. It can be shown that $\Pr(\mathbf{c}_t \in C(a_{1:n})) = P_n(a_{1:n})$ is given by the two-parameter Ewens sampling formula (Pitman, 1995)

$$P_n(a_1, \ldots, a_n) = \frac{n! \prod_{i=1}^{\sum_j a_j} (\theta + (i-1)\alpha)}{\prod_{i=1}^n (\theta + i - 1)} \prod_{i=1}^n \left(\frac{\prod_{j=1}^{i-1}(j - \alpha)}{i!} \right)^{a_i} \frac{1}{a_i!}. \tag{9}$$

In this paper, we introduce a class of statistical models with dependencies between the distributions $\{F_t\}$ and mixing distributions $\{\mathbb{G}_t\}$ while preserving (1) and (2) at any time t. This allows us to explicitly characterize the marginal model at each time step (more generally, at each value of the covariate) and have fine control over prior parameterization of the marginal model. Methods that preserve stationarity in this way have found use in other Bayesian nonparametric models (Teh et al., 2011; Griffin and Steel, 2011), and allow us to achieve good empirical performance in epidemiological and video applications in Section 5. We briefly review constructions in the literature for dependent processes below.

2.1 Literature review

Several authors have considered previously the problem of defining dependent nonparametric models, and in particular dependent Dirichlet processes for time series and spatial models, see e.g. Foti and Williamson (2013) for a recent review.

In an early contribution, Cifarelli and Regazzini (1978) introduced dependencies between distributions by defining a parametric model on the base distribution $\mathbb{H}_s$ dependent on a covariate s and $\mathbb{G}_s \sim \text{DP}(\theta, \mathbb{H}_s)$. This approach is different from ours as we follow here the setting introduced by MacEachern et al. (1999) and introduce dependencies directly on two successive mixing distributions while $\mathbb{H}$ is fixed.

The great majority of recent papers use the stick-breaking representation (5) to introduce dependencies. Under this representation, a realization of a Dirichlet process is represented by two (infinite dimensional) vectors of weights $V_{1:\infty,s}$ and cluster locations $U_{1:\infty,s}$. Dependency with respect to a covariate s is introduced on $V_{1:\infty,s}$ in (Griffin and Steel, 2006; Rodriguez and Dunson, 2011; Arbel et al., 2014), on $U_{1:\infty,s}$ in (MacEachern, 2000; Iorio et al., 2004; Gelfand et al., 2005; Caron et al., 2008) and on both cluster locations and weights in (Griffin and Steel, 2009).

An alternative approach consists of considering the mixing distribution to be a convex combination of independent random probability measures sampled from a Dirichlet process. The dependency is then introduced through some weighting coefficients; e.g. (Dunson et al., 2006; Dunson and Park, 2007; Müller et al., 2004). More recently, various classes of dependent Dirichlet processes were proposed by Griffin (2011), Rao and Teh (2009), Huggins and Wood (2014) and Lin et al. (2010) which rely on the representation of the DP as a normalized random measure.

Although these previous approaches have merits, we believe that it is possible to build more intuitive models in the time domain based on Pólya urn-type schemes. In (Zhu et al., 2005; Ahmed and Xing, 2008; Blei and Frazier, 2011), time-varying Pólya urn models were proposed but these models do not marginally preserve a Dirichlet process. The only model we know of which satisfies this property is presented in (Walker and Muliere, 2003). The authors define a joint distribution $p(\mathbb{G}_1, \mathbb{G}_2)$ such that $\mathbb{G}_1$ and $\mathbb{G}_2$ are marginally $\mathrm{DP}(\theta, \mathbb{H})$ by introducing m artificial auxiliary variables $\mathbf{w}_i \overset{\text{iid}}{\sim} \mathbb{G}_1$ and then $\mathbb{G}_2|\mathbf{w}_{1:m} \sim \mathrm{DP}(\theta+m, \frac{\theta\mathbb{H}+\sum_{i=1}^m \delta_{\mathbf{w}_i}}{\theta+m})$. An extension to time series is discussed in (Srebro and Roweis, 2005). An important drawback of this approach is that it requires introducing a very large number m of auxiliary variables to model strongly dependent distributions. When inference is performed, these auxiliary variables need to be inferred from the data and the resulting algorithm can be computationally intensive.

2.2 Contributions and Organization

The models developed here are based on a Pólya urn representation of the Pitman-Yor process but do not require introducing a large number of auxiliary variables to model strongly dependent distributions.

To obtain a first-order stationary Pitman-Yor process mixture using such an approach, we need to ensure that any time t

(A) the sequence $\mathbf{c}_t$ induces a random partition distributed according to the two-parameter Ewens sampling formula (9),

(B) for $j \in \mathbf{c}_t$, the $U_{j,t}$s are identically and independently distributed from $\mathbb{H}$.

The main contribution of this paper consists of defining models satisfying (**A**) using a generalized Pólya urn prediction rule based on the consistence properties under specific deletion procedures of the Ewens sampling formula (Kingman, 1978; Gnedin and Pitman, 2005). Ensuring (**B**) can be performed using standard methods from the time series literature; e.g. (Joe, 1997; Pitt and Walker, 2005).

Our models allow us to modify both the cluster locations and their weights. Furthermore, they rely on simple and intuitive birth and death procedures. By using a Pólya urn approach, the models are defined on the space of partitions; i.e. the labelling of the class to which each data belongs is irrelevant. From a computational point of view, it is usually easier to design efficient MCMC and SMC algorithms for inference based on this finite-dimensional representation than the infinite-dimensional stick-breaking representation, where slice sampling (Walker, 2007; Kalli et al., 2011) or retrospective sampling (Papaspiliopoulos and Roberts, 2008) techniques can be used.

3. Stationary Pitman-Yor Process Mixtures

We present here some models ensuring property (**A**) is satisfied. We then briefly discuss in Section 3.2 how to ensure (**B**).

3.1 Stationary Pitman-Yor Processes

The main idea behind our models consists at each time step t of

- deleting randomly a subset of the allocations variables sampled from time 1 to $t-1$ which had survived the previous $t-1$ deletion steps,

- sampling n new allocation variables corresponding to the n observations $\mathbf{z}_t$.

For any $t \geq 2$, we have generated the allocation variables $\mathbf{c}_{1:t-1}$ corresponding to $\mathbf{z}_{1:t-1}$ from time 1 to $t-1$. We denote by $\mathbf{c}^{t-1}_{1:t-1}$ the subset of $\mathbf{c}_{1:t-1}$ corresponding to variables having survived the deletion steps from time 1 to $t-1$, and we denote by $\mathbf{c}^{t}_{1:t-1}$ the subset corresponding to those having survived from time 1 to t. Let K_{t-1} be the number of clusters created from time 1 to $t-1$. We denote by $\mathbf{m}^{t-1}_{t-1}$ the vector of size K_{t-1} containing the size of the clusters associated to $\mathbf{c}^{t-1}_{1:t-1}$, and we denote by $\mathbf{m}^{t}_{t-1}$ the vector containing the size of clusters associated to $\mathbf{c}^{t}_{1:t-1}$. Hence, these vectors have zero entries corresponding to 'dead' clusters. The introduction of $\mathbf{m}^{t-1}_{t-1}$ and $\mathbf{m}^{t}_{t-1}$ simplifies the presentation of the procedure but note that, from a practical point of view, there is obviously no need to store these vectors of increasing dimension. It is only necessary to store the size of the non-empty clusters and their associated labels.

At time 1, we just generate $\mathbf{c}_1$ according to a standard Pólya urn described in the introduction. At time $t \geq 2$ we have $\mathbf{c}^{t-1}_{1:t-1} = \left(\mathbf{c}^{t-1}_{1:t-2}, \mathbf{c}_{t-1}\right)$ and we sample $\mathbf{c}^{t}_{1:t} = \left(\mathbf{c}^{t}_{1:t-1}, \mathbf{c}_{t}\right)$ as follows. We first obtain $\mathbf{c}^{t}_{1:t-1}$ by deleting a random number of allocation variables from $\mathbf{c}^{t-1}_{1:t-1}$ according to one of the following rules.

- **Uniform deletion**: delete each allocation variable in $\mathbf{c}^{t-1}_{1:t-1}$ with probability $1-\rho$ where $0 \leq \rho \leq 1$. This is statistically equivalent to sampling a number r from a binomial distribution $\mathcal{B}\mathrm{in}(\sum_k m^{t-1}_{k,t-1}, 1-\rho)$ and then removing r items uniformly from $\mathbf{c}^{t-1}_{1:t-1}$ to obtain $\mathbf{c}^{t}_{1:t-1}$. For $\rho = 0$, the partitions $\mathbf{c}_t$ and $\mathbf{c}_{t+1}$ are independent whereas for $\rho = 1$ we have a static Pitman-Yor process.

- **Deterministic deletion**: delete the allocation variables $\mathbf{c}_{t-r}$ from $\mathbf{c}^{t-1}_{1:t-1}$, where $r \in \mathbb{N}$ and $r < t$.

- **Cluster deletion** (for α, θ verifying condition (3) with $\theta \geq 0$): compute the following discrete probability distribution over the set of non-empty clusters

$$\pi_{k,t} = \frac{(\sum_\ell m^{t-1}_{\ell,t-1} - m^{t-1}_{k,t-1})\gamma + m^{t-1}_{k,t-1}(1-\gamma)}{(\sum_\ell m^{t-1}_{\ell,t-1})(1-\gamma+(K_{t-1}-1)\gamma)}$$

where $\sum_k \pi_{k,t} = 1$, $\gamma = \frac{\alpha}{\alpha+\theta}$ then sample an index from this distribution and delete the corresponding cluster to obtain $\mathbf{c}^{t}_{1:t-1}$. The cluster deletion allows us to model large potential 'jumps' in the distributions of the observations. Dependent on the value of γ, we

delete clusters with a probability independent of their size, proportional to their size or proportional to the size of the partition minus their size (Gnedin and Pitman, 2005). The introduction of the Pitman-Yor process gives us this extra modeling flexibility here. In particular, the following three cases are of special interest:

Size-biased deletion For $\alpha = 0$ and $\theta > 0$, and hence $\gamma = 0$, each cluster of size r is selected with probability proportional to r. This result is known as Kingman's characterization of the Ewens family of $(0, \theta)$ partition structures (Kingman, 1978).

Unbiased (uniform) deletion For $\gamma = \frac{\alpha}{\alpha+\theta} = \frac{1}{2}$, given that there are l clusters, each cluster is chosen with probability $\frac{1}{l}$ i.e., each cluster is deleted independently of its size. For $0 \leq \alpha \leq 1$, the (α, α) partition structures are the only partition structures invariant under uniform deletion.

Cosize-biased deletion For $\gamma = 1$ (hence $\theta = 0$), each cluster of size r is selected with probability proportional to the size $n - r$ of the remaining partition.

It is also possible to consider any mixture and composition of these deletion procedures. For example, we can pick w.p. ξ the uniform deletion strategy and w.p. $1 - \xi$ the cluster deletion strategy or perform one uniform deletion followed by one cluster deletion or a deterministic deletion etc. Finally, after these deletion steps, we sample the allocation variables $\mathbf{c}_t$ according to a standard Pólya urn scheme based on the surviving allocation variables $\mathbf{c}^t_{1:t-1}$.

To summarize, the generalized Pólya urn scheme proceeds as in Algorithm 1, where $\mathcal{I}\left(\mathbf{m}^t_t\right)$ and $\left|\mathcal{I}\left(\mathbf{m}^t_t\right)\right|$ denote respectively the indices corresponding to the non-zero entries of $\mathbf{m}^t_t$ and the number of non-zero entries.

Algorithm 1 Generalized Pólya Urn

At time $t = 1$

- Set $c^1_{1,1} = 1$, $m^1_{1,1} = 1$ and $K_1 = 1$.
- For $k = 2, ..., n$

w.p. $\frac{m^1_{i,1}-\alpha}{k-1+\theta}$, $i \in \{1, \ldots, K_1\}$ set $c^1_{k,1} = i$, $m^1_{i,1} = m^1_{i,1} + 1$,
w.p. $\frac{K_1\alpha+\theta}{k-1+\theta}$, set $K_1 = K_1 + 1$, $c^1_{k,1} = K_1$, $m^1_{K_1,1} = 1$.

At time $t \geq 2$

- Kill a subset of $\mathbf{c}^{t-1}_{1:t-1}$ using a mixture/composition of uniform, size-biased and deterministic deletions to obtain $\mathbf{c}^t_{1:t-1}$ (hence $\mathbf{m}^t_{t-1}$) and set $\mathbf{m}^t_t = \mathbf{m}^t_{t-1}$, $K_t = K_{t-1}$.
- For $k = 1, ..., n$

w.p. $\frac{m^t_{i,t}-\alpha}{\sum_i m^t_{i,t}+\theta}$, $i \in \mathcal{I}\left(\mathbf{m}^t_t\right)$ set $c^t_{k,t} = i$, $m^t_{i,t} = m^t_{i,t} + 1$,
w.p. $\frac{|\mathcal{I}(\mathbf{m}^t_t)|\alpha+\theta}{\sum_i m^t_{i,t}+\theta}$, set $K_t = K_t + 1$, $c^t_{k,t} = K_t$, $m^t_{K_t,t} = 1$.

The proof that $\mathbf{c}_t$ satisfies (**A**) is a direct consequence of the remarkable consistence properties under deletion of the Ewens sampling formula which have been first established in (Kingman, 1978) for the one-parameter case and then extended to the two-parameter case in (Gnedin and Pitman, 2005).

Proposition. At any time $t \geq 1$, $\mathbf{c}_t$ induces a random partition distributed according to the Ewens sampling formula.

Proof. We prove by induction a stronger result; that is $\mathbf{c}^t_{1:t}$ induces a random partition following (9). At time 1, this is trivially true as $\mathbf{c}^1_1 = \mathbf{c}_1$ is generated according to a standard Pólya urn. Assume it is true at time $t - 1$. For the deterministic and uniform deletion, exchangeability of the partition ensures that $\mathbf{c}^t_{1:t-1}$ also induces a random partition following (9). For the cluster deletion procedure, consistency follows from the results of (Kingman, 1978, pp. 3 and 5) and (Gnedin and Pitman, 2005, p. 4) on regenerative partitions. Finally, as $\mathbf{c}_t$ is sampled according to a standard Pólya urn scheme based on the surviving allocation variables $\mathbf{c}^t_{1:t-1}$ then $\mathbf{c}^t_{1:t}$ indeed induces by construction a random partition following (9). Thanks to exchangeability, it implies that $\mathbf{c}_t$ also induces a random partition distributed according to the Ewens sampling formula.■

So far, so as to simplify presentation, we have considered that the number of allocation variables at each time t is fixed to a value n corresponding to the number of observations received at each time instant. The value of n impacts on the number of alive allocation variables and the correlations between successive vectors $\mathbf{m}^t_{1:t}$. More precisely, the statistical model is not consistent in the Kolmogorov sense. For example, let $\pi_1(c_{1,1}, c_{1,2})$ and $\pi_2(c_{1,1}, c_{2,1}, c_{1,2}, c_{2,2})$ be two models defined for $n = 1$ and $n = 2$, then

$$\left(\sum_{c_{2,1}}\sum_{c_{2,2}} \pi_2(c_{1,1}, c_{2,1}, c_{1,2}, c_{2,2})\right) \neq \pi_1(c_{1,1}, c_{1,2}).$$

This lack of consistency is shared by other models based on the Pólya urn construction (Zhu et al., 2005; Ahmed and Xing, 2008; Blei and Frazier, 2011). Blei and Frazier (2011) provide a detailed discussion on this issue and describe cases where this property is relevant or not.

It is nonetheless possible to define a slightly modified version of our model that is consistent under marginalisation, at the expense of an additional set of latent variables. This is described in Appendix C.

3.2 Stationary Models for Cluster Locations

To ensure we obtain a first-order stationary Pitman-Yor process mixture model, we also need to satisfy (**B**). This can be easily achieved if for $k \in \mathcal{I}(\mathbf{m}^t_t)$

$$U_{k,t} \sim \begin{cases} p\left(\cdot|U_{k,t-1}\right) & \text{if } k \in \mathcal{I}(\mathbf{m}^t_{t-1}) \\ \mathbb{H} & \text{otherwise} \end{cases}$$

where $\mathbb{H}$ is the invariant distribution of the Markov transition kernel $p\left(\cdot|\cdot\right)$. In the time series literature, many approaches are available to build such transition kernels based on copulas (Joe, 1997) or Gibbs sampling techniques (Pitt and Walker, 2005).

Combining the stationary Pitman-Yor and cluster locations models, we can summarize the full model by the following Bayesian network in Figure 1. It can also be summarized using a Chinese restaurant metaphor (see Figure 2).

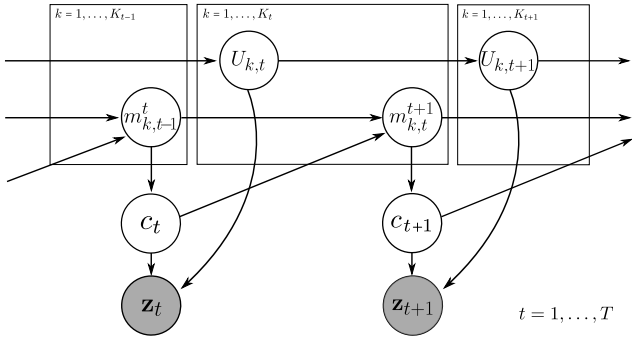

Figure 1: A representation of the time-varying Pitman-Yor process mixture as a directed graphical model, representing conditional independencies between variables. All assignment variables and observations at time t are denoted c_t and $\mathbf{z}_t$, respectively.

3.3 Properties of the Models

Under the uniform deletion model, the number $A_t = \sum_i m^t_{i,t-1}$ of alive allocation variables at time t can be written as

$$A_t = \sum_{j=1}^{t-1} \sum_{k=1}^{n} X_{j,k}$$

where $X_{j,i}$ are independently distributed from a Bernoulli of parameter ρ^j. A_t is therefore distributed from a Poisson binomial (also called Pólya Frequency) distribution (Pitman, 1997). The asymptotic mean and variance of the distribution of A_t are respectively $\frac{n\rho}{1-\rho}$ and $\frac{n\rho}{1-\rho^2}$, and the distribution $\Pr(A_t = k) \propto a_{k,t-1}$ where $a_{k,t}$, $k = 0, \ldots, nt$ satisfies the algebraic identity

$$\prod_{i=1}^{t} \left(x + \frac{1-\rho^i}{\rho^i} \right)^n = \sum_{k=0}^{nt} a_{k,t} x^k. \tag{10}$$

Its stationary distribution is obtained by taking the limit as $t \to \infty$.

Clearly the sequence $\{\mathbf{c}_t\}$ is not Markovian but $\{\mathbf{c}^t_{1:t}\}$ and $\{\mathbf{c}^t_{1:t-1}\}$ and the associated vectors $\{\mathbf{m}^t_{1:t}\}$ and $\{\mathbf{m}^t_{1:t-1}\}$ are for the uniform and cluster deletions. The transition probabilities for these processes are quite complex. However it can be shown easily for example that, for the uniform deletion model, we have for $k \in \mathcal{I}(\mathbf{m}^t_{t-1})$

$$\begin{aligned}
\mathbb{E}\left[m^{t+1}_{k,t} | \mathbf{m}^t_{t-1} \right] &= \mathbb{E}\left[\mathbb{E}\left[m^{t+1}_{k,t} \middle| m^t_{k,t} \right] | \mathbf{m}^t_{t-1} \right] \\
&= \rho \mathbb{E}\left[m^t_{k,t} | \mathbf{m}^t_{t-1} \right] \\
&= \rho \left(m^t_{k,t-1} + n \frac{m^t_{k,t-1} - \left| \mathcal{I}\left(\mathbf{m}^t_{t-1}\right) \right| \alpha}{\theta + \sum_k m^t_{k,t-1}} \right)
\end{aligned}$$

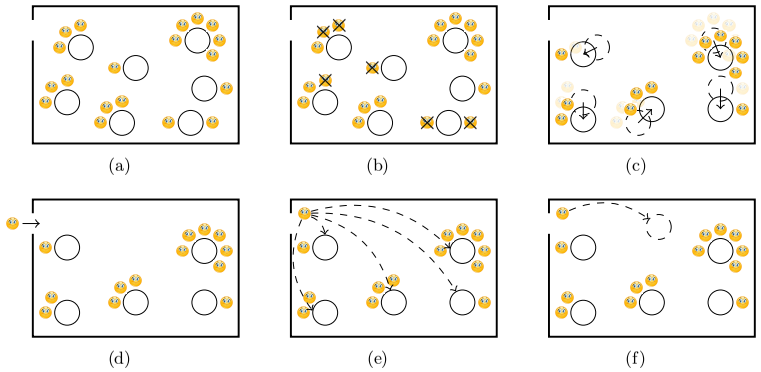

Figure 2: Illustration of the uniform deletion time-varying Pitman-Yor process mixture. Consider a restaurant with a countably infinite number of tables. (a) At time t, there are a certain number of customers in the restaurant, shared between several tables. Each customer remains seated at her/his table (w.p. ρ), or leaves the restaurant (w.p. $(1-\rho)$). (b) Once this choice has been made by each customer, empty tables are removed, and a certain number of customers remain in the restaurant. (c) Each table that is still occupied has its location evolved according to the transition kernel $p(\cdot|\cdot)$. (d) A new customer enters the restaurant and either (e) sits at a table with a probability proportional to the number of people at this table or (f) sits alone at a new table whose location has distribution $\mathbb{H}$. When $n-1$ other new customers enter the restaurant, repeat operations (d)-(f).

and

$$\mathbb{E}[\sum_{k \notin \mathcal{I}(\mathbf{m}^t_{t-1})} m^{t+1}_{k,t} | \mathbf{m}^t_{t-1}] = \frac{\rho n \left[\left| \mathcal{I}\left(\mathbf{m}^t_{t-1}\right) \right| \alpha + \theta \right]}{\theta + \sum_k m^t_{k,t-1}}.$$

For any deletion model, it can be additionally shown that we have, conditional on $\mathbf{m}^t_{t-1}$ (Pitman, 1996)

$$\mathbb{G}_t = \sum_{j \in \mathcal{I}(\mathbf{m}^t_{t-1})} P_j U_{j,t} + R_t \mathbb{G}^\star_t$$

where $\mathbb{G}^\star_t \sim \mathcal{PY}(\alpha, \theta + \alpha \left| \mathcal{I}\left(\mathbf{m}^t_{t-1}\right) \right|, \mathbb{H})$ and

$$\left(\{P_j | j \in \mathcal{I}(\mathbf{m}^t_{t-1})\}, R_t \right) | \mathbf{m}^t_{t-1} \sim \mathcal{D}(\{m^t_{j,t-1} - \alpha | j \in \mathcal{I}(\mathbf{m}^t_{t-1})\}, \left| \mathcal{I}(\mathbf{m}^t_{t-1}) \right| \alpha + \theta)$$

where $\mathcal{D}$ is the standard Dirichlet distribution. Moreover, $\mathbb{G}^\star_t$ and $\left(\{P_j | j \in \mathcal{I}(\mathbf{m}^t_{t-1})\}, R_t \right)$ are statistically independent. In particular, in the Dirichlet process case, we have

$$\mathbb{G}_t | \mathbf{c}^t_{1:t-1}, U_{j,t} \sim DP\left(\theta + \left| \mathcal{I}\left(\mathbf{m}^t_{t-1}\right) \right|, \frac{1}{\theta + \left| \mathcal{I}\left(\mathbf{m}^t_{t-1}\right) \right|} (\theta \mathbb{H} + \sum_k m^{t-1}_{k,t} \delta_{U_{k,t}}) \right).$$

We display a Monte Carlo estimate of $\mathrm{corr}\big(\int \mathbf{y}\mathbb{G}_t(d\mathbf{y}), \int \mathbf{y}\mathbb{G}_{t+\tau}(d\mathbf{y})\big)$ when $\mathbb{H}(\mathbf{y})$ is a standard normal distribution for different values of ρ, ξ and r resp. for the uniform, size-biased and deterministic deletions, and θ (with $\alpha = 0$) in Fig. 3. The correlations decrease faster as ρ, r and ξ decrease as expected.

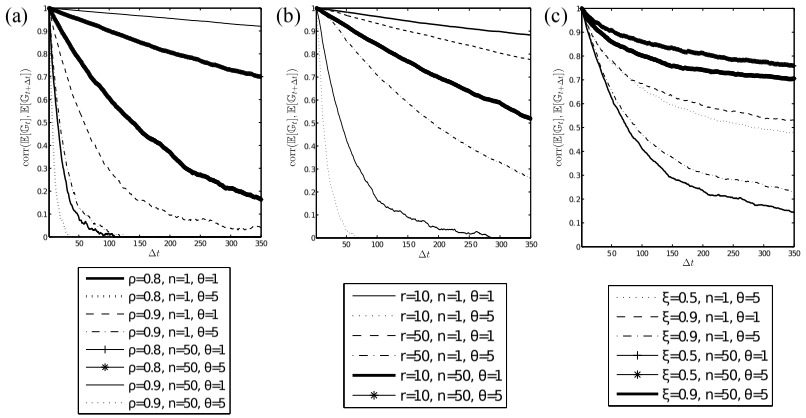

Figure 3: Plots of $\mathrm{corr}\big(\int \mathbf{y}\mathbb{G}_t(d\mathbf{y}), \int \mathbf{y}\mathbb{G}_{t+\Delta t}(d\mathbf{y})\big)$ approximated by Monte Carlo simulations as a function of the time difference Δt for (a) uniform (b) deterministic and (c) cluster deletions, for different values of θ and (a) ρ, (b) r and (c) ξ.

4. Bayesian Inference in Time-Varying PYPM

Bayesian inference is based on the posterior distribution of the cluster assignment variables $\mathbf{c}_t$, the vectors $\mathbf{m}_{t-1}^t$ and $U_{1:K_t}$ given by $p(\mathbf{c}_{1:t}, \mathbf{m}_{1:t-1}^{1:t}, U_{1:K_t}|\mathbf{z}_{1:t})$ at time t. We describe sequential Monte Carlo methods to fit our models.

To sample approximately from the sequence of distributions $p(\mathbf{c}_{1:t}, \mathbf{m}_{1:t-1}^{1:t}, U_{1:K_t}|\mathbf{z}_{1:t})$ as t increases, we propose an SMC method also known as particle filter. In this approach, the posterior distribution is approximated by a large collection of random samples—termed particles—which are propagated through time using Sequential Importance Sampling with resampling steps; see (Doucet et al., 2001) for a review of the literature. MacEachern et al. (1999) developed a sequential importance sampling method for Beta-Binomial Dirichlet process mixtures and Fearnhead (2004) proposed a SMC method for general conjugate Dirichlet process mixtures. In these papers, even in cases where the mixed distribution $\mathbb{G}$ can be integrated out analytically, the fact that $\mathbb{G}$ is a static parameter leads to an accumulation of the Monte Carlo errors over time (Kantas et al., 2009; Poyiadjis et al., 2011). This prevents using such techniques for large datasets with long time sequences. We deal here with time-varying models whose forgetting properties limit drastically this accumulation of errors.

We present in Algorithm 2 a general SMC algorithm. It relies on importance distributions denoted generically by $q(\cdot)$ and is initialized with weights $w_0^{(i)} = N^{-1}$ and cluster sizes $m_0^{0\ (i)} = 0$ for $i = 1, ..., N$. The simplest case of this algorithm consists of selecting the prior as an importance distribution. Note that we use $\overline{A}$ to denote the complementary of the set $A \subset \mathbb{N}$ in $\mathbb{N}$.

Algorithm 2 Sequential Monte Carlo for Time-Varying Pitman-Yor mixture processes

At time $t \geq 1$

- For each particle $i = 1, .., N$
  - Sample $\widetilde{\mathbf{m}}_{t-1}^{t\ (i)} | \mathbf{m}_{t-1}^{t-1\ (i)} \sim \Pr(\mathbf{m}_{t-1}^t | \mathbf{m}_{t-1}^{t-1\ (i)})$
  - Sample $\widetilde{\mathbf{c}}_t^{(i)} \sim q(\mathbf{c}_t | \widetilde{\mathbf{m}}_{t-1}^{t\ (i)}, U^{(i)}_{\mathcal{I}(\widetilde{\mathbf{m}}_t^{(i)}),t-1}, z_t)$
  - For $k \in \mathcal{J}(\widetilde{\mathbf{c}}_t^{(i)}) \cap \overline{\mathcal{I}(\widetilde{\mathbf{m}}_{t-1}^{t\ (i)})}$, sample $\widetilde{U}_{k,t}^{(i)} \sim q(U_{k,t} | \{\mathbf{z}_{j,t} | \widetilde{c}_{j,t}^{(i)} = k\})$
  - For $k \in \mathcal{I}(\widetilde{\mathbf{m}}_{t-1}^{t\ (i)})$, sample $\widetilde{U}_{k,t}^{(i)} \sim \begin{cases} q(U_{k,t} | U_{k,t-1}^{(i)}, \{\mathbf{z}_{j,t} | \widetilde{c}_{j,t}^{(i)} = k\}) & \text{if } k \in \mathcal{J}(\widetilde{\mathbf{c}}_t^{(i)}) \\ p(U_{k,t} | U_{k,t-1}^{(i)}) & \text{otherwise} \end{cases}$
- For $i = 1, .., N$, update the weights

$$\widetilde{w}_t^{(i)} \propto w_{t-1}^{(i)} \frac{p(\mathbf{z}_t | \widetilde{U}_t^{(i)}, \widetilde{\mathbf{c}}_t^{(i)}) \Pr(\widetilde{\mathbf{c}}_t^{(i)} | \widetilde{\mathbf{m}}_{t-1}^{t\ (i)})}{q(\widetilde{\mathbf{c}}_t^{(i)} | \widetilde{\mathbf{m}}_{t-1}^{t\ (i)}, U^{(i)}_{\mathcal{I}(\widetilde{\mathbf{m}}_t^{(i)}),t-1}, \mathbf{z}_t)} \times \prod_{k \in \mathcal{I}(\widetilde{\mathbf{m}}_{t-1}^{t\ (i)})} \frac{p(\widetilde{U}_{k,t}^{(i)} | U_{k,t-1}^{(i)})}{q(\widetilde{U}_{k,t}^{(i)} | U_{k,t-1}^{(i)}, \{\mathbf{z}_{j,t} | \widetilde{c}_{j,t}^{(i)} = k\})} \times \prod_{k \in \mathcal{J}(\widetilde{\mathbf{c}}_t^{(i)}) \cap \overline{\mathcal{I}(\widetilde{\mathbf{m}}_{t-1}^{t\ (i)})}} \frac{\mathbb{H}(\widetilde{U}_{k,t}^{(i)})}{q(\widetilde{U}_{k,t}^{(i)} | \{\mathbf{z}_{j,t} | \widetilde{c}_{j,t}^{(i)} = k\})} \tag{11}$$

  with $\sum_{i=1}^N \widetilde{w}_t^{(i)} = 1$.
- Resampling. Compute $N_{\text{eff}} = \left[\sum \left(\widetilde{w}_t^{(i)}\right)^2\right]^{-1}$. If $N_{\text{eff}} \leq N_T$, multiply the particles with large weights and remove the particles with small weights, resulting in a new set of particles denoted $\cdot_t^{(i)}$ with weights $w_t^{(i)} = 1/N$. Otherwise, rename the particles and weights by removing the $\widetilde{\cdot}$.

In this algorithm, N_T is a threshold triggering the resampling step; typically we set $N_T = N/2$. The posterior $p(\mathbf{c}_{1:t}, \mathbf{m}_{1:t-1}^{1:t}, U_{1:K_t}|\mathbf{z}_{1:t})$ is approximated using the set of weighted samples $\left\{w_t^{(i)}, \left(\mathbf{c}_{1:t}^{(i)}, \mathbf{m}_{1:t-1}^{1:t\ (i)}, U_{1:K_t}^{(i)}\right)\right\}$. In cases where $\mathbb{H}$ is a conjugate prior for f, we can integrate out the cluster locations and sample only the allocation variables.

We also develop a particle MCMC (PMCMC) inference algorithm (Andrieu et al., 2010) for this model. PMCMC is a method that uses SMC as an intermediate sampling step to move efficiently through high dimensional state spaces. It is an alternative to other common forms of MCMC, such as single-site Gibbs sampling, which we have found suffer from worse empirical performance due to quasi-ergodicity (i.e. poor mixing as the Markov chain becomes stuck in posterior modes). We implement the iterated-conditional SMC form of PMCMC (Andrieu et al., 2009, 2010), which involves iterating through the SMC algorithm described above while conditioning on a sampled particle at each iteration. While

this algorithm does not operate in an online fashion, as SMC does, we show in Section 5 that it yields improved performance in tasks such as video object tracking (shown in Section 5).

An alternative approach consists of modelling the observations as follows (we discuss here the deterministic deletion model but the uniform deletion can be defined similarly). In this model, the predictive distribution of $\mathbf{z}_t$ conditional on $c_t = k$ only depends on the observations assigned to the same cluster in the time interval $\{t-r+1, ..., t-1\}$ and

$$\begin{aligned} p(\mathbf{z}_t|c_t = k, \mathbf{z}_{1:t-1}, c_{1:t-1}) &= p(\mathbf{z}_t|\{\mathbf{z}_j : c_j = k \text{ for } j = t-r+1, \ldots, t-1\}) \\ &= \frac{\int_{\mathcal{Y}} f(\mathbf{z}_t|\mathbf{y}) \prod_{\{j\in\{t-r+1,\ldots t-1\}:c_j=k\}} f(\mathbf{z}_j|\mathbf{y}) d\mathbb{H}(\mathbf{y})}{\int_{\mathcal{Y}} \prod_{\{j\in\{t-r+1,\ldots t-1\}:c_j=k\}} f(\mathbf{z}_j|\mathbf{y}) d\mathbb{H}(\mathbf{y})}. \end{aligned} \tag{12}$$

This distribution can be computed in closed-form in the conjugate case. We propose the simple deterministic Algorithm 3 to approximate the posterior in the context of this model. The posterior $p(\mathbf{c}_{1:t}|\mathbf{z}_{1:t})$ is approximated using the set of weighted samples $\left\{w_t^{(i)}, \mathbf{c}_{1:t}^{(i)}\right\}$. This algorithm uses a deterministic selection step. Alternatively, we could have used the stochastic resampling procedure of Fearnhead (2004).

Algorithm 3 $N-$best algorithm for Deterministic Deletion

At time $t \geq 1$

- Set $w_{0,t}^{(i)} = w_{n,t-1}^{(i)}$
- For $k = 1, \ldots, n$
  - For each particle $i = 1, .., N$
    - For $j \in \mathcal{J}(\{c_{1:k-1,t}^{(i)}, c_{1:t-1}^{(i)}\}) \cup \{0\} \cup \{c_{new}\}$, let $\widetilde{c}_{k,t}^{(i,j)} = j$ and compute the weight

$$\widetilde{w}_{k,t}^{(i,j)} \propto w_{k-1,t}^{(i)} p\left(\mathbf{z}_{k,t}|\, \mathbf{z}_{1:k-1,t}, \mathbf{z}_{1:t-1}, c_{1:k-1,t}^{(i)}, c_{1:t-1}^{(i)}, \widetilde{c}_{k,t}^{(i,j)}\right) p\left(\widetilde{c}_{k,t}^{(i,j)} \middle| c_{1:k-1,t}^{(i)}, c_{1:t-1}^{(i)}\right) \tag{13}$$

  - Keep the N particles $\left(c_{1:k-1,t}^{(i)}, c_{1:t-1}^{(i)}, \widetilde{c}_{k,t}^{(i,j)}\right)$ with highest weights $\widetilde{w}_{k,t}^{(i,j)}$, rename them $\left(c_{1:k,t}^{(i)}, c_{1:t-1}^{(i)}\right)$ and denote $w_{k,t}^{(i)}$ the associated weights.

5. Applications

In this Section, we demonstrate the models and algorithms on simulated data, modeling of the spread of a disease, and multi-object tracking.

5.1 Sequential Time-Varying Density Estimation

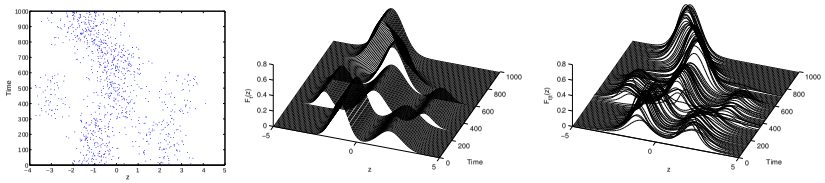
We consider the synthetic problem of estimating sequentially time-varying densities F_t on the real line using observations $\mathbf{z}_t$. We assume the observations $\mathbf{z}_t$ (where $n = 1$) follow a time-varying Dirichlet process with both uniform and size-biased deletion, a Gaussian mixed density and normal-inverse Wishart base distribution, whose pdf is given by

$$p(\mu, \Sigma|\mu_0, \kappa_0, \nu_0, \Lambda_0) \propto |\Sigma|^{-\frac{\nu_0+p+1}{2}} \exp\left[-\frac{1}{2} tr(\Lambda_0\Sigma^{-1} - \frac{\kappa_0}{2}(\mu-\mu_0)^T\Sigma^{-1}(\mu-\mu_0))\right]$$

where $p = 1$ in this case. To keep the presentation simple, we assume here that the hyperparameters of the base distribution are assumed fixed and known $\mu_0 = 0$, $\kappa_0 = 0.1$, $\nu_0 = 2$ and $\Lambda_0 = 1$. Following Pitt et al. (2002), we introduce a time-varying model on the cluster location using r auxiliary variables $\omega_{j,t}$, $j = 1, \ldots, r$

$$\begin{aligned} \omega_{j,t} &\sim \mathcal{N}\left(\mu_t, \frac{\Sigma_t}{\tau}\right) \text{ for all } j \\ (\mu_{t+1}, \Sigma_{t+1})|\omega_{1:r,t} &\sim \mathcal{N}iW(\mu_0', \kappa_0', \nu_0', \Lambda_0') \end{aligned}$$

where $\tau = 0.5$ and $r = 4000$ are fixed parameters, $\kappa_0' = \kappa_0 + r\tau$, $\nu_0' = \nu_0 + r$, $\mu_0' = \frac{r\tau}{\kappa_0+r\tau}\overline{w} + \frac{\kappa_0}{\kappa_0+r\tau}\mu_0$ and $\Lambda_0' = \Lambda_0 + \frac{\kappa_0 r\tau}{\kappa_0+r\tau}(\overline{\omega}-\mu_0)(\overline{\omega}-\mu_0)^T + \tau\sum_{j=1}^n(\omega_{j,t}-\overline{\omega})(\omega_{j,t}-\overline{\omega})^T$ and $\overline{\omega} = \frac{1}{n}\sum_{j=1}^r \omega_{j,t}$. The DP scale parameter is $\theta = 3$. Instead of fixing ρ, we assume it is time-varying with $\rho_t|\rho_{t-1} \sim \mathcal{B}(a_\rho, a_\rho\frac{1-\rho_{t-1}}{\rho_{t-1}})$ where $a_\rho = 1000$, such that $\mathbb{E}[\rho_t|\rho_{t-1}] = \rho_{t-1}$ and $var(\rho_t|\rho_{t-1}) = \frac{\rho_{t-1}^2(1-\rho_{t-1})}{a_\rho+\rho_{t-1}}$. Note that the resulting model is still first-order stationary. We select a mixture of uniform and cluster deletions with $\xi = 0.98$. The observations $\mathbf{z}_t$ are generated for $t = 1, \ldots, 1000$ from a sequence of mixtures of normal distributions, see Figure 4. Abrupt changes occur at times $t = 301$ and $t = 601$ where modes of the true density appear/disappear whereas the mode moves smoothly from 0 to -1.5 between $t = 701$ and $t = 850$. For illustration purposes, we compute the average number of alive allocation variables $N_{t|t}$ as follows



$$N_{t|t} = \mathbb{E}\left[\sum_{k=1}^{K_t} m_{k,t}^t \middle| \mathbf{z}_{1:t}\right]. \tag{14}$$

A SMC algorithm is implemented with 1000 particles (Doucet et al., 2001); this algorithm is a slight generalization of the Algorithm 2 where ρ_t is also sampled. Results are displayed in Figure 4 and the estimates of $N_{t|t}$ and $\rho_{t|t} = \mathbb{E}[\,\rho_t|\,\mathbf{z}_{1:t}]$ are plotted in Figure 5.

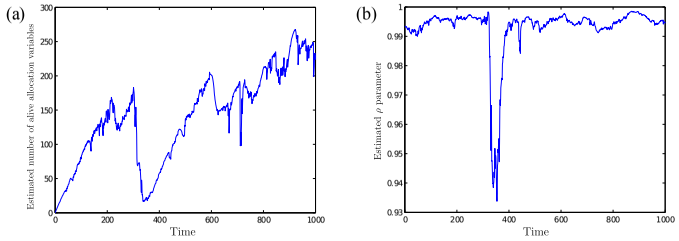
In Figure 4, we display the filtered density estimate $F_{t|t} = \mathbb{E}[F_t|\mathbf{z}_{1:t}]$ which manages to track the slow and abrupt changes of the true density. In Figure 5, we see that the model adapts to F_t quickly by also estimating ρ_t: ρ_t suddenly decreases at times $t = 300$ where the modes of the density suddenly change. $N_{t|t}$ follows a similar evolution: whenever F_t does not evolve, we use as many previously collected observations as possible to estimate the density by letting $N_{t|t}$ increases. When F_t changes abruptly, $N_{t|t}$ also decreases abruptly and the model quickly gets rid of the old clusters. Moreover, the cluster deletion procedure allows us to only delete irrelevant clusters. This is illustrated at $t = 600$ where the two minor modes disappear whereas the main mode is preserved.

5.2 Foot and Mouth Disease

Foot and Mouth disease is a highly transmissible viral infection which can spread rapidly among livestock. The epidemic which started in February 2001 and ended in October 2001 saw 2000 cases of death in farms throughout England. Although complex models have been designed in the epidemiology literature relying for example on the spatial distribution of farms (Keeling et al., 2001), we propose to use our model to estimate clusters of cases of Foot and Mouth disease. Let $\mathbf{z}_{k,t}$ be the two-dimensional geographical position of case k

(a) Data (b) True density (c) Estimated density

Figure 4: (a) Data (b) True density and (c) filtered density estimate. Abrupt changes occur at times $t = 301$ and $t = 601$. The mode of the density evolves smoothly between times $t = 700$ and $t = 850$.



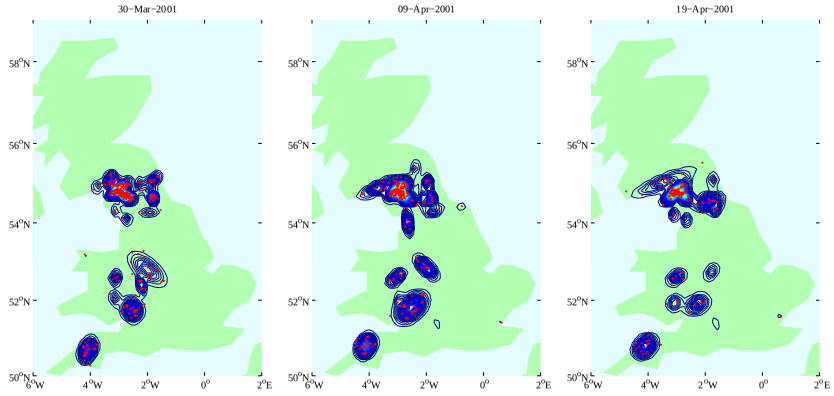


Figure 5: (a) Time evolution of the average number of alive clusters. (b) Time evolution of $\rho_{t|t}$.

at day number t. We assume that $\mathbf{z}_t$ follows a time-varying Dirichlet process mixture with a Gaussian mixed pdf whereas $\mathbb{H}$ is a Normal inverse Wishart distribution. We consider a deterministic deletion model where $r = 7$; seven days being an upper bound for the incubation of the disease. For the cluster locations, we use the model defined by Eq. (12). Inference is performed using the $N-$best algorithm 3 with $N = 1000$ particles. The marginal maximum a posteriori estimates of the cluster locations for some days during the epidemic are represented in Figure 6.

We computed the predictive cumulative density function $\Pr(\mathbf{z}_{k,t} \leq z | \mathbf{z}_{1:k-1,t}, \mathbf{z}_{1:t-1})$ for each disease case. The inverse Gaussian cumulative density function transform of it is plotted in Figure 7 for each of the two dimensions. As can be shown, our simple model does fit the data relatively well, considering that no prior information about farm locations is used here.

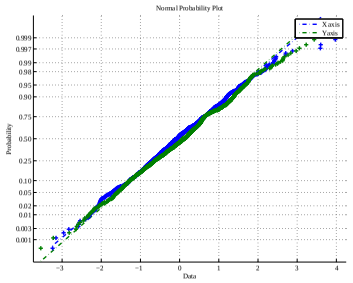

Figure 7: Normal qq-plot of the transformed predictive distribution for foot-and-mouth disease dataset for the two dimensions.

5.3 Object Tracking in Videos

The time-varying Pitman-Yor process can also be used as a prior in models used to find, track, and learn representations of arbitrary objects in a video without a predefined method

for object detection[2]. We present a model that localizes objects via unsupervised tracking while learning a representation of each object, avoiding the need for pre-built detectors. This model uses the Pitman-Yor prior to capture the uncertainty in the number and appearance of objects and requires only spatial and color video data that can be efficiently extracted via frame differencing. Nonparametric mixture models have been used in the past for a variety of computer vision tasks, including tracking (Topkaya et al., 2013; Neiswanger et al., 2014), trajectory clustering (Wang et al., 2011), and video retrieval (Li et al., 2008).

To find and track arbitrary video objects, we model spatial and color features that are extracted as objects travel within a video scene. The model isolates independently moving video objects and learns object models for each that capture their shape and appearance. The learned object models allow for tracking through occlusions and in crowded videos. The unifying framework is a time-varying Pitman-Yor process mixture, where each component is a (time-varying) object model. This setup allows us to estimate the number of objects in a video and track moving objects that may undergo changes in orientation, perspective, and appearance.

We describe the form of the extracted data, define the components of the model, and demonstrate this model on three real video datasets: a video of foraging ants, where we show improved performance over other detection-free methods; a human tracking benchmark video, where we show comparable performance against object-specific methods designed to detect humans; and a T cell tracking task where we demonstrate our method on a video with a large number of objects and show how our unsupervised method can be used to automatically train a supervised object detector.

Data. At each frame t, we assume we are given a set of N_t foreground pixels, extracted via some background subtraction method (such as those detailed in (Yilmaz et al., 2006)). These methods primarily segment foreground objects based on their motion relative to the video background. For example, an efficient method applicable for stationary videos is frame differencing: in each frame t, one finds the pixel values that have changed beyond some threshold, and records their positions $\mathbf{z}^s_{t,n} = (z^{s_1}_{t,n}, z^{s_2}_{t,n})$. In addition to the position of each foreground pixel, we extract color information. The spectrum of RGB color values is discretized into V bins, and the local color distribution around each pixel is described by counts of surrounding pixels (in an $m \times m$ grid) that fall into each color bin, denoted $\mathbf{z}^c_{t,n} = (z^{c_1}_{t,n}, \ldots, z^{c_V}_{t,n})$. Observations are therefore of the form

$$\mathbf{z}_{t,n} = (\mathbf{z}^s_{t,n}, \mathbf{z}^c_{t,n}) = (z^{s_1}_{t,n}, z^{s_2}_{t,n}, z^{c_1}_{t,n}, \ldots, z^{c_V}_{t,n}). \tag{15}$$

Examples of spatial pixel data extracted via frame differencing are shown in Figure 8 (a)-(g).

The time-varying Pitman-Yor process mixture of objects We define an object model, $\mathrm{F}(U_{k,t})$, which is a distribution over pixel data, where $U_{k,t}$ represents the parameters of the k^{th} object at time t. We wish to keep our object model general enough to be applied to arbitrary video objects, but specific enough to learn a representation that can aid in tracking. In this paper, we model each object with

$$\mathbf{z}_{t,n} \sim \mathrm{F}(U_{k,t}) = \mathcal{N}(\mathbf{z}^s_{t,n}|\mu_{k,t}, \Sigma_{k,t}) Mult(\mathbf{z}^c_{t,n}|\delta_{k,t}) \tag{16}$$

2. A preliminary version of this work has been presented as a conference paper (Neiswanger et al., 2014). Matlab code is available at `https://github.com/willieneis/DirichletProcessTracking`.

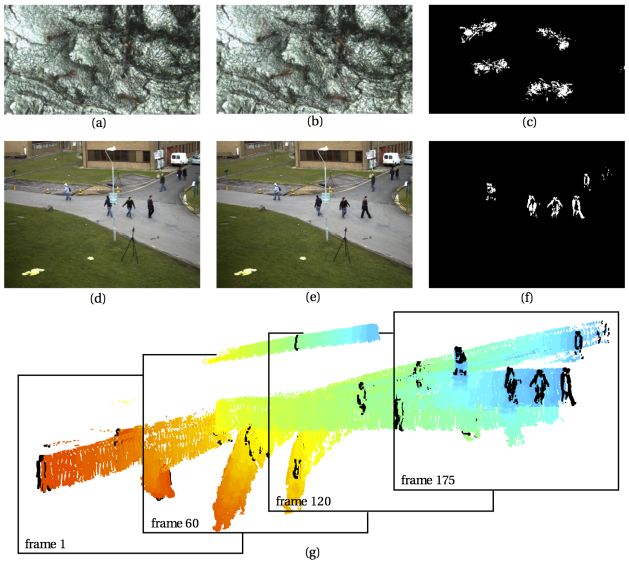

Figure 8: (a - f) Two pairs of consecutive frames and the spatial observations $\mathbf{z}^s_{t,n}$ extracted by taking the pixel-wise frame difference between each pair. (g) The results of frame differencing over a sequence of images (from the PETS2010 dataset).

where object parameters $U_{k,t} = \{\mu_{k,t}, \Sigma_{k,t}, \delta_{k,t}\}$, and $\sum_{j=1}^{V} \delta^j_{k,t} = 1$. The object model captures the objects' locus and extent with the multivariate Gaussian and color distribution with the multinomial. We demonstrate in the following experiments that this representation can capture the physical characteristics of a wide range of objects while allowing objects with different shapes, orientations, and appearances to remain isolated during tracking. We define $\mathbb{H}$, which represents the prior distribution over object parameters, to be

$$\mathbb{H}(\mu_{k,t}, \Sigma_{k,t}, \delta_{k,t}|\mu_0, \kappa_0, \nu_0, \Lambda_0, q_0) = \mathcal{N}iW(\mu_{k,t}, \Sigma_{k,t}|\mu_0, \kappa_0, \nu_0, \Lambda_0)\mathcal{D}(\delta_{k,t}|q_0). \tag{17}$$

To satisfy stationarity, we introduce a set of M auxiliary variables $\mathbf{a}^k_t = (a^k_{t,1}, \ldots, a^k_{t,M})$ for cluster k at time t (Pitt and Walker, 2005). Due to the form of the object parameter priors (i.e the base distribution of the Dirichlet process) and the object model, we can easily apply this auxiliary variable method. With this addition, object parameters do not directly depend on their values at a previous time, but are instead dependent through an intermediate sequence of variables. This allows the cluster parameters at each time step to be marginally distributed according to the base distribution $\mathbb{H}$ while maintaining simple time varying behavior. We can therefore sample from the transition kernel using

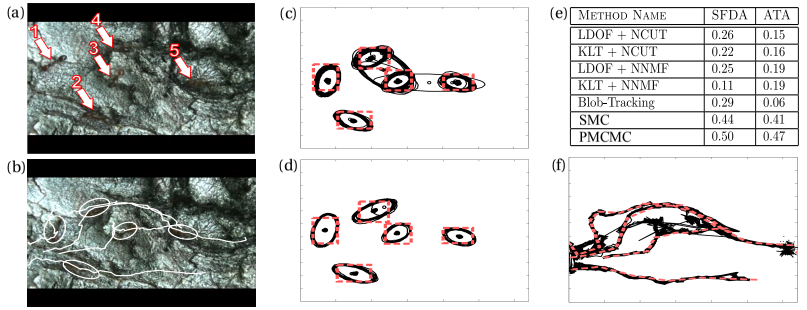
$U_{k,t} \sim T(U_{k,t-1}) = T_2 \circ T_1(U_{k,t-1})$, where

$$a^k_{t,1:M} \sim T_1(U_{k,t-1}) = \mathcal{N}(\mu_{k,t-1}, \frac{\Sigma_{k,t-1}}{\tau}) Mult(\delta_{k,t-1}) \quad (18)$$

$$\mu_{k,t}, \Sigma_{k,t}, \delta_{k,t} \sim T_2(a^k_{t,1:M}) = \mathcal{N}iW(\mu_M, \kappa_M, \nu_M, \Lambda_M)\mathcal{D}(q_M) \quad (19)$$

where we choose $\tau = 1$ for all experiments, and formulae for $\mu_M, \kappa_M, \nu_M, \Lambda_M$ and q_M are given in Appendix B.

We apply uniform deletion of allocation variables in this application, to maintain generality of the method over a variety of object types in videos. Additionally, we chose hyperparameter values by simulating from the prior and inspecting the simulated parameters for similarity with existing data. We found that the algorithm performance was not very sensitive to the hyperparameter values settings, and remained fairly consistent over a wide range of settings. In the following experiments we perform inference using both the SMC and PMCMC inference algorithms with $N = 100$ particles, and compare performance of both algorithms.



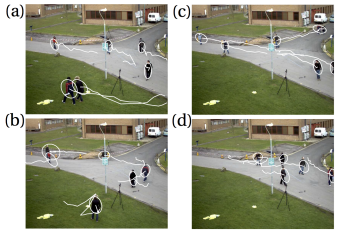
Detection-free comparison methods. Detection-free tracking strategies aim to find and track objects without any prior information about the objects' characteristics nor any manual initialization. One type of existing strategy uses optical flow or feature tracking algorithms to produce short tracklets, which are then clustered into full object tracks. We use implementations of Large Displacement Optical Flow (LDOF) (Brox and Malik, 2011) and the Kanade-Lucas-Tomasi (KLT) feature tracker (Tomasi and Kanade, 1991) to produce tracklets[3]. Full trajectories are then formed using the popular normalized-cut (NCUT) method (Shi and Malik, 2000) to cluster the tracklets or with a variant that uses non-negative matrix factorization (NNMF) to cluster motion using tracklet velocity information (Cheriyadat and Radke, 2009)[4]. We also compare against a detection-free blob-tracking method, where extracted foreground pixels are segmented into components in each frame (Stauffer and Grimson, 2000) and then associated with the nearest neighbor criterion (Yilmaz et al., 2006).

Performance metrics. For quantitative comparison, we report two commonly used performance metrics for object detection and tracking, known as the sequence frame detection accuracy (SFDA) and average tracking accuracy (ATA) (Kasturi et al., 2008). These metrics compare detection and tracking results against human-authored ground-truth, where SFDA$\in [0,1]$ corresponds to detection performance and ATA$\in [0,1]$ corresponds to tracking performance, the higher the better. We authored the ground-truth for all videos with the Video Performance Evaluation Resource (ViPER) tool (Doermann and Mihalcik, 2000).

Insect tracking. The video contains six ants with a similar texture and color distribution as the background. The ants are hard to discern, and it is unclear how a predefined detection criteria might be constructed. Further, the ants move erratically and the spatial data extracted via frame differencing does not yield a clear segmentation of the

3. The LDOF implementation can be found at `http://www.seas.upenn.edu/~katef/LDOF.html` and the KLT implementation at `http://www.ces.clemson.edu/~stb/klt/`.
4. The NCUT implementation can be found at `http://www.cis.upenn.edu/~jshi/software/` and the NNMF implementation at `http://www.ornl.gov/~czx/research.html`.

objects in individual frames. A still image from the video, with ant locations shown, is given in Figure 3(a).



Method Name	SFDA	ATA
LDOF + NCUT	0.26	0.15
KLT + NCUT	0.22	0.16
LDOF + NNMF	0.25	0.19
KLT + NNMF	0.11	0.19
Blob-Tracking	0.29	0.06
SMC	0.44	0.41
PMCMC	0.50	0.47

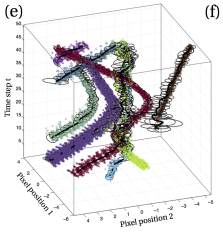


Figure 9: The ants in (a) are difficult to discern (positions labeled). We plot 100 samples from the inferred posterior over object parameters (using SMC (c) and PMCMC (d)) with ground-truth bounding boxes overlaid (dashed). PMCMC proves to give more accurate object parameter samples. We also plot samples over object tracks (sequences of mean parameters) using PMCMC in (f) , and its MAP sample in (b). We show the SFDA and ATA scores for all comparison methods in (e).

We compare the SMC and PMCMC inference algorithms, and find that PMCMC yields more accurate posterior samples (3(d)) than SMC (3(c)). Note that we run PMCMC as described in Section 4 for 100 iterations, where the first pass is equivalent to the SMC algorithm. Ground-truth bounding boxes (dashed) are overlaid on the posterior samples. The MAP PMCMC sample is shown in 3(b) and posterior samples of the object tracks are shown in 3(f), along with overlaid ground-truth tracks (dashed). SFDA and ATA performance metrics for all comparison methods are shown in 3(e). Our model yields higher metric values than all other detection-free comparison methods, with PMCMC inference scoring higher than SMC. The comparison methods seemed to suffer from two primary problems: very few tracklets could follow object positions for an extended sequence of frames, and clustering tracklets into full tracks sharply decreased in accuracy when the objects came into close contact with one another.

Comparisons with detector-based methods. Next, we aim to show that our general-purpose algorithm can compete against state of the art object-specific algorithms, even when it has no prior information about the objects. We use a benchmark human-tracking video from the International Workshop on Performance Evaluation of Tracking and Surveillance (PETS) 2009-2013 conferences (Ellis and Ferryman, 2010), due to its prominence in a number of studies (listed in Figure 10(f)). It consists of a monocular, stationary camera, 794 frame video sequence containing a number of walking humans. Due to the large number of frames and objects in this video, we perform inference with the SMC algorithm only.

Our model is compared against ten object-specific detector-based methods from the PETS conferences. These methods all either leverage assumptions about the orientation, position, or parts of humans, or explicitly use pre-trained human detectors. For example, out of the three top scoring comparison methods, (Breitenstein et al., 2009) uses a state of the art pedestrian detector, (Yang et al., 2009) performs head and feet detection, and (Conte et al., 2010) uses assumptions about human geometry and orientation to segment humans and remove shadows.

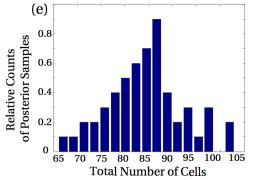

Figure 10: Results on the PETS human tracking benchmark dataset and comparison with object-detector-based methods. The MAP object parameter samples are overlaid on four still video frames (a-d). The MAP object parameter samples are also shown for a sequence of frames (a 50 time-step sequence) along with spatial pixel observations (e) (where the assignment variables $c_{t,n}$ for each pixel are represented by marker type and color). The SFDA and ATA performance metric results for our model and ten human-specific, detection-based tracking algorithms are shown in (f), demonstrating that the our model achieves comparable performance to these human-specific methods. Comparison results were provided by the authors of (Ellis and Ferryman, 2010).

In Figure 4(a-d), the MAP sample from the posterior distribution over the object parameters is overlayed on the extracted data over a sequence of frames. The first 50 frames from the video are shown in 4(e), where the assignment of each data point is represented by color and marker type. We show the SFDA and ATA values for all methods in 4(f), and can see that our model yields comparable results, receiving the fourth highest SFDA score and tying for the second highest ATA score.

Tracking populations of T cells. Automated tracking tools for cells are useful for cell biologists and immunologists studying cell behavior (Manolopoulou et al., 2012). We present results on a video containing T cells that are hard to detect using conventional methods due to their low contrast appearance against a background (Figure 5(a)). Furthermore, there are a large number of cells (roughly 60 per frame, 92 total). In this experiment, we aim to demonstrate the ability of our model to perform a tough detection task while scaling up to a large number of objects. Ground-truth bounding boxes for the cells at a single frame are shown in 5(b) and PMCMC inference results (where the MAP sample is

plotted) are shown in in 5(c). A histogram illustrating the inferred posterior over the total number of cells is shown in 5(e). It peaks around 87, near the true value of 92 cells.

(f)

Method Name	SFDA	ATA
LDOF + NCUT	0.17	0.02
KLT + NCUT	0.18	0.08
LDOF + NNMF	0.09	0.03
KLT + NNMF	0.1	0.09
Blob-Tracking	0.24	0.03
SMC	0.31	0.11
PMCMC	0.36	0.19

Figure 11: T cells are numerous, and hard to detect due to low contrast images (a). For a single frame, ground-truth bounding boxes are overlaid in (b), and inferred detection and tracking results are overlaid in (c). A histogram showing the posterior distribution over the total number of cells is shown in (e). The SFDA and ATA for the detection-free comparison methods are shown in (f). Inferred cell positions (unsupervised) were used to automatically train an SVM for supervised cell detection; SVM detected cell positions for a single frame are shown in (d).

Manually hand-labeling cell positions to train a detector is feasible but time consuming; we show how unsupervised detection results from our model can be used to automatically train a supervised cell detector (a linear SVM), which can then be applied (via a sliding window across each frame) as a secondary, speedy method of detection (Figure 5(d)). This type of strategy in conjunction with our model could allow for an ad-hoc way of constructing detectors for arbitrary objects on the fly, which could be taken and used in other vision applications, without needing an explicit predefined algorithm for object detection.

6. Discussion

In this article, we have presented a class of first-order stationary Pitman-Yor processes for time-varying density estimation and clustering. These models are based on a simple generalized Pólya urn sampling scheme whose validity follows from the consistence properties under specific deletion rules of the two-parameter Ewens sampling formula. We have proposed SMC and PMCMC methods to fit these models and have demonstrated them on several applications. The model proposed in the present paper has also been successfully

applied to dynamic spike sorting (Gasthaus et al., 2008) and to cell fluorescent microscopic imaging tracking (Ji and West, 2009).

There are numerous potential extensions to this work. We have focused on specifying directly the marginal distribution of the allocation variables, the underlying infinite-dimensional process $\{\mathbb{G}_t\}$ being integrated out. This has allowed us to develop intuitive models and simple algorithms to fit them. However, it would be interesting to explore whether it is possible to obtain an explicit representation for $\{\mathbb{G}_t\}$ and whether this can be related to the class of models described in (Griffin, 2011).

The uniform and deterministic deletion steps can be applied to any hierarchical model, as long as the predictive distribution is known. We could therefore develop time-varying versions of exchangeable models such as the Bernoulli trips introduced by Walker et al. (1999). The same methodology could also be extended to dynamic social networks. In this context, a classical model is Friend I, which assumes a finite Pólya Urn scheme as the reinforcement procedure for friends interactions (Skyrms and Pemantle, 2000). In order to take into account fading memory, a model called 'discounted from the past' has been proposed, where the weights of the Pólya Urn are discounted at each time step– an approach similar to that of Zhu et al. (2005). However this model has poor asymptotic properties, as each individual always ends up being friend with a single individual (Skyrms and Pemantle, 2000). We conjecture that uniform deletion rules would have nicer properties.

Finally in some applications, it would be interesting to develop models allowing clusters to merge and split over time. We believe that it is possible to build first-order stationary models including such merge-split mechanisms exploiting once more the remarkable properties of the Poisson-Dirichlet distributions under splitting and merging transformations; see e.g. (Pitman, 2002).

Appendix A. Extensions

A.1 Species Sampling Priors

The consistence properties under size-biased deletion are remarkable properties specific to the two-parameter Ewens sampling formula (Gnedin and Pitman, 2005). However, the uniform and deterministic deletion steps can be extended to any model with a given prediction rule which ensures exchangeability over the data. In particular, the class of species sampling priors - which includes the two-parameter Ewens sampling formula - is of particular interest as it enjoys these two properties (Pitman, 1996; Lee, 2009). A sequence $\{\mathbf{y}_n\}$ is called a

5. The contents reflect only the authors views and not the views of the European Commission.

species sampling sequence if the following prediction rule holds

$$\begin{aligned}\mathbf{y}_1 &\sim \mathbb{G}_0 \\ \mathbf{y}_{n+1}|\mathbf{y}_1,\ldots,\mathbf{y}_n &\sim \sum_{j=1}^{k} \frac{p(n_1,\ldots,n_j+1,\ldots,n_k)}{p(n_1,\ldots,n_j,\ldots,n_k)}\delta_{U_j} + \frac{p(n_1,\ldots,n_j,\ldots,n_k,1)}{p(n_1,\ldots,n_j,\ldots,n_k)}\mathbb{G}_0 \end{aligned} \quad (20)$$

where $\mathbb{G}_0$ is a base distribution, U_j and n_j, $j = 1,\ldots k$, are respectively the set of distinct values within $\mathbf{y}_{1:n}$ and their relative occurrences. Here $p : \cup_{k=1}^{\infty}\mathbb{N}^k \to [0,1]$ is a *symmetric* function of k-tuples of non-negative integers with sum n called the *Exchangeable Partition Probability Function*. This function must satisfy

$$p(1) = 1 \text{ and } p(n_1,\ldots,n_k) = \sum_{j=1}^{k} p(n_1,\ldots,n_j+1,\ldots,n_k) + p(n_1,\ldots,,n_k,1).$$

To obtain first-order stationary species sampling process, we can apply the uniform and deterministic deletion steps followed by the predictive step (20).

A.2 Time-varying Hierarchical and Coloured Dirichlet Processes

Various hierarchical extensions of the Dirichlet process have been proposed such as the popular hierarchical Dirichlet process (Teh et al., 2006) and the coloured Dirichlet process (Green, 2010). We show here how time-varying stationary versions of these models can easily be designed.

The hierarchical Dirichlet process consists of embedded Dirichlet processes where we have at the top of the hierarchy

$$\mathbb{G} \sim \mathrm{DP}(\alpha, \mathbb{G}_0)$$

then for each group $k = 1,\ldots,d$

$$\mathbb{G}_k|\mathbb{G} \sim \mathrm{DP}(a, \mathbb{G})$$

and finally for each item $i = 1,\ldots,n_k$ within group k

$$\begin{aligned}\mathbf{y}_{i,k}|\mathbb{G}_k &\sim \mathbb{G}_k \\ \mathbf{z}_{i,k}|\mathbf{y}_{i,k} &\sim f(\cdot|\mathbf{y}_{i,k}).\end{aligned}$$

A popular application of this model is topic clustering. In this case, a group k represents a document and data $\mathbf{z}_{i,k}$ represent words within documents. The 'mother' mixing distribution $\mathbb{G}$ represents the overall mixture over topics, and each 'child' mixing distribution $\mathbb{G}_k$ represents the mixture associated to a document k, sampled from a Dirichlet process of base measure $\mathbb{G}$. This model can be straightforwardly extended to take into account a time-varying base measure $\mathbb{G}_t$. Similarly to (Teh et al., 2006), a 'Chinese restaurant franchise' formulation can be expressed based on the set of alive allocation variables at time t.

The coloured Dirichlet process consists of a finite mixture of Dirichlet process mixtures where

$$\pi_{1:K} \sim \mathcal{D}(a_1,\ldots,a_K).$$

Here $\mathcal{D}$ denotes the Dirichlet distribution. For each group $k = 1, \ldots, K$, we have

$$\mathbb{G}_k \sim \mathrm{DP}(\alpha_k, \mathbb{G}_{0,k}).$$

Finally for each item $i = 1, \ldots, n$, we have

$$\begin{aligned} c_i|\pi_{1:K} &\sim \pi_{1:K}, \\ \mathbf{y}_i|c_i &\sim \mathbb{G}_{c_i}, \\ \mathbf{z}_i|\mathbf{y}_i &\sim f(\cdot|\mathbf{y}_i). \end{aligned}$$

The main application of such models is for clustering data in presence of some background noise. Again, a time-varying version of this model, where the weights and cluster locations evolve over time, can straightforwardly be developed by deleting allocation variables as described in Section 3 and sampling them conditionally on the set of alive variables as described in (Green, 2010).

Appendix B. Auxiliary Variable Formulae

The parameters $\mu_M, \kappa_M, \nu_M, \Lambda_M$ and q_M in Eq. (19) can be written as

$$\kappa_M = \kappa_0 + M \tag{21}$$

$$\nu_M = \nu_0 + M \tag{22}$$

$$\mu_M = \frac{\kappa_0}{\kappa_0 + M}\mu_0 + \frac{M}{\kappa_0 + M}\overline{\mathbf{a}}^s \tag{23}$$

$$\Lambda_M = \Lambda_0 + S_{\mathbf{a}^s} \tag{24}$$

$$q_M = q_0 + \sum_{i=1}^{M} \mathbf{a}_i^c \tag{25}$$

where $\mathbf{a}^s$ and $\mathbf{a}^c$ respectively denote the spatial and color components of the auxiliary variables, and $\overline{\mathbf{a}}$ and $S_{\mathbf{a}}$ respectively denote the sample mean and sample covariance of the auxiliary variables.

Appendix C. Kolmogorov-Consistent Model

As mentioned in Section 3, the model is not Kolmogorov-consistent. Consider a sequence of distributions $\pi_n(\mathbf{c}_{1:n,1:t})$, $n = 1, 2, \ldots$, where there are n allocation variables at each time t, then, except in the trivial cases $\rho = 0$ or $\rho = 1$

$$\sum_{\mathbf{c}_{n,1:t}} \pi_n(\mathbf{c}_{1:n,1:t}) \neq \pi_{n-1}(\mathbf{c}_{1:n-1,1:t}). \tag{26}$$

It is possible to construct a slightly different model that satisfies the above equality. Consider that there are p latent variables $\widetilde{c}_{k,t}$ which evolve according to the generalized Pólya urn defined in Algorithm 1. We denote by $\widetilde{\mathbf{c}}_{1:t-1}^{t-1}$ the subset of $\widetilde{\mathbf{c}}_{1:t-1}$ corresponding to variables having survived the deletion steps from time 1 to $t-1$, and we denote by $\widetilde{\mathbf{c}}_{1:t-1}^{t}$ the subset corresponding to those having survived from time 1 to t. Let $\widetilde{K}_{t-1}$ be the number of

clusters created from time 1 to $t-1$. We denote by $\widetilde{\mathbf{m}}_{t-1}^{t-1}$ the vector of size $\widetilde{K}_{t-1}$ containing the size of the clusters associated to $\widetilde{\mathbf{c}}_{1:t-1}^{t-1}$, and we denote by $\widetilde{\mathbf{m}}_{t-1}^{t}$ the vector containing the size of clusters associated to $\widetilde{\mathbf{c}}_{1:t-1}^{t}$.

Conditional on $(\widetilde{\mathbf{c}}_{1:t-1}^{t}, \widetilde{c}_t)$ (or equivalently $(\widetilde{\mathbf{m}}_{t-1}^{t}, , \widetilde{c}_t)$), the allocation variables $c_{k,t}$ of the n observations are simply drawn from a standard Pólya urn. The whole model is represented in Figure 12. As the Markov process is on the latent variables and not on the allocation variables $c_{k,t}$ associated to observations, this model is Kolmogorov-consistent:

$$\sum_{\mathbf{c}_{n,1:t}} \pi_n(\mathbf{c}_{1:n,1:t}) = \pi_{n-1}(\mathbf{c}_{1:n-1,1:t}). \tag{27}$$

Note that we have in this case an additional tuning parameter p. Larger values of p induce higher correlations.

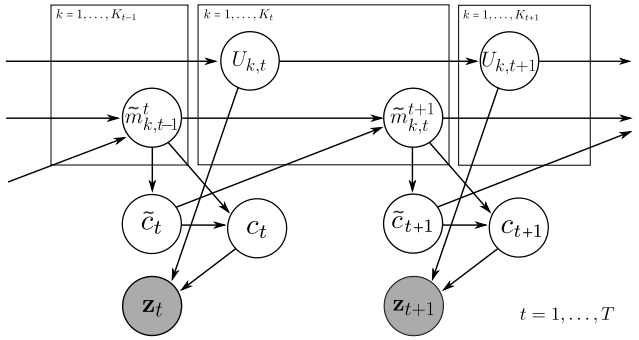

Figure 12: A representation of the time-varying Pitman-Yor process mixture as a directed graphical model, representing conditional independencies between variables. All assignment variables and observations at time t are denoted c_t and $\mathbf{z}_t$, respectively.

Abstract

This paper presents an original Markov chain Monte Carlo method to sample from the posterior distribution of conjugate mixture models. This algorithm relies on a flexible split-merge procedure built using the particle Gibbs sampler introduced in Andrieu et al. (2009, 2010). The resulting so-called Particle Gibbs Split-Merge sampler does not require the computation of a complex acceptance ratio and can be implemented using existing sequential Monte Carlo libraries. We investigate its performance experimentally on synthetic problems as well as on geolocation data. Our results show that for a given computational budget, the Particle Gibbs Split-Merge sampler empirically outperforms existing split merge methods. The code and instructions allowing to reproduce the experiments is available at `https://github.com/aroth85/pgsm`.

Keywords: Dirichlet process mixture models; Gibbs sampler; Particle Gibbs sampler; Sequential Monte Carlo.

1. Introduction

Mixture models are very commonly used to perform clustering and density estimation, and they have consequently found numerous applications in a wide range of scientific fields. Since the introduction of Markov chain Monte Carlo (MCMC) methods in statistics over twenty five years ago, the Bayesian approach to mixture models has become very popular (Marin et al., 2005; Richardson and Green, 1997). However, sampling from the posterior distribution of mixture models remains a challenging computational problem.

When conjugate priors are used, it is possible to analytically integrate out the mixing proportions and the parameters of the components. This is the scenario we will focus on in this article. In this case, we aim to sample from the posterior distribution of the latent indicator variables associated with the observations, each latent variable indicating which component of the mixture generates a given data point. A simple Gibbs sampler can be used which updates the latent indicator variables one-at-a-time (MacEachern, 1994; Escobar and West, 1995) but this algorithm is inefficient when the number of observed data points T is large. First, the simulated Markov chain would have to visit a long chain of lower probability configurations in order to split and merge large clusters. As a result, it is prone to getting trapped in severe local modes. Second, it is non-trivial to parallelize due to the inherently sequential nature of the updates.

The limitations of the simple Gibbs sampler has motivated a rich literature on MCMC algorithms for Bayesian mixture models which partially address these issues; see, e.g., Ishwaran and James (2001); Liang et al. (2007); Walker (2007); Kalli et al. (2011). In particular, procedures proposing to split and merge existing clusters in one single step have become prominent as they generally perform better than the simple Gibbs sampler (Richardson and Green, 1997; Neal, 2000; Dahl, 2003; Jain and Neal, 2004).

While designing an efficient merge proposal is simple, designing an efficient split proposal is a more complicated task. When the mixing proportions and parameters are not integrated out, split-merge moves were first proposed in Richardson and Green (1997). The proposals were built to ensure the conservation of some moments and accepted/rejected using Metropolis-Hastings steps. However, it is difficult to design efficient proposals in this context.

When the mixing proportions and parameters are integrated out, split-merge moves on the latent indicator variables were first proposed in Jain and Neal (2004). Assume one is interested in splitting a block/cluster of points $b \subset \{1, \ldots, T\}$ into two blocks. We select two points in b, which will be in distinct blocks after the split. There are $2^{|b|-2}$ possible ways to split the original block b, hence any efficient proposal needs to be informed by the observations corresponding to the indices in b. In Jain and Neal (2004), one selects two points at random which are used as anchors. When the two anchors are in separate clusters, a merging of the two clusters is proposed. When the two anchors are in the same cluster, a split is proposed as follows: first, the two anchor points seed a pair of new clusters, and second, several restricted Gibbs scans are performed to reallocate the remaining points originally clustered with the anchors to the two new clusters. All clusters which do not contain the anchors are not altered, leading to a restricted Gibbs move. After either a split or a merge is proposed, the Metropolis-Hastings ratio is computed to accept or reject the move. The number of Gibbs scans in the split move is a free tuning parameter for this sampler. In Dahl (2003), an alternative approach is proposed for split moves. The restricted Gibbs scans are replaced by a sequential allocation step whereby the anchors define two new clusters and all points which were originally clustered with these points are sequentially allocated to one of the anchor clusters.

These split-merge algorithms have become popular as they provide state-of-the-art performance but they are relatively difficult to implement due to their complex Metropolis-Hastings acceptance ratios.

In the present work, we propose a novel split-merge sampler based on the conditional Sequential Monte Carlo (SMC) algorithm appearing in the Particle Gibbs (PG) sampler (Andrieu et al., 2009, 2010), which we call the Particle Gibbs Split Merge (PGSM) sampler. Most of the complexity inherent to split-merge operators is encapsulated into the well-understood PG sampling procedure (Chopin and Singh, 2015), and no acceptance ratio

needs to be computed. Moreover, as the PGSM sampler relies on SMC methods, it benefits from advanced simulation methods from the SMC literature, such as adaptation schemes (Lee, 2011) and methods for parallel and distributed inference (Lee et al., 2010; Jun et al., 2012; Lee and Whiteley, 2016), as well as from efficient SMC software libraries (Johansen, 2009; Murray, 2015). The PGSM sampler does not make any topological assumption on the observation space in contrast to the posterior simulation techniques described in Dahl (2009) and Liang et al. (2007). This methodology complements the maximum *a posteriori* inference techniques developed in Daumé III (2007); Wang and Dunson (2011).

There has been previous work on applying sequential importance sampling and SMC methods for posterior simulation of Dirichlet processes and related mixture models. However, to the best of our knowledge, SMC methods have never been previously used to design split-merge moves. Indeed, the methods proposed in MacEachern et al. (1999); Fearnhead (2004); Fearnhead and Meligkotsidou (2007); Mansinghka et al. (2007); Caron and Doucet (2009); Carvalho et al. (2010) directly apply a single pass SMC algorithm to the entire clustering problem. Empirical results in Kantas et al. (2015) suggest that such methods may require a number of particle which scales at least quadratically with respect to the number of datapoints. The work of Ülker et al. (2010) uses SMC within the context of the SMC Samplers methodology (Del Moral et al., 2006), which makes it closer in spirit to existing MCMC methods. Our contribution is to provide a principled approach for breaking down the clustering problem into smaller sub-problems more amenable to the use of SMC techniques.

Finally, other lines of work are devoted to parallelization and distribution of MCMC methods for mixture models (Chang and Fisher III, 2013; Williamson et al., 2013; Gal and Ghahramani, 2014; Ge et al., 2015). As alluded to earlier, our method can potentially be parallelized and distributed using existing approaches from the SMC literature (Lee et al., 2010; Jun et al., 2012; Lee and Whiteley, 2016). Like the other available split-merge procedures, it is also possible to consider different split-merge moves simultaneously when the prior clustering distribution restricted to the clusters being updated does not depend on the number of clusters for the whole dataset. However, we do not focus on these aspects here.

The rest of this article is organized as follows. Section 2 introduces our notation for the types of Bayesian mixture models that we consider. Section 3 details the PGSM sampler. Section 4 applies the method to synthetic datasets, as well as real data from a geolocation application. We conclude with some directions for future work and discussion in Section 5.

2. Mixture models and Bayesian inference

In this section we first layout notation and then describe Bayesian mixture models. We focus on the case where the component base measure is conjugate to the data likelihood, so that the posterior distribution of any clustering can be evaluated analytically up to a normalizing constant.

2.1 Notation

We use bold letters for (random) vectors, and normal fonts for (random) scalars, sets, and matrices. For quantities such as an individual observation y_i, or a parameter θ, which can

be either scalars or vectors without affecting our methodology, we consider them as scalars without loss of generality. Given a vector $\mathbf{x} = (x_1, x_2, \ldots, x_n)$, and $i \leq j$, we use $\mathbf{x}_{i:j}$ to denote the sub-vector $\mathbf{x}_{i:j} = (x_i, x_{i+1}, \ldots, x_j)$. To simplify notation, we do not distinguish random variables from their realization. We define discrete probability distributions with their probability mass functions, and continuous probability distributions with their density functions with respect to the Lebesgue measure. A list of symbols is available in the Appendix.

2.2 Bayesian mixture model

Consider T observations $\mathbf{y} \coloneqq (y_1, \ldots, y_T)$. A mixture model assumes that the observations indices $[T] \coloneqq \{1, \ldots, T\}$ are partitioned into subsets. This partition is called a clustering, $c \coloneqq \{b_1, \ldots, b_{|c|} : b_k \subseteq [T]\}$ where $|c|$ denotes the cardinality of the set c and each block b in the partition is referred to as a cluster. Given the clustering c, we define the following likelihood for the data

$$\pi(\mathbf{y}|c) \coloneqq \prod_{b \in c} L(\mathbf{y}_b), \tag{1}$$

where $L(\mathbf{y}_b)$ is the likelihood of the observations in cluster b

$$L(\mathbf{y}_b) \coloneqq \int \left(\prod_{i \in b} L(y_i|\theta) \right) H(\,\mathrm{d}\theta). \tag{2}$$

In this expression, $L(y_i|\theta)$ is a probability density function parametrized by θ and $H(\,\mathrm{d}\theta)$ a prior measure over this parameter.

The clustering c is unknown and is viewed as a random variable. Let $\tau(c)$ denote its prior probability, defined over the space of partitions of $[T]$ and assumed to factorize as

$$\tau(c) \propto \tau_1(|c|) \prod_{b \in c} \tau_2(|b|), \tag{3}$$

where $\tau_1 : \mathbb{N} \to \mathbb{R}^+$ and $\tau_2 : \mathbb{N} \to \mathbb{R}^+$ are arbitrary functions.

This assumption on the prior clustering distribution is not restrictive and includes several popular priors, such as:

Dirichlet process prior (Ferguson, 1973) with parameter $\alpha_0 > 0$: $\tau_1(j) \propto {\alpha_0}^j$ and $\tau_2(j) \propto (j-1)!$.

Pitman-Yor process prior (Pitman and Yor, 1997; Ishwaran and James, 2003) with parameters α_0, d ($\alpha_0 > -d$, $0 \leq d < 1$): $\tau_1(j) \propto \prod_{j'=1}^{j} \{\alpha_0 + d\,(j'-1)\}$ and $\tau_2(j) \propto \Gamma(j-d)$, where $\Gamma(\cdot)$ is the Gamma function.

Finite Dirichlet mixture with parameter $\alpha_{\mathrm{Dir}} > 0$ and k_0 components and symmetric concentration $(\alpha_{\mathrm{Dir}}, \ldots, \alpha_{\mathrm{Dir}})$: $\tau_1(j) \propto \mathbf{1}\,[j \leq k_0]$ and $\tau_2(j) \propto \Gamma(j + \alpha_{\mathrm{Dir}})$.

The likelihood (1)-(2) and prior (3) define the following target posterior distribution

$$\pi(c) \coloneqq \pi(c \mid \mathbf{y}) \propto \tau(c) \prod_{b \in c} L(\mathbf{y}_b). \tag{4}$$

Since we view the observations as fixed, we drop the dependency on $\mathbf{y}$ from the notation throughout the paper. We detail in the following sections an original approach to sample from this posterior distribution.

3. Methodology

We organize the description of our method into two main parts. First, we define a generic construction for decomposing the problem of sampling from the posterior (Equation (4)) with arbitrary numbers of clusters into *split-merge* sub-problems. Second, we show how the PG methodology can be used to address these sub-problems.

3.1 Decomposing the clustering problem into split-merge subproblems

Algorithm 1 allows us to break down the problem of sampling from the posterior into split-merge subproblems. We refer the reader to Figure 1 for an illustrative example of the notation used throughout this description.

Algorithm 1

function SplitMerge($c, h(s), K_{c,s}(\overline{c}'|\overline{c})$)
  $s \sim h(\cdot)$ ▷ $s = \{i_1, i_2\}$
  $\overline{c} \leftarrow \{b \in c : b \cap \overline{s} \neq \emptyset\}$ ▷ Clustering restricted to the anchors
  $\overline{s} \leftarrow \bigcup_{b \in \overline{c}} b$ ▷ Closure of the anchors with respect to the clustering $\overline{c}$
  $\overline{c}' \sim K_{c,s}(\cdot|\overline{c})$
  $c' \leftarrow \overline{c}' \cup (c \backslash \overline{c})$
  return c'
end function

The algorithm requires three inputs:

1. c: the current clustering,
2. $h(s)$: a distribution for proposing an unordered pair of *anchors* $s = \{i_1, i_2\} \subset [T]$,
3. $K_{c,s}(\overline{c}'|\overline{c})$: a Markov transition kernel over the space of partitions of $\overline{s}$. This kernel is assumed to be invariant with respect to the following target distribution:

$$\overline{\pi}_{c,s}(\overline{c}') \propto \overline{\tau}_1(|\overline{c}'|) \left(\prod_{b \in \overline{c}'} \tau_2(|b|) L(\mathbf{y}_b) \mathbf{1}\left[b \cap s \neq \emptyset\right] \right), \qquad (5)$$
$$\overline{\tau}_1(j) \coloneqq \tau_1(j + |c| - |\overline{c}|).$$

In the following, we drop the subscripts from the kernel K and target $\overline{\pi}$ for simplicity.

The distribution $\overline{\pi}$ has a form similar to the posterior distribution defined in Equation (4) with two modifications. First, $\tau_1(|c|)$ is replaced by $\overline{\tau}_1(|\overline{c}'|)$. Second, the support of the distribution is restricted so that each block in $\overline{c}'$ must contain at least one anchor point. This also implicitly enforces the constraint that $|\overline{c}'| \leq |s| = 2$.

Algorithm 1 returns an updated clustering where only the allocation of points in $\overline{s}$ have changed; i.e. the updated clustering c' only potentially differs from c at points which were

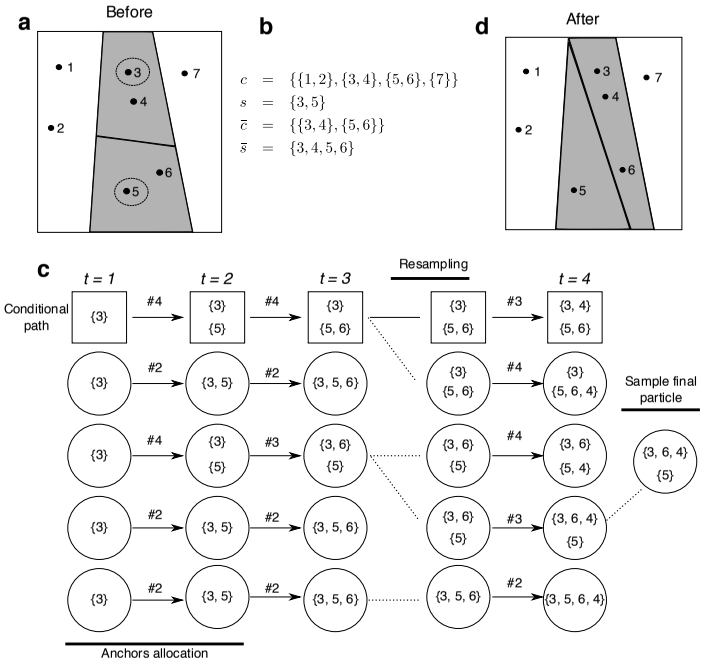

Figure 1: (**a**) Example illustrating the setup of a split merge and (**b**) the notation used in Section 3.1. The seven points denote the observation indices. While we show points in a two-dimensional space for visualization, the methodology does not rely on any topological properties of the observation space. The dashed circles denote the anchors s, and the shaded region, the closure of the anchors. (**c**) Example of a single PGSM step with $\boldsymbol{\sigma} = (3, 5, 6, 4)$. Square boxes represent particles corresponding to the fixed conditional path. Circles represent regular particles. Each particle has an associated clustering denoted by the set or pair of sets written inside each particle. Arrows indicate proposal draws labelled by the proposed state (see Figure 2). Dashed lines indicate when resampling occurs. (**d**) Configuration after the PGSM update illustrated in **c**.

initially clustered with the anchor points. The anchor proposal distribution h obviously impacts the performance of this procedure. We empirically compare the performance of three anchor proposal distributions h in Section 4.3.

This scheme has the following property:

Proposition 1 *If $c \sim \pi$, where π is given by Equation (4), then the output of Algorithm 1, c', satisfies $c' \sim \pi$. That is, the Markov kernel $K(c'|c)$ induced by Algorithm 1 is π-invariant.*

3.2 Overview of the particle Gibbs algorithm

Ideally, we would like to sample independently from $\overline{\pi}$ in Algorithm 1, that is we would like to have $K(\overline{c}'|\overline{c}) = \overline{\pi}(\overline{c}')$, but this is too computationally expensive if $|\overline{s}|$ is large. Our primary contribution is an original way to address this issue using SMC-based methods.

In principle, it would be possible to use SMC methods to obtain a sample approximately distributed according to $\overline{\pi}$ (Fearnhead, 2004). However, if we were to use this sample within Algorithm 1, the resulting invariant distribution would not be π. For this reason, we consider Particle MCMC (PMCMC) methods (Andrieu et al., 2009, 2010).

PMCMC methods allow us to use SMC ideas in a principled way within MCMC schemes. We will focus here on the PG sampler and show how one can use this methodology to obtain an efficient MCMC kernel K targeting the distribution $\overline{\pi}$ given in Equation (5). The outcome of the PG sampling steps will be either to cluster all the points in $\overline{s}$ into one block or to break $\overline{s}$ into two clusters, with the restriction that each of the two blocks should contain one anchor. Interestingly, the form of the PG algorithm is the same no matter if the two anchors were previously together or apart before its execution. This contrasts with previous split-merge algorithms such as Jain and Neal (2004), which require a different treatment for split and merge moves.

To sample from $\overline{\pi}$, PG breaks the sampling of $\overline{c}'$ into a sequence of $n := |\overline{s}|$ simpler sampling problems. In this scenario, contrary to most applications of PG, there is no intrinsic time ordering of the observations. We randomize the order in which the points are included by introducing, conditionally on s and $\overline{s}$, a random permutation $\boldsymbol{\sigma} := (\sigma_1, \ldots, \sigma_n)$. This permutation is sampled using Algorithm 2.

Algorithm 2

1: **function** SamplePermutation$(s, \overline{s})$
2: $\quad\sigma_1 \sim \text{Uniform}(s)$
3: $\quad\sigma_2 \leftarrow s \backslash \{\sigma_1\}$
4: $\quad(\sigma_3, \sigma_4, \ldots, \sigma_n) \leftarrow \text{UniformPermutation}(\overline{s} \backslash s)$
5: $\quad$**return** $\boldsymbol{\sigma}$
6: **end function**

In other words, $\boldsymbol{\sigma}$ is uniform over the permutations of the observation indices in $\overline{s}$ such that the members of s appear in the first two entries. The variable σ_t specifies the index of the observation y_{σ_t} introduced into the PG algorithm at SMC iteration ("algorithmic" time) t and x_t is the corresponding allocation decision. A particle $\mathbf{x}_t$ is defined as a sequence of allocation decisions, $\mathbf{x}_t := (x_1, \ldots, x_t)$, where $x_t \in \mathcal{X}$, $t \in \{1, \ldots, n\}$.

Given $\boldsymbol{\sigma}$, we denote the SMC proposals used within PG by $q_t^{\boldsymbol{\sigma}}(x_t|\mathbf{x}_{t-1})$, and the intermediate unnormalized target distributions, by $\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)$. We remind the reader that both $\gamma_t^{\boldsymbol{\sigma}}$ and $q_t^{\boldsymbol{\sigma}}$ are allowed to depend on arbitrary subsets of the observations $\mathbf{y}$; see, e.g., (Del Moral et al., 2006). However, we omit this dependency for notational simplicity. Our methodology is flexible with respect to the choice of the proposals and the choice of the intermediate

unnormalized target distributions. For our methodology to provide consistent estimates, only the following weak assumptions have to be satisfied.

Assumption 1 *For all $t \in \{1, \ldots, n\}$, we assume* $\text{support}(\gamma_t^{\boldsymbol{\sigma}}) \subseteq \text{support}(q_t^{\boldsymbol{\sigma}})$ *where* $q_t^{\boldsymbol{\sigma}}(\mathbf{x}_t) := q_1^{\boldsymbol{\sigma}}(x_1) \prod_{k=2}^{t} q_k^{\boldsymbol{\sigma}}(x_k|\mathbf{x}_{k-1})$ *for $t \geq 2$.*

Assumption 2 *We assume that there exists a bijection $\phi^{\boldsymbol{\sigma}}$ taking a particle as input, and outputting a clustering of $\overline{s}$. More precisely, $\phi^{\boldsymbol{\sigma}}$ is a bijection between the support of the proposal, and the support of the split-merge target distribution, $\phi^{\boldsymbol{\sigma}} : \text{support}(q_n^{\boldsymbol{\sigma}}) \to \text{support}(\overline{\pi})$.*

Assumption 3 *We assume that $\gamma_n^{\boldsymbol{\sigma}}(\mathbf{x}_n) \propto \overline{\pi}(\phi^{\boldsymbol{\sigma}}(\mathbf{x}_n))$.*

Assumption 1 ensures that all the importance weights appearing in the SMC method are well-defined. Assumption 2 is a simple condition ensuring that we can consistently relabel the particles. Assumption 3 ensures that we target the desired distribution at algorithmic time n. Note that Assumption 3 only restricts the choice of γ_t for the final SMC iteration, $t = n$. We use this flexibility in Section 3.4. We show in the next section how to design $q^{\boldsymbol{\sigma}}$, $\gamma^{\boldsymbol{\sigma}}$, $\phi^{\boldsymbol{\sigma}}$ and $\mathcal{X}$ that satisfy these assumptions.

PG proceeds in a way similar to standard SMC algorithms, with the important difference that one of the N particle paths is fixed. In our setup, this path is obtained using the inverse of the bijection described in Assumption 2, applied to the state of the restricted clustering $\overline{c}$ prior to the current PG step. As discussed in Chopin and Singh (2015), we can without loss of generality set the genealogy of the conditioning path $\overline{c}$ to $(1, ..., 1)$, i.e. we use the particle index $p = 1$ for this conditioning path: $\mathbf{x}_n^1 := (\phi^{\boldsymbol{\sigma}})^{-1}(\overline{c})$. This defines a path by taking a prefix of length t of the vector $\mathbf{x}_n^1$ for $\mathbf{x}_t^1$, i.e. $\mathbf{x}_t^1 = \left(\mathbf{x}_n^1\right)_{1:t}$.

The final ingredient required to describe the PG algorithm is a *conditional resampling* distribution $r(\boldsymbol{a} \mid \boldsymbol{w})$, where $\boldsymbol{a} := (a_2, \ldots, a_N)$ denotes the resampling ancestors, $a_p \in \{1, \ldots, N\}$, and $\boldsymbol{w} := (w^1, \ldots, w^N)$ denotes a vector of probabilities. We limit ourselves to multinomial resampling:

$$r(\boldsymbol{a} \mid \boldsymbol{w}) = \prod_{p=2}^{N} r(a_p \mid \boldsymbol{w}) = \prod_{p=2}^{N} w^{a_p}. \tag{6}$$

More elaborate schemes can be used, see Andrieu et al. (2009, 2010). Instead of resampling at each time step as in vanilla SMC algorithms, we only resample when the relative Effective Sampling Size (ESS) criterion, which takes values between 0 and 1, is below a pre-specified threshold β, $\beta \in [0, 1]$. The adaptive resampling procedure was proposed by Liu and Chen (1995) for standard particle methods and the correctness of this procedure for PG has been established in Lee (2011). The resulting procedure is described in Algorithm 3.

Most of Algorithm 3 is concerned with the creation of temporary auxiliary variables (lines 1–34). These auxiliary variables can all be discarded after the algorithm returns $\overline{c}'$, as they can be resampled from scratch every time Algorithm 3 is run. The part of the algorithm that performs the actual split or merge is in lines 35 and 36. At this point of the execution of the algorithm, the particle population at SMC generation n can be interpreted (via $\phi^{\boldsymbol{\sigma}}$) as a distribution over clusterings of $\overline{s}$, with some particles corresponding to merging

Algorithm 3

function ParticleGibbsSplitMerge($s, \overline{s}, \overline{c}, \overline{\pi}$) ▷ Inputs coming from Algorithm 1

all points in $\overline{s}$ into one block (i.e. when $|\phi^{\boldsymbol{\sigma}}(\mathbf{x}'_n)| = 1$), and others, to various way of splitting $\overline{s}$ into two blocks (when $|\phi^{\boldsymbol{\sigma}}(\mathbf{x}'_n)| = 2$).

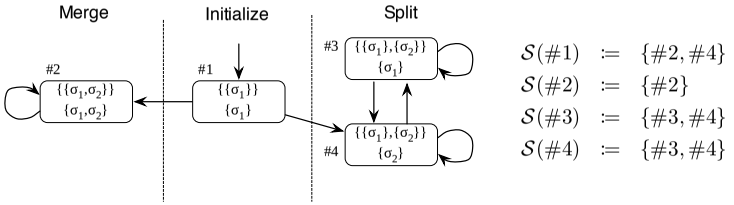

Figure 2: Left: State space $\mathcal{X}$ and allowed transitions $\mathcal{S}(\cdot)$ for the local allocation decisions. Right: allowed transitions between the states.

Correctness of this procedure follows straightforwardly from the original PG argument (see Appendix B for details):

Proposition 2 *Under Assumptions 1, 2, and 3, the output of Algorithm 3, $\overline{c}'$, satisfies $\overline{c}' \sim \overline{\pi}$ if $\overline{c} \sim \overline{\pi}$, for any $N \geq 2$, i.e. the Markov kernel $\overline{K}(\overline{c}'|\overline{c})$ induced by Algorithm 3 is $\overline{\pi}$-invariant.*

3.3 Intermediate target distributions and proposals construction

We detail here the construction of a set of proposal distributions $q^{\boldsymbol{\sigma}}$, unnormalized target distributions $\gamma^{\boldsymbol{\sigma}}$, and mappings $\phi^{\boldsymbol{\sigma}}$ satisfying Assumptions 1 to 3. We denote the space of possible allocation decisions at a given PG iteration by $\mathcal{X}$. Our construction is based on an encoding where the space $\mathcal{X}$ consists in the rectangles shown in Figure 2. We call the rectangles *states* for short. These states are used to build particles: recall that a particle $\mathbf{x}_t$ is defined as a list of local decisions, $\mathbf{x}_t \coloneqq (x_1, \ldots, x_t)$, $x_{t'} \in \mathcal{X}$.

The state appended to a particle at time t represents (a) the clustering restricted to the anchors (shown in the first line of each rectangle in Figure 2), and (b), the cluster joined by y_{σ_t} (encoded by the anchor(s) contained in the joined cluster, second line in the same figure). As shown in Figure 2, the "merge state" (left) is an absorbing state, encoding the fact that following this local decision, all children particles are forced to join the unique block in the restricted clustering. The two "split states" (right), on the other hand, both have two outgoing transitions, encoding the fact that for each index in $\overline{s} \backslash s$, the corresponding observation needs to be allocated to one of the two blocks.

There is a bijection between the support of $\overline{\pi}$, and particles respecting the transition constraints defined by the arrows in Figure 2. More precisely, for each state $x \in \mathcal{X}$, we let $\mathcal{S}(x)$ denote the set of allowed transitions from x. We write $\mathbf{x}_t \in \mathcal{S}_t$ if (a) $x_1 = \#1$, and (b) for all $t' \in \{2, \ldots, t\}$, $x_{t'} \in \mathcal{S}(x_{t'-1})$. From this definition, we obtain the following result whose proof is given in Appendix C.

Proposition 3 *For any permutation $\boldsymbol{\sigma}$ satisfying $\{\sigma_1, \sigma_2\} = s$, there is a bijective map $\phi^{\boldsymbol{\sigma}}$ from the space of particles respecting the transition constraints, $\mathcal{S}_n$, to the support of the restricted target,* $\text{support}(\overline{\pi})$.

We use this bijection to define a sequence of intermediate target and proposal distributions. The intermediate target at time t of support $\mathcal{S}_t$ is given by:

$$\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t) \coloneqq \overline{\tau}_1(\overline{c}_t) \left(\prod_{b \in \overline{c}_t} \tau_2(|b|) L(\mathbf{y}_b) \right), \tag{7}$$

where $\overline{c}_t = \phi^{\boldsymbol{\sigma}_{1:t}}(\mathbf{x}_t)$. By construction, we have that for $t = n$, $\gamma_n^{\boldsymbol{\sigma}}(\mathbf{x}_n) \propto \overline{\pi}(\phi^{\boldsymbol{\sigma}}(\mathbf{x}_n))$ so Assumption 3 is satisfied.

We define as proposals:

$$\begin{aligned} q_1^{\boldsymbol{\sigma}}(x_1) &\coloneqq \delta_{\#1}(x_1), \\ q_t^{\boldsymbol{\sigma}}(x_t \mid \mathbf{x}_{t-1}) &\coloneqq \frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)}{\sum_{x_t' \in \mathcal{S}(x_{t-1})} \gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1}, x_t')}, \end{aligned} \tag{8}$$

where $(\mathbf{x}_{t-1}, x_t')$ denotes the concatenation of x_t' to the vector $\mathbf{x}_{t-1}$, and $\mathbf{x}_t = (\mathbf{x}_{t-1}, x_t)$. These definitions satisfy Assumption 1, and yield the following weight updates:

$$\begin{aligned} w_t(\mathbf{x}_{t-1}, x_t) &\coloneqq \frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)}{\gamma_{t-1}^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1})} \frac{1}{q_t^{\boldsymbol{\sigma}}(x_t \mid \mathbf{x}_{t-1})} \\ &= \frac{\sum_{x_t' \in \mathcal{S}(x_{t-1})} \gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1}, x_t')}{\gamma_{t-1}^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1})} \\ &= \sum_{x_t' \in \mathcal{S}(x_{t-1})} \frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1}, x_t')}{\gamma_{t-1}^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1})}. \end{aligned} \tag{9}$$

If $t > |s|$ then Equation (10) simplifies as follows

$$\frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)}{\gamma_{t-1}^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1})} = \frac{\tau_2(|b_t^+|)}{\tau_2(|b_t^-|)} L\left(\mathbf{y}_{b_t^+} \mid \mathbf{y}_{b_t^-}\right), \tag{10}$$

where

$$L\left(\mathbf{y}_{b_t^+} \mid \mathbf{y}_{b_t^-}\right) \coloneqq \frac{L\left(\mathbf{y}_{b_t^+}\right)}{L\left(\mathbf{y}_{b_t^-}\right)}. \tag{11}$$

Here b_t^- and b_t^+ encode the block in which a point is added to when transitioning from $\mathbf{x}_{t-1}$ to $\mathbf{x}_t$, the first being the block before the addition, and the second, the same block after the addition:

$$b_t^- \coloneqq \overline{c}_{t-1} \backslash \overline{c}_t, \;\; b_t^+ \coloneqq b^- \cup \{\sigma_t\}. \tag{12}$$

Depending on the form of the partition prior and likelihood it may be possible to simplify these quantities into more computationally efficient forms.

3.4 An improved sequence of intermediate target distributions

We now describe an improvement over the basic intermediate and proposal distributions presented in the previous section. This improvement addresses a "greediness" problem of the (conditional) SMC procedure. Consider a case where the ratio $\overline{\tau}_1(1)/\overline{\tau}_1(2)$ between a merge and a split is large. This can occur for example when the Dirichlet process concentration parameter α_0 is small. In this case, the proposal in the first non-trivial step, $q_2^{\boldsymbol{\sigma}}$, will assign most of its mass to the transition from state #1 to state #2 (see Figure 2). However, the likelihood might overcome this prior when $|\overline{s}|$ is large. But proposing such split has low probability under the definitions given in the previous section, as #2 is an absorbing state.

To overcome this issue, we build a new sequence of intermediate distributions, which delay the incorporation of the prior:

$$\widehat{\gamma_t^{\boldsymbol{\sigma}}}(\mathbf{x}_t) \coloneqq \begin{cases} \mathbf{1}[\mathbf{x}_t \in \mathcal{S}_t], & \text{if } t \in \{1, 2\}, \\ (\gamma_2^{\boldsymbol{\sigma}}(\mathbf{x}_{1:2}))^{\zeta_t} \frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)}{\gamma_2^{\boldsymbol{\sigma}}(\mathbf{x}_{1:2})}, & \text{otherwise.} \end{cases} \tag{13}$$

where ζ_t is a positive increasing annealing schedule such that $\zeta_n = 1$. We use the following proposal based on these new intermediate distributions:

$$\begin{aligned} \widehat{q_1^{\boldsymbol{\sigma}}}(x_1) &\coloneqq \delta_{\#1}(x_1), \\ \widehat{q_t^{\boldsymbol{\sigma}}}(x_t \mid \mathbf{x}_{t-1}) &\coloneqq \frac{\widehat{\gamma_t^{\boldsymbol{\sigma}}}(\mathbf{x}_t)}{\sum_{x_t' \in \mathcal{S}(x_{t-1})} \widehat{\gamma_t^{\boldsymbol{\sigma}}}(\mathbf{x}_{t-1}, x_{t-1}')}. \end{aligned} \tag{14}$$

This yields the weight updates:

$$\widehat{w_t}(\mathbf{x}_{t-1}, x_t) \coloneqq \sum_{x_t' \in \mathcal{S}(x_{t-1})} \frac{\widehat{\gamma_t^{\boldsymbol{\sigma}}}(\mathbf{x}_{t-1}, x_t')}{\widehat{\gamma_{t-1}^{\boldsymbol{\sigma}}}(\mathbf{x}_{t-1})}. \tag{15}$$

For simplicity, we pick $\zeta_t = \frac{t-2}{n-2}$. This choice simplifies ratios of intermediate distributions to:

$$\frac{\widehat{\gamma_t^{\boldsymbol{\sigma}}}(\mathbf{x}_t)}{\widehat{\gamma_{t-1}^{\boldsymbol{\sigma}}}(\mathbf{x}_{t-1})} = \begin{cases} 1 & \text{if } t = 2, \\ (\gamma_2^{\boldsymbol{\sigma}}(\mathbf{x}_{1:2}))^{\Delta\zeta} \frac{\gamma_t^{\boldsymbol{\sigma}}(\mathbf{x}_t)}{\gamma_{t-1}^{\boldsymbol{\sigma}}(\mathbf{x}_{t-1})} & \text{if } t > 2, \end{cases} \tag{16}$$

where $\Delta\zeta \coloneqq (n-2)^{-1}$.

3.5 Runtime analysis

To simplify the analysis of the running time, we make a few assumptions.

Assumption 4 *The parametric likelihood model has the following properties:*

1. *let $\psi \coloneqq \psi(\mathbf{y}_b)$ denote a sufficient statistic, and define, with a slight abuse of notation, $L(\psi) \coloneqq L(\mathbf{y}_b)$. For a given sufficient statistic value ψ, the likelihood $L(\psi)$ can be computed in time $O(l)$,*
2. *the sufficient statistic for b^+, $\psi^+ \coloneqq \psi(\mathbf{y}_{b^+})$, can be updated in time $O(u)$ from the sufficient statistic for b^-, $\psi^- \coloneqq \psi(\mathbf{y}_{b^-})$.*

The next assumption holds for all the clustering priors reviewed in Section 2.

Assumption 5 *The ratio* $\frac{\tau_2(j+1)}{\tau_2(j)}$ *can be computed in constant time.*

For example, with a Dirichlet process, this ratio is equal to $j!/(j-1)! = j$. Since $|b^+| = |b^-| + 1$, Assumption 5 implies that the ratio $\frac{\tau_2(|b^+|)}{\tau_2(|b^-|)}$ in Equation (10) can be computed in constant time.

Proposition 4 *Under Assumptions 4 and 5, one weight computation, Equation (15), takes time* $O(u+l)$. *The storage cost per particle is* $O(1)$. *Moreover, the running time per weight computation is independent of the number of clusters.*

The running time result follows directly from the fact that $|\mathcal{S}(\cdot)| \leq 2$, and hence the sum in Equation (15) has a constant number of terms. The constant storage cost follows from the finite dimensionality of the sufficient statistics (see Assumption 4), and from $|\mathcal{X}| = 4$.

We also remind the reader that for most resampling schemes, including the one in Equation (6), the computational cost as a function of the number of particles and SMC iterations is $O(Nn) = O(N|\overline{s}|)$ (Doucet and Johansen, 2011).

3.6 Generalization

For simplicity, we have assumed so far that $|s| = 2$, and hence, according to the auxiliary variable analysis of Appendix B, $|\overline{c}| \leq 2$. In fact, the same auxiliary variables with more than two anchor points can be used to construct novel sampling algorithms. Details are given in Appendix D.

This generalization loses some interpretability compared to the split-merge case ($|s| = 2$), but can be useful in finite clustering models. In this case, it may only be possible to split a cluster if a merge is performed simultaneously. For this reason, we use $|s| = 3$ in the finite Dirichlet mixture model examples in Section 4.3. For the Dirichlet Process, we did not observe notable improvements by going from $|s| = 2$ to $|s| = 3$, so we use the former setting for the non-parametric models.

4. Applications

In this section, we demonstrate the performance of our methodology and compare it to standard alternatives. We use a series of synthetic datasets covering a large spectrum of cluster separateness, as well as real data coming from a geolocation application.

4.1 Implementation and evaluation

We have implemented the following three Dirichlet Process (DP) clustering samplers in the same Python codebase: the PGSM method described in this work, the efficient Sequentially-Allocated Merge Split (SAMS) method of Dahl (2003), as well as the standard Gibbs sampler. The code and instructions allowing to reproduce the experiments is available at `https://github.com/aroth85/pgsm`. The implementation of the likelihood computations are the same for all samplers, thus the running times are comparable. We have tested

the correctness of our computer implementations by computing the true posterior distribution on small examples via combinatorial enumeration, and verified that the Monte Carlo estimates converged to this distribution for all three methods.

Unless we state otherwise, we initialized the samplers with the single-cluster configuration. In datasets much smaller than those studied in this work, initializing the Gibbs sampler to the fully disconnected clustering is advantageous (Sudderth, 2006), but in larger datasets, the quadratic burn-in cost involved with this initialization is not scalable. However, we verified that after a long burn-in period the Gibbs method initialized to the fully disconnected clustering eventually reaches the same likelihood values in the synthetic examples. We also investigate the high cost of the fully disconnected initialization in the results shown in Figure 9.

To evaluate the performance of the samplers, we held-out a random but fixed 10% of each dataset. We collected samples and computed the predictive likelihood and V-measure (Rosenberg and Hirschberg, 2007) every 100 iterations. All experiments are replicated 10 times, and smoothed using a moving average with a window size of 20 for plotting.

4.2 Likelihoods and priors

In six of the synthetic experiments and the geolocation experiments discussed further in Section 4.3 and Section 4.4, we used a Normal-Inverse-Wishart conjugate likelihood model. In two of the synthetic experiments in Section 4.3 we used Bernoulli mixture models with 50 dimensions. Each dimension is an independent draw from a Bernoulli random variable with cluster specific parameters. We set a proportion of the dimensions to be uninformative as follows. Values for uninformative dimensions were drawn from Bernoulli variables with parameter 0.5 regardless of the cluster membership. Values for the remaining dimensions were drawn from cluster specific Bernoulli variables with parameters sampled from the Uniform distribution. For the cancer data discussed in Section 4.5, we use the application-specific PyClone likelihood model (Roth et al., 2014). The PyClone model uses genomic sequence data from tumours to identify mutations which co-occur in cells and estimates the proportion of cells harbouring the mutations. The model is not conjugate, so we apply a discretization that allows us to treat the model as conjugate. Complete details for each model are provided in Appendix E.

We use a DP prior with base measure given by the conjugate prior of the corresponding likelihood model in all experiments. We use a Gamma$(1, 0.1)$ prior and resample the value of the concentration parameters α_0 using a standard auxiliary variable method (Escobar and West, 1995). The value of α_0 is initialized to 1.0.

4.3 Artificial datasets

We used four sources of synthetic data. First, the four datasets from Franti and Virmajoki (2006) denoted S1–4. Each of the four datasets consists in 5000 points generated from 15 bivariate Normal distributions with increasing amount of overlap between the clusters. Second, we created another synthetic dataset, which we call C1, shown in Figure 5, right. Third, we simulated two datasets with 5000 points from a Bernoulli mixture model with 50 dimensions and 16 clusters, where we set 25% (Ber-0.25) and 50% (Ber-0.5) of dimensions

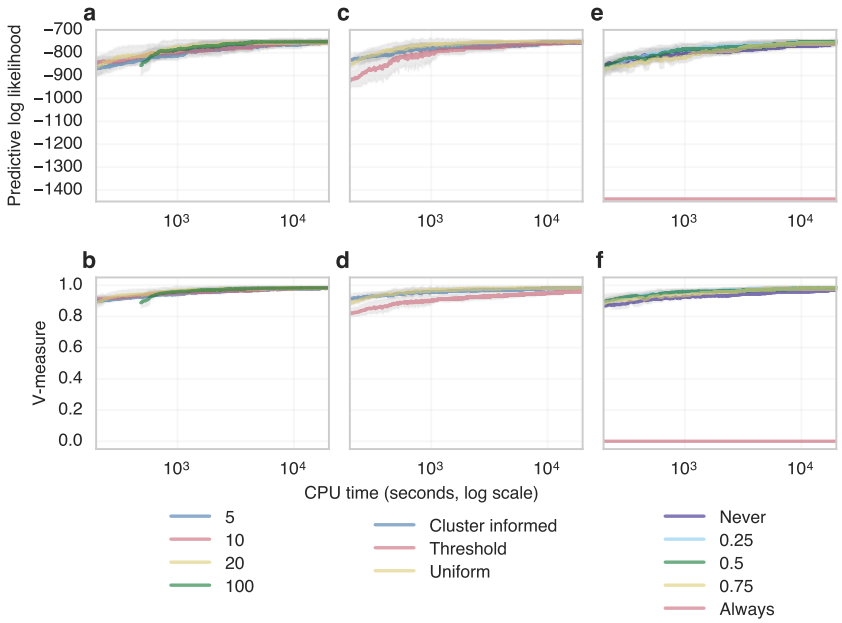

Figure 3: Effect on the predictive performance and clustering accuracy as a function of CPU time in log scale. **a**) and **b**) Varying the number of particles with the cluster informed proposal and a relative ESS resampling threshold of 0.5. **c**) and **d**) Varying the distribution for proposing pairs of anchor points, h, with 20 particles and an ESS resampling threshold of 0.5. **e**) and **f**) Varying the relative ESS resampling threshold with the cluster informed anchor proposal and 20 particles.

to be uninformative. Finally, we used 64 (DIM064) and 128 (DIM128) dimensional Normal datasets from Fränti et al. (2006) with 1024 data points and 16 clusters.

We started with a series of pilot experiments on S1 only, designed to assess the effect of various tuning parameters on the performance of PGSM. For all pilot experiments we use the unmixed PGSM sampler to isolate the effect of each tuning parameter. In practice it is usually better to alternate between one iteration of the PGSM sampler and one iteration of the Gibbs sampler. The effect of this mixing is explored later in this section.

We first explore the performance as we vary the number of particles used for each PGSM iteration (Figures 3 **a** and **b**). The curves with more particles take more time per iteration to run, however seem to achieve slightly better V-measure and predictive likelihood after

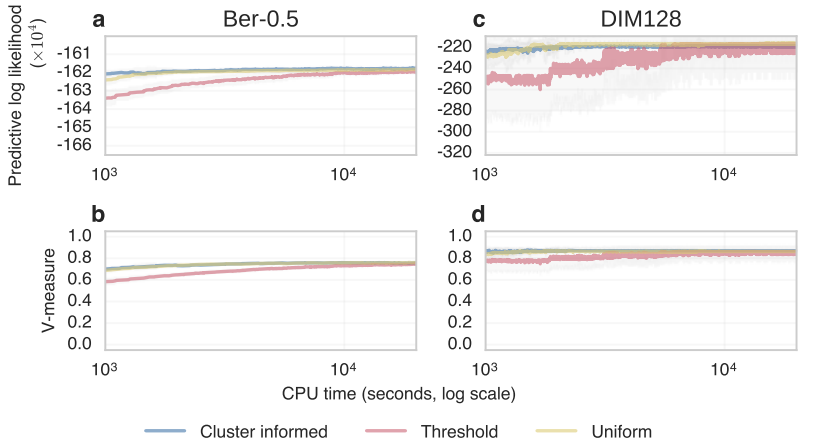

Figure 4: Effect on the predictive performance and clustering accuracy as a function of CPU time in log scale with different distribution h for proposing pairs of anchor points. **a**) and **b**) Comparison using a 50 dimensional Bernoulli dataset with 50% of the dimensions being uninformative. **c**) and **d**) Comparison using a 128 dimensional Normal dataset.

the initial iterations. The performance difference are negligible and the PGSM sampler generally seems insensitive to the number of particles for this dataset. For subsequent experiments we used 20 particles.

Next we compare the performance of different proposal distributions for the anchor auxiliary variables (Figures 3 **c** and **d**). For this experiment we kept the number of particles fixed at 20 and the resampling threshold at 0.5. We consider three proposal distributions.

Uniform: Sample the anchors uniformly at random from the $\binom{T}{2}$ possibilities.

Cluster informed: Sample the first anchor uniformly at random. Sample a cluster to draw the second anchor from with probability $\frac{1}{|c-1|}$ for the cluster containing the first anchor; otherwise proportional to

$$\frac{L(y_{\bar{b}\cup b})}{L(y_{\bar{b}})L(y_b)}$$

where $\bar{b}$ is the cluster containing the first anchor and b is the candidate cluster. Sample the second anchor uniformly from the chosen cluster.

Threshold informed: Sample the first anchor uniformly at random and the second anchor from clusters that have Chinese restaurant attachment probabilities greater than a threshold of 0.01.

To ensure the adaptation of the informed proposals stops, and does not perturb the invariant distribution of the sampler, we only update the proposal distributions when the number of clusters instantiated breaks the previous record. Adaptation is guaranteed to terminate in finite time given there are only a finite number of points. This would usually take a long time, so in practice it is advantageous to stop adaptation after a fixed period of time. Detailed implementations of the cluster informed and threshold informed proposals are given in Appendix F. Our results suggest that performance is not strongly affected by the anchor proposal distribution h. We only saw a small advantage when using the informed proposal distributions for the auxiliary anchor variables in s. We also explored the effect of h in higher dimensional datasets (Figure 4). Again we found the results are not sensitive to the choice of h. With the exception of the circle dataset, where we used the uniform proposal, we used the cluster informed prior for both the PGSM and SAMS samplers in subsequent experiments.

The frequency of the resampling step had a larger effect. A critical implementation point in order for the PGSM method to work is that resampling should be done adaptively by monitoring the ESS of the particle approximations in Algorithm 3 (Liu and Chen, 1995; Lee, 2011). We varied the relative ESS resampling threshold β from 0 (never resample) to 1 (always resample) (Figures 3 **e** and **f**). We observed that the performance is markedly degraded if resampling is performed after each SMC iteration, but similar for all other resampling thresholds. We used a threshold of 0.5 in all other experiments.

Next, we used the dataset C1 to investigate the effectiveness of our method with the finite clustering model introduced in Section 2, with the number of clusters fixed to $k_0 = 5$. In this case, standard split-merge methods such as SAMS are less helpful since only merging can be performed when the maximum number of clusters has been allocated. The PGSM sampler does not have this restriction and naturally allows simultaneously splitting and merging while preserving the total number of clusters. Furthermore, the PGSM sampler can use more than two anchors, potentially allowing for large changes in configuration without altering the number of clusters. We compared the PGSM with two ($|s| = 2$) and three ($|s| = 3$) anchors to the Gibbs sampler. The PGSM method outperformed the Gibbs sampler, though increasing the number of anchors did not improve the performance (Figure 5 **a**). We plot the predictive densities (Figure 5 **b**, **d**, **f**) and cluster allocations (Figure 5 **c**, **e**, **g**) after running each sampler for 1000 seconds. At this point the PGSM sampler used a single cluster to model the points in the middle, while the Gibbs samplers used two clusters to model the central cluster.

In Figures 6 and 7 we show a series of experiments on the four datasets S1–4 describe in the previous section. We compare the PGSM to standard Gibbs and the SAMS method of Dahl (2003). We first compared pure kernels, where the split-merge samplers are not mixed with standard Gibbs moves (Figure 6). The pure PGSM kernel outperformed both Gibbs and SAMS on datasets S1 and S2. The Gibbs kernel and PGSM perform similarly for datasets S3 and S4, and both outperformed SAMS. When the split-merge moves are mixed with standard Gibbs moves, the split-merge methods outperformed Gibbs on datasets S1 and S2, with all methods showing similar performance on datasets S3 and S4 (Figure 7).

Finally, we explored the performance of the methods on four high dimensional datasets. The mixed PGSM and Gibbs samplers performed the best on the Bernoulli datasets, while the unmixed PGSM sampler is slower to reach the same predictive likelihood and V-measure

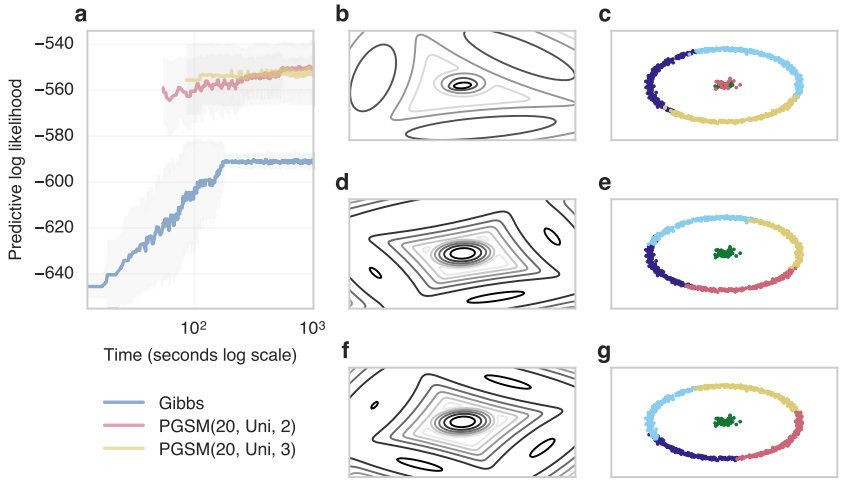

Figure 5: Comparison of Gibbs and PGSM for finite Dirichlet prior with $k_0 = 5$. **a**) Predictive log likelihood comparison of Gibbs and PGSM using two (PGSM(20, Uni, 2)) or three (PGSM(20, Uni, 3)) anchors. Predictive density after 1000 seconds for **b**) Gibbs; **d**) PGSM(20, Uni, 2); **f**) PGSM(20, Uni, 3). Cluster assignment after 1000 seconds for **c**) Gibbs; **e**) PGSM(20, Uni, 2); **g**) PGSM(20, Uni, 3).

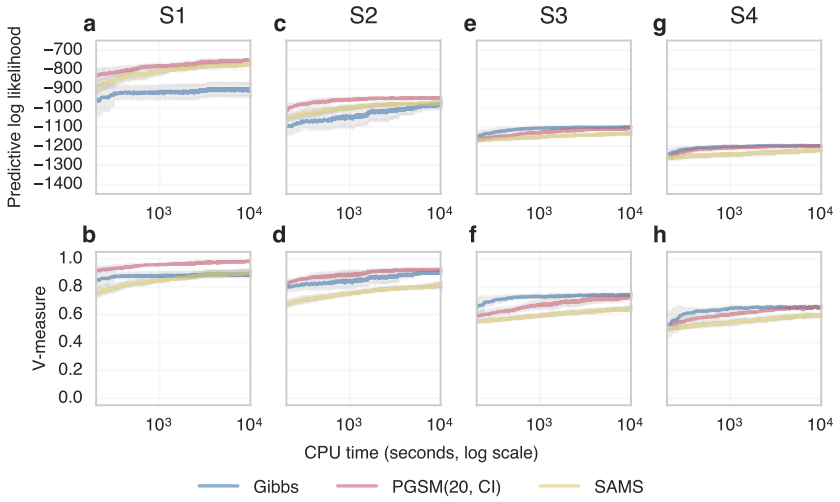

Figure 6: Comparison of MCMC algorithm using only a single kernel at a time (pure kernels) on 2D Normal datasets. Predictive log likelihood for datasets **a**) S1; **c**) S2; **e**) S3; **g**) S4. V-measure for datasets **b**) S1; **d**) S2; **f**) S3; **h**) S4.

(Figures 8 **a-d**). The mixed SAMS sampler failed to reach the same predictive likelihood as the PGSM and Gibbs methods, oscillating around lower values. The unmixed SAMS sampler appears to be trapped in a local mode, corresponding to poor predictive likelihood and V-measure. For the Normal datasets, the Gibbs sampler was trapped in a local mode and had markedly worse performance than other methods (Figures 8 **e-h**). The unmixed samplers outperformed the mixed equivalents on the 64 dimensional data. Furthermore, the unmixed PGSM method had a large performance advantage over all other methods on the 128 dimensional dataset.

4.4 Geolocation data

We compared the performance of the three sampling methods on a geolocation dataset. The dataset, described in more detail in Fränti et al. (2010), consists of a subset of data collected by MOPSI, a Finnish mobile application where users can post their current geographic location via their mobile device. The subset we used consists of a list of 13,467 locations (latitude-longitude pairs) from users located in Finland until 2012. The data is freely accessible from `http://cs.joensuu.fi/sipu/datasets/`.

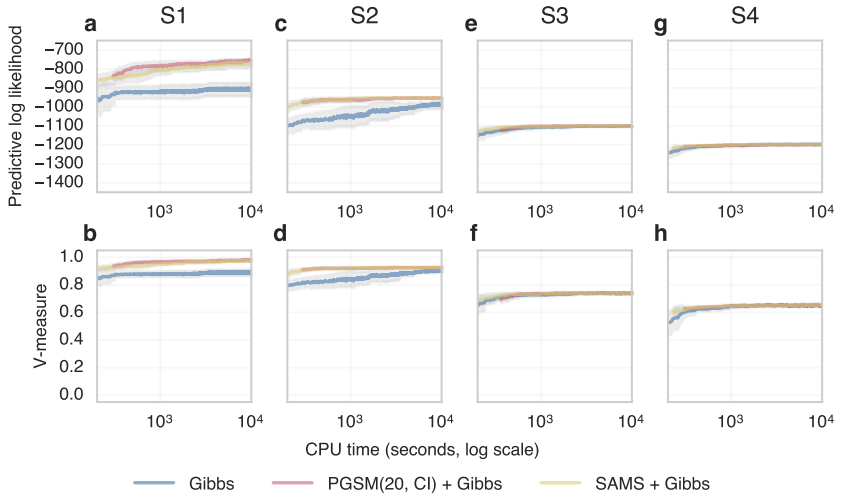

Figure 7: Comparison of MCMC algorithm using split-merge moves combined with standard Gibbs moves (mixed kernels) on 2D Normal datasets. Predictive log likelihood for datasets **a**) S1; **c**) S2; **e**) S3; **g**) S4. V-measure for datasets **b**) S1; **d**) S2; **f**) S3; **h**) S4.

We use this data as a proxy for the estimation of mobile device user density. The DP mixture of Normal-Inverse-Wishart distributions provides a natural way to obtain a parsimonious estimate of population density, where the flexibility on the shape and number of clusters can accommodate a broad range of density variability factors ranging from densely populated cities to vast low-density rural areas.

We summarize the results in Figure 9. In Figures 9 **a-c**, we display quantitative results as measured by held-out predictive likelihood performance. In Figure 9 **a**, we show that mixed PGSM, mixed SAMS and Gibbs samplers perform similarly. In Figure 9 **b**, we show that the performance of SAMS is considerably degraded if SAMS is not mixed with a Gibbs kernel. In Figure 9 **c**, we show that the performance of PGSM is less degraded if not mixed with a Gibbs kernel.

In Figures 9 **e-j**, we visualize the posterior predictive density approximated using MCMC samples. We also show the raw data in Figure 9 **d** for reference. The following three pairs of density plots are included to illustrate the high computational cost of initializing a standard Gibbs sampler at a fully disconnected configuration. From left to right: the first pair shows the predictive density after one round of Gibbs sampling initialized at the fully disconnected configuration (Figures **e** and **f**); the second pair, after sampling with PGSM

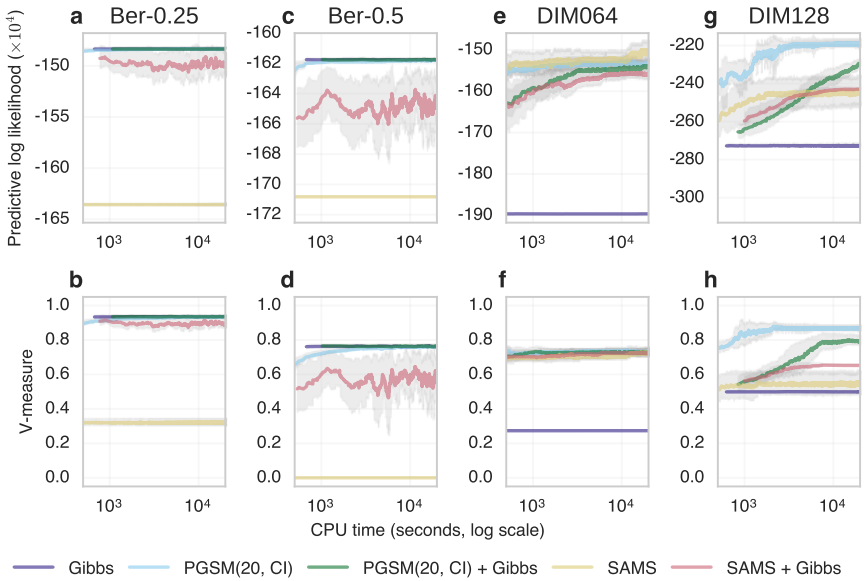

Figure 8: Comparison of MCMC algorithm using split-merge moves with combined with standard Gibbs moves (mixed kernels) on 50 dimensional Bernoulli data with 25% (Ber-0.25) and 50% (Ber-0.5) and Normal data 64 (DIM064) and 128 (DIM128) dimensions. Predictive log likelihood for datasets **a**) Ber-0.25; **c**) Ber-0.5; **e**) DIM064; **g**) DIM128. V-measure for datasets **b**) Ber-0.25; **d**) Ber-0.5; **f**) DIM064; **h**) DIM128.

initialized at the fully connected configuration for the same time (Figures **g** and **h**); the third, after running the Gibbs sampler for 10^5 seconds (Figures **i** and **j**). This demonstrates that our method can produce accurate and compact density estimates without relying on an expensive initialization phase.

4.5 Inferring population structure in heterogeneous tumours

The PyClone model (Roth et al., 2014) is designed to infer the proportion of cancer cells in a tumour sample which contain a mutation, which we refer to as the cellular prevalence of the mutation. The input data consists of a set of digital measurements of allelic abundance which is assumed to be proportional to the true abundance of the allele in the sample. The key factors which need to be deconvolved to convert this measurement to an estimate of

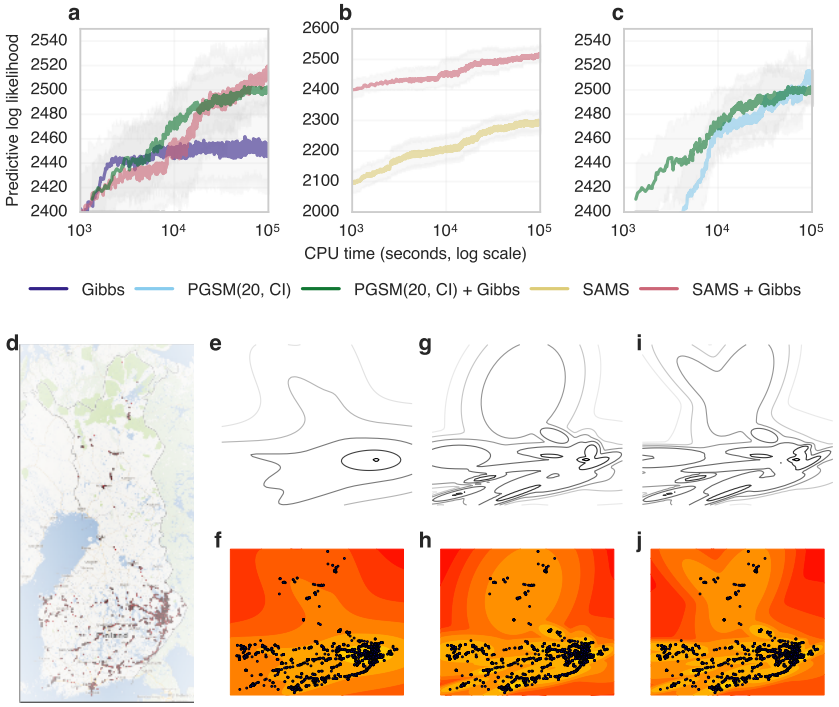

Figure 9: Geolocation dataset. Comparison of predictive likelihoods of **a**) mixed kernels; **b**) PGSM pure and mixed kernels; **c**) SAMS pure and mixed kernels. **d**) MOPSI geolocation dataset. **e**) Predictive density of Gibbs initialized from the disconnected configurations after one iteration; **d**) with point data points overlayed. **g**) and **h**) Predictive density of mixed PGSM kernel after an equivalent amount of time. **i**) and **j**) Predictive density of disconnected Gibbs after 10^5 seconds.

cellular prevalence are that some cells derive from healthy (normal) tissue and the genomes of cancer cells contain multiple copies of a locus. The model assumes that mutations will group by cellular prevalence due to the expansion of populations of genetically identical cells. The number of populations is unknown, thus the PyClone model uses a DP prior with a Uniform($[0, 1]$) base measure. The component parameters are interpreted as the cellular prevalence of the mutations associated with the component.

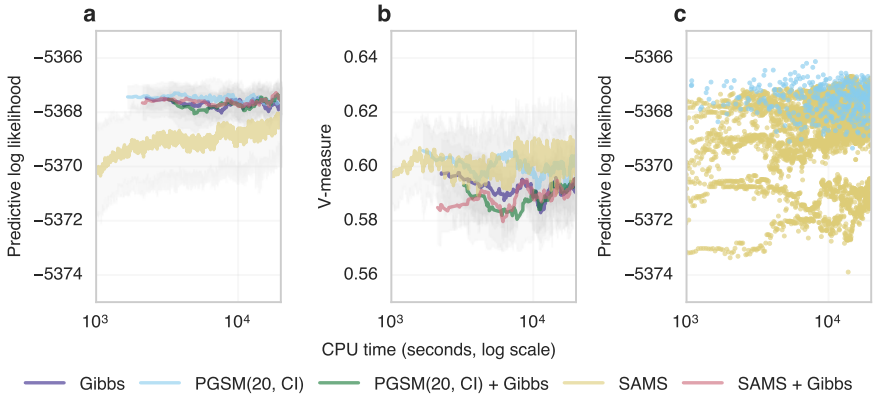

Figure 10: Clustering of cancer mutations from synthetic next-generation sequencing data. **a**) Comparison of predictive likelihood. **b**) Trace of log predictive likelihood for PGSM and SAMS pure kernels from 10 random restarts.

We show results on a dataset with 10,000 synthetic mutations in Figure 4.5. All methods except the pure SAMS kernel performed similarly in terms of predictive likelihood, while the pure SAMS kernel performed significantly worse (Figure 4.5 **a**). The pure PGSM and SAMS kernels outperformed the other methods in terms of V-measure, though the difference were small (Figures 4.5 **b**).

As observed in the other domains, the performance of SAMS critically depends on mixing the kernel with GIBBS moves. We show the data points for each replication of the pure split-merge kernels further supporting this point (Figure 4.5 **c**).

5. Discussion

We have proposed a new methodology to design efficient split-merge moves for Bayesian mixture models. The method also generalizes to new types of moves useful for finite clustering models when $|s| > 2$. We have shown empirically that the proposed method is competitive in a range of clustering and likelihood models, including synthetic and real datasets from geolocation and genomics applications.

Our method, being based on the established PMCMC framework, opens up many directions for future improvements. This includes applying recent advances in parallel implementations of SMC, for example via graphical processing units (Lee et al., 2010), or modifications of the SMC algorithm itself (Jun et al., 2012; Murray et al., 2016; Lee and Whiteley, 2016).

Another area of improvement comes from the development of resampling schemes tailored to discrete latent variables. In Algorithm 3, the number of possible distinct successors for each given particle is a small finite number (at most two if $|s| = 2$ for example). The complexity of the problem comes from the fact that a potentially long sequence of such decisions need to be made in order to split a cluster. In these specific scenarios, custom PMCMC methods based on the early work of Fearnhead and Clifford (2003) have been developed in Whiteley et al. (2010) and would provide futher improvement.

The fact that the state transitions $\mathcal{S}(\cdot)$ have an absorbing state has both advantages and disadvantages. On the one hand it may cause Algorithm 3 to be greedy, as explained in Section 3.4. We have described in the same section a choice of intermediate and proposal distributions tailored to alleviate this issue. A potential alternative consists in designing a resampling distribution r, which conditions on the survival of at least one representative of both a merge and a split. None of the existing resampling schemes have this property. On the other hand, having an absorbing state has the advantage that if all particles simulated by Algorithm 3 at some iteration t are equal to the merge absorbing state (i.e. $x_t^p = \#2$ for all particle index $p \in \{1, \ldots, N\}$), then there is no need to continue the computation of the particle filter for $t' > t$.

In standard applications of the PG algorithm, coalescence of the particle genealogy may cause slow mixing as noted in Andrieu et al. (2010). The issue is that the particles $\mathbf{x}_n^1, \mathbf{x}_n^2, \ldots, \mathbf{x}_n^N$ appearing in Algorithm 3 have components at time t for $t \ll n$ which coincide with high probability with the components of the conditioning path. This can be resolved using more sophisticated MCMC moves on the PG auxiliary variables (Whiteley, 2010; Whiteley et al., 2010; Lindsten et al., 2014). In our non-standard setup, this issue is partially mitigated by the fact that the order $\boldsymbol{\sigma}$ at which the particles are introduced is itself random. Nonetheless, it would be interesting to implement these more advanced schemes to the problem at hand.

We have shown in Section 4.5 a simple and effective method for handling models where each cluster component is governed by a non-conjugate model with a low-dimensional parameterization. We leave for future work the extension of our method to higher dimensional non-conjugate likelihood models. This problem can be approached, for example, by combining our method with the auxiliary variables described in Neal (2000).

Appendix A. Correctness of the decomposition into split-merge subproblems

We present in this section the proof of correctness of the decomposition of the clustering into split-merge sub-problems. The main tool used to prove this result is an auxiliary variable construction. The auxiliary variable consists of a pair (s, c_-), where s is the set of anchors,

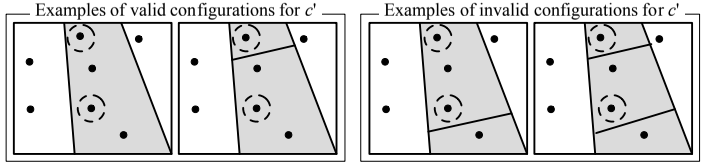

Figure 11: Assuming that the values of c, c_- and s are as in Figure 1, this illustrates some examples of configurations c' that are part of (left), or excluded from (right), the support of $c'|s, c_-$.

and c_- consists of the blocks of the partition c that do not contain anchor points:

$$c_- \coloneqq \{b \in c : b \cap s = \emptyset\}, \tag{17}$$

These intuitively correspond to the blocks of the partition that are forced to stay unchanged in this split-merge step. We will view the split-merge step as a Gibbs step conditioning on c_-, s.

A slight subtlety is that conditioning on the auxiliary variables not only forces the blocks in c_- to stay constant; it also forces the other blocks to each contain at least one of the anchors. See Figure 11 for an example. This leads to condition 2 in Lemma 5.

Lemma 5 *Let c, c' denote two partitions of $[T]$. Let $s \subseteq [T]$. Define $c_- \coloneqq \{b \in c : s \cap b = \emptyset\}$ and $c_-{}' \coloneqq \{b \in c' : s \cap b = \emptyset\}$. Then $c_- = c_-{}'$ if and only if the following two conditions hold:*

1. *$c \cap c_- = c' \cap c_-$, and,*
2. *$b \in c' \backslash c_- \implies b \cap s \neq \emptyset$.*

Proof ($\implies$) Condition 1 holds trivially. For condition 2, suppose (a) $c_- = c_-{}'$, (b), $b \in c' \backslash c_-$, but (c) $b \cap s = \emptyset$. By (b), $b \in c'$ and $b \notin c_-$. This and (c) implies that $b \in c_-{}'$. But this contradicts (a), so condition 2 holds as well.

($\impliedby$) First, suppose $b \in c_-$. By condition 1, $b \in c_-{}'$. Therefore, $c_- \subseteq c_-{}'$.

Second, suppose $b \in c_-{}'$. By the contrapositive of condition 2, $b \notin c' \backslash c_-$. This point and $c_-{}' \subseteq c'$ implies that $b \in c_-$. ■

We can now turn to the proof of Proposition 1. We copy its statement here for convenience:

Proposition 6 *If $c \sim \pi$, then the output of Algorithm 1, c', satisfies $c' \sim \pi$; i.e. the Markov kernel $K(c'|c)$ induced by Algorithm 1 is π-invariant.*

Proof Consider the model augmented with the auxiliary variables s and c_- (see Figure 12(a)), defined formally using the following auxiliary distribution:

$$\tilde{\pi}(s, c_-, c) \coloneqq \pi(c) h(s) \mathbf{1}[c_- = c_-(s, c)], \tag{18}$$

where $c_-(s, c) \coloneqq \{b \in c : b \cap s = \emptyset\}$. Note that this auxiliary distribution admits the target distribution as a marginal:

$$\begin{aligned} \sum_s \sum_{c_-} \tilde{\pi}(s, c_-, c) &= \pi(c) \sum_s h(s) \sum_{c_-} \mathbf{1}[c_- = c_-(s, c)] \\ &= \pi(c) \sum_s h(s) = \pi(c), \end{aligned} \tag{19}$$

where the sum over c_- is over all sets of subsets of $[T]$, and the sum over s is over all subsets of $[T]$. We used the fact that only one c_- satisfies $c_-(s, c) = c_-$, and that h is a probability mass function.

Next, we introduce three kernels with inputs and outputs denoted by:

$$c \overset{K_1}{\longmapsto} (s, c_-, c) \overset{K_2}{\longmapsto} (s, c_-, c') \overset{K_3}{\longmapsto} c'. \tag{20}$$

These kernels play the following roles:

- K_1 samples the auxiliary variables according to $\tilde{\pi}(s, c_- \mid c)$, while keeping c fixed,
- K_2 performs a Metropolis-within-Gibbs step on c targeting the auxiliary distribution $\tilde{\pi}$,
- K_3 deterministically projects the triplet back to the original space, retaining only the clustering c.

Formally:

$$\begin{aligned} K_1(s', c_-{}', c' \mid c) &\coloneqq h(s') \mathbf{1}[c = c'] \mathbf{1}[c_-{}' = c_-(s, c)], \\ K_2(s', c_-{}', c' \mid s, c_-, c) &\coloneqq \tilde{\pi}(c'|s, c_-) \mathbf{1}[s' = s] \mathbf{1}[c_-{}' = c_-], \\ K_3(c'|s, c_-, c) &\coloneqq \mathbf{1}[c' = c]. \end{aligned} \tag{21}$$

Since $\tilde{\pi}$ admits π as a marginal, the composition of K_1, K_2, and K_3 is clearly π-invariant. It is therefore enough to show that when $c_- = c_-(s, c)$ where c is a valid partition of $[T]$, sampling from K_2 is equivalent to sampling from the Markov kernel $K(c'|c)$ induced by Algorithm 1:

$$\begin{aligned} \tilde{\pi}(c' \mid s, c_-) &\propto \pi(c') \mathbf{1}[c_- = c_-(s, c')] \\ &= \pi(c') \mathbf{1}[c_-(s, c) = c_-(s, c')] \\ &= \tau_1(|c'|) \left(\prod_{b \in c'} \tau_2(|b|) L(\mathbf{y}_b) \right) \mathbf{1}[c_-(s, c) = c_-(s, c')]. \end{aligned} \tag{22}$$

Using Lemma 5, we now rewrite the support as follows:

$$\mathbf{1}[c_-(s, c') = c_-(s, c)] = \mathbf{1}[c \cap c_- = c' \cap c_-] \mathbf{1}[b \in c' \backslash c_- \implies b \cap s \neq \emptyset]. \tag{23}$$

Figure 12: Graphical models of the auxiliary variables used in the correctness proofs. The structure of the dependencies give an intuitive justification that the original model can be recovered as a marginal in both cases, as there are not directed path from the auxiliary variables to the original variables. (a) In Appendix A, the auxiliary variables are s and c_-, and the original variable is c. (b) In Appendix B, the auxiliary variables are $\boldsymbol{\sigma}$ and g, and the original variable is $\overline{c}$.

Let now $\overline{c}' = c' \backslash c_-$. Plugging in the last line of Equation (22), we obtain:

$$\begin{aligned} \tilde{\pi}(c' \mid s, c_-) &= \overline{\tau}_1(|\overline{c}'|) \left(\prod_{b \in \overline{c}'} \tau_2(|b|) L(\mathbf{y}_b) \right) \mathbf{1}[c \cap c_- = c' \cap c_-] \mathbf{1}[b \cap s \neq \emptyset] \qquad (24) \\ &= \overline{\pi}(\overline{c}') \mathbf{1}[c \cap c_- = c' \cap c_-], \end{aligned}$$

where $\overline{\pi}(\overline{c}')$ is defined in Equation (5). Since Algorithm 1 does not change the clustering of points outside of $\overline{s}$ (line 6 of Algorithm 1), it follows that the indicator function in the last line of Equation (24) is equal to one. ■

Appendix B. Correctness of particle Gibbs for split merge

We provide here the proof of Proposition 2. The main steps in the proof follow a structure similar to the proof of Proposition 1.

Proposition 7 *Under Assumption 1, 2, and 3, and if $\overline{c} \sim \overline{\pi}$, then the output of Algorithm 3, $\overline{c}'$, satisfies $\overline{c}' \sim \overline{\pi}$ for any $N \geq 2$; i.e. the Markov kernel $\overline{K}(\overline{c}'|\overline{c})$ induced by Algorithm 3 is $\overline{\pi}$-invariant.*

Proof We augment the model $\overline{c}$ with the auxiliary variables $\boldsymbol{\sigma}$ and g (see Figure 12(b)), defined as:

1. $\boldsymbol{\sigma}$ is distributed according to the output of Algorithm 2, defined in Section 3.2.
2. Given $\boldsymbol{\sigma}$ and $\overline{c}$, the variables $g = (\boldsymbol{a}_{2:n}, \mathbf{x}_{1:n}^{1:N}, k)$ are distributed according to the specification of Algorithm 3, with the exception that all particle indices are shuffled according to an independent permutation of $\{1, \ldots, N\}$ at each generation. Here k is the index of the particle sampled at iteration n (on line (35)).

Next, we introduce three kernels with inputs and outputs denoted by:

$$\overline{c} \overset{\overline{K}_1}{\longmapsto} (\boldsymbol{\sigma}, \overline{c}) \overset{\overline{K}_2}{\longmapsto} (\boldsymbol{\sigma}, g, \overline{c}') \overset{\overline{K}_3}{\longmapsto} \overline{c}'. \qquad (25)$$

These kernels play the following roles:

- $\overline{K}_1$ samples the permutation $\boldsymbol{\sigma}$ while keeping the auxiliary variables $\overline{c}$ fixed,
- $\overline{K}_2$ samples g using the PG step then sets $\overline{c}'$ to $\phi^{\boldsymbol{\sigma}}(\mathbf{x}_n^k)$,
- $\overline{K}_3$ deterministically projects the triplet back to the original space, retaining only the restricted clustering $\overline{c}'$.

The kernel $\overline{K}_2$ is equivalent to a standard PG algorithm. Assumption 1, 3, and Theorem 5(a) of Andrieu et al. (2010) imply that $\overline{K}_2$ is $\overline{\pi}$-invariant (and in fact, irreducible). Assumption 2 ensures that the computation of the conditioned path is well-defined. ■

Appendix C. Construction of the bijection

We provide here the proof of Proposition 3:

Proposition 8 *For any permutation $\boldsymbol{\sigma}$ satisfying $\{\sigma_1, \sigma_2\} = s$, there is a bijective map $\phi^{\boldsymbol{\sigma}}$ from the space of particles respecting the transition constraints, $\mathcal{S}_n$, to the support of the restricted target,* $\mathrm{support}(\overline{\pi})$.

Proof Consider the following mapping:

$$\phi^{\boldsymbol{\sigma}}(\mathbf{x}_t) \coloneqq \begin{cases} \{\{\sigma_1, \ldots, \sigma_t\}\} & \text{if } x_t \in \{\#1, \#2\}, \\ \{\overline{\sigma}_1(\mathbf{x}_t), \overline{\sigma}_2(\mathbf{x}_t)\} & \text{otherwise,} \end{cases} \qquad (26)$$

where $\overline{\sigma}_i(\mathbf{x}_t) \coloneqq \{\sigma_{t'} : x_{t'} = \#(2+i), 1 \leq t' \leq t\}$. It is easy to check that it has an inverse given by:

$$\left((\phi^{\boldsymbol{\sigma}})^{-1} (\overline{c}) \right)_t \coloneqq \begin{cases} \#1 & \text{if } t = 1, \\ \#2 & \text{if } t > 1, |\overline{c}| = 1, \\ \#3 & \text{if } t > 1, |\overline{c}| > 1, \sigma_1 \sim_{\overline{c}} \sigma_t, \\ \#4 & \text{if } t > 1, |\overline{c}| > 1, \sigma_2 \sim_{\overline{c}} \sigma_t, \end{cases} \qquad (27)$$

where $\sigma_i \sim_{\overline{c}} \sigma_j$ means that y_{σ_i} is in the same block as y_{σ_j} for the clustering $\overline{c}$. By the construction of the support of $\overline{\pi}$, exactly one of the four cases above holds when $\overline{c} \in \mathrm{support}(\overline{\pi})$.

■

Appendix D. Generalization to $|s| > 2$

We describe here the algorithmic implications of increasing the number of anchor points, $|s|$, to some constant greater than two. This constant should be selected so that the number of partitions of $|s|$ points is much lower than the number of particles.

The algorithm is generally unchanged, with the following exceptions:

1. Algorithm 2 is modified to sample $(\sigma_1, \sigma_2, \ldots, \sigma_{|s|})$ uniformly over the permutations of s, and $(\sigma_{|s|+1}, \ldots, \sigma_n)$, over the permutations of $\overline{s} \backslash s$,

2. as before, the local allocation state space $\mathcal{X}$ can be viewed as a pair each containing a partition and a block in this partition (see Figure 2). In the case where $|s| = 2$, the partitions are taken from the union of the set of partitions of a set of size one with the set of partitions of a set of size two. When $|s| > 2$, we add more states, corresponding to partitions of a set of size three, etc. until we add states corresponding to partitions of a set of size $|s|$. The support of the transition $\mathcal{S}$ consists in (a) edges $x \to x'$ linking a state x' such that removing one element from one of its blocks yields x, and (b) edges $x \to x'$ where x and x' correspond to the same partition of a set of size $|s|$. This is a generalization of the case $|s| = 2$ shown in Figure 2. The mapping $\phi^{\boldsymbol{\sigma}}$ is generalized in the obvious way,

3. in Section 3.4 the following equations are substituted,

   (a) $t \in \{1, 2\} \to t \in \{1, 2, \ldots, |s|\}$,
   (b) $t = 2 \to t \in \{2, \ldots, |s|\}$,
   (c) $t > 2 \to t > |s|$,
   (d) $\Delta\zeta \coloneqq (n-2)^{-1} \to \Delta\zeta \coloneqq (n - |s|)^{-1}$.

Appendix E. Models

E.1 Multivariate normal

The first likelihood we use is the multivariate normal (MVN) with density denoted $\mathcal{N}(y|\mu, \Sigma)$. We specify a normal inverse Wishart (NIW) prior for the mean and covariance parameters with density denoted $\mathcal{NIW}(\mu, \Sigma|\nu, r, u, S)$. The densities are given by

$$\begin{aligned}
\mathcal{NIW}(\mu, \Sigma|\nu, r, u, S) &= \mathcal{N}\left(\mu|u, \frac{1}{r}\Sigma\right)\mathcal{IW}(\Sigma|\nu, S), \qquad (28)\\
\mathcal{N}(y|\mu, \Sigma) &= \frac{1}{(2\pi)^{\frac{D}{2}}|\Sigma|^{\frac{1}{2}}}\exp\left(-\frac{1}{2}(y-\mu)^T\Sigma^{-1}(y-\mu)\right),\\
\mathcal{IW}(\Sigma|\nu, S) &= \frac{|S|^{\frac{\nu}{2}}}{2^{\frac{\nu p}{2}}\Gamma_D\left(\frac{\nu}{2}\right)}|\Sigma|^{-\frac{\nu+p+1}{2}}\exp\left(-\frac{1}{2}\mathrm{tr}(S\Sigma^{-1})\right),
\end{aligned}$$

where $\Gamma_D(x) = \pi^{\frac{D(D-1)}{4}}\prod_{d=1}^{D}\Gamma\left(x + \frac{d-1}{2}\right)$.

We use the following priors for all experiments $(\nu, r, u, S) = (\nu_0, r_0, u_0, S_0) = (2 + D, 1, \mathbf{0}, \boldsymbol{I})$, where $\mathbf{0}$ is the D dimensional vector of zeros, and $\boldsymbol{I}$ is the D dimensional identity matrix. The posterior distribution of μ, Σ given $\boldsymbol{y} = (y_1, \ldots, y_m)$ is $\mathcal{NIW}(\mu, \Sigma|\nu_m, r_m, u_m, S_m)$ where

$$\begin{aligned}
\nu_m &= \nu_0 + m, \qquad (29)\\
r_m &= r_0 + m,\\
u_m &= \frac{r_0 u_0 + \sum_{i=1}^{m} y_i}{r_m},\\
S_m &= S_0 + \sum_{i=1}^{m} y_i y_i^T + r_0 u_0 u_0^T - r_m u_m u_m^T.
\end{aligned}$$

For computational efficiency it is convenient to express these updates iteratively using the following equations:

$$\begin{aligned}
\nu_m &= \nu_{m-1} + 1, \qquad (30)\\
r_m &= r_{m-1} + 1,\\
u_m &= \frac{r_{m-1}u_{m-1} + y_m}{r_m},\\
S_m &= S_{m-1} + \frac{r_m}{r_{m-1}}(y_m - u_m)(y_m - u_m)^T.
\end{aligned}$$

Using these equations the Cholesky decomposition of S_0 can be performed once using $O(D^3)$ operations and cached. This decomposition can then be updated using m rank one updates, each requiring $O(D^2)$ operations, to obtain S_m. This allows for efficient evaluation of the marginal and predictive likelihoods as $|S_m|$ can be evaluated using $O(D)$ operations using the Cholesky decomposition, instead of the standard $O(D^3)$ operations.

The marginal likelihood for the MVN-NIW congugate pair is

$$\begin{aligned}
L(\boldsymbol{y}) &= \int\prod_{i=1}^{m} L(y_i|\theta)H(\mathrm{d}\theta) \qquad (31)\\
&= \int\prod_{i=1}^{m}\mathcal{N}(y_i|\mu, \Sigma)\mathcal{NIW}(\mu, \Sigma|\nu, r, u, S)\,\mathrm{d}\mu\,\mathrm{d}\Sigma\\
&= \frac{1}{\pi^{\frac{mD}{2}}}\frac{r_0^{\frac{D}{2}}}{r_m^{\frac{D}{2}}}\frac{|S_0|^{\frac{\nu_0}{2}}}{|S_m|^{\frac{\nu_m}{2}}}\frac{\prod_{d=1}^{D}\Gamma\left(\frac{\nu_m+d-1}{2}\right)}{\prod_{d=1}^{D}\Gamma\left(\frac{\nu_0+d-1}{2}\right)}.
\end{aligned}$$

The predictive likelihood is given by

$$\begin{aligned}
L(\boldsymbol{y}^+|\boldsymbol{y}^-) &= \frac{L(y_1, \ldots, y_m)}{L(y_1, \ldots, y_{m-1})} \qquad (32)\\
&= \frac{1}{\pi^{\frac{D}{2}}}\frac{r_{m-1}^{\frac{D}{2}}}{r_m^{\frac{D}{2}}}\frac{|S_{m-1}|^{\frac{\nu_{m-1}}{2}}}{|S_m|^{\frac{\nu_m}{2}}}\frac{\prod_{d=1}^{D}\Gamma\left(\frac{\nu_m+d-1}{2}\right)}{\prod_{d=1}^{D}\Gamma\left(\frac{\nu_{m-1}+d-1}{2}\right)}.
\end{aligned}$$

E.2 Bernoulli

We use a Bernoulli likelihood, $\mathrm{Bernoulli}(x|\theta)$, with a Beta prior distribution, $\mathrm{Beta}(\theta|\alpha, \beta)$. We use the following priors $(\alpha, \beta) = (\alpha_0, \beta_0) = (1, 1)$ for all experiments. The densities are

$$\begin{aligned}
\mathrm{Bernoulli}(x|\theta) &= \theta^x(1-\theta)^{1-x}, \qquad (33)\\
\mathrm{Beta}(\theta|\alpha, \beta) &= \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)}\theta^{\alpha-1}\theta^{\beta-1}.
\end{aligned}$$

The posterior density of θ given $\boldsymbol{y} = (y_1, \ldots, y_m)$ is $\text{Beta}(\alpha_m, \beta_m)$ where $\alpha_m = \alpha_0 + \sum_{i=1}^m y_i$ and $\beta_m = \beta_0 + \sum_{i=1}^m (1 - y_i)$. The marginal likelihood is

$$\begin{aligned} L(\boldsymbol{y}) &= \int \prod_{i=1}^m L(y_i|\theta) H(\mathrm{d}\theta) \\ &= \int \prod_{i=1}^m \text{Bernoulli}(y_i|\theta)\text{Beta}(\theta|\alpha_0, \beta_0)\,\mathrm{d}\theta \\ &= \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha_m)\Gamma(\beta_m)} \frac{\Gamma(\alpha_m + \beta_m)}{\Gamma(\alpha_0 + \beta_0)}, \end{aligned} \tag{34}$$

and the predictive log likelihood is

$$\begin{aligned} L(\boldsymbol{y}^+|\boldsymbol{y}^-) &= \frac{L(y_1, \ldots, y_m)}{L(y_1, \ldots, y_{m-1})} \\ &= \frac{\Gamma(\alpha_{m-1})\Gamma(\beta_{m-1})}{\Gamma(\alpha_m)\Gamma(\beta_m)} \frac{\Gamma(\alpha_m + \beta_m)}{\Gamma(\alpha_{m-1} + \beta_{m-1})}. \end{aligned} \tag{35}$$

E.3 PyClone

For the cancer genomics data we use the application-specific PyClone likelihood model over clonal prevalences, genotypes, and observed read counts. The key variables in the model are as follows (see Roth et al. (2014) for a more detailed description of the model):

$$\begin{aligned} \phi_i &: \text{proportion of cancer cells with mutation } i,\ \phi_i \in [0,1], \\ t &: \text{proportion of cancer cells in a sample (treated as known)},\ t \in [0,1], \\ \psi_i &: \text{genotype of normal, non-mutated cancer and mutated cancer cells},\ \psi_i \in (g_N, g_R, g_V), \\ g_x &\in \mathcal{G} = \{\text{A}, \text{B}, \text{AA}, \text{AB}, \ldots\}, \\ \pi_{i,\psi_i} &: \text{probability that mutation } i \text{ has genotype } \psi_i \text{ (elicited from auxillary data)}, \\ c(g_x) &= \#\text{A}(g_x) + \#\text{B}(g_x), \\ \mu(g_x) &= \frac{\#\text{A}(g_x)}{c(g_x)}, \\ \xi(\psi, \phi, t) &: \text{probability of sampling a B from the population of cells in the sample, i.e.:} \\ &= \frac{(1-t)c(g_N)\mu(g_N) + t(1-\phi)c(g_R)\mu(g_R) + t\phi c(g_V)\mu(g_V)}{(1-t)c(g_N) + t(1-\phi)c(g_R) + t\phi c(g_V)}, \\ y_i &: \text{number of sequence reads with a B and total number of reads covering mutation } i, \text{ i.e.:} \\ &= (y_{i,b}, y_{i,d}) \in \mathbb{N}^2. \end{aligned}$$

The generative model is specified as follow:

$$\begin{aligned} H_0 &= \text{Uniform}([0,1]), \\ \alpha_0 &\sim \text{Gamma}(\alpha_0|a, b), \\ H|\alpha_0, H_0 &\sim \text{DP}(H|\alpha_0, H_0), \\ \phi_i|H &\sim H, \\ y_i|\psi_i, \phi_i, t &\sim \text{Binomial}(y_{i,b}|y_{i,d}, \xi(\psi_i, \phi, t)). \end{aligned} \tag{36}$$

This model is not conjugate. However, if we let $x \in \{x_0, \ldots, x_M\} = \left\{0, \frac{1}{M-1}, \ldots, \frac{M-2}{M-1}, 1\right\}$ be a discretization of the interval $[0,1]$ and replace the continuous uniform base measure, $H_0 = \text{Uniform}([0,1])$, with the discrete uniform measure, $H_0 = \text{Uniform}(\{x_0, \ldots, x_M\})$, then we can approximate the model. Using this approximation, we can now treat the model as if it were conjugate. The marginal likelihood for data $(y_1, ..., y_m)$ is given by

$$\begin{aligned} \int \prod_{i=1}^m L(y_i|\theta) H(\mathrm{d}\theta) &= \int \prod_{i=1}^m \sum_{\psi_i \in \mathcal{G}^3} \pi_{i,\psi_i} \text{Binomial}(y_{i,b}|y_{i,d}, \xi(\psi_i, \phi, t)) H(\mathrm{d}\phi) \\ &= \sum_{k=0}^M \prod_{i=1}^m \sum_{\psi_i \in \mathcal{G}^3} \pi_{i,\psi_i} \text{Binomial}(y_{i,b}|y_{i,d}, \xi(\psi_i, x_k, t)) \frac{1}{M} \\ &= \sum_{k=0}^M \prod_{i=1}^m \exp\left(\underbrace{\log \sum_{\psi_i \in \mathcal{G}^3} \pi_{i,\psi_i} \text{Binomial}(y_{i,b}|y_{i,d}, \xi(\psi_i, x_k, t))}_{\Xi_k(y_i)} \right) \frac{1}{M} \\ &= \sum_{k=0}^M \exp\left(\sum_{i=1}^m \Xi_k(y_i) \right) \frac{1}{M}, \end{aligned} \tag{37}$$

where we have the sufficient statistics

$$\boldsymbol{\Xi}(y_i) = (\Xi_0(y_i), \ldots, \Xi_M(y_i)). \tag{38}$$

Remark 9 *The possibly infinite sum $\sum_{\psi_i \in \mathcal{G}^3}$ is truncated to a finite sum over biologically plausible states.*

Appendix F. Anchor proposal distribution

The anchor proposal distribution, h, is a free tuning parameter for the PGSM sampler. In principle, proposals which are informed by the current clustering state of the chain or by the topology of the space may improve the performance of the sampler.

We consider two informed proposal distributions. While bespoke proposals for each model may perform better, we restrict attention here to proposals which can be applied generically to any class of model for which the PGSM sampler is applicable. In particular, we do not assume a distance metric is available. Both proposals we discuss are only applicable when two anchor points are used.

Remark 10 *If the any of the sets that we sample uniformly from are empty, we return two anchors sampled uniformly at random.*

Algorithm 4 Cluster informed (CI) proposal

$i_1 \sim \text{Uniform}([T])$
$\bar{b} \leftarrow b \in c$ s.t. $i_1 \in b$
$c' \leftarrow c \setminus \{\bar{b}\}$
for $b \in c'$ **do**
  $s_b \leftarrow \frac{L(y_{\bar{b} \setminus b})}{L(y_{\bar{b}})L(y_b)}$
end for
$s_{\bar{b}} \leftarrow \frac{\sum_{b \in c'} s_b}{|c|-1}$ ▷ Merge probability is set to $\frac{1}{|c|-1}$
for $b \in c$ **do**
  $p_b \leftarrow \frac{s_b}{\sum_{b \in c} s_b}$
end for
$b' \sim \text{Discrete}(c, p_b)$ ▷ Sample a block b' in c with probability p_b
$i_2 \sim \text{Uniform}(b' \setminus i_1)$
return i_1, i_2

Algorithm 5 Threshold informed (TI) proposal

$i_1 \sim \text{Uniform}([T])$
for $b \in c$ **do**
  if $i_1 \in b$ **then**
    $b \leftarrow b \setminus i_1$
  end if
  $s_b \leftarrow \tau_2(b) L(y_{i_1} | b)$ ▷ CRP attachment probability where $L(\cdot|b)$ is the predictive distribution
end for
for $b \in c$ **do**
  $p_b \leftarrow \frac{s_b}{\sum_{b \in c} s_b}$
end for
$b' \sim \text{Uniform}(\{b : p_b \geq t\})$ ▷ t is a pre-specified threshold, set to 0.01 in the experiments
$i_2 \sim \text{Uniform}(b' \setminus i_1)$
return i_1, i_2

List of Symbols

α_{Dir}	Symmetric concentration parameters for the finite Dirichlet model
β	Relative ESS threshold used for adaptive resampling
$\mathbf{x}$	Particle
$\mathbf{y}$	All observations
$\boldsymbol{\sigma}$	Permutation auxiliary variable vector
$\boldsymbol{a}$	Resampling ancestry vector
$\boldsymbol{w}$	Weight vector
k_0	Maximum number of clusters in the finite Dirichlet model
$\mathcal{S}$	Support defining valid sequences of allocation decisions
$\mathcal{X}$	State space containing the possible allocation decisions
$\overline{\pi}$	Split merge target distribution
$\overline{\tau}_1$	Split merge modification of the prior factor depending on the number of clusters
$\overline{c}$	Restriction of the clustering to the closure subset
$\overline{K}$	Markov kernel used to conceptualized a particle Gibbs step
$\overline{s}$	Closure of a subset of datapoint indices relative to a clustering
α_0	Concentration parameter used in clustering priors such as the Dirichlet process
τ_1	Factor in the clustering prior depending on the number of clusters
τ_2	Factor in the clustering prior depending on the size of each block
ψ	Sufficient statistics for the likelihood
γ	Intermediate un-normalized distributions
ϕ	Bijection from particles to restricted clusterings
π	Target density of interest
σ	Permutation auxiliary variable component
τ	Prior over clusterings
θ	Parameter of the parametric family
$\sim$	A binary relationship indicating whether two datapoint indices are in the same block (relative to some clustering specified as a subscript)
$\tilde{\pi}$	Auxiliary target distribution
ζ	Annealing schedule used to delay the introduction of the clustering prior
a	Resampling ancestry variable
b	One block in a clustering
c_-	Blocks of the partition outside of the closure
c	Partition or clustering of the observation indices
d	Discount parameter used in the Pitman-Yor process
g	Particle Gibbs auxiliary variables

H	Prior for the parametric family, and base measure of the process
h	Distribution of the anchors
i	Observation index
K	Markov kernel used to conceptualized a whole split-merge step
k	Index of a block (cluster)
L	Likelihood of the parametric family
N	Number of particles used in the particle Gibbs algorithms
n	Number of points to allocate, also coincides with the number of particle Gibbs generations (iterations)
p	Particle index
q	Proposal distribution for the particle Gibbs algorithm
r	Conditional resampling distribution
s	Subset of observation indices; in particular, set of anchor points
T	Number of datapoints
t	SMC generation (iteration) index
w	Weight variable
x	Allocation decision (a particle is made of a vector of such allocations)
y	One observed datapoint

Abstract

Factor Analysis (FA) is a technique of fundamental importance that is widely used in classical and modern multivariate statistics, psychometrics, and econometrics. In this paper, we revisit the classical rank-constrained FA problem which seeks to approximate an observed covariance matrix ($\mathbf{\Sigma}$) by the sum of a Positive Semidefinite (PSD) low-rank component ($\mathbf{\Theta}$) and a diagonal matrix ($\mathbf{\Phi}$) (with nonnegative entries) subject to $\mathbf{\Sigma} - \mathbf{\Phi}$ being PSD. We propose a flexible family of rank-constrained, nonlinear Semidefinite Optimization based formulations for this task. We introduce a reformulation of the problem as a smooth optimization problem with convex, compact constraints and propose a unified algorithmic framework, utilizing state of the art techniques in nonlinear optimization to obtain high-quality feasible solutions for our proposed formulation. At the same time, by using a variety of techniques from discrete and global optimization, we show that these solutions are *certifiably optimal* in many cases, even for problems with thousands of variables. Our techniques are general and make *no* assumption on the underlying problem data. The estimator proposed herein aids statistical interpretability and provides computational scalability and significantly improved accuracy when compared to current, publicly available popular methods for rank-constrained FA. We demonstrate the effectiveness of our proposal on an array of synthetic and real-life datasets. To our knowledge, this is the first paper that demonstrates how a previously intractable rank-constrained optimization problem can be solved to provable optimality by coupling developments in convex analysis and in global and discrete optimization.

Keywords: factor analysis, rank minimization, semidefinite optimization, first order methods, nonlinear optimization, global optimization, discrete optimization

1. Introduction

Factor Analysis (FA) (Anderson, 2003; Bartholomew et al., 2011; Mardia et al., 1979), a widely used methodology in classical and modern multivariate statistics, is used as a tool to obtain a parsimonious representation of the correlation structure among a set of variables in terms of a smaller number of common hidden factors. A basic FA model is of the form $\mathbf{x} = \mathbf{L}\mathbf{f} + \boldsymbol{\epsilon}$, where $\mathbf{x}_{p\times 1}$ is the observed random vector, $\mathbf{f}_{r_1\times 1}$ (with $r_1 \leq p$; note that we do not necessarily restrict r_1 to be small) is a random vector of common factor variables or scores, $\mathbf{L}_{p\times r_1}$ is a matrix of factor loadings and $\boldsymbol{\epsilon}_{p\times 1}$ is a vector of uncorrelated random variables. We assume that the variables are mean-centered, $\mathbf{f}$ and $\boldsymbol{\epsilon}$ are uncorrelated and without loss of generality, the covariance of $\mathbf{f}$ is the identity matrix. We will denote $\text{Cov}(\boldsymbol{\epsilon}) = \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p)$. It follows that

$$\mathbf{\Sigma} = \mathbf{\Sigma}_c + \mathbf{\Phi}, \tag{1}$$

where $\mathbf{\Sigma}$ is the covariance matrix of $\mathbf{x}$ and $\mathbf{\Sigma}_c := \mathbf{L}\mathbf{L}'$ is the covariance matrix corresponding to the common factors. Decomposition (1) suggests that $\mathbf{\Sigma}$ can be written as the sum of a positive semidefinite (PSD) matrix $\mathbf{\Sigma}_c$ of rank r_1 and a nonnegative diagonal matrix ($\mathbf{\Phi}$) corresponding to the errors. In particular, the variance of the ith coordinate of $\mathbf{x} := (x_1, \ldots, x_p)$, i.e., $\text{var}(x_i) = \sum_k l_{ik}^2 + \Phi_i, i = 1, \ldots, p$, splits into two parts, where $\mathbf{L} = ((l_{ik}))$. The first part $(\sum_k l_{ik}^2)$ is known as the *communality estimate* (since this is the variance of the factors common to all the x_i's) and the remaining part Φ_i is the variance specific to the ith variable (Φ_i's are also referred to as the *unique variances* or simply *uniquenesses*).

Formulation of the estimator: In decomposition (1), the assumption that the rank (r_1) of $\mathbf{\Sigma}_c$ is small compared to p is fairly stringent—see Guttman (1958); Shapiro (1982); ten Berge (1998) for a historical overview of the concept. In a classical paper of Guttman (1958), the author argued based on psychometric evidence that $\mathbf{\Sigma}_c$ is often found to have high algebraic rank. In psychometric case studies it is rather rare that the covariance structure can be *completely* explained by a *few* common factors corresponding to mental abilities—in fact there is evidence of at least hundreds of common factors being present with the number growing without an upper bound. Formally, this means that instead of assuming that $\mathbf{\Sigma}_c$ has *exactly* low-rank it is practical to assume that it can be well-approximated by a low-rank matrix, namely, $\mathbf{L}_1\mathbf{L}_1'$ with $\mathbf{L}_1 \in \mathbb{R}^{p\times r}$. More precisely, $\mathbf{L}_1\mathbf{L}_1'$ is the best rank-r approximation to $\mathbf{\Sigma}_c$ in the matrix q-norm (also known as the Schatten norm), as defined in (5), and $(\mathbf{\Sigma}_c - \mathbf{L}_1\mathbf{L}_1')$ is the *residual* component. Following psychometric terminology, $\mathbf{L}_1$ corresponds to the r *most significant* factors representative of mental abilities and the residual $\mathbf{\Sigma}_c - \mathbf{L}_1\mathbf{L}_1'$ corresponds to the remaining psychometric factors unexplained by $\mathbf{L}_1\mathbf{L}_1'$. Thus we can rewrite decomposition (1) as follows:

$$\mathbf{\Sigma} = \underbrace{\mathbf{L}_1\mathbf{L}_1'}_{:=\mathbf{\Theta}} + \underbrace{(\mathbf{\Sigma}_c - \mathbf{L}_1\mathbf{L}_1')}_{:=\mathcal{N}} + \mathbf{\Phi}, \tag{2}$$

where we use the notation $\mathbf{\Theta} = \mathbf{L}_1\mathbf{L}_1'$ and $\mathcal{N} = (\mathbf{\Sigma}_c - \mathbf{L}_1\mathbf{L}_1')$ with $\mathbf{\Theta} + \mathcal{N} = \mathbf{\Sigma}_c = \mathbf{\Sigma} - \mathbf{\Phi}$. Note that $\mathbf{\Theta}$ denotes the best rank-r approximation to $(\mathbf{\Sigma} - \mathbf{\Phi})$, with the residual component being $\mathcal{N} = \mathbf{\Sigma} - \mathbf{\Phi} - \mathbf{\Theta}$. Note that the entries in $\mathbf{\Phi}$ need to be non-negative[1] and $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$. In fact, in the words of ten Berge (1998) (see p. 326)

1. Negative estimates of the diagonals of $\mathbf{\Phi}$ are unwanted since they correspond to variances, but some FA estimation procedures often lead to negative estimates of $\mathbf{\Phi}$—these are popularly known in the literature as Heywood cases and have invited a significant amount of discussion in the community.

"*... However, when* $\mathbf{\Sigma} - \mathbf{\Phi}$ *the covariance matrix for the common parts of the variables, would appear to be indefinite, that would be no less embarrassing than having a negative unique variance in* $\mathbf{\Phi}$*...*"

We further refer the reader to Mardia et al. (1979) discussing the importance of $\mathbf{\Sigma} - \mathbf{\Phi}$ being PSD.[2] We thus have the following natural structural constraints on the parameters:

$$\mathbf{\Theta} \succeq \mathbf{0}, \quad \mathbf{\Phi} = \text{diag}(\Phi, \ldots, \Phi_p) \succeq \mathbf{0} \quad \text{and} \quad \mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}. \tag{3}$$

Motivated by the above considerations, we present the following rank-constrained estimation problem for FA:

$$\begin{aligned} \text{minimize} \quad & \|\mathbf{\Sigma} - (\mathbf{\Theta} + \mathbf{\Phi})\|_q^q \\ \text{s.t.} \quad & \text{rank}(\mathbf{\Theta}) \leq r \\ & \mathbf{\Theta} \succeq \mathbf{0} \\ & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0} \\ & \mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}, \end{aligned} \tag{4}$$

where $\mathbf{\Theta} \in \mathbb{R}^{p \times p}$, $\mathbf{\Phi} \in \mathbb{R}^{p \times p}$ are the optimization variables, and for a real symmetric matrix $\mathbf{A}_{p \times p}$, its matrix q-norm, also known as the Schatten norm (or Schatten-von-Neumann norm) is defined as

$$\|\mathbf{A}\|_q := \left(\sum_{i=1}^{p} |\lambda_i(\mathbf{A})|^q \right)^{\frac{1}{q}}, \tag{5}$$

where $\lambda_i(\mathbf{A}),\ i = 1, \ldots, p$, are the (real) eigenvalues of $\mathbf{A}$.

Interpreting the estimator: The estimation criterion (4) seeks to *jointly* obtain the (low-rank) common factors and *uniquenesses* that best explain $\mathbf{\Sigma}$ in terms of minimizing the matrix q-norm of the error $\mathbf{\Sigma} - (\mathbf{\Theta} + \mathbf{\Phi})$ under the PSD constraints (3). Note that criterion (4) does not necessarily assume that $\mathbf{\Sigma}$ *exactly* decomposes into a low-rank PSD matrix and a non-negative diagonal matrix. Problem (4) enjoys curious similarities with Principal Component Analysis (PCA). In PCA, given a PSD matrix $\mathbf{\Sigma}$ the leading r principal component directions of $\mathbf{\Sigma}$ are obtained by minimizing $\|\mathbf{\Sigma} - \mathbf{\Theta}\|_q$ subject to $\mathbf{\Theta} \succeq \mathbf{0}$ and $\text{rank}(\mathbf{\Theta}) \leq r$. If the optimal solution $\mathbf{\Phi}$ to Problem (4) is *given*, Problem (4) is analogous to a rank-r PCA on the residual matrix $\mathbf{\Sigma} - \mathbf{\Phi}$—thus it is naturally desirable to have $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$. In PCA one is interested in understanding the proportion of variance explained by the top-r principal component directions: $\sum_{i=1}^{r} \lambda_i(\mathbf{\Sigma}) / \sum_{i=1}^{p} \lambda_i(\mathbf{\Sigma})$. The denominator $\sum_{i=1}^{p} \lambda_i(\mathbf{\Sigma}) = \text{Tr}(\mathbf{\Sigma})$ accounts for the total variance explained by the covariance matrix $\mathbf{\Sigma}$. Analogously, the proportion of variance explained by $\widehat{\mathbf{\Theta}}_r$ (which denotes the best rank r approximation to $\mathbf{\Sigma} - \mathbf{\Phi}$) is given by $\sum_{i=1}^{r} \lambda_i(\mathbf{\Sigma} - \mathbf{\Phi}) / \sum_{i=1}^{p} \lambda_i(\mathbf{\Sigma} - \mathbf{\Phi})$—for this quantity to be interpretable it is imperative that $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$. In the above argument, of course, we assumed that $\mathbf{\Phi}$ is given. In general, $\mathbf{\Phi}$ needs to be estimated: Problem (4) achieves this goal by *jointly* learning $\mathbf{\Phi}$ and $\mathbf{\Theta}$. We note that certain popular approaches of FA (see Sections 1.1 and 1.2) do not impose the PSD constraint $\mathbf{\Sigma} - \mathbf{\Phi}$ as a part of the estimation

2. However, the estimation method described in Mardia et al. (1979) does not guarantee that $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$.

scheme—leading to indefinite $\mathbf{\Sigma} - \mathbf{\Phi}$—thereby rendering statistical interpretations troublesome. Our numerical evidence suggests that the quality of estimates of $\mathbf{\Theta}$ and $\mathbf{\Phi}$ obtained from Problem (4) outperform those obtained by other competing procedures which do not incorporate the PSD constraints into their estimation criteria.

Choice of r: In exploratory FA, it is standard to consider several choices of r and study the manner in which the proportion of variance explained by the common factors *saturates* with increasing r. We refer the reader to popularly used methods described in Anderson (2003); Bartholomew et al. (2011); Mardia et al. (1979) and more modern techniques (Bai and Ng, 2008, see also references therein) for the choice of r.

Estimate of Covariance Matrix: In the finite sample setting, we set $\mathbf{\Sigma}$ to be the sample covariance matrix. A *consequence* of solving Problem (4) is that we get an *estimate* for the covariance matrix given by $\hat{\mathbf{\Theta}} + \hat{\mathbf{\Phi}}$—in this sense, criterion (4) can be viewed as a regularization scheme: the rank constraint on $\mathbf{\Theta}$ encourages parsimony and the PSD constraints encourage interpretability, as discussed above.

In this paper, we propose a general computational framework to solve Problem (4) for any $q \geq 1$. The well-known Schatten q-norm appearing in the loss function is chosen for flexibility—it underlines the fact that our approach can be applied for *any* $q \geq 1$. Note that the estimation criterion (4) (even for the case $q = 1$) does not seem to appear in prior work on *approximate minimum rank Factor Analysis* (MRFA) (ten Berge and Kiers, 1991; Shapiro and ten Berge, 2002). However, we show in Proposition 1 that Problem (4) for the special case $q = 1$ turns out to be equivalent to MRFA. For $q = 2$, the loss function is the familiar squared Frobenius norm also used in MINRES, though the latter formulation is not equivalent to Problem (4), as explained in Section 1.1. We place more emphasis on studying the computational properties for the more common norms $q \in \{1, 2\}$.

The presence of the rank constraint in Problem (4) makes the optimization problem nonconvex. Globally optimizing Problem (4) or for that matter obtaining a good stationary point is quite challenging. We propose a new *equivalent* smooth formulation to Problem (4) which does not contain the combinatorial rank constraint. We employ simple and tractable sequential convex relaxation techniques with guaranteed convergence properties and excellent computational properties to obtain a stationary point for Problem (4). An important novelty of this paper is to present certifiable lower bounds on Problem (4) without resorting to structural assumptions, thus making it possible to solve Problem (4) to *provable* optimality. Towards this end we propose new methods and ideas that incorporate state-of-the-art developments in nonlinear and global optimization.[3]

1.1 A selective overview of related FA estimators

FA has a long and influential history which dates back more than a hundred years. The notion of FA possibly first appeared in Spearman (1904) for the one factor model, which was then generalized to the multiple factors model by various authors (see, for example,

3. The class of optimization problems studied in this paper involve global minimization of nonconvex, continuous semidefinite optimization problems. Computational methods for this class of problems are in a nascent stage; further, such methods are significantly less developed when compared to those for mixed integer linear optimization problems, thus posing a major challenge in this work.

Thurstone 1947). Significant contributions related to computational methods for FA have been nicely documented in Bai and Ng (2008); Harman and Jones (1966); Jöreskog (1967, 1978); Lawley and Maxwell (1962); Ledermann (1937); Rao (1973); Shapiro (1982); and ten Berge and Kiers (1991), among others.

We will briefly describe some widely used approaches for FA that are closely related to the approach pursued herein and also point out their connections.

Constrained Minimum Trace Factor Analysis (MTFA): This approach (ten Berge et al., 1981; Riccia and Shapiro, 1982) seeks to decompose $\mathbf{\Sigma}$ exactly into the sum of a diagonal matrix and a low-rank component, which are estimated via the following convex optimization problem:

$$\begin{array}{rl} \text{minimize} & \text{Tr}(\mathbf{\Theta}) \\ \text{s.t.} & \mathbf{\Theta} \succeq \mathbf{0} \\ & \mathbf{\Sigma} = \mathbf{\Theta} + \mathbf{\Phi} \\ & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0}, \end{array} \tag{6}$$

with variables $\mathbf{\Theta}, \mathbf{\Phi}$. Because $\mathbf{\Theta}$ is PSD, $\text{Tr}(\mathbf{\Theta}) = \sum_{i=1}^{p} \lambda_i(\mathbf{\Theta})$ is a convex surrogate (Fazel, 2002) for the rank of $\mathbf{\Theta}$—Problem (6) may thus be viewed as a convexification of the rank minimization problem

$$\begin{array}{rl} \text{minimize} & \text{rank}(\mathbf{\Theta}) \\ \text{s.t.} & \mathbf{\Theta} \succeq \mathbf{0} \\ & \mathbf{\Sigma} = \mathbf{\Theta} + \mathbf{\Phi} \\ & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0}. \end{array} \tag{7}$$

In general, Problems (6) and (7) are *not* equivalent. See Riccia and Shapiro (1982); Saunderson et al. (2012); Shapiro (1982) (and references therein) for further connections between the minimizers of (6) and (7).

A main difference between formulations (4) and (7) is that the former allows an error in the residual $(\mathbf{\Sigma} - \mathbf{\Theta} - \mathbf{\Phi})$ by constraining $\mathbf{\Theta}$ to have low-rank, unlike (7) which imposes a hard constraint $\mathbf{\Sigma} = \mathbf{\Theta} + \mathbf{\Phi}$. As noted earlier, this can be quite restrictive in various applications. Even if one views Problem (6) as imposing a less stringent requirement than that of Problem (7), we see two distinct advantages of Problem (4) over Problem (6): it offers the modeling flexibility of controlling the complexity, viz. rank, of solutions via the choice of r; and it provides smaller of estimates of rank for a comparable amount of explained variance, as substantiated by experimental findings presented in Section 5.

Approximate Minimum Rank Factor Analysis (MRFA): This method (see for example, ten Berge and Kiers, 1991; Shapiro and ten Berge, 2002) considers the following optimization problem:

$$\begin{array}{rl} \text{minimize} & \displaystyle\sum_{i=r+1}^{p} \lambda_i(\mathbf{\Sigma} - \mathbf{\Phi}) \\ \text{s.t.} & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0} \\ & \mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}, \end{array} \tag{8}$$

where the optimization variable is $\mathbf{\Phi}$. Proposition 1 presented below establishes that Problem (8) is equivalent to the rank-constrained FA formulation (4) for the case $q = 1$. This connection does not appear to be formally established in ten Berge and Kiers (1991). We believe that criterion (4) for $q = 1$ is easier to interpret as an estimation criterion for FA models over (8). ten Berge and Kiers (1981, 1991) describe a method[4] for numerically optimizing (8)—as documented in the code for MRFA (ten Berge and Kiers, 2003), their implementation can handle problems of size $p \leq 20$.

Principal Component (PC) Factor Analysis: Principal Component factor analysis or PC in short (Connor and Korajczyk, 1986; Bai and Ng, 2008) implicitly assumes that $\mathbf{\Phi} = \sigma^2 \mathbf{I}_{p\times p}$, for some $\sigma^2 > 0$ and performs a low-rank PCA on $\mathbf{\Sigma}$. It is not clear how to estimate $\mathbf{\Phi}$ via this method such that $\Phi_i \geq 0$ and $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$. Following Mardia et al. (1979), the $\mathbf{\Phi}$'s may be estimated after estimating $\widehat{\mathbf{\Theta}}$ via the update rule $\widehat{\mathbf{\Phi}} = \text{diag}(\mathbf{\Sigma} - \widehat{\mathbf{\Theta}})$—the estimates thus obtained, however, need not be non-negative. Furthermore, it is not guaranteed that the condition $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$ is met.

Minimum Residual Factor Analysis (MINRES): This approach (Harman and Jones, 1966; Shapiro and ten Berge, 2002) considers the following optimization problem (with respect to the variable $\mathbf{L}_{p\times r}$):

$$\text{minimize} \quad \sum_{1\leq i\neq j\leq p} \left(\sigma_{ij} - (\mathbf{L}\mathbf{L}')_{ij}\right)^2, \tag{9}$$

where $\mathbf{\Sigma} := ((\sigma_{ij}))$, $\mathbf{\Theta} = \mathbf{L}\mathbf{L}'$ and the sum (in the objective) is taken over all the off-diagonal entries. Formulation (9) is equivalent to the nonconvex optimization problem

$$\begin{array}{rl} \text{minimize} & \|\mathbf{\Sigma} - (\mathbf{\Theta} + \mathbf{\Phi})\|_2^2 \\ \text{s.t.} & \text{rank}(\mathbf{\Theta}) \leq r \\ & \mathbf{\Theta} \succeq \mathbf{0} \\ & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p), \end{array} \tag{10}$$

with variables $\mathbf{\Theta}$ and $\mathbf{\Phi}$, where Φ_i, $i \geq 1$, are unconstrained. If $\widehat{\mathbf{\Theta}}$ is a minimizer of Problem (10), then *any* $\widehat{\mathbf{L}}$ satisfying $\widehat{\mathbf{L}}\widehat{\mathbf{L}}' = \widehat{\mathbf{\Theta}}$ minimizes (9) and vice-versa.

Various heuristic approaches are used to for Problem (9). The `R` package `psych`, for example, uses a black box gradient based tool `optim` to minimize the nonconvex Problem (9) with respect to $\mathbf{L}$. Once $\widehat{\mathbf{L}}$ is estimated, the diagonal entries of $\mathbf{\Phi}$ are estimated as $\widehat{\Phi}_i = \sigma_{ii} - (\widehat{\mathbf{L}}\widehat{\mathbf{L}}')_{ii}$, for $i \geq 1$. Note that $\widehat{\Phi}_i$ obtained in this fashion may be negative[5] and the condition $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$ may be violated.

Generalized Least Squares, Principal Axis and variants: The Ordinary Least Squares (OLS) method for FA (Bartholomew et al., 2011) considers formulation (10) with the additional constraint that $\Phi_i \geq 0\ \forall i$. The Weighted Least Squares (WLS) or the generalized least squares method (see for example, Bartholomew et al., 2011) considers a weighted least squares objective:

$$\|\mathbf{W}\left(\mathbf{\Sigma} - (\mathbf{\Theta} + \mathbf{\Phi})\right)\|_2^2 .$$

4. The method is similar to Algorithm 1 presented herein for the case of $q = 1$; however, ten Berge and Kiers (1981, 1991) rely on a heuristic procedure, as described in Bentler and Woodward (1980), for the subproblem with respect to $\mathbf{\Phi}$.
5. If $\widehat{\Phi}_i < 0$, some ad-hoc procedure is used to threshold it to a nonnegative quantity.

As in the ordinary least squares case, here too we assume that $\Phi_i \geq 0$. Various choices of $\mathbf{W}$ are possible depending upon the application, with $\mathbf{W} \in \{\mathbf{\Sigma}^{-1}, \mathbf{\Phi}^{-1}\}$ being a couple of popular choices.

The Principal Axis (PA) FA method (Bartholomew et al., 2011; Revelle, 2015) is popularly used to estimate factor model parameters based on criterion (10) along with the constraints $\Phi_i \geq 0 \ \forall i$. This method starts with a nonnegative estimate $\widehat{\mathbf{\Phi}}$ and performs a rank r eigendecomposition on $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$ to obtain $\widehat{\mathbf{\Theta}}$. The matrix $\widehat{\mathbf{\Phi}}$ is then updated to match the diagonal entries of $\mathbf{\Sigma} - \widehat{\mathbf{\Theta}}$, and the above steps are repeated until the estimate $\widehat{\mathbf{\Phi}}$ stabilizes.[6] Note that in this procedure the estimate $\widehat{\mathbf{\Theta}}$ may fail to be PSD and the entries of $\widehat{\Phi}_i$ may be negative as well. Heuristic restarts and various initializations are often carried out to arrive at a reasonable solution (see for example discussions in Bartholomew et al. 2011).

In summary, the least squares stylized methods described above may lead to estimates that violate one or more of the constraints: $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$, $\mathbf{\Theta} \succeq \mathbf{0}$ and $\mathbf{\Phi} \succeq \mathbf{0}$.

Maximum Likelihood for Factor Analysis: This approach (Bai and Li, 2012; Jöreskog, 1967; Mardia et al., 1979; Roweis and Ghahramani, 1999; Rubin and Thayer, 1982) is another widely used method in FA and typically assumes that the data follows a multivariate Gaussian distribution. This procedure maximizes a likelihood function and is quite different from the loss functions pursued in this paper and discussed above. The estimator need not exist for any $\mathbf{\Sigma}$—see for example Robertson and Symons (2007).

Most of the methods described in Section 1.1 are widely used and their implementations are available in statistical packages `psych` (Revelle, 2015), `nFactors` (Raiche and Magis, 2011), `GPArotation` (Bernaards and Jennrich, 2005), and others and are publicly available from `CRAN`.[7]

1.2 Broad categories of factor analysis estimators

A careful investigation of the methods described above suggests that they can be divided into two broad categories. Some of the above estimators explicitly incorporate a PSD structural assumption on the residual covariance matrix $\mathbf{\Sigma} - \mathbf{\Phi}$ in *addition* to requiring $\mathbf{\Theta} \succeq \mathbf{0}$ and $\mathbf{\Phi} \succeq \mathbf{0}$ while the others do not. As already pointed out, these constraints are important for statistical interpretability. We propose to distinguish between the following two broad categories of FA algorithms:

(A) This category is comprised of FA estimation procedures cast as nonlinear Semidefinite Optimization (SDO) problems—estimation takes place in the presence of constraints of the form $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$, along with $\mathbf{\Theta} \succeq \mathbf{0}$ and $\mathbf{\Phi} \succeq \mathbf{0}$. Members of this category are MRFA, MTFA and more generally Problem (4).

Existing approaches for these problems are typically not scalable: for example, we are not aware of any algorithm (prior to this paper) for Problem (8) (MRFA) that scales to covariance matrices with p larger than thirty. Indeed, while theoretical guarantees of optimality exist in certain cases (Saunderson et al., 2012), the conditions required for such results to hold are generally difficult to verify in practice.

(B) This category includes classical FA methods which are not based on nonlinear SDO based formulations (as in Category (A)). MINRES, OLS, WLS, GLS, PC and PA based FA estimation procedures (as described in Section 1.1) belong to this category. These methods are generally scalable to problem sizes where p is of the order of a few thousand—significantly larger than most procedures belonging to Category (A)—and are implemented in open-source `R`-packages.

Contributions: Our contributions in this paper may be summarized as follows:

1. We consider a flexible family of FA estimators which can be obtained as solutions to rank-constrained nonlinear SDO problems. In particular, our framework provides a unifying perspective on several existing FA estimation approaches.

2. We propose a novel *exact* reformulation of the rank-constrained FA problem (4) as a smooth optimization problem with convex compact constraints. We also develop a unified algorithmic framework utilizing modern optimization techniques to obtain high quality solutions to Problem (4). Our algorithms, at every iteration, simply require computing a low-rank eigendecomposition of a $p \times p$ matrix and a structured scalable convex SDO. Our proposal is capable of solving FA problems involving covariance matrices having dimensions up to a few thousand, thereby making it on par with the most scalable FA methods used currently.[8]

3. Our SDO formulation enables us to estimate the underlying factors and unique variances under the restriction that the residual covariance matrix is PSD—a characteristic that is absent in several popularly used FA methods. This aids statistical interpretability, especially in drawing parallels with PCA and understanding the proportion of variance explained by a given number of factors. Methods proposed herein produce superior quality estimates, in terms of various performance metrics, when compared to existing FA approaches. To our knowledge, this is the first paper demonstrating that certifiably optimal solutions to a rank-constrained problem can be found for problems of realistic sizes, without making any assumptions on the underlying data.

4. Using techniques from discrete and global optimization, we develop a branch-and-bound algorithm which proves that the low-rank solutions found are often optimal in seconds for problems on the order of $p = 10$ variables, in minutes for problems on the order of $p = 100$, and in days for some problems on the order of $p = 4000$. As the selected rank increases, so too does the computational burden of proving optimality. It is particularly crucial to note that the optimal solutions for all problems we consider are found very quickly, and that vast majority of computational time is then spent on proving optimality. Hence, for a practitioner who is not particularly concerned with certifying optimality, our techniques for finding feasible solutions provide high-quality estimates quickly.

6. We are not aware of a proof, however, showing the convergence of this procedure.
7. `http://cran.us.r-project.org`

8. An implementation of our approach is available at `https://github.com/copenhaver/factoranalysis`.

5. We provide computational evidence demonstrating the favorable performance of our proposed method. Finally, to the best of our knowledge this is the first paper that views various FA methods in a unified fashion via a modern optimization lens and attempts to compare a wide range of FA techniques in large scale.

Structure of the paper: The paper is organized as follows. In Section 1 we propose a flexible family of optimization Problems (4) for the task of statistical estimation in FA models. Section 2 presents an exact reformulation of Problem (4) as a nonlinear SDO without the rank constraint. Section 3 describes the use of nonlinear optimization techniques such as the Conditional Gradient (CG) method (Bertsekas, 1999) adapted to provide feasible solutions (upper bounds) to our formulation. First order methods employed to compute the convex SDO subproblems are also described in the same section. In Section 4, we describe our method for certifying optimality of the solutions from Section 3 in the case when $q = 1$. In Section 5, we present computational results demonstrating the effectiveness of our proposed method in terms of (a) modeling flexibility in the choice of the number of factors r and the parameter q, (b) scalability, and (c) the quality of solutions obtained in a wide array of real and synthetic datasets—comparisons with several existing methods for FA are considered. Section 6 contains our conclusions.

2. Reformulations of Problem (4)

Let $\boldsymbol{\lambda}(\mathbf{A})$ denote the vector of eigenvalues of $\mathbf{A}$, arranged in decreasing order, i.e.,

$$\lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{A}) \geq \ldots \geq \lambda_p(\mathbf{A}). \tag{11}$$

The following proposition presents the first reformulation of Problem (4) as a continuous eigenvalue optimization problem with convex compact constraints. Proofs of all results can be found in Appendix A.

Proposition 1 (a) *For any $q \geq 1$, Problem (4) is equivalent to:*

$$\begin{array}{lll} (\text{CFA}_q) & \text{minimize} & f_q(\boldsymbol{\Phi};\boldsymbol{\Sigma}) := \displaystyle\sum_{i=r+1}^{p} \lambda_i^q(\boldsymbol{\Sigma}-\boldsymbol{\Phi}) \\ & \text{s.t.} & \boldsymbol{\Phi} = \text{diag}(\Phi_1,\ldots,\Phi_p) \succeq \mathbf{0} \\ & & \boldsymbol{\Sigma}-\boldsymbol{\Phi} \succeq \mathbf{0}, \end{array} \tag{12}$$

where $\boldsymbol{\Phi}$ is the optimization variable.

(b) *Suppose $\boldsymbol{\Phi}^*$ is a minimizer of Problem (12), and let*

$$\boldsymbol{\Theta}^* = \mathbf{U}\ \text{diag}\left(\lambda_1(\boldsymbol{\Sigma}-\boldsymbol{\Phi}^*),\ldots,\lambda_r(\boldsymbol{\Sigma}-\boldsymbol{\Phi}^*),0,\ldots,0\right)\mathbf{U}', \tag{13}$$

where $\mathbf{U}_{p\times p}$ is the matrix of eigenvectors of $\boldsymbol{\Sigma}-\boldsymbol{\Phi}^*$. Then $(\boldsymbol{\Theta}^*,\boldsymbol{\Phi}^*)$ is a solution to Problem (4).

Problem (12) is a nonlinear SDO in $\boldsymbol{\Phi}$, unlike the original formulation (4) that estimates $\boldsymbol{\Theta}$ and $\boldsymbol{\Phi}$ jointly. Note that the rank constraint does not appear in Problem (12) and the constraint set of Problem (12) is convex and compact. However, Problem (12) is nonconvex due to the nonconvex objective function $\sum_{i=r+1}^{p}\lambda_i^q(\boldsymbol{\Sigma}-\boldsymbol{\Phi})$. For $q = 1$ the function appearing in the objective of (12) is concave and for $q > 1$, it is neither convex nor concave.

Proposition 2 *The estimation Problem (4) is equivalent to*

$$\begin{array}{lll} \text{minimize} & \|\boldsymbol{\Sigma}-(\boldsymbol{\Theta}+\boldsymbol{\Phi})\|_q^q \\ \text{s.t.} & \text{rank}(\boldsymbol{\Theta}) \leq r \\ & \boldsymbol{\Theta} \succeq \mathbf{0} \\ & \boldsymbol{\Phi} = \text{diag}(\Phi_1,\ldots,\Phi_p) \succeq \mathbf{0} \\ & \boldsymbol{\Sigma}-\boldsymbol{\Phi} \succeq \mathbf{0} \\ & \boldsymbol{\Sigma}-\boldsymbol{\Theta} \succeq \mathbf{0}. \end{array} \tag{14}$$

Note that Problem (14) has an additional PSD constraint $\boldsymbol{\Sigma}-\boldsymbol{\Theta} \succeq \mathbf{0}$ which does not explicitly appear in Problem (4). It is interesting to note that the two problems are equivalent. By virtue of Proposition 2, Problem (14) can as well be used as the estimation criterion for rank constrained FA. However, we will work with formulation (4) because it is easier to interpret from a statistical perspecitve.

Special instances of (CFA_q): We show that some well-known FA estimation problems can be viewed as special cases of our general framework.

For $q = 1$, Problem (12) reduces to MRFA, as described in (8). For $q = 1$ and $r = 0$, Problem (12) reduces to MTFA (6). When $q = 2$, we get a variant of (10), i.e., a PSD *constrained* analogue of MINRES

$$\begin{array}{lll} \text{minimize} & \displaystyle\sum_{i=r+1}^{p} \lambda_i^2(\boldsymbol{\Sigma}-\boldsymbol{\Phi}) \\ \text{s.t.} & \boldsymbol{\Phi} = \text{diag}(\Phi_1,\ldots,\Phi_p) \succeq \mathbf{0} \\ & \boldsymbol{\Sigma}-\boldsymbol{\Phi} \succeq \mathbf{0}. \end{array} \tag{15}$$

Note that unlike Problem (10), Problem (15) explicitly imposes PSD constraints on $\boldsymbol{\Phi}$ and $\boldsymbol{\Sigma}-\boldsymbol{\Phi}$. The objective function in (12) is continuous but non-smooth. The function is differentiable at $\boldsymbol{\Phi}$ if and only if the r and $(r+1)$th eigenvalues of $\boldsymbol{\Sigma}-\boldsymbol{\Phi}$ are distinct (Lewis, 1996; Shapiro and ten Berge, 2002), i.e., $\lambda_{r+1}(\boldsymbol{\Sigma}-\boldsymbol{\Phi}) < \lambda_r(\boldsymbol{\Sigma}-\boldsymbol{\Phi})$. The non-smoothness of the objective function in Problem (12) makes the use of standard gradient based methods problematic (Bertsekas, 1999). Theorem 1 presents a reformulation of Problem (12) in which the objective function is continuously differentiable.

Theorem 1 (a) *The estimation criterion given by Problem (4) is equivalent to*[9]

$$\begin{array}{lll} \text{minimize} & g_q(\mathbf{W},\boldsymbol{\Phi}) := & \text{Tr}(\mathbf{W}(\boldsymbol{\Sigma}-\boldsymbol{\Phi})^q) \\ \text{s.t.} & & \boldsymbol{\Phi} = \text{diag}(\Phi_1,\ldots,\Phi_p) \succeq \mathbf{0} \\ & & \boldsymbol{\Sigma}-\boldsymbol{\Phi} \succeq \mathbf{0} \\ & & \mathbf{I} \succeq \mathbf{W} \succeq \mathbf{0} \\ & & \text{Tr}(\mathbf{W}) = p-r. \end{array} \tag{16}$$

(b) *The solution $\widehat{\boldsymbol{\Theta}}$ of Problem (4) can be recovered from the solution $\widehat{\mathbf{W}},\widehat{\boldsymbol{\Phi}}$ of Problem (16) via:*

$$\widehat{\boldsymbol{\Theta}} := \widehat{\mathbf{U}}\,\text{diag}(\widehat{\lambda}_1,\ldots,\widehat{\lambda}_r,0,\ldots,0)\widehat{\mathbf{U}}', \tag{17}$$

9. For any PSD matrix $\mathbf{A}$, with eigendecomposition $\mathbf{A} = \mathbf{U}_A\,\text{diag}(\lambda_1,\ldots,\lambda_p)\mathbf{U}_A'$, we define $\mathbf{A}^q := \mathbf{U}_A\,\text{diag}(\lambda_1^q,\ldots,\lambda_p^q)\mathbf{U}_A'$, for any $q \geq 1$.

where $\widehat{\mathbf{U}}$ is the matrix formed by the p eigenvectors corresponding to the eigenvalues $\widehat{\lambda}_1, \ldots, \widehat{\lambda}_p$ (arranged in decreasing order) of the matrix $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$. Given $\widehat{\mathbf{\Phi}}$, any solution $\widehat{\mathbf{\Theta}}$ (given by (17)) is independent of q.

In Problem (16), if we partially minimize the function $g_q(\mathbf{W}, \mathbf{\Phi})$ over $\mathbf{\Phi}$ (with fixed $\mathbf{W}$), the resulting function is concave in $\mathbf{W}$. This observation leads to the following proposition.

Proposition 3 *The function $G_q(\mathbf{W})$ obtained upon (partially) minimizing $g_q(\mathbf{W}, \mathbf{\Phi})$ over $\mathbf{\Phi}$ (with $\mathbf{W}$ fixed) in Problem (16), given by*

$$\begin{array}{rll} G_q(\mathbf{W}) := & \inf\limits_{\mathbf{\Phi}} & g_q(\mathbf{W}, \mathbf{\Phi}) \\ & \text{s.t.} & \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0} \\ & & \mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}, \end{array} \tag{18}$$

is concave in $\mathbf{W}$. The sub-gradients of the function $G_q(\mathbf{W})$ exist and are given by:

$$\nabla G_q(\mathbf{W}) = (\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}(\mathbf{W}))^q, \tag{19}$$

where $\widehat{\mathbf{\Phi}}(\mathbf{W})$ is a minimizer of the convex optimization Problem (18).

In light of Proposition 3, we present another reformulation of Problem (4) as the following concave minimization problem:

$$\begin{array}{rl} \text{minimize} & G_q(\mathbf{W}) \\ \text{s.t.} & \mathbf{I} \succeq \mathbf{W} \succeq \mathbf{0} \\ & \text{Tr}(\mathbf{W}) = p - r, \end{array} \tag{20}$$

where the function $G_q(\mathbf{W})$ is differentiable if and only if $\widehat{\mathbf{\Phi}}(\mathbf{W})$ is unique.

Note that by virtue of Proposition 1, Problems (12) and (20) are equivalent. Therefore, it is natural to ask whether one formulation might be favored over the other from a computational perspective. Towards this end, note that both Problems (12) and (20) involve the minimization of a non-smooth objective function, over convex compact constraints. However, the objective function of Problem (12) is nonconvex (for $q > 1$) whereas the one in Problem (20) is concave (for all $q \geq 1$). We will see in Section 3 that CG-based algorithms can be applied to a concave minimization problem (even if the objective function is not differentiable); however, CG applied to general non-smooth objective functions has limited convergence guarantees. Thus, formulation (20) is readily amenable to CG-based optimization algorithms, unlike formulation (12). This seems to make Problem (20) computationally more appealing than Problem (12).

3. Finding Upper Bounds

This section presents a unified computational framework for the class of problems (CFA_q). Problem (16) is a nonconvex smooth optimization problem and obtaining a stationary point is quite challenging. We propose iterative schemes based on the Conditional Gradient (CG) algorithm (Bertsekas, 1999)—a generalization of the Frank-Wolfe algorithm (Frank

and Wolfe, 1956)—to obtain a stationary point of the problem. The appealing aspect of our framework is that every iteration of the algorithm requires solving a convex SDO problem which is computationally tractable. While off-the-shelf interior point algorithms—for example `SDPT3` (Toh et al., 1999), `Yalmip` (Löfberg, 2004), and `MOSEK` (Andersen and Andersen, 2000)—can be used to solve the convex SDO problems, they typically do not scale well for large problems due to intensive memory requirements. In this vein, first order algorithms have received a lot of attention (Nesterov, 2004, 2005, 2007) in convex optimization of late, due to their low cost per iteration, low-memory requirements, and ability to deliver solutions of moderate accuracy for large problems within a modest time limit. We use first order methods to solve the convex SDO problems. We present one primary scheme based on the CG algorithm:

> **Algorithm 1:** This scheme, described in Section 3.1, applies CG on the optimization Problem (20), where the function $G_q(\mathbf{W})$ defined in (18) is concave (and possibly non-smooth).

In addition, in Appendix B we present an alternative approach that applies CG to Problem (16), where the objective function $g_q(\mathbf{W}, \mathbf{\Phi})$ is smooth.

To make notation simpler, we will use the following shorthand:

$$\mathbf{\Psi}_{p,p-r} := \{\mathbf{W} \in \mathbb{R}^{p \times p} : \mathbf{I} \succeq \mathbf{W} \succeq \mathbf{0}, \;\; \text{Tr}(\mathbf{W}) = p - r\} \tag{21}$$

and $\mathcal{F}_{\mathbf{\Sigma}} = \{\mathbf{\Phi} : \mathbf{\Sigma} - \mathbf{\Phi} \succcurlyeq \mathbf{0}, \;\; \mathbf{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_p) \succcurlyeq \mathbf{0}\}$.

3.1 A CG based algorithm for Problem (20)

The CG method for Problem (20) requires solving a linearization of the concave objective function. At iteration k, if $\mathbf{W}^{(k)}$ is the current estimate of $\mathbf{W}$, the new estimate $\mathbf{W}^{(k+1)}$ is obtained by

$$\mathbf{W}^{(k+1)} \in \underset{\mathbf{W} \in \mathbf{\Psi}_{p,p-r}}{\arg\min} \left\langle \nabla G_q(\mathbf{W}^{(k)}), \mathbf{W} \right\rangle = \underset{\mathbf{W} \in \mathbf{\Psi}_{p,p-r}}{\arg\min} \; \text{Tr}(\mathbf{W}(\mathbf{\Sigma} - \mathbf{\Phi}^{(k)})^q), \tag{22}$$

where by Proposition 3, $(\mathbf{\Sigma} - \mathbf{\Phi}^{(k)})^q$ is a sub-gradient of $G_q(\mathbf{W})$ at $\mathbf{W}^{(k)}$ with $\mathbf{\Phi}^{(k)}$ given by

$$\mathbf{\Phi}^{(k)} \in \underset{\mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}}{\arg\min} \; \text{Tr}(\mathbf{W}^{(k)}(\mathbf{\Sigma} - \mathbf{\Phi})^q) \tag{23}$$

No explicit line search is necessary here because the minimum will always be at the new point, i.e., $\mathbf{\Phi}^{(k)}$, due to the concavity of the objective function. The sequence $\mathbf{W}^{(k)}$ is recursively computed via (22) until the convergence criterion

$$G_q(\mathbf{W}^{(k)}) - G_q(\mathbf{W}^{(k+1)}) \leq \text{TOL} \cdot G_q(\mathbf{W}^{(k)}), \tag{24}$$

for some user-defined tolerance, TOL > 0, is met. A short description of the procedure appears in Algorithm 1.

Before we present the convergence rate of Algorithm 1, we will need to introduce some notation. For any point $\overline{\mathbf{W}}$ belonging to the feasible set of Problem (20) let us define $\Delta(\overline{\mathbf{W}})$ as follows:

$$\Delta(\overline{\mathbf{W}}) := \inf_{\mathbf{W} \in \mathbf{\Psi}_{p,p-r}} \langle \nabla G_q(\overline{\mathbf{W}}), \mathbf{W} - \overline{\mathbf{W}} \rangle. \tag{25}$$

Algorithm 1 A CG based algorithm for formulation (20)

1. Initialize with $\mathbf{W}^{(1)}$ ($k=1$), feasible for Problem (20) and repeat, for $k \geq 2$, Steps 2-3 until convergence criterion (24) is satisfied.
2. Update $\mathbf{\Phi}$ (with $\mathbf{W}$ fixed) by solving (23).
3. Update $\mathbf{W}$ (with $\mathbf{\Phi}$ fixed) by solving (22), to get $\mathbf{W}^{(k+1)}$.

Further, $\mathbf{W}^*$ satisfies the first order stationary condition for Problem (20) if $\mathbf{W}^*$ is feasible for the problem and $\Delta(\mathbf{W}^*) \geq 0$.

We now present Theorem 2 establishing the rate of convergence and associated convergence properties of Algorithm 1. The proof (along with all other omitted proofs) is contained in Appendix A.

Theorem 2 *If $\mathbf{W}^{(k)}$ is a sequence produced by Algorithm 1, then $G_q(\mathbf{W}^{(k)})$ is a monotone decreasing sequence and every limit point $\mathbf{W}^{(\infty)}$ of the sequence $\mathbf{W}^{(k)}$ is a stationary point of Problem* (20)*. Furthermore, Algorithm 1 has a convergence rate of $O(1/K)$ (with K denoting the iteration index) to a first order stationary point of Problem* (20)*, i.e.,*

$$\min_{i=1,\ldots,K} \left\{-\Delta(\mathbf{W}^{(i)})\right\} \leq \frac{G_q(\mathbf{W}^{(1)}) - G_q(\mathbf{W}^{(\infty)})}{K}. \tag{26}$$

3.2 Solving the convex SDO problems

Algorithm 1 requires sequentially solving convex SDO problems in $\mathbf{W}$ and $\mathbf{\Phi}$. We describe herein how these subproblems can be solved efficiently.

3.2.1 Solving the SDO problem with respect to $\mathbf{W}$

A generic SDO problem associated with Problem (22) requires updating $\mathbf{W}$ as

$$\widehat{\mathbf{W}} \in \underset{\mathbf{W} \in \mathbf{\Psi}_{p,p-r}}{\arg\min} \langle \mathbf{W}, \widetilde{\mathbf{W}} \rangle, \tag{27}$$

for some fixed symmetric $\widetilde{\mathbf{W}}_{p\times p}$, depending upon the algorithm and the choice of q, described as follows. For Algorithm 1 the update in $\mathbf{W}$ at iteration k for Problem (22), corresponds to $\widetilde{\mathbf{W}} = (\mathbf{\Sigma} - \mathbf{\Phi}^{(k+1)})^q$.

A solution to Problem (27) is given by $\widehat{\mathbf{W}} = \sum_{i=r+1}^{p} \mathbf{u}_i \mathbf{u}_i'$, where $\mathbf{u}_1, \ldots, \mathbf{u}_p$ are the eigenvectors of the matrix $\widetilde{\mathbf{W}}$, corresponding to the eigenvalues $\lambda_1(\widetilde{\mathbf{W}}), \ldots, \lambda_p(\widetilde{\mathbf{W}})$.

3.2.2 Solving the SDO problem with respect to $\mathbf{\Phi}$

The SDO problem arising from the update of $\mathbf{\Phi}$ is not as straightforward as the update with respect to $\mathbf{W}$. Before presenting the general case, it helps to consider a few special cases of (CFA$_q$). For $q=1$ the objective function of Problem (16)

$$g_1(\mathbf{W}, \mathbf{\Phi}) = \langle \mathbf{W}, \mathbf{\Sigma} \rangle - \sum_{i=1}^{p} w_{ii} \Phi_i \tag{28}$$

is linear in $\mathbf{\Phi}$ (for fixed $\mathbf{W}$). For $q=2$, the objective function of Problem (16)

$$g_2(\mathbf{W}, \mathbf{\Phi}) = \mathrm{Tr}(\mathbf{W}\mathbf{\Sigma}^2) + \sum_{i=1}^{p} (w_{ii}\Phi_i^2 - 2\langle \mathbf{w}_i, \boldsymbol{\sigma}_i \rangle \Phi_i) \tag{29}$$

is a convex quadratic in $\mathbf{\Phi}$ (for fixed $\mathbf{W}$).

For Algorithm 1, the partial minimizations with respect to $\mathbf{\Phi}$, for $q=1$ and $q=2$, require minimizing Problems (28) and (29), respectively.

Various instances of optimization problems with respect to $\mathbf{\Phi}$ such as those appearing in Algorithm 1 can be viewed as special cases of the following family of SDO problems:

$$\underset{\mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}}{\text{minimize}} \quad \sum_{i=1}^{p} \left(c_i \Phi_i^2 + d_i \Phi_i\right) \tag{30}$$

where $c_i \geq 0$ and d_i for $i = 1, \ldots, p$ are problem parameters that depend upon the choice of algorithm and q. We now present a first order convex optimization scheme for solving (30).

A First Order Scheme for Problem (30)

With the intention of providing a simple and scalable algorithm for the convex SDO problem, we use the Alternating Direction Method of Multipliers (Bertsekas, 1999; Boyd et al., 2011) (ADMM). We introduce a splitting variable $\mathbf{\Lambda} = \mathbf{\Sigma} - \mathbf{\Phi}$ and rewrite Problem (30) in the following equivalent form:

$$\begin{aligned} \underset{\mathbf{\Phi}, \mathbf{\Lambda}}{\text{minimize}} \quad & \sum_{i=1}^{p} (c_i \Phi_i^2 + d_i \Phi_i) \\ \text{s.t.} \quad & \mathbf{\Phi} = \mathrm{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0} \\ & \mathbf{\Lambda} \succeq \mathbf{0} \\ & \mathbf{\Lambda} = \mathbf{\Sigma} - \mathbf{\Phi}. \end{aligned} \tag{31}$$

The Augmented Lagrangian for the above problem is:

$$\mathcal{L}_\rho(\mathbf{\Phi}, \mathbf{\Lambda}, \boldsymbol{\nu}) := \sum_{i=1}^{p} (c_i \Phi_i^2 + d_i \Phi_i) + \left\langle \boldsymbol{\nu}, \mathbf{\Lambda} - (\mathbf{\Sigma} - \mathbf{\Phi}) \right\rangle + \frac{\rho}{2} \|\mathbf{\Lambda} - (\mathbf{\Sigma} - \mathbf{\Phi})\|_2^2, \tag{32}$$

where $\rho > 0$ is a scalar and $\langle \cdot, \cdot \rangle$ denotes the standard trace inner product. ADMM involves the following three updates:

$$\mathbf{\Phi}^{(k+1)} \in \underset{\mathbf{\Phi} = \mathrm{diag}(\Phi_1, \ldots, \Phi_p) \succeq \mathbf{0}}{\arg\min} \quad \mathcal{L}_\rho(\mathbf{\Phi}, \mathbf{\Lambda}^{(k)}, \boldsymbol{\nu}^{(k)}), \tag{33}$$

$$\mathbf{\Lambda}^{(k+1)} \in \underset{\mathbf{\Lambda} \succeq \mathbf{0}}{\arg\min} \quad \mathcal{L}_\rho(\mathbf{\Phi}^{(k+1)}, \mathbf{\Lambda}, \boldsymbol{\nu}^{(k)}), \tag{34}$$

$$\boldsymbol{\nu}^{(k+1)} = \boldsymbol{\nu}^{(k)} + \rho(\mathbf{\Lambda}^{(k+1)} - (\mathbf{\Sigma} - \mathbf{\Phi}^{(k+1)})), \tag{35}$$

and produces a sequence $\{(\mathbf{\Phi}^{(k)}, \boldsymbol{\lambda}^{(k)}, \boldsymbol{\nu}^{(k)})\}$, $k \geq 1$ — the convergence properties of the algorithm are quite well known (Boyd et al., 2011).

Problem (33) can be solved in closed form as

$$\Phi_i^{(k+1)} = \frac{\rho}{\rho + 2c_i} \max\left\{ (\sigma_{ii} - \lambda_{ii}^{(k)}) - \frac{(d_i + \nu_{ii}^{(k)})}{\rho}, 0 \right\}, \quad i = 1, \ldots, p. \tag{36}$$

The update with respect to $\mathbf{\Lambda}$ in (34) requires an eigendecomposition:

$$\begin{aligned} \mathbf{\Lambda}^{(k+1)} =& \arg\min_{\mathbf{\Lambda} \succeq \mathbf{0}} \left\| \mathbf{\Lambda} - (\mathbf{\Sigma} - \mathbf{\Phi}^{(k+1)} - \frac{1}{\rho}\boldsymbol{\nu}^{(k)}) \right\|_2^2 \\ =& \mathcal{P}_{S_p^+}\left(\mathbf{\Sigma} - \mathbf{\Phi}^{(k+1)} - \frac{1}{\rho}\boldsymbol{\nu}^{(k)} \right), \end{aligned} \tag{37}$$

where, the operator $\mathcal{P}_{S_p^+}(\mathbf{A})$ denotes the projection of a symmetric matrix $\mathbf{A}$ onto the cone of PSD matrices of dimension $p \times p$: $\mathcal{P}_{S_p^+}(\mathbf{A}) = \mathbf{U}_A \operatorname{diag}\left(\max\{\lambda_1, 0\}, \ldots, \max\{\lambda_p, 0\} \right) \mathbf{U}_A'$, where, $\mathbf{A} = \mathbf{U}_A \operatorname{diag}(\lambda_1, \ldots, \lambda_p) \mathbf{U}_A'$ is the eigendecomposition of $\mathbf{A}$.

Stopping criterion: The ADMM iterations (33)—(35) are continued till the values of $\|\mathbf{\Lambda}^{(k+1)} - (\mathbf{\Sigma} - \mathbf{\Phi}^{(k+1)})\|_2$ and the relative change in the objective values of Problem (30) become smaller than a certain threshold, say, TOL $\times \alpha$, where $\alpha \in \{10^{-1}, \ldots, 10^{-3}\}$—this is typically taken to be smaller than the convergence threshold for the CG iterations (TOL).

Computational cost of Problem (30): The most intensive computational stage in the ADMM procedure is in performing the projection operation (37); this requires $O(p^3)$ operations due to the associated eigendecomposition. This needs to be done for as many ADMM steps, until convergence.

Since Problem (30) is embedded inside iterative procedures like Algorithm 1, the estimates of $(\mathbf{\Phi}, \mathbf{\Lambda}, \boldsymbol{\nu})$ obtained by solving Problem (30) for a iteration index (of the CG algorithm) provides a good warm-start for the Problem (30) in the subsequent CG iteration. This is often found to decrease the number of iterations required by the ADMM algorithm to converge to a prescribed level of accuracy.[10]

3.3 Computational cost of Algorithm 1

For Algorithm 1 and other CG-based algorithms for factor analysis (see Appendix B), the computational bottleneck is in performing the eigendecomposition of a $p \times p$ matrix: the $\mathbf{W}$ update requires performing a low-rank eigendecomposition of a $p \times p$ matrix and the $\mathbf{\Phi}$ update requires solving a problem of the form (30), which also costs $O(p^3)$. Since eigendecompositions can easily be done for p of the order of a few thousands, the proposed algorithms can be applied to that scale.

Note that most existing popular algorithms for FA belonging to Category (B) (see Section 1.2) also perform an eigendecomposition with cost $O(p^3)$. Thus it appears that

10. The utility of warm starts is another compelling reason to apply a first-order-based approach instead of interior point methods. Indeed, warm starts are well-known to perform quite poorly when incorporated into interior point methods—often they can perform worse than cold starts (Yildirim and Wright, 2002; John and Yildirim, 2008). Given the need to repeatedly solve similarly structured SDOs for both upper bounds (as presented in this section) as well as lower bounds (as presented in Section 4), the ability to effectively incorporate warm start information is crucial.

Category (B) and the algorithms proposed herein have the same computational complexity and hence these two estimation approaches are equally scalable.

4. Certificates of Optimality via Lower Bounds

In this section, we outline our approach to computing lower bounds to (CFA_q) via techniques from global optimization and matrix analysis. In particular, we focus on the case when $q = 1$.[11] We begin with an overview of the method. We then discuss initialization parameters for the method as well as branching rules and other refinements employed in our approach.

4.1 Overview of Method

Our primary problem of interest is to provide lower bounds to (CFA_1), i.e.,

$$\underset{\mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}}{\text{minimize}} \sum_{i=r+1}^{p} \sigma_i(\mathbf{\Sigma} - \mathbf{\Phi}), \tag{38}$$

or equivalently vis-à-vis Theorem 1,

$$\underset{\substack{\mathbf{W} \in \mathbf{\Psi}_{p,p-r} \\ \mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}}}{\text{minimize}} \langle \mathbf{W}, \mathbf{\Sigma} - \mathbf{\Phi} \rangle. \tag{39}$$

One possible approach is to consider *convex* lower bounds to (39).

Definition 3 *For a function $f : \Gamma \subseteq \mathbb{R}^n \to \mathbb{R}$ we define its convex envelope on Γ, denoted* $\text{convenv}_\Gamma(f)$*, to be the largest convex function g with $g \leq f$. In symbols,*

$$g = \sup\{h : \Gamma \to \mathbb{R} \mid h \text{ convex on } \Gamma \text{ and } h \leq f\}.$$

The convex envelope acts as the best possible convex lower bound for a given function. Further, its precise form is well-known for certain classes of functions; one such function of principle interest here is described in the following theorem. This is in some contexts referred to as a McCormick hull and is widely used throughout the nonconvex optimization literature (Floudas, 1999; Tawarmalani and Sahinidis, 2002a).

Theorem 4 (Al-Khayyal and Falk, 1983) *If $f : \Gamma = [0,1] \times [\ell, u] \to \mathbb{R}$ is defined by $f(x,y) = -xy$, then the convex envelope of f on Γ is precisely*

$$\text{convenv}_\Gamma(f)(x,y) = \max\{-ux, \ell - \ell x - y\}.$$

Further, $|f(x,y) - \text{convenv}_\Gamma(f)(x,y)| \leq (u - \ell)/4$. In particular, if $|u - \ell| \to 0$, then $\text{convenv}_\Gamma(f) \to f$.

11. The general case for $q > 1$ can be addressed using similar (although more complicated) techniques as applied to Problem (16), again applying principles developed in global optimization.

Using this result we proceed to describe our approach for computing lower bounds to (CFA_1) as in (39). First observe that if $\Phi_i \in [\ell_i, u_i]$ and $W_{ii} \in [0,1]$, then

$$\begin{aligned}\text{convenv}(-W_{ii}\Phi_i)(W_{ii}, \Phi_i) &= \max\{-u_i W_{ii}, \ell_i - \ell_i W_{ii} - \Phi_i\} \\ &= -\min\{u_i W_{ii}, \Phi_i + \ell_i W_{ii} - \ell_i\}.\end{aligned}$$

Hence, the best possible convex lower bound to the objective in Problem (39), namely $\langle \mathbf{W}, \mathbf{\Sigma} - \mathbf{\Phi}\rangle = \langle \mathbf{W}, \mathbf{\Sigma}\rangle - \sum_i W_{ii}\Phi_i$, for $\boldsymbol{\ell} \leq \text{diag}(\mathbf{\Phi}) \leq \mathbf{u}$ and $\mathbf{I} \succeq \mathbf{W} \succeq \mathbf{0}$ is

$$\langle \mathbf{W}, \mathbf{\Sigma}\rangle - \sum_{i=1}^{p} \min\{u_i W_{ii}, \Phi_i + \ell_i W_{ii} - \ell_i\}.$$

By introducing auxiliary variables $\mathbf{e} \in \mathbb{R}^p$ to represent these convex envelopes, we obtain the following linear SDO that is a lower bound to (39):

$$(\text{LS}_{\boldsymbol{\ell},\mathbf{u}}) \quad \begin{array}{lll} \underset{\mathbf{W},\mathbf{\Phi},\mathbf{e}}{\text{minimize}} & \langle \mathbf{W}, \mathbf{\Sigma}\rangle - \sum_{i=1}^{p} e_i & \\ \text{s. t.} & \mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}} & \\ & \mathbf{W} \in \mathbf{\Psi}_{p,p-r} & \\ & \left.\begin{array}{r} \ell_i \leq \Phi_i \leq u_i \\ e_i \leq \Phi_i + \ell_i W_{ii} - \ell_i \\ e_i \leq u_i W_{ii} \end{array}\right\} & \forall\, i \end{array}$$

The approach now lies in iteratively refining the lower and upper bounds on the diagonal entries of $\mathbf{\Phi}$, denoted $\boldsymbol{\ell}$ and $\mathbf{u}$, respectively, in order to improve the quality of the approximations obtained via convex envelopes (*cf.* Theorem 4). This classical scheme is known as *spatial branch and bound* and is shown in pseudocode in Algorithm 2 as it applies to solving (39) by way of using ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$).

In words, Algorithm 2 involves treating a given "node" $\mathtt{n} = [\boldsymbol{\ell}, \mathbf{u}]$, which represents bounds on $\mathbf{\Phi}$, namely, $\boldsymbol{\ell} \leq \text{diag}(\mathbf{\Phi}) \leq \mathbf{u}$. Here we solve ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) with the lower and upper bounds $\boldsymbol{\ell}$ and $\mathbf{u}$, respectively, and see whether the resulting new feasible solution is better (lower in objective value) than the best known incumbent solution encountered thus far. We then see if the the bound for this node as obtained via ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) is better than the currently known best feasible solution; if it is not at least the current best feasible solution's objective value (up to some numerical tolerance), then we must further branch on this node, generating two new nodes $\mathtt{n}_1$ and $\mathtt{n}_2$ which partition the existing node $\mathtt{n}$. Throughout, we keep track of the worst lower bound encountered, which allows for us to terminate the algorithm early while still having a provable suboptimality guarantee on the best feasible solution $\mathbf{\Phi}_f \in \mathcal{F}_{\mathbf{\Sigma}}$ found thus far.

In light of Theorem 4, we have as a corollary the following theorem.

Theorem 5 *Given numerical tolerance* $\mathtt{TOL} > 0$*, Algorithm 2 (with an appropriate branching rule)*[12] *terminates in finitely many iterations and solves* (CFA_1) *to within an additive optimality gap of at most* $\mathtt{TOL}$*. Further, if Algorithm 2 is terminated early (i.e., before* $\mathtt{Nodes} = \emptyset$*), then the best feasible solution* $\mathbf{\Phi}_f$ *at termination is guaranteed to be within an additive optimality gap of* $z_f - z_{\text{lb}}$*.*

12. A branching rule that is sufficient for convergence is selecting $i \in \arg\max_i (u_i^c - \ell_i^c)$ and $\alpha = (u_i^c + \ell_i^c)/2$.

The algorithm we have considered here omits some important details. After discussing properties of ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) in Section 4.2, we will discuss various aspects of Algorithm 2. In Section 4.3, we detail how to choose input $\mathbf{u}^0$. We then turn our attention to branching (line 5) in Section 4.4. In Section 4.5, we use results from matrix analysis coupled with ideas from the modern practice of discrete optimization to make tailored refinements to Algorithm 2. Finally, in Section 4.6 we include a discussion of node selection strategies.

Algorithm 2 Spatial branch and bound scheme to solve (39). The inputs are as follows: (a) upper bounds $\mathbf{u}^0$ such that for any i and any $\mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}$, we have $\Phi_i \leq u_i^0$ (see Section 4.3); (b) optimality tolerance $\mathtt{TOL}$; and (c) initial feasible solution $\mathbf{\Phi}_f \in \mathcal{F}_{\mathbf{\Sigma}}$.

1. Initialize $z_f \leftarrow \sum_{i>r} \sigma_i(\mathbf{\Sigma} - \mathbf{\Phi}_f)$; $\mathtt{Nodes} \leftarrow \{([\mathbf{0}, \mathbf{u}^0], -\infty)\}$; and $z_{\text{lb}} \leftarrow -\infty$.
2. While $\mathtt{Nodes} \neq \emptyset$, remove some node $([\boldsymbol{\ell}^c, \mathbf{u}^c], z^c) \in \mathtt{Nodes}$.
3. Solve ($\text{LS}_{\boldsymbol{\ell}^c,\mathbf{u}^c}$). Let $\mathbf{\Phi}$ be an optimal solution with z the optimal objective value; set $z_u \leftarrow \sum_{i>r} \sigma_i(\mathbf{\Sigma} - \mathbf{\Phi})$.
4. If $z_u < z_f$ (i.e., a better feasible solution is found), update the best feasible solution found thus far ($\mathbf{\Phi}_f$) to be $\mathbf{\Phi}$ and update the corresponding value (z_f) to z_u.
5. If $z < z_f - \mathtt{TOL}$ (i.e., a $\mathtt{TOL}$–optimal solution has not yet been found), then pick some $i \in \{1, \ldots, p\}$ and some $\alpha \in (\ell_i^c, u_i^c)$. Then add two new nodes to $\mathtt{Nodes}$:
$$\left(\prod_{j<i}[\ell_j^c, u_j^c] \times [\ell_i^c, \alpha] \times \prod_{j>i}[\ell_j^c, u_j^c], z\right) \quad \text{and} \quad \left(\prod_{j<i}[\ell_j^c, u_j^c] \times [\alpha, u_i^c] \times \prod_{j>i}[\ell_j^c, u_j^c], z\right).$$
6. Update the best lower bound $z_{\text{lb}} \leftarrow \min_{([\boldsymbol{\ell},\mathbf{u}],z)\in\mathtt{Nodes}} z$ and return to Step 2.

Global Optimization—State of the Art: We close this section by discussing similarities between the branch-and-bound approach we develop here and existing methods in nonconvex optimization. Our approach is very similar in spirit to approaches to global optimization (Floudas, 1999), and in particular for (nonconvex) quadratic optimization problems, quadratically-constrained convex optimization problems, and bilinear optimization problems (Hansen et al., 1993; Bao et al., 2009; Tawarmalani and Sahinidis, 2002b; Tawarmalani et al., 2013; Costa and Liberti, 2012; Anstreicher and Burer, 2010; Misener and Floudas, 2012). The primary similarity is that we work within a branch and bound framework using successively better convex lower bounds. However, while global optimization software for a variety of nonconvex problems with underlying vector variables is generally well-developed (as evidenced by solvers like `BARON`, see Sahinidis 2014), this is not the case for problems with underlying matrix variables and semidefinite constraints.

The presence of semidefinite structure presents several substantial computational challenges. First and foremost, algorithmic implementations for solving linear SDOs are not nearly as advanced as those which exist for linear optimization problems. Therefore, each

subproblem, which is itself a linear SDO, carries a larger computational cost than the usual corresponding linear program which typically arises in other global optimization problems with vector variables. Secondly, a critical component of the success of global optimization software is the ability to quickly resolve multiple instances of subproblems which have similar structure. Corresponding methods for SDOs, as solved via interior point methods, are generally not well-developed. Finally, semidefinite structure complicates the traditional process of computing convex envelopes. Such computations are critical to the success of modern global optimization solvers like `BARON`.

There are a variety of other possible approaches to computing lower bounds to (CFA_q). One such approach is the method of moments (Lasserre, 2009). However, for problems of the size we are considering, such an approach is likely not computationally feasible, so we do not make a direct comparison here. There is also recent work in complementarity constraints literature (Bai et al., 2016) which connects rank-constrained optimization problems to copositive optimization (Burer, 2012). In short, such an approach turns (38) into an equivalent convex problem; despite the transformation, the new problem is not particularly amenable to computation at this time. For this reason, we do not consider the copositive optimization approach.

4.2 Properties of ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$)

We now examine properties of ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$), the main subproblem of interest. Observe that it is a linear SDO problem, and therefore we can consider its dual, namely

$$
\begin{array}{lll}
 & \underset{q,\boldsymbol{f}_u,\boldsymbol{f}_\ell,\boldsymbol{\mu},\boldsymbol{\sigma},\mathbf{M},\mathbf{N},\mathbf{P}}{\text{maximize}} & (p-r)q - \mathbf{u}'\boldsymbol{f}_u - \text{Tr}(\mathbf{N}) - \langle \mathbf{P}, \boldsymbol{\Sigma} - \text{diag}(\boldsymbol{\ell})\rangle \\
 & \text{s.t.} & \boldsymbol{\mu} + \boldsymbol{\sigma} = \mathbf{1} \\
(\text{DS}_{\boldsymbol{\ell},\mathbf{u}}) & & \text{diag}(\mathbf{P}) + \boldsymbol{f}_u - \boldsymbol{f}_\ell - \boldsymbol{\mu} = \mathbf{0} \\
 & & \boldsymbol{\Sigma} - \text{diag}(\mathbf{u}) + \mathbf{M} + \mathbf{N} + \text{diag}(\text{diag}(\mathbf{u}-\boldsymbol{\ell})\boldsymbol{\mu}) - q\mathbf{I} = \mathbf{0} \\
 & & \boldsymbol{f}_u, \boldsymbol{f}_\ell, \boldsymbol{\mu}, \boldsymbol{\sigma} \geq \mathbf{0} \\
 & & \mathbf{M}, \mathbf{N}, \mathbf{P} \succcurlyeq \mathbf{0}.
\end{array}
$$

Observation 1 *We now include some remarks about structural properties of* ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) *and its dual* ($\text{DS}_{\boldsymbol{\ell},\mathbf{u}}$).

1. *If* $\text{rank}(\boldsymbol{\Sigma}) = p$ *then the Slater condition (Boyd and Vandenberghe, 2004) holds and hence there is strong duality, so we can work with* ($\text{DS}_{\boldsymbol{\ell},\mathbf{u}}$) *instead of* ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) *as an exact reformulation.*

2. *There exists an optimal solution to the dual with* $\boldsymbol{f}_u = \mathbf{0}$. *This is a variable reduction which is not immediately obvious. Note that* $\boldsymbol{f}_u$ *appears as the multiplier for the constraints in the primal of the form* $\text{diag}(\boldsymbol{\Phi}) \leq \mathbf{u}$. *To claim that we can set* $\boldsymbol{f}_u = \mathbf{0}$ *it suffices to show that the corresponding constraints in the primal can be ignored. Namely, if* $(\mathbf{W}^*, \boldsymbol{\Phi}^*)$ *solves* ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) *with the constraints* $\Phi_i \leq u_i \; \forall i$ *omitted, then the pair* $(\mathbf{W}^*, \widetilde{\boldsymbol{\Phi}})$ *is feasible and optimal to* ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) *with all the constraints included, where* $\widetilde{\boldsymbol{\Phi}}$ *is defined by*

$$\widetilde{\Phi}_i = \min\{\Phi_i^*, u_i\}.$$

Hereinafter we set $\boldsymbol{f}_u = \mathbf{0}$ *and omit the constraint* $\text{diag}(\boldsymbol{\Phi}) \leq \mathbf{u}$ *(with the caveat that, upon solving a problem and identifying some* $\boldsymbol{\Phi}^*$, *we must instead work with* $\min\{\boldsymbol{\Phi}^*, \text{diag}(\mathbf{u})\}$, *taken entrywise).*

Solving Subproblems: We briefly detail how to solve ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$). In light of the discussion in Section 3.2, we choose to apply a first-order method. Observe that we cannot solve the primal form ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) within the branch-and-bound framework unless we solve it to optimality. Therefore, we instead choose to work with its dual ($\text{DS}_{\boldsymbol{\ell},\mathbf{u}}$). We apply an off-the-shelf solver `SCS` (O'Donoghue et al., 2016) to solve ($\text{DS}_{\boldsymbol{\ell},\mathbf{u}}$) and find reasonably accurate, *feasible* solutions for this dual problem, which guarantees that we have a lower bound to ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$).[13] In this way, we maintain the provable optimality properties of Algorithm 2 without needing to solve nodes in the branch-and-bound tree to full optimality.

4.3 Input Parameters

In solving the root node of Algorithm 2, we must begin with some choice of $\mathbf{u}^0 = \mathbf{u}$. An obvious first choice for u_i is $u_i = \Sigma_{ii}$, but one can do better. Let us optimally set u_i, defining it as

$$
u_i := \begin{array}{ll} \underset{x \in \mathbb{R}}{\text{maximize}} & x \\ \text{s.t.} & \boldsymbol{\Sigma} - x\mathbf{E}^{(i)} \succcurlyeq \mathbf{0}, \end{array} \tag{40}
$$

where $\mathbf{E}^{(i)} \in \mathbb{R}^{p \times p}$ is a matrix with all zeros except $\mathbf{E}^{(i)}_{ii} = 1$. These bounds are useful because if $\boldsymbol{\Phi} \in \mathcal{F}_{\boldsymbol{\Sigma}}$, then $\Phi_i \leq u_i$. Note that problem (40) is a linear SDO for which strong duality holds. Its dual is precisely

$$
u_i = \begin{array}{ll} \underset{\mathbf{M} \in \mathbb{R}^{p \times p}}{\text{minimize}} & \langle \mathbf{M}, \boldsymbol{\Sigma} \rangle \\ \text{s.t.} & M_{ii} = 1 \\ & \mathbf{M} \succcurlyeq \mathbf{0}, \end{array} \tag{41}
$$

a linear SDO in standard form with a single equality constraint. By a result of (Barvinok, 1995; Pataki, 1998), there exists a rank one solution to (41). This implies that (41) can actually be solved as a convex quadratic program:

$$
u_i = \begin{array}{ll} \underset{\mathbf{m} \in \mathbb{R}^p}{\text{minimize}} & \mathbf{m}'\boldsymbol{\Sigma}\mathbf{m} \\ \text{s.t.} & m_i^2 = 1. \end{array} = \begin{array}{ll} \underset{\mathbf{m}}{\text{minimize}} & \mathbf{m}'\boldsymbol{\Sigma}\mathbf{m} \\ \text{s.t.} & m_i = 1. \end{array} \tag{42}
$$

This formulation given in (42) is computationally inexpensive to solve (given a large number of specialized convex quadratic problem solvers), in contrast to both formulations (40) and (41).[14]

13. One notable feature of the ADMM-based approach is that we can extract an approximately feasible primal solution $\boldsymbol{\Phi}$, which is useful for branching. Note that in Algorithm 2, we can replace the best incumbent solution if we find a new $\boldsymbol{\Phi}$ which has better objective value $\sum_{i>r} \sigma_i(\boldsymbol{\Sigma} - \boldsymbol{\Phi})$. Because $\boldsymbol{\Phi}$ may not be feasible (i.e., $\boldsymbol{\Phi} \notin \mathcal{F}_{\boldsymbol{\Sigma}}$), we take care here. Namely, compute $t = \sum_{i>r} \lambda_i(\boldsymbol{\Sigma} - \boldsymbol{\Phi})$, where $\lambda_1(\boldsymbol{\Sigma} - \boldsymbol{\Phi}) \geq \cdots \geq \lambda_p(\boldsymbol{\Sigma} - \boldsymbol{\Phi})$ are the sorted eigenvalues of $\boldsymbol{\Sigma} - \boldsymbol{\Phi}$. If $t < z_f$, then we perform an iteration of CG scheme for finding feasible solutions (outlined in Section 3) to find a feasible $\bar{\boldsymbol{\Phi}} \in \mathcal{F}_{\boldsymbol{\Sigma}}$. We then use this as a possible candidate for replacing the incumbent.

14. In the case when $\boldsymbol{\Sigma} \succ \mathbf{0}$, it is not necessary to use quadratic optimization problems to compute $\mathbf{u}$. In this case once can apply a straightforward Schur complement argument (Boyd and Vandenberghe, 2004) to show that $\mathbf{u}$ can be computed by solving for inverse of p different $(p-1) \times (p-1)$ matrices (or equivalently, by finding the diagonal of the precision matrix $\boldsymbol{\Sigma}^{-1}$).

4.4 Branching

Here we detail two methods for branching (line 5 in Algorithm 2). The problem of branching is as follows: having solved ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$) for some particular $\mathtt{n} = [\boldsymbol{\ell}, \mathbf{u}]$, we must choose some $i \in \{1, \ldots, p\}$ and split the interval $[\ell_i, u_i]$ to create two new subproblems. We begin with a simple branching rule. Given a solution $(\mathbf{W}^*, \boldsymbol{\Phi}^*, \mathbf{e}^*)$ to ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$), compute $i \in \text{argmax}_i |e_i^* - W_{ii}^* \Phi_i^*|$ and branch on variable Φ_i, generating two new subproblems with the intervals

$$\prod_{j<i}[\ell_j, u_j] \times [\ell_i, \Phi_i^*] \times \prod_{j>i}[\ell_j, u_j] \quad \text{and} \quad \prod_{j<i}[\ell_j, u_j] \times [\Phi_i^*, u_i] \times \prod_{j>i}[\ell_j, u_j].$$

Observe that, so long as $\max_i |e_i^* - W_{ii}^* \Phi_i^*| > 0$, the solution $(\mathbf{W}^*, \boldsymbol{\Phi}^*, \mathbf{e}^*)$ is not optimal for either of the subproblems created.

We now briefly describe an alternative rule which we employ instead. We again pick the branching index i as before, but now the two new nodes we generate are

$$\prod_{j<i}[\ell_j, u_j] \times [\ell_i, (1-\epsilon)\Phi_i^* + \epsilon \ell_i] \times \prod_{j>i}[\ell_j, u_j] \quad \text{and} \quad \prod_{j<i}[\ell_j, u_j] \times [(1-\epsilon)\Phi_i^* + \epsilon \ell_i, u_i] \times \prod_{j>i}[\ell_j, u_j],$$

where $\epsilon \in [0, 1)$ is some parameter. For the computational experiments, we set $\epsilon = 0.4$.

Such an approach, which lowers the location of the branch in the ith interval $[\ell_i, u_i]$ from Φ_i^*, serves to improve the objective value from the first node, while hurting the objective value from the second node (here by objective value, we mean the objective value of the optimal solution to the two new subproblems). In this way, it spreads out the distance between the two, and so it is more likely that the first node may have an objective value that is higher than $z_f - \mathtt{TOL}$ than before, and hence, this would mean there are fewer nodes necessary to consider to solve for an additive gap of $\mathtt{TOL}$. While this heuristic explanation is only partially satisfying, we have observed throughout a variety of numerical experiments that this rule, even though simple, performs better across a variety of example classes than the basic branching rule outlined. At the same time, recent work on the theory of branching rules supports such a heuristic rule (le Bodic and Nemhauser, 2015). In Section 5.4, we give evidence on the impact of the use of the modified branching rule.

4.5 Weyl's Method—Pruning and Bound Tightening

In this subsection, we develop another method for lower bounds for the factor analysis problem. While we use it to supplement our approach detailed throughout Section 4, it is of interest as a standalone method, particularly for its computational speed and simplicity. In Section 5.3, we discuss the performance of this approach in both contexts.

The central problem of interest in factor analysis involves the spectrum of a symmetric matrix ($\boldsymbol{\Sigma} - \boldsymbol{\Phi}$) which is the difference of two other symmetric matrices ($\boldsymbol{\Sigma}$ and $\boldsymbol{\Phi}$). From a linear algebraic perspective, the spectrum of the sum of real symmetric matrices is an extensively studied problem (Horn and Johnson, 2013; Bhatia, 2007).Therefore, it is natural to inquire how such results carry over to our setting. We discuss the implications of a well-known result from this literature, namely *Weyl's inequality* (see, e.g., Bhatia 2007):

Theorem 6 (Weyl's Inequality) *For symmetric matrices $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{p \times p}$ with sorted eigenvalues*

$$\lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{A}) \geq \cdots \geq \lambda_p(\mathbf{A}) \quad \text{and} \quad \lambda_1(\mathbf{B}) \geq \lambda_2(\mathbf{B}) \geq \cdots \geq \lambda_p(\mathbf{B})$$

one has for any $k \in \{1, \ldots, p\}$ that

$$\lambda_k(\mathbf{A} + \mathbf{B}) \geq \lambda_{k+j}(\mathbf{A}) + \lambda_{p-j}(\mathbf{B}) \; \forall j = 0, \ldots, p-k.$$

For any vector $\mathbf{x} \in \mathbb{R}^p$ we let $\{x_{(i)}\}_{i=1}^p$ denote sorted $\{x_i\}_{i=1}^p$ with $x_{(1)} \geq x_{(2)} \geq \cdots \geq x_{(p)}$. Using this notation, we arrive at the following theorem.

Theorem 7 *For any diagonal matrix $\bar{\boldsymbol{\Phi}}$ one has that*

$$\underset{\boldsymbol{\Phi} \in \mathcal{F}_{\boldsymbol{\Sigma}}}{\text{minimize}} \sum_{i>r} \sigma_i(\boldsymbol{\Sigma} - \boldsymbol{\Phi}) \geq \underset{\boldsymbol{\Phi} \in \mathcal{F}_{\boldsymbol{\Sigma}}}{\text{minimize}} \left(\sum_{i>r} \max_{j=0,\ldots,p-i} \left\{ \lambda_{i+j}(\boldsymbol{\Sigma} - \bar{\boldsymbol{\Phi}}) + \text{diag}\left(\bar{\boldsymbol{\Phi}} - \boldsymbol{\Phi}\right)_{(p-j)}, 0 \right\} \right).$$

Proof Apply Weyl's inequality with $\mathbf{A} = \boldsymbol{\Sigma} - \text{diag}(\bar{\boldsymbol{\Phi}})$ and $\mathbf{B} = \bar{\boldsymbol{\Phi}} - \boldsymbol{\Phi}$, and use the fact that $\boldsymbol{\Phi} \in \mathcal{F}_{\boldsymbol{\Sigma}}$ so $\boldsymbol{\Sigma} - \boldsymbol{\Phi} \succcurlyeq \mathbf{0}$. ■

Weyl's Method: The new lower bound introduced in Theorem 7 is a nonconvex problem in general. We begin by discussing one situation in which Theorem 7 provides computationally tractable (and fast) lower bounds; we deem this *Weyl's method*, detailed as follows:

1. Compute bounds u_i as in (40), so that for all $\boldsymbol{\Phi} \in \mathcal{F}_{\boldsymbol{\Sigma}}$, one has $\Phi_i \leq u_i \; \forall i$.
2. For each $r \in \{1, \ldots, p\}$, one can compute a lower bound to (CFA_1) (for a given r) of

$$\sum_{i>r} \max\{\lambda_i(\boldsymbol{\Sigma} - \text{diag}(\mathbf{u})), 0\},$$

by taking Theorem 7 with $\bar{\boldsymbol{\Phi}} = \text{diag}(\mathbf{u})$.

As per the above remarks, computing $\mathbf{u}$ in Step 1 of Weyl's method can be carried out efficiently. Step 2 only relies on computing the eigenvalues of $\boldsymbol{\Sigma} - \text{diag}(\mathbf{u})$. Therefore, this lower bounding procedure is quite simple to carry out. What is perhaps surprising is that this simple lower bounding procedure is effective as a standalone method. We describe such results in Section 5.3. We now turn our attention to how Weyl's method can be utilized within the branch and bound tree as described in Algorithm 2.

Pruning: We begin by considering how Weyl's method can be used for *pruning*. The notion of pruning for branch and bound trees is grounded in the theory and practice of discrete optimization. In short, pruning in the elimination of nodes from the tree without actually solving them. We make this precise in our context.

Consider some point in the branch and bound process in Algorithm 2, where we have some collection of nodes, $([\boldsymbol{\ell}^c, \mathbf{u}^c], z^c) \in \mathtt{Nodes}$. Recall that z^c is the optimal objective

value of the parent node of $\mathtt{n}$. Vis-à-vis Weyl's method, we know *a priori*, without solving $(\mathrm{LS}_{\boldsymbol{\ell}^c,\mathbf{u}^c})$, that

$$\underset{\substack{\boldsymbol{\Phi}\in\mathcal{F}_{\boldsymbol{\Sigma}}\\ \boldsymbol{\ell}^c\leq\mathrm{diag}(\boldsymbol{\Phi})\leq\mathbf{u}^c}}{\text{minimize}} \sum_{i>r}\sigma_i(\boldsymbol{\Sigma}-\boldsymbol{\Phi}) \geq \sum_{i>r}\max\{\lambda_i(\boldsymbol{\Sigma}-\mathrm{diag}(\mathbf{u}^c)),0\}.$$

Hence, if $z_f - \mathtt{TOL} < \sum_{i>r}\max\{\lambda_i(\boldsymbol{\Sigma}-\mathrm{diag}(\mathbf{u}^c)),0\}$, where z_f is as in Algorithm 2, then node $\mathtt{n}$ can be discarded, i.e., there is no need to actually compute $(\mathrm{LS}_{\boldsymbol{\ell}^c,\mathbf{u}^c})$ or further consider this branch. This is because if we were to solve $(\mathrm{LS}_{\boldsymbol{\ell}^c,\mathbf{u}^c})$, and then branch again, solving further down this branch to optimality, then the final lower bound obtained would necessarily be at least as large as the best feasible objective already found (within tolerance $\mathtt{TOL}$).

In this way, because Weyl's method is relatively fast, this provides a simple method for pruning. In the computational results detailed in Section 5.3, we always use Weyl's method to discard nodes which are not fruitful to consider.

Bound Tightening: We now turn our attention to another way in which Weyl's method can be used to improve the performance of Algorithm 2—*bound tightening*. In short, bound tightening is the use of implicit constraints to strengthen bounds obtained for a given node. We detail this with the same node notation as above. Namely, consider a given node $\mathtt{n} = [\boldsymbol{\ell}^c, \mathbf{u}^c]$. Fix some $j \in \{1,\ldots,p\}$ and let $\alpha \in (\ell_j^c, u_j^c)$. If we have that

$$z_f - \mathtt{TOL} < \sum_{i>r}\max\{\lambda_i(\boldsymbol{\Sigma}-\mathrm{diag}(\tilde{\mathbf{u}})),0\},$$

where $\tilde{\mathbf{u}}$ is $\mathbf{u}^c$ with the jth entry replaced by α, then we can replace the node $\mathtt{n}$ with the "tightened" node $\tilde{\mathtt{n}} = [\tilde{\boldsymbol{\ell}}, \mathbf{u}^c]$, where $\tilde{\boldsymbol{\ell}}$ is $\boldsymbol{\ell}^c$ with the jth entry replaced by α.

We consider why this is valid. Suppose that one were to solve $(\mathrm{LS}_{\boldsymbol{\ell}^c,\mathbf{u}^c})$ and choose to branch on index j at α. Then one would create two new nodes: $[\boldsymbol{\ell}^c, \tilde{\mathbf{u}}]$ and $[\tilde{\boldsymbol{\ell}}, \mathbf{u}^c]$. We would necessarily then prune away the node $[\boldsymbol{\ell}^c, \tilde{\mathbf{u}}]$ as just described; hence, we can replace $[\boldsymbol{\ell}^c, \mathbf{u}^c]$ without loss of generality with $[\tilde{\boldsymbol{\ell}}, \mathbf{u}^c]$. Note that here $\alpha \in (\ell_j^c, u_j^c)$ and $j \in \{1,\ldots,p\}$ were arbitrary. Hence, for each j, one can choose the largest such $\alpha_j \in (\ell_j^c, u_j^c)$ (if one exists) so that $z_f - \mathtt{TOL} < \sum_{i>k}\max\{\lambda_i(\boldsymbol{\Sigma}-\mathrm{diag}(\tilde{\mathbf{u}})),0\}$, and then replace $\boldsymbol{\ell}^c$ by $\tilde{\boldsymbol{\ell}}$.[15]

Such a procedure is somewhat expensive (because of its use of repeated eigenvalue calculations), but can be thought of as "optimal" pruning via Weyl's method. In our experience the benefit of bound tightening does not warrant its computational cost when used at every node in the branch-and-bound tree except in a small number of problems. For this reason, in the computational results in Section 5.3 we only employ bound tightening at the root node $\mathtt{n} = [\mathbf{0}, \mathbf{u}^0]$.

4.6 Node Selection

In this section, we briefly describe our method of node selection. The problem of node selection has been considered extensively in discrete optimization and is still an active area of research. Here we describe a simple node selection strategy.

15. An obvious choice to find such an α is a grid-search-based bisection method. For simplicity we use a linear search on a grid instead of resorting to the bisection method.

To be precise, consider some point in Algorithm 2 were we have a certain collection of nodes, $([\boldsymbol{\ell}^c, \mathbf{u}^c], z^c) \in \mathtt{Nodes}$. The most obvious node selection strategy is to pick the node $\mathtt{n}$ for which z^c is smallest among all nodes in $\mathtt{Nodes}$. In this way, the algorithm is likely to improve the gap $z_f - z_{\mathrm{lb}}$ at every iteration. Such greedy selection strategies tend to not perform particularly well in general global optimization problems (see, e.g., Tawarmalani and Sahinidis, 2002a).

For these reasons, we employ a slightly modified greedy selection strategy which utilizes Weyl's method. For a given node $\mathtt{n}$, we also consider its corresponding lower bound w^c obtained from Weyl's method, namely, $w^c := \sum_{i>r}\max\{\lambda_i(\boldsymbol{\Sigma}-\mathrm{diag}(\mathbf{u}^c)),0\}$. For each node, we now consider $\max\{z^c, w^c\}$. There are two cases to consider:

1. With probability β, we select the node with smallest value of $\max\{z^c, w^c\}$.

2. In the remaining scenarios (occurring with probability $1-\beta$), we choose randomly between selecting the node with smallest value of z^c and the node with smallest value of w^c. To be precise, let Z be the minimum of z^c over all nodes and likewise let W be the minimum of w^c over all nodes. Then with (independent) probability β, we choose the node with worst z^c *or* w^c (i.e., with $\min\{z^c, w^c\} = \min\{Z, W\}$); with probability $1-\beta$, if $Z < W$ we choose a node with $w^c = W$, and if $Z > W$ we choose a node with $z^c = Z$.

In this way, we allow for the algorithm to switch between trying to make progress towards improving the convex envelope bounds and making progress towards improving the best of the two bounds (the convex envelope bounds along with the Weyl bounds). We set $\beta = 0.9$ for all computational experiments. It is possible that a more dynamic branching strategy could perform substantially better; however, the method here has a desirable level of simplicity.

We close by noting that while this node selection strategy appears naïve, it is not necessarily so simple. Improved node selection strategies from discrete optimization often take into account some sort of duality theory. Weyl's inequality is at its core a result from duality theory (principally Wielandt's minimax principle; see Bhatia, 2007), and therefore our strategy is not as unsophisticated as it might appear on first inspection.

5. Computational experiments

In this section, we perform various computational experiments to study the properties of our different algorithmic proposals for (CFA_q), for $q \in \{1,2\}$. Using a variety of statistical measures, we compare our methods with existing popular approaches for FA, as implemented in standard `R` statistical packages `psych` (Revelle, 2015), `nFactors` (Raiche and Magis, 2011), and `GPArotation` (Bernaards and Jennrich, 2005). We then turn our attention to certificates of optimality as described in Section 4 for (CFA_1).

5.1 Synthetic examples

For our synthetic experiments, we considered distinctly different groups of examples. Classes A_1 and A_2 have subspaces of the low-rank common factors which are random and the values

of Φ_i are taken to be equally spaced. The underlying matrix corresponding to the common factors in type A_1 is exactly low-rank, while this is not the case in type A_2.

Class $A_1(R/p)$. We generated a matrix $\mathbf{L}_{p\times R} := ((L_{ij}))$ (with $R < p$) with $L_{ij} \overset{\text{iid}}{\sim} N(0,1)$. The *unique variances* $\Phi_1, \ldots, \Phi_p$, are taken to be proportional to p equi-spaced values on the interval $[\lambda_R(\mathbf{L}'\mathbf{L}), \lambda_1(\mathbf{L}'\mathbf{L})]$ such that $\Phi_i = \bar{\phi} \cdot \left(\lambda_1(\mathbf{L}'\mathbf{L}) + (\lambda_R(\mathbf{L}'\mathbf{L}) - \lambda_1(\mathbf{L}'\mathbf{L}))\frac{i-1}{p}\right)$, for $1 \le i \le p$. Here $\bar{\phi}$, which controls the ratio of the variances between the *uniquenesses* and the common latent factors is chosen such that $\sum_{i=1}^{p} \Phi_i = \mathrm{Tr}(\mathbf{L}\mathbf{L}')$, i.e., the contribution to the total variance from the common factors matches that from the uniqueness factors. The covariance matrix is thus given by: $\mathbf{\Sigma} = \mathbf{L}\mathbf{L}' + \mathbf{\Phi}$.

Class $A_2(p)$. Here $\mathbf{L}_{p\times p}$ is generated as $L_{ij} \overset{\text{iid}}{\sim} N(0,1)$. We did a full singular value decomposition on $\mathbf{L}$—let $\mathbf{U}_L$ denote the set of p (left) singular vectors. We created a positive definite matrix with exponentially decaying eigenvalues as follows: $\widetilde{\mathbf{L}}\widetilde{\mathbf{L}}' = \mathbf{U}_L\,\mathrm{diag}(\lambda_1, \ldots, \lambda_p)\mathbf{U}_L'$, where the eigenvalues were chosen as $\lambda_i = 0.8^{i/2}, i = 1, \ldots, p$. We chose the diagonal entries of $\mathbf{\Phi}$ (like data Type-A_1), as a scalar multiple ($\bar{\phi}$) of a uniformly spaced grid in $[\lambda_p, \lambda_1]$ and $\bar{\phi}$ was chosen such that $\sum_i \Phi_i = \mathrm{Tr}(\widetilde{\mathbf{L}}\widetilde{\mathbf{L}}')$.

In contrast, classes B_1, B_2, and B_3 are qualitatively different from the aforementioned ones—the subspaces corresponding to the common factors are more structured, and hence different from the coherence-like assumptions on the eigenvectors which are necessary for nuclear norm based methods (Saunderson et al., 2012) to work well.

Class $B_1(R/p)$. We set $\mathbf{\Theta} = \mathbf{L}\mathbf{L}'$, where $\mathbf{L}_{p\times R}$ is given by

$$L_{ij} = \begin{cases} 1, & i \le j \\ 0, & i > j. \end{cases}$$

Class $B_2(r/R/p)$. Here we set $\mathbf{\Theta} = \mathbf{L}\mathbf{L}'$, where $\mathbf{L}_{p\times R}$ is such that

$$L_{ij} = \begin{cases} 1, & i,j = 1, \ldots, r \\ \overset{\text{iid}}{\sim} N(0,1), & i > r, j = 1, \ldots, R \\ 0, & i = 1, \ldots, r,\ j > r. \end{cases}$$

Class $B_3(r/R/p)$. Here we define $\mathbf{\Theta} = \mathbf{L}\mathbf{L}'$, where $\mathbf{L}_{p\times R}$ is such that

$$L_{ij} = \begin{cases} 1, & j = 1, \ldots, r,\ i \le j \\ \overset{\text{iid}}{\sim} N(0,1), & j > r,\ i = 1, \ldots, R \\ 0, & i > j,\ j = 1, \ldots, r. \end{cases}$$

In all the B classes, we generated $\Phi_i \overset{\text{iid}}{\sim} \mathrm{abs}(N(0,1))$ and the covariance matrix $\mathbf{\Sigma}$ was taken to be $\mathbf{\Sigma} = \mathbf{\Theta} + \alpha\mathbf{\Phi}$, where α is so that $\mathrm{Tr}(\mathbf{\Theta}) = \alpha\,\mathrm{Tr}(\mathbf{\Phi})$.

Comparisons with other FA methods

We performed a suite of experiments using Algorithm 1 for the cases $q \in \{1, 2\}$. We compared our proposed algorithm with the following popular FA estimation procedures as described in Section 1.1:

1. MINRES: minimum residual factor analysis
2. WLS: weighted least squares method with weights being the *uniquenesses*
3. PA: this is the principal axis factor analysis method
4. MTFA: constrained minimum trace factor analysis—formulation (6)
5. PC: The method of principal component factor analysis
6. MLE: this is the maximum likelihood estimator (MLE)
7. GLS: the generalized least squares method

For MINRES, WLS, GLS, and PA, we used the implementations available in the `R` package `psych` (Revelle, 2015) available from `CRAN`. For MLE we investigated the methods `factanal` from `R` package `stats` and the `fa` function from `R` package `psych`. The estimates obtained by the different MLE implementations were similar in our experiments; therefore, we report the results obtained from `factanal`.

For MTFA, we used our own implementation by adapting the ADMM algorithm (Section 3.2.2) to solve Problem (6). For the experiments in Section 5.1, we took the convergence thresholds for Algorithm 1 as $\mathrm{TOL} = 10^{-5}$ and ADMM as $\mathrm{TOL} \times \alpha = 10^{-9}$. For the PC method we followed the description in Bai and Ng (2008) (as described in Section 1.1)—the $\mathbf{\Phi}$ estimates were thresholded at zero if they became negative.

Note that all the methods considered in the experiments, apart from MTFA, allow the user to specify the desired number of factors in the problem. Since standard implementations of MINRES, WLS and PA require $\mathbf{\Sigma}$ to be a correlation matrix, we standardized all covariance matrices to correlation matrices at the outset.

5.1.1 Performance measures

We consider the following measures of "goodness of fit" (see Bartholomew et al. 2011 and references therein) to assess the performances of the different FA estimation procedures.

Estimation error in $\mathbf{\Phi}$: We use the following measure to assess the quality of an estimator for $\mathbf{\Phi}$:

$$\mathrm{Error}(\mathbf{\Phi}) := \sum_{i=1}^{p} (\widehat{\Phi}_i - \Phi_i)^2. \tag{43}$$

The estimation of $\mathbf{\Phi}$ plays an important role in FA—given a good estimate $\widehat{\mathbf{\Phi}}$, the r-common factors can be obtained by a rank-r eigendecomposition on the residual covariance matrix $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$.

Proportion of variance explained and semi-definiteness of $(\mathbf{\Sigma} - \mathbf{\Phi})$: A fundamental objective in FA lies in understanding how well the r-common factors explain the residual covariance, i.e., $(\mathbf{\Sigma} - \widehat{\mathbf{\Phi}})$—a direct analogue of what is done in PCA, as explained in Section 1. For a given r, the proportion of variance explained by the r common factors is given by

$$\text{Explained Variance} = \sum_{i=1}^{r} \lambda_i(\widehat{\mathbf{\Theta}}) / \sum_{i=1}^{p} \lambda_i(\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}). \tag{44}$$

As r increases, the explained variance increases to one. This trade-off between r and "Explained Variance" plays an important role in exploratory FA and in particular the choice

of r. For the expression (44) to be meaningful, it is desirable to have $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}} \succeq \mathbf{0}$. Note that our framework (CFA$_q$), and in particular MTFA, estimates $\mathbf{\Phi}$ under a PSD constraint on $\mathbf{\Sigma} - \mathbf{\Phi}$. However, as seen in our experiments $(\widehat{\mathbf{\Phi}}, \widehat{\mathbf{\Theta}})$ estimated by the remaining methods MINRES, PA, WLS, GLS, MLE and others often violate the PSD condition on $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$ for some choices of r, thereby rendering the interpretation of "Explained Variance" troublesome.

For the MTFA method with estimator $\widehat{\mathbf{\Theta}}$, the measure (44) applies only for the value of $r = \text{rank}(\widehat{\mathbf{\Theta}})$ and the explained variance is one.

For the methods we have included in our comparisons, we report the values of "Explained Variance" as delivered by the R-package implementations.

Proximity between $\widehat{\mathbf{\Theta}}$ and $\mathbf{\Theta}$: A relevant measure of the proximity between $\mathbf{\Theta}$ and its estimate $(\widehat{\mathbf{\Theta}})$ is given by

$$\text{Error}(\mathbf{\Theta}) := \|\widehat{\mathbf{\Theta}} - \mathbf{\Theta}_r\|_2^2 / \|\mathbf{\Theta}_r\|_2^2, \tag{45}$$

where $\mathbf{\Theta}_r$ is the best rank-r approximation to $\mathbf{\Theta}$ and can be viewed as the natural "oracle" counterpart of $\widehat{\mathbf{\Theta}}$. Note that MTFA does not incorporate any constraint on rank$(\widehat{\mathbf{\Theta}})$ in its formulation. Since the estimates obtained by this procedure satisfy $\widehat{\mathbf{\Theta}} = \mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$, rank$(\widehat{\mathbf{\Theta}})$ may be quite different from r.

Discussion of experimental results. We next discuss our findings from the numerical experiments for the synthetic datasets.

Table 1 shows the performances of the various methods for different choices of p and R for class A_1. For the problems (CFA$_q$), $q \in \{1, 2\}$, we present the results of Algorithm 1. (Results obtained by the approach in Appendix B were similar.) In all the examples, with the exception of MTFA, we set the number of factors to be $r = (R-1)$, one less than the rank of the covariance matrix for the common underlying factors; in other words, the "remaining" rank one component can be considered as noise. For MTFA, the rank of $\widehat{\mathbf{\Theta}}$ was computed as the number of eigenvalues of $\widehat{\mathbf{\Theta}}$ larger than 10^{-5}. MTFA and (CFA$_q$), $q \in \{1, 2\}$, estimate $\mathbf{\Phi}$ with zero error—significantly better than competing methods. While MTFA and (CFA$_q$), $q \in \{1, 2\}$, result in estimates such that $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$ is PSD, other methods, however, fail to do so; indeed, the discrepancy can often be quite large. MTFA performs poorly in terms of estimating $\mathbf{\Theta}$ since the estimated $\mathbf{\Theta}$ has rank different than r. In terms of the proportion of variance explained (CFA$_q$) performs significantly better than all other methods. The notion of "Explained Variance" by MTFA for $r = (R-1)$ is not applicable since the rank of the estimated $\mathbf{\Theta}$ is larger than r.

Figure 1 displays results for type A_2. Here we present the results for (CFA$_q$), $q \in \{1, 2\}$, using Algorithm 1. For all the methods (with the exception of MTFA) we computed estimates of $\mathbf{\Theta}$ and $\mathbf{\Phi}$ for a range of values of r. MTFA and (CFA$_1$) do a perfect job in estimating $\mathbf{\Phi}$ and both deliver PSD matrices $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$. MTFA computes solutions $(\widehat{\mathbf{\Theta}})$ with a higher numerical rank and with large errors in estimating $\mathbf{\Theta}$ (for smaller values of r). Among the four performance measures corresponding to MTFA, Error$(\mathbf{\Theta})$ is the only one that varies with different r values. Each of the other three measures deliver a single value corresponding to $r = \text{rank}(\widehat{\mathbf{\Theta}})$. Overall, it appears that (CFA$_q$) is significantly better than all other methods.

Figure 2 shows the results for classes B_1, B_2, and B_3. We present the results for (CFA$_q$) for $q \in \{1, 2\}$ using Algorithm 1 as before. Figure 2 shows the performance of the different

Table 1: Comparative performances of the various FA methods for data of type A_1, for different choices of R and p. In all the above methods (apart from MTFA) r was taken to be $(R-1)$. In all the cases rank$(\widehat{\mathbf{\Theta}})$ obtained by MTFA is seen to be R. The "-" symbol implies that the notion of explained variance is not meaningful for MTFA for $r = R-1$. No method in Category (B) satisfies $\mathbf{\Sigma} - \mathbf{\Phi} \succeq \mathbf{0}$. Methods proposed in this paper seem to significantly outperform their competitors, across the different performance measures.

methods in terms of four different metrics: error in $\mathbf{\Phi}$ estimation, proportion of variance explained, violation of the PSD constraint on $\mathbf{\Sigma} - \mathbf{\Phi}$, and error in $\mathbf{\Theta}$ estimation. For the case of B_1, we see that the proportion of explained variance for (CFA$_q$) reaches one at a rank smaller than that of MTFA—this shows that the nonconvex criterion (CFA$_q$) provides smaller estimates of the rank than its convex relaxation MTFA when one seeks a model that explains the full proportion of residual variance. This result is qualitatively different from the behavior seen for A_1 and A_2 where the benefit of (CFA$_q$) over MTFA was mainly due to its flexibility to control the rank of $\mathbf{\Theta}$. Algorithms in Category (A) do an excellent job in estimating $\mathbf{\Phi}$. All other competing methods perform poorly in estimating $\mathbf{\Phi}$ for small/moderate values of r. We observe that none of the methods apart from (CFA$_q$) and MTFA lead to PSD estimates of $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$ (unless r becomes sufficiently large which corresponds to a model with a saturated fit). In terms of the proportion of variance explained, our proposal performs much better than the competing methods. We see that the error in $\mathbf{\Theta}$ estimation incurred by (CFA$_q$), increases marginally as soon as the rank r becomes larger than a certain value for B_1. Note that around the same values of r, the proportion of explained variance reaches one in both these cases, thereby suggesting that this is possibly not a region of statistical interest. In summary, Figure 2 suggests that (CFA$_q$) performs very well compared to all its competitors.

Summary: All methods of Category (B) (see Section 1.2) used in the experimental comparisons perform worse than Category (A) in terms of measures Error($\mathbf{\Phi}$), Error($\mathbf{\Theta}$) and Explained Variance for small/moderate values of r. They also lead to indefinite estimates of $\mathbf{\Sigma} - \widehat{\mathbf{\Phi}}$. MTFA performs well in estimating $\mathbf{\Phi}$ but fails in estimating $\mathbf{\Theta}$ mainly due to the lack in flexibility of imposing a rank constraint; in some cases the trace heuristic falls short of doing a good job in approximating the rank function when compared to its nonconvex counterpart (CFA$_q$). The estimation methods proposed herein have a significant edge over existing methods in producing high quality solutions across various performance metrics.

5.2 Real data examples

This section describes the performance of different FA methods on some real-world benchmark datasets popularly used in the context of FA. These datasets can be found in the `R` libraries `datasets` (R Core Team, 2014), `psych` (Revelle, 2015), and `FactoMineR` (Husson et al., 2015) and are as follows:

- The bfi data set has 2800 observations on 28 variables (25 personality self-reported items and 3 demographic variables).
- The neo data set has 1000 measurements for $p = 30$ dimensions.
- The Harman data set is a correlation matrix of 24 psychological tests given to 145 seventh- and eighth-grade children.
- The geomorphology data set is a collection of geomorphological data collected across $p = 10$ variables and 75 observations. (The geomorphology data set originally has $p = 11$, but we remove the one categorical feature, leaving $p = 10$.)

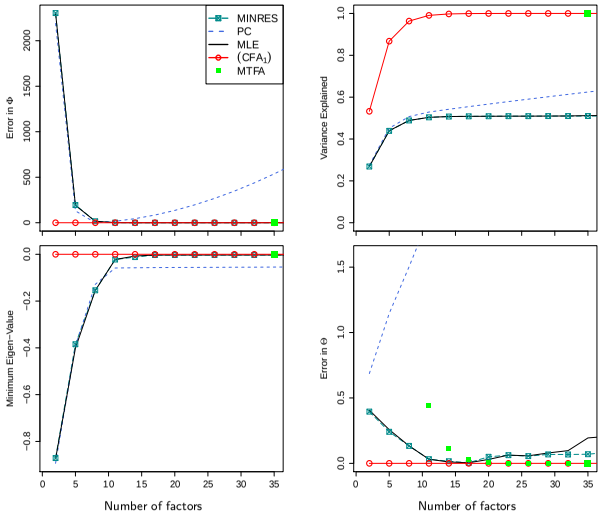

Figure 1: Performance of various FA methods for examples from class $A_2(p = 200)$ as a function of the number of factors. The y-axis label "Minimum Eigenvalue" refers to $\lambda_{\min}(\mathbf{\Sigma} - \widehat{\mathbf{\Phi}})$. We present the results of (CFA$_1$), as obtained via Algorithm 1—the results of (CFA$_2$) were similar, and hence omitted from the plot. Our methods seems to perform better than all the other competitors. For large values of r, as the fits saturate, the methods become similar. The methods (as available from the `R` package implementations) that experienced convergence difficulties do not appear in the plot.

- The JO data set records athletic performance in Olympic events, and involves 24 observations with $p = 58$. This example is distinctive because the corresponding correlation matrix $\mathbf{\Sigma}$ is not full rank (having more variables than observations).

We present the results in Figure 3. We also experimented with other methods—such as WLS and GLS—but the results were similar to MINRES and hence have not been shown in the figure. For the real examples, most of the performance measures described in Section 5.1.1 do not apply[16]; however, the notion of explained variance (44) does apply. We used this metric to compare the performance of different competing estimation procedures. We observe that solutions delivered by Category (B) explain the maximum amount of residual variance for a given rank r, which is indeed desirable, especially in the light of its analogy with PCA on the residual covariance matrix $\mathbf{\Sigma} - \mathbf{\Phi}$.

16. Understanding performance of FA methods on real data is difficult because it is an unsupervised problem. However, we can understand the performances of different methods by drawing parallels with PCA in terms of the proportion of variance explained of the matrix $\mathbf{\Sigma} - \mathbf{\Phi}$—see our discussion in Section 1.

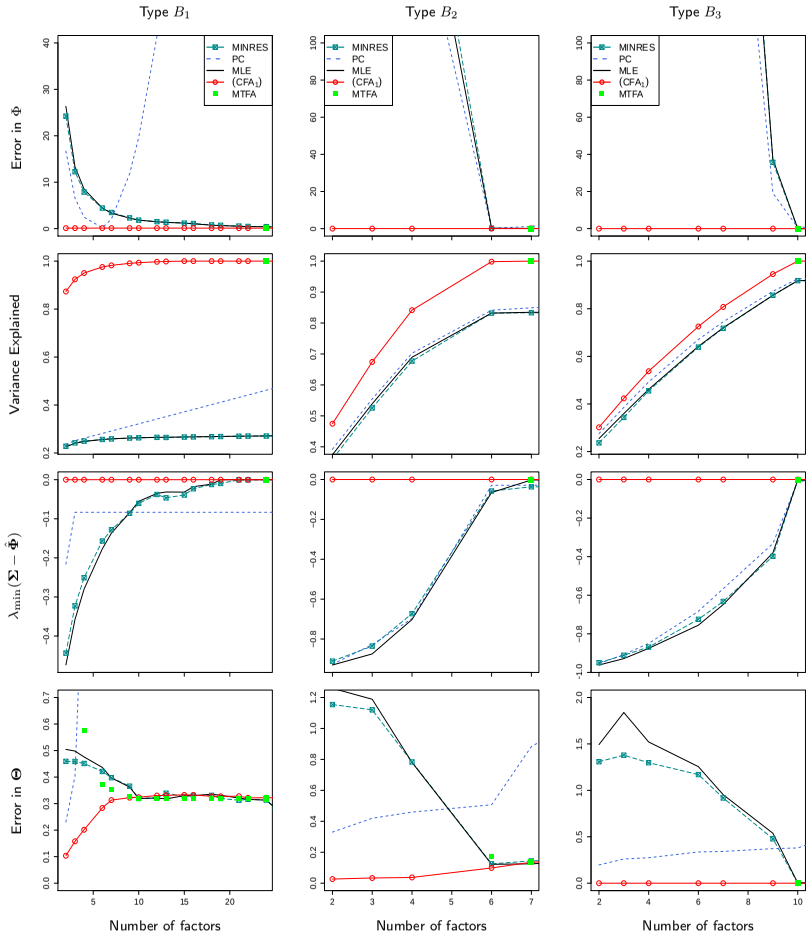

Figure 2: Performance of different methods for instances of $B_1(30/100)$, $B_2(5/10/100)$, and $B_3(5/10/100)$. We see that (CFA$_1$) exhibits very good performance across all instances, significantly outperforming the competing methods (the results of (CFA$_2$) were similar).

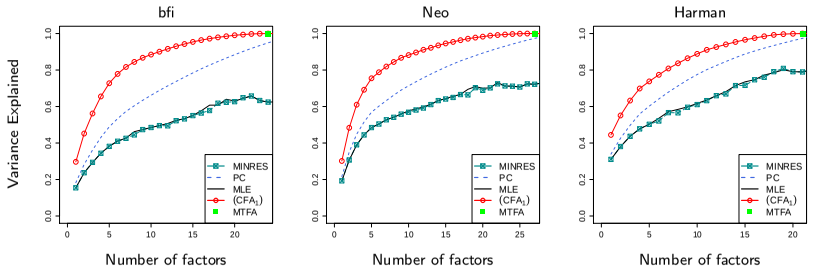

Figure 3: Figure showing proportion of variance explained by different methods for real-data examples. We see that in terms of the proportion of explained variance, (CFA$_1$) delivers the largest values for different values of r, which is indeed desirable. (CFA$_1$) also shows nice flexibility in delivering different models with varying r, in contrast to MTFA which delivers one model with proportion of variance explained equal to one. The results of (CFA$_2$) were found to be similar to (CFA$_1$).

5.3 Certificates of Optimality via Algorithm 2

We now turn our attention to certificates of optimality using Algorithm 2. Computational results of Algorithm 2 for a variety of problem sizes across all six classes can be found in Tables 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11. In general, we provide results for p ranging between 10 and 4000. Parametric choices are outlined in depth in Table 2.[17] We always initialize Algorithm 2 with an initial feasible solution as found via Algorithm 1 so that we can understand if the estimators found via the CG-based approach are indeed optimal. In particular, if the best feasible objective value does not change throughout the branch-and-bound algorithm, then the initial estimator was indeed optimal (within the numerical tolerance).

Root Node Gap: Let us first consider the gap at the root node. In classes A_1, B_1, B_2, and B_3, we see that the Weyl bound at the root node often provides a better bound than the one given by using convex envelopes. Indeed, the bound provided by Weyl's method can in many instances certify optimality (up to numerical tolerance) at the *root node*. For example, this is the case in many instances of classes A_1 and half of the instances in B_3. Given that Weyl's method is computationally inexpensive (only requiring the computation of p convex quadratic optimization problems and an eigenvalue decomposition), this suggests that Weyl's inequality as used within the context of factor analysis is particularly fruitful.

In contrast, in class A_2 and the real examples, we see that the convex envelope bound tends to perform better. Because of the structure of Weyl's inequality, Weyl's method is well-suited for correlation matrices $\mathbf{\Sigma}$ with very quickly decaying eigenvalues. Examples in

17. All computational experiments are performed in a shared cluster computing environment with highly variable demand, and therefore runtimes are not necessarily a reliable measure of problem complexity; hence, the number of nodes considered is always displayed. Further, Algorithm 2 is highly parallelizable, like many branch-and-bound algorithms; however, our implementation is serial. Therefore, with improvements in code design, it is very likely that runtimes can be substantially improved beyond those shown here.

		Root node			Terminal node

Table 2: Computational results for Algorithm 2 for class $C = A_1(R/p)$. All computations are performed in `julia` using SDO solvers `MOSEK` (for primal feasible solutions) and `SCS` (for dual feasible solutions within tolerance 10^{-3}). Computation time does not include preprocessing (such as computation of $\mathbf{u}$ as in (40) and finding an initial incumbent feasible solution $\mathbf{\Phi}_f$ as computed via the conditional gradient algorithm in Section 3). We always use default tolerance `TOL` $= 0.1$ for algorithm termination. Parameters for branching, pruning, node selection, etc., are detailed throughout Section 4. For each problem size, we run three instances (the instance number is the random seed provided to `julia`). Upper bounds denote z_f, which is the best feasible solution found thus far (either at the root node or at algorithm termination). At the root node, we display two lower bounds: the lower bound arising from convex envelopes (denoted "CE LB") and the one arising from the Weyl bound (denoted "Weyl LB"). Note that for lower bound at the termination node, we mean the worst bound $\max\{z^c, w^c\}$ (see Section 4.6; z^c is from the convex envelope approach, while w^c comes from Weyl's method). "Nodes" indicates the number of nodes considered in the course of execution, while "Time (s)" denotes the runtime (in seconds). We set r^*, the rank used within Algorithm 2, to $r^* = R - 1$, where R is the generative rank displayed. All results displayed to two decimals. Computations run on high-demand, shared cluster computing environment with variable architectures. Runtime is capped at 400000s (approximately 5 days), and any instance which is still running at that time is marked with an asterisk next to its runtime.

Table 3: Computational results for larger examples from class $C = A_1(R/p)$. Same parameters as in Table 2 but with larger problem instances. Again we set $r^* = R - 1$.

these two classes do not have such a spectrum, and indeed Weyl's method does not provide the best root node bound.[18] Because neither Weyl's method nor the convex envelope bound strictly dominate one another at the root node across all examples, our approach incorporating both can leverage the advantages of each.

Observe that the root node gap (either in terms of the absolute difference between the initial feasible solution found and the better of the convex envelope bound and the Weyl bound) tends to be smaller when r^* is much smaller than p. This suggests that the approach we take is well-suited to certify optimality of particularly low-rank decompositions in noisy factor analysis settings. We see that this phenomenon is true across all classes. The numerical results suggest that corresponding theoretical guarantees for Weyl's method are potentially of interest in their own right and warrant further consideration.

Finally, we remark that if the true convex envelope of the objective over the set of semidefinite constraints was taken, then the convex envelope objective would always be non-negative. However, because we have taken the convex envelope of the objective over the polyhedral constraints only, this is not the case.

Performance at Termination: It is particularly encouraging that the initial feasible solutions provided via Algorithm 1 remain the best feasible solution throughout the execution of Algorithm 2 for all but three problem instances. (Of course, this need not be

18. However, it is worth remarking that Weyl's method still provides lower bounds on the rank of solutions to the noiseless factor analysis problem. Hence, even in settings where Weyl's method is not necessarily well-suited for proving optimality for the noisy factor analysis problem, it can still be applied successfully to lower bound rank for noiseless factor analysis.

Table 4: Computational results for class $C = A_2(p)$. All parameters as per Table 2. Here we show the behavior across a variety of choices of the parameter r^*. Recall that the class A_2 is generated by a common variance component with high rank and exponentially decaying eigenvalues.

universally true.) This is an important observation to make because without a provable optimality scheme such as the one we consider here, it is difficult to quantify the performance of heuristic upper bound methods. As we demonstrate here, despite the only local guarantees of solutions obtained via a conditional gradient scheme, they tend to perform quite well in the setting of factor analysis. Indeed, even in the three examples where the best feasible solution is improved, the improved solution is found very early in the branching process.

Across the different example classes, we see that in general the gap tends to decrease more when r^* is small relative to p and p is smaller. To appropriately contextualize and appreciate the number of nodes solved for a problem with $p = 100$ on the timescale of 100s, with state-of-the-art implementations of interior point methods, solving a single node in the branch and bound tree can take on the order of 40s (for the specifically structured problems of interest and on the same machine). In other words, if one were to naïvely use interior point methods, it would only be possible to solve approximately three nodes during a 100s time limit. In contrast, by using a first-order method approach which facilitates warm starts, we are able to solve hundreds of nodes in the same amount of time.

We see that Algorithm 2 performs particularly well for classes A_1 (Tables 2 and 3) and B_1 (Table 5), for problems of reasonable size with relatively small underlying ranks. This

Table 5: Computational results for class $C = B_1(R/p)$. We choose r^* during computation as the largest r such that the CG method of Section 3 is strictly positive (up to additive tolerance 0.05; we use a smaller value here because the objective values are smaller across this class). For this class, examples can be preprocessed because $\mathbf{\Sigma} \sim B_1(R/p)$ has a block of size $R \times R$ in the upper left, with all other entries set to zero except the diagonal. Hence, it suffices to perform factor analysis with the truncated matrix $\mathbf{\Sigma}_{1:R,1:R}$.

is highly encouraging. Class A_1 forms a set of prototypical examples for which theoretical recovery guarantees perform well; in stark contrast, problems such as those in B_1 which have highly structured underlying factors tend to not satisfy the requirements of such recovery guarantees. Indeed, if $\mathbf{\Sigma} \sim B_1(R/p)$, then there generally appears to be a rank $R/2$ matrix $\mathbf{\Theta} \succcurlyeq \mathbf{0}$ so that $\mathbf{\Sigma} - \mathbf{\Theta}$ is positive semidefinite and diagonal. In such a problem, for r^* on the order of $R/2 - 1$, we provide nearly optimal solutions within a reasonable time frame.

Further, we note that similar results to those obtained for classes A_1 and B_1 are obtained for the other classes and are detailed in Tables 4 (class A_2), 6 (class B_2), 7 (class B_3), and

Table 6: Computational results for class $B_2(r/R/p)$. Parameters as set in Table 2. Here r^* is chosen during computation as largest k such that the CG method of Section 3 is strictly positive (up to 0.1). Here $r^* = R - 1$ ends up being an appropriate choice.

8 and 9. In a class such as A_2, which is generated as a high rank matrix (with decaying spectrum) with added individual variances, theoretical recovery guarantees do not generally apply, so again it is encouraging to see that our approach still makes significant progress towards proving optimality. Further, as shown in Table 11, for a variety of problems with p on the order of 1000 or 4000, solutions can be found in seconds and optimality can be certified within minutes via Weyl bounds, with no need for convex envelope bounds as computed via Algorithm 2, so long as the rank r^* is sufficiently small (for classes A_1, B_2, and B_3 on the order of hundreds, and for A_2 on the order of tens). This strongly supports the value of such an eigenvalue-based approach. When computing lower bounds solely via Weyl's method, the only necessary computations are solving quadratic programs (to find $\mathbf{u}$ as in Section 4.3) and an eigenvalue decomposition. As Table 11 suggests, for sufficiently small rank, one can still quickly find certifiably optimal solutions even for very large-scale factor analysis problems.

A particularly interesting example that stands apart from the rest is JO from the set of real examples. In particular, the correlation matrix for this example is not full rank (as there are fewer observations than variables). As displayed in Table 10, solutions found via conditional gradient methods are certified to be optimal at the root node. Indeed, the initial $\mathbf{u}_0$ as in Section 4.3 can be quickly verified to be $\mathbf{u}_0 = \mathbf{0}$ for this example, i.e., factor analysis is only possible with no individual variances. Hence, Algorithm 2 terminates at the root node without needing any branching.

Table 10: Computational results for the example JO ($p = 58$). Parameters as set in Table 2. Here we display results for the choices of $r^* \in \{1, 2, \ldots, 22\}$ (for $r^* > 22$, the upper bound is below the numerical tolerance, so we do not include those). For all choices of r^*, the optimal solution is found and certified to be optimal at the root node, and therefore we do not display any information other than the optimal values.

Finally, we note that all synthetic examples we have considered have equal proportions of common and individual variances (although, of course, this is not exploited by our approach as this information is not *a priori* possible to specify without additional contextual information). If one modifies the classes so that the proportion of the common variances is higher than the proportion of individual variances (in the generative example), then Algorithm 2 is able to deliver better bounds on a smaller time scale. (Results are not included here.) This is not particularly surprising because the branch-and-bound approach we take essentially hinges on how well the products $W_{ii}\Phi_i$ can be approximated. When there is underlying factor structure with a lower proportion of individual variances, the scale of $W_{ii}\Phi_i$ is smaller and hence these products are easier to approximate well.

5.4 Additional Considerations

We now turn our attention to assessing the benefits of various algorithmic modifications as presented in Section 4. We illustrate the impact of these by focusing on four representative examples from across the classes: $A_1(3/10)$, $B_1(6/50)$, $B_3(3/5/20)$, and $G :=$ geomorphology.

Performance of Branching Strategy: We begin by considering the impact of our branching strategy as developed in Section 4.4. The results across the four examples are shown in Table 12. Recall that $\epsilon \in [0, 1)$ controls the extent of deviation from the canonical branching location, with $\epsilon = 0$ corresponding to no deviation. Across all examples, we see that the number of nodes considered to prove optimality is approximately convex in $\epsilon \in [0, 0.5]$. In particular, for all examples, the "optimal" choice of ϵ is not the canonical choice of $\epsilon = 0$. This contrast is stark for the examples $B_3(3/5/20)$ and G. Indeed, for these two examples, the number of nodes considered when $\epsilon = 0$ is over five times larger than for any $\epsilon \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$.

Example	r^*	Upper bound	Lower bound
$A_1(100/1000)$	10	460.35	457.46

	150	630.25	628.54
	200	253.50	252.50
	240	7.89	7.46

Table 11: Computational results across several classes for larger scale instances with $p \in \{1000, 4000\}$. Here for a given example, the random seed is set as 1. Results are displayed across a variety of choices of rank r^*. Class B_1 is not shown because of the reduction noted in Table 5 (which reduces this class to a much smaller-dimensional class, and hence it is not truly large scale). The "Upper bound" denotes the upper bound found by the conditional gradient method, while "Lower bound" denotes the Weyl bound at the root node (no convex envelope bounds via Algorithm 2 are shown here because of the large nature of the SDO-based convex envelope lower bounds which are prohibitive to solve for problems of this size). These instances are completed in `MATLAB` because of its superior support (over `julia`) for solving large-scale quadratic optimization problems, which is the only computation necessary for computing Weyl bounds.

Example	r^*	Nodes considered for $\epsilon =$					
		0.0	0.1	0.2	0.3	0.4	0.5
$A_1(3/10)$	2	103	72	59	62	78	101

geomorphology	1	937	162	59	46	44	52

Table 12: Computational results for effect of branching strategy across different examples. In particular, we consider how the number of nodes needed to prove optimality (up to numerical tolerance) changes across different choices of ϵ, where ϵ is as in Section 4.4. Recall that $\epsilon = 0$ corresponds to a naïve choice of branching, while $\epsilon > 0$ corresponds to a modified branching. All other parameters as in Table 2, including the branching index. For synthetic examples, the instances are initialized with random seed 1.

Example	r^*	Nodes considered for	
		Naïve strategy	Modified strategy
$A_1(3/10)$	2	99	78
$B_1(6/50)$	2	135	50
$B_3(3/5/20)$	2	375	217
geomorphology	1	43	44

Table 13: Computational results for effect of node selection strategy across different examples. In particular, we consider how the number of nodes needed to prove optimality (up to numerical tolerance) changes across the naïve and modified branching strategies as described in Section 4.4. All other parameters as in Table 2. For synthetic examples, the instances are initialized with random seed 1.

Example	r^*	Upper Bound	CE LB with tightening	CE LB without tightening
$A_1(3/10)$	2	0.88	0.70	0.39
$B_1(6/50)$	2	0.11	−0.15	−0.17
$B_3(3/5/20)$	2	1.00	0.62	0.51
geomorphology	1	4.06	3.78	3.78

Table 14: Computational results for effect of root node bound tightening across different examples. In particular, we consider how the convex envelope lower bound (denoted "CE LB") compares with and without bound tightening at the root node (see Section 4.5). All other parameters as in Table 2. "Upper bound" displayed is as in Table 2 and is included for scale (i.e., to compare the relative impact of tightening). For synthetic examples, the instances are initialized with random seed 1.

Example	r^*	Nodes considered for TOL =		
		0.10	0.05	0.025
$A_1(3/10)$	2	78	287	726
$B_1(6/50)$	2	1	50	262
$B_3(3/5/20)$	2	217	1396	5132
geomorphology	1	44	217	978

Table 15: Computational results for numerical tolerance TOL across different examples. In particular, we consider how the number of nodes needed to prove optimality changes as a function of the additive numerical tolerance TOL chosen for algorithm termination. All other parameters as in Table 2. For synthetic examples, the instances are initialized with random seed 1.

In other words, the alternative branching strategy can have a substantial impact on the number of nodes considered in the branch-and-bound tree. As a direct consequence, this strategy can drastically reduce the computation time needed to prove optimality. As the examples suggest, it is likely that ϵ should be chosen dynamically during algorithm execution, as the particular choice depends on a given problem's structure. However, we set $\epsilon = 0.4$ for all other computational experiments because this appears to offer a distinct benefit over the naïve strategy of setting $\epsilon = 0$.

Performance of Node Selection Strategy: We now turn our attention to the node selection strategy as detailed in Section 4.6. Recall that node selection considers how to pick which node to consider next in the current branch-and-bound tree at any iteration of Algorithm 2. We compare two strategies: the naïve strategy which selects the node with worst convex envelope bound (as explicitly written in Algorithm 2) and the modified strategy which employs randomness and Weyl bounds to consider nodes which might not be advantageous to fathom when only convex envelope bounds are considered.

The comparison is shown in Table 13. We see that this strategy is advantageous overall (with only the example G giving a negligible decrease in performance). The benefit is particularly strong for examples from the B classes which have highly structured underlying factors. For such examples, there is a large difference between the convex envelope bounds and the Weyl bounds at the root node (see e.g. Table 5). Hence, an alternative branching strategy which incorporates the eigenvalue information provided by Weyl bounds has potential to improve beyond the naïve strategy. Indeed, this appears to be the case across all examples where such behavior occurs.

Performance of Bound Tightening All computational results employ bound tightening as developed in Section 4.5, but only at the root node. Bound tightening, which requires repeated eigenvalue computations, is a computationally expensive process. For this reason, we have chosen not to employ bound tightening at every node in the branch-and-bound tree. From a variety of computational experiments, we observed that the most important node for bound tightening is the root node, and therefore it is a reasonable choice to only employ bound tightening there. Consequently, we employ pruning via Weyl's method (detailed in Section 4.5 as well) at all nodes in the branch-and-bound tree. (Recall that bound tightening can be thought of as optimal pruning via Weyl's method.)

In Table 14 we show the impact of bound tightening at the root node in terms of the improvement in the lower bounds provided by convex envelopes. The results for the class A_1 are particularly distinctive. Indeed, for this class bound tightening has a substantial impact on the quality of the convex envelope bound (for the example $A_1(3/10)$ given, the improvement is from a relative gap at the root node of 56% to a gap of 20%). For the examples shown, bound tightening offers the least improvement in the real example geomorphology. In light of Table 8 this is not too surprising, as Weyl's method (at the root node) is not particular effective for this example. As Weyl's inequality is central to bound tightening, problems for which Weyl's inequality is not particularly effective tend to experience less benefit from bound tightening at the root node.

Influence of Optimality Tolerance We close this section by assessing the influence of the optimality tolerance for termination, TOL. In particular, we study how the number of

nodes to prove optimality changes as a function of additive gap necessary for termination. The corresponding results across the four examples are shown in Table 15. Not surprisingly, as the gap necessary for termination is progressively halved, the corresponding number of nodes considered increases substantially. However, it is important to note that even though the gap at termination is smaller as this tolerance decreases (by design), for these examples the best feasible solution remains unchanged. In other words, the increase in the number of nodes is the price for more accurately proving optimality and not for finding better feasible solutions. Indeed, as noted earlier, the solutions found via conditional gradient methods at the outset are of remarkably high quality.

6. Conclusions

We analyze the classical rank-constrained FA problem from a computational perspective. We proposed a general, flexible family of rank-constrained, nonlinear SDO-based formulations for the task of approximating an observed covariance matrix $\mathbf{\Sigma}$ as the sum of a PSD low-rank component $\mathbf{\Theta}$ and a diagonal matrix $\mathbf{\Phi}$ (with nonnegative entries) subject to $\mathbf{\Sigma}-\mathbf{\Phi}$ being PSD. Our framework enables us to estimate the underlying factors and unique variances under the restriction that the residual covariance matrix is semidefinite—this is important for statistical interpretability and understanding the proportion of variance explained by a given number of factors. This constraint, however, seems to ignored by most other widely used methods in FA.

We introduce a novel *exact* reformulation of the rank-constrained FA problem as a smooth optimization problem with convex, compact constraints. We present a unified algorithmic framework, utilizing modern techniques in nonlinear optimization and first order methods in convex optimization to obtain high-quality solutions for the FA problem. At the same time, we use techniques from discrete and global optimization to demonstrate that these solutions are often provably optimal. We provide computational evidence demonstrating that the methods proposed herein provide high quality estimates with improved accuracy when compared to existing, popularly-used methods in FA.

In this work we have demonstrated that a previously intractable rank optimization problem can be solved to provable optimality. We envision that ideas similar to those used here can be used to address an even larger class of estimation problems with underlying matrix structure. In this way, we anticipate significant progress on such problems in the next decade, particularly in light of myriad advances throughout distinct areas of modern optimization.

Appendix A

This appendix contains all proofs for results presented in the main text.

Proof of Proposition 1:

(a) We start by observing that for any two real symmetric matrices $\mathbf{A}, \mathbf{B}$ (with dimensions $p \times p$) and the matrix q-norm, a result due to Mirsky (this is also known as the q-Wielandt-Hoffman inequality; see e.g. Stewart and Sun 1990, p. 205) states:

$$\|\mathbf{A}-\mathbf{B}\|_q \geq \|\boldsymbol{\lambda}(\mathbf{A})-\boldsymbol{\lambda}(\mathbf{B})\|_q, \tag{46}$$

where $\boldsymbol{\lambda}(\mathbf{A})$ and $\boldsymbol{\lambda}(\mathbf{B})$ denote the vector of eigenvalues of $\mathbf{A}$ and $\mathbf{B}$, respectively, arranged in decreasing order, i.e., $\lambda_1(\mathbf{A}) \geq \lambda_2(\mathbf{A}) \geq \ldots \geq \lambda_p(\mathbf{A})$ and $\lambda_1(\mathbf{B}) \geq \lambda_2(\mathbf{B}) \geq \ldots \geq \lambda_p(\mathbf{B})$. Using this result for Problem (4), it is easy to see that for fixed $\mathbf{\Phi}$

$$\{\mathbf{\Theta} : \mathbf{\Theta} \succeq \mathbf{0}, \text{rank}(\mathbf{\Theta}) \leq r\} = \{\mathbf{\Theta} : \boldsymbol{\lambda}(\mathbf{\Theta}) \geq \mathbf{0}, \|\boldsymbol{\lambda}(\mathbf{\Theta})\|_0 \leq r\}, \tag{47}$$

where $\|\boldsymbol{\lambda}(\mathbf{\Theta})\|_0$ counts the number of non-zero elements of $\boldsymbol{\lambda}(\mathbf{\Theta})$. If we partially minimize the objective function in Problem (4), with respect to $\mathbf{\Theta}$ (with $\mathbf{\Phi}$ fixed), and use (46) along with (47), we have the following inequality:

$$\begin{array}{rll} & \inf\limits_{\mathbf{\Theta}} & \|(\mathbf{\Sigma}-\mathbf{\Phi})-\mathbf{\Theta}\|_q^q \quad \text{s.t.} \quad \mathbf{\Theta} \succeq \mathbf{0}, \text{rank}(\mathbf{\Theta}) \leq r \\ \geq & \inf\limits_{\boldsymbol{\lambda}(\mathbf{\Theta})} & \|\boldsymbol{\lambda}(\mathbf{\Sigma}-\mathbf{\Phi})-\boldsymbol{\lambda}(\mathbf{\Theta})\|_q^q \quad \text{s.t.} \quad \boldsymbol{\lambda}(\mathbf{\Theta}) \geq \mathbf{0}, \|\boldsymbol{\lambda}(\mathbf{\Theta})\|_0 \leq r. \end{array} \tag{48}$$

Since $\mathbf{\Sigma}-\mathbf{\Phi} \succeq \mathbf{0}$, it follows that the minimum objective value of the r.h.s. optimization Problem (48) is given by $\sum_{i=r+1}^p \lambda_i^q(\mathbf{\Sigma}-\mathbf{\Phi})$ and is achieved for $\lambda_i(\mathbf{\Theta}) = \lambda_i(\mathbf{\Sigma}-\mathbf{\Phi})$ for $i = 1, \ldots, r$. This leads to the following inequality:

$$\inf_{\mathbf{\Theta}:\mathbf{\Theta}\succeq\mathbf{0},\text{rank}(\mathbf{\Theta})\leq r} \|(\mathbf{\Sigma}-\mathbf{\Phi})-\mathbf{\Theta}\|_q^q \geq \sum_{i=r+1}^p \lambda_i^q(\mathbf{\Sigma}-\mathbf{\Phi}). \tag{49}$$

Furthermore, if $\mathbf{U}_{p\times p}$ denotes the matrix of p eigenvectors of $\mathbf{\Sigma}-\mathbf{\Phi}$, then the following choice of $\mathbf{\Theta}^*$:

$$\mathbf{\Theta}^* := \mathbf{U}\ \text{diag}\left(\lambda_1(\mathbf{\Sigma}-\mathbf{\Phi}), \ldots, \lambda_r(\mathbf{\Sigma}-\mathbf{\Phi}), 0, \ldots, 0\right)\ \mathbf{U}', \tag{50}$$

gives equality in (49). This leads to the following result:

$$\inf_{\mathbf{\Theta}:\mathbf{\Theta}\succeq\mathbf{0},\text{rank}(\mathbf{\Theta})\leq r} \|\mathbf{\Sigma}-(\mathbf{\Theta}+\mathbf{\Phi})\|_q^q = \|\mathbf{\Sigma}-(\mathbf{\Theta}^*+\mathbf{\Phi})\|_q^q = \sum_{i=r+1}^p \lambda_i^q(\mathbf{\Sigma}-\mathbf{\Phi}). \tag{51}$$

(b) The minimizer $\mathbf{\Theta}^*$ of Problem (51) is given by (50). In particular, if $\mathbf{\Phi}^*$ solves Problem (12) and we compute $\mathbf{\Theta}^*$ via (50) (with $\mathbf{\Phi} = \mathbf{\Phi}^*$), then the tuple $(\mathbf{\Phi}^*, \mathbf{\Theta}^*)$ solves Problem (4). This completes the proof of the proposition.

■

Proof of Proposition 2: We build upon the proof of Proposition 1. Note that any $\mathbf{\Phi}$ that is feasible for Problems (14) and (4) is PSD. Observe that $\mathbf{\Theta}^*$ (appearing in the proof of Proposition 1) as given by (50) satisfies:

$$\mathbf{\Sigma} - \mathbf{\Phi} - \mathbf{\Theta}^* \succeq \mathbf{0} \implies \mathbf{\Sigma} - \mathbf{\Theta}^* \succeq \mathbf{0}, \tag{52}$$

where, the right hand side of (52) follows since $\mathbf{\Phi} \succeq \mathbf{0}$. We have thus established that the solution $\mathbf{\Theta}^*$ to the following problem

$$\begin{array}{ll} \underset{\mathbf{\Theta}}{\text{minimize}} & \|(\mathbf{\Sigma} - \mathbf{\Phi}) - \mathbf{\Theta}\|_q^q \\ \text{s.t.} & \mathbf{\Theta} \succeq \mathbf{0} \\ & \text{rank}(\mathbf{\Theta}) \leq r, \end{array} \tag{53}$$

is feasible for the following optimization problem:

$$\begin{array}{ll} \underset{\mathbf{\Theta}}{\text{minimize}} & \|(\mathbf{\Sigma} - \mathbf{\Phi}) - \mathbf{\Theta}\|_q^q \\ \text{s.t.} & \mathbf{\Theta} \succeq \mathbf{0} \\ & \text{rank}(\mathbf{\Theta}) \leq r \\ & \mathbf{\Sigma} - \mathbf{\Theta} \succeq \mathbf{0}. \end{array} \tag{54}$$

Since Problem (54) involves minimization over a subset of the feasible set of Problem (53), it follows that $\mathbf{\Theta}^*$ is also a minimizer for Problem (54). This completes the proof of the equivalence. ■

Proof of Theorem 1:

(a) The proof is based on ideas appearing in Overton and Womersley (1992), where it was shown that the sum of the top r eigenvalues of a real symmetric matrix can be written as the solution to a linear SDO problem.

By an elegant classical result due to Fan (Stewart and Sun, 1990), the smallest $(p-r)$ eigenvalues of a real symmetric matrix $\mathbf{A}$ can be written as

$$\begin{array}{rll} \sum_{i=r+1}^{p} \lambda_i(\mathbf{A}) = & \inf & \text{Tr}\,(\mathbf{V}'\mathbf{A}\mathbf{V}) \\ & \text{s.t.} & \mathbf{V}'\mathbf{V} = \mathbf{I}, \end{array} \tag{55}$$

where the optimization variable is $\mathbf{V} \in \mathbb{R}^{p \times (p-r)}$. We will show that the solution to the above nonconvex problem can be obtained via the following linear (convex) SDO problem:

$$\begin{array}{ll} \text{minimize} & \text{Tr}\,(\mathbf{W}\mathbf{A}) \\ \text{s.t.} & \mathbf{I} \succeq \mathbf{W} \succeq \mathbf{0} \\ & \text{Tr}(\mathbf{W}) = p - r. \end{array} \tag{56}$$

Clearly, Problem (56) is a convex relaxation of Problem (55)—hence its minimum value is at least smaller than $\sum_{i=r+1}^{p} \lambda_i(\mathbf{A})$. By standard results in convex analysis (Rockafellar, 1996), it follows that the minimum of the above linear SDO problem (56) is attained at the extreme points of the feasible set of (56). The extreme points (see for example, Overton and Womersley, 1992; Vandenberghe and Boyd, 1996) of this set are given by the set of orthonormal matrices of rank $p-r$:

$$\left\{\mathbf{V}\mathbf{V}' : \mathbf{V} \in \mathbb{R}^{p \times (p-r)} : \mathbf{V}'\mathbf{V} = \mathbf{I}\right\}.$$

It thus follows that the (global) minima of Problems (56) and (55) are the same. Applying this result to the PSD matrix $\mathbf{A} = (\mathbf{\Sigma} - \mathbf{\Phi})^q$ appearing in the objective of (12), we arrive at (16). This completes the proof of part **(a)**.

(b) The statement follows from (50).

■

Proof of Proposition 3: Observe that, for every fixed $\mathbf{\Phi}$, the function $g_q(\mathbf{W}, \mathbf{\Phi})$ is concave (in fact, it is linear). Since $G_q(\mathbf{W})$ is obtained by taking a point-wise infimum (with respect to $\mathbf{\Phi}$) of the concave function $g_q(\mathbf{W}, \mathbf{\Phi})$, the resulting function $G_q(\mathbf{W})$ is concave (Boyd and Vandenberghe, 2004).

The expression of the sub-gradient (19) is an immediate consequence of Danskin's Theorem (Bertsekas, 1999; Rockafellar, 1996). ■

Proof of Theorem 2: Using the concavity of the function $G_q(\mathbf{W})$ we have:

$$\begin{array}{rcl} G_q(\mathbf{W}^{(i+1)}) & \leq & G_q(\mathbf{W}^{(i)}) + \langle \nabla G_q(\mathbf{W}^{(i)}), \mathbf{W}^{(i+1)} - \mathbf{W}^{(i)} \rangle \\ & = & G_q(\mathbf{W}^{(i)}) + \Delta(\mathbf{W}^{(i)}). \end{array} \tag{57}$$

Note that $\Delta(\mathbf{W}^{(i)}) \leq 0$ and $G_q(\mathbf{W}^{(i+1)}) \leq G_q(\mathbf{W}^{(i)})$ for all $i \leq k$. Hence the (decreasing) sequence of objective values converge to $G_q(\mathbf{W}^{(\infty)})$ (say) and $\Delta(\mathbf{W}^{(\infty)}) \geq 0$. Adding up the terms in (57) from $i = 1, \ldots, k$ we have:

$$G_q(\mathbf{W}^{(\infty)}) - G_q(\mathbf{W}^{(1)}) \leq G_q(\mathbf{W}^{(k+1)}) - G_q(\mathbf{W}^{(1)}) \leq -k \min_{i=1,\ldots,k} \left\{-\Delta(\mathbf{W}^{(k)})\right\} \tag{58}$$

from which (26) follows. ■

Proof of Theorem 5: By construction,

$$\max_{[\boldsymbol{\ell},\mathbf{u}] \in \texttt{Nodes}} \|\mathbf{u} - \boldsymbol{\ell}\|_1$$

decreases monotonically to zero as the iterative scheme proceeds. Therefore, to show convergence it suffices to show that the additive error at a node $\texttt{n} = [\boldsymbol{\ell}, \mathbf{u}] \in \texttt{Nodes}$ is $O(\|\mathbf{u} - \boldsymbol{\ell}\|_1)$. Fix an arbitrary node $\texttt{n} = [\boldsymbol{\ell}, \mathbf{u}] \in \texttt{Nodes}$. Without loss of generality, we may assume that (CFA_1) as restricted to $\text{diag}(\mathbf{\Phi}) \in [\boldsymbol{\ell}, \mathbf{u}]$ has a feasible solution; as

such, let $\mathbf{\Phi}^*$ be an optimal solution. Likewise, let $\mathbf{\Phi}^\dagger$ be an optimal solution ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$). First note that $\sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^*) \leq \sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^\dagger)$. Now, by two applications of the bound in Theorem 4 and the fact that $\mathbf{\Phi}^\dagger$ is optimal to ($\text{LS}_{\boldsymbol{\ell},\mathbf{u}}$), we have that $\sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^\dagger) \leq \sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^*) + \|\mathbf{u}-\boldsymbol{\ell}\|_1/2$. Hence, the additive error satisfies

$$\left| \sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^\dagger) - \sum_{i=r+1}^p \sigma_i(\mathbf{\Sigma}-\mathbf{\Phi}^*) \right| \leq \|\mathbf{u}-\boldsymbol{\ell}\|_1/2,$$

as was to be shown. ■

Appendix B

This appendix contains an alternative conditional gradient method for finding feasible solutions. Since Problem (16) involves the minimization of a smooth function over a compact convex set, the CG method requires iteratively solving the following convex optimization problem:

$$\begin{array}{ll} \text{minimize} & \left\langle \nabla g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}), \begin{pmatrix}\mathbf{W}\\ \mathbf{\Phi}\end{pmatrix} \right\rangle \\ \text{s.t.} & \mathbf{W} \in \mathbf{\Psi}_{p,p-r} \\ & \mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}, \end{array} \tag{59}$$

where $\nabla g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)})$ is the derivative of $g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)})$ at the current iterate ($\mathbf{W}^{(k)}$, $\mathbf{\Phi}^{(k)}$). Note that due to the separability of the constraints in $\mathbf{W}$ and $\mathbf{\Phi}$, Problem (59) splits into two independent optimization problems with respect to $\mathbf{W}$ and $\mathbf{\Phi}$. The overall procedure is outlined in Algorithm 3.

Since $\nabla_{\mathbf{W}} g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}) = (\mathbf{\Sigma}-\mathbf{\Phi}^{(k)})^q$, the update for $\mathbf{W}$ appearing in (60) requires solving:

$$\underset{\mathbf{W}\in\mathbf{\Psi}_{p,p-r}}{\text{minimize}} \quad \langle \mathbf{W}, (\mathbf{\Sigma}-\mathbf{\Phi}^{(k)})^q \rangle. \tag{63}$$

Similarly, the update for $\mathbf{\Phi}$ appearing in (61) requires solving:

$$\underset{\mathbf{\Phi}\in\mathcal{F}_{\mathbf{\Sigma}}}{\text{minimize}} \quad \sum_{i=1}^p \Phi_i \ell_i, \tag{64}$$

where the vector $(\ell_1,\ldots,\ell_p)$ is given by $\text{diag}(\ell_1,\ldots,\ell_p) = -q \ \text{diag}\left(\mathbf{W}^{(k)}(\mathbf{\Sigma}-\mathbf{\Phi})^{q-1}\right)$, where $\text{diag}(\mathbf{A})$ is a diagonal matrix having the same diagonal entries as $\mathbf{A}$. The sequence $(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)})$ is recursively computed via Algorithm 3 until a convergence criterion is met:

$$g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}) - g_p(\mathbf{W}^{(k+1)},\mathbf{\Phi}^{(k+1)}) \leq \text{TOL}\cdot g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}), \tag{65}$$

for some user-defined tolerance $\text{TOL} > 0$.

Algorithm 3 A CG based algorithm for Problem (16)

1 Initialize with $(\mathbf{W}^{(1)},\mathbf{\Phi}^{(1)})$, feasible for Problem (16) and repeat the following Steps 2-3 until the convergence criterion described in (65) is met.

2 Solve the linearized Problem (59), which requires solving two separate (convex) SDO problems over $\mathbf{W}$ and $\mathbf{\Phi}$:

$$\overline{\mathbf{W}}^{(k+1)} \in \underset{\mathbf{W}\in\mathbf{\Psi}_{p,p-r}}{\arg\min} \ \langle \mathbf{W}, \nabla_{\mathbf{W}} g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}) \rangle \tag{60}$$

$$\overline{\mathbf{\Phi}}^{(k+1)} \in \underset{\mathbf{\Phi}\in\mathcal{F}_{\mathbf{\Sigma}}}{\arg\min} \ \langle \mathbf{\Phi}, \nabla_{\mathbf{\Phi}} g_p(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)}) \rangle \tag{61}$$

where $\nabla_{\mathbf{W}} g_p(\mathbf{W},\mathbf{\Phi})$ (and $\nabla_{\mathbf{\Phi}} g_p(\mathbf{W},\mathbf{\Phi})$) is the partial derivative with respect to $\mathbf{W}$ (respectively, $\mathbf{\Phi}$).

3 Obtain the new iterates:

$$\begin{array}{rcl} \mathbf{W}^{(k+1)} & = & \mathbf{W}^{(k)} + \eta_k(\overline{\mathbf{W}}^{(k+1)} - \mathbf{W}^{(k)}), \\ \mathbf{\Phi}^{(k+1)} & = & \mathbf{\Phi}^{(k)} + \eta_k(\overline{\mathbf{\Phi}}^{(k+1)} - \mathbf{\Phi}^{(k)}). \end{array} \tag{62}$$

with $\eta_k \in [0,1]$ chosen via an Armijo type line-search rule (Bertsekas, 1999).

A tuple $(\mathbf{W}^*,\mathbf{\Phi}^*)$ satisfies the first order stationarity conditions (Bertsekas, 1999) for Problem (16), if the following condition is satisfied:

$$\begin{array}{lll} \inf & \left\langle \nabla g_p(\mathbf{W}^*,\mathbf{\Phi}^*), \begin{pmatrix}\mathbf{W}-\mathbf{W}^*\\ \mathbf{\Phi}-\mathbf{\Phi}^*\end{pmatrix} \right\rangle & \geq \quad 0 \\ \text{s.t.} & \mathbf{W} \in \mathbf{\Psi}_{p,p-r} & \\ & \mathbf{\Phi} \in \mathcal{F}_{\mathbf{\Sigma}}. & \end{array} \tag{66}$$

Note that $\mathbf{\Phi}^*$ defined above also satisfies the first order stationarity conditions for Problem (12).

The following theorem presents a global convergence guarantee for Algorithm 3:

Theorem 8 *(Bertsekas, 1999) Every limit point* $(\mathbf{W}^{(\infty)},\mathbf{\Phi}^{(\infty)})$ *of a sequence* $(\mathbf{W}^{(k)},\mathbf{\Phi}^{(k)})$ *produced by Algorithm 3 is a first order stationary point of the optimization Problem* (16).

Numerical experiments (in line with those from Section 5) suggest that Algorithm 3 performs similarly to Algorithm 1, and therefore we only present the results for Algorithm 1 in the main text. Algorithm 1 has the advantage that it does not require a line search, unlike Algorithm 3. Finally, we note that for Algorithm 3 the update for $\mathbf{W}$ at iteration k for solving Problem (63) corresponds to $\widetilde{\mathbf{W}} = (\mathbf{\Sigma}-\mathbf{\Phi}^{(k)})^q$.

Abstract

In this paper, we investigate a group sparse optimization problem via $\ell_{p,q}$ regularization in three aspects: theory, algorithm and application. In the theoretical aspect, by introducing a notion of group restricted eigenvalue condition, we establish an oracle property and a global recovery bound of order $\mathcal{O}(\lambda^{\frac{2}{2-q}})$ for any point in a level set of the $\ell_{p,q}$ regularization problem, and by virtue of modern variational analysis techniques, we also provide a local analysis of recovery bound of order $\mathcal{O}(\lambda^2)$ for a path of local minima. In the algorithmic aspect, we apply the well-known proximal gradient method to solve the $\ell_{p,q}$ regularization problems, either by analytically solving some specific $\ell_{p,q}$ regularization subproblems, or by using the Newton method to solve general $\ell_{p,q}$ regularization subproblems. In particular, we establish a local linear convergence rate of the proximal gradient method for solving the $\ell_{1,q}$ regularization problem under some mild conditions and by first proving a second-order growth condition. As a consequence, the local linear convergence rate of proximal gradient method for solving the usual ℓ_q regularization problem $(0 < q < 1)$ is obtained. Finally in the aspect of application, we present some numerical results on both the simulated data and the real data in gene transcriptional regulation.

Keywords: group sparse optimization, lower-order regularization, nonconvex optimization, restricted eigenvalue condition, proximal gradient method, iterative thresholding algorithm, gene regulation network

1. Introduction

In recent years, a great amount of attention has been paid to sparse optimization, which is to find the sparse solutions of an underdetermined linear system. The sparse optimization problem arises in a wide range of fields, such as compressive sensing, machine learning, pattern analysis and graphical modeling; see Blumensath and Davies (2008); Candès et al. (2006b); Chen et al. (2001); Donoho (2006a); Fan and Li (2001); Tibshirani (1994) and references therein.

In many applications, the underlying data usually can be represented approximately by a linear system of the form

$$Ax = b + \varepsilon,$$

where $A \in \mathbb{R}^{m\times n}$ and $b \in \mathbb{R}^m$ are known, $\varepsilon \in \mathbb{R}^m$ is an unknown noise vector, and $x = (x_1, x_2, \ldots, x_n)^\top \in \mathbb{R}^n$ is the variable to be estimated. If $m \ll n$, the above linear system is seriously ill-conditioned and may have infinitely many solutions. The sparse optimization problem is to recover x from information b such that x is of a sparse structure. The sparsity of variable x has been measured by the ℓ_p norm $\|x\|_p$ ($p = 0$, see Blumensath and Davies (2008); $p = 1$, see Beck and Teboulle (2009); Chen et al. (2001); Daubechies et al. (2004); Donoho (2006a); Tibshirani (1994); Wright et al. (2009); Yang and Zhang (2011); and $p = 1/2$, see Chartrand and Staneva (2008); Xu et al. (2012)). The ℓ_p norm $\|x\|_p$ for $p > 0$ is defined by

$$\|x\|_p := \left(\sum_{i=1}^n |x_i|^p\right)^{1/p},$$

while the ℓ_0 norm $\|x\|_0$ is defined by the number of nonzero components of x. The sparse optimization problem can be modeled as

$$\begin{array}{ll} \min & \|Ax - b\|_2 \\ \text{s.t.} & \|x\|_0 \le s, \end{array}$$

where s is the given sparsity level.

For the sparse optimization problem, a popular and practical technique is the regularization method, which is to transform the sparse optimization problem into an unconstrained optimization problem, called the regularization problem. For example, the ℓ_0 regularization problem is

$$\min_{x\in\mathbb{R}^n} \|Ax - b\|_2^2 + \lambda\|x\|_0,$$

where $\lambda > 0$ is the regularization parameter, providing a tradeoff between accuracy and sparsity. However, the ℓ_0 regularization problem is nonconvex and non-Lipschitz, and thus it is generally intractable to solve it directly (indeed, it is NP-hard; see Natarajan, 1995).

To overcome this difficulty, two typical relaxations of the ℓ_0 regularization problem are introduced, which are the ℓ_1 regularization problem

$$\min_{x\in\mathbb{R}^n} \|Ax-b\|_2^2+\lambda\|x\|_1 \tag{1}$$

and the ℓ_q regularization problem $(0<q<1)$

$$\min_{x\in\mathbb{R}^n} \|Ax-b\|_2^2+\lambda\|x\|_q^q. \tag{2}$$

1.1 ℓ_q Regularization Problems

The ℓ_1 regularization problem (1), also called Lasso (Tibshirani, 1994) or Basis Pursuit (Chen et al., 2001), has attracted much attention and has been accepted as one of the most useful tools for sparse optimization. Since the ℓ_1 regularization problem is a convex optimization problem, many exclusive and efficient algorithms have been proposed and developed for solving problem (1); see Beck and Teboulle (2009); Combettes and Wajs (2005); Daubechies et al. (2004); Hu et al. (2016); Nesterov (2012, 2013); Xiao and Zhang (2013); Yang and Zhang (2011). However, the ℓ_1 regularization problem (1) suffers some frustrations in practical applications. It was revealed by extensive empirical studies that the solutions obtained from the ℓ_1 regularization problem are much less sparse than the true sparse solution, that it cannot recover a signal or image with the least measurements when applied to compressed sensing, and that it often leads to sub-optimal sparsity in reality; see Chartrand (2007); Xu et al. (2012); Zhang (2010).

Recently, to overcome these drawbacks of ℓ_1 regularization, the lower-order regularization technique (that is, the ℓ_q regularization with $0<q<1$) is proposed to improve the performance of sparsity recovery of the ℓ_1 regularization problem. Chartrand and Staneva (2008) claimed that a weaker restricted isometry property is sufficient to guarantee perfect recovery in the ℓ_q regularization, and that it can recover sparse signals from fewer linear measurements than that required by the ℓ_1 regularization. Xu et al. (2012) showed that the $\ell_{1/2}$ regularization admits a significantly stronger sparsity promoting capability than the ℓ_1 regularization in the sense that it allows to obtain a more sparse solution or predict a sparse signal from a smaller amount of samplings. Qin et al. (2014) exhibited that the $\ell_{1/2}$ regularization achieves a more reliable solution in biological sense than the ℓ_1 regularization when applied to infer gene regulatory network from gene expression data of mouse embryonic stem cell. However, the ℓ_q regularization problem is nonconvex, nonsmooth and non-Lipschitz, and thus it is difficult in general to design efficient algorithms for solving it. It was presented in Ge et al. (2011) that finding the global minimal value of the ℓ_q regularization problem (2) is strongly NP-hard; while fortunately, computing a local minimum could be done in polynomial time. Some effective and efficient algorithms have been proposed to find a local minimum of problem (2), such as interior-point potential reduction algorithm (Ge et al., 2011), smoothing methods (Chen, 2012; Chen et al., 2010), splitting methods (Li and Pong, 2015a,b) and iterative reweighted minimization methods (Lai and Wang, 2011; Lai et al., 2013; Lu, 2014).

The ℓ_q regularization problem (2) is a variant of lower-order penalty problems, investigated in Huang and Yang (2003); Luo et al. (1996); Yang and Huang (2001), for a constrained optimization problem. The main advantage of the lower-order penalty functions

over the classical ℓ_1 penalty function is that they require weaker conditions to guarantee an exact penalization property and that their least exact penalty parameter is smaller; see Huang and Yang (2003). It was reported in Yang and Huang (2001) that the first- and second-order necessary optimality conditions of lower-order penalty problems converge to that of the original constrained optimization problem under a linearly independent constraint qualification.

Besides the preceding numerical algorithms, one of the most widely studied methods for solving the sparse optimization problem is the class of the iterative thresholding algorithms, which is studied in a unified framework of proximal gradient methods; see Beck and Teboulle (2009); Blumensath and Davies (2008); Combettes and Wajs (2005); Daubechies et al. (2004); Gong et al. (2013); Nesterov (2013); Xu et al. (2012) and references therein. It is convergent fast and of very low computational complexity. Benefitting from its simple formulation and low storage requirement, it is very efficient and applicable for large-scale sparse optimization problems. In particular, the iterative hard (resp. soft, half) thresholding algorithm for the ℓ_0 (resp. ℓ_1, $\ell_{1/2}$) regularization problem was studied in Blumensath and Davies (2008) (resp. Daubechies et al., 2004; Xu et al., 2012).

1.2 Global Recovery Bound

To estimate how far is the solution of regularization problems from that of the linear system, the global recovery bound (also called the ℓ_2 consistency) of the ℓ_1 regularization problem has been investigated in the literature. More specifically, under some mild conditions on A, such as the restricted isometry property (RIP, Candès and Tao, 2005) or restricted eigenvalue condition (REC, Bickel et al., 2009), van de Geer and Bühlmann (2009) established a deterministic recovery bound for the (convex) ℓ_1 regularization problem:

$$\|x^*(\ell_1)-\bar{x}\|_2^2=\mathcal{O}(\lambda^2 s), \tag{3}$$

where $x^*(\ell_1)$ is a solution of problem (1), $\bar{x}$ is a solution of the linear system $Ax=b$, and sparsity $s:=\|\bar{x}\|_0$. In the statistics literature, Bickel et al. (2009); Bunea et al. (2007); Meinshausen and Yu (2009); Zhang (2009) provided the recovery bound in a high probability for the ℓ_1 regularization problem when the size of the variable tends to infinity, under REC/RIP or some relevant conditions. However, to the best of our knowledge, the recovery bound for the general (nonconvex) ℓ_p regularization problem is still undiscovered. We will establish such a deterministic property in section 2.

1.3 Group Sparse Optimization

In applications, a wide class of problems usually have certain special structures, and recently, enhancing the recoverability due to the special structures has become an active topic in sparse optimization. One of the most popular structures is the group sparsity structure, that is, the solution has a natural grouping of its components, and the components within each group are likely to be either all zeros or all nonzeros. In general, the grouping information can be an arbitrary partition of x, and it is usually pre-defined based on prior knowledge of specific problems. Let $x:=(x_{\mathcal{G}_1}^\top,\cdots,x_{\mathcal{G}_r}^\top)^\top$ represent the group structure of x. The group

sparsity of x with such a group structure can be measured by an $\ell_{p,q}$ norm, defined by

$$\|x\|_{p,q} := \left(\sum_{i=1}^{r} \|x_{\mathcal{G}_i}\|_p^q\right)^{1/q}.$$

Exploiting the group sparsity structure can reduce the degrees of freedom in the solution, thereby leading to better recovery performance. Benefitting from these advantages, the group sparse optimization model has been applied in birthweight prediction (Bach, 2008; Yuan and Lin, 2006), dynamic MRI (Usman et al., 2011) and gene finding (Meier et al., 2008; Yang et al., 2010) with the $\ell_{2,1}$ norm. More specifically, the $\ell_{2,1}$ regularization problem

$$\min_{x\in\mathbb{R}^n} \|Ax-b\|_2^2 + \lambda\|x\|_{2,1}$$

was introduced by Yuan and Lin (2006) to study the grouped variable selection in statistics under the name of group Lasso. The $\ell_{2,1}$ regularization, an important extension of the ℓ_1 regularization, proposes an ℓ_2 regularization for each group and ultimately yields the sparsity in a group manner. Since the $\ell_{2,1}$ regularization problem is a convex optimization problem, some effective algorithms have been proposed, such as, the spectral projected gradient method (van den Berg et al., 2008), SpaRSA (Wright et al., 2009) and the alternating direction method (Deng et al., 2011).

1.4 The Aim of This Paper

In this paper, we will investigate the group sparse optimization via $\ell_{p,q}$ regularization ($p \geq 1, 0 \leq q \leq 1$), also called the $\ell_{p,q}$ regularization problem

$$\min_{x\in\mathbb{R}^n} F(x) := \|Ax-b\|_2^2 + \lambda\|x\|_{p,q}^q. \tag{4}$$

We will investigate the oracle property and recovery bound for the $\ell_{p,q}$ regularization problem, which extends the existing results in two ways: one is the lower-order regularization, including the ℓ_q regularization problem ($q<1$); the other is the group sparse optimization, including the $\ell_{2,1}$ regularization problem (group Lasso) as a special case. To this end, we will introduce the weaker notions of REC: the lower-order REC and the group REC (GREC). We will further establish the relationships between the new notions with the classical one: the lower-order REC is weaker than the classical REC, but the reverse is not true (see Example 1); and the GREC is weaker than the REC. Under the lower-order GREC, we will provide the oracle property and the global recovery bound for the $\ell_{p,q}$ regularization problem (see Theorem 9). Furthermore, we will conduct a local analysis of recovery bound for the $\ell_{p,q}$ regularization problem by virtue of modern variational analysis techniques (Rockafellar and Wets, 1998). More precisely, we assume that any nonzero group of $\bar{x}$ is active and the columns of A corresponding to the active components of $\bar{x}$ (a solution of $Ax=b$) are linearly independent, which matches the nature of the group sparsity structure. This leads us to the application of implicit function theorem and thus guarantees the existence of a local path around $\bar{x}$ which satisfies a second-order growth condition. As such, in the local recovery bound, we will establish a uniform recovery bound $\mathcal{O}(\lambda^2 S)$ for all the $\ell_{p,q}$ regularization problems; see Theorem 2.2.

The proximal gradient method is one of the most popular and practical methods for the sparse optimization problems, either convex or nonconvex problems. We will apply the proximal gradient method to solve the $\ell_{p,q}$ regularization problem (4). The advantage of the proximal gradient method is that the proximal optimization subproblems of some specific regularization have the analytical solutions, and the resulting algorithm is thus practically attractive. In the general cases when the analytical solutions of the proximal optimization subproblems seem not available, we will employ the Newton method to solve them. Furthermore, we will investigate a local linear convergence rate of the proximal gradient method for solving the $\ell_{p,q}$ regularization problem when $p=1$ and $0<q<1$ under the assumption that any nonzero group of a local minimum is active. Problem (4) of the case $p=1$ and $0<q<1$ possesses the properties that the regularization term $\|\cdot\|_{p,q}^q$ is concave near a local minimum and that the objective function $F(\cdot)$ of (4) satisfies a second-order growth condition, which plays an important role in the establishment of the local linear convergence rate. To the best of our knowledge, this is the first attempt to study the local linear convergence rate of proximal gradient method for solving the lower-order optimization problems. As a consequence of this result, we will obtain the local linear convergence rate of proximal gradient method for solving ℓ_q regularization problem ($0<q<1$), which includes the iterative half thresholding algorithm ($q=1/2$) proposed in Xu et al. (2012) as a special case. The result on local linear convergence rate of proximal gradient method for solving the ℓ_q regularization problem is still new, as far as we know.

In the aspect of application, we will conduct some numerical experiments on both simulated data and real data in gene transcriptional regulation to demonstrate the performance of the proposed proximal gradient method. From the numerical results, it is demonstrated that the $\ell_{p,1/2}$ regularization is the best one among the $\ell_{p,q}$ regularizations for $q\in[0,1]$, and it outperforms the $\ell_{p,1}$ and $\ell_{p,0}$ regularizations on both accuracy and robustness. This observation is consistent with several previous numerical studies on the ℓ_p regularization problem; see Chartrand and Staneva (2008); Xu et al. (2012). It is also illustrated from the numerical results that the proximal gradient method ($\ell_{2,1/2}$) outperforms most solvers in group sparse learning, such as OMP (Cai and Wang, 2011), FoBa (Zhang, 2011), ℓ_1-Magic (Candès et al., 2006a), ISTA (Daubechies et al., 2004), YALL1 (Yang and Zhang, 2011) etc. The R package of the proximal gradient method for solving group sparse optimization, named GSparO in CRAN, is available at https://CRAN.R-project.org/package=GSparO

1.5 Main Contributions

This paper is to investigate the group sparse optimization under a unified framework of the $\ell_{p,q}$ regularization problem (4). In this paper, we establish the oracle property and recovery bound, design an efficient numerical method for problem (4), and apply the proposed method to solve the problem of gene transcriptional regulation. The main contributions are presented as follows.

(i) We establish the following global recovery bound for the $\ell_{p,q}$ regularization problem (4) under the (p,q)-GREC:

$$\|x^*-\bar{x}\|_2^2 \leq \begin{cases} \mathcal{O}(\lambda^{\frac{2}{2-q}} S), & 2^{K-1}q = 1, \\ \mathcal{O}(\lambda^{\frac{2}{2-q}} S^{\frac{3-q}{2-q}}), & 2^{K-1}q > 1, \end{cases} \tag{5}$$

where $\bar{x}$ is a solution of $Ax = b$, $S := \|\bar{x}\|_{p,0}$ is the group sparsity, $0 < q \le 1 \le p \le 2$, x^* is any point in the level set $\mathrm{lev}_F(\bar{x})$ of problem (4), and K is the smallest integer such that $2^{K-1}q \ge 1$.

(ii) By virtue of the variational analysis technique, for all the $\ell_{p,q}$ regularization problems, we establish a uniform local recovery bound

$$\|x^*_{p,q}(\lambda) - \bar{x}\|_2^2 \le \mathcal{O}(\lambda^2 S) \quad \text{for small } \lambda,$$

where $0 < q < 1 \le p$ and $x^*_{p,q}(\lambda)$ is a local optimal solution of problem (4) (near $\bar{x}$).

(iii) We present the analytical formulae for the proximal optimization subproblems of specific $\ell_{p,q}$ regularizations when $p = 1, 2$ and $q = 0, 1/2, 2/3, 1$. Moreover, we prove that any sequence $\{x^k\}$, generated by proximal gradient method for solving the $\ell_{1,q}$ regularization problem, linearly converges to a local minimum x^* under some mild conditions, that is, there exist $N \in \mathbb{N}$, $C > 0$ and $\eta \in (0, 1)$ such that

$$F(x^k) - F(x^*) \le C\eta^k \quad \text{and} \quad \|x^k - x^*\|_2 \le C\eta^k \quad \text{for any } k \ge N.$$

(iv) Our numerical experiments show that, measured by the biological golden standards, the accuracy of the gene regulation networks forecasting can be improved by exploiting the group structure of TF complexes. The successful application of group sparse optimization to gene transcriptional regulation will facilitate biologists to study the gene regulation of higher model organisms in a genome-wide scale.

1.6 The Organization of This Paper

This paper is organized as follows. In section 2, we introduce the notions of q-REC and GREC, and establish the oracle property and (global and local) recovery bounds for the $\ell_{p,q}$ regularization problem. In section 3, we apply the proximal gradient method to solve the group sparse optimization using different types of $\ell_{p,q}$ regularization, and investigate the local linear convergence rate of the resulting proximal gradient method. Finally, section 4 exhibits the numerical results on both simulated data and real data in gene transcriptional regulation.

2. Global and Local Recovery Bounds

This section is devoted to the study of the oracle property and (global and local) recovery bounds for the $\ell_{p,q}$ regularization problem (4). To this end, we first present some basic inequalities of ℓ_p norm and introduce the notions of RECs, as well as their relationships.

The notations adopted in this paper are described as follows. We let the lowercase letters x, y, z denote the vectors, calligraphic letters $\mathcal{I}$, $\mathcal{T}$, $\mathcal{S}$, $\mathcal{J}$, $\mathcal{N}$ denote the index sets, capital letters N, S denote the numbers of groups in the index sets. In particular, we use $\mathcal{G}_i$ to denote the index set corresponding to the i-th group and $\mathcal{G}_\mathcal{S}$ to denote the index set $\{\mathcal{G}_i : i \in \mathcal{S}\}$. For $x \in \mathbb{R}^n$ and $\mathcal{T} \subseteq \{1, \ldots, n\}$, we use $x_\mathcal{T}$ to denote the subvector of x corresponding to $\mathcal{T}$. We use $\mathrm{sign} : \mathbb{R} \to \mathbb{R}$ to denote the signum function, defined by

$$\mathrm{sign}(t) = \begin{cases} 1, & t > 0, \\ 0, & t = 0, \\ -1, & t < 0. \end{cases}$$

Throughout this paper, we assume that the group sparse optimization problem is of the group structure described as follows. Let $x := (x_{\mathcal{G}_1}^\top, \cdots, x_{\mathcal{G}_r}^\top)^\top$ represent the group structure of x, where $\{x_{\mathcal{G}_i} \in \mathbb{R}^{n_i} : i = 1, \cdots, r\}$ is the grouping of x, $\sum_{i=1}^r n_i = n$ and $n_{\max} := \max\{n_i : i \in \{1, \ldots, r\}\}$. For a group $x_{\mathcal{G}_i}$, we use $x_{\mathcal{G}_i} = 0$ (reps. $x_{\mathcal{G}_i} \ne 0$, $x_{\mathcal{G}_i} \neq_{\mathbf{a}} 0$) to denote a zero (reps. nonzero, active) group, where $x_{\mathcal{G}_i} = 0$ means that $x_j = 0$ for all $j \in \mathcal{G}_i$; $x_{\mathcal{G}_i} \ne 0$ means that $x_j \ne 0$ for some $j \in \mathcal{G}_i$; and $x_{\mathcal{G}_i} \neq_{\mathbf{a}} 0$ means that $x_j \ne 0$ for all $j \in \mathcal{G}_i$. It is trivial to see that

$$x_{\mathcal{G}_i} \neq_{\mathbf{a}} 0 \quad \Rightarrow \quad x_{\mathcal{G}_i} \ne 0.$$

For this group structure and $p > 0$, the $\ell_{p,q}$ norm of x is defined by

$$\|x\|_{p,q} = \begin{cases} (\sum_{i=1}^r \|x_{\mathcal{G}_i}\|_p^q)^{1/q}, & q > 0, \\ \sum_{i=1}^r \|x_{\mathcal{G}_i}\|_p^0, & q = 0, \end{cases} \tag{6}$$

which proposes the ℓ_p norm for each group and then processes the ℓ_q norm for the resulting vector. When $p = q$, the $\ell_{p,q}$ norm coincides with the ℓ_p norm, that is, $\|x\|_{p,p} = \|x\|_p$. Furthermore, all $\ell_{p,0}$ norms share the same formula, that is, $\|x\|_{p,0} = \|x\|_{2,0}$ for all $p > 0$. In particular, when the grouping structure is degenerated to the individual feature level, that is, if $n_{\max} = 1$ or $n = r$, we have $\|x\|_{p,q} = \|x\|_q$ for all $p > 0$ and $q > 0$.

Moreover, we assume that A and b in (4) are related by a linear model (noiseless)

$$b = A\bar{x}.$$

Let $\mathcal{S} := \{i \in \{1, \ldots, r\} : \bar{x}_{\mathcal{G}_i} \ne 0\}$ be the index set of nonzero groups of $\bar{x}$, $\mathcal{S}^c := \{1, \ldots, r\} \setminus \mathcal{S}$ be the complement of $\mathcal{S}$, $S := |\mathcal{S}|$ be the group sparsity of $\bar{x}$, and $n_\mathbf{a} := \sum_{i \in \mathcal{S}} n_i$.

2.1 Inequalities of $\ell_{p,q}$ Norm

We begin with some basic inequalities of the ℓ_p and $\ell_{p,q}$ norms, which will be useful in the later discussion of RECs and recovery bounds. First, we recall the following well-known inequality

$$\left(\sum_{i=1}^n |x_i|^{\gamma_2}\right)^{1/\gamma_2} \le \left(\sum_{i=1}^n |x_i|^{\gamma_1}\right)^{1/\gamma_1} \quad \text{if } 0 < \gamma_1 \le \gamma_2, \tag{7}$$

or equivalently ($x = (x_1, x_2, \ldots, x_n)^\top$),

$$\|x\|_{\gamma_2} \le \|x\|_{\gamma_1} \quad \text{if } 0 < \gamma_1 \le \gamma_2.$$

The following lemma improves Huang and Yang (2003, lem. 4.1) and extends to the $\ell_{p,q}$ norm. It will be useful in providing a shaper global recovery bound (see Theorem 9 later).

Lemma 1 *Let $0 < q \le p \le 2$, $x \in \mathbb{R}^n$ and K be the smallest integer such that $2^{K-1}q \ge 1$. Then the following relations hold.*

(i) $\|x\|_q^q \le n^{1-2^{-K}} \|x\|_2^q$.

(ii) $\|x\|_{p,q}^q \le r^{1-2^{-K}} \|x\|_{p,2}^q$.

Proof (i) Repeatedly using the property that $\|x\|_1 \le \sqrt{n}\|x\|_2$, one has that

$$\|x\|_q^q \le \sqrt{n}\left(\sum_{i=1}^n |x_i|^{2q}\right)^{1/2} \le \cdots \le n^{\frac{1}{2}+\cdots+\frac{1}{2^K}}\left(\sum_{i=1}^n |x_i|^{2^K q}\right)^{2^{-K}}.$$

Since $2^{K-1}q \ge 1$, by (7), we obtain that

$$\left(\sum_{i=1}^n |x_i|^{2^K q}\right)^{2^{-K}} = \left(\sum_{i=1}^n (|x_i|^2)^{2^{K-1}q}\right)^{\frac{1}{2^{K-1}q}\frac{q}{2}} \le \left(\sum_{i=1}^n |x_i|^2\right)^{q/2} = \|x\|_2^q.$$

Therefore, we arrive at the conclusion that

$$\|x\|_q^q \le n^{1-2^{-K}}\|x\|_2^q.$$

(ii) By (6), it is a direct consequence of (i). ■

For example, if $q = 1$, then $K = 1$; if $q = \frac{1}{2}$ or $\frac{2}{3}$, then $K = 2$. The following lemma describes the triangle inequality of $\|\cdot\|_{p,q}^q$.

Lemma 2 *Let $0 < q \le 1 \le p$ and $x, y \in \mathbb{R}^n$. Then*

$$\|x\|_{p,q}^q - \|y\|_{p,q}^q \le \|x - y\|_{p,q}^q.$$

Proof By the subadditivity of the ℓ_p norm and (7), it is easy to see that

$$\|x_{\mathcal{G}_i}\|_p^q - \|y_{\mathcal{G}_i}\|_p^q \le \|x_{\mathcal{G}_i} - y_{\mathcal{G}_i}\|_p^q, \quad \text{for } i = 1, \ldots, r.$$

Consequently, the conclusion directly follows from (6). ■

The following lemma will be beneficial to studying properties of the lower-order REC in Proposition 5 later.

Lemma 3 *Let $\gamma \ge 1$, and two finite sequences $\{y_i : i \in \mathcal{I}\}$ and $\{x_j : j \in \mathcal{J}\}$ satisfy that $y_i \ge x_j \ge 0$ for all $(i, j) \in \mathcal{I} \times \mathcal{J}$. If $\sum_{i\in\mathcal{I}} y_i \ge \sum_{j\in\mathcal{J}} x_j$, then $\sum_{i\in\mathcal{I}} y_i^\gamma \ge \sum_{j\in\mathcal{J}} x_j^\gamma$.*

Proof Set $\bar{y} := \frac{1}{|\mathcal{I}|}\sum_{i\in\mathcal{I}} y_i$ and $\alpha := \min_{i\in\mathcal{I}} y_i$. By Huang and Yang (2003, lem. 4.1), one has that

$$\sum_{i\in\mathcal{I}} y_i^\gamma \ge \frac{1}{|\mathcal{I}|^{\gamma-1}}\left(\sum_{i\in\mathcal{I}} y_i\right)^\gamma = |\mathcal{I}|\bar{y}^\gamma. \tag{8}$$

On the other hand, let $M \in \mathbb{N}$ and $\beta \in [0, \alpha)$ be such that $\sum_{j\in\mathcal{J}} x_j = M\alpha + \beta$. Observing that $\gamma \ge 1$ and $0 \le x_j \le \alpha$ for all $j \in \mathcal{J}$, we obtain that $x_j^\gamma \le x_j\alpha^{\gamma-1}$, and thus, $\sum_{j\in\mathcal{J}} x_j^\gamma \le M\alpha^\gamma + \alpha^{\gamma-1}\beta$. By (8), it remains to show that

$$|\mathcal{I}|\bar{y}^\gamma \ge M\alpha^\gamma + \alpha^{\gamma-1}\beta. \tag{9}$$

If $|\mathcal{I}| > M$, the relation (9) is trivial since $\bar{y} \ge \alpha > \beta$; otherwise, $|\mathcal{I}| \le M$, from the facts that $|\mathcal{I}|\bar{y} \ge M\alpha + \beta$ (that is, $\sum_{i\in\mathcal{I}} y_i \ge \sum_{j\in\mathcal{J}} x_j$) and that $\gamma \ge 1$, it follows that

$$|\mathcal{I}|\bar{y}^\gamma \ge M^{1-\gamma}(M\alpha + \beta)^\gamma \ge M^{1-\gamma}(M^\gamma\alpha^\gamma + \gamma M^{\gamma-1}\alpha^{\gamma-1}\beta) \ge M\alpha^\gamma + \alpha^{\gamma-1}\beta.$$

Therefore, we verify the relation (9), and the proof is complete. ■

2.2 Group Restricted Eigenvalue Conditions

This subsection aims at the development of the critical conditions on the matrix A to guarantee the oracle property and the global recovery bound of the $\ell_{p,q}$ regularization problem (4). In particular, we will focus on the restricted eigenvalue condition (REC), and extend it to the lower-order setting and equip it with the group structure.

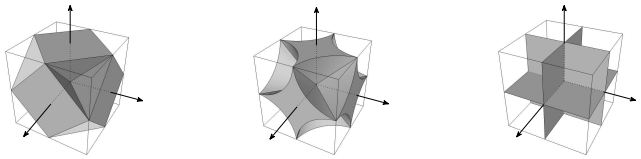
In the scenario of sparse optimization, given the sparsity level s, it is always assumed that the $2s$-sparse minimal eigenvalue of $A^\top A$ is positive (see Bickel et al., 2009; Bunea et al., 2007; Meinshausen and Yu, 2009), that is,

$$\phi_{\min}(2s) := \min_{\|x\|_0\le 2s} \frac{x^\top A^\top Ax}{x^\top x} > 0, \tag{10}$$

which is the minimal eigenvalue of any $2s \times 2s$ dimensional submatrix. It is well-known that the solution at sparsity level s of the linear system $Ax = b$ is unique if the condition (10) is satisfied; otherwise, assume that there are two distinct vectors $\hat{x}$ and $\tilde{x}$ such that $A\hat{x} = A\tilde{x}$ and $\|\hat{x}\|_0 = \|\tilde{x}\|_0 = s$. Then $x := \hat{x} - \tilde{x}$ is a vector such that $Ax = 0$ and $\|x\|_0 \le 2s$, and thus $\phi_{\min}(2s) = 0$, which is contradict with (10). Therefore, if the $2s$-sparse minimal eigenvalue of $A^\top A$ is zero (that is, $\phi_{\min}(2s) = 0$), one has no hope of recovering the true sparse solution from noisy observations.

However, only condition (10) is not enough and some further condition is required to maintain the nice recovery of regularization problems; see Bickel et al. (2009); Bunea et al. (2007); Meinshausen and Yu (2009); van de Geer and Bühlmann (2009); Zhang (2009) and references therein. For example, the REC was introduced in Bickel et al. (2009) to investigate the ℓ_2 consistency of the ℓ_1 regularization problem (Lasso), where the minimum in (10) is replaced by a minimum over a restricted set of vectors measured by an ℓ_1 norm inequality and the denominator is replaced by the ℓ_2 norm of only a part of x.

We now introduce the notion of the lower-order REC. Note that the residual $\hat{x} := x^*(\ell_q) - \bar{x}$, where $x^*(\ell_q)$ is an optimal solution of the ℓ_q regularization problem and $\bar{x}$ is a sparse solution of $Ax = b$, of the ℓ_q regularization problem always satisfies



$$\|\hat{x}_{\mathcal{S}^c}\|_q \le \|\hat{x}_{\mathcal{S}}\|_q, \tag{11}$$

where $\mathcal{S}$ is the support of $\bar{x}$. Thus we introduce a lower-order REC, where the minimum is taken over a restricted set measured by an ℓ_q norm inequality such as (11), for establishing the global recovery bound of the ℓ_q regularization problem. Given $s \le t \ll n$, $x \in \mathbb{R}^n$ and $\mathcal{I} \subseteq \{1, \ldots, n\}$, we denote by $\mathcal{I}(x; t)$ the subset of $\{1, \ldots, n\}$ corresponding to the first t largest coordinates in absolute value of x in $\mathcal{I}^c$.

Definition 4 *Let $0 \le q \le 1$. The q-restricted eigenvalue condition relative to (s, t) (q-REC(s, t)) is said to be satisfied if*

$$\phi_q(s, t) := \min\left\{\frac{\|Ax\|_2}{\|x_{\mathcal{T}}\|_2} : |\mathcal{I}| \le s, \|x_{\mathcal{I}^c}\|_q \le \|x_{\mathcal{I}}\|_q, \mathcal{T} = \mathcal{I}(x; t) \cup \mathcal{I}\right\} > 0.$$

The q-REC describes a kind of restricted positive definiteness of $A^\top A$, which is valid only for the vectors satisfying the relation measured by an ℓ_q norm. The q-REC presents a unified framework of the REC-type conditions whenever $q \in [0, 1]$. In particular, we note by

(a) REC (b) 1/2-REC (c) 0-REC

Figure 1: The geometric interpretation of the RECs: the gray regions show the feasible sets $C_q(s)$ $(q = 1, 1/2, 0)$. The q-REC holds if and only if the null space of A does not intersect the gray region.

definition that 1-REC reduces to the classical REC (Bickel et al., 2009), and that $\phi_{\min}(2s) = \phi_0^2(s,s)$, and thus

$$(10) \quad \Leftrightarrow \quad 0\text{-REC}(s,s) \text{ is satisfied.}$$

It is well-known in the literature that the 1-REC is a stronger condition than the 0-REC (10). A natural question arises what are the relationships between the general q-RECs. To answer this question, associated with the q-REC, we consider the feasible set

$$C_q(s) := \{x \in \mathbb{R}^n : \|x_{\mathcal{I}^c}\|_q \le \|x_{\mathcal{I}}\|_q \text{ for some } |\mathcal{I}| \le s\},$$

which is a cone. Since the objective function associated with the q-REC is homogeneous, the q-REC(s,t) says that the null space of A does not cross over $C_q(s)$. Figure 1 presents the geometric interpretation of the q-RECs. It is shown in Figure 1 that $C_0(s) \subseteq C_{1/2}(s) \subseteq C_1(s)$, and thus

$$1\text{-REC} \quad \Rightarrow \quad 1/2\text{-REC} \quad \Rightarrow \quad 0\text{-REC}.$$

It is also observed from Figure 1 that the gap between the 1-REC and 1/2-REC and that between 1/2-REC and 0-REC are the matrices whose null spaces fall in the cones of $C_1(s) \setminus C_{1/2}(s)$ and $C_{1/2}(s) \setminus C_0(s)$, respectively.

We now provide a rigorous proof in the following proposition to identify the relationship between the feasible sets $C_q(s)$ and between the general q-RECs: the lower the q, the smaller the cone $C_q(s)$, and the weaker the q-REC.

Proposition 5 *Let $0 \le q_1 \le q_2 \le 1$ and $1 \le s \le t \ll n$. Then the following statements are true:*

(i) *$C_{q_1}(s) \subseteq C_{q_2}(s)$, and*

(ii) *if the q_2-REC(s,t) holds, then the q_1-REC(s,t) holds.*

Proof (i) Fix $x \in C_{q_1}(s)$. We use $\mathcal{I}_*$ to denote the index set of the first s largest coordinates in absolute value of x. Since $x \in C_{q_1}(s)$, it follows that $\|x_{\mathcal{I}_*^c}\|_{q_1} \le \|x_{\mathcal{I}_*}\|_{q_1}$ ($|\mathcal{I}_*| \le s$ due to the construction of $\mathcal{I}_*$). By Lemma 3 (taking $\gamma = q_2/q_1$), one has that

$$\|x_{\mathcal{I}_*^c}\|_{q_2} \le \|x_{\mathcal{I}_*}\|_{q_2},$$

that is, $x \in C_{q_2}(s)$. Hence it follows that $C_{q_1}(s) \subseteq C_{q_2}(s)$.
(ii) As proved by (i) that $C_{q_1}(s) \subseteq C_{q_2}(s)$, by the definition of q-REC, it follows that

$$\phi_{q_1}(s,t) \ge \phi_{q_2}(s,t) > 0.$$

The proof is complete. ■

To the best of our knowledge, this is the first work on introducing the lower-order REC and establishing the relationship of the lower-order RECs. In the following, we provide a counter example to show that the reverse of Proposition 5 is not true.

Example 1 (A matrix satisfying 1/2-REC but not REC) *Consider the matrix*

$$A := \begin{pmatrix} a & a+c & a-c \\ \tilde{a} & \tilde{a}-\tilde{c} & \tilde{a}+\tilde{c} \end{pmatrix} \in \mathbb{R}^{2\times 3},$$

where $a > c > 0$ and $\tilde{a} > \tilde{c} > 0$. This matrix A does not satisfy the REC$(1,1)$. Indeed, by letting $\mathcal{J} = \{1\}$ and $x = (2,-1,-1)^\top$, we have $Ax = 0$ and thus $\phi(1,1) = 0$.

Below, we claim that A satisfies the 1/2-REC$(1,1)$. It suffices to show that $\phi_{1/2}(1,1) > 0$. Let $x = (x_1,x_2,x_3)^\top$ satisfy the constraint associated with 1/2-REC$(1,1)$. As $s = 1$, the deduction is divided into the following three cases.

(i) *$\mathcal{J} = \{1\}$. Then*

$$|x_1| \ge \|x_{\mathcal{J}^c}\|_{1/2} = |x_2| + |x_3| + 2|x_2|^{1/2}|x_3|^{1/2}. \tag{12}$$

Without loss of generality, we assume $|x_1| \ge |x_2| \ge |x_3|$. Hence, $\mathcal{T} = \{1,2\}$ and

$$\frac{\|Ax\|_2}{\|x_{\mathcal{T}}\|_2} \ge \frac{\min\{a,\tilde{a}\}|x_1 + x_2 + x_3| + \min\{c,\tilde{c}\}|x_2 - x_3|}{|x_1| + |x_2|}. \tag{13}$$

If $|x_2| \le \frac{1}{3}|x_1|$, (13) reduces to

$$\frac{\|Ax\|_2}{\|x_{\mathcal{T}}\|_2} \ge \frac{\frac{\min\{a,\tilde{a}\}}{3}|x_1|}{\frac{4}{3}|x_1|} = \frac{\min\{a,\tilde{a}\}}{4}. \tag{14}$$

If $|x_2| \ge \frac{1}{3}|x_1|$, substituting (12) into (13), one has that

$$\frac{\|Ax\|_2}{\|x_{\mathcal{T}}\|_2} \ge \begin{cases} \frac{\min\{c,\tilde{c}\}}{8}, & |x_3| \le \frac{1}{2}|x_2|, \\ \frac{\min\{a,\tilde{a}\}}{4}, & |x_3| \ge \frac{1}{2}|x_2|. \end{cases} \tag{15}$$

(ii) *$\mathcal{J} = \{2\}$. Since $\mathcal{T} = \{2,1\}$ or $\{2,3\}$, it follows from Huang and Yang (2003, lem. 4.1) that*

$$|x_2| \ge \|x_{\mathcal{J}^c}\|_{1/2} \ge |x_1| + |x_3|. \tag{16}$$

Thus, it is easy to verify that $\|x_{\mathcal{T}}\|_2 \le 2|x_2|$ and that

$$\frac{\|Ax\|_2}{\|x_{\mathcal{T}}\|_2} \ge \frac{|ax_1 + (a+c)x_2 + (a-c)x_3|}{2|x_2|} = \frac{|a(x_1 + x_2 + \frac{a-c}{a}x_3) + cx_2|}{2|x_2|} \ge \frac{c}{2}, \tag{17}$$

where the last inequality follows from (16) and the fact that $a > c$.

(iii) $\mathcal{J}=\{3\}$. *Similar to the deduction of* (ii)*, one has that*

$$\frac{\|Ax\|_2}{\|x_\mathcal{T}\|_2}\geq\frac{|\tilde{a}x_1+(\tilde{a}-\tilde{c})x_2+(\tilde{a}+\tilde{c})x_3|}{2|x_3|}\geq\frac{\tilde{c}}{2}. \tag{18}$$

Therefore, by (14)-(15) *and* (17)-(18)*, we conclude that* $\phi_{1/2}(1,1)\geq\frac{1}{8}\min\{c,\tilde{c}\}>0$*, and thus, the matrix* A *satisfies the* $1/2$*-REC*$(1,1)$.

In order to establish the oracle property and the global recovery bound for the $\ell_{p,q}$ regularization problem, we further introduce the notion of group restricted eigenvalue condition (GREC). Given $S\leq N\ll r$, $x\in\mathbb{R}^n$ and $\mathcal{J}\subseteq\{1,\ldots,r\}$, we use $\mathrm{rank}_i(x)$ to denote the rank of $\|x_{\mathcal{G}_i}\|_p$ among $\{\|x_{\mathcal{G}_j}\|_p: j\in\mathcal{J}^c\}$ (in a decreasing order), $\mathcal{J}(x;N)$ to denote the index set of the first N largest groups in the value of $\|x_{\mathcal{G}_i}\|_p$ among $\{\|x_{\mathcal{G}_j}\|_p: j\in\mathcal{J}^c\}$, that is,

$$\mathcal{J}(x;N):=\{i\in\mathcal{J}^c:\mathrm{rank}_i(x)\in\{1,\ldots,N\}\}.$$

Furthermore, by letting $R:=\lceil\frac{r-|\mathcal{J}|}{N}\rceil$, we denote

$$\mathcal{J}_k(x;N):=\begin{cases}\{i\in\mathcal{J}^c:\mathrm{rank}_i(x)\in\{kN+1,\ldots,(k+1)N\}\}, & k=1,\ldots,R-1,\\ \{i\in\mathcal{J}^c:\mathrm{rank}_i(x)\in\{RN+1,\ldots,r-|\mathcal{J}|\}\}, & k=R.\end{cases} \tag{19}$$

Note that the residual $\hat{x}:=x^*(\ell_{p,q})-\bar{x}$ of the $\ell_{p,q}$ regularization problem always satisfies $\|\hat{x}_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}\leq\|\hat{x}_{\mathcal{G}_\mathcal{S}}\|_{p,q}$. Thus we introduce the notion of GREC, where the minimum is taken over a restricted set measured by an $\ell_{p,q}$ norm inequality, as follows.

Definition 6 *Let* $0<q\leq p\leq 2$*. The* (p,q)*-group restricted eigenvalue condition relative to* (S,N) *(*(p,q)*-GREC*(S,N)*) is said to be satisfied if*

$$\phi_{p,q}(S,N):=\min\left\{\frac{\|Ax\|_2}{\|x_{\mathcal{G}_\mathcal{N}}\|_{p,2}}:|\mathcal{J}|\leq S,\|x_{\mathcal{G}_{\mathcal{J}^c}}\|_{p,q}\leq\|x_{\mathcal{G}_\mathcal{J}}\|_{p,q},\mathcal{N}=\mathcal{J}(x;N)\cup\mathcal{J}\right\}>0.$$

The (p,q)-GREC extends the q-REC to the setting equipping with a pre-defined group structure. Handling the components in each group as one element, the (p,q)-GREC admits the fewer degree of freedom, which is S (about $s/n_{\max}$), on its associated constraint than that of the q-REC, and thus it characterizes a weaker condition than the q-REC. For example, the 0-REC(s,s) is to indicate the restricted positive definiteness of $A^\top A$, which is valid only for the vectors whose cardinality is less than $2s$; while the $(p,0)$-GREC(S,S) is to describe the restricted positive definiteness of $A^\top A$ on any $2S$-group support, whose degree of freedom is much less than the $2s$-support. Thus the $(p,0)$-GREC(S,S) provides a broader condition than the 0-REC(s,s). Similar to the proof of Proposition 5, we can show that if $0\leq q_1\leq q_2\leq 1\leq p\leq 2$ and the (p,q_2)-GREC(S,N) holds, then the (p,q_1)-GREC(S,N) also holds.

We end this subsection by providing the following lemma, which will be useful in establishing the global recovery bound for the $\ell_{p,q}$ regularization problem in Theorem 9.

Lemma 7 *Let* $0<q\leq 1\leq p$*,* $\tau\geq 1$ *and* $x\in\mathbb{R}^n$*,* $\mathcal{N}:=\mathcal{J}(x;N)\cup\mathcal{J}$ *and* $\mathcal{J}_k:=\mathcal{J}_k(x;N)$ *for* $k=1,\ldots,R$*. Then the following inequalities hold*

$$\|x_{\mathcal{G}_{\mathcal{N}^c}}\|_{p,\tau}\leq\sum_{k=1}^R\|x_{\mathcal{G}_{\mathcal{J}_k}}\|_{p,\tau}\leq N^{\frac{1}{\tau}-\frac{1}{q}}\|x_{\mathcal{G}_{\mathcal{J}^c}}\|_{p,q}.$$

Proof By the definition of $\mathcal{J}_k$ (19), for each $j\in\mathcal{J}_k$, one has that

$$\|x_{\mathcal{G}_j}\|_p\leq\|x_{\mathcal{G}_i}\|_p,\quad\text{for each } i\in\mathcal{J}_{k-1},$$

and thus

$$\|x_{\mathcal{G}_j}\|_p^q\leq\frac{1}{N}\sum_{i\in\mathcal{J}_{k-1}}\|x_{\mathcal{G}_i}\|_p^q=\frac{1}{N}\|x_{\mathcal{G}_{\mathcal{J}_{k-1}}}\|_{p,q}^q.$$

Consequently, we obtain that

$$\|x_{\mathcal{G}_{\mathcal{J}_k}}\|_{p,\tau}^\tau=\sum_{i\in\mathcal{J}_k}\|x_{\mathcal{G}_i}\|_p^\tau\leq N^{1-\tau/q}\|x_{\mathcal{G}_{\mathcal{J}_{k-1}}}\|_{p,q}^\tau.$$

Further by Huang and Yang (2003, lem. 4.1) ($\tau\geq 1$ and $q\leq 1$), it follows that

$$\begin{aligned}\|x_{\mathcal{G}_{\mathcal{N}^c}}\|_{p,\tau}&=\left(\textstyle\sum_{k=1}^R\sum_{i\in\mathcal{J}_k}\|x_{\mathcal{G}_i}\|_p^\tau\right)^{1/\tau}\\&\leq\textstyle\sum_{k=1}^R\|x_{\mathcal{G}_{\mathcal{J}_k}}\|_{p,\tau}\\&\leq N^{\frac{1}{\tau}-\frac{1}{q}}\textstyle\sum_{k=1}^R\|x_{\mathcal{G}_{\mathcal{J}_{k-1}}}\|_{p,q}\\&\leq N^{\frac{1}{\tau}-\frac{1}{q}}\|x_{\mathcal{G}_{\mathcal{J}^c}}\|_{p,q}.\end{aligned}$$

The proof is complete. ■

2.3 Global Recovery Bound

In recent years, many articles have been devoted to establishing the oracle property and the global recovery bound for the ℓ_1 regularization problem (1) under the RIP or REC; see Bickel et al. (2009); Meinshausen and Yu (2009); van de Geer and Bühlmann (2009); Zhang (2009). However, to the best of our knowledge, there is few paper devoted to investigating these properties for the lower-order regularization problem.

In the preceding subsections, we have introduced the general notion of (p,q)-GREC. Under the (p,q)-GREC(S,S), the solution of $Ax=b$ with group sparsity being S is unique. In this subsection, we will present the oracle property and the global recovery bound for the $\ell_{p,q}$ regularization problem (4) under the (p,q)-GREC. The oracle property provides an upper bound on the squares error of the linear system and the violation of the true nonzero groups for each point in the level set of the objective function of problem (4)

$$\mathrm{lev}_F(\bar{x}):=\{x\in\mathbb{R}^n:\|Ax-b\|_2^2+\lambda\|x\|_{p,q}^q\leq\lambda\|\bar{x}\|_{p,q}^q\}.$$

Proposition 8 *Let* $0<q\leq 1\leq p$*,* $S>0$ *and let the* (p,q)*-GREC*(S,S) *hold. Let* $\bar{x}$ *be the unique solution of* $Ax=b$ *at a group sparsity level* S*, and* $\mathcal{S}$ *be the index set of nonzero groups of* $\bar{x}$*. Let* K *be the smallest integer such that* $2^{K-1}q\geq 1$*. Then, for any* $x^*\in\mathrm{lev}_F(\bar{x})$*, the following oracle inequality holds*

$$\|Ax^*-A\bar{x}\|_2^2+\lambda\|x^*_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^q\leq\lambda^{\frac{2}{2-q}}S^{\left(1-2^{-K}\right)\frac{2}{2-q}}/\phi_{p,q}^{\frac{2q}{2-q}}(S,S). \tag{20}$$

Moreover, letting $\mathcal{N}_*:=\mathcal{S}\cup\mathcal{S}(x^*;S)$*, we have*

$$\|x^*_{\mathcal{G}_{\mathcal{N}_*}}-\bar{x}_{\mathcal{G}_{\mathcal{N}_*}}\|_{p,2}^2\leq\lambda^{\frac{2}{2-q}}S^{\left(1-2^{-K}\right)\frac{2}{2-q}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S).$$

Proof Let $x^* \in \mathrm{lev}_F(\bar{x})$. That is, $\|Ax^* - b\|_2^2 + \lambda\|x^*\|_{p,q}^q \le \lambda\|\bar{x}\|_{p,q}^q$. By Lemmas 1(ii) and 2, one has that

$$\begin{aligned} \|Ax^* - A\bar{x}\|_2^2 + \lambda\|x^*_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^q &\le \lambda\|\bar{x}_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q - \lambda\|x^*_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q \\ &\le \lambda\|\bar{x}_{\mathcal{G}_{\mathcal{S}}} - x^*_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q \\ &\le \lambda S^{1-2^{-K}}\|\bar{x}_{\mathcal{G}_{\mathcal{S}}} - x^*_{\mathcal{G}_{\mathcal{S}}}\|_{p,2}^q. \end{aligned} \tag{21}$$

Noting that

$$\|x^*_{\mathcal{G}_{\mathcal{S}^c}} - \bar{x}_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^q - \|x^*_{\mathcal{G}_{\mathcal{S}}} - \bar{x}_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q \le \|x^*_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^q - (\|\bar{x}_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q - \|x^*_{\mathcal{G}_{\mathcal{S}}}\|_{p,q}^q) = \|x^*\|_{p,q}^q - \|\bar{x}\|_{p,q}^q \le 0.$$

Then the (p,q)-GREC(S,S) implies that

$$\|\bar{x}_{\mathcal{G}_{\mathcal{S}}} - x^*_{\mathcal{G}_{\mathcal{S}}}\|_{p,2} \le \|Ax^* - A\bar{x}\|_2/\phi_{p,q}(S,S).$$

This, together with (21), yields that

$$\|Ax^* - A\bar{x}\|_2^2 + \lambda\|x^*_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^q \le \lambda S^{1-2^{-K}}\|Ax^* - A\bar{x}\|_2^q/\phi_{p,q}^q(S,S), \tag{22}$$

and consequently,

$$\|Ax^* - A\bar{x}\|_2 \le \lambda^{\frac{1}{2-q}} S^{\left(1-2^{-K}\right)/(2-q)}/\phi_{p,q}^{\frac{q}{2-q}}(S,S). \tag{23}$$

Therefore, by (22) and (23), we arrive at the oracle inequality (20). Furthermore, by the definition of $\mathcal{N}_*$, the (p,q)-GREC(S,S) implies that

$$\|x^*_{\mathcal{G}_{\mathcal{N}_*}} - \bar{x}_{\mathcal{G}_{\mathcal{N}_*}}\|_{p,2}^2 \le \|Ax^* - A\bar{x}\|_2^2/\phi_{p,q}^2(S,S) \le \lambda^{\frac{2}{2-q}} S^{\left(1-2^{-K}\right)\frac{2}{2-q}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S).$$

The proof is complete. ■

One of the main results of this section is presented as follows, where we establish the global recovery bound for the $\ell_{p,q}$ regularization problem under the (p,q)-GREC. We will apply oracle inequality (20) and Lemma 7 in our proof.

Theorem 9 *Let $0 < q \le 1 \le p \le 2$, $S > 0$ and let the (p,q)-GREC(S,S) hold. Let $\bar{x}$ be the unique solution of $Ax = b$ at a group sparsity level S, and $\mathcal{S}$ be the index set of nonzero groups of $\bar{x}$. Let K be the smallest integer such that $2^{K-1}q \ge 1$. Then, for any $x^* \in \mathrm{lev}_F(\bar{x})$, the following global recovery bound for problem* (4) *holds*

$$\|x^* - \bar{x}\|_2^2 \le 2\lambda^{\frac{2}{2-q}} S^{\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S). \tag{24}$$

More precisely,

$$\|x^* - \bar{x}\|_2^2 \le \begin{cases} \mathcal{O}(\lambda^{\frac{2}{2-q}} S), & 2^{K-1}q = 1, \\ \mathcal{O}(\lambda^{\frac{2}{2-q}} S^{\frac{3-q}{2-q}}), & 2^{K-1}q > 1. \end{cases} \tag{25}$$

Proof Let $\mathcal{N}_* := \mathcal{S} \cup \mathcal{S}(x^*; S)$ as in Proposition 8. Since $p \le 2$, it follows from Lemma 7 and Proposition 8 that

$$\|x^*_{\mathcal{G}_{\mathcal{N}_*^c}}\|_2^2 \le \|x^*_{\mathcal{G}_{\mathcal{N}_*^c}}\|_{p,2}^2 \le S^{1-2/q}\|x^*_{\mathcal{G}_{\mathcal{S}^c}}\|_{p,q}^2 \le \lambda^{\frac{2}{2-q}} S^{\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S).$$

Then by Proposition 8, one has that

$$\begin{aligned} \|x^* - \bar{x}\|_2^2 &= \|x^*_{\mathcal{G}_{\mathcal{N}_*}} - \bar{x}_{\mathcal{G}_{\mathcal{N}_*}}\|_2^2 + \|x^*_{\mathcal{G}_{\mathcal{N}_*^c}}\|_2^2 \\ &\le \lambda^{\frac{2}{2-q}} S^{\left(1-2^{-K}\right)\frac{2}{2-q}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S) + \lambda^{\frac{2}{2-q}} S^{\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S) \\ &\le 2\lambda^{\frac{2}{2-q}} S^{\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)}}/\phi_{p,q}^{\frac{4}{2-q}}(S,S), \end{aligned}$$

where the last inequality follows from the fact that $2^{K-1}q \ge 1$. This proves (24). In particular, if $2^{K-1}q = 1$, then $\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)} = 1$ and thus

$$\|x^* - \bar{x}\|_2^2 \le \mathcal{O}(\lambda^{\frac{2}{2-q}} S).$$

If $2^{K-1}q > 1$, then $2^{K-2}q < 1$. Hence, $\frac{q-2}{q} + \left(1-2^{-K}\right)\frac{4}{q(2-q)} < \frac{3-q}{2-q}$, and consequently

$$\|x^* - \bar{x}\|_2^2 \le \mathcal{O}(\lambda^{\frac{2}{2-q}} S^{\frac{3-q}{2-q}}).$$

Hence (25) is obtained. The proof is complete. ■

The global recovery bound (25) is deduced under general (p,q)-GREC(S,S), which is weaker than the REC as used in van de Geer and Bühlmann (2009). It shows that the sparse solution $\bar{x}$ may be recovered by any point x^* in the level set $\mathrm{lev}_F(\bar{x})$, in particular, when x^* is a global optimal solution of problem (4), as long as λ is sufficiently small. It is well-known that when $p = 2$ and $q = 1$, convex regularization problem (4) is numerically intractable for finding the sparse solution and that when $q < 1$ finding a point in the nonconvex level set $\mathrm{lev}_F(\bar{x})$ is equivalent to finding a global minimum of minimizing the indicator function of the nonconvex level set, which is NP-hard. Thus Theorem 9 is only a theoretical result and does not provide any insight for the numerical computation of a sparse solution by virtue of problem (4). We will design a proximal gradient method in section 3, test its numerical efficiency and provide some general guidance on which q is more attractive in practical applications in section 4.

To conclude this subsection, we illustrate by an example in which (24) does not hold when $q = 1$, but it does and is also tight when $q = \frac{1}{2}$. We will testify the recovery bound $\mathcal{O}(\lambda^{4/3}S)$ in (24) when $q = \frac{1}{2}$ by using a global optimization method.

Example 2 *By letting $a = \tilde{a} = 2$ and $c = \tilde{c} = 1$ in Example 1, we consider the following matrix:*

$$A := \begin{pmatrix} 2 & 3 & 1 \\ 2 & 1 & 3 \end{pmatrix}.$$

We set $b := (2,2)^\top$ and then a true solution of $Ax = b$ is $\bar{x} := (1,0,0)^\top$. Denoting $x := (x_1, x_2, x_3)^\top$, the objective function associated with the ℓ_1 regularization problem (1) *is*

$$\begin{aligned} F(x) &:= \|Ax - b\|_2^2 + \lambda\|x\|_1 \\ &= (2x_1 + 3x_2 + x_3 - 2)^2 + (2x_1 + x_2 + 3x_3 - 2)^2 + \lambda(|x_1| + |x_2| + |x_3|). \end{aligned}$$

Let $x^*(\ell_1) := (x_1^*, x_2^*, x_3^*)^\top$ *be an optimal solution of problem* (1). *Without loss of generality, we assume* $\lambda \le 1$. *The necessary condition of* $x^*(\ell_1)$ *being an optimal solution of problem* (1) *is* $0 \in \partial F(x^*(\ell_1))$, *that is,*

$$0 \in 16x_1^* + 16x_2^* + 16x_3^* - 16 + \lambda\partial|x_1^*|, \tag{26a}$$
$$0 \in 16x_1^* + 20x_2^* + 12x_3^* - 16 + \lambda\partial|x_2^*|, \tag{26b}$$
$$0 \in 16x_1^* + 12x_2^* + 20x_3^* - 16 + \lambda\partial|x_3^*|, \tag{26c}$$

where $\partial|\mu| := \begin{cases} sign(\mu), & \mu \neq 0, \\ [-1,1], & \mu = 0. \end{cases}$

We first show that $x_i^* \ge 0$ *for* $i = 1, 2, 3$ *by contradiction. Indeed, if* $x_1^* < 0$, (26a) *reduces to*

$$16x_1^* + 16x_2^* + 16x_3^* - 16 = \lambda.$$

Summing (26b) *and* (26c), *we further have*

$$\lambda = 16x_1^* + 16x_2^* + 16x_3^* - 16 \in -\frac{\lambda}{2}(\partial|x_2^*| + \partial|x_3^*|),$$

which implies that $x_2^* \le 0$ *and* $x_3^* \le 0$. *Hence, it follows that* $F(x^*) > F(0)$, *which indicates that* x^* *is not an optimal solution of problem* (1), *and thus,* $x_1^* < 0$ *is impossible. Similarly, we can show that* $x_2^* \ge 0$ *and* $x_3^* \ge 0$.

Next, we find the optimal solution $x^*(\ell_1)$ *by only considering* $x^*(\ell_1) \ge 0$. *It is easy to obtain that the solution of* (26) *and the corresponding objective value associated with problem* (1) *can be represented respectively by*

$$x_1^* = 1 - \frac{\lambda}{16} - 2x_3^*, \quad x_2^* = x_3^* \left(0 \le x_3^* \le \frac{1}{2} - \frac{\lambda}{32}\right), \quad \text{and} \quad F\left(x^*(\ell_1)\right) = \lambda - \frac{\lambda^2}{32}.$$

Hence, $x^*(\ell_1) := \left(0, \frac{1}{2} - \frac{\lambda}{32}, \frac{1}{2} - \frac{\lambda}{32}\right)^\top$ *is an optimal solution of problem* (1). *The estimated error for this* $x^*(\ell_1)$ *is*

$$\|x^*(\ell_1) - \bar{x}\|_2^2 = 1 + \frac{1}{2}\left(1 - \frac{\lambda}{16}\right)^2 > 1,$$

which does not meet the recovery bound (25) *for any* $\lambda \le 1$.

It is revealed from Example 1 that this matrix A *satisfies the* $1/2$*-REC*$(1,1)$. *Then the hypothesis of Theorem 9 is verified, and thus, Theorem 9 is applicable to establishing the recovery bound* (25) *for the* $\ell_{1/2}$ *regularization problem. Although we cannot obtain the closed-form solution of this nonconvex* $\ell_{1/2}$ *regularization problem, as it is of only 3-dimensions, we can apply a global optimization method, the filled function method (Ge, 1990), to find the global optimal solution* $x^*(\ell_{1/2})$ *and thus to testify the recovery bound* (25). *This is done by computing the* $\ell_{1/2}$ *regularization problem for many* λ *to plot the curve* $\|x^*(\ell_{1/2}) - \bar{x}\|_2^2$. *Figure 2 illustrates the variation of the estimated error* $\|x^*(\ell_{1/2}) - \bar{x}\|_2^2$ *and the bound* $2\lambda^{4/3}$ *(that is the right-hand side of* (24), *where* $S = 1$ *and* $\phi_{1/2}(1,1) \le 1$ *(see Example 1)), when varying the regularization parameter* λ *from* 10^{-8} *to* 1. *It is illustrated from Figure 2 the recovery bound* (25) *is satisfied, and it is indeed tight, for this example.*

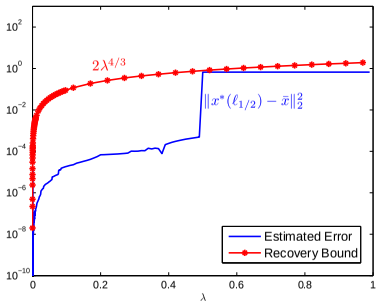


Figure 2: The illustration of the recovery bound (24) and estimated error.

2.4 Local Recovery Bound

In the preceding subsection, we provided the global analysis of the recovery bound for the $\ell_{p,q}$ regularization problem under the (p,q)-GREC; see Theorem 9. One can also observe from Figure 2 that the global recovery bound (25) is tight for the $\ell_{1/2}$ regularization problem as the curves come together at $\lambda \simeq 0.5$, but there is still a big gap for the improvement when λ is small.

This subsection is devoted to providing a local analysis of the recovery bound for the $\ell_{p,q}$ regularization problem by virtue of the variational analysis technique (Rockafellar and Wets, 1998). For $x \in \mathbb{R}^n$ and $\delta \in \mathbb{R}_+$, we use $\mathbf{B}(x,\delta)$ to denote the open ball of radius δ centered at x. For a lower semi-continuous (lsc) function $f : \mathbb{R}^n \to \mathbb{R}$ and $x, w \in \mathbb{R}^n$, the subderivative of f at x along the direction w is defined by

$$df(\bar{x})(w) := \liminf_{\tau \downarrow 0,\, w' \to w} \frac{f(\bar{x} + \tau w') - f(\bar{x})}{\tau}.$$

To begin with, we show in the following lemma a significant advantage of lower-order regularization over the ℓ_1 regularization: the lower-order regularization term can easily induce the sparsity of the local minimum.

Lemma 10 *Let* $0 < q < 1 \le p$. *Let* $f : \mathbb{R}^n \to \mathbb{R}$ *be a lsc function satisfying* $df(0)(0) = 0$. *Then the function* $F := f + \lambda\|\cdot\|_{p,q}^q$ *has a local minimum at* 0 *with the first-order growth condition being fulfilled, that is, there exist some* $\epsilon > 0$ *and* $\delta > 0$ *such that*

$$F(x) \ge F(0) + \epsilon\|x\|_2 \quad \text{for any } x \in \mathbf{B}(0,\delta).$$

Proof Let $\varphi := \lambda\|\cdot\|_{p,q}^q$ and then $F = f + \varphi$. Since φ is grouped separable, by Rockafellar and Wets (1998, prop. 10.5), it follows from the definition that $d\varphi(0) = \delta_{\{0\}}$, where δ_X is the indicator function of X. Applying Rockafellar and Wets (1998, prop. 10.9), it follows that

$$dF(0) \ge df(0) + d\varphi(0) = df(0) + \delta_{\{0\}}. \tag{27}$$

By the assumption that f is finite and $df(0)(0) = 0$, its subderivative $df(0)$ is proper (see Rockafellar and Wets, 1998, ex. 3.19). Noting that $df(0)(0) = 0$, we obtain that $df(0) + \delta_{\{0\}} = \delta_{\{0\}}$. This, together with (27), yields that $dF(0) \geq \delta_{\{0\}}$. Therefore, by definition, there exist some $\epsilon > 0$ and $\delta > 0$ such that

$$F(x) \geq F(0) + \epsilon\|x\|_2 \quad \text{for any } x \in \mathbf{B}(0, \delta).$$

The proof is complete. ■

With the help of the above lemma, we can present in the following a local version of the recovery bound. This is done by constructing a path of local minima depending on the regularization parameter λ for the regularization problem, which starts from a sparse solution of the original problem and shares the same support as this sparse solution has, resulting in a sharper bound in terms of λ^2.

Theorem 11 *Let $\bar{x}$ be a solution of $Ax = b$, S be the group sparsity of $\bar{x}$, and B be a submatrix of A consisting of its columns corresponding to the active components of $\bar{x}$. Suppose that any nonzero group of $\bar{x}$ is active, and that the columns of A corresponding to the active components of $\bar{x}$ are linearly independent. Let $0 < q < 1 \leq p$. Then there exist $\kappa > 0$ and a path of local minima of problem (4), $x^*(\lambda)$, such that*

$$\|x^*(\lambda) - \bar{x}\|_2^2 \leq \lambda^2 q^2 S \|(B^\top B)^{-1}\|^2 \max_{\bar{x}_{\mathcal{G}_i} \neq 0} \left(\|\bar{x}_{\mathcal{G}_i}\|_p^{2(q-p)} \|\bar{x}_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \right) \quad \textit{for any } \lambda < \kappa.$$

Proof Without loss of generality, we let $\bar{x}$ be of structure $\bar{x} = (\bar{z}^\top, 0)^\top$ with

$$\bar{z} = (\bar{x}_{\mathcal{G}_1}^\top, \ldots, \bar{x}_{\mathcal{G}_S}^\top)^\top \text{ and } \bar{x}_{\mathcal{G}_i} \neq_{\mathbf{a}} 0 \text{ for } i = 1, \ldots, S,$$

and let s be the sparsity of $\bar{x}$. Let $A = (B, D)$ with B being the submatrix involving the first s columns of A (corresponding to the active components of $\bar{x}$). By the assumption, we have that B is of full column rank and thus $B^\top B$ is invertible. In this setting, the linear relation $A\bar{x} = b$ reduces to $B\bar{z} = b$. The proof of this theorem is divided into the following three steps:

(a) construct a smooth path from $\bar{x}$ by the implicit function theorem;

(b) validate that every point of the constructed path is a local minimum of (4); and

(c) establish the recovery bound for the constructed path.

First, to show (a), we define $H : \mathbb{R}^{s+1} \to \mathbb{R}^s$ by

$$H(z, \lambda) = 2B^\top(Bz - b) + \lambda q \begin{pmatrix} \|z_{\mathcal{G}_1}\|_p^{q-p} \sigma(z_{\mathcal{G}_1}) \\ \vdots \\ \|z_{\mathcal{G}_S}\|_p^{q-p} \sigma(z_{\mathcal{G}_S}) \end{pmatrix},$$

where $\sigma(z_{\mathcal{G}_i}) = \text{vector}\left(|z_j|^{p-1}\text{sign}(z_j)\right)_{\mathcal{G}_i}$, denoting a vector consisting of $|z_j|^{p-1}\text{sign}(z_j)$ for all $j \in \mathcal{G}_i$. Let $\bar{\delta} > 0$ be sufficiently small such that $\text{sign}(z) = \text{sign}(\bar{z})$ for any $z \in \mathbf{B}(\bar{z}, \bar{\delta})$

and thus H is smooth on $\mathbf{B}(\bar{z}, \bar{\delta}) \times \mathbb{R}$. Note that $H(\bar{z}, 0) = 0$ and $\frac{\partial H}{\partial z}(\bar{z}, 0) = 2B^\top B$. By the implicit function theorem (Rudin, 1976), there exist some $\kappa > 0$, $\delta \in (0, \bar{\delta})$ and a unique smooth function $\xi : (-\kappa, \kappa) \to \mathbf{B}(\bar{z}, \delta)$ such that

$$\{(z, \lambda) \in \mathbf{B}(\bar{z}, \bar{\delta}) \times (-\kappa, \kappa) : H(z, \lambda) = 0\} = \{(\xi(\lambda), \lambda) : \lambda \in (-\kappa, \kappa)\}, \tag{28}$$

and

$$\frac{d\xi}{d\lambda} = -q \left(2B^\top B + \lambda q \begin{pmatrix} M_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & M_{\mathcal{S}} \end{pmatrix} \right)^{-1} \begin{pmatrix} \|\xi(\lambda)_{\mathcal{G}_1}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_1}) \\ \vdots \\ \|\xi(\lambda)_{\mathcal{G}_S}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_S}) \end{pmatrix}, \tag{29}$$

where M_i for each $i = 1, \ldots, S$ is denoted by

$$M_i = (q-p)\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{q-2p} (\sigma(\xi(\lambda)_{\mathcal{G}_i}))(\sigma(\xi(\lambda)_{\mathcal{G}_i}))^\top + (p-1)\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{q-p} \text{diag}\left(|\xi(\lambda)_j|^{p-2}\right),$$

and $\text{diag}\left(|\xi(\lambda)_j|^{p-2}\right)$ denotes a diagonal matrix generated by vector $\left(|\xi(\lambda)_j|^{p-2}\right)$. Thus, by (28) and (29), we have constructed a smooth path $\xi(\lambda)$ near $\bar{z}$, $\lambda \in (-\kappa, \kappa)$, such that

$$2B^\top(B\xi(\lambda) - b) + \lambda q \begin{pmatrix} \|\xi(\lambda)_{\mathcal{G}_1}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_1}) \\ \vdots \\ \|\xi(\lambda)_{\mathcal{G}_S}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_S}) \end{pmatrix} = 0 \tag{30}$$

and

$$2B^\top B + \lambda q \begin{pmatrix} M_1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & M_{\mathcal{S}} \end{pmatrix} \succ 0. \tag{31}$$

This shows that (a) is done as desired.

For fixed $\lambda \in (-\kappa, \kappa)$, let $x^*(\lambda) := (\xi(\lambda)^\top, 0)^\top$. To verify (b), we prove that $x^*(\lambda)$, with $\xi(\lambda)$ satisfying (30) and (31), is a local minimum of problem (4). Let $h : \mathbb{R}^s \to \mathbb{R}$ be a function with $h(z) := \|Bz - b\|_2^2 + \lambda\|z\|_{p,q}^q$ for any $z \in \mathbb{R}^s$. Note that $h(\xi(\lambda)) = \|Ax^*(\lambda) - b\|_2^2 + \lambda\|x^*(\lambda)\|_{p,q}^q$ and that h is smooth around $\xi(\lambda)$. By noting that $\xi(\lambda)$ satisfies (30) and (31) (the first- and second- derivative of h at $\xi(\lambda)$), one has that h satisfies the second-order growth condition at $\xi(\lambda)$, that is, there exist $\epsilon_\lambda > 0$ and $\delta_\lambda > 0$ such that

$$h(z) \geq h(\xi(\lambda)) + 2\epsilon_\lambda\|z - \xi(\lambda)\|_2^2 \quad \text{for any } z \in \mathbf{B}(\xi(\lambda), \delta_\lambda). \tag{32}$$

In what follows, let $\epsilon_\lambda > 0$ and $\delta_\lambda > 0$ be given as above, and select $\epsilon_0 > 0$ such that

$$\sqrt{\epsilon_\lambda \epsilon_0} - \|B\|\|D\| > 0. \tag{33}$$

According to Lemma 10 (with $\|D \cdot\|_2^2 + 2\langle B\xi(\lambda) - b, D\cdot\rangle - 2\epsilon_0\|\cdot\|_2^2$ in place of f), there exists $\delta_0 > 0$ such that

$$\|Dy\|_2^2 + 2\langle B\xi(\lambda) - b, Dy\rangle - 2\epsilon_0\|y\|_2^2 + \lambda\|y\|_{p,q}^q \geq 0 \quad \text{for any } y \in \mathbf{B}(0, \delta_0). \tag{34}$$

Thus, for each $x := (z, y) \in \mathbf{B}(\xi(\lambda), \delta_\lambda) \times \mathbf{B}(0, \delta_0)$, it follows that

$$\begin{aligned}
&\|Ax - b\|_2^2 + \lambda \|x\|_{p,q}^q \\
&= \|Bz - b + Dy\|_2^2 + \lambda \|z\|_{p,q}^q + \lambda \|y\|_{p,q}^q \\
&= \|Bz - b\|_2^2 + \lambda \|z\|_{p,q}^q + \|Dy\|_2^2 + 2\langle Bz - b, Dy\rangle + \lambda \|y\|_{p,q}^q \\
&= h(z) + \|Dy\|_2^2 + 2\langle B\xi(\lambda) - b, Dy\rangle + \lambda \|y\|_{p,q}^q + 2\langle B(z - \xi(\lambda)), Dy\rangle.
\end{aligned}$$

By (32) and (34), it yields that

$$\begin{aligned}
&\|Ax - b\|_2^2 + \lambda \|x\|_{p,q}^q \\
&\geq h(\xi(\lambda)) + 2\epsilon_\lambda \|z - \xi(\lambda)\|_2^2 + 2\epsilon_0 \|y\|_2^2 + 2\langle B(z - \xi(\lambda)), Dy\rangle \\
&\geq h(\xi(\lambda)) + 4\sqrt{\epsilon_\lambda \epsilon_0} \|z - \xi(\lambda)\|_2 \|y\|_2 - 2\|B\|\|D\|\|z - \xi(\lambda)\|_2 \|y\|_2 \\
&= \|Ax^*(\lambda) - b\|_2^2 + \lambda \|x^*(\lambda)\|_{p,q}^q + 2(2\sqrt{\epsilon_\lambda \epsilon_0} - \|B\|\|D\|) \|z - \xi(\lambda)\|_2 \|y\|_2 \\
&\geq \|Ax^*(\lambda) - b\|_2^2 + \lambda \|x^*(\lambda)\|_{p,q}^q,
\end{aligned}$$

where the last inequality follows from (33). Hence $x^*(\lambda)$ is a local minimum of problem (4), and (b) is verified.

Finally, we check (c) by providing an upper bound on the distance from $\xi(\lambda)$ to $\bar{z}$. By (30), one has that

$$\xi(\lambda) - \bar{z} = -\frac{\lambda q}{2}((B^\top B)^{-1}) \begin{pmatrix} \|\xi(\lambda)_{\mathcal{G}_1}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_1}) \\ \vdots \\ \|\xi(\lambda)_{\mathcal{G}_S}\|_p^{q-p} \sigma(\xi(\lambda)_{\mathcal{G}_S}) \end{pmatrix}. \tag{35}$$

Noting that $\{\xi(\lambda) : \lambda \in (-\kappa, \kappa)\} \subseteq \mathbf{B}(\bar{z}, \bar{\delta})$, without loss of generality, we assume for any $\lambda < \kappa$ that

$$\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{2(q-p)} \leq 2\|\bar{z}_{\mathcal{G}_i}\|_p^{2(q-p)} \quad \text{and} \quad \|\xi(\lambda)_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \leq 2\|\bar{z}_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \quad \text{for } i = 1, \ldots, S$$

(otherwise, we choose a smaller $\bar{\delta}$). Recall that $\sigma(\xi(\lambda)_{\mathcal{G}_i}) = \text{vector}\left(|\xi(\lambda)_j|^{p-1}\text{sign}(\xi(\lambda)_j)\right)_{\mathcal{G}_i}$. We obtain from (35) that

$$\begin{aligned}
\|\xi(\lambda) - \bar{z}\|_2^2 &\leq \tfrac{\lambda^2 q^2}{4} \|(B^\top B)^{-1}\|^2 \textstyle\sum_{i=1}^S \left(\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{2(q-p)} \sum_{j \in \mathcal{G}_i} |\xi(\lambda)_j|^{2p-2} \right) \\
&= \tfrac{\lambda^2 q^2}{4} \|(B^\top B)^{-1}\|^2 \textstyle\sum_{i=1}^S \left(\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{2(q-p)} \|\xi(\lambda)_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \right) \\
&\leq \tfrac{\lambda^2 q^2}{4} \|(B^\top B)^{-1}\|^2 S \max_{i=1,\ldots,S} \left(\|\xi(\lambda)_{\mathcal{G}_i}\|_p^{2(q-p)} \|\xi(\lambda)_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \right) \\
&\leq \lambda^2 q^2 S \|(B^\top B)^{-1}\|^2 \max_{i=1,\ldots,S} \left(\|\bar{z}_{\mathcal{G}_i}\|_p^{2(q-p)} \|\bar{z}_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \right).
\end{aligned}$$

Hence we arrive at that

$$\|x^*(\lambda) - \bar{x}\|_2^2 = \|\xi(\lambda) - \bar{z}\|_2^2 \leq \lambda^2 q^2 S \|(B^\top B)^{-1}\|^2 \max_{\bar{x}_{\mathcal{G}_i} \neq 0} \left(\|\bar{x}_{\mathcal{G}_i}\|_p^{2(q-p)} \|\bar{x}_{\mathcal{G}_i}\|_{2p-2}^{2p-2} \right)$$

for any $\lambda < \kappa$, and the proof is complete. ■

Theorem 11 provides a uniform local recovery bound for all the $\ell_{p,q}$ regularization problems ($0 < q < 1 \leq p$), which is

$$\|x_{p,q}^*(\lambda) - \bar{x}\|_2^2 \leq \mathcal{O}(\lambda^2 S),$$

where $x_{p,q}^*(\lambda)$ is a local optimal solution of problem (4) (near $\bar{x}$). This bound improves the global recovery bound given in Theorem 9 (of order $\mathcal{O}(\lambda^{\frac{2}{2-q}})$) and shares the same one with the $\ell_{p,1}$ regularization problem (group Lasso); see Blumensath and Davies (2008); van de Geer and Bühlmann (2009). It is worth noting that our proof technique is not working when $q = 1$ as Lemma 10 fails in this case.

3. Proximal Gradient Method for Group Sparse Optimization

Many efficient algorithms have been proposed to solve sparse optimization problems, and one of the most popular optimization algorithms is the proximal gradient method (PGM); see Beck and Teboulle (2009); Combettes and Wajs (2005); Xiao and Zhang (2013) and references therein. It was reported in Combettes and Wajs (2005) that the PGM for solving the ℓ_1 regularization problem (1) reduces to the well-known iterative soft thresholding algorithm (ISTA), and that the ISTA has a local linear convergence rate under some assumptions; see Bredies and Lorenz (2008); Hale et al. (2008); Tao et al. (2016). Recently, the global convergence of the PGM for solving some types of nonconvex regularization problems have been studied under the framework of the Kurdyka-Łojasiewicz theory (Attouch et al., 2010; Bolte et al., 2013), the majorization-minimization scheme (Mairal, 2013), the coordinate gradient descent method (Tseng and Yun, 2009), the general iterative shrinkage and thresholding (Gong et al., 2013) and the successive upper-bound minimization approach (Razaviyayn et al., 2013).

In this section, we apply the PGM to solve the group sparse optimization problem (4) (PGM-GSO), which is stated as follows.

Algorithm 1 (PGM-GSO) *Select a stepsize v, start with an initial point $x_0 \in \mathbb{R}^n$, and generate a sequence $\{x^k\} \subseteq \mathbb{R}^n$ via the iteration*

$$z^k = x^k - 2vA^\top(Ax^k - b), \tag{36}$$

$$x^{k+1} \in \arg\min_{x \in \mathbb{R}^n} \left\{ \lambda \|x\|_{p,q}^q + \frac{1}{2v} \|x - z^k\|_2^2 \right\}. \tag{37}$$

Global convergence of the PGM-GSO falls in the framework of the Kurdyka-Łojasiewicz theory (see Attouch et al., 2010). In particular, following from Bolte et al. (2013, prop. 3), the sequence generated by the PGM-GSO converges to a critical point, especially a global minimum when $q \geq 1$ and a local minimum when $q = 0$ (inspired by the idea in Blumensath and Davies, 2008), as summarized as follows.

Theorem 12 *Let $p \geq 1$, and let $\{x^k\}$ be a sequence generated by the PGM-GSO with $v < \frac{1}{2}\|A\|_2^{-2}$. Then the following statements hold:*

(i) *if $q \geq 1$, then $\{x^k\}$ converges to a global minimum of problem (4),*

(ii) *if $q = 0$, then $\{x^k\}$ converges to a local minimum of problem* (4)*, and*

(iii) *if $0 < q < 1$, then $\{x^k\}$ converges to a critical point* [1] *of problem* (4).

Although the global convergence of the PGM-GSO has been provided in Theorem 12, some important issues of the PGM-GSO have not been discovered yet. The section is to continue the development of the PGM-GSO, concentrating on its efficiency and applicability. In particular, we will establish the local convergence rate of the PGM-GSO under some mild conditions, and derive the analytical solutions of subproblem (37) for some specific p and q.

3.1 Local Linear Convergence Rate

In this subsection, we establish the local linear convergence rate of the PGM-GSO for the case when $p = 1$ and $0 < q < 1$. For the reminder of this subsection, we always assume that $p = 1$ and $0 < q < 1$.

To begin with, by virtue of the second-order necessary condition of subproblem (37), the following lemma provides a lower bound for nonzero groups of sequence $\{x^k\}$ generated by the PGM-GSO and shows that the index set of nonzero groups of $\{x^k\}$ maintains constant for large k.

Lemma 13 *Let $K = (v\lambda q(1-q))^{\frac{1}{2-q}}$, and let $\{x^k\}$ be a sequence generated by the PGM-GSO with $v < \frac{1}{2}\|A\|_2^{-2}$. Then the following statements hold:*

(i) *For any i and k, if $x^k_{\mathcal{G}_i} \neq 0$, then $\|x^k_{\mathcal{G}_i}\|_1 \geq K$.*

(ii) *x^k shares the same index set of nonzero groups for large k, that is, there exist $N \in \mathbb{N}$ and $\mathcal{I} \subseteq \{1, \ldots, r\}$ such that*

$$\begin{cases} x^k_{\mathcal{G}_i} \neq 0, & i \in \mathcal{I}, \\ x^k_{\mathcal{G}_i} = 0, & i \notin \mathcal{I}, \end{cases} \quad \text{for all } k \geq N.$$

Proof (i) For each group $x^k_{\mathcal{G}_i}$, by (37), one has that

$$x^k_{\mathcal{G}_i} \in \underset{x \in \mathbb{R}^{n_i}}{\arg\min} \left\{ \lambda \|x\|_1^q + \frac{1}{2v}\|x - z^{k-1}_{\mathcal{G}_i}\|_2^2 \right\}. \tag{38}$$

If $x^k_{\mathcal{G}_i} \neq 0$, we define $\mathcal{A}_i^k := \{j \in \mathcal{G}_i : x_j^k \neq 0\}$ and $a_i^k := |\mathcal{A}_i^k|$. Without loss of generality, we assume that the first a_i^k components of $x^k_{\mathcal{G}_i}$ are nonzeros. Then (38) implies that

$$x^k_{\mathcal{G}_i} \in \underset{x \in \mathbb{R}^{a_i^k} \times \{0\}}{\arg\min} \left\{ \lambda \|x\|_1^q + \frac{1}{2v}\|x - z^{k-1}_{\mathcal{G}_i}\|_2^2 \right\}.$$

Its second-order necessary condition says that

$$\frac{1}{v} I_i^k + \lambda q(q-1) M_i^k \succeq 0,$$

1. A point x is said to be a critical point of F if 0 belongs to its limiting subdifferential at x; see Mordukhovich (2006).

where I_i^k is the identity matrix in $R^{a_i^k \times a_i^k}$ and $M_i^k = \|x^k_{\mathcal{A}_i^k}\|_1^{q-2}(\mathrm{sign}(x^k_{\mathcal{A}_i^k}))(\mathrm{sign}(x^k_{\mathcal{A}_i^k}))^\top$. Let e be the first column of I_i^k. Then, we obtain that

$$\frac{1}{v} e^\top I_i^k e + \lambda q(q-1) e^\top M_i^k e \geq 0,$$

that is,

$$\frac{1}{v} + \lambda q(q-1)\|x^k_{\mathcal{A}_i^k}\|_1^{q-2} \geq 0.$$

Consequently, it implies that

$$\|x^k_{\mathcal{G}_i}\|_1 = \|x^k_{\mathcal{A}_i^k}\|_1 \geq (v\lambda q(1-q))^{\frac{1}{2-q}} = K.$$

Hence, it completes the proof of (i).
(ii) Recall from Theorem 12 that $\{x^k\}$ converges to a critical point x^*. Then there exists $N \in \mathbb{N}$ such that $\|x^k - x^*\|_2 < \frac{K}{2\sqrt{n}}$, and thus,

$$\|x^{k+1} - x^k\|_2 \leq \|x^{k+1} - x^*\|_2 + \|x^k - x^*\|_2 < \frac{K}{\sqrt{n}}, \tag{39}$$

for any $k \geq N$. Proving by contradiction, without loss of generality, we assume that there exist $k \geq N$ and $i \in \{1, \ldots, r\}$ such that $x^{k+1}_{\mathcal{G}_i} \neq 0$ and $x^k_{\mathcal{G}_i} = 0$. Then it follows from (i) that

$$\|x^{k+1} - x^k\|_2 \geq \frac{1}{\sqrt{n}}\|x^{k+1} - x^k\|_1 \geq \frac{1}{\sqrt{n}}\|x^{k+1}_{\mathcal{G}_i} - x^k_{\mathcal{G}_i}\|_1 \geq \frac{K}{\sqrt{n}},$$

which yields a contradiction with (39). The proof is complete. ■

Let $x^* \in \mathbb{R}^n$, and let

$$\mathcal{S} := \left\{ i \in \{1, \ldots, r\} : x^*_{\mathcal{G}_i} \neq 0 \right\} \quad \text{and} \quad B := (A_{\cdot j})_{j \in \mathcal{G}_\mathcal{S}}.$$

Consider the following restricted problem

$$\min_{y \in \mathbb{R}^{n_\mathbf{a}}} \quad f(y) + \varphi(y), \tag{40}$$

where $n_\mathbf{a} := \sum_{i \in \mathcal{S}} n_i$, and

$$f : \mathbb{R}^{n_\mathbf{a}} \to \mathbb{R} \quad \text{with} \quad f(y) := \|By - b\|_2^2 \quad \text{for any } y \in \mathbb{R}^{n_\mathbf{a}},$$

$$\varphi : \mathbb{R}^{n_\mathbf{a}} \to \mathbb{R} \quad \text{with} \quad \varphi(y) := \lambda\|y\|_{1,q}^q \quad \text{for any } y \in \mathbb{R}^{n_\mathbf{a}}.$$

The following lemma provides the first- and second-order conditions for a local minimum of the $\ell_{1,q}$ regularization problem, and shows a second-order growth condition for the restricted problem (40), which is useful for establishing the local linear convergence rate of the PGM-GSO.

Lemma 14 *Assume that x^* is a local minimum of problem (4). Suppose that any nonzero group of x^* is active, and the columns of B are linearly independent* [2]*. Then the following statements are true:*

(i) *The following first- and second-order conditions hold*

$$2B^\top(By^*-b)+\lambda q\begin{pmatrix}\|y^*_{\mathcal{G}_1}\|_1^{q-1}\mathrm{sign}(y^*_{\mathcal{G}_1})\\ \vdots\\ \|y^*_{\mathcal{G}_S}\|_1^{q-1}\mathrm{sign}(y^*_{\mathcal{G}_S})\end{pmatrix}=0, \tag{41}$$

and

$$2B^\top B+\lambda q(q-1)\begin{pmatrix}M_1^* & 0 & 0\\ 0 & \ddots & 0\\ 0 & 0 & M_S^*\end{pmatrix}\succ 0, \tag{42}$$

where

$$M_i^*=\|y^*_{\mathcal{G}_i}\|_1^{q-2}\left(\mathrm{sign}(y^*_{\mathcal{G}_i})\right)\left(\mathrm{sign}(y^*_{\mathcal{G}_i})\right)^\top.$$

(ii) *The second-order growth condition holds at y^* for problem (40), that is, there exist $\varepsilon>0$ and $\delta>0$ such that*

$$(f+\varphi)(y)\geq(f+\varphi)(y^*)+\varepsilon\|y-y^*\|_2^2 \quad \textit{for any } y\in\mathbf{B}(y^*,\delta). \tag{43}$$

Proof Without loss of generality, we assume that $\mathcal{S}:=\{1,\ldots,S\}$. By assumption, x^* is of structure $x^*:=(y^{*\top},0)^\top$ with

$$y^*:=(x^{*\top}_{\mathcal{G}_1},\ldots,x^{*\top}_{\mathcal{G}_S})^\top \text{ and } x^*_{\mathcal{G}_i}\neq_{\mathbf{a}}0 \text{ for } i=1,\ldots,S. \tag{44}$$

(i) By (44), one has that $\varphi(\cdot)$ is smooth around y^* with its first- and second-derivatives being

$$\varphi'(y^*)=\lambda q\begin{pmatrix}\|y^*_{\mathcal{G}_1}\|_1^{q-1}\mathrm{sign}(y^*_{\mathcal{G}_1})\\ \vdots\\ \|y^*_{\mathcal{G}_S}\|_1^{q-1}\mathrm{sign}(y^*_{\mathcal{G}_S})\end{pmatrix},$$

and

$$\varphi''(y^*)=\lambda q(q-1)\begin{pmatrix}M_1^* & 0 & 0\\ 0 & \ddots & 0\\ 0 & 0 & M_S^*\end{pmatrix};$$

hence $(f+\varphi)(\cdot)$ is also smooth around y^*. Therefore, we obtain the following first- and second-order necessary conditions of problem (40)

$$f'(y^*)+\varphi'(y^*)=0 \quad\text{and}\quad f''(y^*)+\varphi''(y^*)\succeq 0,$$

2. This assumption is mild, and it holds automatically for the case when $n_{\max}=1$ (see Chen et al., 2010, thm. 2.1).

which are (41) and

$$2B^\top B+\lambda q(q-1)\begin{pmatrix}M_1^* & 0 & 0\\ 0 & \ddots & 0\\ 0 & 0 & M_S^*\end{pmatrix}\succeq 0,$$

respectively. Proving by contradiction, we assume that (42) does not hold, that is, there exists some $w\neq 0$ such that

$$2w^\top B^\top Bw+\lambda q(q-1)\sum_{i=1}^S\left(\|y^*_{\mathcal{G}_i}\|_1^{q-2}\cdot\left(\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)^2\right)=0. \tag{45}$$

By assumption, one has that $B^\top B\succ 0$, and thus it follows from (45) that

$$\left(\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)^2>0 \quad \text{for some } i\in\{1,\ldots,S\}. \tag{46}$$

Let $h:\mathbb{R}\to\mathbb{R}$ with $h(t):=\|B(y^*+tw)-b\|_2^2+\lambda\|y^*+tw\|_p^p$ for any $t\in\mathbb{R}$. Clearly, $h(\cdot)$ has a local minimum at 0, and $h(\cdot)$ is smooth around 0 with its derivatives being

$$h'(0)=2w^\top B^\top(By^*-b)+\lambda q\sum_{i=1}^S\left(\|y^*_{\mathcal{G}_i}\|_1^{q-1}\cdot\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)=0,$$

$$h''(0)=2w^\top B^\top Bw+\lambda q(q-1)\sum_{i=1}^S\left(\|y^*_{\mathcal{G}_i}\|_1^{q-2}\cdot\left(\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)^2\right)=0 \text{ (by (45))},$$

$$h^{(3)}(0)=\lambda q(q-1)(q-2)\sum_{i=1}^S\left(\|y^*_{\mathcal{G}_i}\|_1^{q-3}\cdot\left(\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)^3\right)=0,$$

$$h^{(4)}(0)=\lambda q(q-1)(q-2)(q-3)\sum_{i=1}^S\left(\|y^*_{\mathcal{G}_i}\|_1^{q-4}\cdot\left(\sum_{j\in\mathcal{G}_i}w_j\mathrm{sign}(y^*_j)\right)^4\right)<0; \tag{47}$$

due to (46). However, by elementary of calculus, it is clear that $h^{(4)}(0)$ must be nonnegative (since $h(\cdot)$ obtains a local minimum at 0), which yields a contradiction to (47). Therefore, we proved (42).

(ii) By the structure of y^* (44), $\varphi(\cdot)$ is smooth around y^*, and thus, $(f+\varphi)(\cdot)$ is also smooth around y^* with its derivatives being

$$f'(y^*)+\varphi'(y^*)=0 \quad\text{and}\quad f''(y^*)+\varphi''(y^*)\succ 0;$$

due to (41) and (42). Hence (43) follows from Rockafellar and Wets (1998, thm. 13.24). This completes the proof. ■

The key for the study of local convergence rate of the PGM-GSO is the descent property of the function $f+\varphi$ in each iteration step. The following lemma states some basic properties of active groups of sequence $\{x^k\}$ generated by the PGM-GSO.

Lemma 15 *Let $\{x^k\}$ be a sequence generated by the PGM-GSO with $v < \frac{1}{2}\|A\|_2^{-2}$, which converges to x^* (by Theorem 12). Assume that the assumptions in Lemma 14 are satisfied. We define*

$$\alpha := \|B\|_2^2, \quad L := 2\|A\|_2^2 \quad \text{and} \quad D_k := \varphi(y^k) - \varphi(y^{k+1}) + \langle f'(y^k), y^k - y^{k+1}\rangle.$$

Then there exist $\delta > 0$ and $N \in \mathbb{N}$ such that the following inequalities hold for any $k \geq N$:

$$D_k \geq \left(\frac{1}{v} - \alpha\right)\|y^k - y^{k+1}\|_2^2, \tag{48}$$

and

$$(f+\varphi)(y^{k+1}) \leq (f+\varphi)(y^k) - \left(1 - \frac{Lv}{2(1-v\alpha)}\right) D_k. \tag{49}$$

Proof By Lemma 13(ii) and the fact that $\{x^k\}$ converges to x^*, one has that x^k shares the same index set of nonzero groups with that of x^* for large k; further by the structure of y^* (44), we obtain that all components in nonzero groups of y^k are nonzero for large k. In another word, we have

$$\text{there exists } N \in \mathbb{N} \text{ such that } y^k \neq_{\mathbf{a}} 0 \text{ and } x^k_{\mathcal{G}_{\mathcal{S}^c}} = 0 \text{ for any } k \geq N; \tag{50}$$

hence $\varphi(\cdot)$ is smooth around y^k for any $k \geq N$.

In view of PGM-GSO and the decomposition of $x = \left(y^\top, z^\top\right)^\top$, one has that

$$y^{k+1} \in \arg\min\left\{\varphi(y) + \frac{1}{2v}\left\|y - \left(y^k - vf'(y^k)\right)\right\|_2^2\right\}.$$

Its first-order necessary condition is

$$\varphi'(y^{k+1}) = \frac{1}{v}\left(y^k - vf'(y^k) - y^{k+1}\right). \tag{51}$$

Recall from (42) that $\varphi''(y^*) \succ -2B^\top B$. Since $\varphi(\cdot)$ is smooth around y^*, then there exists $\delta > 0$ such that $\varphi''(w) \succ -2B^\top B$ for any $w \in \mathbf{B}(y^*, \delta)$. Noting that $\{y^k\}$ converges to y^*, without loss of generality, we assume that $\|y^k - y^*\| < \delta$ for any $k \geq N$ (otherwise, we can choose a larger N). Therefore, one has that $\varphi''(y^k) \succ -2B^\top B$ for any $k \geq N$. Then by Taylor expansion, we can assume without loss of generality that the following inequality holds for any $k \geq N$ and any $w \in \mathbf{B}(y^*, \delta)$ (otherwise, we can choose a smaller δ):

$$\varphi(w) > \varphi(y^{k+1}) + \langle\varphi'(y^{k+1}), w - y^{k+1}\rangle - \alpha\|w - y^{k+1}\|_2^2.$$

Hence, by (51), it follows that

$$\varphi(w) - \varphi(y^{k+1}) > \frac{1}{v}\langle y^k - vf'(y^k) - y^{k+1}, w - y^{k+1}\rangle - \alpha\|w - y^{k+1}\|_2^2. \tag{52}$$

Then (48) follows by setting $w = y^k$. Furthermore, by the definition of $f(\cdot)$, it is of class $C_L^{1,1}$ and it follows from Bertsekas (1999, prop. A.24) that

$$\|f(y) - f(x) - f'(x)(y-x)\| \leq \frac{L}{2}\|y - x\|^2 \quad \text{for any } x, y.$$

Then, by the definition of D_k, it follows that

$$\begin{aligned}(f+\varphi)(y^{k+1}) - (f+\varphi)(y^k) + D_k &= f(y^{k+1}) - f(y^k) + \langle f'(y^k), y^k - y^{k+1}\rangle \\ &\leq \tfrac{L}{2}\|y^k - y^{k+1}\|_2^2 \\ &\leq \tfrac{Lv}{2(1-v\alpha)} D_k,\end{aligned}$$

where the last inequality follows from (48), and thus, (49) is proved. ■

The main result of this subsection is presented as follows, in which we establish the local linear convergence rate of the PGM-GSO to a local minimum for the case when $p = 1$ and $0 < q < 1$ under some mild assumptions.

Theorem 16 *Let $\{x^k\}$ be a sequence generated by the PGM-GSO with $v < \frac{1}{2}\|A\|_2^{-2}$. Then $\{x^k\}$ converges to a critical point x^* of problem (4). Assume that x^* is a local minimum of problem (4). Suppose that any nonzero group of x^* is active, and the columns of B are linearly independent. Then there exist $N \in \mathbb{N}$, $C > 0$ and $\eta \in (0,1)$ such that*

$$F(x^k) - F(x^*) \leq C\eta^k \quad \text{and} \quad \|x^k - x^*\|_2 \leq C\eta^k \quad \textit{for any } k \geq N. \tag{53}$$

Proof The convergence of $\{x^k\}$ to a critical point x^* of problem (4) directly follows from Theorem 12. Let D_k, N and δ be defined as in Lemma 15, and let

$$r_k := F(x^k) - F(x^*).$$

Note in (50) that $y^k \neq_{\mathbf{a}} 0$ and $x^k_{\mathcal{G}^c_{\mathcal{S}}} = 0$ for any $k \geq N$. Thus

$$r_k = (f+\varphi)(y^k) - (f+\varphi)(y^*) \quad \text{for any } k \geq N.$$

It is trivial to see that $\varphi(\cdot)$ is smooth around y^* (as it is active) and that

$$\varphi''(y^*) = \lambda q(q-1)\begin{pmatrix} M_1^* & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & M_S^* \end{pmatrix} \prec 0, \quad f''(y^*) + \varphi''(y^*) \succ 0;$$

as shown in (42). This shows that $\varphi(\cdot)$ is concave around y^*, while $(f+\varphi)(\cdot)$ is convex around y^*. Without loss of generality, we assume that $\varphi(\cdot)$ is concave and $(f+\varphi)(\cdot)$ is convex in $\mathbf{B}(y^*, \delta)$ and that $y^k \in \mathbf{B}(y^*, \delta)$ for any $k \geq N$ (since $\{y^k\}$ converges to y^*).

By the convexity of $(f+\varphi)(\cdot)$ in $\mathbf{B}(y^*, \delta)$, it follows that for any $k \geq N$

$$\begin{aligned} r_k &= (f+\varphi)(y^k) - (f+\varphi)(y^*) \\ &\leq \langle f'(y^k) + \varphi'(y^k), y^k - y^*\rangle \\ &= \langle f'(y^k) + \varphi'(y^k), y^k - y^{k+1}\rangle + \langle f'(y^k) + \varphi'(y^k), y^{k+1} - y^*\rangle \\ &= D_k - \varphi(y^k) + \varphi(y^{k+1}) + \langle\varphi'(y^k), y^k - y^{k+1}\rangle + \langle f'(y^k) + \varphi'(y^k), y^{k+1} - y^*\rangle. \end{aligned} \tag{54}$$

Noting that $\varphi(\cdot)$ is concave in $\mathbf{B}(y^*, \delta)$, it follows that

$$\varphi(y^k) - \varphi(y^{k+1}) \geq \langle\varphi'(y^k), y^k - y^{k+1}\rangle.$$

Consequently, (54) is reduced to

$$\begin{aligned} r_k &\le D_k + \langle f'(y^k) + \varphi'(y^k), y^{k+1} - y^* \rangle \\ &= D_k + \langle \varphi'(y^k) - \varphi'(y^{k+1}), y^{k+1} - y^* \rangle + \langle f'(y^k) + \varphi'(y^{k+1}), y^{k+1} - y^* \rangle \\ &\le D_k + \left(L_\varphi + \tfrac{1}{v}\right) \|y^k - y^{k+1}\|_2 \|y^{k+1} - y^*\|_2, \end{aligned} \tag{55}$$

where the last inequality follows from the smoothness of φ on $\mathbf{B}(y^*, \delta)$ and (51), and L_φ is the Lipschitz constant of $\varphi'(\cdot)$ on $\mathbf{B}(y^*, \delta)$. Let $\beta := 1 - \frac{Lv}{2(1-v\alpha)} \in (0,1)$ (due to the assumption $v < \frac{1}{L}$). Then, (49) is reduced to

$$r_k - r_{k+1} = (f+\varphi)(y^k) - (f+\varphi)(y^{k+1}) \ge \beta D_k > 0,$$

and thus, it follows from (55) and (48) that

$$\begin{aligned} \beta r_k &\le \beta D_k + \beta \left(L_\varphi + \tfrac{1}{v}\right) \|y^k - y^{k+1}\|_2 \|y^{k+1} - y^*\|_2 \\ &\le r_k - r_{k+1} + \beta \left(L_\varphi + \tfrac{1}{v}\right) \|y^{k+1} - y^*\|_2 \sqrt{\tfrac{v}{1-v\alpha} D_k} \\ &\le r_k - r_{k+1} + \left(L_\varphi + \tfrac{1}{v}\right) \sqrt{\tfrac{v\beta}{1-v\alpha}} \|y^{k+1} - y^*\|_2 \sqrt{r_k - r_{k+1}}. \end{aligned} \tag{56}$$

Recall from Lemma 14(ii) that there exists $c > 0$ such that

$$\|y - y^*\|_2^2 \le c\left((f+\varphi)(y) - (f+\varphi)(y^*)\right) \quad \text{for any } y \in \mathbf{B}(y^*, \delta).$$

Thus, it follows that

$$\|y^{k+1} - y^*\|_2^2 \le c r_{k+1} \le c r_k \quad \text{for any } k \ge N. \tag{57}$$

Let $\epsilon := \frac{c}{\beta}\left(L_\varphi + \frac{1}{v}\right)^2$. By Young's inequality, (56) yields that

$$\begin{aligned} \beta r_k &\le r_k - r_{k+1} + \tfrac{1}{2\epsilon} \|y^{k+1} - y^*\|_2^2 \left(L_\varphi + \tfrac{1}{v}\right)^2 + \tfrac{ev\beta}{2(1-v\alpha)}(r_k - r_{k+1}) \\ &\le r_k - r_{k+1} + \tfrac{\beta}{2} r_k + \tfrac{cv}{2(1-v\alpha)} \left(L_\varphi + \tfrac{1}{v}\right)^2 (r_k - r_{k+1}). \end{aligned} \tag{58}$$

Let $\gamma := \frac{cv}{2(1-v\alpha)}\left(L_\varphi + \frac{1}{v}\right)^2 > 0$. Then, (58) is reduced to

$$r_{k+1} \le \frac{1 + \gamma - \frac{\beta}{2}}{1+\gamma} r_k = \eta_1 r_k,$$

where $\eta_1 := \frac{1+\gamma-\frac{\beta}{2}}{1+\gamma} \in (0,1)$. Thus, by letting $C_1 := r_N \eta_1^{-N}$, it follows that

$$r_k \le \eta_1^{k-N} r_N = C_1 \eta_1^k \quad \text{for any } k \ge N.$$

By letting $\eta_2 = \sqrt{\eta_1}$ and $C_2 = \sqrt{cC_1}$, it follows from (57) that

$$\|x^k - x^*\|_2 = \|y^k - y^*\|_2 \le (cr_k)^{1/2} \le C_2 \eta_2^k \quad \text{for any } k \ge N.$$

Letting $C := \max\{C_1, C_2\}$ and $\eta := \max\{\eta_1, \eta_2\}$, we obtain (53). The proof is complete. ■

Theorem 16 establishes the linear convergence rate of the PGM for solving the $\ell_{1,q}$ regularization problem under two assumptions: (i) the critical point x^* of the sequence produced by the PGM is a local minimum of problem (4), and (ii) any nonzero group of the local minimum is an active one. The assumption (i) is important by which we are able to establish a second-order growth property, which plays a crucial role in our analysis. Note that the assumption (ii) is satisfied automatically for the sparse optimization problem ($n_{max} = 1$). Hence, when $n_{max} = 1$, we obtain the linear convergence rate of the PGM for solving ℓ_q regularization problem ($0 < q < 1$). This result is stated below as a corollary.

Corollary 17 *Let $0 < q < 1$, and let $\{x^k\}$ be a sequence generated by the PGM for solving the following ℓ_q regularization problem*

$$\min_{x \in \mathbb{R}^n} F(x) := \|Ax - b\|_2^2 + \lambda \|x\|_q^q \tag{59}$$

with $v < \frac{1}{2}\|A\|_2^{-2}$. Then $\{x^k\}$ converges to a critical point x^* of problem (59). Further assume that x^* is a local minimum of problem (59). Then there exist $N \in \mathbb{N}$, $C > 0$ and $\eta \in (0,1)$ such that

$$F(x^k) - F(x^*) \le C\eta^k \quad \text{and} \quad \|x^k - x^*\|_2 \le C\eta^k \quad \text{for any } k \ge N.$$

While we are carrying out the revision of our manuscript, we have found that the local linear convergence rate of the PGM has been studied in the literature. On one hand, the local linear convergence rate of the PGM for solving the ℓ_1 regularization problem (ISTA) has been established under some assumptions in Bredies and Lorenz (2008); Hale et al. (2008); Tao et al. (2016), and, under the framework of the so-called KL theory, it is established that the sequence generated by the PGM linearly converges to a critical point of a KL function if its KL exponent is in $(0, \frac{1}{2}]$; see Frankel et al. (2015); Li and Pong (2016); Xu and Yin (2013). However, the KL exponent of the ℓ_q regularized function is still unknown, and thus the linear convergence result in these references cannot directly be applied to the ℓ_q regularization problem. On the other hand, Zeng et al. (2015) has obtained the linear convergence rate of the ℓ_q regularization problem under the framework of a restricted KL property. However, it seems that their result is restrictive as it is assumed that the stepsize v and the regularization component q satisfy

$$\frac{q}{2} < \frac{\lambda_{\min}(A_{\mathcal{S}}^T A_{\mathcal{S}})}{\|A\|_2^2} \quad \text{and} \quad \frac{q}{4\lambda_{\min}(A_{\mathcal{S}}^T A_{\mathcal{S}})} < v < \frac{1}{2\|A\|_2^2},$$

where $\mathcal{S}$ is the active index of the limiting point x^*, while our result in Corollary 17 holds for all the stepsize $v < \frac{1}{2}\|A\|_2^{-2}$ and the regularization component $0 < q < 1$.

3.2 Analytical Solutions of Proximal Subproblems

Since the main computation of the PGM is the proximal step (37), it is significant to investigate the solutions of subproblem (37) for the specific applications so as to spread the application of the PGM. Note that $\|x\|_{p,q}^q$ and $\|x - z^k\|_2^2$ are both grouped separable. Then

the proximal step (37) can be achieved parallelly in each group, and is equivalent to solve a cycle of low dimensional proximal optimization subproblems

$$x_{\mathcal{G}_i}^{k+1} \in \arg\min_{x\in\mathbb{R}^{n_i}} \left\{ \lambda\|x_{\mathcal{G}_i}\|_p^q + \frac{1}{2v}\|x_{\mathcal{G}_i} - z_{\mathcal{G}_i}^k\|_2^2 \right\} \quad \text{for } i = 1, \cdots, r. \tag{60}$$

When p and q are given as some specific numbers, such as $p = 1, 2$ and $q = 0, 1/2, 2/3, 1$, the solution of subproblem (60) of each group can be given explicitly by an analytical formula, as shown in the following proposition.

Proposition 18 *Let $z \in \mathbb{R}^l$, $v > 0$ and the proximal regularization be*

$$Q_{p,q}(x) := \lambda\|x\|_p^q + \frac{1}{2v}\|x - z\|_2^2 \quad \textit{for any } x \in \mathbb{R}^l.$$

Then the proximal operator

$$P_{p,q}(z) \in \arg\min_{x\in\mathbb{R}^l} \{Q_{p,q}(x)\}$$

has the following analytical formula:

(i) *if $p = 2$ and $q = 1$, then*

$$P_{2,1}(z) = \begin{cases} \left(1 - \frac{v\lambda}{\|z\|_2}\right) z, & \|z\|_2 > v\lambda, \\ 0, & \text{otherwise}, \end{cases}$$

(ii) *if $p = 2$ and $q = 0$, then*

$$P_{p,0}(z) = \begin{cases} z, & \|z\|_2 > \sqrt{2v\lambda}, \\ 0 \text{ or } z, & \|z\|_2 = \sqrt{2v\lambda}, \\ 0, & \|z\|_2 < \sqrt{2v\lambda}, \end{cases}$$

(iii) *if $p = 2$ and $q = 1/2$, then*

$$P_{2,1/2}(z) = \begin{cases} \frac{16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)}{3\sqrt{3}v\lambda + 16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)} z, & \|z\|_2 > \frac{3}{2}(v\lambda)^{2/3}, \\ 0 \text{ or } \frac{16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)}{3\sqrt{3}v\lambda + 16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)} z, & \|z\|_2 = \frac{3}{2}(v\lambda)^{2/3}, \\ 0, & \|z\|_2 < \frac{3}{2}(v\lambda)^{2/3}, \end{cases} \tag{61}$$

with

$$\psi(z) = \arccos\left(\frac{v\lambda}{4}\left(\frac{3}{\|z\|_2}\right)^{3/2}\right), \tag{62}$$

(iv) *if $p = 1$ and $q = 1/2$, then*

$$P_{1,1/2}(z) = \begin{cases} \tilde{z}, & Q_{1,1/2}(\tilde{z}) < Q_{1,1/2}(0), \\ 0 \text{ or } \tilde{z}, & Q_{1,1/2}(\tilde{z}) = Q_{1,1/2}(0), \\ 0, & Q_{1,1/2}(\tilde{z}) > Q_{1,1/2}(0), \end{cases}$$

with

$$\tilde{z} = z - \frac{\sqrt{3}v\lambda}{4\sqrt{\|z\|_1}\cos\left(\frac{\pi}{3} - \frac{\xi(z)}{3}\right)}\text{sign}(z), \quad \xi(z) = \arccos\left(\frac{v\lambda l}{4}\left(\frac{3}{\|z\|_1}\right)^{3/2}\right),$$

(v) *if $p = 2$ and $q = 2/3$, then*

$$P_{2,2/3}(z) = \begin{cases} \frac{3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)}{32v\lambda a^2 + 3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)} z, & \|z\|_2 > 2\left(\frac{2}{3}v\lambda\right)^{3/4}, \\ 0 \text{ or } \frac{3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)}{32v\lambda a^2 + 3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)} z, & \|z\|_2 = 2\left(\frac{2}{3}v\lambda\right)^{3/4}, \\ 0, & \|z\|_2 < 2\left(\frac{2}{3}v\lambda\right)^{3/4}, \end{cases} \tag{63}$$

with

$$a = \frac{2}{\sqrt{3}}(2v\lambda)^{1/4}\left(\cosh\left(\frac{\varphi(z)}{3}\right)\right)^{1/2}, \quad \varphi(z) = \text{arccosh}\left(\frac{27\|z\|_2^2}{16(2v\lambda)^{3/2}}\right), \tag{64}$$

(vi) *if $p = 1$ and $q = 2/3$, then*

$$P_{1,2/3}(z) = \begin{cases} \bar{z}, & Q_{1,2/3}(\bar{z}) < Q_{1,2/3}(0), \\ 0 \text{ or } \bar{z}, & Q_{1,2/3}(\bar{z}) = Q_{1,2/3}(0), \\ 0, & Q_{1,2/3}(\bar{z}) > Q_{1,2/3}(0), \end{cases}$$

with

$$\bar{z} = z - \frac{4v\lambda\bar{a}^{1/2}}{3\left(\bar{a}^{3/2} + \sqrt{2\|z\|_1 - \bar{a}^3}\right)}\text{sign}(z),$$

and

$$\bar{a} = \frac{2}{\sqrt{3}}(2v\lambda l)^{1/4}\left(\cosh\left(\frac{\zeta(z)}{3}\right)\right)^{1/2}, \quad \zeta(z) = \text{arccosh}\left(\frac{27\|z\|_1^2}{16(2v\lambda l)^{3/2}}\right).$$

Proof Since the proximal regularization $Q_{p,q}(\cdot) := \lambda\|\cdot\|_p^q + \frac{1}{2v}\|\cdot - z\|_2^2$ is non-differentiable only at 0, $P_{p,q}(z)$ must be 0 or some point $\tilde{x}(\neq 0)$ satisfying the first-order optimality condition

$$\lambda q\|\tilde{x}\|_p^{q-p}\begin{pmatrix} |\tilde{x}_1|^{p-1}\text{sign}(\tilde{x}_1) \\ \vdots \\ |\tilde{x}_l|^{p-1}\text{sign}(\tilde{x}_l) \end{pmatrix} + \frac{1}{v}(\tilde{x} - z) = 0. \tag{65}$$

Thus, to derive the analytical formula of the proximal operator $P_{p,q}(z)$, we just need to calculate such $\tilde{x}$ via (65), and then compare the objective function values $Q_{p,q}(\tilde{x})$ and $Q_{p,q}(0)$ to obtain the solution inducing a smaller value. The proofs of the six statements follow in the above routine, and we only provide the detailed proofs of (iii) and (v) as samples.

(iii) When $p = 2$ and $q = 1/2$, (65) reduces to

$$\frac{\lambda\tilde{x}}{2\|\tilde{x}\|_2^{3/2}} + \frac{1}{v}(\tilde{x} - z) = 0, \tag{66}$$

and consequently,

$$\|\tilde{x}\|_2^{3/2} - \|z\|_2\|\tilde{x}\|_2^{1/2} + \frac{1}{2}v\lambda = 0. \tag{67}$$

Denote $\eta = \|\tilde{x}\|_2^{1/2} > 0$. The equation (67) can be transformed into the following cubic algebraic equation

$$\eta^3 - \|z\|_2\eta + \frac{1}{2}v\lambda = 0. \tag{68}$$

Due to the hyperbolic solution of the cubic equation (see Short, 1937), by denoting

$$r = 2\sqrt{\frac{\|z\|_2}{3}},\ \alpha = \arccos\left(\frac{v\lambda}{4}\left(\frac{3}{\|z\|_2}\right)^{3/2}\right) \text{ and } \beta = \operatorname{arccosh}\left(-\frac{v\lambda}{4}\left(\frac{3}{\|z\|_2}\right)^{3/2}\right),$$

the solution of (68) can be expressed as the follows.

(1) If $0 \le \|z\|_2 \le 3\left(\frac{v\lambda}{4}\right)^{2/3}$, then the three roots of (68) are given by

$$\eta_1 = r\cosh\frac{\beta}{3},\ \eta_2 = -\frac{r}{2}\cosh\frac{\beta}{3} + i\frac{\sqrt{3}r}{2}\sinh\frac{\beta}{3},\ \eta_3 = -\frac{r}{2}\cosh\frac{\beta}{3} - i\frac{\sqrt{3}r}{2}\sinh\frac{\beta}{3},$$

where i denotes the imaginary unit. However, this β does not exist since the value of hyperbolic cosine must be positive. Thus, in this case, $P_{2,1/2}(z) = 0$.

(2) If $\|z\|_2 > 3\left(\frac{v\lambda}{4}\right)^{2/3}$, then the three roots of (68) are

$$\eta_1 = r\cos\left(\frac{\pi}{3} - \frac{\alpha}{3}\right),\ \eta_2 = -r\sin\left(\frac{\pi}{2} - \frac{\alpha}{3}\right),\ \eta_3 = -r\cos\left(\frac{2\pi}{3} - \frac{\alpha}{3}\right).$$

The unique positive solution of (68) is $\|\tilde{x}\|_2^{1/2} = \eta_1$, and thus, the unique solution of (66) is given by

$$\tilde{x} = \frac{2\eta_1^3}{v\lambda + 2\eta_1^3}z = \frac{16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)}{3\sqrt{3}v\lambda + 16\|z\|_2^{3/2}\cos^3\left(\frac{\pi}{3} - \frac{\psi(z)}{3}\right)}z.$$

Finally, we compare the objective function values $Q_{2,1/2}(\tilde{x})$ and $Q_{2,1/2}(0)$. For this purpose, when $\|z\|_2 > 3\left(\frac{v\lambda}{4}\right)^{2/3}$, we define

$$\begin{aligned} H(\|z\|_2) &:= \tfrac{v}{\|\tilde{x}\|_2}\left(Q_{2,1/2}(0) - Q_{2,1/2}(\tilde{x})\right) \\ &= \tfrac{v}{\|\tilde{x}\|_2}\left(\tfrac{1}{2v}\|z\|_2^2 - \lambda\|\tilde{x}\|_2^{1/2} - \tfrac{1}{2v}\|\tilde{x} - z\|_2^2\right) \\ &= \|z\|_2 - \tfrac{\|\tilde{x}\|_2^2 + 2v\lambda\|\tilde{x}\|_2^{1/2}}{2\|\tilde{x}\|_2} \\ &= \tfrac{1}{2}\|z\|_2 - \tfrac{3}{4}v\lambda\|\tilde{x}\|_2^{-1/2}, \end{aligned}$$

where the third equality holds since that $\tilde{x}$ is proportional to z, and fourth equality follows from (67). Since both $\|z\|_2$ and $\|\tilde{x}\|_2$ are strictly increasing on $\|z\|_2$, $H(\|z\|_2)$ is also strictly increasing when $\|z\|_2 > 3\left(\frac{v\lambda}{4}\right)^{2/3}$. Thus the unique solution of $H(\|z\|_2) = 0$ satisfies

$$\|z\|_2\|\tilde{x}\|_2^{1/2} = \frac{3}{2}v\lambda,$$

and further, (67) implies that the solution of $H(\|z\|_2) = 0$ is

$$\|z\|_2 = \frac{3}{2}(v\lambda)^{2/3}.$$

Therefore, we arrive at the formulae (61) and (62).
(v) When $p = 2$ and $q = 2/3$, (65) reduces to

$$\frac{2\lambda\tilde{x}}{3\|\tilde{x}\|_2^{4/3}} + \frac{1}{v}(\tilde{x} - z) = 0, \tag{69}$$

and consequently,

$$\|\tilde{x}\|_2^{4/3} - \|z\|_2\|\tilde{x}\|_2^{1/3} + \frac{2}{3}v\lambda = 0. \tag{70}$$

Denote $\eta = \|\tilde{x}\|_2^{1/3} > 0$ and $h(t) = t^4 - \|z\|_2 t + \frac{2}{3}v\lambda$ for any $t \in \mathbb{R}$. Thus, η is the positive solution of $h(t) = 0$. Next, we seek η by the method of undetermined coefficients. Assume that

$$h(t) = t^4 - \|z\|_2 t + \frac{2}{3}v\lambda = (t^2 + at + b)(t^2 + ct + d), \quad \text{where } a, b, c, d \in \mathbb{R}. \tag{71}$$

By expansion and comparison, we have that

$$a + c = 0, \quad b + d + ac = 0, \quad ad + bc = -\|z\|_2, \quad bd = \frac{2}{3}v\lambda,$$

and thus,

$$c = -a, b = \frac{1}{2}\left(a^2 + \frac{\|z\|_2}{a}\right), d = \frac{1}{2}\left(a^2 - \frac{\|z\|_2}{a}\right), bd = \frac{1}{4}\left(a^4 - \frac{\|z\|_2^2}{a^2}\right) = \frac{2}{3}v\lambda. \tag{72}$$

By letting $M = a^2$, the last one of the above equalities reduces to the following cubic algebraic equation

$$M^3 - \frac{8}{3}v\lambda M - \|z\|_2^2 = 0. \tag{73}$$

According to the Cardano formula for the cubic equation, the root of (73) can be represented by

$$a^2 = M = \left(\frac{\|z\|_2^2}{2} + \sqrt{\frac{\|z\|_2^4}{4} - \left(\frac{8}{9}v\lambda\right)^3}\right)^{1/3} + \left(\frac{\|z\|_2^2}{2} - \sqrt{\frac{\|z\|_2^4}{4} - \left(\frac{8}{9}v\lambda\right)^3}\right)^{1/3},$$

which can also be reformulated in the following hyperbolic form (see Short, 1937)

$$a^2 = M = \frac{4}{3}\sqrt{2v\lambda}\cosh\left(\frac{\varphi(z)}{3}\right), \tag{74}$$

where $\varphi(z)$ is given by (64). By (71) and (72), we have that η, the positive root of $h(t) = 0$, satisfies

$$\eta^2 + a\eta + \frac{1}{2}\left(a^2 + \frac{\|z\|_2}{a}\right) = 0 \quad \text{or} \quad \eta^2 - a\eta + \frac{1}{2}\left(a^2 - \frac{\|z\|_2}{a}\right) = 0.$$

Hence, the real roots of the above equations, that is, the real roots of $h(t) = 0$, are

$$\eta_1 = \frac{1}{2}\left(|a| + \sqrt{\frac{2\|z\|_2}{|a|} - a^2}\right) \quad \text{and} \quad \eta_2 = \frac{1}{2}\left(|a| - \sqrt{\frac{2\|z\|_2}{|a|} - a^2}\right). \tag{75}$$

It is easy to see that $\eta_1 > \eta_2$ and that η_2 should be discarded as it induces the saddle point rather than a minimum (since $h(t) > 0$ when $t < \eta_2$). Thus, by (69), (74) and (75), one has

$$\tilde{x} = \frac{3\eta_1^4}{2v\lambda + 3\eta_1^4} z = \frac{3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)}{32v\lambda a^2 + 3\left(a^{3/2} + \sqrt{2\|z\|_2 - a^3}\right)} z,$$

where a is given by (64). Finally, we compare the objective function values $Q_{2,2/3}(\tilde{x})$ and $Q_{2,2/3}(0)$. For this purpose, we define

$$\begin{aligned} H(\|z\|_2) &:= \tfrac{v}{\|\tilde{x}\|_2}\left(Q_{2,2/3}(0) - Q_{2,2/3}(\tilde{x})\right) \\ &= \tfrac{v}{\|\tilde{x}\|_2}\left(\tfrac{1}{2v}\|z\|_2^2 - \lambda\|\tilde{x}\|_2^{2/3} - \tfrac{1}{2v}\|\tilde{x} - z\|_2^2\right) \\ &= \|z\|_2 - \tfrac{\|\tilde{x}\|_2^2 + 2v\lambda\|\tilde{x}\|_2^{2/3}}{2\|\tilde{x}\|_2} \\ &= \tfrac{1}{2}\|z\|_2 - \tfrac{2}{3}v\lambda\|\tilde{x}\|_2^{-1/3}, \end{aligned}$$

where the third equality holds since that $\tilde{x}$ is proportional to z, and fourth equality follows from (70). Since both $\|z\|_2$ and $\|\tilde{x}\|_2$ are strictly increasing on $\|z\|_2$, $H(\|z\|_2)$ is also strictly increasing when $\|z\|_2 > 4(\frac{2}{9}v\lambda)^{3/4}$. Thus the unique solution of $H(\|z\|_2) = 0$ satisfies

$$\|z\|_2\|\tilde{x}\|_2^{1/3} = \frac{4}{3}v\lambda,$$

and further, (70) implies that the solution of $H(\|z\|_2) = 0$ is

$$\|z\|_2 = 2\left(\frac{2}{3}v\lambda\right)^{3/4}.$$

Therefore, we arrive at the formulae (63) and (64). The proof is complete. ■

Remark 19 *Note from Proposition 18 that the solutions of the proximal optimization subproblems might not be unique when $Q_{p,q}(\tilde{x}) = Q_{p,q}(0)$. To avoid this obstacle in numerical computations, we select the solution $P_{p,q}(z) = 0$ whenever $Q_{p,q}(\tilde{x}) = Q_{p,q}(0)$, which achieves a more sparse solution, in the definition of the proximal operator to guarantee a unique update.*

Remark 20 *By Proposition 18, one sees that the PGM-GSO meets the group sparsity structure, since the components of each iterate within each group are likely to be either all zeros or all nonzeros. When $n_{\max} = 1$, the data do not form any group structure in the feature space, and the sparsity is achieved only on the individual feature level. In this case, the proximal operators $P_{2,1}(z)$, $P_{2,0}(z)$, and $P_{2,1/2}(z)$ and $P_{1,1/2}(z)$ reduce to the soft thresholding function in Daubechies et al. (2004), the hard thresholding function in Blumensath and Davies (2008) and the half thresholding function in Xu et al. (2012), respectively.*

Remark 21 *Proposition 18 presents the analytical solution of the proximal optimization subproblems* (60) *when $q = 0, 1/2, 2/3, 1$. However, in other cases, the analytical solution of problem* (60) *seems not available, since the algebraic equation* (65) *does not have an analytical solution (it is difficult to find an analytical solution for the algebraic equation whose order is larger than four). Thus, in the general cases of $q \in (0, 1)$, we alternatively use the Newton method to solve the nonlinear equation* (65)*, which is the optimality condition of the proximal optimization subproblem. The numerical simulation in Figure 5 of section 4 shows that the Newton method works in solving the proximal optimization subproblems* (60) *for the general q, while the $\ell_{p,1/2}$ regularization is the best one among the $\ell_{p,q}$ regularizations for $q \in [0, 1]$.*

4. Numerical Experiments

The purpose of this section is to carry out the numerical experiments of the proposed PGM for the $\ell_{p,q}$ regularization problem. We illustrate the performance of the PGM-GSO among different types of $\ell_{p,q}$ regularization, in particular, when $(p, q) =$(2,1), (2,0), (2,1/2), (1,1/2), (2,2/3) and (1,2/3), by comparing them with several state-of-the-art algorithms for simulated data and applying them to infer gene regulatory network from gene expression data of mouse embryonic stem cell. All numerical experiments are implemented in Matlab R2013b and executed on a personal desktop (Intel Core Duo E8500, 3.16 GHz, 4.00 GB of RAM). The R package of the PGM for solving group sparse optimization, named GSparO in CRAN, is available at https://CRAN.R-project.org/package=GSparO

4.1 Simulated Data

In the numerical experiments on simulated data, the numerical data are generated as follows. We first randomly generate an i.i.d. Gaussian ensemble $A \in \mathbb{R}^{m\times n}$ satisfying $A^\top A = I$. Then we generate a group sparse solution $\bar{x} \in \mathbb{R}^n$ via randomly splitting its components into r groups and randomly picking k of them as active groups, whose entries are also randomly generated as i.i.d. Gaussian, while the remaining groups are all set to be zeros. We generate the data b by the Matlab script

$$b = A * \bar{x} + sigma * randn(m, 1),$$

where *sigma* is the standard deviation of additive Gaussian noise. The problem size is set to $n = 1024$ and $m = 256$, and we test on the noisy measurement data with *sigma* $= 0.1\%$. Assuming the group sparsity level S is predefined, the regularization parameter λ is iteratively updated by obeying the rule: we set the iterative threshold to be the S-th largest value of $\|z^k_{\mathcal{G}_i}\|_2$ and solve the λ by virtue of Proposition 18.

For each given sparsity level, which is k/r, we randomly generate the data A, $\bar{x}$, b (as above) 500 times, run the algorithm, and average the 500 numerical results to illustrate the performance of the algorithm. We choose the stepsize $v = 1/2$ in the tests of the PGM-GSO. Two key criteria to characterize the performance are the relative error $\|x - \bar{x}\|_2/\|\bar{x}\|_2$ and the successful recovery rate, where the recovery is defined as *success* when the relative error between the recovered data and the true data is smaller than 0.5%; otherwise, it is regarded as *failure*.

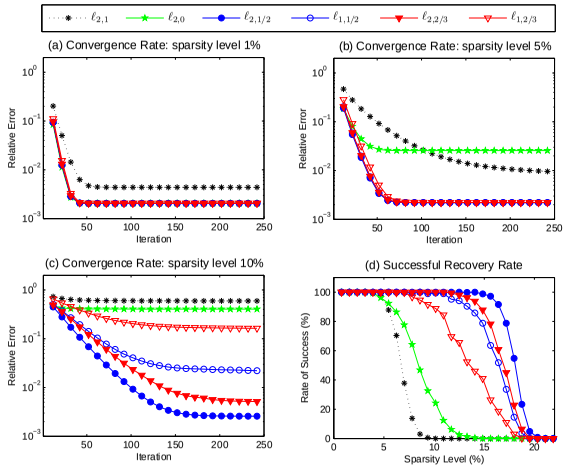

Figure 3: Convergence results and recovery rates for different sparsity levels.

We carry out six experiments with the initial point $x_0 = 0$ (unless otherwise specified). In the first experiment, setting $r = 128$ (so group size $G = 1024/128 = 8$), we compare the convergence rates and the successful recovery rates of the PGM-GSO with $(p, q) = (2, 1), (2, 0), (2, 1/2), (1, 1/2), (2, 2/3)$ and $(1, 2/3)$ for different sparsity levels. In Figure 3, (a), (b), and (c) illustrate the convergence rate results on sparsity level 1%, 5%, and 10%, respectively, while (d) plots the successful recovery rates on different sparsity levels. When the solution is of high sparse level, as shown in Figure 3(a), all $\ell_{p,q}$ regularization problems perform perfect and achieve a fast convergence rate. As demonstrated in Figure 3(b), when the sparsity level drops to 5%, $\ell_{p,1/2}$ and $\ell_{p,2/3}$ ($p = 1$ and 2) perform better and arrive at a more accurate level than $\ell_{2,1}$ and $\ell_{2,0}$. As illustrated in Figure 3(c), when the sparsity level is 10%, $\ell_{p,1/2}$ further outperforms $\ell_{p,2/3}$ ($p = 1$ or 2), and it surprises us that $\ell_{2,q}$ performs better than $\ell_{1,q}$ ($q = 1/2$ or $2/3$). From Figure 3(d), it is illustrated that $\ell_{p,1/2}$ achieves a better successful recovery rate than $\ell_{p,2/3}$ ($p = 1$ or 2), which outperforms $\ell_{2,0}$ and $\ell_{2,1}$. Moreover, we surprisingly see that $\ell_{2,q}$ also outperforms $\ell_{1,q}$ ($q = 1/2$ or $2/3$) on the successful recovery rate. In a word, $\ell_{2,1/2}$ performs as the best one of these six regularizations on both accuracy and robustness. In this experiment, we also note that the running times are at a same level, about 0.9 second per 500 iterations.

The second experiment is performed to show the sensitivity analysis on the group size ($G = 4, 8, 16, 32$) of the PGM-GSO with the six types of $\ell_{p,q}$ regularization. As shown in Figure 4, the six types of $\ell_{p,q}$ regularization reach a higher successful recovery rate for the larger group size. We also note that the larger the group size, the shorter the running time.

The third experiment is implemented to study the variation of the PGM-GSO when varying the regularization order q (fix $p = 2$). Recall from Theorem 18 that the analytical solu-

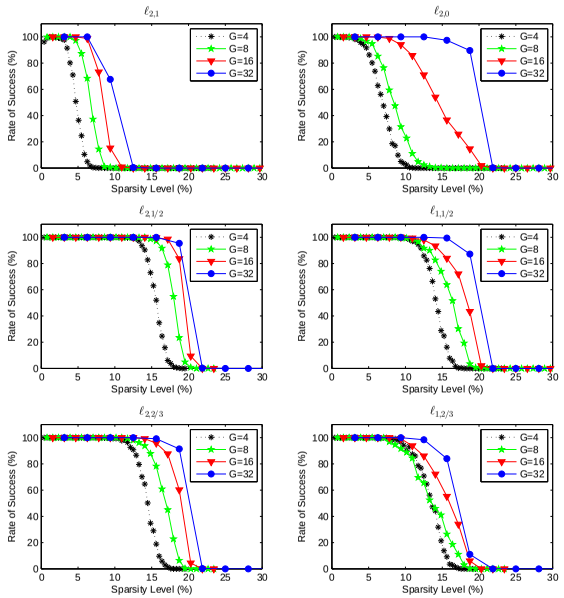

Figure 4: Sensitivity analysis on group size.

tion of the proximal optimization subproblem (60) can be obtained when $q = 0, 1/2, 2/3, 1$. However, in other cases, the analytical solution of subproblem (60) seems not available, and thus we apply the Newton method to solve the nonlinear equation (65), which is the optimality condition of the proximal optimization subproblem. Figure 5 shows the variation of successful recovery rates by decreasing the regularization order q from 1 to 0. It is illustrated that the PGM-GSO achieves the best successful recovery rate when $q = 1/2$, which arrives at the same conclusion as the first experiment. The farther the distance of q from 1/2, the lower the successful recovery rate.

The fourth experiment is to compare the PGM-GSO with several state-of-the-art algorithms in the field of sparse optimization, either convex or nonconvex algorithms, as listed in Table 1. All these algorithms, including PGM-GSO, can successfully recover the signal when the solution is of high sparse level. However, some of these algorithms fails to obtain the group sparsity structure along with the group sparsity level decreases. Figure 7 plots the signals estimated by these algorithms in a random trial at a group sparsity level of 15%. It is illustrated that the solutions of the MultiFoBa and the PGM-GSO type solvers are of group sparsity structure, while other algorithms do not obtain the group sparse solutions.

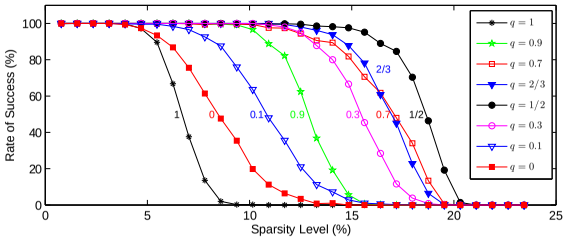

Figure 5: Variation of the PGM-GSO when varying the regularization order q.

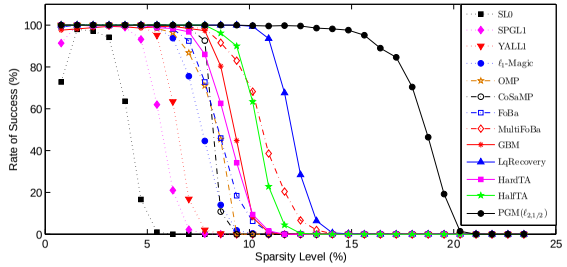

Figure 6: Comparison between the PGM-GSO and several state-of-the-art algorithms.

In these solvers, the MultiFoBa and the $\ell_{2,1}$ obtain the true active groups but inaccurate weights, the $\ell_{2,0}$ achieves the accurate weights but some incorrect active groups, while $\ell_{p,1/2}$ and $\ell_{p,2/3}$ recover perfect solutions in both true active groups and accurate weights. Figure 6 demonstrates the overall performance of these algorithms by plotting the successful recovery rates on different sparsity levels. It is indicated by Figure 6 that $\ell_{2,1/2}$ can achieve the higher successful recovery rate than other algorithms, by exploiting the group sparsity structure and lower-order regularization. From this experiment, it is demonstrated that the PGM-GSO ($\ell_{2,1/2}$) outperforms most solvers of sparse learning in solving sparse optimization problems with group structure.

The fifth experiment is devoted to the phase diagram study (see Donoho, 2006b) of the $\ell_{p,q}$ regularization problem, which further demonstrates the stronger sparsity promoting capability of $\ell_{p,1/2}$ and $\ell_{p,2/3}$ $(p = 1, 2)$ regularization over $\ell_{2,1}$ regularization. In this experiment, we consider a noiseless signal recovery problem with $n = 512$, $G = 4$, $r = 128$ and $sigma = 0$ as a prototype. More specifically, for each fixed m, we vary the number of active groups k from 1 to m/G, that is, the sparsity level varies from $1/r$ to $m/(Gr)$, and then, we increase m from G to n in the way such that 128 equidistributed values $m_j = jG$ are considered. For each specific problem size, we randomly generate the data 500 times and apply the PGM-GSO to solve the $\ell_{p,q}$ regularization problem. For these noiseless data,

SL0	SL0 is an algorithm for finding the sparsest solutions of an underdetermined system of linear equations based on Smoothed ℓ_0 norm (Mohimani et al., 2009). The package is available at http://ee.sharif.edu/~SLzero/
SPGL1	SPGL1 is a Matlab solver for large-scale sparse reconstruction (van den Berg and Friedlander, 2008). The package is available at http://www.cs.ubc.ca/~mpf/spgl1/
YALL1	YALL1 (Your ALgorithm for L1) is a package of Matlab solvers for the ℓ_1 sparse reconstruction, by virtue of the alternating direction method (Deng et al., 2011; Yang and Zhang, 2011). The package is available at http://yall1.blogs.rice.edu/
OMP	Orthogonal Matching Pursuit algorithm for the recovery of a high-dimensional sparse signal (Cai and Wang, 2011). The package is available at MathWorks.
CoSaMP	Compressive Sampling Matched Pursuit algorithms for the recovery of a high-dimensional sparse signal (Needell and Tropp, 2009). The packages are available at MathWorks.
FoBa	Adaptive forward-backward greedy algorithm for sparse learning (Zhang, 2011). The R package is available at https://CRAN.R-project.org/package=foba
MultiFoBa	MultiFoBa is group FoBa for multi-task learning (Tian et al., 2016).
ℓ_1-Magic	ℓ_1-Magic is a collection of Matlab routines for solving the convex optimization programs central to compressive sampling, based on standard interior-point methods (Candès et al., 2006a). The package is available at https://statweb.stanford.edu/~candes/l1magic/
ISTA	Iterative Shrinkage/Thresholding Algorithm (Daubechies et al., 2004) for solving the ℓ_1 regularization problem.
GBM	Gradient Based Method for solving the $\ell_{1/2}$ regularization problem (Wu et al., 2014). Suggested by the authors, we choose the initial point as the solution obtained by the ℓ_1-Magic.
LqRecovery	LqRecovery is an iterative algorithm for the ℓ_p norm minimization (Foucart and Lai, 2009). The code is available at http://www.math.drexel.edu/~foucart/software.htm
HardTA	Iterative Hard Thresholding Algorithm (Blumensath and Davies, 2008) for solving the ℓ_0 regularization problem.
HalfTA	Iterative Half Thresholding Algorithm (Xu et al., 2012) for solving the $\ell_{1/2}$ regularization problem.

Table 1: List of the state-of-the-art algorithms for sparse learning.

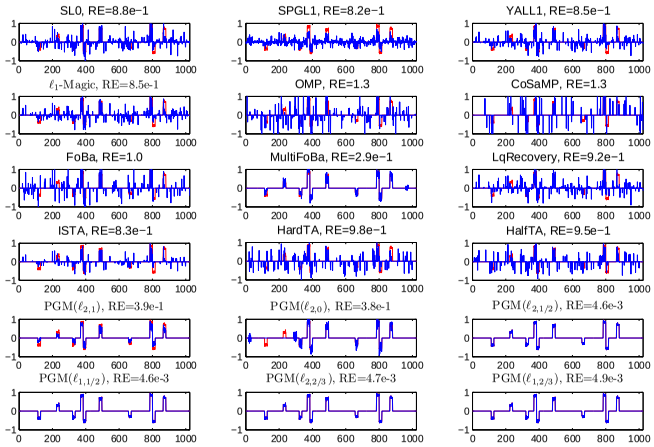

Figure 7: Simulation of the PGM-GSO and several state-of-the-art algorithms.

the recovery is defined as *success* whenever the relative error between the recovered data and the true data is smaller than 10^{-5}, otherwise, it is regarded as *failure*. Also, we embody a pixel blue whenever the point is in the case of *success*, otherwise, red when *failure*. In this way, a phase diagram of an algorithm is plotted in Figure 8, where the color of each cell reflects the empirical recovery rate (scaled between 0 and 1). It is illustrated in Figure 8 that the phase transition phenomenon does appear for the PGM-GSO with the six types of $\ell_{p,q}$ regularization. It is shown that $\ell_{p,1/2}$ and $\ell_{p,2/3}$ $(p = 1, 2)$ regularizations are more robust than that of $\ell_{2,0}$ and $\ell_{2,1}$ in the sense that they allow to achieve higher recovery rates and recover a sparse signal from a smaller amount of samples. It is also revealed by Figure 8 that $\ell_{2,1/2}$ regularization is the most robust one of these six regularizations, which achieves the same conclusion as the first and third experiments.

Even though some global optimization method, such as the filled function method (Ge, 1990), can find the global solution of the lower-order regularization problem as in Example 2, however, it does not work for the large-scale sparse optimization problems. Because, in the filled function method, all the directions need to be searched or compared in each iteration, which costs a large amount of time and hampers the efficiency for solving the large-scale problems.

4.2 Real Data in Gene Transcriptional Regulation

Gene transcriptional regulation is the process that a combination of transcription factors (TFs) act in concert to control the transcription of the target genes. Inferring gene regulatory network from high-throughput genome-wide data is still a major challenge in systems

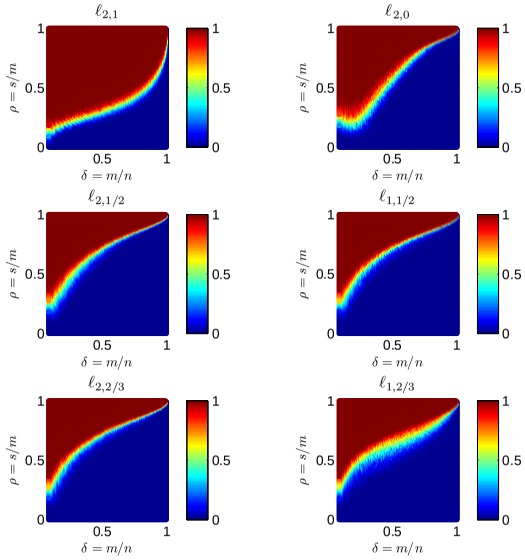

Figure 8: Phase diagram study of $\ell_{p,q}$ regularization of group sparse optimization. Blue denotes perfect recovery in all experiments, and red denotes failure for all experiments.

biology, especially when the number of genes is large but the number of experimental samples is small. In large genomes, such as human and mouse, the complexity of gene regulatory system dramatically increases. Thousands of TFs combine in different ways to regulate tens of thousands target genes in various tissues or biological processes. However, only a few TFs collaborate and usually form complexes (groups of cooperative TFs) to control the expression of a specific gene in a specific cell type or developmental stage. Thus, the prevalence of TF complex makes the solution of gene regulatory network have a group structure, and the gene regulatory network inference in such large genomes becomes a group sparse optimization problem, which is to search a small number of TF complexes (or TFs) from a pool of thousands of TF complexes (or TFs) for each target gene based on the dependencies between the expression of TF complexes (or TFs) and the targets. Even though TFs often work in the form of complexes (Xie et al., 2013), and TF complexes are very important in the control of cell identity and diseases (Hnisz et al., 2013), current methods to infer gene regulatory network usually consider each TF separately. To take the grouping information of TF complexes into consideration, we can apply the group sparse optimization to gene

regulatory network inference with the prior knowledge of TF complexes as the pre-defined grouping.

4.2.1 Materials

Chromatin immunoprecipitation (ChIP) coupled with next generation sequencing (ChIP-seq) identifies *in vivo* active and cell-specific binding sites of a TF. They are commonly used to infer TF complexes recently. Thus, we manually collect ChIP-seq data in mouse embryonic stem cells (mESCs), as shown in Table 2. Transcriptome is the gene expression profile of the whole genome that is measured by microarray or RNA-seq. The transcriptome data in mESCs for gene regulatory network inference are downloaded from Gene Expression Omnibus (GEO). 245 experiments under perturbations in mESC are collected from three papers Correa-Cerro et al. (2011); Nishiyama et al. (2009, 2013). Each experiment produced transcriptome data with or without overexpression or knockdown of a gene, in which the control and treatment have two replicates respectively. Gene expression fold changes between control samples and treatment samples of 12488 target genes in all experiments are $\log 2$ transformed and form matrix $B \in \mathbb{R}^{245\times 12488}$ (Figure 9A). The known TFs are collected from four TF databases, TRANSFAC, JASPAR, UniPROBE and TFCat, as well as literature. Let matrix $H \in \mathbb{R}^{245\times 939}$ be made up of the expression profiles of 939 known TFs, and matrix $Z \in \mathbb{R}^{939\times 12488}$ describe the connections between these TFs and targets. Then, the regulatory relationship between TFs and targets can be represented approximately by a linear system

$$HZ = B + \epsilon.$$

The TF-target connections defined by ChIP-seq data are converted into an initial matrix Z^0 (see Qin et al., 2014). Indeed, if TF i has a binding site around the gene j promoter within a defined distance (10 kbp), a non-zero number is assigned on Z^0_{ij} as a prior value.

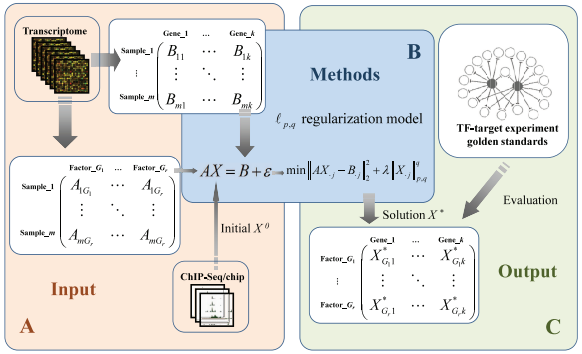

Figure 9: Workflow of gene regulatory network inference with $\ell_{p,q}$ regularization.

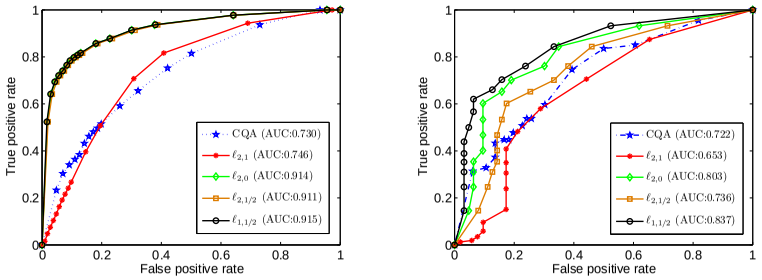
Now we add the grouping information (TF complexes) into this linear system. The TF complexes are inferred from ChIP-seq data (Table 2) via the method described in Giannopoulou and Elemento (2013). Let the group structure of Z be a matrix $W \in \mathbb{R}^{2257\times 939}$ (actually, the number of groups is 1439), whose Moore-Penrose pseudoinverse is denoted by W^+ (Horn and Johnson., 1985). We further let $A := HW^+$ and $X := WZ$. Then the linear system can be converted into



$$AX = B + \epsilon,$$

where A denotes expression profiles of TF complexes, and X represents connections between TF complexes and targets (Figure 9A).

Table 2: ChIP-seq data for TF complex inference.

A literature-based golden standard (low-throughput golden standard) TF-target pair set from biological studies (Figure 9C), including 97 TF-target interactions between 23 TFs and 48 target genes, is downloaded from iScMiD (Integrated Stem Cell Molecular Interactions Database). Each TF-target pair in this golden standard data set has been verified by biological experiments. Another more comprehensive golden standard mESC network is constructed from high-throughput data (high-throughput golden standard) by ChIP-Array (Qin et al., 2011) using the methods described in Qin et al. (2014). It contains 40006 TF-target pairs between 13092 TFs or targets (Figure 9C). Basically, each TF-target pair in the network is evidenced by a cell-type specific binding site of the TF on the target's promoter and the expression change of the target in the perturbation experiment of the TF,

(b) Evaluation with literature-based low-throughput golden standard.

Figure 10: ROC curves and AUCs of the PGM-GSO on mESC gene regulatory network inference.

which is generally accepted as a true TF-target regulation. These two independent golden standards are both used to validate the accuracy of the inferred gene regulatory networks.

4.2.2 Numerical Results

We apply the PGM-GSO, starting from the initial matrix $X^0 := WZ^0$, to the gene regulatory network inference problem (Figure 9B), and compare with the CQ algorithm (CQA), which is shown in Wang et al. (2017) an efficient solver for gene regulatory network inference based on the group structure of TF complexes. The area under the curve (AUC) of a receiver operating characteristic (ROC) curve is widely recognized as an important index of the overall classification performance of an algorithm (see Fawcett, 2006). Here, we apply AUC to evaluate the performance of the PGM-GSO with four types of $\ell_{p,q}$ regularization, $(p,q) = (2,1), (2,0), (2,1/2)$ and $(1,1/2)$, as well as the CQA. A series of numbers of predictive TF complexes (or TFs), denoted by k, from 1 to 100 (that is, the sparsity level varies from about 0.07% to 7%) are tested. For each k and each pair of TF complex (or TF) i and target j, if the $X^{(k)}_{Gij}$ is non-zero, this TF complex (or TF) is regarded as a potential regulator of this target in this test. In biological sense, we only concern about whether the true TF is predicted, but not the weight of this TF. We also expect that the TF complexes (or TFs) which are predicted in a higher sparsity level should be more important than those that are only reported in a lower sparsity level. Thus, when calculating the AUC, a score Score_{ij} is applied as the predictor for TF i on target j:

$$\text{Score}_{ij} := \begin{cases} \max_k\{1/k\}, & X^{(k)}_{ij} \neq 0, \\ 0, & \text{otherwise.} \end{cases}$$

Both high-throughput and low-throughput golden standards are used to draw the ROC curves of the PGM-GSO with four types of $\ell_{p,q}$ regularization and the CQA in Figure 10

to compare their accuracy. When matched with the high-throughput golden standard, it is illustrated from Figure 10(a) that $\ell_{2,1/2}$, $\ell_{1,1/2}$ and $\ell_{2,0}$ perform almost the same (as indicated by the almost same AUC value), and significantly outperform $\ell_{2,1}$ and CQA. With the low-throughput golden standard, it is demonstrated from Figure 10(b) that $\ell_{1,1/2}$ is slightly better than $\ell_{2,1/2}$, $\ell_{2,0}$ and CQA, and these three regularizations perform much better than $\ell_{2,1}$. These results are basically consistent with the results from simulated data. Since the golden standards we use here are obtained from real biological experiments, which are well-accepted as true TF-target regulations, the higher AUC, the more biologically accurate the result gene regulatory network is. Thus, our results indicate that the $\ell_{p,1/2}$ and $\ell_{p,0}$ regularizations are applicable to gene regulatory network inference in biological researches that study higher organisms but generate transcriptome data for only a small number of samples, which facilitates biologists to analyze gene regulation in a system level.

Acknowledgments

We are grateful to the anonymous reviewers for their valuable suggestions and remarks which helped to improve the quality of the paper. We are also thankful to Professor Marc Teboulle for providing the reference Bolte et al. (2013) and the suggestion that the global convergence of the PGM-GSO can be established by using the so-called Kurdyka-Łojasiewicz theory, and Professor Junwen Wang for providing the gene expression data and biological golden standards for inferring gene regulatory network of mouse embryonic stem cell. Abstract

We introduce a new model of teaching named "preference-based teaching" and a corresponding complexity parameter—the preference-based teaching dimension (PBTD)—representing the worst-case number of examples needed to teach any concept in a given concept class. Although the PBTD coincides with the well-known recursive teaching dimension (RTD) on finite classes, it is radically different on infinite ones: the RTD becomes infinite already for trivial infinite classes (such as half-intervals) whereas the PBTD evaluates to reasonably small values for a wide collection of infinite classes including classes consisting of so-called closed sets w.r.t. a given closure operator, including various classes related to linear sets over $\mathbb{N}_0$ (whose RTD had been studied quite recently) and including the class of Euclidean half-spaces. On top of presenting these concrete results, we provide the reader with a theoretical framework (of a combinatorial flavor) which helps to derive bounds on the PBTD.

Keywords: teaching dimension, preference relation, recursive teaching dimension, learning half-spaces, linear sets

1. Introduction

The classical model of teaching (Shinohara and Miyano, 1991; Goldman and Kearns, 1995) formulates the following interaction protocol between a teacher and a student:

- Both of them agree on a "classification-rule system", formally given by a concept class $\mathcal{L}$.
- In order to teach a specific concept $L \in \mathcal{L}$, the teacher presents to the student a *teaching set*, i.e., a set T of labeled examples so that L is the only concept in $\mathcal{L}$ that is consistent with T.
- The student determines L as the unique concept in $\mathcal{L}$ that is consistent with T.

Goldman and Mathias (1996) pointed out that this model of teaching is not powerful enough, since the teacher is required to make *any* consistent learner successful. A challenge is to model powerful teacher/student interactions without enabling unfair "coding tricks". Intuitively, the term "coding trick" refers to any form of undesirable collusion between teacher and learner, which would reduce the learning process to a mere decoding of a code the teacher sent to the learner. There is no generally accepted definition of what constitutes a coding trick, in part because teaching an exact learner could always be considered coding to some extent: the teacher presents a set of examples which the learner "decodes" into a concept.

In this paper, we adopt the notion of "valid teacher/learner pair" introduced by Goldman and Mathias (1996). They consider their model to be intuitively free of coding tricks while it provably allows for a much broader class of interaction protocols than the original teaching model. In particular, teaching may thus become more efficient in terms of the number of examples in the teaching sets. Further definitions of how to avoid unfair coding tricks have been suggested (Zilles et al., 2011), but they were less stringent than the one proposed by Goldman and Mathias. The latter simply requests that, if the learner hypothesizes concept L upon seeing a sample set S of labeled examples, then the learner will still hypothesize L when presented with any sample set $S \cup S'$, where S' contains only examples labeled consistently with L. A coding trick would then be any form of exchange between the teacher and the learner that does not satisfy this definition of validity.

The model of recursive teaching (Zilles et al., 2011; Mazadi et al., 2014), which is free of coding tricks according to the Goldman-Mathias definition, has recently gained attention because its complexity parameter, the recursive teaching dimension (RTD), has shown relations to the VC-dimension and to sample compression (Chen et al., 2016; Doliwa et al., 2014; Moran et al., 2015; Simon and Zilles, 2015), when focusing on finite concept classes. Below though we will give examples of rather simple infinite concept classes with infinite RTD, suggesting that the RTD is inadequate for addressing the complexity of teaching infinite classes.

In this paper, we introduce a model called *preference-based teaching*, in which the teacher and the student do not only agree on a classification-rule system $\mathcal{L}$ but also on a preference relation (a strict partial order) imposed on $\mathcal{L}$. If the labeled examples presented by the teacher allow for several consistent explanations (= consistent concepts) in $\mathcal{L}$, the student will choose a concept $L \in \mathcal{L}$ that she prefers most. This gives more flexibility to the teacher than the classical model: the set of labeled examples need not distinguish a target concept L from any other concept in $\mathcal{L}$ but only from those concepts L' over which L is not preferred.[1] At the same time, preference-based teaching yields valid teacher/learner pairs according to Goldman and Mathias's definition. We will show that the new model, despite avoiding coding tricks, is quite powerful. Moreover, as we will see in the course of the paper, it often allows for a very natural design of teaching sets.

Assume teacher and student choose a preference relation that minimizes the worst-case number M of examples required for teaching any concept in the class $\mathcal{L}$. This number M is then called the preference-based teaching dimension (PBTD) of $\mathcal{L}$. In particular, we will show the following:

(i) Recursive teaching is a special case of preference-based teaching where the preference relation satisfies a so-called "finite-depth condition". It is precisely this additional condition that renders recursive teaching useless for many natural and apparently simple infinite concept classes. Preference-based teaching successfully addresses these shortcomings of recursive teaching, see Section 3. For finite classes, PBTD and RTD are equal.

(ii) A wide collection of geometric and algebraic concept classes with infinite RTD can be taught very efficiently, i.e., with low PBTD. To establish such results, we show in Section 4 that spanning sets can be used as preference-based teaching sets with positive examples only — a result that is very simple to obtain but quite useful.

1. Such a preference relation can be thought of as a kind of bias in learning: the student is "biased" towards concepts that are preferred over others, and the teacher, knowing the student's bias, selects teaching sets accordingly.

(iii) In the preference-based model, linear sets over $\mathbb{N}_0$ with origin 0 and at most k generators can be taught with k positive examples, while recursive teaching with a bounded number of positive examples was previously shown to be impossible and it is unknown whether recursive teaching with a bounded number of positive and negative examples is possible for $k \geq 4$. We also give some almost matching upper and lower bounds on the PBTD for other classes of linear sets, see Section 6.

(iv) The PBTD of halfspaces in $\mathbb{R}^d$ is upper-bounded by 6, independent of the dimensionality d (see Section 7), while its RTD is infinite.

(v) We give full characterizations of concept classes that can be taught with only one example (or with only one example, which is positive) in the preference-based model (see Section 8).

Based on our results and the naturalness of the teaching sets and preference relations used in their proofs, we claim that preference-based teaching is far more suitable to the study of infinite concept classes than recursive teaching.

Parts of this paper were published in a previous conference version (Gao et al., 2016).

2. Basic Definitions and Facts

$\mathbb{N}_0$ denotes the set of all non-negative integers and $\mathbb{N}$ denotes the set of all positive integers. A *concept class* $\mathcal{L}$ is a family of subsets over a universe $\mathcal{X}$, i.e., $\mathcal{L} \subseteq 2^{\mathcal{X}}$ where $2^{\mathcal{X}}$ denotes the powerset of $\mathcal{X}$. The elements of $\mathcal{L}$ are called *concepts*. A *labeled example* is an element of $\mathcal{X} \times \{-,+\}$. We slightly deviate from this notation in Section 7, where our treatment of halfspaces makes it more convenient to use $\{-1,1\}$ instead of $\{-,+\}$, and in Section 8, where we perform Boolean operations on the labels and therefore use $\{0,1\}$ instead of $\{-,+\}$. Elements of $\mathcal{X}$ are called *examples*. Suppose that T is a set of labeled examples. Let $T^+ = \{x \in \mathcal{X} : (x,+) \in T\}$ and $T^- = \{x \in \mathcal{X} : (x,-) \in T\}$. A set $L \subseteq \mathcal{X}$ is *consistent with* T if it includes all examples in T that are labeled "+" and excludes all examples in T that are labeled "−", i.e, if $T^+ \subseteq L$ and $T^- \cap L = \emptyset$. A set of labeled examples that is consistent with L but not with L' is said to *distinguish L from L'*. The classical model of teaching is then defined as follows.

Definition 1 (Shinohara and Miyano (1991); Goldman and Kearns (1995)) *A* teaching set *for a concept $L \in \mathcal{L}$ w.r.t. $\mathcal{L}$ is a set T of labeled examples such that L is the only concept in $\mathcal{L}$ that is consistent with T, i.e., T distinguishes L from any other concept in $\mathcal{L}$. Define* $\mathrm{TD}(L,\mathcal{L}) = \inf\{|T| : T$ *is a teaching set for L w.r.t. $\mathcal{L}\}$. i.e., $\mathrm{TD}(L,\mathcal{L})$ is the smallest possible size of a teaching set for L w.r.t. $\mathcal{L}$. If L has no finite teaching set w.r.t. $\mathcal{L}$, then $\mathrm{TD}(L,\mathcal{L}) = \infty$. The number $\mathrm{TD}(\mathcal{L}) = \sup_{L\in\mathcal{L}} \mathrm{TD}(L,\mathcal{L}) \in \mathbb{N}_0 \cup \{\infty\}$ is called the* teaching dimension of $\mathcal{L}$.

For technical reasons, we will occasionally deal with the number $\mathrm{TD}_{min}(\mathcal{L}) = \inf_{L\in\mathcal{L}} \mathrm{TD}(L, \mathcal{L})$, i.e., the number of examples needed to teach the concept from $\mathcal{L}$ that is easiest to teach.

In this paper, we will examine a teaching model in which the teacher and the student do not only agree on a classification-rule system $\mathcal{L}$ but also on a preference relation, denoted as $\prec$, imposed on $\mathcal{L}$. We assume that $\prec$ is a *strict partial order* on $\mathcal{L}$, i.e., $\prec$ is asymmetric and transitive. The partial order that makes every pair $L \neq L' \in \mathcal{L}$ incomparable is denoted by $\prec_\emptyset$. For every $L \in \mathcal{L}$, let

$$\mathcal{L}_{\prec L} = \{L' \in \mathcal{L} : L' \prec L\}$$

be the set of concepts over which L is strictly preferred. Note that $\mathcal{L}_{\prec_\emptyset L} = \emptyset$ for every $L \in \mathcal{L}$.

As already noted above, a teaching set T of L w.r.t. $\mathcal{L}$ distinguishes L from any other concept in $\mathcal{L}$. If a preference relation comes into play, then T will be exempted from the obligation to distinguish L from the concepts in $\mathcal{L}_{\prec L}$ because L is strictly preferred over them anyway.

Definition 2 *A* teaching set for $L \subseteq X$ w.r.t. $(\mathcal{L},\prec)$ *is defined as a teaching set for L w.r.t. $\mathcal{L} \setminus \mathcal{L}_{\prec L}$. Furthermore define*

$$\mathrm{PBTD}(L,\mathcal{L},\prec) = \inf\{|T| : T \text{ is a teaching set for } L \text{ w.r.t. } (\mathcal{L},\prec)\} \in \mathbb{N}_0 \cup \{\infty\} \ .$$

The number $\mathrm{PBTD}(\mathcal{L},\prec) = \sup_{L\in\mathcal{L}} \mathrm{PBTD}(L,\mathcal{L},\prec) \in \mathbb{N}_0 \cup \{\infty\}$ *is called the* teaching dimension of $(\mathcal{L},\prec)$.

Definition 2 implies that

$$\mathrm{PBTD}(L,\mathcal{L},\prec) = \mathrm{TD}(L, \mathcal{L} \setminus \mathcal{L}_{\prec L}) \ . \tag{1}$$

Let $L \mapsto T(L)$ be a mapping that assigns a teaching set for L w.r.t. $(\mathcal{L},\prec)$ to every $L \in \mathcal{L}$. It is obvious from Definition 2 that T must be injective, i.e., $T(L) \neq T(L')$ if L and L' are distinct concepts from $\mathcal{L}$. The classical model of teaching is obtained from the model described in Definition 2 when we plug in the empty preference relation $\prec_\emptyset$ for $\prec$. In particular, $\mathrm{PBTD}(\mathcal{L},\prec_\emptyset) = \mathrm{TD}(\mathcal{L})$.

We are interested in finding the partial order that is optimal for the purpose of teaching and we aim at determining the corresponding teaching dimension. This motivates the following notion:

Definition 3 *The* preference-based teaching dimension of $\mathcal{L}$ *is given by*

$$\mathrm{PBTD}(\mathcal{L}) = \inf\{\mathrm{PBTD}(\mathcal{L},\prec) : \prec \text{ is a strict partial order on } \mathcal{L}\} \ .$$

A relation R' on $\mathcal{L}$ is said to be an *extension of a relation R* if $R \subseteq R'$. The *order-extension principle* states that any partial order has a linear extension (Jech, 1973). The following result (whose second assertion follows from the first one in combination with the order-extension principle) is pretty obvious:

Lemma 4 *1. Suppose that $\prec'$ extends $\prec$. If T is a teaching set for L w.r.t. $(\mathcal{L},\prec)$, then T is a teaching set for L w.r.t. $(\mathcal{L},\prec')$. Moreover* $\mathrm{PBTD}(\mathcal{L},\prec') \leq \mathrm{PBTD}(\mathcal{L},\prec)$.

2. $\mathrm{PBTD}(\mathcal{L}) = \inf\{\mathrm{PBTD}(\mathcal{L},\prec) : \prec$ *is a strict linear order on* $\mathcal{L}\}$.

Recall that Goldman and Mathias (1996) suggested to avoid coding tricks by requesting that any superset S of a teaching set for a concept L remains a teaching set, if S is consistent with L. This property is obviously satisfied in preference-based teaching. A preference-based teaching set needs to distinguish a concept L from all concepts in $\mathcal{L}$ that are preferred over L. Adding more labeled examples from L to such a teaching set will still result in a set distinguishing L from all concepts in $\mathcal{L}$ that are preferred over L.

Preference-based teaching with positive examples only. Suppose that $\mathcal{L}$ contains two concepts L, L' such that $L \subset L'$. In the classical teaching model, any teaching set for L w.r.t. $\mathcal{L}$ has to employ a negative example in order to distinguish L from L'. Symmetrically, any teaching set for L' w.r.t. $\mathcal{L}$ has to employ a positive example. Thus classical teaching cannot be performed with one type of examples only unless $\mathcal{L}$ is an antichain w.r.t. inclusion. As for preference-based teaching, the restriction to one type of examples is much less severe, as our results below will show.

A teaching set T for $L \in \mathcal{L}$ w.r.t. $(\mathcal{L}, \prec)$ is said to be *positive* if it does not make use of negatively labeled examples, i.e., if $T^- = \emptyset$. In the sequel, we will occasionally identify a positive teaching set T with T^+. A positive teaching set for L w.r.t. $(\mathcal{L}, \prec)$ can clearly not distinguish L from a proper superset of L in $\mathcal{L}$. Thus, the following holds:

Lemma 5 *Suppose that $L \mapsto T^+(L)$ maps each $L \in \mathcal{L}$ to a positive teaching set for L w.r.t. $(\mathcal{L}, \prec)$. Then $\prec$ must be an extension of $\supset$ (so that proper subsets of a set L are strictly preferred over L) and, for every $L \in \mathcal{L}$, the set $T^+(L)$ must distinguish L from every proper subset of L in $\mathcal{L}$.*

Define

$$\mathrm{PBTD}^+(L, \mathcal{L}, \prec) = \inf\{|T| : T \text{ is a positive teaching set for } L \text{ w.r.t. } (\mathcal{L}, \prec)\} \ . \tag{2}$$

The number $\mathrm{PBTD}^+(\mathcal{L}, \prec) = \sup_{L \in \mathcal{L}} \mathrm{PBTD}^+(L, \mathcal{L}, \prec)$ (possibly ∞) is called the *positive teaching dimension of* $(\mathcal{L}, \prec)$. The *positive preference-based teaching dimension of* $\mathcal{L}$ is then given by

$$\mathrm{PBTD}^+(\mathcal{L}) = \inf\{\mathrm{PBTD}^+(\mathcal{L}, \prec) : \prec \text{ is a strict partial order on } \mathcal{L}\} \ . \tag{3}$$

Monotonicity. A complexity measure K that assigns a number $K(\mathcal{L}) \in \mathbb{N}_0$ to a concept class $\mathcal{L}$ is said to be *monotonic* if $\mathcal{L}' \subseteq \mathcal{L}$ implies that $K(\mathcal{L}') \leq K(\mathcal{L})$. It is well known (and trivial to see) that TD is monotonic. It is fairly obvious that PBTD is monotonic, too:

Lemma 6 PBTD *and* PBTD^+ *are monotonic.*

As an application of monotonicity, we show the following result:

Lemma 7 *For every finite subclass $\mathcal{L}'$ of $\mathcal{L}$, we have* $\mathrm{PBTD}(\mathcal{L}) \geq \mathrm{PBTD}(\mathcal{L}') \geq \mathrm{TD}_{min}(\mathcal{L}')$.

Proof The first inequality holds because PBTD is monotonic. The second inequality follows from the fact that a finite partially ordered set must contain a minimal element. Thus, for any fixed choice of $\prec$, $\mathcal{L}'$ must contain a concept L' such that $\mathcal{L}'_{\prec L'} = \emptyset$. Hence,

$$\mathrm{PBTD}(\mathcal{L}', \prec) \geq \mathrm{PBTD}(L', \mathcal{L}', \prec) \overset{(1)}{=} \mathrm{TD}(L', \mathcal{L}' \setminus \mathcal{L}'_{\prec L'}) = \mathrm{TD}(L', \mathcal{L}') \geq \mathrm{TD}_{min}(\mathcal{L}') \ .$$

Since this holds for any choice of $\prec$, we get $\mathrm{PBTD}(\mathcal{L}') \geq \mathrm{TD}_{min}(\mathcal{L}')$, as desired. ■

3. Preference-based versus Recursive Teaching

The preference-based teaching dimension is a relative of the recursive teaching dimension. In fact, both notions coincide on finite classes, as we will see shortly. We first recall the definitions of the recursive teaching dimension and of some related notions (Zilles et al., 2011; Mazadi et al., 2014).

A *teaching sequence for* $\mathcal{L}$ is a sequence of the form $\mathcal{S} = (\mathcal{L}_i, d_i)_{i \geq 1}$ where $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3, \ldots$ form a partition of $\mathcal{L}$ into non-empty sub-classes and, for every $i \geq 1$, we have that

$$d_i = \sup_{L \in \mathcal{L}_i} \mathrm{TD}\left(L, \mathcal{L} \setminus \cup_{j=1}^{i-1} \mathcal{L}_j\right) \ . \tag{4}$$

If, for every $i \geq 1$, d_i is the supremum over all $L \in \mathcal{L}_i$ of the smallest size of a *positive teaching set* for L w.r.t. $\cup_{j \geq i} \mathcal{L}_j$ (and $d_i = \infty$ if some $L \in \mathcal{L}_i$ does not have a positive teaching set w.r.t. $\cup_{j \geq i} \mathcal{L}_j$), then $\mathcal{S}$ is said to be a *positive teaching sequence for* $\mathcal{L}$. The *order* of a teaching sequence or a positive teaching sequence $\mathcal{S}$ (possibly ∞) is defined as $\mathrm{ord}(\mathcal{S}) = \sup_{i \geq 1} d_i$. The *recursive teaching dimension of* $\mathcal{L}$ (possibly ∞) is defined as the order of the teaching sequence of lowest order for $\mathcal{L}$. More formally, $\mathrm{RTD}(\mathcal{L}) = \inf_{\mathcal{S}} \mathrm{ord}(\mathcal{S})$ where $\mathcal{S}$ ranges over all teaching sequences for $\mathcal{L}$. Similarly, $\mathrm{RTD}^+(\mathcal{L}) = \inf_{\mathcal{S}} \mathrm{ord}(\mathcal{S})$, where $\mathcal{S}$ ranges over all positive teaching sequences for $\mathcal{L}$. Note that the following holds for every $\mathcal{L}' \subseteq \mathcal{L}$ and for every teaching sequence $\mathcal{S} = (\mathcal{L}_i, d_i)_{i \geq 1}$ for $\mathcal{L}'$ such that $\mathrm{ord}(\mathcal{S}) = \mathrm{RTD}(\mathcal{L}')$:

$$\mathrm{RTD}(\mathcal{L}) \geq \mathrm{RTD}(\mathcal{L}') = \mathrm{ord}(\mathcal{S}) \geq d_1 = \sup_{L \in \mathcal{L}_1} \mathrm{TD}(L, \mathcal{L}') \geq \mathrm{TD}_{min}(\mathcal{L}') \ . \tag{5}$$

Note an important difference between PBTD and RTD: while $\mathrm{RTD}(\mathcal{L}) \geq \mathrm{TD}_{min}(\mathcal{L}')$ for *all* $\mathcal{L}' \subseteq \mathcal{L}$, in general the same holds for PBTD only when restricted to finite $\mathcal{L}'$, cf. Lemma 7. This difference will become evident in the proof of Lemma 10.

The *depth* of $L \in \mathcal{L}$ w.r.t. a strict partial order imposed on $\mathcal{L}$ is defined as the length of the longest chain in $(\mathcal{L}, \prec)$ that ends with the $\prec$-maximal element L (resp. as ∞ if there is no bound on the length of these chains). The recursive teaching dimension is related to the preference-based teaching dimension as follows:

Lemma 8 $\mathrm{RTD}(\mathcal{L}) = \inf_{\prec} \mathrm{PBTD}(\mathcal{L}, \prec)$ *and* $\mathrm{RTD}^+(\mathcal{L}) = \inf_{\prec} \mathrm{PBTD}^+(\mathcal{L}, \prec)$ *where $\prec$ ranges over all strict partial orders on $\mathcal{L}$ that satisfy the following "finite-depth condition": every $L \in \mathcal{L}$ has a finite depth w.r.t. $\prec$.*

The following is an immediate consequence of Lemma 8 and the trivial observation that the finite-depth condition is always satisfied if $\mathcal{L}$ is finite:

Corollary 9 $\mathrm{PBTD}(\mathcal{L}) \leq \mathrm{RTD}(\mathcal{L})$*, with equality if $\mathcal{L}$ is finite.*

While $\mathrm{PBTD}(\mathcal{L})$ and $\mathrm{RTD}(\mathcal{L})$ refer to the same finite number when $\mathcal{L}$ is finite, there are classes for which the RTD is infinity and yet the PBTD is finite, as Lemma 10 will show.

Lemma 10 *There exists an infinite class $\mathcal{L}_\infty$ of VC-dimension 1 such that* $\mathrm{PBTD}^+(\mathcal{L}_\infty) = 1$ *and* $\mathrm{RTD}(\mathcal{L}_\infty) = \infty$.

Proof Let $\mathcal{L}_\infty$ be the family of closed half-intervals over $[0,1)$, i.e., $\mathcal{L}_\infty = \{[0,a] : 0 \leq a < 1\}$. We first prove that $\mathrm{PBTD}^+(\mathcal{L}_\infty) = 1$. Consider the preference relation given by $[0,b] \prec [0,a]$ iff $a < b$. Then, for each $0 \leq a < 1$, we have

$$\mathrm{PBTD}([0,a], \mathcal{L}_\infty, \prec) \stackrel{(1)}{=} \mathrm{TD}([0,a], \{[0,b] : \ 0 \leq b \leq a\}) = 1$$

because the single example $(a,+)$ suffices for distinguishing $[0,a]$ from any interval $[0,b]$ with $b < a$.

It was observed by Moran et al. (2015) already that $\mathrm{RTD}(\mathcal{L}_\infty) = \infty$ because every teaching set for some $[0,a]$ must contain an infinite sequence of distinct reals that converges from above to a. Thus, using Equation (5) with $\mathcal{L}' = \mathcal{L}$, we have $\mathrm{RTD}(\mathcal{L}_\infty) \geq \mathrm{TD}_{min}(\mathcal{L}_\infty) = \infty$. ■

Remark 11 *For every $k \geq 1$, there exists an infinite class $\mathcal{L}_k$ such that $\mathrm{PBTD}^+(\mathcal{L}_k) = 1$ and $\mathrm{RTD}(\mathcal{L}_k) = k$; see (Gao et al., 2017, Lemma 6).*

4. Preference-based Teaching with Positive Examples Only

The main purpose of this section is to relate positive preference-based teaching to "spanning sets" and "closure operators", which are well-studied concepts in the computational learning theory literature. Let $\mathcal{L}$ be a concept class over the universe $\mathcal{X}$. We say that $S \subseteq \mathcal{X}$ is a *spanning set* of $L \in \mathcal{L}$ w.r.t. $\mathcal{L}$ if $S \subseteq L$ and any set in $\mathcal{L}$ that contains S must contain L as well.[2] In other words, L is the unique smallest concept in $\mathcal{L}$ that contains S. We say that $S \subseteq \mathcal{X}$ is a *weak spanning set* of $L \in \mathcal{L}$ w.r.t. $\mathcal{L}$ if $S \subseteq L$ and S is not contained in any proper subset of L in $\mathcal{L}$.[3] We denote by $I(\mathcal{L})$ (resp. $I'(\mathcal{L})$) the smallest number k such that every concept $L \in \mathcal{L}$ has a spanning set (resp. a weak spanning set) w.r.t. $\mathcal{L}$ of size at most k. Note that S is a spanning set of L w.r.t. $\mathcal{L}$ iff S distinguishes L from all concepts in $\mathcal{L}$ except for supersets of L, i.e., iff S is a positive teaching set for L w.r.t. $(\mathcal{L}, \supset)$. Similarly, S is a weak spanning set of L w.r.t. $\mathcal{L}$ iff S distinguishes L from all its proper subsets in $\mathcal{L}$ (which is necessarily the case when S is a positive teaching set). These observations can be summarized as follows:

$$I'(\mathcal{L}) \leq \mathrm{PBTD}^+(\mathcal{L}) \leq \mathrm{PBTD}^+(\mathcal{L}, \supset) \leq I(\mathcal{L}) \ . \tag{6}$$

The last two inequalities are straightforward. The inequality $I'(\mathcal{L}) \leq \mathrm{PBTD}^+(\mathcal{L})$ follows from Lemma 5, which implies that no concept L can have a preference-based teaching set T smaller than its smallest weak spanning set. Such a set T would be consistent with some proper subset of L, which is impossible by Lemma 5.

Suppose $\mathcal{L}$ is intersection-closed. Then $\cap_{L \in \mathcal{L}: S \subseteq L} L$ is the unique smallest concept in $\mathcal{L}$ containing S. If $S \subseteq L_0$ is a weak spanning set of $L_0 \in \mathcal{L}$, then $\cap_{L \in \mathcal{L}: S \subseteq L} L = L_0$ because, on the one hand, $\cap_{L \in \mathcal{L}: S \subseteq L} L \subseteq L_0$ and, on the other hand, no proper subset of L_0 in $\mathcal{L}$ contains S. Thus the distinction between spanning sets and weak spanning sets is blurred for intersection-closed classes:

2. This generalizes the classical definition of a spanning set (Helmbold et al., 1990), which is given w.r.t. intersection-closed classes only.
3. Weak spanning sets have been used in the field of recursion-theoretic inductive inference under the name "tell-tale sets" (Angluin, 1980).

Lemma 12 *Suppose that $\mathcal{L}$ is intersection-closed. Then $I'(\mathcal{L}) = \mathrm{PBTD}^+(\mathcal{L}) = I(\mathcal{L})$.*

Example 1 *Let $\mathcal{R}_d$ denote the class of d-dimensional axis-parallel hyper-rectangles (= d-dimensional boxes). This class is intersection-closed and clearly $I(\mathcal{R}_d) = 2$. Thus $\mathrm{PBTD}^+(\mathcal{R}_d) = 2$.*

A mapping $\mathrm{cl} : 2^{\mathcal{X}} \to 2^{\mathcal{X}}$ is said to be a *closure operator* on the universe $\mathcal{X}$ if the following conditions hold for all sets $A, B \subseteq \mathcal{X}$:

$$A \subseteq B \Rightarrow \mathrm{cl}(A) \subseteq \mathrm{cl}(B) \ \text{ and } \ A \subseteq \mathrm{cl}(A) = \mathrm{cl}(\mathrm{cl}(A)) \ .$$

The following notions refer to an arbitrary but fixed closure operator. The set $\mathrm{cl}(A)$ is called the *closure* of A. A set C is said to be *closed* if $\mathrm{cl}(C) = C$. It follows that precisely the sets $\mathrm{cl}(A)$ with $A \subseteq \mathcal{X}$ are closed. With this notation, we observe the following lemma.

Lemma 13 *Let $\mathcal{C}$ be the set of all closed subsets of $\mathcal{X}$ under some closure operator* cl*, and let $L \in \mathcal{C}$. If $L = \mathrm{cl}(S)$, then S is a spanning set of L w.r.t. $\mathcal{C}$.*

Proof Suppose $L' \in \mathcal{C}$ and $S \subseteq L'$. Then $L = \mathrm{cl}(S) \subseteq \mathrm{cl}(L') = L'$. ■

For every closed set $L \in \mathcal{L}$, let $s_{cl}(L)$ denote the size (possibly ∞) of the smallest set $S \subseteq \mathcal{X}$ such that $\mathrm{cl}(S) = L$. With this notation, we get the following (trivial but useful) result:

Theorem 14 *Given a closure operator, let $\mathcal{C}[m]$ be the class of all closed subsets $C \subseteq \mathcal{X}$ with $s_{cl}(C) \leq m$. Then $\mathrm{PBTD}^+(\mathcal{C}[m]) \leq \mathrm{PBTD}^+(\mathcal{C}[m], \supset) \leq m$. Moreover, this holds with equality provided that $\mathcal{C}[m] \setminus \mathcal{C}[m-1] \neq \emptyset$.*

Proof The inequality $\mathrm{PBTD}^+(\mathcal{C}[m], \supset) \leq m$ follows directly from Equation (6) and Lemma 13. Pick a concept $C_0 \in \mathcal{C}[m]$ such that $s_{cl}(C_0) = m$. Then any subset S of C_0 of size less than m spans only a proper subset of C_0, i.e., $\mathrm{cl}(S) \subset C_0$. Thus S does not distinguish C_0 from $\mathrm{cl}(S)$. However, by Lemma 5, any preference-based learner must strictly prefer $\mathrm{cl}(S)$ over C_0. It follows that there is no positive teaching set of size less than m for C_0 w.r.t. $\mathcal{C}[m]$. ■

Many natural classes can be cast as classes of the form $\mathcal{C}[m]$ by choosing the universe and the closure operator appropriately; the following examples illustrate the usefulness of Theorem 14 in that regard.

Example 2 *Let*

$$\mathrm{LINSET}_k = \{\langle G \rangle : (G \subset \mathbb{N}) \wedge (1 \leq |G| \leq k)\}$$

where $\langle G \rangle = \left\{ \sum_{g \in G} a(g) g : a(g) \in \mathbb{N}_0 \right\}$. In other words, LINSET_k is the set of all non-empty linear subsets of $\mathbb{N}_0$ that are generated by at most k generators. Note that the mapping $G \mapsto \langle G \rangle$ is a closure operator over the universe $\mathbb{N}_0$. Since obviously $\mathrm{LINSET}_k \setminus \mathrm{LINSET}_{k-1} \neq \emptyset$, we obtain $\mathrm{PBTD}^+(\mathrm{LINSET}_k) = k$.

Example 3 *Let $\mathcal{X} = \mathbb{R}^2$ and let $\mathcal{C}_k$ be the class of convex polygons with at most k vertices. Defining $\mathrm{cl}(S)$ to be the convex closure of S, we obtain $\mathcal{C}[k] = \mathcal{C}_k$ and thus $\mathrm{PBTD}^+(\mathcal{C}_k) = k$.*

Example 4 *Let $\mathcal{X} = \mathbb{R}^n$ and let $\mathcal{C}_k$ be the class of polyhedral cones that can be generated by k (or less) vectors in $\mathbb{R}^n$. If we take $\mathrm{cl}(S)$ to be the conic closure of $S \subseteq \mathbb{R}^n$, then $\mathcal{C}[k] = \mathcal{C}_k$ and thus $\mathrm{PBTD}^+(\mathcal{C}_k) = k$.*

5. A Convenient Technique for Proving Upper Bounds

In this section, we give an alternative definition of the preference-based teaching dimension using the notion of an "admissible mapping". Given a concept class $\mathcal{L}$ over a universe $\mathcal{X}$, let T be a mapping $L \mapsto T(L) \subseteq \mathcal{X} \times \{-,+\}$ that assigns a set $T(L)$ of labeled examples to every set $L \in \mathcal{L}$ such that the labels in $T(L)$ are consistent with L. The *order* of T, denoted as $\mathrm{ord}(T)$, is defined as $\sup_{L\in\mathcal{L}} |T(L)| \in \mathbb{N} \cup \{\infty\}$. Define the mappings T^+ and T^- by setting $T^+(L) = \{x : (x,+) \in T(L)\}$ and $T^-(L) = \{x : (x,-) \in T(L)\}$ for every $L \in \mathcal{L}$. We say that T is *positive* if $T^-(L) = \emptyset$ for every $L \in \mathcal{L}$. In the sequel, we will occasionally identify a positive mapping $L \mapsto T(L)$ with the mapping $L \mapsto T^+(L)$. The symbol "+" as an upper index of T will always indicate that the underlying mapping T is positive.
The following relation will help to clarify under which conditions the sets $(T(L))_{L\in\mathcal{L}}$ are teaching sets w.r.t. a suitably chosen preference relation:

$$R_T = \{(L,L') \in \mathcal{L} \times \mathcal{L} : \ (L \neq L') \wedge (L \text{ is consistent with } T(L'))\} \ .$$

The transitive closure of R_T is denoted as $\mathrm{trcl}(R_T)$ in the sequel. The following notion will play an important role in this paper:

Definition 15 *A mapping $L \mapsto T(L)$ with L ranging over all concepts in $\mathcal{L}$ is said to be* admissible for $\mathcal{L}$ *if the following holds:*

1. *For every $L \in \mathcal{L}$, L is consistent with $T(L)$.*
2. *The relation $\mathrm{trcl}(R_T)$ is asymmetric (which clearly implies that R_T is asymmetric too).*

If T is admissible, then $\mathrm{trcl}(R_T)$ is transitive and asymmetric, i.e., $\mathrm{trcl}(R_T)$ is a strict partial order on $\mathcal{L}$. We will therefore use the notation $\prec_T$ instead of $\mathrm{trcl}(R_T)$ whenever T is known to be admissible.

Lemma 16 *Suppose that T^+ is a positive admissible mapping for $\mathcal{L}$. Then the relation $\prec_{T^+}$ on $\mathcal{L}$ extends the relation $\supset$ on $\mathcal{L}$. More precisely, the following holds for all $L, L' \in \mathcal{L}$:*

$$L' \subset L \Rightarrow (L,L') \in R_{T^+} \Rightarrow L \prec_{T^+} L' \ .$$

Proof If T^+ is admissible, then L' is consistent with $T^+(L')$. Thus $T^+(L') \subseteq L' \subset L$ so that L is consistent with $T^+(L')$ too. Therefore $(L,L') \in R_{T^+}$, i.e., $L \prec_{T^+} L'$. ■

The following result clarifies how admissible mappings are related to preference-based teaching:

Lemma 17 *For each concept class $\mathcal{L}$, the following holds:*

$$\mathrm{PBTD}(\mathcal{L}) = \inf_T \mathrm{ord}(T) \ \textit{ and } \ \mathrm{PBTD}^+(\mathcal{L}) = \inf_{T^+} \mathrm{ord}(T^+)$$

where T ranges over all mappings that are admissible for $\mathcal{L}$ and T^+ ranges over all positive mappings that are admissible for $\mathcal{L}$.

Proof We restrict ourselves to the proof for $\mathrm{PBTD}(\mathcal{L}) = \inf_T \mathrm{ord}(T)$ because the equation $\mathrm{PBTD}^+(\mathcal{L}) = \inf_{T^+} \mathrm{ord}(T^+)$ can be obtained in a similar fashion. We first prove that $\mathrm{PBTD}(\mathcal{L}) \leq \inf_T \mathrm{ord}(T)$. Let T be an admissible mapping for $\mathcal{L}$. It suffices to show that, for every $L \in \mathcal{L}$, $T(L)$ is a teaching set for L w.r.t. $(\mathcal{L}, \prec_T)$. Suppose $L' \in \mathcal{L} \setminus \{L\}$ is consistent with $T(L)$. Then $(L',L) \in R_T$ and thus $L' \prec_T L$. It follows that $\prec_T$ prefers L over all concepts $L' \in \mathcal{L} \setminus \{L\}$ that are consistent with $T(L)$. Thus T is a teaching set for L w.r.t. $(\mathcal{L}, \prec_T)$, as desired.

We now prove that $\inf_T \mathrm{ord}(T) \leq \mathrm{PBTD}(\mathcal{L})$. Let $\prec$ be a strict partial order on $\mathcal{L}$ and let T be a mapping such that, for every $L \in \mathcal{L}$, $T(L)$ is a teaching set for L w.r.t. $(\mathcal{L}, \prec)$. It suffices to show that T is admissible for $\mathcal{L}$. Consider a pair $(L',L) \in R_T$. The definition of R_T implies that $L' \neq L$ and that L' is consistent with $T(L)$. Since $T(L)$ is a teaching set w.r.t. $(\mathcal{L}, \prec)$, it follows that $L' \prec L$. Thus, $\prec$ is an extension of R_T. Since $\prec$ is transitive, it is even an extension of $\mathrm{trcl}(R_T)$. Because $\prec$ is asymmetric, $\mathrm{trcl}(R_T)$ must be asymmetric, too. It follows that T is admissible. ■

6. Preference-based Teaching of Linear Sets

Some work in computational learning theory (Abe, 1989; Gao et al., 2015; Takada, 1992) is concerned with learning *semi-linear sets*, i.e., unions of linear subsets of $\mathbb{N}^k$ for some fixed $k \geq 1$, where each linear set consists of exactly those elements that can be written as the sum of some constant vector c and a linear combination of the elements of some fixed set of generators, see Example 2. While semi-linear sets are of common interest in mathematics in general, they play a particularly important role in the theory of formal languages, due to *Parikh's theorem*, by which the so-called Parikh vectors of strings in a context-free language always form a semi-linear set (Parikh, 1966).

A recent study (Gao et al., 2015) analyzed computational teaching of classes of linear subsets of $\mathbb{N}$ (where $k = 1$) and some variants thereof, as a substantially simpler yet still interesting special case of semi-linear sets. In this section, we extend that study to preference-based teaching.

Within the scope of this section, all concept classes are formulated over the universe $\mathcal{X} = \mathbb{N}_0$. Let $G = \{g_1, \ldots, g_k\}$ be a finite subset of $\mathbb{N}$. We denote by $\langle G \rangle$ resp. by $\langle G \rangle_+$ the following sets:

$$\langle G \rangle = \left\{ \sum_{i=1}^{k} a_i g_i : \ a_1, \ldots, a_k \in \mathbb{N}_0 \right\} \ \text{ and } \ \langle G \rangle_+ = \left\{ \sum_{i=1}^{k} a_i g_i : \ a_1, \ldots, a_k \in \mathbb{N} \right\} \ .$$

We will determine (at least approximately) the preference-based teaching dimension of the following concept classes over $\mathbb{N}_0$:

$$\begin{aligned}
\mathrm{LINSET}_k &= \{\langle G \rangle : \ (G \subset \mathbb{N}) \wedge (1 \leq |G| \leq k)\} \ . \\
\mathrm{CF\text{-}LINSET}_k &= \{\langle G \rangle : \ (G \subset \mathbb{N}) \wedge (1 \leq |G| \leq k) \wedge (\gcd(G) = 1)\} \ . \\
\mathrm{NE\text{-}LINSET}_k &= \{\langle G \rangle_+ : \ (G \subset \mathbb{N}) \wedge (1 \leq |G| \leq k)\} \ . \\
\mathrm{NE\text{-}CF\text{-}LINSET}_k &= \{\langle G \rangle_+ : \ (G \subset \mathbb{N}) \wedge (1 \leq |G| \leq k) \wedge (gcd(G) = 1)\} \ .
\end{aligned}$$

A subset of $\mathbb{N}_0$ whose complement in $\mathbb{N}_0$ is finite is said to be *co-finite*. The letters "CF" in CF-LINSET mean "co-finite". The concepts in LINSET_k have the algebraic structure of a monoid w.r.t. addition. The concepts in $\mathrm{CF\text{-}LINSET}_k$ are also known as "numerical semigroups" (Rosales

and García-Sánchez, 2009). A zero coefficient $a_j = 0$ erases g_j in the linear combination $\sum_{i=1}^{k} a_i g_i$. Coefficients from $\mathbb{N}$ are non-erasing in this sense. The letters "NE" in "NE-LINSET" mean "non-erasing".

The *shift-extension* $\mathcal{L}'$ of a concept class $\mathcal{L}$ over the universe $\mathbb{N}_0$ is defined as follows:

$$\mathcal{L}' = \{c + L : (c \in \mathbb{N}_0) \wedge (L \in \mathcal{L})\} \ . \tag{7}$$

The following bounds on RTD and RTD^+ (for sufficiently large values of k)[4] are known from (Gao et al., 2015):

	RTD^+	RTD
LINSET_k	$= \infty$	?
$\mathrm{CF\text{-}LINSET}_k$	$= k$	$\in \{k-1, k\}$
$\mathrm{NE\text{-}LINSET}'_k$	$= k+1$	$\in \{k-1, k, k+1\}$

Here $\mathrm{NE\text{-}LINSET}'_k$ denotes the shift-extension of $\mathrm{NE\text{-}LINSET}_k$.

The following result shows the corresponding bounds with PBTD in place of RTD:

Theorem 18 *The bounds in the following table are valid:*

	PBTD^+	PBTD
LINSET_k	$= k$	$\in \{k-1, k\}$
$\mathrm{CF\text{-}LINSET}_k$	$= k$	$\in \{k-1, k\}$
$\mathrm{NE\text{-}LINSET}_k$	$\in \left[\left\lfloor \frac{k-1}{2} \right\rfloor : k\right]$	$\in \left[\left\lfloor \frac{k-1}{2} \right\rfloor : k\right]$
$\mathrm{NE\text{-}CF\text{-}LINSET}_k$	$\in \left[\left\lfloor \frac{k-1}{2} \right\rfloor : k\right]$	$\in \left[\left\lfloor \frac{k-1}{2} \right\rfloor : k\right]$

Moreover

$$\mathrm{PBTD}^+(\mathcal{L}') = k+1 \ \wedge \ \mathrm{PBTD}(\mathcal{L}') \in \{k-1, k, k+1\} \tag{8}$$

holds for all $\mathcal{L} \in \{\mathrm{LINSET}_k, \mathrm{CF\text{-}LINSET}_k, \mathrm{NE\text{-}LINSET}_k, \mathrm{NE\text{-}CF\text{-}LINSET}_k\}$.

Note that the equation $\mathrm{PBTD}^+(\mathrm{LINSET}_k) = k$ was already proven in Example 2, using the fact that $G \mapsto \langle G \rangle$ is a closure operator. Since $G \mapsto \langle G \rangle_+$ is not a closure operator, we give a separate argument to prove an upper bound of k on $\mathrm{PBTD}^+(\mathrm{NE\text{-}LINSET}_k)$ (see Lemma 37 in Appendix A). All other upper bounds in Theorem 18 are then easy to derive. The lower bounds in Theorem 18 are much harder to obtain. A complete proof of Theorem 18 will be given in Appendix A.

Remark 19 *The lower bound on* $\mathrm{PBTD}^+(\mathrm{NE\text{-}LINSET}_k)$ *and* $\mathrm{PBTD}^+(\mathrm{NE\text{-}CF\text{-}LINSET}_k)$ *may be improved to* $k-1$*; see (Gao et al., 2017, Theorem 2, Appendix A.3).*

4. For instance, $\mathrm{RTD}^+(\mathrm{LINSET}_k) = \infty$ holds for all $k \geq 2$ and $\mathrm{RTD}(\mathrm{LINSET}_k) =$? (where "?" means "unknown") holds for all $k \geq 4$.

7. Preference-based Teaching of Halfspaces

In this section, we study preference-based teaching of halfspaces. We will denote the all-zeros vector as $\vec{0}$. The vector with 1 in coordinate i and with 0 in the remaining coordinates is denoted as $\vec{e}_i$. The dimension of the Euclidean space in which these vectors reside will always be clear from the context. The sign of a real number x (with value 1 if $x > 0$, value -1 if $x < 0$, and value 0 if $x = 0$) is denoted by $\mathrm{sign}(x)$.

Suppose that $w \in \mathbb{R}^d \setminus \{\vec{0}\}$ and $b \in \mathbb{R}$. The *(positive) halfspace induced by* w *and* b is then given by

$$H_{w,b} = \{x \in \mathbb{R}^d : \ w^\top x + b \geq 0\} \ .$$

Instead of $H_{w,0}$, we simply write H_w. Let $\mathcal{H}_d$ denote the class of d-dimensional Euclidean halfspaces:

$$\mathcal{H}_d = \{H_{w,b} : \ w \in \mathbb{R}^d \setminus \{\vec{0}\} \wedge b \in \mathbb{R}\} \ .$$

Similarly, $\mathcal{H}_d^0$ denotes the class of d-dimensional homogeneous Euclidean halfspaces:

$$\mathcal{H}_d^0 = \{H_w : \ w \in \mathbb{R}^d \setminus \{\vec{0}\}\} \ .$$

Let S_{d-1} denote the $(d-1)$-dimensional unit sphere in $\mathbb{R}^d$. Moreover $S_{d-1}^+ = \{x \in S_{d-1} : x_d > 0\}$ denotes the "northern hemisphere". If not stated explicitly otherwise, we will represent homogeneous halfspaces with normalized vectors residing on the unit sphere. We remind the reader of the following well-known fact:

Remark 20 *The orthogonal group in dimension* d *(i.e., the multiplicative group of orthogonal* $(d \times d)$*-matrices) acts transitively on* S_{d-1} *and it conserves the inner product.*

We now prove a helpful lemma, stating that each vector w^* in the northern hemisphere may serve as a representative for some homogeneous halfspace H_u in the sense that all other elements of H_u in the northern hemisphere have a strictly smaller d-th component than w^*. This will later help to teach homogeneous halfspaces with a preference that orders vectors by the size of their last coordinate.

Lemma 21 *Let* $d \geq 2$*, let* $0 < h \leq 1$ *and let* $R_{d,h} = \{w \in S_{d-1} : w_d = h\}$*. With this notation the following holds. For every* $w^* \in R_{d,h}$*, there exists* $u \in \mathbb{R}^d \setminus \{\vec{0}\}$ *such that*

$$(w^* \in H_u) \wedge (\forall w \in (S_{d-1}^+ \cap H_u) \setminus \{w^*\} : w_d < h) \ . \tag{9}$$

Proof For $h = 1$, the statement is trivial, since $R_{d,1} = \{\vec{e}_d\}$. So let $h < 1$.

Because of Remark 20, we may assume without loss of generality that the vector $w^* \in R_{d,h}$ equals $(0, \ldots, 0, \sqrt{1-h^2}, h)$. It suffices therefore to show that, with this choice of w^*, the vector $u = (0, \ldots, 0, w_d^*, -w_{d-1}^*)$ satisfies (9). Note that $w \in H_u$ iff $\langle u, w \rangle = w_d^* w_{d-1} - w_{d-1}^* w_d \geq 0$. Since $\langle u, w^* \rangle = 0$, we have $w^* \in H_u$. Moreover, it follows that

$$S_{d-1}^+ \cap H_u = \left\{ w \in S_{d-1}^+ : \frac{w_{d-1}}{w_d} \geq \frac{w_{d-1}^*}{w_d^*} > 0 \right\} \ .$$

It is obvious that no vector $w \in S_{d-1}^+ \cap H_u$ can have a d-th component w_d exceeding $w_d^* = h$ and that setting $w_d = h = w_d^*$ forces the settings $w_{d-1} = w_{d-1}^* = \sqrt{1-h^2}$ and $w_1 = \ldots = w_{d-2} = 0$.

Consequently, (9) is satisfied, which concludes the proof. ■

With this lemma in hand, we can now prove an upper bound of 2 for the preference-based teaching dimension of the class of homogeneous halfspaces, independent of the underlying dimension d.

Theorem 22 $\mathrm{PBTD}(\mathcal{H}_1^0) = \mathrm{TD}(\mathcal{H}_1^0) = 1$ *and, for every* $d \geq 2$*, we have* $\mathrm{PBTD}(\mathcal{H}_d^0) \leq 2$.

Proof Clearly, $\mathrm{PBTD}(\mathcal{H}_1^0) = \mathrm{TD}(\mathcal{H}_1^0) = 1$ since $\mathcal{H}_1^0$ consists of the two sets $\{x \in \mathbb{R} : x \geq 0\}$ and $\{x \in \mathbb{R} : x \leq 0\}$.
Suppose now that $d \geq 2$. Let w^* be the target weight vector (i.e., the weight vector that has to be taught). Under the following conditions, we may assume without loss of generality that $w_d^* \neq 0$:

- For any $0 < s_1 < s_2$, the student prefers any weight vector that ends with s_2 zero coordinates over any weight vector that ends with only s_1 zero coordinates.
- If the target vector ends with (exactly) s zero coordinates, then the teacher presents only examples ending with (at least) s zero coordinates.

In the sequel, we specify a student and a teacher such that these conditions hold, so that we will consider only target weight vectors w^* with $w_d^* \neq 0$.
The student has the following preference relation:

- Among the weight vectors w with $w_d \neq 0$, the student prefers vectors with larger values of $|w_d|$ over those with smaller values of $|w_d|$.

The teacher will use two examples. The first one is chosen as

$$\begin{cases} (-\vec{e}_d, -) & \text{if } w_d^* > 0 \\ (\vec{e}_d, -) & \text{if } w_d^* < 0 \end{cases} .$$

This example reveals whether the unknown weight vector $w^* \in S_{d-1}$ has a strictly positive or a strictly negative d-th component. For reasons of symmetry, we may assume that $w_d^* > 0$. We are now precisely in the situation that is described in Lemma 21. Given w^* and $h = w_d^*$, the teacher picks as a second example $(u, +)$ where $u \in \mathbb{R}^d \setminus \{\vec{0}\}$ has the properties described in the lemma. It follows immediately that the student's preferences will make her choose the weight vector w^*. ■

The upper bound of 2 given in Theorem 22 is tight, as is stated in the following lemma.

Lemma 23 *For every* $d \geq 2$*, we have* $\mathrm{PBTD}(\mathcal{H}_d^0) \geq 2$.

Proof We verify this lemma via Lemma 7, by providing a finite subclass $\mathcal{F}$ of $\mathcal{H}_2^0$ such that $\mathrm{TD}_{min}(\mathcal{F}) = 2$. Let $\mathcal{F} = \{H_w : \vec{0} \neq w \in \{-1, 0, 1\}^2\}$. It is easy to verify that each of the 8 halfspaces in $\mathcal{F}$ has a teaching dimension of 2 with respect to $\mathcal{F}$. This example can be extended to higher dimensions in the obvious way. ■

We thus conclude that the class of homogeneous halfspaces has a preference-based teaching dimension of 2, independent of the dimensionality $d \geq 2$.

Corollary 24 *For every* $d \geq 2$*, we have* $\mathrm{PBTD}(\mathcal{H}_d^0) = 2$.

By contrast, we will show next that the recursive teaching dimension of the class of homogeneous halfspaces grows with the dimensionality.

Theorem 25 *For any* $d \geq 2$, $\mathrm{TD}(\mathcal{H}_d^0) = \mathrm{RTD}(\mathcal{H}_d^0) = d + 1$.

Proof Assume by normalization that the target weight vector has norm 1, i.e., it is taken from S_{d-1}. Remark 20 implies that all weight vectors in S_{d-1} are equally hard to teach. It suffices therefore to show that $\mathrm{TD}(H_{\vec{e}_1}, \mathcal{H}_d^0) = d + 1$.

We first show that $\mathrm{TD}(H_{\vec{e}_1}, \mathcal{H}_d^0) \leq d + 1$. Define $u = -\sum_{i=2}^d \vec{e}_i$. We claim that $T = \{(\vec{e}_i, +) : 2 \leq i \leq d\} \cup \{(u, +), (\vec{e}_1, +)\}$ is a teaching set for $H_{\vec{e}_1}$ w.r.t. $\mathcal{H}_d^0$. Consider any $w \in S_{d-1}$ such that H_w is consistent with T. Note that $w_i = \langle \vec{e}_i, w \rangle \geq 0$ for all $i \in \{2, \ldots, d\}$ and $\langle u, w \rangle = -\sum_{i=2}^d w_i \geq 0$ together imply that $w_i = 0$ for all $i \in \{2, \ldots, d\}$ and therefore $w = \pm\vec{e}_1$. Furthermore, $w_1 = \langle w, \vec{e}_1 \rangle \geq 0$, and so $w = \vec{e}_1$, as required.

Now we show that $\mathrm{TD}(H_{\vec{e}_1}, \mathcal{H}_d^0) \geq d + 1$ holds for all $d \geq 2$. It is easy to see that two examples do not suffice for distinguishing $\vec{e}_1 \in \mathbb{R}^2$ from all weight vectors in S_1. In other words, $\mathrm{TD}(H_{\vec{e}_1}, \mathcal{H}_2^0) \geq 3$. Suppose now that $d \geq 3$. It is furthermore easy to see that a teaching set T which distinguishes $\vec{e}_1$ from all weight vectors in S_{d-1} must contain at least one positive example u that is orthogonal to $\vec{e}_1$. The inequality $\mathrm{TD}(H_{\vec{e}_1}, \mathcal{H}_d^0) \geq d + 1$ is now obtained inductively because the example $(u, +) \in T$ leaves open a problem that is not easier than teaching $\vec{e}_1$ w.r.t. the $(d-2)$-dimensional sphere $\{x \in S_{d-1} : x \perp u\}$. ■

We have thus established that the class of homogeneous halfspaces has a recursive teaching dimension growing linearly with d, while its preference-based teaching dimension is constant. In the case of general (i.e., not necessarily homogeneous) d-dimensional halfspaces, the difference between RTD and PBTD is even more extreme. On the one hand, by generalizing the proof of Lemma 10, it is easy to see that $\mathrm{RTD}(\mathcal{H}_d) = \infty$ for all $d \geq 1$. On the other hand, we will show in the remainder of this section that $\mathrm{PBTD}(\mathcal{H}_d) \leq 6$, independent of the value of d.

We will assume in the sequel (by way of normalization) that an inhomogeneous halfspace has a bias $b \in \{\pm 1\}$. We start with the following result:

Lemma 26 *Let* $w^* \in \mathbb{R}^d$ *be a vector with a non-trivial* d*-th component* $w_d^* \neq 0$ *and let* $b^* \in \{\pm 1\}$ *be a bias. Then there exist three examples labeled according to* H_{w^*,b^*} *such that the following holds. Every weight-bias pair* (w, b) *consistent with these examples satisfies* $b = b^*$, $\mathrm{sign}(w_d) = \mathrm{sign}(w_d^*)$ *and*

$$\begin{cases} |w_d| \geq |w_d^*| & \text{if } b^* = -1 \\ |w_d| \leq |w_d^*| & \text{if } b^* = +1 \end{cases} . \tag{10}$$

Proof Within the proof, we use the label "1" instead of "+" and the label "−1" instead of "−". The pair (w, b) denotes the student's hypothesis for the target weight-bias pair (w^*, b^*). The examples shown to the student will involve the unknown quantities w^* and b^*. Each example will lead to a new constraint on w and b. We will see that the collection of these constraints reveals the required information. We proceed in three stages:

1. The first example is chosen as $(\vec{0}, b^*)$. The pair (w, b) can be consistent with this example only if $b = -1$ in the case that $b^* = -1$ and $b \in \{0, 1\}$ in the case that $b^* = 1$.

2. The next example is chosen as $\vec{a}_2 = -\frac{2b^*}{w_d^*} \cdot \vec{e}_d$ and labeled "$-b^*$". Note that $\langle w^*, \vec{a}_2 \rangle + b^* = -b^*$. We obtain the following new constraint:

$$\langle w, \vec{a}_2 \rangle + b = \begin{cases} -2\frac{w_d}{w_d^*} + \overbrace{b}^{\in\{0,1\}} < 0 & \text{if } b^* = 1 \\ +2\frac{w_d}{w_d^*} + \underbrace{b}_{=-1} \geq 0 & \text{if } b^* = -1 \end{cases} .$$

   The pair (w, b) with $b = b^*$ if $b^* = -1$ and $b \in \{0, 1\}$ if $b^* = 1$ can satisfy the above constraint only if the sign of w_d equals the sign of w_d^*.

3. The third example is chosen as the example $\vec{a}_3 = -\frac{b^*}{w_d^*} \cdot \vec{e}_d$ with label "1". Note that $\langle w^*, \vec{a}_3 \rangle^* + b^* = 0$. We obtain the following new constraint:

$$\langle w, \vec{a}_3 \rangle = -\frac{b^* w_d}{w_d^*} + b \geq 0 \ .$$

   Given that w is already constrained to weight vectors satisfying $\text{sign}(w_d) = \text{sign}(w_d^*)$, we can safely replace w_d / w_d^* by $|w_d|/|w_d^*|$. This yields $|w_d|/|w_d^*| \leq b$ if $b^* = 1$ and $|w_d|/|w_d^*| \geq -b$ if $b^* = -1$. Since b is already constrained as described in stage 1 above, we obtain $|w_d|/|w_d^*| \leq b \in \{0, 1\}$ if $b^* = 1$ and $|w_d|/|w_d^*| \geq -b = 1$ if $b^* = -1$. The weight-bias pair (w, b) satisfies these constraints only if $b = b^*$ and if (10) is valid.

The assertion of the lemma is immediate from this discussion. ■

Theorem 27 $\text{PBTD}(\mathcal{H}_d) \leq 6$.

Proof As in the proof of Lemma 26, we use the label "1" instead of "+" and the label "-1" instead of "$-$". As in the proof of Theorem 22, we may assume without loss of generality that the target weight vector $w^* \in \mathbb{R}^d$ satisfies $w_d^* \neq 0$. The proof will proceed in stages. On the way, we specify six rules which determine the preference relation of the student.

Stage 1 is concerned with teaching homogeneous halfspaces given by w^* (and $b^* = 0$). The student respects the following rules:

Rule 1: She prefers any pair $(w, 0)$ over any pair (w', b) with $b \neq 0$. In other words, any homogeneous halfspace is preferred over any non-homogeneous halfspace.

Rule 2: Among homogeneous halfspaces, her preferences are the same as the ones that were used within the proof of Theorem 22 for teaching homogeneous halfspaces.

Thus, if $b^* = 0$, then we can simply apply the teaching protocol for homogeneous halfspaces. In this case, w^* can be taught at the expense of only two examples.

Stage 1 reduces the problem to teaching inhomogeneous halfspaces given by (w^*, b^*) with $b^* \neq 0$. We assume, by way of normalization, that $b^* \in \{\pm 1\}$, but note that w^* can now not be assumed to be of unit (or any other fixed) length.

In **stage 2**, the teacher presents three examples in accordance with Lemma 26. It follows that the student will take into consideration only weight-bias pairs (w, b) such that the constraints $b = b^*$, $\text{sign}(w_d) = \text{sign}(w_d^*)$ and (10) are satisfied. The following rule will then induce the constraint $w_d = w_d^*$:

Rule 3: Among the pairs (w, b) such that $w_d \neq 0$ and $b \in \{\pm 1\}$, the student's preferences are as follows. If $b = -1$ (resp. $b = 1$), then she prefers vectors w with a smaller (resp. larger) value of $|w_d|$ over those with a larger (resp. smaller) value of $|w_d|$.

Thanks to Lemma 26 and thanks to Rule 3, we may from now on assume that $b = b^*$ and $w_d = w_d^*$. In the sequel, let w^* be decomposed according to $w^* = (\vec{w}_{d-1}^*, w_d^*) \in \mathbb{R}^{d-1} \times \mathbb{R}$. We think of $\vec{w}_{d-1}$ as the student's hypothesis for $\vec{w}_{d-1}^*$.

Stage 3 is concerned with the special case where $\vec{w}_{d-1}^* = \vec{0}$. The student will automatically set $\vec{w}_{d-1} = \vec{0}$ if we add the following to the student's rule system:

Rule 4: Given that the values for w_d and b have been fixed already (and are distinct from 0), the student prefers weight-bias pairs with $\vec{w}_{d-1} = \vec{0}$ over any weight-bias pair with $\vec{w}_{d-1} \neq \vec{0}$.

Stage 3 reduces the problem to teaching (w^*, b^*) with fixed non-zero values for w_d and b^* (known to the student) and with $\vec{w}_{d-1}^* \neq \vec{0}$. Thus, essentially, only $\vec{w}_{d-1}^*$ has still to be taught. In the next stage, we will argue that the problem of teaching $\vec{w}_{d-1}^*$ is equivalent to teaching a homogeneous halfspace.

In **stage 4**, the teacher will present only examples a such that $a_d = -\frac{b^*}{w_d^*}$ so that the contribution of the d-th component to the inner product of w^* and a cancels with the bias b^*. Given this commitment for a_d, the first $d-1$ components of the examples can be chosen so as to teach the homogeneous halfspace $H_{\vec{w}_{d-1}^*}$. According to Theorem 22, this can be achieved at the expense of two more examples. Of course the student's preferences must match with the preferences that were used in the proof of this theorem:

Rule 5: Suppose that the values of w_d and b have been fixed already (and are distinct from 0) and suppose that $\vec{w}_{d-1} \neq \vec{0}$. Then the preferences for the choice of $\vec{w}_{d-1}$ match with the preferences that were used in the protocol for teaching homogeneous halfspaces.

After stage 4, the student takes into consideration only weight-bias pairs (w, b) such that $w_d = w_d^*$, $b = b^*$ and $H_{\vec{w}_{d-1}} = H_{\vec{w}_{d-1}^*}$. However, since we had normalized the bias and not the weight vector, this does not necessarily mean that $\vec{w}_{d-1} = \vec{w}_{d-1}^*$. On the other hand, the two weight vectors already coincide modulo a positive scaling factor, say

$$\vec{w}_{d-1} = s \cdot \vec{w}_{d-1}^* \text{ for some } s > 0 \ . \tag{11}$$

In order to complete the proof, it suffices to teach the L_1-norm of $\vec{w}_{d-1}^*$ to the student (because (11) and $\|\vec{w}_{d-1}\|_1 = \|\vec{w}_{d-1}^*\|_1$ imply that $\vec{w}_{d-1} = \vec{w}_{d-1}^*$). The next (and final) stage serves precisely this purpose.

As for **stage 5**, we first fix some notation. For $i = 1, \ldots, k-1$, let $\beta_i = \text{sign}(w_i^*)$. Note that (11) implies that $\beta_i = \text{sign}(w_i)$. Let $L = \|\vec{w}_{d-1}^*\|_1$ denote the L_1-norm of $\vec{w}_{d-1}^*$. The final example is chosen as $\vec{a}_6 = (\beta_1, \ldots, \beta_{d-1}, -(L + b^*)/w_d^*)$ and labeled "1". Note that

$$\langle w^*, \vec{a_6} \rangle + b^* = |w_1^*| + \ldots + |w_{d-1}^*| - L = 0 \ .$$

Given that $\beta_i = \text{sign}(w_i)$, $w_d = w_d^*$ and $b = b^*$, the student can derive from $\vec{a_6}$ and its label the following constraint on $\vec{w}_{d-1}$:

$$\langle w, \vec{a_6} \rangle + b = |w_1| + \ldots + |w_{d-1}| - L \geq 0 \ .$$

In combination with the following rule, we can now force the constraint $\|\vec{w}_{d-1}\|_1 = L$:

Rule 6: Suppose that the values of w_d and b have been fixed already (and are distinct from 0) and suppose that $H_{\vec{w}_{d-1}}$ has already been fixed. Then, among the vectors representing $H_{\vec{w}_{d-1}}$, the ones with a smaller L_1-norm are preferred over the ones with a larger L_1-norm.

An inspection of the six stages reveals that at most six examples altogether were shown to the student (three in stage 2, two in stage 4, and one in stage 5). This completes the proof of the theorem. ■

Note that Theorems 22 and 27 remain valid when we allow w to be the all-zero vector, which extends $\mathcal{H}_d^0$ by $\{\mathbb{R}^d\}$ and $\mathcal{H}_d$ by $\{\mathbb{R}^d, \emptyset\}$. $\mathbb{R}^d$ will be taught with a single positive example, and $\emptyset$ with a single negative example. The student will give the highest preference to $\mathbb{R}^d$, the second highest to $\emptyset$, and among the remaining halfspaces, the student's preferences stay the same.

8. Classes with PBTD or PBTD^+ Equal to One

In this section, we will give complete characterizations of (i) the concept classes with a positive preference-based teaching dimension of 1, and (ii) the concept classes with a preference-based teaching dimension of 1. Throughout this section, we use the label "1" to indicate positive examples and the label "0" to indicate negative examples.

Let I be a (possibly infinite) index set. We will consider a mapping $A : I \times I \to \{0,1\}$ as a binary matrix $A \in \{0,1\}^{I \times I}$. A is said to be *lower-triangular* if there exists a linear ordering $\prec$ on I such that $A(i,i') = 0$ for every pair (i,i') such that $i \prec i'$.

We will occasionally identify a set $L \subseteq \mathcal{X}$ with its indicator function by setting $L(x) = \mathbb{1}_{[x \in L]}$. For each $M \subseteq \mathcal{X}$, we define

$$M \oplus L = (L \setminus M) \cup (M \setminus L)$$

and

$$M \oplus \mathcal{L} = \{M \oplus L : L \in \mathcal{L}\} \ .$$

For $T \subseteq \mathcal{X} \times \{0,1\}$, we define similarly

$$M \oplus T = \{(x, \bar{y}) : (x,y) \in T \text{ and } x \in M\} \cup \{(x,y) \in T : x \notin M\} \ .$$

Moreover, given $M \subseteq \mathcal{X}$ and a linear ordering $\prec$ on $\mathcal{L}$, we define a linear ordering $\prec_M$ on $M \oplus \mathcal{L}$ as follows:

$$M \oplus L' \prec_M M \oplus L \Leftrightarrow \underbrace{M \oplus (M \oplus L')}_{=L'} \prec \underbrace{M \oplus (M \oplus L)}_{=L} \ .$$

Lemma 28 *With this notation, the following holds. If the mapping $\mathcal{L} \ni L \mapsto T(L) \subseteq \mathcal{X} \times \{0,1\}$ assigns a teaching set to L w.r.t. $(\mathcal{L}, \prec)$, then the mapping $M \oplus \mathcal{L} \ni M \oplus L \mapsto M \oplus T(L) \subseteq \mathcal{X} \times \{0,1\}$ assigns a teaching set to $M \oplus L$ w.r.t. $(M \oplus \mathcal{L}, \prec_M)$.*

Since this result is rather obvious, we skip its proof.

We say that $\mathcal{L}$ and $\mathcal{L}'$ are *equivalent* if $\mathcal{L}' = M \oplus \mathcal{L}$ for some $M \subseteq \mathcal{X}$ (and this clearly is an equivalence relation). As an immediate consequence of Lemma 28, we obtain the following result:

Lemma 29 *If $\mathcal{L}$ is equivalent to $\mathcal{L}'$, then $\mathrm{PBTD}(\mathcal{L}) = \mathrm{PBTD}(\mathcal{L}')$.*

The following lemma provides a necessary condition for a concept class to have a preference-based teaching dimension of one.

Lemma 30 *Suppose that $\mathcal{L} \subseteq 2^{\mathcal{X}}$ is a concept class of PBTD 1. Pick a linear ordering $\prec$ on $\mathcal{L}$ and a mapping $\mathcal{L} \ni L \mapsto (x_L, y_L) \in \mathcal{X} \times \{0,1\}$ such that, for every $L \in \mathcal{L}$, $\{(x_L, y_L)\}$ is a teaching set for L w.r.t. $(\mathcal{L}, \prec)$. Then*

- *either every instance $x \in \mathcal{X}$ occurs at most once in $(x_L)_{L \in \mathcal{L}}$*
- *or there exists a concept $L^* \in \mathcal{L}$ that is preferred over all other concepts in $\mathcal{L}$ and x_{L^*} is the only instance from $\mathcal{X}$ that occurs twice in $(x_L)_{L \in \mathcal{L}}$.*

Proof Since the mapping T must be injective, no instance can occur twice in $(x_L)_{L \in \mathcal{L}}$ with the same label. Suppose that there exists an instance $x \in \mathcal{X}$ and concepts $L \prec L^*$ such that $x = x_L = x_{L^*}$ and, w.l.o.g., $y_L = 1$ and $y_{L^*} = 0$. Since $\{(x,1)\}$ is a teaching set for L w.r.t. $(\mathcal{L}, \prec)$, every concept $L' \succ L$ (including the ones that are preferred over L^*) must satisfy $L'(x) = 0$. For analogous reasons, every concept $L' \succ L^*$ (if any) must satisfy $L'(x) = 1$. A concept $L' \in \mathcal{L}$ that is preferred over L^* would have to satisfy $L'(x) = 0$ and $L'(x) = 1$, which is impossible. It follows that there can be no concept that is preferred over L^*. ■

The following result is a consequence of Lemmas 28 and 30.

Theorem 31 *If $\mathrm{PBTD}(\mathcal{L}) = 1$, then there exists a concept class $\mathcal{L}'$ that is equivalent to $\mathcal{L}$ and satisfies $\mathrm{PBTD}(\mathcal{L}') = \mathrm{PBTD}^+(\mathcal{L}') = 1$.*

Proof Pick a linear ordering $\prec$ on $\mathcal{L}$ and, for every $L \in \mathcal{L}$, a pair $(x_L, y_L) \in \mathcal{X} \times \{0,1\}$ such that $T(L) = \{(x_L, y_L)\}$ is a teaching set for L w.r.t. $(\mathcal{L}, \prec)$.

Case 1: Every instance $x \in \mathcal{X}$ occurs at most once in $(x_L)_{L \in \mathcal{L}}$.
Then choose $M = \{x_L : y_L = 0\}$ and apply Lemma 28.

Case 2: There exists a concept $L^* \in \mathcal{L}$ that is preferred over all other concepts in $\mathcal{L}$ and x_{L^*} is the only instance from $\mathcal{X}$ that occurs twice in $(x_L)_{L \in \mathcal{L}}$.
Then choose $M = \{x_L : y_L = 0 \wedge L \neq L^*\}$ and apply Lemma 28. With this choice, we obtain $M \oplus T(L) = \{(x_L, 1)\}$ for every $L \in \mathcal{L} \setminus \{L^*\}$. Since L^* is preferred over all other concepts in $\mathcal{L}$, we may teach L^* w.r.t. $(\mathcal{L}, \prec)$ by the empty set (instead of employing a possibly 0-labeled example).

The discussion shows that there is a class $\mathcal{L}'$ that is equivalent to $\mathcal{L}$ and can be taught in the preference-based model with positive teaching sets of size 1 (or size 0 in case of L^*). ■

We now have the tools required for characterizing the concept classes whose positive PBTD equals 1.

Theorem 32 $\mathrm{PBTD}^+(\mathcal{L}) = 1$ *if and only if there exists a mapping $\mathcal{L} \ni L \mapsto x_L \in \mathcal{X}$ such that the matrix $A \in \{0,1\}^{(\mathcal{L} \setminus \{\emptyset\}) \times (\mathcal{L} \setminus \{\emptyset\})}$ given by $A(L, L') = L'(x_L)$ is lower-triangular.*

Proof Suppose first that $\mathrm{PBTD}^+(\mathcal{L}) = 1$. Pick a linear ordering $\prec$ on $\mathcal{L}$ and, for every $L \in \mathcal{L}\setminus\{\emptyset\}$, pick $x_L \in \mathcal{X}$ such that $\{x_L\}$ is a positive teaching set for L w.r.t. $(\mathcal{L}, \prec)$.[5] If $L \prec L'$ (so that L' is preferred over L), we must have $L'(x_L) = 0$. It follows that the matrix A, as specified in the theorem, is lower-triangular.

Suppose conversely that there exists a mapping $\mathcal{L} \ni L \mapsto x_L \in \mathcal{X}$ such that the matrix $A \in \{0,1\}^{(\mathcal{L}\setminus\{\emptyset\})\times(\mathcal{L}\setminus\{\emptyset\})}$ given by $A(L, L') = L'(x_L)$ is lower-triangular, say w.r.t. the linear ordering $\prec$ on $\mathcal{L} \setminus \{\emptyset\}$. Then, for every $L \in \mathcal{L} \setminus \{\emptyset\}$, the singleton $\{x_L\}$ is a positive teaching set for L w.r.t. $(\mathcal{L}, \prec)$ because it distinguishes L from $\emptyset$ (of course) and also from every concept $L' \in \mathcal{L} \setminus \{\emptyset\}$ such that $L' \succ L$. If $\emptyset \in \mathcal{L}$, then extend the linear ordering $\prec$ by preferring $\emptyset$ over every other concept from $\mathcal{L}$ (so that $\emptyset$ is a positive teaching set for $\emptyset$ w.r.t. $(\mathcal{L}, \prec)$). ■

In view of Theorem 31, Theorem 32 characterizes every class $\mathcal{L}$ with $\mathrm{PBTD}(\mathcal{L}) = 1$ up to equivalence.

Let $\mathrm{Sg}(\mathcal{X}) = \{\{x\} : x \in \mathcal{X}\}$ denote the class of singletons over $\mathcal{X}$ and suppose that $\mathrm{Sg}(\mathcal{X})$ is a sub-class of $\mathcal{L}$ and $\mathrm{PBTD}(\mathcal{L}) = 1$. We will show that only fairly trivial extensions of $\mathrm{Sg}(\mathcal{X})$ with a preference-based dimension of 1 are possible.

Lemma 33 *Let $\mathcal{L} \subseteq 2^{\mathcal{X}}$ be a concept class of $\mathrm{PBTD}\,1$ that contains $\mathrm{Sg}(\mathcal{X})$. Let T be an admissible mapping for $\mathcal{L}$ that assigns a labeled example $(x_L, y_L) \in \mathcal{X} \times \{0,1\}$ to each $L \in \mathcal{L}$. For $b = 0, 1$, let $\mathcal{L}^b = \{L \in \mathcal{L} : y_L = b\}$. Similarly, let $\mathcal{X}^b = \{x \in \mathcal{X} : y_{\{x\}} \in \mathcal{L}^b\}$. With this notation, the following holds:*

1. *If $L \in \mathcal{L}^1$ and $L \subset L' \in \mathcal{L}$, then $L' \in \mathcal{L}^1$.*
2. *If $L' \in \mathcal{L}^0$ and $L' \supset L \in \mathcal{L}$, then $L \in \mathcal{L}^0$.*
3. *$|\mathcal{X}^0| \leq 2$. Moreover if $|\mathcal{X}^0| = 2$, then there exist $q \neq q' \in \mathcal{X}$ such that $\mathcal{X}^0 = \{q, q'\}$ and $x_{\{q\}} = q'$.*

Proof Recall that $R_T = \{(L, L') \in \mathcal{L} \times \mathcal{L} : \ (L \neq L') \wedge (L \text{ is consistent with } T(L'))\}$ and that R_T (and even the transitive closure of R_T) is asymmetric if T is admissible.

1. If $L \in \mathcal{L}^1$ and $L \subset L'$, then $y_L = 1$ so that L' is consistent with the example (x_L, y_L). It follows that $(L', L) \in R_T$. $L' \in \mathcal{L}^0$ would similarly imply that $(L, L') \in R_T$ so that R_T would not be asymmetric. This is in contradiction with the admissibility of T.

2. The second assertion in the lemma is a logically equivalent reformulation of the first assertion.

3. Suppose for the sake of contradiction that $\mathcal{X}^0$ contains three distinct points, say q_1, q_2, q_3. Since, for $i = 1, 2, 3$, T assigns a 0-labeled example to $\{q_i\}$, at least one of the remaining two points is consistent with $T(\{q_i\})$. Let G be the digraph with the nodes q_1, q_2, q_3 and with an edge from q_j to q_i iff $\{q_j\}$ is consistent with $T(\{q_i\})$. Then each of the three nodes has an indegree of at least 1. Digraphs of this form must contain a cycle so that $\mathrm{trcl}(R_T)$ is not asymmetric. This is in contradiction with the admissibility of R_T.

5. Such an x_L always exists, even if $\emptyset$ is a teaching set for L, because every superset of a teaching set for L that is still consistent with L is still a teaching set for L, cf. the discussion immediately after Lemma 4.

A similar argument holds if $\mathcal{X}^0$ contains only two distinct elements, say q and q'. If neither $x_{\{q\}} = q'$ nor $x_{\{q'\}} = q$, then $(\{q'\}, \{q\}) \in R_T$ and $(\{q\}, \{q'\}) \in R_T$ so that R_T is not asymmetric — again a contradiction to the admissibility of R_T.

■

We are now in the position to characterize those classes of PBTD one that contain all singletons.

Theorem 34 *Suppose that $\mathcal{L} \subseteq 2^{\mathcal{X}}$ is a concept class that contains $\mathrm{Sg}(\mathcal{X})$. Then $\mathrm{PBTD}(\mathcal{L}) = 1$ if and only if the following holds. Either $\mathcal{L}$ coincides with $\mathrm{Sg}(\mathcal{X})$ or $\mathcal{L}$ contains precisely one additional concept, which is either the empty set or a set of size 2.*

Proof We start with proving "⇐". It is well known that $\mathrm{PBTD}^+(\mathcal{L}) = 1$ for $\mathcal{L} = \mathrm{Sg}(\mathcal{X}) \cup \{\emptyset\}$: prefer $\emptyset$ over any singleton set, set $T(\emptyset) = \emptyset$ and, for every $x \in \mathcal{X}$, set $T(\{x\}) = \{(x, 1)\}$. In a similar fashion, we can show that $\mathrm{PBTD}(\mathcal{L}) = 1$ for $\mathcal{L} = \mathrm{Sg}(\mathcal{X}) \cup \{\{q, q'\}\}$ for any choice of $q \neq q' \in \mathcal{X}$. Prefer $\{q, q'\}$ over $\{q\}$ and $\{q'\}$, respectively. Furthermore, prefer $\{q\}$ and $\{q'\}$ over all other singletons. Finally, set $T(\{q, q'\}) = \emptyset$, $T(\{q\}) = \{(q', 0)\}$, $T(\{q'\}) = \{(q, 0)\}$ and, for every $x \in \mathcal{X} \setminus \{q, q'\}$, set $T(\{x\}) = \{(x, 1)\}$.

As for the proof of "⇒", we make use of the notions $T, x_L, y_L, \mathcal{L}^0, \mathcal{L}^1, \mathcal{X}^0, \mathcal{X}^1$ that had been introduced in Lemma 33 and we proceed by case analysis.

Case 1: $\mathcal{X}^0 = \emptyset$.
Since $\mathcal{X}^0 = \emptyset$, we have $\mathcal{X} = \mathcal{X}^1$. In combination with the first assertion in Lemma 33, it follows that $\mathcal{L} \setminus \{\emptyset\} = \mathcal{L}^1$. We claim that no concept in $\mathcal{L}$ contains two distinct elements. Assume for the sake of contradiction that there is a concept $L \in \mathcal{L}$ such that $|L| \geq 2$. It follows that, for every $q \in L$, $x_{\{q\}} = q$ and $y_{\{q\}} = 1$ so that $(L, \{q\}) \in R_T$. Moreover, there exists $q_0 \in L$ such that $x_L = q_0$ and $y_L = 1$. It follows that $(\{q_0\}, L) \in R_T$, which contradicts the fact that R_T is asymmetric.

Case 2: $\mathcal{X}^0 = \{q\}$ for some $q \in \mathcal{X}$.
Set $q' = x_{\{q\}}$ and note that $y_{\{q\}} = 0$. Moreover, since $\mathcal{X}^1 = \mathcal{X} \setminus \{q\}$, we have $x_{\{p\}} = p$ and $y_{\{p\}} = 1$ for every $p \in \mathcal{X} \setminus \{q\}$. We claim that $\mathcal{L}$ cannot contain a concept L of size at least 2 that contains an element of $\mathcal{X} \setminus \{q, q'\}$. Assume for the sake of contradiction, that there is a set L such that $|L| \geq 2$ and $p \in L$ for some $p \in \mathcal{X} \setminus \{q, q'\}$. The first assertion in Lemma 33 implies that $y_L = 1$ (because $y_{\{p\}} = 1$ and $\{p\} \subseteq L$). Since all pairs $(x, 1)$ with $x \neq q$ are already in use for teaching the corresponding singletons, we may conclude that $q \in L$ and $T(L) = \{(q, 1)\}$. This contradicts the fact that $\mathrm{trcl}(R_T)$ is asymmetric, because our discussion implies that $(L, \{p\}), (\{p\}, \{q\}), (\{q\}, L) \in R_T$. We may therefore safely assume that there is no concept of size at least 2 in $\mathcal{L}$ that has a non-empty intersection with $\mathcal{X} \setminus \{q, q'\}$. Thus, except for the singletons, the only remaining sets that possibly belong to $\mathcal{L}$ are $\emptyset$ and $\{q, q'\}$. We still have to show that not both of them can belong to $\mathcal{L}$. Assume for the sake of contradiction that $\emptyset, \{q, q'\} \in \mathcal{L}$. Since $\emptyset$ is consistent with $T(\{q\}) = \{(q', 0)\}$, we have $(\emptyset, \{q\}) \in R_T$. Clearly, $y_\emptyset = 0$. Since $\{q\}$ is consistent with every pair $(x, 0)$ except for $(q, 0)$, we must have $x_\emptyset = q$. (Otherwise, we have $(\{q\}, \emptyset) \in R_T$ and arrive at a contradiction.) Let us now inspect the possible teaching sets for $L = \{q, q'\}$. Since $\{q, q'\}$ is consistent with $T(\{q'\}) = \{(q', 1)\}$, setting $y_L = 0$ would lead to a contradiction. The example $(q', 1)$

is already in use for teaching $\{q'\}$. It is therefore necessary to set $T(L) = \{(q, 1)\}$. An inspection of the various teaching sets shows that $(\emptyset, \{q\}), (\{q\}, L), (L, \{q'\}), (\{q'\}, \emptyset) \in R_T$, which contradicts the fact that $\mathrm{trcl}(R_T)$ is asymmetric.

Case 3: $\mathcal{X}^0 = \{q, q'\}$ for some $q \neq q' \in \mathcal{X}$.
Note first that $y_{\{q\}} = y_{\{q'\}} = 0$ and $y_{\{p\}} = 1$ for every $p \in \mathcal{X} \setminus \{q, q'\}$. We claim that $\emptyset \notin \mathcal{L}$. Assume for the sake of contradiction that $\emptyset \in \mathcal{L}$. Then $(\emptyset, \{q\}), (\emptyset, \{q'\}) \in R_T$ since $\emptyset$ is consistent with the teaching sets for instances from $\mathcal{X}^0$. But then, no matter how x in $T(\emptyset) = \{(x, 0)\}$ is chosen, at least one of the sets $\{q\}$ and $\{q'\}$ will be consistent with $T(\emptyset)$ so that at least one of the pairs $(\{q\}, \emptyset)$ and $(\{q'\}, \emptyset)$ belongs to R_T. This contradicts the fact that R_T must be asymmetric. Thus $\emptyset \notin \mathcal{L}$, indeed. Now it suffices to show that $\mathcal{L}$ cannot contain a concept of size at least 2 that contains an element of $\mathcal{X} \setminus \{q, q'\}$. Assume for the sake of contradiction that there is a set $L \in \mathcal{L}$ such that $|L| \geq 2$ and $p \in L$ for some $p \in \mathcal{X} \setminus \{q, q'\}$. Observe that $(L, \{p\}) \in R_T$. Another application of the first assertion in Lemma 33 shows that $y_L = 1$ (because $y_{\{p\}} = 1$ and $p \in L$) and $x_L \in \{q, q'\}$ (because the other 1-labeled instances are already in use for teaching the corresponding singletons). It follows that one of the pairs $(\{q\}, L)$ and $(\{q'\}, L)$ belongs to R_T. The third assertion of Lemma 33 implies that $T(q) = \{(q', 0)\}$ or $T(q') = \{(q, 0)\}$. For reasons of symmetry, we may assume that $T(q) = \{(q', 0)\}$. This implies that $(\{p\}, \{q\}) \in R_T$. Let q'' be given by $T(q') = \{(q'', 0)\}$. Note that either $q'' = q$ or $q'' \in \mathcal{X} \setminus \{q, q'\}$. In the former case, we have that $(\{p\}, \{q'\}) \in R_T$ and in the latter case we have that $(\{q\}, \{q'\}) \in R_T$. Since $(\{p\}, \{q\}) \in R_T$ (which was observed above already), we conclude that in both cases, $(\{p\}, \{q\}), (\{p\}, \{q'\}) \in \mathrm{trcl}(R_T)$. Combining this with our observations above that $(L, \{p\}) \in R_T$ and that one of the pairs $(\{q\}, L)$ and $(\{q'\}, L)$ belongs to R_T, yields a contradiction to the fact that $\mathrm{trcl}(R_T)$ is asymmetric.

■

Corollary 35 *Let $\mathcal{L} \subseteq 2^{\mathcal{X}}$ be a concept class that contains $\mathrm{Sg}(\mathcal{X})$. If $\mathrm{PBTD}(\mathcal{L}) = 1$, then $\mathrm{RTD}(\mathcal{L}) = 1$.*

Proof According to Theorem 34, either L coincides with $\mathrm{Sg}(\mathcal{X})$ or $\mathcal{L}$ contains precisely one additional concept that is $\emptyset$ or a set of size 2. The partial ordering $\prec$ on $\mathcal{L}$ that is used in the first part of the proof of Theorem 34 (proof direction "$\Leftarrow$") is easily compiled into a recursive teaching plan of order 1 for $\mathcal{L}$.[6] ■

The characterizations proven above can be applied to certain geometric concept classes.

Consider a class $\mathcal{L}$, consisting of bounded and topologically closed objects in the d-dimensional Euclidean space, that satisfies the following condition: for every pair $(A, B) \in \mathbb{R}^d$, there is exactly one object in $\mathcal{L}$, denoted as $L_{A,B}$ in the sequel, such that $A, B \in L$ and such that $\|A - B\|$ coincides with the diameter of L. This assumption implies that $|\mathcal{L} \setminus \mathrm{Sg}(\mathbb{R}^d)| = \infty$. By setting $A = B$, it furthermore implies $\mathrm{Sg}(\mathbb{R}^d) \subseteq \mathcal{L}$. Let us prefer objects with a small diameter over objects with a larger diameter. Then, obviously, $\{A, B\}$ is a positive teaching set for $L_{A,B}$. Because

6. This also follows from Lemma 8 and the fact that there are no chains of a length exceeding 2 in $(\mathcal{L}, \prec)$.

of $|\mathcal{L} \setminus \mathrm{Sg}(\mathbb{R}^d)| = \infty$, $\mathcal{L}$ does clearly not satisfy the condition in Theorem 34, which is necessary for $\mathcal{L}$ to have a PBTD of 1. We may therefore conclude that $\mathrm{PBTD}(\mathcal{L}) = \mathrm{PBTD}^+(\mathcal{L}) = 2$.

The family of classes with the required properties is rich and includes, for instance, the class of d-dimensional balls as well as the class of d-dimensional axis-parallel rectangles.

9. Conclusions

Preference-based teaching uses the natural notion of preference relation to extend the classical teaching model. The resulting model is (i) more powerful than the classical one, (ii) resolves difficulties with the recursive teaching model in the case of infinite concept classes, and (iii) is at the same time free of coding tricks even according to the definition by Goldman and Mathias (1996). Our examples of algebraic and geometric concept classes demonstrate that preference-based teaching can be achieved very efficiently with naturally defined teaching sets and based on intuitive preference relations such as inclusion. We believe that further studies of the PBTD will provide insights into structural properties of concept classes that render them easy or hard to learn in a variety of formal learning models.

We have shown that spanning sets lead to a general-purpose construction for preference-based teaching sets of only positive examples. While this result is fairly obvious, it provides further justification of the model of preference-based teaching, since the teaching sets it yields are often intuitively exactly those a teacher would choose in the classroom (for instance, one would represent convex polygons by their vertices, as in Example 3). It should be noted, too, that it can sometimes be difficult to establish whether the upper bound on PBTD obtained this way is tight, or whether the use of negative examples or preference relations other than inclusion yield smaller teaching sets. Generally, the choice of preference relation provides a degree of freedom that increases the power of the teacher but also increases the difficulty of establishing lower bounds on the number of examples required for teaching.

Appendix A. Proof of Theorem 18

In Section A.1, we present a general result which helps to verify the upper bounds in Theorem 18. These upper bounds are then derived in Section A.2. Section A.3 is devoted to the derivation of the lower bounds.

A.1 The Shift Lemma

In this section, we assume that $\mathcal{L}$ is a concept class over a universe $\mathcal{X} \in \{\mathbb{N}_0, \mathbb{Q}_0^+, \mathbb{R}_0^+\}$. We furthermore assume that 0 is contained in every concept $L \in \mathcal{L}$. We can extend $\mathcal{L}$ to a larger class, namely the shift-extension $\mathcal{L}'$ of $\mathcal{L}$, by allowing each of its concepts to be shifted by some constant which is taken from $\mathcal{X}$:

$$\mathcal{L}' = \{c + L : \ (c \in \mathcal{X}) \wedge (L \in \mathcal{L})\} \ .$$

The next result states that this extension has little effect only on the complexity measures PBTD and PBTD^+:

Lemma 36 (Shift Lemma) *With the above notation and assumptions, the following holds:*

$$\mathrm{PBTD}(\mathcal{L}) \leq \mathrm{PBTD}(\mathcal{L}') \leq 1{+}\mathrm{PBTD}(\mathcal{L}) \text{ and } \mathrm{PBTD}^+(\mathcal{L}) \leq \mathrm{PBTD}^+(\mathcal{L}') \leq 1{+}\mathrm{PBTD}^+(\mathcal{L}) \ .$$

Proof It suffices to verify the inequalities $\mathrm{PBTD}(\mathcal{L}') \leq 1 + \mathrm{PBTD}(\mathcal{L})$ and $\mathrm{PBTD}^+(\mathcal{L}') \leq 1 + \mathrm{PBTD}^+(\mathcal{L})$ because the other inequalities hold by virtue of monotonicity. Let T be an admissible mapping for $\mathcal{L}$. It suffices to show that T can be transformed into an admissible mapping T' for $\mathcal{L}'$ such that $\mathrm{ord}(T') \leq 1 + \mathrm{ord}(T)$ and such that T' is positive provided that T is positive. To this end, we define T' as follows:

$$T'(c + L) = \{(c, +)\} \cup \{(c + x, b) : \ (x, b) \in T(L)\} \ .$$

Obviously $\mathrm{ord}(T') \leq 1{+}\mathrm{ord}(T)$. Note that $c \in c{+}L$ because of our assumption that 0 is contained in every concept in $\mathcal{L}$. Moreover, since the admissibility of T implies that L is consistent with $T(L)$, the above definition of $T'(c{+}L)$ makes sure that $c{+}L$ is consistent with $T'(c{+}L)$. It suffices therefore to show that the relation $\mathrm{trcl}(R_{T'})$ is asymmetric. Consider a pair $(c'{+}L', c{+}L) \in R_{T'}$. By the definition of $R_{T'}$, it follows that $c'{+}L'$ is consistent with $T'(c{+}L)$. Because of $(c, +) \in T'(c{+}L)$, we must have $c' \leq c$. Suppose that $c' = c$. In this case, L' must be consistent with $T(L)$. Thus $L' \prec_T L$. This reasoning implies that $(c' + L', c + L) \in R_{T'}$ can happen only if either $c' < c$ or $(c' = c) \wedge (L' \prec_T L)$. Since $\prec_T$ is asymmetric, we may now conclude that $\mathrm{trcl}(R_{T'})$ is asymmetric, as desired. Finally note that, according to our definition above, the mapping T' is positive provided that T is positive. This concludes the proof. ■

A.2 The Upper Bounds in Theorem 18

We remind the reader that the equality $\mathrm{PBTD}^+(\mathrm{LINSET}_k) = k$ was stated in Example 2. We will show in Lemma 37 that $\mathrm{PBTD}^+(\text{NE-LINSET}_k) \leq k$. In combination with the Shift Lemma, this implies that $\mathrm{PBTD}^+(\mathrm{LINSET}'_k) \leq k + 1$ and $\mathrm{PBTD}^+(\text{NE-LINSET}'_k) \leq k + 1$. All remaining upper bounds in Theorem 18 follow now by virtue of monotonicity.

Lemma 37 $\mathrm{PBTD}^+(\text{NE-LINSET}_k) \leq k$.

Proof We want to show that there is a preference relation for which k positive examples suffice to teach any concept in NE-LINSET_k. To this end, let $G = \{g_1, \ldots, g_\ell\}$ be a generator set with $\ell \leq k$ where $g_1 < \ldots < g_\ell$. We use $\mathrm{sum}(G) = g_1 + \ldots + g_\ell$ to denote the sum of all generators in G. We say that g_i is a *redundant generator* in G if $g_i \in \langle\{g_1, \ldots, g_{i-1}\}\rangle$. Let $G^* = \{g_1^*, \ldots, g_{\ell^*}^*\} \subseteq G$

with $g_1^* < \ldots < g_{\ell^*}^*$ be the set of non-redundant generators in G and let $\mathrm{tuple}(G) = (g_1^*, \ldots, g_{\ell^*}^*)$ be the corresponding ordered sequence. Then G^* is an independent subset of G generating the same linear set as G when allowing zero coefficients, i.e., we have $\langle G^* \rangle = \langle G \rangle$ (although $\langle G^* \rangle_+ \neq \langle G \rangle_+$ whenever G^* is a proper subset of G).

To define a suitable preference relation, let $G, \widehat{G}$ be generator sets of size k or less with $\mathrm{tuple}(G) = (g_1^*, \ldots, g_{\ell^*}^*)$ and $\mathrm{tuple}(\widehat{G}) = (\widehat{g}_1^*, \ldots, \widehat{g}_{\widehat{\ell}^*}^*)$. Let the student prefer G over $\widehat{G}$ if any of the following conditions is satisfied:

Condition 1: $\mathrm{sum}(G) > \mathrm{sum}(\widehat{G})$.

Condition 2: $\mathrm{sum}(G) = \mathrm{sum}(\widehat{G})$ and $\mathrm{tuple}(G)$ is lexicographically greater than $\mathrm{tuple}(\widehat{G})$ without having $\mathrm{tuple}(\widehat{G})$ as prefix.

Condition 3: $\mathrm{sum}(G) = \mathrm{sum}(\widehat{G})$ and $\mathrm{tuple}(G)$ is a proper prefix of $\mathrm{tuple}(\widehat{G})$.

To teach a concept $\langle G \rangle \in \text{NE-LINSET}_k$ with $\mathrm{sum}(G) = g$ and $\mathrm{tuple}(G) = (g_1^*, \ldots, g_{\ell^*}^*)$, one uses the teaching set

$$S = \{(g, +), (g + g_1^*, +), \ldots, (g + g_{h^*}^*, +)\}$$

where

$$h = \begin{cases} \ell^* - 1 & \text{if } G^* = G \\ \ell^* & \text{if } G^* \subset G \end{cases} . \tag{12}$$

Note that S contains at most $|G| \leq k$ examples. Let $\widehat{G}$ with $\left\langle \widehat{G} \right\rangle_+ \in \text{NE-LINSET}_k$ denote the generator set that is returned by the student. Clearly $\left\langle \widehat{G} \right\rangle$ satisfies $\mathrm{sum}(\widehat{G}) = g$ since

- concepts with larger generator sums are inconsistent with $(g, +)$, and
- concepts with smaller generator sums have a lower preference (compare with Condition 1 above).

It follows that $g + g_i^* \in \left\langle \widehat{G} \right\rangle_+$ is equivalent to $g_i^* \in \left\langle \widehat{G} \right\rangle = \left\langle \widehat{G}^* \right\rangle$. We conclude that the smallest generator in $\mathrm{tuple}(\widehat{G})$ equals g_1^* since

- a smallest generator in $\mathrm{tuple}(\widehat{G})$ that is greater than g_1^* would cause an inconsistency with $(g + g_1^*, +)$, and
- a smallest generator in $\mathrm{tuple}(\widehat{G})$ that is smaller than g_1^* would have a lower preference (compare with Condition 2 above).

Assume inductively that the $i-1$ smallest generators in $\mathrm{tuple}(\widehat{G})$ are $g_1^*, \ldots, g_{i-1}^*$. Since $g_i^* \notin \left\langle \{g_1^*, \ldots, g_{i-1}^*\} \right\rangle$, we may apply a reasoning that is similar to the above reasoning concerning g_1^* and conclude that the i'th smallest generator in $\mathrm{tuple}(\widehat{G})$ equals g_i^*. The punchline of this discussion is that the sequence $\mathrm{tuple}(\widehat{G})$ starts with $g_1^*, \ldots, g_h^*$ with h given by (12). Let $G' = G \setminus G^*$ be the set of redundant generators in G and note that

$$g - \sum_{i=1}^{h} g_i^* = \begin{cases} g_{\ell^*}^* & \text{if } G^* = G \\ \sum_{g' \in G'} g' & \text{if } G^* \subset G \end{cases} .$$

Let $\widehat{G}' = \widehat{G} \setminus \{g_1^*, \ldots, g_h^*\}$. We proceed by case analysis:

Case 1: $G^* = G$.
Since $\widehat{G}$ is consistent with $(g, +)$, we have $\sum_{g' \in \widehat{G}'} g' = g_{\ell^*}^*$. Since $g_{\ell^*}^* \notin \left\langle \{g_1^*, \ldots, g_{\ell^*-1}^*\} \right\rangle$, the set $\widehat{G}'$ must contain an element that cannot be generated by $g_1^*, \ldots, g_{\ell^*-1}^*$. Given the preferences of the student (compare with Condition 2), she will choose $\widehat{G}' = \{g_{\ell^*}^*\}$. It follows that $\widehat{G} = G$.

Case 2: $G^* \subset G$.
Here, we have $\sum_{g' \in \widehat{G}'} g' = \sum_{g' \in G'} g'$. Given the preferences of the student (compare with Condition 3), she will choose $\widehat{G}$ such that $\widehat{G}^* = G^*$ and $\widehat{G}'$ consists of elements from $\langle G^* \rangle$ that sum up to $\sum_{g' \in G'} g'$ (with $\widehat{G}' = \left\{ \sum_{g' \in G'} g' \right\}$ among the possible choices). Clearly, $\left\langle \widehat{G} \right\rangle_+ = \langle G \rangle_+$.

Thus, in both cases, the student comes up with the right hypothesis. ■

A.3 The Lower Bounds in Theorem 18

The lower bounds in Theorem 18 are an immediate consequence of the following result:

Lemma 38 *The following lower bounds are valid:*

$$\begin{aligned} \mathrm{PBTD}^+(\text{NE-CF-LINSET}'_k) &\geq k+1 . && (13) \\ \mathrm{PBTD}(\text{NE-CF-LINSET}'_k) &\geq k-1 . && (14) \\ \mathrm{PBTD}(\text{NE-CF-LINSET}_k) &\geq \frac{k-1}{2} . && (15) \\ \mathrm{PBTD}(\text{CF-LINSET}_k) &\geq k-1 . && (16) \end{aligned}$$

This lemma can be seen as an extension and a strengthening of a similar result in (Gao et al., 2015) where the following lower bounds were shown:

$$\begin{aligned} \mathrm{RTD}^+(\text{NE-LINSET}'_k) &\geq k+1 . \\ \mathrm{RTD}(\text{NE-LINSET}'_k) &\geq k-1 . \\ \mathrm{RTD}(\text{CF-LINSET}_k) &\geq k-1 . \end{aligned}$$

The proof of Lemma 38 builds on some ideas that are found in (Gao et al., 2015) already, but it requires some elaboration to obtain the stronger results.

We now briefly explain why the lower bounds in Theorem 18 directly follow from Lemma 38. Note that the lower bound $k-1$ in (8) is immediate from (14) and a monotonicity argument. This is because $\text{NE-LINSET}'_k \supseteq \text{NE-CF-LINSET}'_k$ as well as $\text{LINSET}'_k \supseteq \text{CF-LINSET}'_k \supseteq \text{NE-CF-LINSET}'_k$. Note furthermore that $\mathrm{PBTD}^+(\text{CF-LINSET}'_k) \geq k+1$ because of (13) and a monotonicity argument. Then the Shift Lemma implies that $\mathrm{PBTD}^+(\text{CF-LINSET}_k) \geq k$. All remaining lower bounds in Theorem 18 are obtained from these observations by virtue of monotonicity.

The proof of Theorem 18 can therefore be accomplished by proving Lemma 38. It turns out that the proof of this lemma is quite involved. We will present in Section A.3.1 some theoretical prerequisites. Sections A.3.2 and A.3.3 are devoted to the actual proof of the lemma.

A.3.1 SOME BASIC CONCEPTS IN THE THEORY OF NUMERICAL SEMIGROUPS

Recall from Section 6 that $\langle G\rangle = \left\{\sum_{g\in G} a(g)g : a(g)\in\mathbb{N}_0\right\}$. The elements of G are called *generators* of $\langle G\rangle$. A set $P\subset\mathbb{N}$ is said to be *independent* if none of the elements in P can be written as a linear combination (with coefficients from $\mathbb{N}_0$) of the remaining elements (so that $\langle P'\rangle$ is a proper subset of $\langle P\rangle$ for every proper subset P' of P). It is well known (Rosales and García-Sánchez, 2009) that independence makes generating systems unique, i.e., if P, P' are independent, then $\langle P\rangle = \langle P'\rangle$ implies that $P = P'$. Moreover, for every independent set P, the following implication is valid:

$$(S\subseteq\langle P\rangle \wedge P\not\subseteq S) \Rightarrow (\langle S\rangle\subset\langle P\rangle)\ . \tag{17}$$

Let $P=\{a_1,\ldots,a_k\}$ be independent with $a_1=\min P$. It is well known[7] and easy to see that the residues of $a_1, a_2,\ldots,a_k$ modulo a_1 must be pairwise distinct (because, otherwise, we would obtain a dependence). If a_1 is a prime and $|P|\geq 2$, then the independence of P implies that $\gcd(P)=1$. Thus the following holds:

Lemma 39 *If $P\subset\mathbb{N}$ is an independent set of cardinality at least 2 and $\min P$ is a prime, then $\gcd(P)=1$.*

In the remainder of the paper, the symbols P and P' are reserved for denoting independent sets of generators.

It is well known that $\langle G\rangle$ is co-finite iff $\gcd(G)=1$ (Rosales and García-Sánchez, 2009). Let P be a finite (independent) subset of $\mathbb{N}$ such that $\gcd(P)=1$. The largest number in $\mathbb{N}\setminus\langle P\rangle$ is called the *Frobenius number of* P and is denoted as $F(P)$. It is well known (Rosales and García-Sánchez, 2009) that

$$F(\{p,q\}) = pq-p-q \tag{18}$$

provided that $p,q\geq 2$ satisfy $\gcd(p,q)=1$.

A.3.2 PROOF OF (13)

The shift-extension of NE-CF-LINSET$_k$ is (by way of definition) the following class:

$$\text{NE-CF-LINSET}'_k = \{c+\langle P\rangle_+ :\ (c\in\mathbb{N}_0)\wedge(P\subset\mathbb{N})\wedge(|P|\leq k)\wedge(\gcd(P)=1)\}\ . \tag{19}$$

It is easy to see that this can be written alternatively in the form

$$\text{NE-CF-LINSET}'_k = \left\{N+\langle P\rangle :\ N\in\mathbb{N}_0\wedge P\subset\mathbb{N}\wedge|P|\leq k\wedge\gcd(P)=1\wedge\sum_{p\in P}p\leq N\right\} \tag{20}$$

where N in (20) corresponds to $c+\sum_{p\in P}p$ in (19).

For technical reasons, we define the following subfamilies of NE-CF-LINSET$'_k$. For each $N\geq 0$, let

$$\text{NE-CF-LINSET}'_k[N] = \{N+L : L\in\text{LINSET}_k[N]\}$$

7. E.g., see (Rosales and García-Sánchez, 2009)

where

$$\text{LINSET}_k[N] = \left\{\langle P\rangle\in\text{LINSET}_k : (\gcd(P)=1)\wedge\left(\sum_{p\in P}p\leq N\right)\right\}\ .$$

In other words, NE-CF-LINSET$'_k[N]$ is the subclass consisting of all concepts in NE-CF-LINSET$'_k$ (written in the form (20)) whose constant is N.
A central notion for proving (13) is the following one:

Definition 40 *Let $k,N\geq 2$ be integers. We say that a set $L\in$ NE-CF-LINSET$'$ is (k,N)-*special *if it is of the form $L=N+\langle P\rangle$ such that the following holds:*

1. *P is an independent set of cardinality k and $\min P$ is a prime (so that $\gcd(P)=1$ according to Lemma 39, which furthermore implies that $\langle P\rangle$ is co-finite).*
2. *Let $q(P)$ denote the smallest prime that is greater than $F(P)$ and greater than $\max P$. For $a=\min P$ and $r=0,\ldots,a-1$, let*

$$t_r(P)=\min\{s\in\langle P\rangle : s\equiv r \pmod a\} \text{ and } t_{max}(P)=\max_{0\leq r\leq a-1}t_r(P)\ .$$

Then

$$N\geq k(a+t_{max}(P)) \text{ and } N\geq q(P)+\sum_{p\in P\setminus\{a\}}p\ . \tag{21}$$

We need at least k positive examples in order to distinguish a (k,N)-special set from all its proper subsets in NE-CF-LINSET$'_k[N]$, as the following result shows:

Lemma 41 *For all $k\geq 2$, the following holds. If $L\in$ NE-CF-LINSET$'$ is (k,N)-special, then $L\in$ NE-CF-LINSET$'[N]$ and $I'(L,\text{NE-CF-LINSET}_k[N])\geq k$.*

Proof Suppose that $L=N+\langle P\rangle$ is of the form as described in Definition 40. Let $P=\{a,a_2\ldots,a_k\}$ with $a=\min P$. For the sake of simplicity, we will write t_r instead of $t_r(P)$ and t_{max} instead of $t_{max}(P)$. The independence of P implies that $t_{a_i \bmod a}=a_i$ for $i=2,\ldots,k$. It follows that $t_{max}\geq\max P$. Since, by assumption, $N\geq k\cdot t_{max}$, it becomes obvious that $L\in$ NE-CF-LINSET$'[N]$.

Assume by way of contradiction that the following holds:

(A) There is a weak spanning set S of size $k-1$ for L w.r.t. NE-CF-LINSET$'_k[N]$.

Since N is contained in any concept from NE-CF-LINSET$'_k[N]$, we may assume that $N\notin S$ so that S is of the form $S=\{N+x_1,\ldots,N+x_{k-1}\}$ for integers $x_i\geq 1$. For $i=1,\ldots,k-1$, let $r_i=x_i \bmod a\in\{0,1,\ldots,a-1\}$. It follows that each x_i is of the form $x_i=q_ia+t_{r_i}$ for some integer $q_i\geq 0$. Let $X=\{x_1,\ldots,x_{k-1}\}$. We proceed by case analysis:

Case 1: $X\subseteq\{a_2,\ldots,a_k\}$ (so that, in view of $|X|=k-1$, we even have $X=\{a_2,\ldots,a_k\}$). Let $L'=N+\langle X\rangle$. Then $S\subseteq L'$. Note that $X\subseteq P$ but $P\not\subseteq X$. We may conclude from (17) that $\langle X\rangle\subset\langle P\rangle$ and, therefore, $L'\subset L$. Thus L' is a proper subset of L which contains S. Note that (21) implies that $N\geq\sum_{i=2}^{k}a_i=\sum_{i=1}^{k-1}x_i$. If $\gcd(X)=1$, then $L'\in$ NE-CF-LINSET$[N]$ and we have an immediate contradiction to the above assumption (A).

Otherwise, if $\gcd(X) \geq 2$, then we define $L'' = N + \langle X \cup \{q(P)\}\rangle$. Note that $S \subseteq L' \subseteq L''$. Since $q(P) > F(P)$, we have $X \cup \{q(P)\} \subseteq \langle P\rangle$ and, since $q(P) > \max P$, we have $P \not\subseteq X \cup \{q(P)\}$. We may conclude from (17) that $\langle X \cup \{q(P)\}\rangle \subset \langle P\rangle$ and, therefore, $L'' \subset L$. Thus, L'' is a proper subset of L which contains S. Because $X = \{a_2, \ldots, a_k\}$ and $q(P)$ is a prime that is greater than $\max P$, it follows that $\gcd(X \cup \{q(P)\}) = 1$. In combination with (21), it easily follows now that $L'' \in$ NE-CF-LINSET$[N]$. Putting everything together, we arrive at a contradiction to the assumption (A).

Case 2: $X \not\subseteq \{a_2, \ldots, a_k\}$.

If $r_i = 0$ for $i = 1, \ldots, k-1$, then each x_i is a multiple of a. In this case, $N + \langle a, q(P)\rangle$ is a proper subset of $L = N + \langle P\rangle$ that is consistent with S, which yields a contradiction. We may therefore assume that there exists $i' \in \{1, \ldots, k-1\}$ such that $r_{i'} \neq 0$. From the case assumption, $X \not\subseteq \{a_2, \ldots, a_k\}$, it follows that there must exist an index $i'' \in \{1, \ldots, k-1\}$ such that $q_{i''} \geq 1$ or $t_{r_{i''}} \notin \{a_2, \ldots, a_k\}$. For $i = 1, \ldots, k-1$, let $q'_i = \min\{q_i, 1\}$ and $x'_i = q'_i a + t_{r_i}$. Note that $q'_{i''} = 1$ iff $q_{i''} \geq 1$. Define $L'' = N + \langle X'\rangle$ for $X' = \{a, x'_1, \ldots, x'_{k-1}\}$ and observe the following. First, the set L'' clearly contains S. Second, the choice of $x'_1, \ldots, x'_{k-1}$ implies that $X' \subseteq \langle P\rangle$. Third, it easily follows from $q'_{i''} = 1$ or $t_{r_{i''}} \notin \{a_2, \ldots, a_k\}$ that $P \not\subseteq \{a, x'_1, \ldots, x'_{k-1}\}$. We may conclude from (17) that $\langle X'\rangle \subset \langle P\rangle$ and, therefore, $L'' \subset L$. Thus, L'' is a proper subset of L which contains S. Since $r_{i'} \neq 0$ and a is a prime, it follows that $\gcd(a, x'_{i'}) = 1$ and, therefore, $\gcd(X') = 1$. In combination with (21), it easily follows now that $L'' \in$ NE-CF-LINSET$[N]$. Putting everything together, we obtain again a contradiction to the assumption (A).

■

For the sake of brevity, let $\mathcal{L} =$ NE-CF-LINSET$'$. Assume by way of contradiction that there exists a positive mapping T of order k that is admissible for $\mathcal{L}_k$. We will pursue the following strategy:

1. We define a set $L \in \mathcal{L}_k$ of the form $L = N + p + \langle 1\rangle$.
2. We define a second set $L' = N + \langle G\rangle \in \mathcal{L}$ that is (k, N)-special and consistent with $T^+(L)$. Moreover, $L' \setminus L = \{N\}$.

If this can be achieved, then the proof will be accomplished as follows:

- According to Lemma 41, $T^+(L')$ must contain at least k examples (all of which are different from N) for distinguishing L' from all its proper subsets in $\mathcal{L}_k[N]$.
- Since L' is consistent with $T^+(L)$, the set $T^+(L')$ must contain an example which distinguishes L' from L. But the only example which fits this purpose is $(N, +)$.
- The discussion shows that $T^+(L')$ must contain k examples in order to distinguish L' from all its proper subsets in $\mathcal{L}_k$ plus one additional example, N, needed to distinguish L' from L.
- We obtain a contradiction to our initial assumption that T^+ is of order k.

We still have to describe how our proof strategy can actually be implemented. We start with the definition of L. Pick the smallest prime $p \geq k+1$. Then $\{p, p+1, \ldots, p+k\}$ is independent. Let $M = F(\{p, p+1\}) \overset{(18)}{=} p(p+1) - p - (p+1)$. An easy calculation shows that $k \geq 2$ and $p \geq k+1$ imply that $M \geq p+k$. Let $I = \{p, p+1, \ldots, M\}$. Choose N large enough so that all concepts of the form

$$N + \langle P\rangle \text{ where } |P| = k,\ p = \min P \text{ and } P \subseteq I$$

are (k, N)-special. With these choices of p and N, let $L = N + p + \langle 1\rangle$. Note that $N+p, N+p+1 \in T^+(L)$ because, otherwise, one of the concepts $N + p + 1 + \langle 1\rangle, N + p + \langle 2, 3\rangle \subset L$ would be consistent with $T^+(L)$ whereas $T^+(L)$ must distinguish L from all its proper subsets in $\mathcal{L}_k$. Setting $A = \{x : N + x \in T^+(L)\}$, it follows that $|A| = |T^+(L)| \leq k$ and $p, p+1 \in A$. The set A is not necessarily independent but it contains an independent subset B such that $p, p+1 \in B$ and $\langle A\rangle = \langle B\rangle$. Since $M = F(\{p, p+1\})$, it follows that any integer greater than M is contained in $\langle p, p+1\rangle$. Since B is an independent extension of $\{p, p+1\}$, it cannot contain any integer greater than M. It follows that $B \subseteq I$. Clearly, $|B| \leq k$ and $\gcd(B) = 1$. We would like to transform B into another generating system $G \subseteq I$ such that

$$\langle B\rangle \subseteq \langle G\rangle, \gcd(G) = 1 \text{ and } |G| = k\ .$$

If $|B| = k$, we can simply set $G = B$. If $|B| < k$, then we make use of the elements in the independent set $\{p, p+1, \ldots, p+k\} \subseteq I$ and add them, one after the other, to B (thereby removing other elements from B whenever their removal leaves $\langle B\rangle$ invariant) until the resulting set G contains k elements. We now define the set L' by setting $L' = N + \langle G\rangle$. Since $G \subseteq I = \{p, p+1, \ldots, M\}$, and $p, p+1 \in G$, it follows that $p = \min G$, $\gcd(G) = 1$ and $\min(L' \setminus \{N\})$ is $N + p$. Thus, $L' \setminus L = \{N\}$, as desired. Moreover, since N had been chosen large enough, the set L' is (k, N)-special. Thus L and L' have all properties that are required by our proof strategy and the proof of (13) is complete.

A.3.3 PROOF OF (14), (15), AND (16)

We make use of some well known (and trivial) lower bounds on TD_{min}:

Example 5 *For every $k \in \mathbb{N}$, let $[k] = \{1, 2, \ldots, k\}$, let $2^{[k]}$ denote the powerset of $[k]$ and, for all $\ell = 0, 1, \ldots, k$, let*

$$\binom{[k]}{\ell} = \{S \subseteq [k] :\ |S| = \ell\}$$

denote the class of those subsets of $[k]$ that have exactly ℓ elements. It is trivial to verify that

$$\mathrm{TD}_{min}\left(2^{[k]}\right) = k \text{ and } \mathrm{TD}_{min}\left(\binom{[k]}{\ell}\right) = \min\{\ell, k-\ell\}\ .$$

In view of $\mathrm{PBTD}^+(\mathrm{LINSET}_k) = k$, the next results show that negative examples are of limited help only as far as preference-based teaching of concepts from LINSET_k is concerned:

Lemma 42 *For every $k \geq 1$ and for all $\ell = 0, \ldots, k-1$, let*

$$\begin{aligned} \mathcal{L}_k &= \{\langle k, p_1, \ldots, p_{k-1}\rangle : \ p_i \in \{k+i, 2k+i\}\} \ , \\ \mathcal{L}_{k,\ell} &= \{\{\langle k, p_1, \ldots, p_{k-1}\rangle \in \mathcal{L}_k : \ |\{i : p_i = k+i\}| = \ell\} \ . \end{aligned}$$

With this notation, the following holds:

$$\mathrm{TD}_{min}(\mathcal{L}_k) \geq k-1 \ \textit{and} \ \mathrm{TD}_{min}(\mathcal{L}_{k,\ell}) \geq \min\{\ell, k-1-\ell\} \ .$$

Proof For $k = 1$, the assertion in the lemma is vacuous. Suppose therefore that $k \geq 2$. An inspection of the generators $k, p_1, \ldots, p_{k-1}$ with $p_i \in \{k+i, 2k+i\}$ shows that

$$\begin{aligned} \mathcal{L}_k &= \{L_{k,S} : \ S \subseteq \{k+1, k+2, \ldots, 2k-1\}\} \\ \mathcal{L}_{k,\ell} &= \{L_{k,S} : \ (S \subseteq \{k+1, k+2, \ldots, 2k-1\}) \wedge (|S| = \ell)\} \end{aligned}$$

where

$$L_{k,S} = \{0, k\} \cup \{2k, 2k+1, \ldots\} \cup S \ .$$

Note that the examples in $\{0, 1, \ldots, k\} \cup \{2k, 2k+1, \ldots, \}$ are redundant because they do not distinguish between distinct concepts from $\mathcal{L}_k$. The only useful examples are therefore contained in the interval $\{k+1, k+2, \ldots, 2k-1\}$. From this discussion, it follows that teaching the concepts of $\mathcal{L}_k$ (resp. of $\mathcal{L}_{k,\ell}$) is not essentially different from teaching the concepts of $2^{[k-1]}$ $\left(\text{resp. of } \binom{[k-1]}{\ell}\right)$. This completes the proof of the lemma because we know from Example 5 that $\mathrm{TD}_{min}(2^{[k-1]}) = k-1$ and $\mathrm{TD}_{min}\left(\binom{[k-1]}{\ell}\right) = \min\{\ell, k-1-\ell\}$. ■

We claim now that the inequalities (14), (15) and (16) are valid, i.e., we claim that the following holds:

1. $\mathrm{PBTD}(\text{CF-LINSET}_k) \geq k-1$.
2. $\mathrm{PBTD}(\text{NE-CF-LINSET}_k) \geq \lfloor (k-1)/2 \rfloor$.
3. $\mathrm{PBTD}(\text{NE-CF-LINSET}'_k) \geq k-1$.

Proof For $k = 1$, the inequalities are obviously valid. Suppose therefore that $k \geq 2$.

1. Since $\gcd(k, k+1) = \gcd(k, 2k+1) = 1$, it follows that $\mathcal{L}_k$ is a finite subclass of CF-LINSET_k. Thus $\mathrm{PBTD}(\text{CF-LINSET}_k) \geq \mathrm{PBTD}(\mathcal{L}_k) \geq \mathrm{TD}_{min}(\mathcal{L}_k) \geq k-1$.

2. Define $\mathcal{L}_k[N] = \{N + L : \ L \in \mathcal{L}_k\}$ and $\mathcal{L}_{k,\ell}[N] = \{N + L : \ L \in \mathcal{L}_{k,\ell}\}$. Clearly $\mathrm{TD}_{min}(\mathcal{L}_k[N]) = \mathrm{TD}_{min}(\mathcal{L}_k)$ and $\mathrm{TD}_{min}(\mathcal{L}_{k,\ell}[N]) = \mathrm{TD}_{min}(\mathcal{L}_{k,\ell})$ holds for every $N \geq 0$. It follows that the lower bounds in Lemma 42 are also valid for the classes $\mathcal{L}_k[N]$ and $\mathcal{L}_{k,\ell}[N]$ in place of $\mathcal{L}_k$ and $\mathcal{L}_{k,\ell}$, respectively. Let

$$N(k) = k^2 + (k-1-\lfloor (k-1)/2 \rfloor)k + \sum_{i=1}^{k-1} i = k^2 + (k-1-\lfloor (k-1)/2 \rfloor)k + \frac{1}{2}(k-1)k \ . \quad (22)$$

It suffices to show that $N(k) + \mathcal{L}_{k,\lfloor (k-1)/2 \rfloor}$ is a finite subclass of NE-CF-LINSET_k. To this end, first note that

$$\langle k, p_1, \ldots, p_{k-1}\rangle_+ = k + \sum_{i=1}^{k-1} p_i + \langle k, p_1, \ldots, p_{k-1}\rangle \ .$$

Call p_i "light" if $p_i = k+i$ and call it "heavy" if $p_i = 2k+i$. Note that a concept L from $N(k) + \mathcal{L}_{k,\ell}$ is of the general form

$$L = N(k) + \langle k, p_1, \ldots, p_{k-1}\rangle \quad (23)$$

with exactly ℓ light parameters among $p_1, \ldots, p_{k-1}$. A straightforward calculation shows that, for $\ell = \lfloor (k-1)/2 \rfloor$, the sum $k + \sum_{i=1}^{k-1} p_i$ equals the number $N(k)$ as defined in (22). Thus, the concept L from (23) with exactly $\lfloor (k-1)/2 \rfloor$ light parameters among $\{p_1, \ldots, p_{k-1}\}$ can be rewritten as follows:

$$L = N(k) + \langle k, p_1, \ldots, p_{k-1}\rangle = \langle k, p_1, \ldots, p_{k-1}\rangle_+ \ .$$

This shows that $L \in \text{NE-CF-LINSET}_k$. As L is a concept from $N(k) + \mathcal{L}_{k,\lfloor (k-1)/2 \rfloor}$ in general form, we may conclude that $N(k) + \mathcal{L}_{k,\lfloor (k-1)/2 \rfloor}$ is a finite subclass of NE-CF-LINSET_k, as desired.

3. The proof of the third inequality is similar to the above proof of the second one. It suffices to show that, for every $k \geq 2$, there exists $N \in \mathbb{N}$ such that $N + \mathcal{L}_k$ is a subclass of $\text{NE-CF-LINSET}'_k$. To this end, we set $N = 3k^2$. A concept L from $3k^2 + \mathcal{L}_k$ is of the general form

$$L = 3k^2 + \langle k, p_1, \ldots, p_{k-1}\rangle$$

with $p_i \in \{k+i, 2k+i\}$ (but without control over the number of light parameters). It is easy to see that the constant $3k^2$ is large enough so that L can be rewritten as

$$L = 3k^2 - \left(k + \sum_{i=1}^{k-1} p_i\right) + \langle k, p_1, \ldots, p_{k-1}\rangle_+$$

where $3k^2 - \left(k + \sum_{i=1}^{k-1} p_i\right) \geq 0$. This shows that $L \in \text{NE-CF-LINSET}'_k$. As L is a concept from $3k^2 + \mathcal{L}_k$ in general form, we may conclude that $3k^2 + \mathcal{L}_k$ is a finite subclass of $\text{NE-CF-LINSET}'_k$, as desired.

Abstract

We derive generalization error bounds for traditional time-series forecasting models. Our results hold for many standard forecasting tools including autoregressive models, moving average models, and, more generally, linear state-space models. These non-asymptotic bounds need only weak assumptions on the data-generating process, yet allow forecasters to select among competing models and to guarantee, with high probability, that their chosen model will perform well. We motivate our techniques with and apply them to standard economic and financial forecasting tools—a GARCH model for predicting equity volatility and a dynamic stochastic general equilibrium model (DSGE), the standard tool in macroeconomic forecasting. We demonstrate in particular how our techniques can aid forecasters and policy makers in choosing models which behave well under uncertainty and mis-specification.

Keywords: generalization error, prediction risk, model selection, VC dimension, state-space models, linear time-invariant systems

1. Introduction

Generalization error bounds are probabilistically valid, non-asymptotic tools for characterizing the predictive ability of forecasting models. This methodology is fundamentally about choosing particular prediction functions out of some class of plausible alternatives so that, with high reliability, the resulting predictions will be nearly as accurate as possible ("probably approximately correct"). While many of these results are aimed at classification problems with independent and identically distributed (i.i.d.) data, this paper adapts and extends these methods to time-series models, so that economic and financial forecasting techniques can be evaluated rigorously. In particular, these methods control the expected accuracy of future predictions from mis-specified models based on finite samples. This allows for immediate model comparisons which neither appeal to asymptotics nor make strong assumptions about the data-generating process, in stark contrast to such popular model-selection tools as AIC.

To fix ideas, imagine i.i.d. data $((Y_1, X_1), \ldots, (Y_n, X_n))$ with $(Y_i, X_i) \in \mathcal{Y} \times \mathcal{X}$, some prediction function $f : \mathcal{X} \to \mathcal{Y}$, and a loss function $\ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$ which measures the cost of bad predictions. The *generalization error* or *risk* of f is

$$R(f) := \mathbb{E}[\ell(Y, f(X))],$$

where the expectation is taken with respect to $\mathbb{P}$, the joint distribution of (Y, X). The generalization error measures the inaccuracy of our predictions when we use f on future data, making it a natural criterion for model selection, and a target for performance guarantees. To actually calculate the risk, we would need to know the data-generating distribution $\mathbb{P}$ and have a single fixed prediction function f, neither of which is common. Because explicitly calculating the risk is infeasible, forecasters typically try to estimate it, which calls for detailed assumptions on $\mathbb{P}$. The alternative we employ here is to find upper bounds on risk which hold uniformly over large classes of models $\mathcal{F}$ from which some particular f is chosen, possibly in a data-dependent way, and uniformly over distributions $\mathbb{P}$.

Our main results in Section 5 assert that for wide classes of time-series models, the expected cost of poor predictions is bounded by the model's in-sample performance inflated by a term which balances the amount of observed data with the complexity of the model. The bound holds with high probability under the unknown distribution $\mathbb{P}$ assuming only mild conditions—existence of some moments, stationarity, and the decay of temporal dependence as data points become widely separated in time. We give applications in Section 6.

Our goal in this paper is to provide general bounds for common time-series models with unbounded loss functions, no explicit regularization, and potential dependence on the entirety of the observed data. The bounds we derive here are relevant for the time-series models typically used in applied settings—finance, economics, engineering, etc.—as well as covering models more common in machine learning. In particular, we derive results for non-linear models which depend only on a fixed quantity of recent data and linear time invariant systems, state-space models, which use the entire past to predict new data. These results however do not cover, e.g. HMMs in the strictest sense, as they require absolutely continuous latent states rather than discrete valued ones.

The remainder of this paper is structured as follows. Section 2 provides motivation and background for our results, giving intuition in the i.i.d. setting by focusing on concentration of measure ideas and characterizations of model complexity. Section 3 gives the explicit assumptions we make and describes how to leverage powerful ideas from time series to generalize the i.i.d. methods. Section 4 introduces linear time-invariant systems and discusses how such forecasters are different from, e.g., autoregressive models. Section 5 states and proves risk bounds for the time-series forecasting setting, while we demonstrate how to use the results in Section 6 and give some properties of those results in Section 7. Finally, Section 8 concludes and illustrates the path toward generalizing our methods to more elaborate model classes.

1.1 Related Work

Yu (1994) and Nobel and Dembo (1993) showed that it was possible to transfer some i.i.d. results to β-mixing sequences, albeit without explicit rates of convergence (c.f. Vidyasagar, 2003, §3.4). Karandikar and Vidyasagar (2002); Meir (2000); Vidyasagar (2003) presented

bounds for model classes with finite covering numbers (a sufficient condition for which is finite VC-dimension of a related class) but additionally require that $\mathcal{Y}$ is compact and ℓ is bounded. Early work in signal processing (Modha and Masry, 1998) proposes predictors based on sequences of parametric models of increasing memory which minimize a complexity regularized least squares criterion and establish that these predictors deliver the same statistical performance as oracle predictors. Steinwart and Christmann (2009) prove an oracle inequality regularized ERM algorithms when observations are α-mixing which are close to the optimal i.i.d. rates. Mohri and Rostamizadeh (2009) give results using Rademacher complexity which are both tighter than those using VC-dimension or covering numbers as well as being computable from the data in many cases. Mohri and Rostamizadeh (2010) and Agarwal and Duchi (2013) consider another family of bounds for ϕ-mixing and β-mixing sequences when the predictors are algorithmically stable. Many classes of common machine learning algorithms are amenable to either Rademacher or algorithmic-stability bounds: Kernel-regularized methods, support-vector machines, relative-entropy based regularization, and kernel ridge regression among others. However, methods common to time-series such as AR models, ARIMA models, ARCH and GARCH models (Engle, 1982, 2001), state-space models, and other Box-Jenkins type predictors are not because they are not explicitly regularized, the loss functions are not bounded, and the predictions can depend on more than simply a fixed dimensional past. McDonald et al. (2011b) shows that stationarity alone can be used to impose a kernel-type regularization on an AR model, and hence, following the results of Mohri and Rostamizadeh (2009), is amenable to Rademacher complexity for a bounded loss function.

Other dependence conditions apart from stationary and strong mixing are also considered in the literature. Alquier et al. (2012) develop oracle inequalities and model selection procedures for linear models, neural networks, and non-parametric autoregressions when observations come from causal Bernoulli shifts or bounded, weakly-dependent processes. Under the same weak-dependence conditions, Alquier et al. (2014) extends this result to convex Lipschitz loss functions and examines forecasting of the French GDP. Finally, recent work by Kuznetsov and Mohri (2014) examines both average-path generalization and path-dependent generalization for certain types of non-stationary mixing processes and derives Rademacher complexity bounds.

2. Statistical Learning Theory for I.I.D. Data

Our goal is to control the risk of predictive models, that is, their expected inaccuracy on new data from the same stochastic source as the data used to fit the model. To orient readers, we present some standard results for i.i.d. data, which are adapted to the dependent setting in Section 5.

Let $f : \mathcal{X} \to \mathcal{Y}$ be some function used for making predictions of Y from X. We define a loss function $\ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}^+$ which measures the cost of making poor predictions. Throughout this paper, we will assume that $\ell(y, y')$ is a function solely of the difference $y - y'$ where $\ell(\cdot)$ is nonnegative and $\ell(0) = 0$; we take the liberty of denoting that function $\ell(y - y')$. Then the risk of any predictor $f \in \mathcal{F}$ (where f is fixed independently of the data)

is given by

$$R(f) = \mathbb{E}\left[\ell\left(Y - f(X)\right)\right],$$

where $(X, Y) \sim \mathbb{P}$. The risk or generalization error is the expected cost of using f to predict Y from X on a new observation.

Since the true distribution $\mathbb{P}$ is unknown, so is $R(f)$, but we can try to estimate it based on our observed data. The *training error* or *empirical risk* of f is

$$\widehat{R}_n(f) := \frac{1}{n}\sum_{i=1}^{n} \ell\left(Y_i - f(X_i)\right).$$

In other words, the in-sample training error, $\widehat{R}_n(f)$, is the average loss over the actual training points. For any given f, we can bound $R(f)$ in terms of $\widehat{R}_n(f)$ using deviation inequalities, as illustrated below.

When we use the data to chose an $\widehat{f}$ from $\mathcal{F}$, we would like to bound $R(\widehat{f})$. To do so, we must consider not just $\widehat{R}_n(\widehat{f})$, but also the size, in some sense, of $\mathcal{F}$. There are a number of measures for the size or capacity of a model many of which lead to learning theoretic risk bounds. Algorithmic stability (Bousquet and Elisseeff, 2002; Kearns and Ron, 1999) quantifies the sensitivity of the chosen function to small perturbations to the data. Similarly, maximal discrepancy (Vapnik, 2000) asks how different the predictions could be if two functions are chosen using two separate data sets. A more direct, functional-analytic approach partitions $\mathcal{F}$ into equivalence classes under some metric, leading to covering numbers (Pollard, 1984, 1990). Rademacher complexity (Bartlett and Mendelson, 2002; Koltchinskii and Panchenko, 2002) directly describes a model's ability to fit random noise. We focus on a measure which is both intuitive and powerful: Vapnik-Chervonenkis (VC) dimension (Vapnik, 2000; Vapnik and Chervonenkis, 1971).

VC dimension starts as an idea about collections of sets.

Definition 1 *Let $\mathbb{U}$ be some (infinite) set and S a finite-cardinality subset of $\mathbb{U}$. Let $\mathcal{C}$ be a family of subsets of $\mathbb{U}$. We say that $\mathcal{C}$* shatters *S if for every $S' \subseteq S$, $\exists C \in \mathcal{C}$ such that $S' = S \cap C$.*

Essentially, $\mathcal{C}$ can shatter a set S if it can pick out every subset of points in S. This says that the collection $\mathcal{C}$ is very complicated or flexible. The cardinality of the largest set S that can be shattered by $\mathcal{C}$ is the latter's VC dimension.

Definition 2 (VC dimension) *The* Vapnik-Chervonenkis (VC) dimension *of a collection $\mathcal{C}$ of subsets of $\mathbb{U}$ is*

$$\text{VCD}(\mathcal{C}) := \sup\{|S| : S \subseteq \mathbb{U} \text{ and } S \text{ is shattered by } \mathcal{C}\}.$$

To see why this is a "dimension", we need one more notion.

Definition 3 (Growth function) *The* growth function *$G(n, \mathcal{C})$ of a collection $\mathcal{C}$ of subsets of $\mathbb{U}$ is the maximum number of subsets which can be formed by intersecting a set $S \subset \mathbb{U}$ of cardinality n with $\mathcal{C}$,*

$$G(n, \mathcal{C}) := \sup_{S \subset U \,:\, |S| = n} |S \wedge \mathcal{C}|,$$

where $\mathcal{A} \wedge \mathcal{B}$ is the class of all sets $A \cap B$, $A \in \mathcal{A}$, $B \in \mathcal{B}$.

The growth function counts how many *effectively* distinct sets the collection contains, when we can only observe what is going on at n points, not all of $\mathbb{U}$. If $n \leq \text{VCD}(\mathcal{C})$, then from the definitions $G(n, \mathcal{C}) = 2^n$, If the VC dimension is finite, however, and $n > \text{VCD}(\mathcal{C})$, then $G(n, \mathcal{C}) < 2^n$, and in fact it can be shown (Vapnik and Chervonenkis, 1971) that

$$G(n, \mathcal{C}) \leq \left(\frac{en}{\text{VCD}(\mathcal{C})}\right)^{\text{VCD}(\mathcal{C})} \leq (n+1)^{\text{VCD}(\mathcal{C})}.$$

This polynomial growth of capacity with n is why VCD is a "dimension".

Using VC dimension to measure the capacity of function classes is straightforward. Define the indicator function $\mathbf{1}_A(x)$ to take the value 1 if $x \in A$ and 0 otherwise. Suppose that $f \in \mathcal{F}$, $f : \mathbb{U} \to \mathbb{R}$. Each f corresponds to the set

$$C_f = \{(u, u_0) \in \mathbb{U} \times \mathbb{R} : \mathbf{1}_{[0,\infty)}(f(u) - u_0) = 1\},$$

so $\mathcal{F}$ corresponds to the class $\mathcal{C}_{\mathcal{F}} := \{C_f : f \in \mathcal{F}\}$. This extension is sometimes called the pseudo dimension (see e.g. Anthony and Bartlett, 1999; Pollard, 1990).

Theorem 4 (Vapnik and Chervonenkis, 1971) *Suppose that $0 \leq \ell(y, y') \leq M < \infty$. Then,*

$$\mathbb{P}\left(\sup_{f \in \mathcal{F}} |R(f) - \widehat{R}_n(f)| > \epsilon\right) \leq 4G(2n, \mathcal{C}_{\mathcal{F}}) \exp\left\{-\frac{n\epsilon^2}{\Upsilon}\right\} ,$$

where Υ depends only on M and not n or $\mathcal{F}$.

When the loss function is unbounded, similar results hold, but we must consider the composition of the loss function with f. This leads to the set

$$C_{\ell \circ f} = \{(u, u_0, u_0') \in \mathbb{U} \times \mathbb{R} \times \mathbb{R} : \mathbf{1}_{[0,\infty)}(\ell(u_0 - f(u)) - u_0') = 1\},$$

and the corresponding class $\mathcal{C}_{\ell \circ \mathcal{F}} := \{C_{\ell \circ f} : f \in \mathcal{F}\}$.

The concentration result in Theorem 4 works well for independent data. However, for time series, we must be able to handle dependent data. In particular the length n of a sample path $Y_1, \ldots, Y_n$ exaggerates how much information it contains relative to independent observations. Knowing the past allows forecasters to predict future data (at least to some degree), so actually observing those future data points gives less information about the underlying process than in the i.i.d. case. Thus, while in Theorem 4 the probability of large discrepancies between empirical means and their expectations decreases exponentially in n, in the dependent case, the effective sample size may be much less than n, resulting in looser bounds.

3. Time Series

In moving from the i.i.d. setting to time-series forecasting, we need a number of modifications to our initial setup. Rather than observing input/output pairs (Y_i, X_i), we observe a single sequence of random variables $Y_1, \ldots, Y_n$ where each Y_i takes values in $\mathbb{R}^p$, though we can generalize to arbitrary metric spaces at some cost in notational clarity. We are interested in using functions which take past observations as inputs and predict future values of the

process. Specifically, given data from time 1 to time n, we wish to predict time $n+1$. To be clear about notation, we will use the following conventions: $Y_{i:j} := (Y_i, Y_{i+1}, \ldots, Y_j)$, $Y_\infty := Y_{-\infty:\infty}$ is an infinite dimensional sequence; we also have the associated joint distributions $\mathbb{P}_{i:j}$ and $\mathbb{P}_\infty$ and σ-fields $\sigma_{i:j} = \sigma(Y_{i:j})$ and $\sigma_\infty = \sigma(Y_\infty)$.

While we no longer presume i.i.d. data, we still need to restrict the sort of dependent process we work with. We first remind the reader of the notion of (strict or strong) stationarity.

Definition 5 (Stationarity) *A random sequence Y_∞ is stationary when all its finite-dimensional distributions are time-invariant: for all t and all non-negative integers i and j, the random vectors $Y_{t:t+i}$ and $Y_{t+j:t+i+j}$ have the same distribution.*

Stationarity does not imply that the random variables Y_i are independent across time i, only that the marginal distribution of Y_i is constant in time. (And similarly for $Y_{i:i+j}$.) We limit ourselves not just to stationary processes, but also to ones in which widely-separated observations are asymptotically independent. Without this restriction, convergence of the training error to the expected risk could occur arbitrarily slowly, and finite-sample bounds may not exist. In fact, Adams and Nobel (2010) demonstrate that for ergodic processes, finite VC dimension is enough to give consistency, but cannot itself provide rates. The next definition describes the sort of serial dependence which we entertain.

Definition 6 (β-Mixing) *Consider a stationary random sequence Y_∞ defined on a probability space $(\Omega, \Sigma, \mathbb{P}_\infty)$. Let $\mathbb{P}_0$ be the restriction of $\mathbb{P}_\infty$ to $\sigma_{-\infty:0}$, $\mathbb{P}_a$ be the restriction of $\mathbb{P}_\infty$ to $\sigma_{a:\infty}$, and $\mathbb{P}_{0\otimes a}$ be the restriction of $\mathbb{P}_\infty$ to $\sigma(Y_{\infty:0}, Y_{a:\infty})$. The* coefficient of absolute regularity*, or* β-mixing coefficient*, β_a, is given by*

$$\beta_a := \|\mathbb{P}_0 \times \mathbb{P}_a - \mathbb{P}_{0\otimes a}\|_{TV},$$

where $\|\cdot\|_{TV}$ is the total variation norm. A stochastic process is absolutely regular*, or* β-mixing*, if $\beta_a \to 0$ as $a \to \infty$.*

This is only one of many equivalent characterizations of β-mixing (see Bradley, 2005, for others). This definition makes clear that a process is β-mixing if the joint probability of events which are widely separated in time approaches the product of the individual probabilities, that is that Y_∞ is asymptotically independent. Many common time-series models are known to be β-mixing, and the rates of decay are known up to constant factors which are functions of the true parameters of the process. Among the processes for which such results are known are ARMA models (Mokkadem, 1988), GARCH models (Carrasco and Chen, 2002), and certain Markov processes (see Doukhan, 1995, for an overview). Additionally, functions of β-mixing processes are β-mixing, so if $\mathbb{P}_\infty$ could be specified by a linear time-invariant system (see below), state-space model, vector auto regression, or some function of a hidden Markov model, the observed data would satisfy this condition.

Knowing β_a would let us determine the effective sample size of a time series $Y_{1:n}$. In effect, having n dependent-but-mixing data points is like having $\mu < n$ independent ones. Once we determine the correct μ, we can (as we will show) use concentration results for i.i.d. data like Theorem 4 with small corrections.

Algorithm 1: Kalman filter

Recursively generate minimum mean squared error predictions $\widehat{Y}_i$ using the state space model in (1).

Input: Initial guesses for the mean and variance of α_1: $\widehat{\alpha}_1$ and $\widehat{P}_1$

Set $\widehat{Y}_1 = T\widehat{\alpha}_1$.

for $1 \leq i \leq n$ **do**

Filter

$$v_i = Y_i - \widehat{Y}_i, \qquad F_i = (Z\widehat{P}_i Z^\top + H)^{-1},$$
$$K_i = T\widehat{P}_i Z^\top F_i, \qquad L_i = T - K_i Z,$$
$$\widehat{\alpha}_{i+1} = T\widehat{\alpha}_i + K_i v_i, \qquad \widehat{P}_{i+1} = T\widehat{P}_i L_i^\top + GQG^\top.$$

Predict $\widehat{Y}_{i+1} = Z\widehat{\alpha}_{i+1}$.

end

return $\widehat{Y}_{1:n+1}$

4. Linear Time-Invariant Dynamical Systems

Our goal in this paper will be to derive risk bounds for linear time-invariant dynamical systems (LTIs). Such models presume an underlying latent process, and attempt, given observations, to learn that process, predict future values of the latent process, and forecast future observations. Learning algorithms for these goals are linear functions of all previously observed values. Such models nest many common time-series forecasting techniques—ARIMA models, GARCH models, linear-Gaussian state-space models—but, due to their (in general) dependence on the entire past, are not covered by the work discussed in Section 1.1. We present the general form of such models here, provide a canonical forecasting algorithm, and discuss some properties of such models.

Linear dynamical systems model observations Y_i as

$$\begin{aligned} Y_i &= Z\alpha_i + \epsilon_i, \\ \alpha_{i+1} &= T\alpha_i + G\eta_{i+1}. \end{aligned} \tag{1}$$

This is essentially a hidden markov model under certain conditions: Y_i denotes observations, α_i are hidden "state" variables, ϵ_i and η_i are both absolutely continuous random noise with with $\mathbb{E}[\epsilon_i] = \mathbb{E}[\eta_i] = 0$, $\mathbb{E}[\epsilon_i \epsilon_j^\top] = \delta_{ij} H$, and $\mathbb{E}[\eta_i \eta_j^\top] = \delta_{ij} Q$ for all i, j. We further assume that ϵ and η are mutually independent even though this is not strictly necessary, because it makes notation simpler. We require stationarity for our results, and so we also require the LTI to be stationary. This amounts to forcing the complex eigenvalues of T to lie inside the unit circle. We note that the condition that the noise distributions are absolutely continuous means that HMMs in the strictest sense are not members of this family. We also allow the parameter matrices Z, T, H, G, and Q to depend on a (possibly unknown) parameter vector θ, and assume that H and Q are positive definite for all θ.

The *filtering* problem uses observations $Y_{1:i}$ up to time i to learn information about the distribution of α_i. Then, conditional on an estimate $\widehat{\alpha}_i$, we can forecast $\widehat{\alpha}_{i+1}$ and hence

derive a prediction $\widehat{Y}_{i+1}$. For models of this form, one uses the Kalman filter (Anderson and Moore, 2012; Durbin and Koopman, 2001; Kalman, 1960) both to estimate the latent variables, $\alpha_{1:n+1}$ and to generate predictions $\widehat{Y}_{1:n+1}$ (Algorithm 1). This procedure gives the minimum mean-squared error predictions of α_{i+1} (and hence of Y_{i+1}) given $Y_{1:i}$ in the sense that

$$\widehat{\alpha}_{i+1} = \operatorname*{argmin}_a \mathbb{E}\left[tr\left((\alpha_{i+1} - a)(\alpha_{i+1} - a)^\top\right) \mid Y_{1:i}\right].$$

Furthermore, if ϵ_i and η_i are Gaussian, then Algorithm 1 also gives the likelihood for the unknown parameter vector θ. To estimate the unknown parameters, we either: (1) maximize the likelihood returned by the filter; or (2) use the EM algorithm, alternating between running the Kalman filter (the E-step) and maximizing the conditional likelihood by least squares (the M-step). Bayesian estimation works like EM, replacing the M-step with Bayesian updating.

Predictions based on Algorithm 1 are linear functions of previous observations, but these predictions depend on of all previous observations rather than simply a fixed number as would be the case with, say, autoregressive models. More specifically, $\widehat{Y}_{1:n+1} = \mathbf{B} Y_{1:n}$ where

$$(\mathbf{B})_{ij} = b_{ij} = \begin{cases} Z \prod_{k=j+1}^{i-1} L_k K_j & i - j > 1 \\ Z K_j & i - j = 1 \\ 0 & i - j \leq 0 \end{cases} \tag{2}$$

for all $1 \leq i \leq n+1$ (Durbin and Koopman, 2001). Here b_{ij} is the weight for predicting Y_i based on Y_j. Because of this dependence on the entire past, we will require some information about the behavior of the matrices b_{ij} in terms of i and j. Define $\lambda_k(A)$ to be the k^{th} largest absolute eigenvalue of a square matrix A, and let $\lambda_{\max}(A) = \max_k |\lambda_k(A)|$ and $\lambda_{\min}(A) = \min_k |\lambda_k(A)|$.

Conditions for good behavior or LTIs are governed entirely by stationarity. In particular, if $r = \lambda_{\max}(T) < 1$, then the sequence of predictions generated by Algorithm 1 will be stationary, and their dependence on the remote past will decay quickly. The rate of this decay depends on r and $\rho = \lambda_{\max}(T - \overline{K}Z)$, where $K_i \to \overline{K}$. The next three results show that the convergence is exponential in ρ. Proofs of these results are given in Section B.

Lemma 7 *If H is positive definite and $r = \lambda_{\max}(T) < 1$, then $\lambda_{\max}(b_{ij}) = O(r^{i-j-1})$ for any $i > 1$, $j < i$.*

While $\widehat{P}_i = Var(\alpha_{i+1} | Y_{1:i})$ changes with i, for stationary LTIs, $\widehat{P}_i$ converges to a limiting value as $i \to \infty$. This means that the algorithm converges to a steady state as i grows. The next result gives the values to which the algorithm converges, and shows that this convergence occurs exponentially fast.

Lemma 8 *If $\lambda_{\max}(T) < 1$ then:*

1. *The solution, $\overline{P}$ to the matrix equation $P = TPT^\top - TPZ^\top(ZPZ^\top + H)^{-1}ZPT^\top + GQG^\top$ exists and is positive definite.*
2. *$\widehat{P}_i \to \overline{P}$ and $K_i \to \overline{K} = T\overline{P}Z^\top(Z\overline{P}Z^\top + H)^{-1}$.*

Algorithm 2: Steady-state approximate filter

Recursively generate approximate minimum mean squared error predictions $\widehat{Y}_i$ using the state space model in (1).
Input: Initial guess for the mean of α_1: $\widehat{\alpha}_1$
Set $\widehat{Y}_1 = Z\widehat{\alpha}_1$.
Solve $P = TPT^\top - TPZ^\top(ZPZ^\top + H)^{-1}ZPT^\top + GQG^\top$ for P, denote the solution as $\overline{P}$
Set $\overline{K} = T\overline{P}Z^\top(Z\overline{P}Z^\top + H)^{-1}$
for $1 \leq i \leq n$ **do**
  Filter

$$v_i = Y_i - \widehat{Y}_i, \qquad \widehat{\alpha}_{i+1} = T\widehat{\alpha}_i + \overline{K}v_i,$$

  Predict $\widehat{Y}_{i+1} = Z\widehat{\alpha}_{i+1}$.
end
return $\widehat{Y}_{1:n+1}$

3. $0 < \lambda_{\max}(T - \overline{K}Z) = \rho < 1$.

4. *For any matrix norm* $\|\cdot\|$, $\|\widehat{P}_i - \overline{P}\| = O\left(\rho^i\right)$, $\|F_i - \overline{F}\| = O(\rho^i)$, *and* $\|K_i - \overline{K}\| = O\left(\rho^i\right)$.

Since the Kalman filter algorithm converges quickly to a steady state, one could instead use Algorithm 2 which approximates Algorithm 1 but is more computationally efficient.

For Algorithm 2, we can similarly write predictions as linear functions of previous observations. In this case, $\widehat{Y}_{1:n+1} = \mathbf{S}Y_{1:n}$ where the prediction weights are given by

$$(\mathbf{S})_{ij} = s_{ij} = s_{i-j-1} = \begin{cases} Z(T - \overline{K}Z)^{i-j-1}\overline{K} & i - j > 0 \\ 0 & i - j \leq 0 \end{cases} \tag{3}$$

To arrive at this formulation, simply substitute $L_k = (T - \overline{K}Z)$ and $K_j = \overline{K}$ in (2). Notice in particular that the weights depend only on the difference $i - j$ for this algorithm. The next result shows that the prediction weights for the two algorithms converge rapidly.

Lemma 9 *If* $\lambda_{\max}(T) < 1$ *and* H *positive definite. Then,* $\|s_{ij}\| = O(\rho^{i-j-1})$ *and for* $j < i$, $\|b_{ij} - s_{ij}\| = O(\rho^j)$.

We will refer to the class of predictors given by Algorithm 1 as $\mathcal{F}_1$ and those given by Algorithm 2 as $\mathcal{F}_2$.

5. Risk Bounds

With the relevant background in place, we can put the pieces together to derive our results. We use β-mixing to find out how much information is in the data and VC dimension to measure the capacity of the state-space model's prediction functions. The result is a bound on the generalization error of the chosen function $\widehat{f}$. After slightly modifying the definition of "risk" to fit the time-series forecasting scenario and stating necessary technical assumptions, we derive risk bounds for traditional time-series forecasting models.

5.1 Setup and Assumptions

We observe a finite subsequence of random vectors $Y_{1:n}$ from a process Y_∞ defined on a probability space $(\Omega, \Sigma, \mathbb{P}_\infty)$, with $Y_i \in \mathbb{R}^p$. We make the following assumption on the process.

Assumption A $\mathbb{P}_\infty$ *is a stationary,* β*-mixing process with mixing coefficients* β_a, $\forall a > 0$.[1]

Under stationarity, the marginal distribution of Y_t is the same for all t. We deal mainly with the joint distribution of $Y_{1:n+1}$, where we observe the first n observations and try predicting Y_{n+1}. For the remainder of this paper, we will call this joint distribution $\mathbb{P}$. Our results extend to predicting more than one step ahead, but the notation becomes cumbersome.

We must define generalization error and training error slightly differently for time series than in the i.i.d. setting. Using the same notion of loss functions as before, we consider prediction functions $f : \mathbb{R}^{n\times p} \to \mathbb{R}^p$. The function f may use some or all of the past to generate predictions. A function using only the most recent d observations as inputs will be said to have *fixed memory* of length d. Other functions, in particular, the linear time-invariant systems we discuss below, have *growing memory* which means that f may use all the previous data to predict the next data point. These concepts require us to state with some care what we mean by prediction functions, and by time-series training error and risk.

Definition 10 (Time-series risk)

$$R_n(f) := \mathbb{E}\Big[\ell\left(Y_{n+1} - f(Y_{1:n})\right)\Big].$$

The expectation is taken with respect to the joint distribution $\mathbb{P}$ and therefore depends on n.

Definition 11 (Time-series training error)

$$\widehat{R}_n(f) := \frac{1}{n-d}\sum_{i=d+1}^{n} \ell\left(Y_i - f(Y_{1:i-1})\right).$$

In order to make use of this single definition of training error, we let $d \geq 0$. In fixed memory cases—say an AR(2)—d has an obvious meaning, and $f(Y_{1:i}) = f(Y_{i-d+1:i})$ by definition of fixed memory, while with growing memory, $d = 0$, and we define $Y_{1:0} := \varnothing$.

To control the generalization error for time-series forecasting, we make one final assumption, about the possible magnitude of the losses. Specifically, we weaken the bounded loss assumption we used in Section 2 to allow for unbounded loss as long as we retain some control on moments of the loss.

1. In order to apply the results, one must either know β_a for some a or be able to estimate it with sufficient precision and accuracy. McDonald et al. (2011a, 2015) show how to estimate the mixing coefficients nonparametrically, based on a single sample from the process. However, those results (and those contained in this paper) only apply if the data generating process *is* β-mixing, an assumption that cannot be verified.

Assumption B *Assume that for all $f \in \mathcal{F}$ and all $d \in \mathbb{N}$*

$$Q_d(f) := \sqrt{\mathbb{E}_{\mathbb{P}}\left[\ell\left(Y_{d+1} - f(Y_{1:d})\right)^2\right]} \leq M < \infty.$$

Assumption B will be satisfied for Y_i sub-Gaussian, as well as other distributions with bounded second moment. These include, for instance, heavy-tailed Lévy noises where the tails of the pdf decay faster than an inverse cubic.

5.2 Fixed Memory

We can now state our results giving finite sample risk bounds for the problem of time-series forecasting. We begin with the fixed memory setting; the next section will allow the memory length to grow.

Theorem 12 *Suppose that Assumption A and Assumption B hold, that the model class $\mathcal{F}$ has a fixed memory length $d < n$, and that we have a sample $Y_{1:n}$. Let μ and $a > d$ be integers such that $2\mu a + d = n$.*[2] *Then, for all $0 < \epsilon < \frac{e^{3/2}}{\sqrt{2}}$,*

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\right) \leq 8G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{\mu \exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\} + 2\mu\beta_{a-d},$$

where $W(\cdot)$ is the Lambert W function.

The implications of this theorem are considerable. Given a finite sample of length n, we can say that with high probability, future prediction errors will not be much larger than our observed training errors. It makes no difference whether the model is correctly specified. This stands in stark contrast to model selection tools like AIC or BIC which appeal to asymptotics. Moreover, given a model class $\mathcal{F}$, we can say exactly how much data we need to have good control of the prediction risk. As the effective data size increases, the training error is a better and better estimate of the generalization error, uniformly over all of $\mathcal{F}$, provided $\mu, a \to \infty$ such that $\beta_{a-d} = o(1/\mu)$.

The Lambert W function in the exponential term deserves some explanation. The Lambert W function is defined as the inverse of $f(w) = w \exp w$ (c.f. Corless et al., 1996). A strictly, but only slightly, worse bound can be achieved by noting that

$$\exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right) \leq \frac{\epsilon^{8/3}}{4^{2/3}}$$

for all $\epsilon \in [0, 1]$ (see Cortes et al., 2010, for the derivation).

The difference between expected and empirical risk is only interesting when $R_n(f)$ exceeds $\widehat{R}_n(f)$. Due to the supremum preceding $\frac{R_n(f)-\widehat{R}_n(f)}{Q_d(f)}$, events where the training error exceeds the expected risk are irrelevant (as this term will be negative). Therefore, we are

2. By making appropriate modifications to the definition of the training error and some of the proof elements, one could allow $2\mu a + d < n$, but we obviate this issue for the sake of clarity.

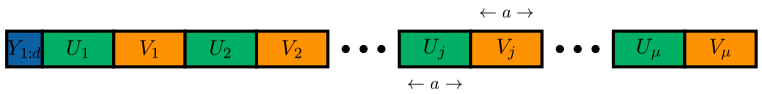

Figure 1: The blocking procedure divides $Y_{d+1:n}$ into 2μ alternating blocks U_j (green) and V_j (orange) each of length a. It ignores the first d observations $Y_{1:d}$ (blue).

only concerned with $0 \leq \widehat{R}_n(f) \leq R_n(f)$. Of course, as discussed in Section 2, for most estimation procedures, f is chosen to make $\widehat{R}_n(f)$ as small as possible.

Before we prove Theorem 12, we will state a corollary which puts the same result in a form that is sometimes easier to use.

Corollary 13 *Under the conditions of Theorem 12, for any $f \in \mathcal{F}$, the following bound holds with probability at least $1 - \eta$, for all $\eta > 2\mu\beta_{a-d}$,*

$$R_n(f) \leq \widehat{R}_n(f) + Me^2\sqrt{\frac{\mathcal{E}(4 - \log \mathcal{E})}{2}},$$

with

$$\mathcal{E} = \frac{4 \log G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) + 4 \log 8/\eta'}{\mu},$$

and $\eta' = \eta - 2\mu\beta_{a-d}$.

We now prove both Theorem 12 and Corollary 13 to provide the reader with some intuition for the types of arguments necessary. We defer proof of the remainder of our results to Section B.

Proof [of Theorem 12 and Corollary 13] The first step is to move from the actual sample size n to the effective sample size μ which depends on the β-mixing behavior. Let a and μ be non-negative integers such that $2a\mu + d = n$. Now divide $Y_{d+1:n}$ into 2μ blocks, each of length a, ignoring the first d observations. Identify the blocks as follows:

$$U_j = \{Y_i : 2(j-1)a + d + 1 \leq i \leq (2j-1)a + d\},$$
$$V_j = \{Y_i : (2j-1)a + d + 1 \leq i \leq 2ja + d\}.$$

Let $\mathbf{U}$ be the sequence of odd blocks U_j, and let $\mathbf{V}$ be the sequence of even blocks V_j. A graphical depiction of the blocking procedure is shown in Figure 1. Finally, let $\mathbf{U}'$ be a sequence of blocks which are mutually independent but such that each block has the same distribution as a block from the original sequence. That is construct U'_j such that

$$\mathcal{L}(U'_j) = \mathcal{L}(U_j) = \mathcal{L}(U_1),$$

where $\mathcal{L}(\cdot)$ means the probability law of the argument.

Let $\widehat{R}_{\mathbf{U}}(f)$, $\widehat{R}_{\mathbf{U}'}(f)$, and $\widehat{R}_{\mathbf{V}}(f)$ be the empirical risk of f based on the block sequences $\mathbf{U}$, $\mathbf{U}'$, and $\mathbf{V}$ respectively. We have

$$\begin{aligned}
\widehat{R}_n(f) &= \frac{1}{n-d}\sum_{i=d+1}^{n} \ell\left(Y_i - f(Y_{1:i-1})\right) \\
&= \frac{1}{n-d}\left[\sum_{i:Y_i\in\mathbf{U}} \ell\left(Y_i - f(Y_{1:i-1})\right) + \sum_{j:Y_j\in\mathbf{V}} \ell\left(Y_j - f(Y_{1:j-1})\right)\right] \\
&= \frac{1}{2}\left[\frac{2}{n-d}\sum_{i:Y_i\in\mathbf{U}} \ell\left(Y_i - f(Y_{1:i-1})\right) + \frac{2}{n-d}\sum_{j:Y_j\in\mathbf{V}} \ell\left(Y_j - f(Y_{1:j-1})\right)\right] \\
&= \frac{1}{2}\left[\widehat{R}_{\mathbf{U}}(f) + \widehat{R}_{\mathbf{V}}(f)\right].
\end{aligned}$$

Then,

$$\begin{aligned}
&\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\right) \\
&= \mathbb{P}\left(\sup_{f\in\mathcal{F}} \left[\frac{R_n(f) - \widehat{R}_{\mathbf{U}}(f)}{2Q_d(f)} + \frac{R_n(f) - \widehat{R}_{\mathbf{V}}(f)}{2Q_d(f)}\right] > \epsilon\right) \\
&\le \mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} + \sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_{\mathbf{V}}(f)}{Q_d(f)} > 2\epsilon\right) \qquad (4) \\
&\le \mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} > \epsilon\right) + \mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_{\mathbf{V}}(f)}{Q_d(f)} > \epsilon\right) \qquad (5) \\
&= 2\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} > \epsilon\right) \\
&= 2\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_d(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} > \epsilon\right). \qquad (6)
\end{aligned}$$

Here, (4) follows by the convexity of the supremum and (5) by a union bound. Now, for (6), as f has fixed memory d, we have that $f(Y_{1:j}) = f(Y_{j-d+1:j})$. Thus

$$\begin{aligned}
R_n(f) &= \mathbb{E}\left[\ell\left(Y_{n+1} - f(Y_{1:n})\right)\right] = \mathbb{E}\left[\ell\left(Y_{n+1} - f(Y_{n-d+1:n})\right)\right] \\
&= \mathbb{E}\left[\ell\left(Y_{d+1} - f(Y_{1:d})\right)\right] = R_d(f)
\end{aligned}$$

by stationarity and, similarly, $Q_d(f) = \sqrt{\mathbb{E}\left[\ell\left(Y_{d+1} - f(Y_{1:d})\right)^2\right]}$. Thus $R_d(f)$ and $Q_d(f)$ depend on only $d+1$ data values. Likewise, a "point" in the training error $\widehat{R}_{\mathbf{U}}(f)$ depends on $d+1$ data values. Therefore, a prediction at any Y_i in some block U_j is separated by at least $a-d$ observations from any $Y_{i'}$ in different block $U_{j'}$. Furthermore, we are estimating an expectation $R_d(f)$ which depends on $d+1$ values with an empirical expectation $\widehat{R}_{\mathbf{U}}(f)$ which is a dependent sum of components each of which depends on $d+1$ observed data values.

Therefore, we can apply Lemma 4.1 in Yu (1994) (reproduced as Lemma 21 in Section A) to the event $\left\{\sup_{f\in\mathcal{F}} \frac{R_d(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} > \epsilon\right\}$. This allows us to move from statements about the dependent blocks in $\widehat{R}_{\mathbf{U}}(f)$ to statements about the independent blocks in $\widehat{R}_{\mathbf{U}'}(f)$ with a slight correction which accounts for the worst-case dependence between adjacent blocks: β_{a-d}. Therefore,

$$2\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_d(f) - \widehat{R}_{\mathbf{U}}(f)}{Q_d(f)} > \epsilon\right) \le 2\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_d(f) - \widehat{R}_{\mathbf{U}'}(f)}{Q_d(f)} > \epsilon\right) + 2\mu\beta_{a-d}, \qquad (7)$$

where the probability on the right of (7) is for the σ-field generated by the independent block sequence $\mathbf{U}'$. Let us now introduce the growth function for the class of "blocked" predictor losses $\mathcal{C}^{\Sigma}_{\ell\circ\mathcal{F}} = \{C^{\Sigma}_{\ell\circ\mathcal{F}} : f \in \mathcal{F}\}$, where[3]

$$C^{\Sigma}_{\ell\circ\mathcal{F}} = \left\{(\mathbf{u}, \mathbf{d}, b) : \mathbf{1}_{[0,\infty)}\left(\sum_{j=1}^{a} \ell(d_j - f(u_j)) - b\right) = 1, \quad \mathbf{u} \in \mathbb{U}^a, \quad \mathbf{d} \in \mathbb{R}^{k\times a}, \ b \in \mathbb{R}\right\}.$$

This allows us to state that

$$2\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_d(f) - \widehat{R}_{\mathbf{U}'}(f)}{Q_d(f)} > \epsilon\right) \le 8G(2\mu, \mathcal{C}^{\Sigma}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{\mu \exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\}, \qquad (8)$$

where we have applied Corollary 23 to bound the independent blocks $\mathbf{U}'$. Since there are μ independent blocks, this upper bound is in terms of μ effectively independent data "points" penalized by the correction β_{a-d} which adjusts for the worst case dependence between "points" rather than n dependent data points. However, the growth function is in terms of the class of blocked predictors and depends on a. To remove this dependence, we present a novel result, Lemma 24. This lemma shows that $G(2\mu, C^{\Sigma}_{\ell\circ\mathcal{F}}) \le G(2\mu a, \mathcal{C}_{\ell\circ\mathcal{F}}) \le G(n, \mathcal{C}_{\ell\circ\mathcal{F}})$, giving the desired result.

To prove the corollary, set the right hand side of (8) to η, take $\eta' = \eta - 2\mu\beta_{a-d}$, and solve for ϵ. We get that with probability at least $1-\eta$, for all $f \in \mathcal{F}$,

$$\frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} \le \epsilon.$$

Solving the equation

$$\eta' = 8G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{\mu \exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\}$$

implies

$$\epsilon = e^2\sqrt{\frac{\mathcal{E}(4 - \log \mathcal{E})}{2}}$$

3. The Σ indicates a sum over the coordinates of the block.

with

$$\mathcal{E} = \frac{4\log G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) + 4\log 8/\eta'}{\mu}.$$

■

The only obstacle to the use of Theorem 12 is knowledge of the $G(n, \mathcal{C}_{\ell\circ\mathcal{F}})$ or $\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}})$. For some models, these can be calculated explicitly.

Theorem 14 *If $\ell(y - y')$ is monotone increasing in $|y - y'|$, then for the class of AR(d) models,*

$$G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) \leq \left(\frac{2en}{d+1}\right)^{d+1}.$$

If $\ell(y-y')$ is monotone increasing in each coordinate of $|y_j - y'_j|$, then for the class of vector autoregressive models of order d with p time-series,

$$G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) \leq \left(\frac{2en}{d+1}\right)^{p(d+1)}.$$

The proof of Theorem 14 is given in Section B. We note that this result applies equally to Bayesian VARs, however, this is likely conservative as the prior tends to restrict the effective complexity of the function class.[4]

5.3 Bounds for LTIs

As discussed in Section 4, our goal is to derive similar bounds for linear time-invariant dynamical systems which produce forecasts via Algorithm 1 or Algorithm 2. We begin with a result for the simple case with predictions generated by Algorithm 2.

Theorem 15 *Suppose that Assumption A and Assumption B hold, and that the model class $\mathcal{F}_2$ is generated by Algorithm 2 with $\lambda_{\max}(T) < 1$. Further assume that the loss function ℓ is a norm and let $\ell^*(A) = \sup_{z\neq 0} \ell(Az)/\ell(z)$ be the matrix norm induced by ℓ. Given a time-series of length n, fix some $1 \leq d < n$, and let μ and a be integers such that $2\mu a + d = n$.*

4. Here we should mention that these risk bounds are frequentist in nature. We mean that if one treats Bayesian methods as a regularization technique and predicts with the posterior mean or mode, then our results hold. However, from a subjective Bayesian perspective, our results add nothing since all inference can be derived from the posterior. For further discussion of the frequentist risk properties of Bayesian methods under mis-specification, see for example Kleijn and van der Vaart (2006); Müller (2013) or Shalizi (2009).

Then

$$\begin{aligned}
&\mathbb{P}\left(\sup_{f_2\in\mathcal{F}_2} \frac{R_n(f_2) - \widehat{R}_n(f_2) - \delta_d(f_2)}{Q_d(f_2)} > \epsilon\right) \\
&\leq 8G(n, \mathcal{C}_{\ell\circ\mathcal{F}'_2}) \exp\left\{-\frac{\mu\exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right)+4\right)}{4}\right\} + 2\mu\beta_{a-d}, \\
&\leq 8\left(\frac{2en}{d+1}\right)^{p(d+1)} \exp\left\{-\frac{\mu\exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right)+4\right)}{4}\right\} + 2\mu\beta_{a-d},
\end{aligned}$$

where

$$\delta_d(f_2) = \frac{1}{n-d}\sum_{i=d+1}^{n}\left[\ell\left(Y_i - \sum_{j=i-d}^{i-1} s_{ij}Y_j\right) - \ell\left(Y_i - \sum_{j=1}^{i-1} s_{ij}Y_j\right)\right] + \mathbb{E}[\ell(Y_1)]\sum_{j=1}^{n-d}\ell^*(s_{nj}).$$

The $\delta_d(f_2)$ term arises from taking a fixed-memory approximation, of length d, to predictors with growing memory[5]. As becomes clear in the proof (see Section B), we make this approximation to apply the previous theorem, but it involves a trade-off. As $d \nearrow n$, $\delta_d(f_2) \searrow 0$, but this drives $\mu \searrow 0$, resulting in fewer effective training points, whereas smaller d has the opposite effect. The summation inside square braces on the left is the difference between empirical risks for f_2 and that of the truncated predictor f'_2 which uses only the most recent d data values. That is

$$\frac{1}{n-d-1}\sum_{i=d}^{n-1}\left[\ell\left(Y_{i+1} - \sum_{j=i-d+1}^{i} s_{ij}Y_j\right) - \ell\left(Y_{i+1} - \sum_{j=1}^{i} s_{ij}Y_j\right)\right] = \widehat{R}_n(f'_2) - \widehat{R}_n(f_2).$$

This term is easily calculated from the data. Also, $\delta_d(f_2)$ depends on $\mathbb{E}\big[\ell(Y_1)\big]$ which is not necessarily desirable. However, Assumption B has the consequence that $\mathbb{E}\big[\ell(Y_1)\big] \leq M < \infty$ as long as $\mathcal{F}_2$ allows $s_{ij} = 0$. Finally, we reiterate that $s_{ij} = s_{i-j-1}$ is a function only of the difference between i and j. Finally, note that the upper bound depends on the growth function of the truncated class $\mathcal{F}'_2$, which can be bounded using Theorem 14.

Corollary 16 *Under the conditions of either Theorem 15, for any $f_2 \in \mathcal{F}_2$, with probability at least $1 - \eta$,*

$$R_n(f_2) \leq \widehat{R}_n(f_2) + \delta_d(f_2) + Me^2\sqrt{\frac{\mathcal{E}(4 - \log\mathcal{E})}{2}},$$

where

$$\mathcal{E} = \frac{4\log G(n, \mathcal{C}_{\ell\circ\mathcal{F}'_2}) + 4\log 8/\eta'}{\mu},$$

and $\eta' = \eta - 2\mu\beta_{a-d}$. Furthermore,

$$\delta_d(f_2) = O_{\mathbb{P}}(\rho^d).$$

5. There are several ways one could make such an approximation. To simplify the proof, we have set all coefficients at lags beyond d to zero rather than, e.g., asking for the d-memory linear predictor coming closest in L_2 to the infinite-memory predictor.

For the case of Algorithm 1, Assumption B no longer makes sense as it fails to reflect the fact each $f_1 \in \mathcal{F}_1$ is a time varying function of previous observations as illustrated in (2). We therefore strengthen the assumption slightly. Notice in particular that f_1' depends on n as illustrated in (2).

Assumption C *For all f_1' generated by truncating Algorithm 1 to depend on the most recent d observations, and all $n > d$,*

1. $$Q_d(f_1') := \sqrt{\mathbb{E}_{\mathbb{P}}\left[\ell\left(Y_{n+1} - f_1'(Y_{n-d+1:n})\right)^2\right]} \leq M < \infty.$$

2. *For every $\epsilon > 0$ there exists $\delta > 0$ such that, for all measurable sets A, with $\mathbb{P}(A) \leq \delta$, and every f_1',*
$$\int_A d\mathbb{P}\left[\ell\left(Y_{n+1} - f_1'(Y_{n-d+1:n})\right)^2\right] \leq \epsilon.$$

The first part of this assumption is analogous to Assumption B but for predictors $f_1 \in \mathcal{F}_1$. However, we need only impose the assumption on a fixed-memory version of these growing memory predictors. Note also that for the case of Algorithm 2, as in Theorem 15, for any n, $f_2 \in \mathcal{F}_2$, we have $Q_d(f_2') = \sqrt{\mathbb{E}_{\mathbb{P}}\left[\ell\left(Y_n - f_2'(Y_{n-d:n-1})\right)^2\right]}$. For Algorithm 1, this is no longer the case (as f_1' depends on n). However, the dependence on n will not be necessary. The second part of this assumption ensures that the loss of the truncated versions of these predictors is uniformly integrable. Under this assumption, since predictions $f_1'(Y_{n-d+1:n}) - f_2'(Y_{n-d+1:n}) = O_{\mathbb{P}}(1)$, we have that $\lim_{n\to} Q_d(f_1') = Q_d(f_2)$. This statement is made rigorous in the proof.

Theorem 17 *Suppose that Assumption A and Assumption C hold, and that the model class $\mathcal{F}_1$ is generated by Algorithm 1 with $\lambda_{\max}(T) < 1$. Further assume that the loss function ℓ is a norm and let $\ell^*(A) = \sup_{z\neq 0} \frac{\ell(Az)}{\ell(z)}$ be the matrix norm induced by ℓ. Given a time-series of length n, fix some $1 \leq d < n$, and let μ and a be integers such that $2\mu a + d = n$. Then*

$$\begin{aligned}
&\mathbb{P}\left(\sup_{f_n \in \mathcal{F}} \frac{R_n(f_1) - \widehat{R}_n(f_1) - \delta_d(f_1)}{\lim_{n\to\infty} Q_d(f_1')} > \epsilon\right) \\
&\leq 8G(n, \mathcal{C}_{\ell\circ\mathcal{F}_2'}) \exp\left\{-\frac{\mu \exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\} + 2\mu\beta_{a-d}, \\
&\leq 8\left(\frac{2en}{d+1}\right)^{p(d+1)} \exp\left\{-\frac{\mu \exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\} + 2\mu\beta_{a-d},
\end{aligned}$$

where

$$\begin{aligned}
\delta_d(f_1) = \frac{1}{n-d}\sum_{i=d+1}^{n}\left[\ell\left(Y_i - \sum_{j=i-d}^{i-1} b_{ij}Y_j\right) - \ell\left(Y_i - \sum_{j=1}^{i-1} s_{i-j-1}Y_j\right)\right] \\
+ \mathbb{E}[\ell(Y_1)]\sum_{j=1}^{n-d}\ell^*(b_{nj}).
\end{aligned}$$

For this result, the summation inside square braces on the left is the difference between empirical risk for f_1 and that of the truncated steady-state predictor f_2' which uses only the most recent d data values. That is

$$\frac{1}{n-d}\sum_{i=d+1}^{n}\left[\ell\left(Y_i - \sum_{j=i-d}^{i-1} b_{ij}Y_j\right) - \ell\left(Y_{i+1} - \sum_{j=1}^{i} s_{ij}Y_j\right)\right] = \widehat{R}_n(f_1) - \widehat{R}_n(f_2')$$

where f_2' is given by Algorithm 2. Again, this term is easily calculated from the data. Furthermore, the upper bound depends on the growth function of the level sets of $\mathcal{F}_2'$ which is easily bounded using Theorem 14.

Corollary 18 *Under the conditions of Theorem 17, for any $f_1 \in \mathcal{F}_1$, with probability at least $1 - \eta$,*

$$R_n(f_1) \leq \widehat{R}_n(f_1) + \delta_d(f_1) + Me^2\sqrt{\frac{\mathcal{E}(4 - \log\mathcal{E})}{2}},$$

where

$$\mathcal{E} = \frac{4\log G(n, \mathcal{C}_{\ell\circ\mathcal{F}_2'}) + 4\log 8/\eta'}{\mu},$$

and $\eta' = \eta - 2\mu\beta_{a-d}$. Furthermore,

$$\delta_d(f_1) = O_{\mathbb{P}}(r^d) + O(\rho^{n-d+1}) + O_{\mathbb{P}}((n-d)^{-1}).$$

This corollary shows that $\delta_d(f_1)$ decays rapidly as long as $d \to \infty$ and $d/n \to 0$. But for LTIs, it is simple to compute $\delta_d(f_1)$ or $\delta_d(f_2)$ using results from Algorithm 1 or Algorithm 2, so this and Corollary 16 let us compute risk bounds for common time-series forecasting models without appealing to the asymptotic form of $\delta_d(f)$.

As this bound is rather complicated, in that d, a, μ and η are expected to go to either 0 or ∞ as functions of n, we provide the following simple example demonstrating convergence.

Example *Suppose Y_∞ is a 1-dimensional geometrically β-mixing time series with $\beta_a = O(k^a)$ for some constant $0 < k < 1$. We will choose as our predictor the state-space model as in* (1)

$$\begin{aligned}
Y_i &= Z\alpha_i + H\epsilon_i, \\
\alpha_{i+1} &= T\alpha_i + G\eta_{i+1},
\end{aligned}$$

with a univariate state α. We will maximize the likelihood to estimate $\theta = (Z, H, T, G)$ and apply Algorithm 1 to generate forecasts from n samples. Thus

$$\mathcal{F}_1 = \{f_1 : Z \in R,\ H, G > 0,\ -1 < T < 1\}.$$

To achieve reasonable bounds, we fix $0 < \gamma < 1$ and choose $\mu = (n-d)^{1-\gamma}$, $a = 0.5(n-d)^{\gamma}$, and $\eta = 3\mu\beta_{a-d}$. With these choices, and using C as a mutable constant independent of n and d,

$$\mathcal{E} = C\frac{4\log(d+1)\log(2en/(d+1)) - (1-\gamma)\log(n-d) + [(n-d)^{\gamma} - d]\log(1/k)}{(n-d)^{1-\gamma}}.$$

Here, we have used Theorem 14 to bound the logarithm of the growth function of the growing memory predictor with $\log(d+1)\log(2en/(d+1))$ for truncation length d. Therefore, for n and d such that $(n-d)^\gamma > C\log(n)\log(d)$, $\mathcal{E} < C(n-d)^{-(1-2\gamma)}$. To complete the bound, we need to choose d such that $\eta \to 0$, $r^d \to 0$, and $n-d \to \infty$. To achieve the first, we have

$$\eta = \mu\beta_{a-d} = g(n-d)^{1-\gamma}k^{0.5(n-d)^\gamma - d}.$$

Therefore, we require $d = o(n^\gamma)$. Thus, as long as $d = o(n^\gamma)$ and $d \to \infty$, for n large enough (depending on many constants), Corollary 18 gives

$$R_n(f_1) \leq \widehat{R}_n(f_1) + C\sqrt{\frac{1}{n^{1-2\gamma}}}$$

for some C with high probability.

6. Bounds in Practice

We now show how the theorems of the previous section can be used both to quantify prediction risk and to select models. We first estimate a simple stochastic volatility model using IBM return data and calculate the bound for the predicted volatility using Corollary 18. Then we show how the same methods can be used for typical macroeconomic forecasting models.

6.1 Stochastic Volatility Model

We estimate a standard stochastic volatility model using daily log returns for IBM from January 1962 until October 2011 ($n = 12541$ observations). Figure 2 shows the squared log-return series.

The model we investigate is

$$\begin{aligned} Y_i &= \sigma z_i \exp(\alpha_i/2), & z_i &\sim \mathrm{N}(0,1), \\ \alpha_{i+1} &= \phi\alpha_i + \eta_i, & \eta_i &\sim \mathrm{N}(0,\sigma_\eta^2), \end{aligned}$$

where the disturbances z_i and w_i are mutually and serially independent. Following Harvey et al. (1994), we linearize this by taking the natural log of the observation equation:

$$\begin{aligned} \log Y_i^2 &= \varsigma + \frac{1}{2}\alpha_i + \epsilon_i, & \epsilon_i &= \log z_i^2 - \xi, \\ \varsigma &= \log\sigma^2 + \xi, & \xi &= \mathbb{E}[\log z_1^2]. \end{aligned}$$

The noise term ϵ_i is no longer Gaussian (it has a shifted log-gamma distribution), but the Kalman filter will still give the minimum-mean-squared-error linear estimate of the variance sequence $\alpha_{1:n+1}$. The observation variance is now $\pi^2/2$.

To match the data to the model, let y_i be the log returns and remove 688 observations where the return was 0 (the price did not change from one day to the next). Using the Kalman filter, the negative log likelihood is given by

$$\mathcal{L}(Y_{1:n}|\varsigma,\phi,\sigma_\eta^2) \propto \sum_{i=1}^{n} \log F_i + v_i^2 F_i^{-1}.$$

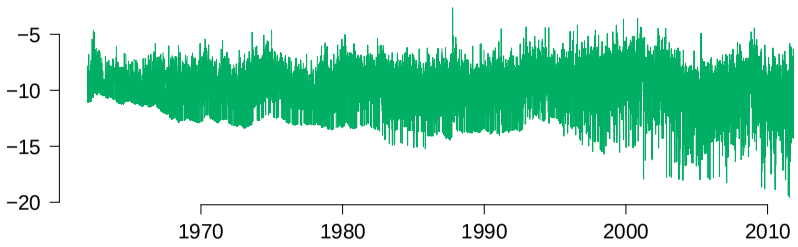

Figure 2: Daily realized volatility (squared log returns) for IBM from 1962–2011.

Model	Training error	AIC-Baseline	Risk bound ($1-\eta > 0.95$)	Effective VC
SV	1.44	-2816	15.92	3
AR(2)	1.49	-348	15.00	3
Mean	1.51	0	12.63	1

Table 1: This table shows the training error and risk bounds for 3 models. AIC is given as the difference from predicting with the global mean (the smaller the value, the more support for that model). The "Effective VC" dimension column reports the exponent in the bound on the growth function. This is slightly different from the VC dimension of the model.

Minimizing this gives estimates $\varsigma = -9.62$, $\phi = 0.996$, and $\sigma_\eta^2 = 0.003$. Using absolute error loss gives training error $\widehat{R}_n(f) = 1.44$.

To actually calculate the bound, we need a few more values. First, using the methods in McDonald et al. (2011a, 2015), we can estimate $\beta_8 = 0.017$. For $a > 8$, the optimal point estimate of β_a is 0. While this is presumably an underestimate, we will take $\beta_a = 0$ for $a > 8$. For the upper bound in Assumption B, we use $M = \sqrt{\pi^2/2}$ which corresponds to the SV model being true.

Combining these values with the VC dimension for the stochastic volatility model, we can bound the prediction risk. Finally, we take $\mu = 538$, $a = 11$, $d = 2$, and $\mathbb{E}[|Y_1|] = M$. The result is the bound $R_n(f) \leq 15.92$ with probability at least 0.95. In other words, the bound is much larger than the training error, but this is to be expected: the data are highly dependent, so the large n translates into a relatively small effective sample size μ.

For comparison, we also computed the bound for forecasts produced with an AR(2) model (with intercept) and with the global mean alone. In the case of the mean, we take $\mu = 658$ and $a = 9$ since in this case, $d = 0$. The results are shown in Table 1. The stochastic volatility model reduces the training error by 5% relative to predicting with the mean, an improvement which is marginal at best. But the resulting risk bound clearly demonstrates that given the small effective sample size, even this gain may be spurious: it is likely that the stochastic volatility model is simply over-fitting.

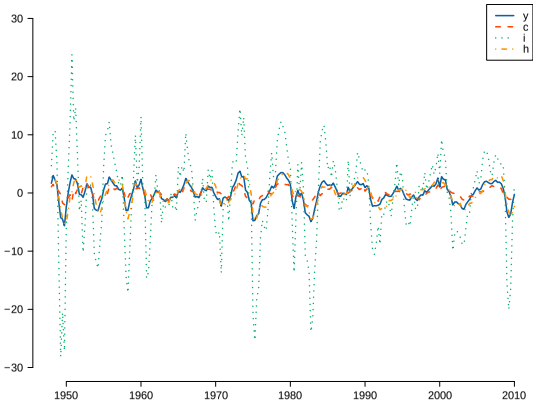

Figure 3: Time series used to estimate the RBC model. These are quarterly data from 1948:I until 2010:I. The blue line is GDP (output), the red line is consumption, the green line is investment, and the orange line is hours worked. These data are plotted as percentage deviations from trend as discussed in the Online Appendix.

6.2 Real Business Cycle Model

In this section, we will discuss the methodology for applying risk bounds to the forecasts generated by the real business cycle (RBC) model. This is a standard tool in macroeconomic forecasting. For a discussion of the RBC model and the standard methods used to bring such models to the data, see, for example DeJong and Dave (2007); DeJong et al. (2000); Fernández-Villaverde (2010); Kydland and Prescott (1982); Romer (2011); Sims (2002); Smets and Wouters (2007).

To estimate the parameters of this model, we use four data series. These are GDP y_t, consumption c_t, investment i_t, and hours worked n_t which are from the Federal Reserve Economic Database. The series we use are shown in Figure 3.

The basic idea of the estimation is to transform the model from an inter-temporal optimization form into a state space model. This leads to a linear, Gaussian state-space model with four observed variables (listed above), and two unobserved state variables. The mapping from parameters of the optimization problem to parameters of the state-space model is nonlinear, but, for each parameter setting, the Kalman filter returns the likelihood, so that likelihood methods are possible. As the data are fairly uninformative about many of the parameters, we estimate by maximizing a penalized likelihood, rather than a simple likelihood. Then the Kalman filter produces in-sample forecasts which are linear in past values of the data, so that we could potentially apply the growing memory bound.

For macroeconomic time series, there is not enough data to give nontrivial bounds, regardless of the mixing coefficients or the size of the finite memory approximation. Figure 3

shows $n = 245$ observations. The minimal possible finite approximation model is a VAR with one lag and four time series. In this case, since we are dealing with vector valued forecasts, we take $\ell(y - y') = \|y - y'\|_2$ so that the induced matrix norm of A is $\ell^*(A) = \sigma_{\max}(A)$, the largest singular value of A. We assume that Assumption C is satisfied with $M = 0.1$ and demand confidence 0.95 ($\eta = 0.05$). By Theorem 14, this class has growth function bounded by $(en)^8$.

Again, using the methods of McDonald et al. (2011a), we can estimate the β-mixing coefficients of the macroeconomic data set. The result is a point estimate $\beta_4 = 0$. Assuming that this is approximately accurate (0 is of course an underestimate), this suggests that the effective size of the macroeconomic data set is no more than about $\mu = 25$, much smaller then $n = 245$. To calculate the bound, we assume that $\mathbb{E}[\|Y\|_2] < 0.1$. The training error of the fitted RBC model is $\widehat{R}_n(f) = 0.046$. The bound is $R_n(f) < 2.29$.

The bound here is three orders of magnitude larger than the training error. If the bound is tight, then this suggests that the training error severely underestimates the true prediction risk. Of course, this should not be too surprising since the RBC model has 11 parameters and we are trying to get confidence intervals using only 25 effective data points.

In some sense, the empirical results in this section may seem slightly unreasonable. Since the results are only upper bounds, it is important to get an idea as to how tight they may be. We address this issue in the next section.

7. Properties of Our Results

In the previous section, we showed that the upper bound for the risk of standard macroeconomic forecasting models may be large. This of course raises the question "How tight are these bounds?" We address this question next and then discuss how to use the bounds for model selection.

7.1 How Tight Are the Bounds?

Here we give some idea of how tight the bounds presented in Section 5 are. Denote the function that minimizes the training error (or penalized training error) over $\mathcal{F}$ by $\widehat{f}_{erm}$, and let

$$f^* = \operatorname*{argmin}_{f \in \mathcal{F}} R_n(f)$$

be the oracle predictor with respect to $\mathcal{F}$. We call

$$L_n(\Pi) := \sup_{\mathbb{P} \in \Pi} \mathbb{E}_{\mathbb{P}}[R_n(\widehat{f}_{erm}) - R_n(f^*)] = \sup_{\mathbb{P} \in \Pi} \mathbb{E}_{\mathbb{P}}[R_n(\widehat{f}_{erm})] - R_n(f^*)$$

the "oracle loss"; it describes how well empirical risk minimization works relative to the best possible predictor f^* over the worst distribution $\mathbb{P}$. Vapnik (1998) shows that for classification and i.i.d. data, for sufficiently large n, there exist constants Υ_* and Υ^* such that

$$\Upsilon_* \sqrt{\frac{\mathrm{VCD}(\mathcal{C}_{\mathcal{F}})}{n}} \leq L_n(\Pi) \leq \Upsilon^* \sqrt{\frac{\mathrm{VCD}(\mathcal{C}_{\mathcal{F}}) \log n}{n}},$$

where Π is the class of all distributions on $\mathbb{U} \times \{0,1\}$ and $\mathcal{C}_\mathcal{F}$ has finite VC-dimension $\text{VCD}(\mathcal{C}_\mathcal{F})$. In other words, for i.i.d. data, the best we can hope to do is a rate of

$$O\left(\sqrt{\frac{\text{VCD}(\mathcal{C}_\mathcal{F})}{n}}\right)$$

, and prediction methods which perform worse than $O\left(\sqrt{\text{VCD}(\mathcal{C}_\mathcal{F}) \log n/n}\right)$ are inefficient. We will derive similar bounds for the β-mixing setting. First, we need a slightly different version of Theorem 12.

Theorem 19 *Suppose that $\ell(y-y') < M$, that Assumption A holds, and that $\mathcal{F}$ has a fixed memory length $d < n$. Let μ and a be integers such that $2\mu a + d \leq n$. Then, for all $\epsilon > 0$,*

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}}(R_n(f) - \widehat{R}_n(f)) > \epsilon\right) \leq 8G(n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{\mu\epsilon^2}{\Upsilon}\right\} + 2\mu\beta_{a-d}.$$

where Υ depends only on M.

The proof of Theorem 19 is exactly like that for Theorem 12 using the result for bounded loss in Theorem 4 rather than that for relative loss in Corollary 23 to control the probability that empirical risk over blocks deviates from its expectation (see (8)).

Assumption D *The time series Y_∞ is* geometrically *β-mixing, that is $\beta_a = \upsilon_1 \exp(-\upsilon_2 a^\kappa)$ for some constants $\upsilon_1, \upsilon_2, \kappa$.*

Theorem 20 *Suppose $\ell(y-y') < M$ and that Assumption D holds. Further assume that $\mathcal{C}_{\ell\circ\mathcal{F}}$ has finite VC-dimension $\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}})$. Then, for sufficiently large n, there exist constants Υ_* and Υ^*, independent of n and $\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}})$, such that*

$$\Upsilon_*\sqrt{\frac{\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}})}{n}} \leq L_n(\Pi) \leq \Upsilon^*\sqrt{\frac{\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}}) \log n}{n^{\kappa/(1+\kappa)}}}.$$

If we instead assume *algebraic mixing*, that is $\beta_a = \upsilon a^{-\rho}$, then we can retrieve the same rate where $0 < \kappa < (\rho-1)/2$ (see Meir, 2000). Theorem 20 says that in dependent data settings, using the blocking approach developed here, we may pay a penalty: the upper bound on $L_n(\Pi)$ goes to zero more slowly than in the i.i.d. case. But, the lower bound cannot be made any tighter since i.i.d. processes are still allowed under Assumption D (and of course under the more general Assumption A). In other words, we may have $\kappa \to \infty$ so we can not rule out the faster learning rate of $O\left(\sqrt{\frac{\text{VCD}(\mathcal{C}_{\ell\circ\mathcal{F}}) \log n}{n}}\right)$.

7.2 Structural Risk Minimization

Our presentation so far has focused on choosing one function $\widehat{f}$ from a model $\mathcal{F}$ and demonstrating that the prediction risk $R_n(\widehat{f})$ is well characterized by the training error inflated by a complexity term. The procedure for actually choosing $\widehat{f}$ has been ignored. Common ways of choosing $\widehat{f}$ are frequently referred to as *empirical risk minimization* or ERM: approximate the expected risk $R_n(f)$ with the empirical risk $\widehat{R}_n(f)$, and choose $\widehat{f}$ to minimize

the empirical risk. Many likelihood based methods have exactly this flavor. But more frequently, forecasters have many different models in mind, each with a different empirical risk minimizer. Regularized model classes (ridge regression, lasso, Bayesian methods) implicitly have this structure — altering the amount of regularization leads to different models $\mathcal{F}$. Or one may have many different forecasting models from which the forecaster would like to choose the best. This scenario leads to a generalization of ERM called *structural risk minimization* or SRM.

Given a collection of models $\mathcal{F}_1, \mathcal{F}_2, \ldots$ each with associated empirical risk minimizers $\widehat{f}_1, \widehat{f}_2, \ldots$, we wish to use the function which has the smallest risk. Of course different models have different complexities, and those with larger complexities will tend to have smaller empirical risk. To choose the best function, we therefore penalize the empirical risk and select that function which minimizes the penalized version. Model selection tools like AIC or BIC have exactly this form, but they rely on specific knowledge of the data likelihood and use asymptotics to derive approximate penalties. In contrast, we have finite-sample bounds for the expected risk. This leads to a natural model selection rule: choose the predictor which has the smallest bound on the expected risk.

The generalization error bounds in Section 5 allow one to perform model selection via the SRM principle without knowledge of the likelihood or appeals to asymptotic results. The penalty accounts for the complexity of the model through the VC dimension. Most useful however is that by using generalization error bounds for model selection, we are minimizing the prediction risk. So in the volatility forecasting exercise above, we would choose the mean.

If we want to make the prediction risk as small as possible, we can minimize the generalization error bound simultaneously over models $\mathcal{F}$ and functions within those models. This amounts to treating VC dimension as a control variable. Therefore, by minimizing both the empirical risk and the VC dimension, we can choose that model and function which has the smallest prediction risk, a claim which other model selection procedures cannot make (Massart, 2007; Vapnik, 2000).

8. Conclusion

This paper demonstrates how to control the generalization error of common time-series forecasting models, especially those used in economics and engineering—ARMA models, vector autoregressions (Bayesian or otherwise), linearized dynamic stochastic general equilibrium models, and linear state-space models. We derive upper bounds on the risk, which hold with high probability while requiring only weak assumptions on the data-generating process. These bounds are finite sample in nature, unlike standard model selection penalties such as AIC or BIC. Furthermore, they do not suffer the biases inherent in other risk estimation techniques such as the pseudo-cross validation approach often used in the economic forecasting literature.

While we have stated these results in terms of standard economic forecasting models, they have very wide applicability. Theorem 12 applies to any forecasting procedure with fixed memory length, linear or non-linear. Theorem 17 applies only to methods whose forecasts are linear in the observations, but a similar result for nonlinear methods would

just need to ensure that the dependence of the forecast on the past decays in some suitable way.

Rather than deriving bounds theoretically, one could attempt to estimate bounds on the risk. While cross-validation is tricky (Racine, 2000), nonparametric bootstrap procedures may do better. A fully nonparametric version is possible, using the circular bootstrap (reviewed in Lahiri, 1999). Bootstrapping lengthy out-of-sample sequences for testing fitted model predictions yields intuitively sensible estimates of $R_n(f)$, but there is currently no theory about the coverage level. Also, while models like VARs can be fit quickly to simulated data, general state-space models, let alone DSGEs, require large amounts of computational power, which is an obstacle to any resampling method.

While our results are a crucial first step for the learning-theoretic analysis of time-series forecasts, many avenues remain for future exploration. To gain a more complete picture of the performance of forecasting algorithms, we would want minimax lower bounds (c.f. Tsybakov, 2008). These would tell us the smallest risk we could hope to achieve using any forecaster in some larger model class, letting us ask whether any of the models in common use actually approach this minimum. Another possibility is to target not the *ex ante* risk of the forecast, but the *ex post* regret: how much better might our forecasts have been, in retrospect and on the actually-realized data, had we used a different prediction function from the model $\mathcal{F}$ (Cesa-Bianchi and Lugosi, 2006; Rakhlin et al., 2010)? Remarkably, we can find forecasters which have low *ex post* regret, even if the data came from an adversary trying to make us perform badly. If we target regret rather than risk, we can actually ignore mixing, and even stationarity (Shalizi et al., 2011).

An increased recognition of the abilities and benefits of statistical learning theory can be of tremendous aid to financial and economic forecasters. The results presented here represent an initial yet productive foray in this direction. They allow for principled model comparisons as well as high probability performance guarantees. Future work in this direction will only serve to sharpen our ability to measure predictive power.

CRS is partially supported by NIH Grant R01 NS047493 and by NSF grants DMS1207759 and DMS 1418124. The authors wish to thank David N. DeJong, Larry Wasserman, Alessandro Rinaldo and Darren Homrighausen for valuable suggestions on early drafts. Finally, we wish to think two anonymous referees for their thorough and invaluable comments. Their suggestions have dramatically improved this paper.

Appendix A. Auxiliary Results

Lemma 21 (Yu, 1994 Lemma 4.1) *Let Z be an event with respect to the block sequence $\mathbf{U}$. Then,*

$$|\mathbb{P}(Z) - \widetilde{\mathbb{P}}(Z)| \leq \beta_a(\mu - 1),$$

where the first probability is with respect to the dependent block sequence, $\mathbf{U}$, and $\widetilde{\mathbb{P}}$ is with respect to the independent sequence, $\mathbf{U}'$.

This lemma essentially gives a way to apply i.i.d. results to β-mixing data. Because the dependence decays as we increase the separation between blocks, widely spaced blocks are nearly independent of each other. In particular, the difference between expectations over these nearly independent blocks and expectations over blocks which are actually independent can be controlled by the β-mixing coefficient. Very similar results are also given in Nobel and Dembo (1993) and Vidyasagar (2003).

Lemma 22 (Cortes et al., 2010 Theorem 7) *Under Assumption B,*

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\sqrt{2 + \log\frac{1}{\epsilon}}\right) \leq 4G(2n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{n\epsilon^2}{4}\right\}.$$

Corollary 23 *Under Assumption B, for $0 < \epsilon \leq e^{3/2}/\sqrt{2}$,*

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\right) \leq 4G(2n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{n\exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\}.$$

Proof Letting $\epsilon' = \epsilon\sqrt{2 + \log\frac{1}{\epsilon}}$ and solving for ϵ gives

$$\epsilon = \exp\left\{\frac{1}{2}\left(W\left(-\frac{2\epsilon'^2}{e^4}\right) + 4\right)\right\}$$

if $0 < \epsilon' \leq e^{3/2}/\sqrt{2}$, so

$$\mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\sqrt{2 + \log\frac{1}{\epsilon}}\right) \leq 4G(2n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{n\epsilon^2}{4}\right\}$$

$$\Rightarrow \mathbb{P}\left(\sup_{f\in\mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f)}{Q_d(f)} > \epsilon\right) \leq 4G(2n, \mathcal{C}_{\ell\circ\mathcal{F}}) \exp\left\{-\frac{n\exp\left(W\left(-\frac{2\epsilon^2}{e^4}\right) + 4\right)}{4}\right\}.$$

■

Lemma 24 *Suppose we have a function class $\mathcal{F}$ with growth function $G(n, \mathcal{F})$. Let $2\mu a = n$. Consider the class $\mathcal{F}^\Sigma = \{\sum_{j=1}^a f(z_j) : f \in \mathcal{F}\}$.*

$$G(\mu, \mathcal{F}^\Sigma) \leq G(n/2, \mathcal{F}).$$

Proof Let $z_1, \ldots, z_\mu \in \mathbb{U}^a$, $b_1, \ldots, b_\mu \in \mathbb{R}$ be a set such that $\exists f_1^\Sigma, \ldots, f_K^\Sigma \in \mathcal{F}^\Sigma$ with $K = G(\mu, \mathcal{F}^\Sigma)$ which shatters$\{z_i\}$. That is, for $v_{ik} \in \{0,1\}$, $i = 1, \ldots, \mu$, $k = 1, \ldots, K$, we have

$$I(f_k^\Sigma(z_i) > b_i) \text{ iff } v_{ik} = 1.$$

But this means, $I(a^{-1}\sum_{j=1}^a f_k(z_{ij}) > b_i/a)$ iff $v_{ik} = 1$. Since this is a convex combination of the $f_k(z_{ij})$, there is a subset of the z_{ij} such that

$$I(f_k(z_{ij}) > b_i/a) \text{ iff } v_{ik} = 1.$$

Thus $G(\mu, \mathcal{F}^\Sigma) \leq G(\mu a, \mathcal{F}) = G(n/2, \mathcal{F})$. ■

Lemma 25 *Let $\mathcal{F}$ be a class of predictor functions $\mathbb{U} \mapsto \mathbb{R}$, and let $h : \mathbb{R} \mapsto \mathbb{R}$, be a monotone-increasing function. Define $h \circ \mathcal{F} = \{h \circ f : f \in \mathcal{F}\}$. Then $\forall n \geq 1$, $G(n, h \circ \mathcal{F}) \leq G(n, \mathcal{F})$.*

Proof Let $z_1, \ldots, z_n \in \mathbb{U}$, $b_1, \ldots, b_n \in \mathbb{R}$ be a set such that $\exists f_1, \ldots, f_K \in \mathcal{F}$ and $K = G(\mu, h \circ \mathcal{F})$ which shatters $\{z_i\}$. That is, for $v_{ik} \in \{0,1\}$, $i = 1, \ldots, n$, $k = 1, \ldots, K$, we have

$$I(h(f_k(z_i)) > b_i) \text{ iff } v_{ik} = 1.$$

Set

$$c_i = \max_{k \in 1:K} \{f_k(z_i) \ : \ h(f_k(u_i)) \leq b_i\}$$

Then, because h is monotone,

$$b_i \geq h(f_k(u_i)) \ \Leftrightarrow \ c_i \geq f_k(u_i)$$

Hence this set of points is shattered by the same collection of functions, and $G(n, h \circ \mathcal{F}) \leq G(n, \mathcal{F})$.

■

Appendix B. Proofs of Selected Results

Proof [Lemma 7] We have that

$$\begin{aligned} b_{ij} &= Z \prod_{k=j+1}^{i-1} L_k K_j \\ &= Z(I - P_{j+1}Z^\top F_{j+1}Z)T(I - P_{j+2}Z^\top F_{j+2}Z) \cdots T(I - P_{i-1}Z^\top F_{i-1}Z)K_j. \end{aligned}$$

Now, by assumption $\lambda_{max}(T) < 1$. Furthermore, $\lambda_{max}\left((I - P_k Z' F_k Z)\right) \leq 1$ for all k. To see this, write

$$\begin{aligned} I - P_k Z^\top F_k Z &= I - P_k Z^\top (Z P_k Z^\top + H)^{-1} Z \\ &= I - Z^\dagger [Z P_k Z^\top][(Z P_k Z^\top + H)^{-1}]Z, \end{aligned}$$

where $Z^\dagger$ is a generalized inverse for Z. As, P_k and H are positive definite, $[ZP_kZ'][(ZP_kZ' + H)^{-1}]$ is positive definite with $\lambda_{\max}([ZP_kZ^\top][(ZP_kZ^\top + H)^{-1}]) < 1$ and therefore $I - Z^\dagger[ZP_kZ^\top][(ZP_kZ^\top + H)^{-1}]Z$ is positive semi-definite if $dim(H) > dim(P_k)$ and positive definite if $dim(P_k) \leq dim(H)$. Therefore, $0 < \lambda_{\max}\left((I - P_kZ'F_kZ)\right) \leq 1$. Finally, $\lambda_{\max}(b_{i,j}) \leq \|Z\|_2 \|T\|_2^{i-j-1} \prod_{k=j+1}^{i-1} \|I - P_kZ'F_kZ\|_2 \leq \lambda_{\max}(T)^{i-j-1} \|Z\|_2 = O(r^{i-j-1})$. ■

Proof [Lemma 8]

1. This result is given in Anderson and Moore (2012, 4.4).

2. The convergence of $\widehat{P}_i$ is in Anderson and Moore (2012, 4.4). As

   $$K_i = T\widehat{P}_i Z^\top (Z\widehat{P}_i Z^\top + H)^{-1}$$

   is continuous in $\widehat{P}_i$, it converges as well.

3. This result is given in Anderson and Moore (2012, 4.4).

4. $\|\widehat{P}_i - \overline{P}\| = O(\lambda_{\max}(T - \overline{K}Z)^i)$ is given Anderson and Moore (2012, 4.4). For F_i,

   $$\|F_i - \overline{F}\| = \|F_i(F_i^{-1} - \overline{F}^{-1})\overline{F}\| = O(\|F_i^{-1} - \overline{F}^{-1}\|)$$

   since $\lambda_{\min}(F_i^{-1}) > \lambda_{\min}(H) > 0 \Rightarrow \lambda_{\max}(F_i) < 1/\lambda_{\min}(H) = O(1)$. Proceeding,

   $$O(\|F_i^{-1} - F^{-1}\|) = O(\|Z\widehat{P}_i Z^\top - Z\overline{P}Z^\top\|) = O(\|\widehat{P}_i - \overline{P}\|) = O(\rho^i).$$

   For K_i, note that

   $$K_i - K = TP_iZ^\top F_i - T\overline{P}Z^\top\overline{F} = TP_iZ^\top F_i - T\overline{P}Z^\top F_i + T\overline{P}Z^\top F_i - T\overline{P}Z^\top\overline{F}.$$

   We have $\|TP_iZ^\top F_i - T\overline{P}Z^\top F_i\| = O(\rho^i)$ by the result for $\widehat{P}_i$ and $\|T\overline{P}Z^\top F_i - T\overline{P}Z^\top\overline{F}\| = O(\rho^i)$ by the result for F_i.

■

Proof [Lemma 9] By (3), $s_{ij} = Z(T - \overline{K}Z)^{i-j-1}\overline{K}$ with $\lambda_{\max}(T - \overline{K}Z) = \rho < 1$. Thus $\|s_{ij}\| = \|s_{i-j-1}\| = O(\rho^{i-j-1})$. For $j < i - 1$,

$$b_{ij} = Z \prod_{k=j+1}^{i-1} (T - K_kZ)K_j \qquad\qquad s_{ij} = Z(T - \overline{K}Z)^{i-j}\overline{K}.$$

Therefore,

$$\begin{aligned}
\|b_{ij} - s_{ij}\| &\leq \|Z\| \left\| \prod_{k=j+1}^{i-1} (T - K_k Z) K_j - (T - \overline{K}Z)^{i-j-1} \overline{K} \right\| \\
&\leq \|Z\| \left\| \prod_{k=j+1}^{i-1} (T - K_k Z) K_j - \prod_{k=j+1}^{i-1} (T - K_k Z) \overline{K} \right\| \\
&\quad + \|Z\| \left\| \prod_{k=j+1}^{i-1} (T - K_k Z) \overline{K} - (T - \overline{K}Z)^{i-j-1} \overline{K} \right\| \\
&\leq \|Z\| \left\| \prod_{k=j+1}^{i-1} (T - K_k Z) \right\| \left\| K_j - \overline{K} \right\| \\
&\quad + \|Z\| \left\| \overline{K} \right\| \left\| \prod_{k=j+1}^{i-1} (T - K_k Z) - (T - \overline{K}Z)^{i-j-1} \right\| \\
&= O\left(\lambda_{\max}(T - \overline{K}Z)^j\right) + O\left(\left\| \prod_{k=j+1}^{i-1} (T - K_k Z) - (T - \overline{K}Z)^{i-j-1} \right\| \right) \quad (9) \\
&= O\left(\lambda_{\max}(T - \overline{K}Z)^j\right) + O\left(\left\| (T - K_{j+1}Z)^{i-j-1} - (T - \overline{K}Z)^{i-j-1} \right\| \right) \quad (10) \\
&= O\left(\lambda_{\max}(T - \overline{K}Z)^j\right).
\end{aligned}$$

Here, (9) follows from Lemma 8 and (10) follows because $\left\|(T - K_k Z) - (T - \overline{K}Z)\right\|$ is increasing in k, so

$$\begin{aligned}
\left\| \prod_{k=j+1}^{i-1} (T - K_k Z) - (T - \overline{K}Z) \right\| &\leq \left\| \prod_{k=j+1}^{i-1} (T - K_{j+1} Z) - (T - \overline{K}Z) \right\| \\
&= \left\| (T - K_{j+1}Z)^{i-j-1} - (T - \overline{K}Z) \right\|.
\end{aligned}$$

For $j = i - 1$,

$$\|b_{i,i-1} - s_{i,i-1}\| = \left\| Z K_j - Z\overline{K} \right\| = O\left(\lambda_{\max}(T - \overline{K}Z)^j\right).$$

■

Proof [Theorem 14] Consider first an AR(d) model and the class

$$\mathcal{C}_{|\mathcal{F}|} = \{(u_0, u_1, u) \in \mathbb{R} \times \mathbb{R} \times \mathbb{R}^d : \mathbf{1}(|u_0 - a^\top u| > u_1) = 1\}.$$

This is the class contains sets of points u for which linear predictions of u_0 are made via a with threshold b. Rewrite $\mathcal{C}_{|\mathcal{F}|}$ as

$$\begin{aligned}
\mathcal{C}_{|\mathcal{F}|} = \Big\{ (u_0, u_1, u) : \max\{ &[\mathrm{sgn}((1 \ -a \ -u_1)^\top (u_0 \ u \ 1))], \\
&[\mathrm{sgn}((-1 \ a \ -u_1)^\top (u_0 \ u \ 1))] \} = 1 \Big\}.
\end{aligned}$$

Then $\mathcal{C}_{|\mathcal{F}|}$ is a 2-combination of $\mathcal{F}$ as in Anthony and Bartlett (1999, Theorem 7.3). As $\mathcal{F}$ is a linear function, it has solution set components bound $B = 1$ (Anthony and Bartlett, 1999, p. 91). We add an intercept to $\mathcal{F}$ so that it will be closed under addition. Then by (Anthony and Bartlett, 1999, Theorem 7.6),

$$G(n, \mathcal{C}_{|\mathcal{F}|}) \leq \left(\frac{2en}{d+1} \right)^{d+1}.$$

Then apply Lemma 25. The result for VARs is similar. Consider the class

$$\begin{aligned}
\mathcal{C}_{\mathcal{G}} = \Big\{ &[\mathrm{sgn}((1 \ -a_1 \ 0 \cdots 0 \ -u_1/k)^\top (u_0 \ u \ 1))] \vee [\mathrm{sgn}((-1 \ a_1 \ 0 \cdots 0 \ -u_1/k)^\top (u_0 \ u \ 1))] \\
&\vee [\mathrm{sgn}((1 \ 0 \ -a_2 \ 0 \cdots 0 \ -u_1/k)^\top (u_0 \ u \ 1))] \vee [\mathrm{sgn}((-1 \ 0 \ a_2 \ 0 \cdots 0 \ -u_1/k)^\top (u_0 \ u \ 1))] \\
&\vee \cdots \vee [\mathrm{sgn}((1 \ 0 \cdots 0 \ -a_k \ -u_1/k)^\top (u_0 \ u \ 1))] \\
&\vee [\mathrm{sgn}((-1 \ 0 \cdots 0 \ a_k \ -u_1/k)^\top (u_0 \ u \ 1))] \Big\}.
\end{aligned}$$

This is the class which correctly classifies at least one of the k coordinates. By (Anthony and Bartlett, 1999, Theorem 7.6),

$$G(n, \mathcal{C}_{\mathcal{G}}) \leq \left(\frac{2ken}{k(d+1)} \right)^{k(d+1)} = \left(\frac{2en}{d+1} \right)^{k(d+1)}.$$

Then apply Lemma 25. As $|\mathcal{F}| \subseteq \mathcal{G}$, we have the result. ■

Proof [Theorem 15 and Corollary 16] Let $\mathcal{F}_2$ be the class of predictors given by Algorithm 2. Let $\mathcal{F}_2'$ be the same class, but predictions are made based on the truncated memory length d. That is for $f_2 \in \mathcal{F}_2$,

$$\widehat{Y}_{d+1:n+1} = \mathbf{S} Y_{1:n}$$

where

$$\mathbf{S} = \begin{bmatrix} s_{d+1,1} & \cdots & s_{d+1,d} & & & 0 \\ s_{d+2,1} & \cdots & s_{d+2,d} & s_{d+2,d+1} & & \\ \vdots & & \vdots & & \ddots & \\ s_{n+1,1} & \cdots & s_{n+1.d} & s_{n+1,d+1} & \cdots & s_{n+1,n} \end{bmatrix} = \begin{bmatrix} s_{d-1} & \cdots & s_0 & & & 0 \\ s_d & \cdots & s_1 & s_0 & & \\ \vdots & & \vdots & & \ddots & \\ s_{n-1} & \cdots & s_{n-d} & s_{n-d+1} & \cdots & s_0 \end{bmatrix}$$

as in (3) (redefining $s_{i,j} \to s_{i-j-1}$), but for $f_2' \in \mathcal{F}_2'$,

$$\widehat{Y}'_{d+1:n+1} = \mathbf{S}' Y_{1:n}$$

where

$$\mathbf{S}' = \begin{bmatrix} s_{d-1} & s_{d-2} & \cdots & s_0 & 0 & & \\ 0 & s_{d-1} & \cdots & s_1 & s_0 & & \\ & & & & \ddots & & \\ & & 0 & & s_{d-1} & \cdots & s_0 \end{bmatrix}. \quad (11)$$

Note that by using Algorithm 2, predictions $\widehat{Y}_i'$ are made using the same linear combination of previous observations at all times i. Thus, truncating the memory, makes these predictions simple autoregressive models of order d.

Define $\widetilde{R}_n(f_2')$ to be the training error of this truncated predictor f_2'. Then, for any $f_2 \in \mathcal{F}_2$,

$$\begin{aligned} R_n(f_2) - \widehat{R}_n(f_2) &= (R_n(f_2) - R_n(f_2')) + (R_n(f_2') - \widetilde{R}_n(f_2')) + (\widetilde{R}_n(f_2') - \widehat{R}_n(f_2)) \\ &= \Delta_1(d) + (R_n(f_2') - \widetilde{R}_n(f_2')) + \Delta_2(d) \\ &= (R_n(f_2') - \widetilde{R}_n(f_2')) + \delta_d(f_2), \end{aligned}$$

where we have defined $\Delta_1(d)$, $\Delta_2(d)$, and $\delta_d(f_2)$ in the obvious way. For now, we will simply proceed with the analysis incorporating the approximation term $\delta_d(f_2)$, before showing that $\delta_d(f_2)$ decays rapidly for this class of models.

Now,

$$R_n(f_2) - \widehat{R}_n(f_2) - \delta_d(f_2) = R_n(f_2') - \widetilde{R}_n(f_2') = R_d(f_2') - \widetilde{R}_n(f_2').$$

Dividing through by $Q_d(f_2') = Q_d(f_2)$ and taking the supremum over $\mathcal{F}_2$ (and therefore over $\mathcal{F}_2'$) gives

$$\sup_{f_2 \in \mathcal{F}_2} \frac{R_n(f_2) - \widehat{R}_n(f_2) - \delta_d(f_2)}{Q_d(f_2)} \leq \sup_{f_2 \in \mathcal{F}_2} \frac{R_n(f_2') - \widetilde{R}_n(f_2')}{Q_d(f_2')}$$

Finally,

$$\mathbb{P}\left(\sup_{f \in \mathcal{F}} \frac{R_n(f) - \widehat{R}_n(f) - \delta_d(f)}{Q_d(f)} > \epsilon \right) \leq \mathbb{P}\left(\sup_{f' \in \mathcal{F}'} \frac{R_n(f') - \widetilde{R}_n(f')}{Q_d(f')} > \epsilon \right)$$

Since $\mathcal{F}'$ is a class with finite memory, we can apply Theorem 12 and Corollary 13 to get the results.

To show that the finite approximation $\delta_d(f)$ decays rapidly for Algorithm 2, consider both components separately. For the case of the difference in expected risks, we need only consider the last rows of $\mathbf{S}$ and $\mathbf{S}'$. As

$$\Delta_1(d) = R_n(f) - R_n(f') = \mathbb{E}[\ell\left(Y_{n+1} - \mathbf{s}_{n+1} Y_{1:n}\right)] - \mathbb{E}[\ell\left(Y_{n+1} - \mathbf{s}'_{n+1} Y_{1:n}\right)],$$

where $\mathbf{s}_{n+1}$ indicates the $(n+1)^{st}$ row of $\mathbf{S}$ and similarly for $\mathbf{s}'_{n+1}$,

$$\begin{aligned} \Delta_1(d) &\leq \mathbb{E}[\ell\left((\mathbf{s}_{n+1} - \mathbf{s}'_{n+1}) Y_{1:n}\right)] && \text{(by the Triangle inequality for } \ell) \\ &= \mathbb{E}\left[\sum_{j=1}^{n-d} \ell(s_{n-j} Y_j) \right] \\ &\leq \sum_{j=1}^{n-d} \ell^*(s_{n-j}) \mathbb{E}[\ell(Y_j)] && \left(\text{as } \ell \text{ is a norm, with } \ell^*(s) = \sup_{x \neq 0} \tfrac{\ell(sx)}{\ell(x)}\right) \\ &= \mathbb{E}[\ell(Y_1)] \left(\sum_{j=1}^{n-d} \ell^*(s_{n-j}) \right) && \text{(by stationarity)} \\ &= \mathbb{E}[\ell(Y_1)] \left(\sum_{j=1}^{n-d} O(\rho^{n-j}) \right) && \text{(Lemma 9 and equivalence of norms)} \\ &= O\left(\frac{\rho^d - \rho^n}{1-\rho} \right) = O(\rho^d). \end{aligned}$$

Similarly,

$$\begin{aligned} \Delta_2(d) &= \widetilde{R}_n(f') - \widehat{R}_n(f) \\ &\leq \frac{1}{n-d} \sum_{i=d+1}^{n} \ell((\mathbf{s}_i - \mathbf{s}'_i) Y_{1:i-1}) \\ &= \frac{1}{n-d} \sum_{i=d+2}^{n} \sum_{j=1}^{i-d-1} \ell(s_{i-j-1} Y_j) \\ &\leq \frac{1}{n-d} \sum_{i=d+2}^{n} O_p(1) \sum_{j=1}^{i-d-1} \ell^*(s_{i-j-1}) \\ &\leq O_{\mathbb{P}}((n-d)^{-1}) \sum_{i=d+2}^{n} \sum_{j=1}^{i-d-1} O(\rho^{i-j-1}) \\ &= O_{\mathbb{P}}((n-d)^{-1}) O\left[\frac{(n-d-1)\rho^d - (n-d)\rho^{d+1} + \rho^n}{(1-\rho)^2} \right] \\ &= O_{\mathbb{P}}(\rho^d) \end{aligned}$$

■

Proof [Theorem 17 and Corollary 18] Let $\mathcal{F}_1$ be the class of predictors given by Algorithm 1. Let $\mathcal{F}_2'$ be the class of predictors given by Algorithm 2 based on the truncated memory length d. That is for $f_1 \in \mathcal{F}_1$,

$$\widehat{Y}_{d+1:n+1} = \mathbf{B} Y_{1:n}$$

where

$$\mathbf{B} = \begin{bmatrix} b_{d,1} & \cdots & b_{d,d} & & \\ b_{d+1,1} & \cdots & b_{d+1,d} & b_{d+1,d+1} & \mathbf{0} \\ \vdots & & \vdots & & \ddots \\ b_{n+1,1} & \cdots & b_{n+1,d} & b_{n+1,d+1} & \cdots \quad b_{n+1,n} \end{bmatrix}$$

as in (2), but for f_2'

$$\widehat{Y}'_{d+1:n+1} = \mathbf{S}' Y_{1:n}$$

as in (11).

Then, proceeding as in the previous proof, define $\widetilde{R}_n(f_2')$ to be the training error of the associated truncated limiting predictor f_2' and write analogously

$$\begin{aligned} R_n(f_1) - \widehat{R}_n(f_1) &= (R_n(f_1) - R_n(f_2')) + (R_n(f_2') - \widetilde{R}_n(f_2')) + (\widetilde{R}_n(f_2') - \widehat{R}_n(f_1)) \\ &= \Delta_1(d) + (R_n(f_2') - \widetilde{R}_n(f_2')) + \Delta_2(d) \\ &= (R_n(f_2') - \widetilde{R}_n(f_2')) + \delta_d(f_1), \end{aligned}$$

where

$$\delta_d(f_1) = (R_n(f_1) - R_n(f_2')) + (\widetilde{R}_n(f_2') - \widehat{R}_n(f_1)) = \Delta_1(d) + \Delta_2(d).$$

Now, by Lemma 9, the truncated version of f_1, f_1' converges to f_2' so that $f_1'(Y_{n-d:n-1})$ converges in distribution to $f_2'(Y_{n-d:n-1})$. And because$\ell(y-x)^2$ is continuous in x, $\ell(Y_n - f_1'(Y_{n-d:n-1}))^2$ converges in distribution to $\ell(Y_n - f_2'(Y_{n-d:n-1}))^2$ by the continuous mapping theorem. By Assumption C, $\ell(Y_n - f_1'(Y_{n-d:n-1}))^2$ is uniformly integrable, so

$$\lim_{n\to\infty} \mathbb{E}\left[\ell(Y_n - f_1'(Y_{n-d:n-1}))^2\right] = \mathbb{E}\left[\ell(Y_n - f_2'(Y_{n-d:n-1}))^2\right].$$

Therefore,

$$\frac{R_n(f_1) - \widehat{R}_n(f_1) - \delta_d(f_1)}{\lim_{n\to\infty} Q_d(f_1)} = \frac{R_n(f_2') - \widetilde{R}_n(f_2')}{Q_d(f_2')}$$

For each $f_1 \in \mathcal{F}_1$ (parameterized by θ), there exists one function $f_2 \in \mathcal{F}_2$ which results from the same parameter vector, so that

$$\sup_{f_1\in\mathcal{F}_1} \frac{R_n(f_1) - \widehat{R}_n(f_1) - \delta_d(f_1)}{\lim_{n\to\infty} Q_d(f_1)} \leq \sup_{f_2'\in\mathcal{F}_2'} \frac{R_n(f_2') - \widetilde{R}_n(f_2')}{Q_d(f_2')}.$$

Therefore,

$$\mathbb{P}\left(\sup_{f_1\in\mathcal{F}_1} \frac{R_n(f_1) - \widehat{R}_n(f_1) - \delta_d(f_1)}{\lim_{n\to\infty} Q_d(f_1)} > \epsilon\right) \leq \mathbb{P}\left(\sup_{f_2'\in\mathcal{F}_2'} \frac{R_n(f_2') - \widetilde{R}_n(f_2')}{Q_d(f_2')} > \epsilon\right)$$

Since $\mathcal{F}_2'$ is a class with finite memory, we can apply Theorem 12 and Corollary 13 to get the results.

To show that the finite approximation $\delta_d(f_1)$ decays rapidly, consider both components separately. For the case of the difference in expected risks, we need only consider the last rows of $\mathbf{B}$ and $\mathbf{S}'$. As

$$\Delta_1(d) = R_n(f_1) - R_n(f_2') = \mathbb{E}[\ell\left(Y_{n+1} - \mathbf{b}_{n+1}Y_{1:n}\right)] - \mathbb{E}[\ell\left(Y_{n+1} - \mathbf{s}'_{n+1}Y_{1:n}\right)],$$

where $\mathbf{b}_{n+1}$ indicates the $(n+1)^{st}$ row of $\mathbf{B}$ and similarly for $\mathbf{s}'_{n+1}$. Then, as in the previous proof,

$$\begin{aligned} \Delta_1(d) &\leq \mathbb{E}[\ell\left((\mathbf{b}_{n+1} - \mathbf{s}'_{n+1})Y_{1:n}\right)] && (12) \\ &\leq \mathbb{E}\left[\left(\sum_{j=1}^{n-d} \ell(b_{n+1,j}Y_j) + \sum_{j=n-d+1}^{n} \ell((b_{n+1,j} - s_{n-j})Y_j)\right)\right] \\ &\leq \sum_{j=1}^{n-d} \ell^*(b_{n+1,j})\mathbb{E}[\ell(Y_j)] + \sum_{j=n-d+1}^{n} \ell^*(b_{n+1,j} - s_{n-j})\mathbb{E}[\ell(Y_j)] && (13) \\ &= \mathbb{E}[\ell(Y_1)]\left(\sum_{j=1}^{n-d} \ell^*(b_{n+1,j}) + \sum_{j=n-d+1}^{n} \ell^*(b_{n+1,j} - s_{n-j})\right) \\ &= \mathbb{E}[\ell(Y_1)]\left(\sum_{j=1}^{n-d} O(r^{n-j}) + \sum_{j=n-d+1}^{n} O(\rho^j)\right) \\ &= O\left(\frac{r^d - r^n}{1-r}\right) + O\left(\frac{\rho^{n-d+1}(1-\rho^d)}{1-\rho}\right) \\ &= O(r^d) + O(\rho^{n-d+1}). \end{aligned}$$

(12) and B are via the triangle inequality for ℓ, while (13) uses the fact that ℓ is a norm, with $\ell^*(b) = \sup_{x \neq 0} \frac{\ell(bx)}{\ell(x)}$. Similarly,

$$\begin{aligned}
\Delta_2(d) &= \widetilde{R}_n(f_2') - \widehat{R}_n(f_1) \\
&\leq \frac{1}{n-d} \sum_{i=d+1}^{n} \ell((\mathbf{b}_i - \mathbf{s}_i')Y_{1:n-1}) \\
&\leq \frac{1}{n-d} \sum_{i=d+1}^{n} \sum_{j=1}^{i-d-1} \ell(b_{ij} Y_j) + \frac{1}{n-d} \sum_{i=d+1}^{n} \sum_{j=i-d}^{i-1} \ell((b_{ij} - s_{n-j}) Y_j) \\
&\leq \frac{1}{n-d} \sum_{i=d+2}^{n} O_{\mathbb{P}}(1) \sum_{j=1}^{i-d-1} \ell^*(b_{ij}) + \frac{1}{n-d} \sum_{i=d+1}^{n} O_{\mathbb{P}}(1) \sum_{j=i-d}^{i-1} \ell^*(b_{ij} - s_{ij}) \\
&\leq O_{\mathbb{P}}((n-d)^{-1}) \sum_{i=d+2}^{n} \sum_{j=1}^{i-d-1} r^{i-j-1} + O_{\mathbb{P}}((n-d)^{-1}) \sum_{i=d+1}^{n} \sum_{j=i-d}^{i-1} \rho^j \\
&= O_{\mathbb{P}}((n-d)^{-1}) O\left[\frac{(n-d-1)r^d - (n-d)r^{d+1} + r^n}{(1-r)^2}\right] \\
&\quad + O_{\mathbb{P}}((n-d)^{-1}) \left[\frac{(1-r^d)(r^d - r^n)}{r^{d-1}(1-r)^2}\right] \\
&= O_{\mathbb{P}}(r^d) + O_{\mathbb{P}}((n-d)^{-1})
\end{aligned}$$

■

Proof [Theorem 20] Theorem 19 implies that simultaneously

$$\mathbb{P}\left(R_n(\widehat{f}_{erm}) - \widehat{R}_n(\widehat{f}_{erm}) > \epsilon\right) \leq 8G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\epsilon^2}{\Upsilon}\right\} + 2\mu\beta_{a-d}$$

and

$$\mathbb{P}\left(R_n(f^*) - \widehat{R}_n(f^*) > \epsilon\right) \leq 8G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\epsilon^2}{\Upsilon}\right\} + 2\mu\beta_{a-d}.$$

Since $\widehat{R}_n(\widehat{f}_{erm}) - \widehat{R}_n(f^*) \leq 0$, then

$$\mathbb{P}\left(R_n(\widehat{f}_{erm}) - R_n(f^*) > \epsilon\right) \leq 16G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\epsilon^2}{\Upsilon}\right\} + 4\mu\beta_{a-d}.$$

For any nonnegative random variable Z, $\mathbb{E}[Z] = \int_0^\infty \mathbb{P}(Z > \epsilon) d\epsilon$, so

$$\begin{aligned}
L_n^2(\Pi) &= \int_0^\infty d\epsilon \mathbb{P}\left((R_n(\widehat{f}_{erm}) - R_n(f^*))^2 > \epsilon\right) \\
&= \int_0^\xi d\epsilon \mathbb{P}\left((R_n(\widehat{f}_{erm}) - R_n(f^*))^2 > \epsilon\right) + \int_\xi^\infty d\epsilon \mathbb{P}\left(R_n(\widehat{f}_{erm}) - R_n(f^*) > \epsilon\right) \\
&= \int_0^\xi d\epsilon \mathbb{P}\left((R_n(\widehat{f}_{erm}) - R_n(f^*))^2 > \epsilon\right) + \int_\xi^\infty d\epsilon \mathbb{P}\left((R_n(\widehat{f}_{erm}) - R_n(f^*))^2 > \sqrt{\epsilon}\right) \\
&= \int_0^\xi d\epsilon \mathbb{P}\left((R_n(\widehat{f}_{erm}) - R_n(f^*))^2 > \epsilon\right) + \int_\xi^{M^2} d\epsilon \mathbb{P}\left(R_n(\widehat{f}_{erm}) - R_n(f^*) > \sqrt{\epsilon}\right) \quad (14) \\
&\leq \xi + \int_\xi^{M^2} d\epsilon \left[16G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\epsilon}{\Upsilon}\right\} + 4\mu\beta_{a-d}\right] \\
&\leq \xi + \int_\xi^\infty d\epsilon 16G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\epsilon}{\Upsilon}\right\} + \int_\xi^{M^2} d\epsilon 4\mu\beta_{a-d} \\
&= \xi + \frac{16\Upsilon G(n, \mathcal{C}_{\ell \circ \mathcal{F}}) \exp\left\{-\frac{\mu\xi}{\Upsilon}\right\}}{\mu} + 4(M^2 - \xi)\mu\beta_{a-d}
\end{aligned}$$

for all $0 < \xi < \Upsilon$. Here, (14) follows because $\mathbb{P}\left(R_n(\widehat{f}_{erm}) - R_n(f^*) > M\right) = 0$. Using Assumption D, take

$$a = (n-d)^{1/(1+\kappa)} = O(n^{1/(1+\kappa)}), \qquad \mu = .5(n-d)^{\kappa/(1+\kappa)} = O(n^{\kappa/(1+\kappa)}),$$

and $\xi = \frac{\log G(n, \mathcal{C}_{\ell \circ \mathcal{F}})}{n^{\kappa/(1+\kappa)}}$ to balance the exponential and linear terms. Then

$$L_n(\Pi) = O\left(\sqrt{\frac{\log G(n, \mathcal{C}_{\ell \circ \mathcal{F}})}{n^{\kappa/(1+\kappa)}}}\right) = O\left(\sqrt{\frac{\mathrm{VCD}(\mathcal{C}_{\ell \circ \mathcal{F}}) \log n}{n^{\kappa/(1+\kappa)}}}\right).$$

as $\mathcal{C}_{\ell \circ \mathcal{F}}$ has finite VC-dimension.

For the lower bound, apply the i.i.d. version, as classification is a special case of bounded regression. The result follows. ■

Abstract

We present online Bayesian Passive-Aggressive (BayesPA) learning, a generic online learning framework for hierarchical Bayesian models with max-margin posterior regularization. We show that BayesPA subsumes the standard online Passive-Aggressive (PA) learning and extends naturally to incorporate latent variables for both parametric and nonparametric Bayesian inference, therefore providing great flexibility for explorative analysis. As an important example, we apply BayesPA to topic modeling and derive efficient online learning algorithms for max-margin topic models. We further develop nonparametric BayesPA topic models to infer the unknown number of topics in an online manner. Experimental results on 20newsgroups and a large Wikipedia multi-label dataset (with 1.1 millions of training documents and 0.9 million of unique terms in the vocabulary) show that our approaches significantly improve time efficiency while achieving comparable accuracy with the corresponding batch algorithms.

1. Introduction

With the fast growth of data volume and variety, it is becoming increasingly important to develop scalable machine learning algorithms, which can be categorized into two major categories — online/stochastic methods on a single core and parallel/distributed algorithms on multiple-cores or multiple machines. This paper focuses on online learning, a process of answering a sequence of questions (e.g., which category does a document belong to?) given knowledge of the correct answers (e.g., the true category labels) to previous questions. Such a process is especially suitable for the applications with streaming data. For the applications with large datasets, online learning algorithms can effectively explore data redundancy relative to the model to be learned, by repeatedly subsampling the data; and they often lead to faster convergence to satisfactory results than the corresponding batch learning algorithms. Among the many popular algorithms, online Passive-Aggressive (PA) learning (Crammer et al., 2006) provides a generic framework of performing online learning for large-margin methods (e.g., SVMs), with many applications in natural language processing and text mining (McDonald et al., 2005; Chiang et al., 2008). Though enjoying strong discriminative ability that is preferable for predictive tasks, existing online PA methods are formulated as a point estimate problem by optimizing some deterministic objective function. This may lead to some potential shortcomings. For example, a single large-margin model could fail to capture the rich underlying structure of complex data.

On the other hand, Bayesian methods enjoy greater flexibility in describing the possible underlying structures of complex data by incorporating a hierarchy of latent variables. Moreover, the recent progress on nonparametric Bayesian methods (Hjort, 2010; Teh et al., 2006a) further provides an increasingly important framework that allows the Bayesian models to have an unbounded model complexity, e.g., an infinite number of components in a mixture model (Hjort, 2010) or an infinite number of units in a latent feature model (Ghahramani and Griffiths, 2005), and to adapt when the learning environment changes. In particular, adaptation to the changing environment is of great importance in online learning. For Bayesian models, one challenging problem is posterior inference, for which both variational and Monte Carlo methods can be too expensive to be applied to large-scale applications. To scale up Bayesian inference, much progress has been made on developing stochastic variational Bayes (Hoffman et al., 2013; Mimno et al., 2012) and stochastic gradient Monte Carlo (Welling and Teh, 2011; Ahn et al., 2012) methods, which repeatedly draw samples from a given finite dataset.[1] To deal with the potentially unbounded streaming data, streaming variational Bayes methods (Broderick et al., 2013) have been developed as a general framework, with an application to topic models for learning latent topic representations. However, due to the generative nature, Bayesian models usually does not perform as well as discriminative models in predictive tasks such as classification.

Successful attempts have been made to bring large-margin learning and Bayesian methods together to solve supervised learning tasks using flexible Bayesian latent variable models. For example, maximum entropy discrimination (MED) made a significant advance in conjoining max-margin learning and Bayesian generative models, in the context of univariate prediction (Jaakkola et al., 1999) and structured output prediction (Zhu and Xing, 2009). Recently, much attention has been devoted to generalizing MED to incorporate latent variables and perform nonparametric Bayesian inference in various contexts, including topic modeling (Zhu et al., 2012), matrix factorization (Xu et al., 2013), and multi-task learning (Jebara, 2011; Zhu et al., 2014c). Regularized Bayesian inference (RegBayes) (Zhu et al., 2014c) provides a unified framework for Bayesian models to perform max-margin learning, where the max-margin principle is incorporated through adding posterior constraints to an information-theoretical optimization problem. By solving this problem involving latent variables, RegBayes can uncover structures that support the supervised learning tasks. RegBayes subsumes the standard Bayes' rule and is more flexible in incorporating domain knowledge or max-margin constraints. Though flexible in discovering latent structures and powerful in discriminative predictions, posterior inference in such models remains a challenge. By exploring data augmentation techniques, recent progress has been made to develop efficient MCMC methods (Zhu et al., 2014b), which can also be implemented in distributed clusters (Zhu et al., 2013). However, these batch learning methods are not applicable to streaming data, and they do not explore the statistical redundancy in large-scale corpora either.

To address the above problems of both online PA on incorporating flexible latent structures and Bayesian max-margin models on scalable streaming inference, this paper presents online Bayesian Passive-Aggressive (BayesPA) learning, a general framework of performing online learning for Bayesian max-margin models. We show that online BayesPA subsumes the standard online PA when the underlying model is linear and the parameter prior is Gaussian (See Table 1 for its close relationships with streaming variational Bayes and RegBayes). We further show that one major significance of BayesPA is its natural generalization to incorporate a hierarchy of latent variables for both parametric and nonparametric Bayesian inference, therefore allowing online BayesPA to have the great flexibility of (nonparametric) Bayesian methods for explorative analysis as well as the strong discriminative ability of large-margin learning for predictive tasks. As concrete examples, we apply the theory of online BayesPA to topic modeling and derive efficient online learning algorithms for max-margin supervised topic models (Zhu et al., 2012). We further develop efficient online learning algorithms for the nonparametric max-margin topic models, an extension of the nonparametric topic models (Teh et al., 2006a) for predictive tasks. Extensive empirical results on real datasets demonstrate significant improvements on time efficiency and maintenance of comparable results with corresponding batch algorithms.

The paper is structured as follows. We discuss the related work in Section 2, and review the preliminary knowledge in Section 3. Then, we move on to the detailed description of BayesPA in Section 4, and present the theoretical analysis. Section 5 presents the concrete instantiations on topic modeling, and Section 6 presents the extensions to nonparametric topic models and multi-task learning. Section 7 presents experimental results. Finally, Section 8 concludes this paper with future directions discussed.

2. Related Work

As a well-established learning paradigm, online learning is of both theoretical and practical interest. The goal of online learning is to make a sequence of decisions, such as classification and regression, and use the knowledge extracted from previous correct answers to produce decisions on incoming ones. The root of online learning could be traced back to early studies of repeated games (Hannan, 1957), where an agent dynamically makes choices with the summary of past information. The idea became popular with the advent of Perceptron algorithms (Rosenblatt, 1958), which adopt an additive update rule for the classifier weights, and its multiplicative counterpart is the Winnow algorithm (Littlestone, 1988). The class of online multiplicative algorithms was further generalized by Adaboost (Freund and Schapire, 1997) in a decision theoretic sense and is now widely applied to various fields of study (Arora et al., 2012).

First presented by Crammer et al. (2006) as a weight updating method, online Passive-Aggressive (PA) algorithms provide a generic online learning framework for max-margin models. In particular, they considered loss functions that enforce max-margin constraints, and showed that surprisingly simple update rules could be derived in closed forms. Motivated by online PA learning and to handle unbalanced training sets, Dredze et al. (2008) proposed confidence-weighted learning, which maintains a Gaussian distribution of the classifier weights at each round and replaces the max-margin constraint in PA with a probabilistic constraint enforcing confidence of classification. Within the same framework, Crammer et al. (2008) derived a new convex form of the constraint and demonstrated performance improvements through empirical evaluations.

The theoretical analysis of online learning typically relies on the notion of *regret*, which is the average loss incurred by an adaptive online learner on streaming data versus the best achievable through a single fixed model having the hindsight of all data (Murphy, 2012). It can be shown that the notion of regret is closely related to *weak duality* in convex optimization, which brings online learning to the algorithmic framework of convex repeated games (Shalev-Shwartz and Singer, 2006).

Although the classical regime of online learning is based on decision theory, recently much attention has been paid to the theory and practice of online probabilistic inference in the context of Big Data. Rooted either in variational inference or Monte Carlo sampling methods, there are broadly two lines of work on the topic of online Bayesian inference. Stochastic variational inference (SVI) (Hoffman et al., 2013) is a stochastic approximation algorithm for mean-field variational inference. By approximating the natural gradients in maximizing the evidence lower bound with stochastic gradients sampled from data points, Hoffman et al. (2013) demonstrated scalable inference of topic models on large corpora. Mimno et al. (2012) showed the performance of SVI could be improved through structured mean-field assumptions and locally collapsed variational inference. SVI is also applicable to the stochastic inference of nonparametric Bayesian models, such as hierarchical Dirichlet process (Wang et al., 2011; Wang and Blei, 2012b).

There is also a large body of work on extending Monte Carlo methods to the online setting. A classic approach is sequential Monte Carlo methods (SMC) or particle filters (Doucet and Johansen, 2009), which arose from the numerical estimation of state-space models. Through Rao-Blackwellized particle filters (Doucet et al., 2000), one could obtain online inference algorithms for latent Dirichlet allocation (LDA) (Canini et al., 2009), and more recently Gao et al. (2016) presented a streaming (collapsed) Gibbs sampler with better accuracy. To tackle the sparsity issues and inadequate coverage of particles, Steinhardt and Liang (2014) leveraged "abstract particles" to represent entire regions of the sample space. Recently, Korattikara et al. (2014) introduced an approximate Metropolis-Hasting rule based on sequential hypothesis testing that allows accepting and rejecting samples using only a fraction of the data. As an alternative, Bardenet et al. (2014) proposed an adaptive sampling strategy of Metropolis-Hastings from a controlled perturbation of the target distribution. With elegant use of gradient information that Metropolis-Hastings algorithms neglected, a line of work (Welling and Teh, 2011; Ahn et al., 2012; Patterson and Teh, 2013) also developed stochastic gradient methods based on Langevin dynamics.

While most online Bayesian inference methods have adopted a *stochastic approximation* of the posterior distribution by sub-sampling a given finite dataset, in many applications data arrives in stream so that the dataset is changing over time and its size is unknown. To relax the previous request on knowing the data size, Broderick et al. (2013) made streaming updates to the estimated posterior and demonstrated the advantage of streaming variational Bayes (SVB) over stochastic variational inference. As will be discussed in this paper, BayesPA also does not impose assumptions on the size of dataset and works on streaming data.

The idea to discriminatively train univariate or structured output classifiers was popularized by the seminal work on support vector machines (Vapnik, 1995) and max-margin Markov networks (aka structural SVMs) (Taskar et al., 2003). Since then, research on developing max-margin models with latent variables has received increasing attention, because of the promise to capture underlying complex structures of the problems. A promising line of work focused on Bayesian approaches, and one representative is maximum entropy discrimination (MED) (Jaakkola et al., 1999; Jebara, 2001; Zhu and Xing, 2009), which learns distributions of model parameters discriminatively from labeled

data. MedLDA (Zhu et al., 2012) extends MED to infer latent topical structure from data with large margin constraints on the target posteriors. Similarly, nonparametric Bayesian max-margin models have also been developed, such as infinite SVMs (iSVM) (Zhu et al., 2011) for building SVM classifiers with a latent mixture structure, and infinite latent SVMs (iLSVM) (Zhu et al., 2014c) for automatic discovering predictive features for SVMs. Furthermore, the idea of nonparametric Bayesian learning has been applied to link prediction (Zhu, 2012), matrix factorization (Xu et al., 2013), etc. Regularized Bayesian inference (RegBayes) (Zhu et al., 2014c) provides a unified framework for performing max-margin learning of (nonparametric) Bayesian models, where the max-margin principle was incorporated through imposing posterior constraints to a variational formulation of the standard Bayes' rule.

Max-margin Bayesian learning in the batch mode has already been one of the common challenges facing this class of models. Despite its general intractability, efficient algorithms have been proposed under different settings. One way is to solve the problem via variational inference under a mean-field (Zhu et al., 2012) or structured mean-field (Jiang et al., 2012) assumption. Recently, Zhu et al. (2014b) provided a key insight in deriving efficient Monte Carlo methods without making strict assumptions. Their technique is based on a data augmentation formulation of the expected margin loss. Based on similar techniques, fast inference algorithms have also been developed for generalized relational topic models (Chen et al., 2015), matrix factorization (Xu et al., 2013), etc. Data augmentation (DA) refers to the method of introducing augmented variables along with the observed data to make their joint distribution tractable. The technique was popularized in the statistics community by the well-known expectation-maximization algorithm (EM) (Dempster et al., 1977) for maximum likelihood estimation with missing data. For posterior inference, the technique is popularized by Tanner and Wong (1987) in statistics and by Swendsen and Wang (1987) for the Ising and Potts models in physics. For a broader introduction to DA methods, we refer the readers to Van Dyk and Meng (2001).

Finally, our conference version of the paper (Shi and Zhu, 2014) has introduced some preliminary work, which we largely extend here.

3. Preliminaries

This section reviews the preliminary knowledge that is needed to develop online Bayesian Passive-Aggressive learning. The relationships with BayesPA will be summarized in Table 1 later.

3.1 Online Passive-Aggressive Learning

Based on a decision-theoretic view, the goal of online supervised learning is to minimize the cumulative loss for a certain prediction task from the sequentially arriving training samples. Online Passive-Aggressive (PA) learning (Crammer et al., 2006) achieves this goal by updating some parametric model $\boldsymbol{w} \in \mathbb{R}^K$ (e.g., the weights of a linear SVM) in an online manner with the instantaneous losses from arriving data $\{\boldsymbol{x}_t\}_{t\geq 0}$ ($\boldsymbol{x}_t \in \mathbb{R}^K$) and corresponding responses $\{y_t\}_{t\geq 0}$, where K is the number of input features. The loss $\ell_\epsilon(\boldsymbol{w}; \boldsymbol{x}_t, y_t)$, as they consider, could be the hinge loss $(\epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t)_+$ for binary classification ($y_t \in \{0, 1\}$) or the ϵ-insensitive loss $(|y_t - \boldsymbol{w}^\top \boldsymbol{x}_t| - \epsilon)_+$ for regression ($y_t \in \mathbb{R}$), where ϵ is a hyper-parameter and $(x)_+ = \max(0, x)$. The online Passive-Aggressive update rule is then derived by defining the new weight $\boldsymbol{w}_{t+1}$ as the solution to the following optimization problem:

$$\min_{\boldsymbol{w}} \frac{1}{2}||\boldsymbol{w} - \boldsymbol{w_t}||^2 \quad \text{s.t.: } \ell_\epsilon(\boldsymbol{w}; \boldsymbol{x}_t, y_t) = 0, \tag{1}$$

where $\|\cdot\|$ is the Euclidean 2-norm. Intuitively, if $\boldsymbol{w_t}$ suffers no loss from the new data, i.e., $\ell_\epsilon(\boldsymbol{w}_t; \boldsymbol{x}_t, y_t) = 0$, the algorithm *passively* assigns $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t$; otherwise, it aggressively projects $\boldsymbol{w_t}$ to the feasible region of parameter vectors that attain zero loss on the new data. With provable regret bounds, Crammer et al. (2006) showed that online PA algorithms could achieve comparable results to the optimal classifier $\boldsymbol{w}^*$, which has the hindsight of all data. In practice, in order to account for inseparable training samples, soft margin constraints are often adopted and the resulting PA learning problem is

$$\min_{\boldsymbol{w}} \frac{1}{2}||\boldsymbol{w} - \boldsymbol{w_t}||^2 + 2c \cdot \ell_\epsilon(\boldsymbol{w}; \boldsymbol{x}_t, y_t), \tag{2}$$

where c is a positive regularization parameter and the constant factor 2 is included for simplicity as will be clear soon. For problems (1) and (2) with samples arriving one at a time, closed-form solutions can be derived (Crammer et al., 2006). For example, for the binary hinge loss the update rule for problem (2) is $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \tau_t y_t \boldsymbol{x}_t$, where $\tau_t = \min(2c, \max(0, \epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t)/||\boldsymbol{x}_t||^2)$; and for the ϵ-insensitive loss, the update rule is $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \text{sign}(y_t - \boldsymbol{w}^\top \boldsymbol{x}_t)\tau_t \boldsymbol{x}_t$, where $\tau_t = \max(0, \epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t)/||\boldsymbol{x}_t||^2$.

3.2 Streaming Variational Bayes

For Bayesian models, Bayes' rule naturally leads to a streaming update procedure for online learning. Specifically, suppose the data $\{\boldsymbol{x}_t\}_{t\geq 0}$ are generated i.i.d. according to a distribution $p(\boldsymbol{x}|\boldsymbol{w})$ and the prior $p(\boldsymbol{w})$ is given. Bayes' theorem implies that the posterior distribution of $\boldsymbol{w}$ given the first T samples ($T \geq 1$) satisfies

$$p(\boldsymbol{w}|\{\boldsymbol{x}_t\}_{t=0}^T) \propto p(\boldsymbol{w}|\{\boldsymbol{x}_t\}_{t=0}^{T-1}) p(\boldsymbol{x}_T|\boldsymbol{w}). \tag{3}$$

In other words, the posterior after observing the first $T-1$ samples is treated as the prior for the incoming data point.

This natural streaming Bayes' rule, however, is often intractable to compute, especially for complex models (e.g., when latent variables are present). Streaming variational Bayes (SVB) (Broderick et al., 2013) suggests that a variational approximation should be adopted and it practically works well. Specifically, let $\mathcal{A}$ be any algorithm that calculates an approximate posterior $q(\boldsymbol{w}) = \mathcal{A}(\boldsymbol{X}, q_0(\boldsymbol{w}))$ based on data $\boldsymbol{X}$ and prior $q_0(\boldsymbol{w})$. Then, the recursive formula for approximate streaming update is:

$$q(\boldsymbol{w}|\{\boldsymbol{x}_t\}_{t=0}^T) = \mathcal{A}\left(\boldsymbol{x}_T, q(\boldsymbol{w}|\{\boldsymbol{x}_t\}_{t=0}^{T-1})\right).$$

The choice of $\mathcal{A}$ can be problem-specific. For topic modeling, Broderick et al. (2013) showed that one may adopt mean-field variational Bayes (Wainwright and Jordan, 2008), expectation propagation (Minka, 2001), and one-pass posterior approximation algorithms using stochastic variational inference (Hoffman et al., 2013) or sufficient statistics update (Honkela and Valpola, 2003; Luts et al., 2013). By applying the streaming update in a distributed setting asynchronously, SVB could also be scaled up across multiple computer clusters (Broderick et al., 2013).

3.3 Regularized Bayesian Inference

The decision-theoretic and Bayesian view of learning can be reciprocal. For example, it would be beneficial to combine the flexibility of Bayesian models with the discriminative power of large-margin methods. The idea of regularized Bayesian inference (RegBayes) (Zhu et al., 2014c) is to treat Bayesian inference as an optimization problem with an imposed loss function for prediction tasks or a regularization term on the target posterior distribution in general. Mathematically, RegBayes for supervised learning can be formulated as

$$\min_{q\in\mathcal{P}} \ \mathbf{KL}\Big[q(\boldsymbol{w})||p_0(\boldsymbol{w})\Big] - \mathbb{E}_{q(\boldsymbol{w})}\Big[\log p(\boldsymbol{X}|\boldsymbol{w})\Big] + 2c\cdot\ell\Big(q(\boldsymbol{w});\boldsymbol{X},\boldsymbol{Y}\Big), \tag{4}$$

where $\mathcal{P}$ is the probability simplex, $p(\boldsymbol{X}|\boldsymbol{w})$ is the likelihood function and $\mathbf{KL}$ is the Kullback-Leibler divergence.[2] Note that if the loss is zero, i.e., $\ell(q(\boldsymbol{w});\boldsymbol{X},\boldsymbol{Y})=0$, then the optimal solution is $q^*(\boldsymbol{w}) \propto p_0(\boldsymbol{w})p(\boldsymbol{X}|\boldsymbol{w})$, which is just the Bayes' rule. However, when $\ell(q(\boldsymbol{w});\boldsymbol{X},\boldsymbol{Y})\neq 0$, RegBayes biases the inferred posterior towards discriminating the supervising side-information $\boldsymbol{Y}$, with the parameter c controlling the extent of regularization. If the posterior regularization term $\ell(\cdot)$ is a convex function of $q(\boldsymbol{w})$ through the linear expectation operator, Zhu et al. (2014c) presented a general representation theorem to characterize the solution to problem (4). To distinguish from the posterior distribution obtained via Bayes' rule, the solution to problem (4) is called *post-data posterior* (Zhu et al., 2014c). Many instantiations have been developed following the generic framework of RegBayes to demonstrate its superior performance than standard Bayesian models in various settings, such as topic modeling (Jiang et al., 2012; Zhu et al., 2014b), matrix factorization (Xu et al., 2013) and link prediction (Zhu, 2012), as well as the flexibility of performing robust Bayesian inference with noisy domain knowledge (Mei et al., 2014).

4. Bayesian Passive-Aggressive Learning

In this section, we present online Bayesian Passive-Aggressive (BayesPA) learning, a general perspective on online max-margin Bayesian inference. Without loss of generality, we consider binary classification. The techniques can be applied to other learning tasks. We provide an extension in Section 6.2.

4.1 Online BayesPA Learning

Instead of updating a point estimate of $\boldsymbol{w}$, online Bayesian PA (BayesPA) sequentially infers a new post-data posterior distribution $q_{t+1}(\boldsymbol{w})$, either parametric or nonparametric, on the arrival of a new data point $(\boldsymbol{x}_t, y_t)$ by solving the following optimization problem:

$$\begin{aligned}\min_{q(\boldsymbol{w})\in\mathcal{F}_t} \ & \mathbf{KL}\Big[q(\boldsymbol{w})||q_t(\boldsymbol{w})\Big] - \mathbb{E}_{q(\boldsymbol{w})}\Big[\log p(\boldsymbol{x}_t|\boldsymbol{w})\Big] \\ \text{s.t.:} \ & \ell_\epsilon\Big(q(\boldsymbol{w});\boldsymbol{x}_t,y_t\Big)=0,\end{aligned} \tag{5}$$

2. We assume that the model space $\boldsymbol{W}$ is a complete separable metric space endowed with its Borel σ-algebra $\mathcal{B}(\boldsymbol{W})$. Let P_0 and Q be probability measures on $\boldsymbol{W}$. The Kullback-Leibler (KL) divergence of the probability measure Q with respect to the measure P_0 is defined as $\mathbf{KL}[Q\|P_0] = \int \frac{\mathrm{d}Q}{\mathrm{d}P_0}(\boldsymbol{w})\log\frac{\mathrm{d}Q}{\mathrm{d}P_0}(\boldsymbol{w})\mathrm{d}P_0(\boldsymbol{w})$, where $\frac{\mathrm{d}Q}{\mathrm{d}P_0}(\boldsymbol{w})$ is the Radon-Nikodym derivative (Durret, 2010). It is required that Q is absolutely continuous with respect to P_0 such that this derivative exists. In this paper, we further assume that P_0 is absolutely continuous with respect to some background measure μ. Thus, there exists a density p_0 that satisfies $\mathrm{d}P_0 = p_0\mathrm{d}\mu$ and there also exists a density q that satisfies $\mathrm{d}Q = q\mathrm{d}\mu$. Then, the KL-divergence can be expressed as $\mathbf{KL}[q\|p_0] = \int q(\boldsymbol{w})\log\frac{q(\boldsymbol{w})}{p_0(\boldsymbol{w})}\mathrm{d}\mu(\boldsymbol{w})$.

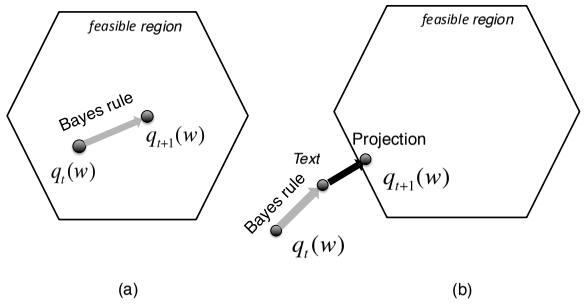

Figure 1: Graphical Illustration of BayesPA learning. **(a)**. Update *passively* by Bayes rule, if the resulting distribution suffer zero loss. **(b)** Otherwise, *aggressively* project the resulting distribution to the feasible region of weights with zero loss.

where $\mathcal{F}_t$ can be some family of distributions or the whole probability simplex $\mathcal{P}$. For notational convenience, we denote the objective as $\mathcal{L}(q(\boldsymbol{w}))$. In words, we find a post-data posterior distribution $q_{t+1}(\boldsymbol{w})$ in the feasible region that is not only close to the current posterior $q_t(\boldsymbol{w})$ in terms of KL-divergence, but also has a high likelihood of explaining the new data. As a result, if Bayes' rule already gives the posterior distribution $q_{t+1}(\boldsymbol{w}) \propto q_t(\boldsymbol{w})p(\boldsymbol{x}_t|\boldsymbol{w})$ that suffers no loss (i.e., $\ell_\epsilon = 0$), BayesPA *passively* updates the posterior following just Bayes' rule;[3] otherwise, BayesPA *aggressively* projects the new posterior to the feasible region of posteriors that attain zero loss. The passive and aggressive update cases are illustrated in Figure 1. We should note that when no likelihood is defined (e.g., $p(\boldsymbol{x}_t|\boldsymbol{w})$ is independent of $\boldsymbol{w}$), BayesPA will passively set $q_{t+1}(\boldsymbol{w}) = q_t(\boldsymbol{w})$ if $q_t(\boldsymbol{w})$ suffers no loss; otherwise, it will aggressively project $q_t(\boldsymbol{w})$ to the feasible region. We call it *non-likelihood* BayesPA.

In practical problems, the constraints in (5) could be unrealizable. To deal with such cases, we introduce the soft-margin version of BayesPA learning, which is equivalent to minimizing the objective function $\mathcal{L}(q(\boldsymbol{w}))$ in problem (5) with a regularization term, similar as in SVMs (Cortes and Vapnik, 1995):

$$q_{t+1}(\boldsymbol{w}) = \operatorname*{argmin}_{q(\boldsymbol{w})\in\mathcal{F}_t} \mathcal{L}\Big(q(\boldsymbol{w})\Big) + 2c\cdot\ell_\epsilon\Big(q(\boldsymbol{w});\boldsymbol{x}_t,y_t\Big). \tag{6}$$

For the max-margin classifiers that we consider, two types of loss functionals $\ell_\epsilon(q(\boldsymbol{w});\boldsymbol{x}_t,y_t)$ are common:

3. Under the Bayesian setting, we regard Bayes' rule as a natural update (passive), since no aggressive projection is applied.

Methods	Max-margin learning ?	Bayesian inference ?	Streaming update ?
PA	yes	no	yes
SVB	no	yes	yes
RegBayes	yes	yes	no
BayesPA	yes	yes	yes

Table 1: The comparison between BayesPA and its various precursors, including online PA, streaming variational Bayes (SVB) and regularized Bayesian inference (RegBayes), in three different aspects.

1. **Averaging classifier**: assume that a post-data posterior distribution $q(\boldsymbol{w})$ is given, then an averaging classifier makes predictions using the sign rule $\hat{y}_t = \text{sign}\ \mathbb{E}_{q(\boldsymbol{w})}[\boldsymbol{w}^\top \boldsymbol{x}_t]$ when the discriminant function has the simple linear form, $f(\boldsymbol{x}_t; \boldsymbol{w}) = \boldsymbol{w}^\top \boldsymbol{x}_t$. For this classifier, its hinge loss is therefore defined as:

$$\ell_\epsilon^{\text{ave}}\Big(q(\boldsymbol{w}); \boldsymbol{x}_t, y_t\Big) = \Big(\epsilon - y_t \mathbb{E}_{q(\boldsymbol{w})}\left[\boldsymbol{w}^\top \boldsymbol{x}_t\right]\Big)_+ .$$

2. **Gibbs classifier**: assume that a post-data posterior distribution $q(\boldsymbol{w})$ is given, then a Gibbs classifier randomly draws a weight vector $\boldsymbol{w} \sim q(\boldsymbol{w})$ to make predictions using the sign rule $\hat{y}_t = \text{sign}\ \boldsymbol{w}^\top \boldsymbol{x}_t$, when the discriminant function has the same linear form as above. For each single $\boldsymbol{w}$, we can measure its hinge loss $(\epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t)_+$. To account for the randomness of $\boldsymbol{w}$, the expected hinge loss of a Gibbs classifier is therefore defined as:

$$\ell_\epsilon^{\text{gibbs}}\Big(q(\boldsymbol{w}); \boldsymbol{x}_t, y_t\Big) = \mathbb{E}_{q(\boldsymbol{w})}\left[\Big(\epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t\Big)_+\right].$$

They are closely connected via the following lemma due to the convexity of the function $(x)_+$.

Lemma 1 *The expected hinge loss ℓ_ϵ^{gibbs} is an upper bound of the hinge loss ℓ_ϵ^{ave}, that is,*

$$\ell_\epsilon^{gibbs}\Big(q(\boldsymbol{w}); \boldsymbol{x}_t, y_t\Big) \geq \ell_\epsilon^{ave}\Big(q(\boldsymbol{w}); \boldsymbol{x}_t, y_t\Big).$$

BayesPA is deeply connected to its various precursors reviewed in Section 3, as summarized in Table 1. First, BayesPA is a natural Bayesian extension of online PA, which is explicated via the following theorem. Note that this theorem only serves as a connection to PA, and will not be relied on by our algorithms, where we are more interested in the cases with nontrivial likelihood models to describe the underlying structures (e.g., topic structures), which are typically out-of-reach for the standard PA. Nevertheless, the idea of the proof details would later be applied to develop practical BayesPA algorithms for topic models. Therefore, we include the complete proof here.

Theorem 2 *If the prior is normal $q_0(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}_0, I)$, $\mathcal{F}_t = \mathcal{P}$, and we use the averaging classifier ℓ_ϵ^{ave}, the non-likelihood BayesPA subsumes the online PA.*

Proof The soft-margin version of BayesPA learning can be reformulated using a slack variable ξ_t:

$$\begin{aligned} q_{t+1}(\boldsymbol{w}) = \quad & \underset{q(\boldsymbol{w})\in\mathcal{P}}{\text{argmin}}\ \text{KL}\Big[q(\boldsymbol{w})||q_t(\boldsymbol{w})\Big] + 2c\cdot\xi_t \\ & \text{s.t.}: y_t \mathbb{E}_{q(\boldsymbol{w})}\left[\boldsymbol{w}^\top \boldsymbol{x}_t\right] \geq \epsilon - \xi_t,\ \ \xi_t \geq 0. \end{aligned} \tag{7}$$

Similar to Corollary 5 in (Zhu et al., 2012), the optimal solution $q^*(\boldsymbol{w})$ of the above problem can be derived from its functional Lagrangian and has the following form:

$$q^*(\boldsymbol{w}) = \frac{1}{\Gamma(\tau_t^*, \boldsymbol{x}_t, y_t)} q_t(\boldsymbol{w}) \exp\Big(\tau_t^* y_t \boldsymbol{w}^\top \boldsymbol{x}_t\Big), \tag{8}$$

where the normalization term $\Gamma(\tau_t, \boldsymbol{x}_t, y_t) = \int_{\boldsymbol{w}} q_t(\boldsymbol{w}) \exp\Big(\tau_t y_t \boldsymbol{w}^\top \boldsymbol{x}_t\Big) d\boldsymbol{w}$, and τ_t^* is the optimal solution to the dual problem

$$\begin{aligned} & \max_{\tau_t}\ \epsilon\tau_t - \log\Gamma(\tau_t, \boldsymbol{x}_t, y_t) \\ & \text{s.t.}\ 0 \leq \tau_t \leq 2c. \end{aligned} \tag{9}$$

Using this primal-dual interpretation, we prove that for the normal prior $p_0(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}_0, I)$, the post-data posterior is also Gaussian: $q_t(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{\mu}_t, I)$ for some $\boldsymbol{\mu}_t$ in each round $t = 0, 1, 2, ...$ This can be shown by induction. By our assumption, $q_0(\boldsymbol{w}) = p_0(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}_0, I)$ is Gaussian. Assume for round $t \geq 0$, the distribution $q_t(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{\mu}_t, I)$. Then for round $t+1$, Eq. (8) suggests the distribution

$$q_{t+1}(\boldsymbol{w}) = \frac{\mathcal{C}}{\Gamma(\tau_t^*, \boldsymbol{x}_t, y_t)} \exp\left(-\frac{1}{2}||\boldsymbol{w} - (\boldsymbol{\mu}_t + \tau_t^* y_t \boldsymbol{x}_t)||^2\right),$$

where the constant $\mathcal{C} = \exp(y_t \tau_t^* \boldsymbol{\mu}_t^\top \boldsymbol{x}_t + \frac{1}{2}\tau_t^{*2} \boldsymbol{x}_t^\top \boldsymbol{x}_t)$. Therefore, the distribution $q_{t+1}(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{\mu}_t + \tau_t^* y_t \boldsymbol{x}_t, I)$, and the normalization term is $\Gamma(\tau_t, \boldsymbol{x}_t, y_t) = (\sqrt{2\pi})^K \exp(\tau_t y_t \boldsymbol{x}_t^\top \boldsymbol{\mu}_t + \frac{1}{2}\tau_t^2 \boldsymbol{x}_t^\top \boldsymbol{x}_t)$ for any $\tau_t \in [0, 2c]$.

Next, we show that $\boldsymbol{\mu}_{t+1} = \boldsymbol{\mu}_t + \tau_t^* y_t \boldsymbol{x}_t$ is the optimal solution of the online PA update rule (Crammer et al., 2006). To see this, we replace $\Gamma(\tau_t, \boldsymbol{x}_t, y_t)$ in problem (9) with our derived form. Ignoring constant terms, we obtain the dual problem

$$\begin{aligned} & \max_{\tau_t}\ \epsilon\tau_t - \tfrac{1}{2}\tau_t^2 \boldsymbol{x}_t^\top \boldsymbol{x}_t - y_t \tau_t \boldsymbol{\mu}_t^\top \boldsymbol{x}_t \\ & \text{s.t.:}\ 0 \leq \tau_t \leq 2c, \end{aligned} \tag{10}$$

which is exactly the dual form of the online PA update equation:

$$\begin{aligned} \boldsymbol{\mu}_{t+1}^{\text{PA}} = & \arg\min_{\boldsymbol{\mu}}\ \tfrac{1}{2}||\boldsymbol{\mu} - \boldsymbol{\mu}_t||^2 + 2c\cdot\xi_t \\ & \text{s.t.}\ y_t \boldsymbol{\mu}^\top \boldsymbol{x}_t \geq \epsilon - \xi_t,\ \ \xi_t \geq 0. \end{aligned}$$

The optimal solution is $\boldsymbol{\mu}_{t+1}^{\text{PA}} = \boldsymbol{\mu}_t + \tau_t^* y_t \boldsymbol{x}_t$. Note that τ_t^* is the optimal solution of dual problem (10) shared by both PA and BayesPA. Therefore, we conclude that $\boldsymbol{\mu}_{t+1} = \boldsymbol{\mu}_{t+1}^{\text{PA}}$. ■

Second, suppose some algorithm $\mathcal{A}$ is capable of solving problem (6), then it would produce streaming updates to the posterior distribution. For averaging classifiers, it is easy to modify the proof of theorem 2 to derive the update rule of BayesPA, which is presented in the following lemma.

Lemma 3 *If $\mathcal{F}_t = \mathcal{P}$ and we use the averaging classifier with loss functional ℓ_ϵ^{ave}, the update rule of online BayesPA is*

$$q_{t+1}(\boldsymbol{w}) = \frac{1}{\Gamma(\tau_t^*, \boldsymbol{x}_t, y_t)} q_t(\boldsymbol{w}) p(\boldsymbol{x}_t|\boldsymbol{w}) \exp\Big(\tau_t^* y_t \boldsymbol{w}^\top \boldsymbol{x}_t\Big), \tag{11}$$

where $\Gamma(\tau_t, \boldsymbol{x}_t, y_t)$ is the normalization term $\Gamma(\tau_t, \boldsymbol{x}_t, y_t) = \int_{\boldsymbol{w}} q_t(\boldsymbol{w}) p(\boldsymbol{x}_t|\boldsymbol{w}) \exp\Big(\tau_t y_t \boldsymbol{w}_t^\top \boldsymbol{x}_t\Big) d\boldsymbol{w}$, and τ_t^* is the optimal solution to the dual problem

$$\begin{array}{ll} \max\limits_{\tau_t} & \epsilon\tau_t - \log\Gamma(\tau_t, \boldsymbol{x}_t, y_t) \\ \text{s.t.} & 0 \le \tau_t \le 2c. \end{array}$$

For Gibbs classifiers, we have the following lemma to characterize its streaming update rule.

Lemma 4 *If $\mathcal{F}_t = \mathcal{P}$ and we use the Gibbs classifier with loss functional ℓ_ϵ^{gibbs}, the update rule of online BayesPA is*

$$q_{t+1}(\boldsymbol{w}) = \frac{q_t(\boldsymbol{w}) p(\boldsymbol{x}_t|\boldsymbol{w}) \exp\Big(-2c\big(\epsilon - y_t \boldsymbol{w}^\top \boldsymbol{x}_t\big)_+\Big)}{\Gamma(\boldsymbol{x}_t, y_t)}, \tag{12}$$

where $\Gamma(\boldsymbol{x}_t, y_t)$ is the normalization constant.

In both update rules (11) and (12), the post-data posterior $q_t(\boldsymbol{w})$ in the previous round t can be treated as a prior, while the newly observed data and the loss it incurs provide a likelihood and an un-normalized pseudo-likelihood respectively. Due to the analytical form, the BayesPA update rule (12) is sequential in nature, simiar as the convential Bayes rule (3). Therefore, the sequential posterior at time T is the same as the batch posterior that observes all the data instances up to T. For the case with averaging classifers, Eq. (11) reduces to the streaming Bayesian update problem if there is no loss functional (i.e., $\ell_\epsilon = 0$). Therefore, BayesPA is an extension to streaming variational Bayes (SVB) with imposed max-margin posterior constraints.

Finally, the update formulation (6) is essentially a RegBayes problem with a single data point $(\boldsymbol{x}_t, y_t)$. Although RegBayes inference is normally intractable, we would show later in the paper how to use variational approximation to bypass the difficulty for specific settings. This would lead to variational approximation algorithm $\mathcal{A}$ for the streaming update of post-data posterior.

Besides treating a single data point at a time, a useful technique in practice to reduce the noise in data is to use mini-batches. Suppose that we have a mini-batch of data points at time t with an index set B_t. Let $\boldsymbol{X}_t = \{\boldsymbol{x}_d\}_{d\in B_t}, \boldsymbol{Y}_t = \{y_d\}_{d\in B_t}$. The online BayesPA update equation for this mini-batch can be defined in a natural way:

$$\min_{q\in\mathcal{F}_t} \mathbf{KL}\Big[q(\boldsymbol{w})||q_t(\boldsymbol{w})\Big] - \mathbb{E}_{q(\boldsymbol{w})}\Big[\log p(\boldsymbol{X}_t|\boldsymbol{w})\Big] + 2c\cdot\ell_\epsilon\Big(q(\boldsymbol{w}); \boldsymbol{X}_t, \boldsymbol{Y}_t\Big),$$

where $\ell_\epsilon(q(\boldsymbol{w}); \boldsymbol{X}_t, \boldsymbol{Y}_t) = \sum_{d\in B_t} \ell_\epsilon(q(\boldsymbol{w}); \boldsymbol{x}_d, y_d)$ is the cumulative loos functional on the mini-batch B_t. Like the vanilla PA methods (Crammer et al., 2006), BayesPA on mini-batches may not have closed-form update rules, and numerical optimization methods are needed to solve this new formulation.

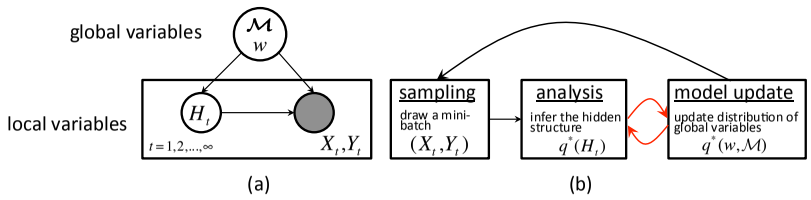

Figure 2: Graphical illustrations of: (a) the abstraction of models with latent structures; and (b) the procedure of BayesPA learning with latent structures.

4.2 BayesPA Learning with Latent Structures

To expressively explain complex real-word data, Bayesian models with latent structures have been extensively developed. The latent structures could typically be characterized by a hierarchy of variables, which are generally grouped into two sets—*local latent variables* $\boldsymbol{h}_d$ $(d \ge 0)$ that characterize the hidden structures of each observed data $\boldsymbol{x}_d$ and *global variables* $\boldsymbol{\mathcal{M}}$ that capture the common properties shared by all data.

As illustrated in Figure 2, BayesPA learning with latent structures aims to update the distribution of $\boldsymbol{\mathcal{M}}$ as well as the classifier weights $\boldsymbol{w}$, based on each incoming mini-batch $(\boldsymbol{X}_t, \boldsymbol{Y}_t)$ and their corresponding latent variables $\boldsymbol{H}_t = \{\boldsymbol{h}_d\}_{d\in B_t}$. Because of the uncertainty in $\boldsymbol{H}_t$, our posterior approximation algorithm $\mathcal{A}$ would first infer the joint posterior distribution $q_{t+1}(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)$ from

$$\min_{q\in\mathcal{F}_t} \mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)\Big) + 2c\cdot\ell_\epsilon\Big(q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t); \boldsymbol{X}_t, \boldsymbol{Y}_t\Big), \tag{13}$$

where $\mathcal{L}(q) = \mathrm{KL}[q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)||q_t(\boldsymbol{w}, \boldsymbol{\mathcal{M}})p_0(\boldsymbol{H}_t)] - \mathbb{E}_{q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)}[\log p(\boldsymbol{X}_t|\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)]$ and $\ell_\epsilon(q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t); \boldsymbol{X}_t, \boldsymbol{Y}_t)$ is some cumulative loss functional on the min-batch data incurred by some classifiers on the latent variables $\boldsymbol{H}_t$ and/or global variables $\boldsymbol{\mathcal{M}}$. As in the case without latent variables, both averaging classifier and Gibbs classifier can be used.

Next, algorithm $\mathcal{A}$ produces the approximate posterior $q_{t+1}(\boldsymbol{w}, \boldsymbol{\mathcal{M}})$. In general we would not obtain a closed-form posterior distribution by marginalizing out $\boldsymbol{H}_t$, especially in dealing with some involved models like MedLDA (Zhu et al., 2012). The intractability is bypassed through the mean-field assumption $q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t) = q(\boldsymbol{w})q(\boldsymbol{\mathcal{M}})q(\boldsymbol{H}_t)$. Specifically, algorithm $\mathcal{A}$ solves problem (13) using an iterative procedure and obtain the optimal distribution $q^*(\boldsymbol{w})q^*(\boldsymbol{\mathcal{M}})q^*(\boldsymbol{H}_t)$. Then it sets $q_{t+1}(\boldsymbol{w}, \boldsymbol{\mathcal{M}}) = q^*(\boldsymbol{w})q^*(\boldsymbol{\mathcal{M}})$ and proceeds to next round. Concrete examples of this method will be discussed in Section 5 and Section 6.

5. Online Max-Margin Topic Models

In this section, we apply the theory of online BayesPA to topic modeling. We first review the basic ideas of max-margin topic models, and develop online learning algorithms based on BayesPA with averaging and Gibbs classifiers respectively.

5.1 Basics of MedLDA

A max-margin topic model consists of a latent Dirichlet allocation (LDA) model (Blei et al., 2003) for describing the underlying topic representations of document content and a max-margin classifier for making predictions. Specifically, LDA is a hierarchical Bayesian model that treats each document as an admixture of K topics, $\boldsymbol{\Phi} = \{\boldsymbol{\phi}_k\}_{k=1}^K$, where each topic $\boldsymbol{\phi}_k$ is a multinomial distribution over a given W-word vocabulary.[4] The generative process of the d-th document ($1 \leq d \leq D$) is described as follows:

- Draw a topic mixture proportion vector $\boldsymbol{\theta}_d|\boldsymbol{\alpha} \sim \text{Dir}(\boldsymbol{\alpha})$
- For the i-th word in document d, where $i = 1, 2, ..., n_d$,
  - draw a latent topic assignment $z_{di} \sim \text{Mult}(\boldsymbol{\theta}_d)$.
  - draw the word instance $x_{di} \sim \text{Mult}(\boldsymbol{\phi}_{z_{di}})$.

where $\text{Dir}(\cdot)$ is the Dirichlet distribution and $\text{Mult}(\cdot)$ is the multinomial distribution. For Bayesian LDA, the topics are also drawn from a Dirichlet distribution, i.e., $\boldsymbol{\phi}_k \sim \text{Dir}(\boldsymbol{\gamma})$.

Given a document set $\boldsymbol{X} = \{\boldsymbol{x}_d\}_{d=1}^D$. Let $\boldsymbol{Z} = \{\boldsymbol{z}_d\}_{d=1}^D$ and $\boldsymbol{\Theta} = \{\boldsymbol{\theta}_d\}_{d=1}^D$ denote all the topic assignments and topic mixing vectors. LDA infers the posterior distribution $p(\boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}|\boldsymbol{X}) \propto p_0(\boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})p(\boldsymbol{X}|\boldsymbol{Z}, \boldsymbol{\Phi})$ via Bayes' rule. From a variational point of view, the posterior is identical to the solution of the optimization problem:

$$\min_{q \in \mathcal{P}} \mathbf{KL}\Big[q(\boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})||p(\boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}|\boldsymbol{X})\Big].$$

The advantage of the variational formulation of Bayesian inference lies in the convenience of posing restrictions on the post-data distribution with a regularization term. For supervised topic models (Blei and McAuliffe, 2010; Zhu et al., 2012), such a regularization term could be a loss function of a prediction model $\boldsymbol{w}$ on the data $\boldsymbol{X} = \{\boldsymbol{x}_d\}_{d=1}^D$ and response signals $\boldsymbol{Y} = \{y_d\}_{d=1}^D$. As a regularized Bayesian (RegBayes) model, MedLDA infers a distribution of the latent variables $\boldsymbol{Z}$ as well as classification weights $\boldsymbol{w}$ by solving the problem:

$$\min_{q \in \mathcal{P}} \mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})\Big) + 2c \sum_{d=1}^D \ell_\epsilon\Big(q(\boldsymbol{w}, \boldsymbol{z}_d); \boldsymbol{x}_d, y_d\Big),$$

where $\mathcal{L}(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})) = \mathbf{KL}[q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})||p(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}|\boldsymbol{X})]$. To specify the loss function, a linear discriminant function needs to be defined with respect to $\boldsymbol{w}$ and $\boldsymbol{z}_d$

$$f(\boldsymbol{w}, \boldsymbol{z}_d) = \boldsymbol{w}^\top \bar{\boldsymbol{z}}_d, \tag{14}$$

where $\bar{z}_{dk} = \frac{1}{n_d} \sum_i \mathbb{I}[z_{di} = k]$ is the average frequency of assigning the words in document d to topic k. Based on the discriminant function, both averaging classifiers with the hinge loss

$$\ell_\epsilon^{\text{ave}}(q(\boldsymbol{w}, \boldsymbol{z}_d); \boldsymbol{x}_d, y_d) = \big(\epsilon - y_d \mathbb{E}_{q(\boldsymbol{w}, \boldsymbol{z}_d)}[f(\boldsymbol{w}, \boldsymbol{z}_d)]\big)_+, \tag{15}$$

4. Without causing confusion, we slightly abused the notation K to denote the topic number (i.e., the latent dimension) in topic models.

and Gibbs classifiers with the expected hinge loss

$$\ell_\epsilon^{\text{gibbs}}(q(\boldsymbol{w}, \boldsymbol{z}_d); \boldsymbol{x}_d, y_d) = \mathbb{E}_{q(\boldsymbol{w}, \boldsymbol{z}_d)}\left[(\epsilon - y_d f(\boldsymbol{w}, \boldsymbol{z}_d))_+\right], \tag{16}$$

have been proposed, with extensive comparisons reported in Zhu et al. (2014b) using batch learning algorithms. As commented in (Chang and Blei, 2010), defining the classifier on $\bar{\boldsymbol{z}}_d$, instead of $\boldsymbol{\theta}_d$, enforces words and labels to share the same topics. Besides, it retains the conjugacy structure between the Dirichlet prior of $\boldsymbol{\theta}$ and the multinomial likelihood of generating $\boldsymbol{z}$; and it will allow us to integrate out $\boldsymbol{\theta}$ for efficient collapsed inference.

5.2 Online MedLDA

We first apply online BayesPA to MedLDA with averaging classifiers, which will be referred to as paMedLDA$^{\text{ave}}$ for convenience. During inference, we integrate out the local variables $\boldsymbol{\Theta}_t$ using the conjugacy between a Dirichlet prior and a multinomial likelihood (Griffiths and Steyvers, 2004; Teh et al., 2006b), which potentially improves the inference accuracy. Then we have the global variables $\boldsymbol{\mathcal{M}} = \boldsymbol{\Phi}$ and local variables $\boldsymbol{H}_t = \boldsymbol{Z}_t$. The latent BayesPA rule (13) becomes:

$$\begin{aligned} \min_{q, \xi_d} \quad & \mathbf{KL}\Big[q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)||q_t(\boldsymbol{w}, \boldsymbol{\Phi})p_0(\boldsymbol{Z}_t)p(\boldsymbol{X}_t|\boldsymbol{\Phi}, \boldsymbol{Z}_t)\Big] + 2c \sum_{d \in B_t} \xi_d, \\ \text{s.t.:} \quad & y_d \mathbb{E}_{q(\boldsymbol{w}, \boldsymbol{z}_d)}[\boldsymbol{w}^\top \bar{\boldsymbol{z}}_d] \geq \epsilon - \xi_d, \quad \xi_d \geq 0, \quad \forall d \in B_t, \\ & q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t) \in \mathcal{P}. \end{aligned} \tag{17}$$

Since directly solving the above problem is intractable, we would impose a mild mean-field assumption $q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t) = q(\boldsymbol{w})q(\boldsymbol{\Phi})q(\boldsymbol{Z}_t)$. Now, problem (17) can be solved using an iterative procedure that alternately updates each factor distribution (Jordan et al., 1998), as detailed below:

1. **Update global $q(\boldsymbol{\Phi})$:** By fixing the distributions $q(\boldsymbol{Z}_t)$ and $q(\boldsymbol{w})$, we can ignore irrelevant terms and solve

$$\min_{q(\boldsymbol{\Phi})} \mathbf{KL}\Big[q(\boldsymbol{\Phi})q(\boldsymbol{Z}_t)||q_t(\boldsymbol{\Phi})p_0(\boldsymbol{Z}_t)p(\boldsymbol{X}_t|\boldsymbol{\Phi}, \boldsymbol{Z}_t)\Big].$$

The optimal solution has the following closed form:

$$q^*(\boldsymbol{\Phi}_k) \propto q_t(\boldsymbol{\Phi}_k) \exp\Big(\mathbb{E}_{q(\boldsymbol{Z}_t)}\Big[\log p_0(\boldsymbol{Z}_t)p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi})\Big]\Big), \quad k = 1, 2, ..., K. \tag{18}$$

If initially the prior is $q_0(\boldsymbol{\Phi}_k) = \text{Dir}(\Delta_{k1}^0, ..., \Delta_{kW}^0)$, then by induction the inferred distributions in each round are also in the family of Dirichlet distributions, namely, $q_t(\boldsymbol{\Phi}_k) = \text{Dir}(\Delta_{k1}^t, ..., \Delta_{kW}^t)$. Using equation (18), we can derive

$$q^*(\boldsymbol{\Phi}_k) = \text{Dir}(\Delta_{k1}^*, ..., \Delta_{kW}^*), \tag{19}$$

where $\Delta_{kw}^* = \Delta_{kw}^t + \sum_{d \in B_t} \sum_{i=1}^{n_d} \gamma_{di}^k \cdot \mathbb{I}[x_{di} = w]$ for all words w ($1 \leq w \leq W$) in the vocuabulary and $\gamma_{di}^k = \mathbb{E}_{q(\boldsymbol{z}_d)}\mathbb{I}[z_{di} = k]$ is the probability of assigning each word x_{di} to topic k.

2. **Update global weight $q(\boldsymbol{w})$:** Keeping all the other distributions fixed, $q(\boldsymbol{w})$ can be solved as

$$\begin{aligned} \min_{q(\boldsymbol{w})} \quad & \mathbf{KL}\Big[q(\boldsymbol{w})||q_t(\boldsymbol{w})\Big] + 2c\sum_{d\in B_t}\xi_d, \\ \text{s.t.:} \quad & y_d\mathbb{E}_{q(\boldsymbol{w})}[\boldsymbol{w}]^\top\widehat{\boldsymbol{z}}_d \geq \epsilon - \xi_d, \quad \xi_d \geq 0, \quad \forall d \in B_t, \end{aligned}$$

where $\widehat{\boldsymbol{z}}_d = \mathbb{E}_{q(\boldsymbol{z}_d)}[\bar{\boldsymbol{z}}_d]$ is the expectation of topic assignments under the fixed distribution $q(\boldsymbol{Z})$. Similar to Proposition 2 in MedLDA (Zhu et al., 2012), the optimal solution is attained by solving the Lagrangian form with respect to $q(\boldsymbol{w})$, which gives

$$q^*(\boldsymbol{w}) = \frac{1}{Z(\tau_d^*)}q_t(\boldsymbol{w})\exp\left(\sum_{d\in B_t}\tau_d^* y_d \boldsymbol{w}^\top\widehat{\boldsymbol{z}}_d\right), \tag{20}$$

where the Lagrange multipliers $\tau_d^*(d \in B_t)$ are obtained by solving the dual problem

$$\max_{0\leq\tau_d\leq 2c} \quad \epsilon\sum_{d\in B_t}\tau_d - \log Z(\tau_d).$$

For the common spherical Gaussian prior $q_0(\boldsymbol{w}) = \mathcal{N}(0, \sigma^2 I)$, by induction the distribution $q_t(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{\mu}_t, \sigma^2 I)$ at each round. So equation (20) gives $q^*(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{\mu}^*, \sigma^2 I)$, where

$$\boldsymbol{\mu}^* = \boldsymbol{\mu}_t + \sigma^2\sum_{d\in B_t}\tau_d^* y_d\widehat{\boldsymbol{z}}_d. \tag{21}$$

Furthermore, the dual problem becomes,

$$\max_{0\leq\tau_d\leq 2c} \quad \epsilon\sum_{d\in B_t}\tau_d - \sum_{d_1,d_2\in B_t}\frac{1}{2}\sigma^2\tau_{d_1}\tau_{d_2}\widehat{\boldsymbol{z}}_{d_1}^\top\widehat{\boldsymbol{z}}_{d_2} - \boldsymbol{\mu}_t^\top\sum_{d\in B_t}y_d\tau_d\widehat{\boldsymbol{z}}_d, \tag{22}$$

which is identical to the Lagrangian dual of the classical PA problem with mini-batch B_t (expressed in the equivalent constrained form by introducing slack variables)

$$\min_{\mu}\frac{||\boldsymbol{\mu} - \boldsymbol{\mu}_t||^2}{2\sigma^2} + 2c\sum_{d\in B_t}\Big(\epsilon - y_d\boldsymbol{\mu}^\top\widehat{\boldsymbol{z}}_d\Big)_+. \tag{23}$$

This equivalence suggests that we could rely on contemporary PA techniques to solve for $\boldsymbol{\mu}^*$. In particular, for instances coming one at a time (i.e., $B_t = \{t\},\ \forall t$), we have the closed-form solution

$$\tau_t^* = \min\left\{2c, \frac{(\epsilon - y_t\mu_t^\top\widehat{\boldsymbol{z}}_t)_+}{||\widehat{\boldsymbol{z}}_t||^2}\right\},$$

whose computation requires $O(K)$ time; for mini-batches, we could adapt methods solving linear SVM to either the dual (22) or primal (23) problem, which by state-of-the-arts require complexity $O(\text{poly}(\epsilon^{-1})K)$ per training instance in order to obtain ϵ-accurate solutions. Here we choose a gradient-based method similar to Shalev-Shwartz et al. (2011). Specifically, we first set $\boldsymbol{\mu}^1 = \boldsymbol{\mu}_t$, and then take the gradient steps $i = 2, 3, ...$ until $\boldsymbol{\mu}^i$ converges to $\boldsymbol{\mu}^*$. Let

A_t^i be the set of instances in B_t that suffer non-zero loss at step i, then we use the gradients to iteratively update

$$\boldsymbol{\mu}^{i+1} \leftarrow \boldsymbol{\mu}^i - \rho_i\nabla_i, \tag{24}$$

where annealing rate $\rho_i = \sigma^2 i^{-1}$ and

$$\nabla_i = \frac{\boldsymbol{\mu}^i - \boldsymbol{\mu}_t}{\sigma^2} - 2c\sum_{d\in A_t^i}y_d\widehat{\boldsymbol{z}}_d.$$

Correspondingly, we can derive the gradient-based update rule for the dual parameters. Imagine that we implicitly maintain the relationship $\boldsymbol{\mu} = \boldsymbol{\mu}_t + \sigma^2\sum_{d\in B_t}\tau_d y_d\widehat{\boldsymbol{z}}_d$. Then the following update rule for $\tau_d\ (d \in B_t)$ naturally implies the update rule (24) for $\boldsymbol{\mu}$:

$$\tau_d^i \leftarrow \begin{cases}(1-\frac{1}{i})\tau_d^i + \frac{2c}{i} & \text{for } d \in A_t^i \\ (1-\frac{1}{i})\tau_d^i & \text{for } d \notin A_t^i.\end{cases}$$

Therefore, the gradient steps adaptively adjust the contribution of each latent $\widehat{\boldsymbol{z}}_d$ to μ based on the loss it incurs. Furthermore, the annealing makes sure that $0 \leq \tau_d^i \leq 2c$ for all i. Since the problem (22) is concave, it can be guaranteed that τ_d^i converges to τ_d^*. This correspondence would be used in updating $q(\boldsymbol{Z}_t)$.

3. **Update local $q(\boldsymbol{Z}_t)$:** Fixing all the other distributions, we aim to solve

$$\begin{aligned} \min_{q(\boldsymbol{Z}_t)} \quad & \mathbf{KL}\Big[q(\boldsymbol{Z}_t)||p_0(\boldsymbol{Z}_t)p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi})\Big] + 2c\sum_{d\in B_t}\xi_d, \\ \text{s.t.:} \quad & y_d\boldsymbol{\mu}^{*\top}\mathbb{E}_{q(\boldsymbol{z}_d)}[\bar{\boldsymbol{z}}_d] \geq \epsilon - \xi_d, \quad \xi_d \geq 0, \quad \forall d \in B_t, \end{aligned}$$

where $\boldsymbol{\mu}^* = \mathbb{E}_{q(\boldsymbol{w})}[\boldsymbol{w}]$ is the expectation of $\boldsymbol{w}$ under the fixed distribution $q(\boldsymbol{w})$. Unlike the weight $\boldsymbol{w}$, the expectation over $\boldsymbol{Z}_t$ during optimization is intractable due to the combinatorial space of values. Instead, we adopt the same approximation strategy as MedLDA (Zhu et al., 2012): fix ξ, τ_d at the previous global step, and use the approximate solution

$$q^*(\boldsymbol{Z}_t) = p_0(\boldsymbol{Z}_t)p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi})\exp\left(\sum_{d\in B_t}\tau_d^* y_d\boldsymbol{\mu}^{*\top}\bar{\boldsymbol{z}}_d\right).$$

Then the expectation of $\bar{\boldsymbol{z}}_d$, as needed in the global updates, could be approximated by samples from the distribution $q^*(\boldsymbol{Z}_t)$. Specifically, we use Gibbs sampling with the conditional distribution

$$q(z_{di} = k \mid \boldsymbol{Z}_t^{\neg di}) \propto \left(\alpha + C_{dk}^{\neg di}\right)\exp\left(\Lambda_{k,x_{di}} + \sum_{d\in B_t}n_d^{-1}y_d\tau_d^*\mu_k^*\right). \tag{25}$$

where $\Lambda_{z_{di},x_{di}} = \mathbb{E}_{q(\boldsymbol{\Phi})}[\log(\Phi_{z_{di},x_{di}})] = \Psi(\Delta^*_{z_{di},x_{di}}) - \Psi(\sum_w\Delta^*_{z_{di},w})$ (note that $\Psi(\cdot)$ is the digamma function) and $\boldsymbol{C}_d^{\neg di}$ is a vector with the k-th entry being the number of words in document d (except the i-th word) that are assigned to topic k.

Then we draw $\mathcal{J}$ samples $\{\boldsymbol{Z}_t^{(j)}\}_{j=1}^{\mathcal{J}}$ using Eq. (25), discard the first β ($0 \leq \beta < \mathcal{J}$) burn-in samples, and approximate $\widehat{z}_{dk}$ with the empirical sum $(J-\beta)^{-1}\sum_{j=\beta+1}^{J}\sum_{d,i}\mathbb{I}[z_{di}^{(j)} = k]$.

Algorithm 1 Online MedLDA

Let $q_0(\boldsymbol{w}) = \mathcal{N}(0; \sigma^2 I), q_0(\boldsymbol{\phi}_k) = \text{Dir}(\gamma),\ \forall\, k$.
for $t = 0 \to \infty$ **do**
  Set $q(\boldsymbol{\Phi}, \boldsymbol{w}) = q_t(\boldsymbol{\Phi}) q_t(\boldsymbol{w})$. Initialize $\boldsymbol{Z}_t$.
  for $i = 1 \to \mathcal{I}$ **do**
    Draw samples $\{\boldsymbol{Z}_t^{(j)}\}_{j=1}^{\mathcal{J}}$ from Eq. (25).
    Discard the first β burn-in samples ($\beta < \mathcal{J}$).
    Use the rest $\mathcal{J} - \beta$ samples to update $q(\boldsymbol{\Phi}, \boldsymbol{w})$ following Eq.s (19, 20).
  end for
  Set $q_{t+1}(\boldsymbol{\Phi}, \boldsymbol{w}) = q(\boldsymbol{\Phi}, \boldsymbol{w})$.
end for

At each round t of BayesPA optimization during training, we run the global and local updates alternately until convergence, and assign $q_t(\boldsymbol{\Phi}, \boldsymbol{w}) = q^*(\boldsymbol{\Phi}) q^*(\boldsymbol{w})$, as outlined in Algorithm 1. To make predictions on testing data, we use the mean $\boldsymbol{\mu}$ as the classification weight and apply the prediction rule. The inference of $\bar{\boldsymbol{z}}$ for testing documents is similar to Zhu et al. (2014b). First, we draw a single sample of $\boldsymbol{\Phi}$, and for each test document d, we infer the MAP of $\boldsymbol{\theta}_d$. Then, we directly run the sampling of $\boldsymbol{z}_d$ until the burn-in stage is completed, and use the average of several samples to compute $\widehat{\boldsymbol{z}}_d$. Then the prediction rule is applied on $\boldsymbol{\mu}$ and $\widehat{\boldsymbol{z}}_d$.

5.3 Online Gibbs MedLDA

In this section, we apply the theory of BayesPA to Gibbs MedLDA. As shown in Zhu et al. (2014b), using Gibbs classifiers admits efficient inference algorithms by exploring *data augmentation* (DA) techniques (Tanner and Wong, 1987; Polson and Scott, 2011). Based on this insight, we will develop our efficient online inference algorithms for Gibbs MedLDA. We denote the model by paMedLDA$^{\text{gibbs}}$. Specifically, let $\zeta_d = \epsilon - y_d f(\boldsymbol{w}, \boldsymbol{z}_d)$ and $\psi(y_d|\boldsymbol{z}_d, \boldsymbol{w}) = e^{-2c(\zeta_d)_+}$. By Lemma 4, the optimal solution to problem (13) is

$$q_{t+1}(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t) = \frac{q_t(\boldsymbol{w}, \boldsymbol{\mathcal{M}}) p_0(\boldsymbol{H}_t) p(\boldsymbol{X}_t|\boldsymbol{H}_t, \boldsymbol{\mathcal{M}}) \psi(\boldsymbol{Y}_t|\boldsymbol{H}_t, \boldsymbol{w})}{\Gamma(\boldsymbol{X}_t, \boldsymbol{Y}_t)}\ ,$$

where $\psi(\boldsymbol{Y}_t|\boldsymbol{H}_t, \boldsymbol{w}) = \prod_{d \in B_t} \psi(y_d|\boldsymbol{h}_d, \boldsymbol{w})$ and $\Gamma(\boldsymbol{X}_t, \boldsymbol{Y}_t)$ is a normalization constant. The basic idea of DA is to construct conjugacy between prior and data during inference by introducing augmented variables. Specifically, we would use the following equality (Zhu et al., 2014b):

$$\psi(y_d|\boldsymbol{z}_d, \boldsymbol{w}) = \int_0^\infty \psi(y_d, \lambda_d|\boldsymbol{z}_d, \boldsymbol{w}) d\lambda_d, \tag{26}$$

where $\psi(y_d, \lambda_d|\boldsymbol{z}_d, \boldsymbol{w}) = (2\pi\lambda_d)^{-1/2} \exp\left(-\frac{(\lambda_d + c\zeta_d)^2}{2\lambda_d}\right)$. Equality (26) essentially implies that the collapsed posterior $q_{t+1}(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)$ is a marginal distribution of

$$q_{t+1}(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t) = \frac{p_0(\boldsymbol{Z}_t) q_t(\boldsymbol{w}, \boldsymbol{\Phi}) p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi}) \psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t|\boldsymbol{Z}_t, \boldsymbol{w})}{\Gamma(\boldsymbol{X}_t, \boldsymbol{Y}_t)}\ ,$$

where $\psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t|\boldsymbol{Z}_t, \boldsymbol{w}) = \prod_{d \in B_t} \psi(y_d, \lambda_d|\boldsymbol{z}_d, \boldsymbol{w})$ and $\boldsymbol{\lambda}_t = \{\lambda_d\}_{d \in B_t}$ are augmented variables locally associated with individual documents. In fact, the augmented distribution $q_{t+1}(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$ is the

solution to the problem:

$$\min_{q \in \mathcal{P}} \mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t)\Big) - \mathbb{E}_q\Big[\log \psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t|\boldsymbol{Z}_t, \boldsymbol{w})\Big], \tag{27}$$

where $\mathcal{L}(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t)) = \mathbf{KL}[q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t) \| q_t(\boldsymbol{w}, \boldsymbol{\Phi}) p_0(\boldsymbol{Z}_t)] - \mathbb{E}_q[\log p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi})]$. In fact, this objective is an upper bound of that in the original problem (13) (See Appendix A for details).

Again, with the mild mean-field assumption that $q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t) = q(\boldsymbol{w}, \boldsymbol{\Phi}) q(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$, we can solve problem (27) via an iterative procedure that alternately updates each factor distribution (Jordan et al., 1998), as detailed below.

1. **Global Update:** By fixing the distribution of local variables, $q(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$, and ignoring irrelevant terms, the optimal distribution of $\boldsymbol{w}$ and $\boldsymbol{\Phi}$ can be shown to have the induced factorization form, $q(\boldsymbol{w}, \boldsymbol{\Phi}) = q(\boldsymbol{w}) q(\boldsymbol{\Phi})$. For $q(\boldsymbol{\Phi})$, the update rule is exactly (19). For $q(\boldsymbol{w})$, we have the update rule

$$q_{t+1}(\boldsymbol{w}) \propto q_t(\boldsymbol{w}) \exp\left(\mathbb{E}_{q(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)}\Big[\log p_0(\boldsymbol{Z}_t) \psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t|\boldsymbol{Z}_t, \boldsymbol{w})\Big]\right).$$

   If the initial prior is normal $q_0(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}; \boldsymbol{\mu}^0, \boldsymbol{\Sigma}^0)$, by induction we can show that the inferred distribution in each round is also a normal distribution, namely, $q_t(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}; \boldsymbol{\mu}^t, \boldsymbol{\Sigma}^t)$. Indeed, the optimal solution of $q(\boldsymbol{w})$ to problem (27) is

$$q^*(\boldsymbol{w}) = \mathcal{N}(\boldsymbol{w}; \boldsymbol{\mu}^*, \boldsymbol{\Sigma}^*), \tag{28}$$

   where the posterior paramters are computed as

$$\boldsymbol{\Sigma}^* = \left((\boldsymbol{\Sigma}^t)^{-1} + c^2 \sum_{d \in B_t} \mathbb{E}_{q(\boldsymbol{z}_d, \lambda_d)}\left[\lambda_d^{-1} \bar{\boldsymbol{z}}_d \bar{\boldsymbol{z}}_d^\top\right]\right)^{-1},$$

$$\boldsymbol{\mu}^* = \boldsymbol{\Sigma}^* \left((\boldsymbol{\Sigma}^t)^{-1} \boldsymbol{\mu}^t + c \sum_{d \in B_t} \mathbb{E}_{q(\boldsymbol{z}_d, \lambda_d)}\left[y_d \left(1 + c\epsilon\lambda_d^{-1}\right) \bar{\boldsymbol{z}}_d\right]\right).$$

   For the sequential update rule, we simply set $\boldsymbol{\mu}^{t+1} = \boldsymbol{\mu}^*$ and $\boldsymbol{\Sigma}^{t+1} = \boldsymbol{\Sigma}^*$.

2. **Local Update:** Given the distribution of global variables, $q(\boldsymbol{\Phi}, \boldsymbol{w})$, the mean-field update equation for $(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$ is

$$q(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t) \propto p_0(\boldsymbol{Z}_t) \prod_{d \in B_t} \frac{1}{\sqrt{2\pi\lambda_d}} \exp\left(\sum_{i \in [n_d]} \Lambda_{z_{di}, x_{di}} - \mathbb{E}_{q(\boldsymbol{\Phi}, \boldsymbol{w})}\left[\frac{(\lambda_d + c\zeta_d)^2}{2\lambda_d}\right]\right),$$

   where Λ admits the same definition as in (25). But it is impossible to evaluate the expectation in the global update using $q(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$ because of the huge number of configurations for $(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t)$. As a result, we turn to Gibbs sampling and estimate the required expectations using multiple empirical samples. This hybrid strategy has shown promising performance for LDA (Mimno et al., 2012). Specifically, the conditional distributions used in the Gibbs sampling are as follows:

Algorithm 2 Online Gibbs MedLDA

Let $q_0(\boldsymbol{w}) = \mathcal{N}(0; \sigma^2 I), q_0(\boldsymbol{\phi}_k) = \text{Dir}(\gamma),\ \forall\, k$.
for $t = 0 \to \infty$ **do**
  Set $q(\boldsymbol{\Phi}, \boldsymbol{w}) = q_t(\boldsymbol{\Phi}) q_t(\boldsymbol{w})$. Initialize $\boldsymbol{Z}_t$.
  for $i = 1 \to \mathcal{I}$ **do**
    Draw samples $\{\boldsymbol{Z}_t^{(j)}, \boldsymbol{\lambda}_t^{(j)}\}_{j=1}^{\mathcal{J}}$ from Eq.s (29, 30).
    Discard the first β burn-in samples ($\beta < \mathcal{J}$).
    Use the rest $\mathcal{J} - \beta$ samples to update $q(\boldsymbol{\Phi}, \boldsymbol{w})$ following Eq.s (19, 28).
  end for
  Set $q_{t+1}(\boldsymbol{\Phi}, \boldsymbol{w}) = q(\boldsymbol{\Phi}, \boldsymbol{w})$.
end for

- **For $\boldsymbol{Z}_t$:** By canceling out common factors, the conditional distribution of one variable z_{di} given $\boldsymbol{Z}_t^{\neg di}$ and $\boldsymbol{\lambda}_t$ is

$$q(z_{di}{=}k|\boldsymbol{Z}_t^{\neg di}, \boldsymbol{\lambda}_t) \propto (\alpha + C_{dk}^{\neg di}) \exp\Big(\frac{c y_d (c\epsilon + \lambda_d) \mu_k^*}{n_d \lambda_d} + \Lambda_{k, x_{di}} - \frac{c^2(\mu_k^{*2} + \Sigma_{kk}^* + 2(\mu_k^* \boldsymbol{\mu}^* + \boldsymbol{\Sigma}_{\cdot,k}^*)^\top \boldsymbol{C}_d^{\neg di})}{2 n_d^2 \lambda_d} \Big), \tag{29}$$

  where $\boldsymbol{\Sigma}_{\cdot,k}^*$ is the k-th column of $\boldsymbol{\Sigma}^*$.

- **For $\boldsymbol{\lambda}_t$:** Let $\bar{\zeta}_d = \epsilon - y_d \bar{\boldsymbol{z}}_d^\top \boldsymbol{\mu}^*$. The conditional distribution of each variable λ_d given $\boldsymbol{Z}_t$ is

$$\begin{aligned} q(\lambda_d|\boldsymbol{Z}_t) &\propto \frac{1}{\sqrt{2\pi\lambda_d}} \exp\left(-\frac{c^2 \bar{\boldsymbol{z}}_d^\top \boldsymbol{\Sigma}^* \bar{\boldsymbol{z}}_d + (\lambda_d + c\bar{\zeta}_d)^2}{2\lambda_d} \right) \\ &= \mathcal{GIG}\left(\lambda_d; \frac{1}{2}, 1, c^2 \left(\bar{\zeta}_d^2 + \bar{\boldsymbol{z}}_d^\top \boldsymbol{\Sigma}^* \bar{\boldsymbol{z}}_d \right) \right), \end{aligned} \tag{30}$$

  a generalized inverse gaussian distribution (Devroye, 1986). Therefore, λ_d^{-1} follows an inverse gaussian distribution, that is,

$$q(\lambda_d^{-1}|\boldsymbol{Z}_t) = \mathcal{IG}\left(\lambda_d^{-1}; \frac{1}{c\sqrt{\bar{\zeta}_d^2 + \bar{\boldsymbol{z}}_d^\top \boldsymbol{\Sigma}^* \bar{\boldsymbol{z}}_d}}, 1 \right),$$

  from which we can draw a sample in constant time (Michael et al., 1976).

For training, we run the global and local updates alternately until convergence at each round of PA optimization, as outlined in Alg. 2. To make predictions on testing data, we then draw one sample of $\hat{\boldsymbol{w}}$ as the classification weight and apply the prediction rule. The inference of $\bar{\boldsymbol{z}}$ for testing documents is the same as online MedLDA.

6. Extensions

In the above topic models, we assume that the number of topics (i.e., K) is pre-specified, which is unfortunately unknown in practice. An extra procedure is often applied to select a good K value.

We now present extensions of online MedLDA to automatically determine the unknown K values by leveraging nonparametric Bayesian techniques. We also present an extension of these models for multi-task learning.

6.1 Online Nonparametric MedLDA

We first present online nonparametric MedLDA for resolving the unknown number of topics, based on the theory of hierarchical Dirichlet process (HDP) (Teh et al., 2006a).

6.1.1 BATCH MEDHDP

A two-level HDP provides an extension to LDA that allows for a nonparametric inference of the unknown topic numbers. The generative process of HDP can be summarized using a stick-breaking construction (Wang and Blei, 2012b), where the stick lengths $\boldsymbol{\pi} = \{\pi_k\}_{k=1}^\infty$ are generated as:

$$\pi_k = \bar{\pi}_k \prod_{i<k} (1 - \bar{\pi}_i),\ \bar{\pi}_k \sim \text{Beta}(1, \eta),\ \text{for } k = 1, ..., \infty,$$

and the topic mixing proportions are generated as $\boldsymbol{\theta}_d \sim \text{Dir}(\alpha\boldsymbol{\pi}),$ for $d = 1, ..., D$. Each topic $\boldsymbol{\phi}_k$ is a sample from a Dirichlet base distribution, i.e., $\boldsymbol{\phi}_k \sim \text{Dir}(\boldsymbol{\gamma})$. After we get the topic mixing proportions $\boldsymbol{\theta}_d$, the generation of words is the same as in the standard LDA.

To extend the HDP topic model for predictive tasks, we introduce a classifier $\boldsymbol{w}$ that is drawn from a Gaussian process, $\mathcal{GP}(0, \boldsymbol{\Sigma})$, where the covariance function is $\Sigma(\boldsymbol{w}, \boldsymbol{w}') = \sigma^2 \mathbb{I}[\boldsymbol{w} = \boldsymbol{w}']$. We still define the linear discriminant function in the same form as Eq. (14). Since the number of words in a document is finite, the average topic assignment vector $\bar{\boldsymbol{z}}_d$ has only a finite number of non-zero elements, and the dot product in Eq. (14) is in fact finite. Therefore, given the latent topic assignments, the conditoinal posterior of $\boldsymbol{w}$ is in fact a multivariate Gaussian distribution.

Let $\bar{\boldsymbol{\pi}} = \{\bar{\pi}_k\}_{k=1}^\infty$. We define maximum entropy discrimination HDP (MedHDP) topic model as solving the following RegBayes problem to infer the joint post-data posterior $q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})$:[5]

$$\min_{q \in \mathcal{P}} \mathcal{L}\Big(q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}) \Big) + 2c \sum_{d=1}^D \ell_\epsilon\Big(q(\boldsymbol{w}, \boldsymbol{z}_d); \boldsymbol{x}_d, \boldsymbol{y}_d \Big), \tag{31}$$

where $\mathcal{L}(q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z})) = \mathbf{KL}[q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}) || p(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{\Theta}, \boldsymbol{Z}|\boldsymbol{X})]$ is the objective corresponding to the standard Bayesian inference under the variational formulation of Bayes' rule. The loss function could be either (15) or (16). We call the resulting model with the averaging classifier MedHDP$^{\text{ave}}$ and that with the Gibbs classifier MedHDP$^{\text{gibbs}}$.

Since MedHDP is a new model, we would briefly discuss the corresponding inference problem. For the inference of MedHDP$^{\text{gibbs}}$, we can use Gibbs sampling based on Chinese Restaurant Franchise (Teh et al., 2006a; Wang and Blei, 2012a) with modifications similar to the techniques introduced in Zhu et al. (2014b). For MedHDP$^{\text{ave}}$, the current state-of-the-art for inferring max-margin Bayesian models with averaging loss resorts to mean-field assumptions and variational inference. Notice that classical mean-field derivation would fail due to the potentially unbounded space of variables. However, it is possible to incorporate Gibbs sampling into mean-field update equations to explore the unbounded space (Welling et al., 2008; Wang and Blei, 2012b) and therefore bypass the difficulty. In this paper, we would not focus on developing inference algorithms for MedHDP,

5. Given $\bar{\boldsymbol{\pi}}$, $\boldsymbol{\pi}$ can be computed via the stick breaking process.

but instead attain batch MedHDP algorithms from the corresponding BayesPA methods, as will be clear at the end of each subsection below.

6.1.2 ONLINE MEDHDP

To apply the ideas of BayesPA to develop online MedHDP algorithms, we have the global variables $\boldsymbol{\mathcal{M}} = (\bar{\boldsymbol{\pi}}, \boldsymbol{\Phi})$, and the local variables $\boldsymbol{H}_t = (\boldsymbol{\Theta}_t, \boldsymbol{Z}_t)$. As in online MedLDA, we marginalize out $\boldsymbol{\Theta}_t$ by conjugacy. Furthermore, to simplify the sampling scheme, we introduce another set of auxiliary latent variables $\boldsymbol{S}_t = \{\boldsymbol{s}_d\}_{d\in B_t}$, where $\boldsymbol{s}_d = \{s_{dk}\}_{k=1}^{\infty}$ and each element s_{dk} represents the number of occupied tables serving dish k in a Chinese restaurant process (CRP) (Teh et al., 2006a; Wang and Blei, 2012b). By definition, we have $p(\boldsymbol{Z}_t, \boldsymbol{S}_t|\bar{\boldsymbol{\pi}}) = \prod_{d\in B_t} p(\boldsymbol{s}_d, \boldsymbol{z}_d|\bar{\boldsymbol{\pi}})$ and

$$p(\boldsymbol{s}_d, \boldsymbol{z}_d|\bar{\boldsymbol{\pi}}) \propto \prod_{k=1}^{\infty} S(n_d\tilde{z}_{dk}, s_{dk})(\alpha\pi_k)^{s_{dk}}, \tag{32}$$

where $S(a, b)$ are unsigned Stirling numbers of the first kind (Antoniak, 1974). It is not hard to verify that $p(\boldsymbol{z}_d|\bar{\boldsymbol{\pi}}) = \sum_{\boldsymbol{s}_d} p(\boldsymbol{s}_d, \boldsymbol{z}_d|\bar{\boldsymbol{\pi}})$. After this "collapse-and-augment" procedure, we now have the local variables $\boldsymbol{H}_t = (\boldsymbol{Z}_t, \boldsymbol{S}_t)$. The global variables remain intact. The new BayesPA problem is now:

$$\min_{q\in\mathcal{F}_t} \mathcal{L}\Big(q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{H}_t)\Big) + 2c\sum_{d\in B_t} \ell_\epsilon\Big(\boldsymbol{w}; \boldsymbol{x}_t, y_t\Big), \tag{33}$$

where $\mathcal{L}(q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{H}_t)) = \mathbf{KL}[q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{H}_t)||q_t(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi})p(\boldsymbol{Z}_t, \boldsymbol{S}_t|\bar{\boldsymbol{\pi}})p(\boldsymbol{X}_t|\boldsymbol{Z}_t, \boldsymbol{\Phi})]$. As in online MedLDA, we adopt the mild mean field assumption $q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{H}_t) = q(\boldsymbol{w})q(\bar{\boldsymbol{\pi}})q(\boldsymbol{\Phi})q(\boldsymbol{H}_t)$ and solve problem (33) via an iterative procedure detailed below.

1. **Global Update:** By fixing the distribution of local variables, $q(\boldsymbol{H}_t)$, and ignoring the irrelevant terms, we have same mean-field update equations (19) for $\boldsymbol{\Phi}$ and (21) for $\boldsymbol{w}$ with the averaging loss. For global variable $\bar{\boldsymbol{\pi}}$, we have

$$q^*(\bar{\pi}_k) \propto q_t(\bar{\pi}_k) \prod_{d\in B_t} \exp\left(\mathbb{E}_{q(\boldsymbol{h}_d)}\Big[\log p(\boldsymbol{s}_d, \boldsymbol{z}_d|\bar{\boldsymbol{\pi}})\Big]\right). \tag{34}$$

   By induction, we can show that $q_t(\bar{\pi}_k) = \text{Beta}(u_k^t, v_k^t)$ is a Beta distribution at each step, and the update equation is

$$q^*(\bar{\pi}_k) = \text{Beta}(u_k^*, v_k^*), \tag{35}$$

   where $u_k^* = u_k^t + \sum_{d\in B_t} \mathbb{E}_{q(\boldsymbol{s}_d)}[s_{dk}]$ and $v_k^* = v_k^t + \sum_{d\in B_t} \mathbb{E}_{q(\boldsymbol{s}_d)}[\sum_{j>k} s_{dj}]$ for $k = \{1, 2, ...\}$ and $u_k^0 = 1, v_k^0 = \eta$.

   Since $\boldsymbol{Z}_t$ contains only a finite number of discrete variables, we only need to maintain and update the above global distributions for a finite number of topics.

2. **Local Update:** Fixing the global distribution $q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi})$, we get the mean-field update equation for $(\boldsymbol{Z}_t, \boldsymbol{S}_t)$:

$$q^*(\boldsymbol{Z}_t, \boldsymbol{S}_t) \propto \tilde{q}(\boldsymbol{Z}_t, \boldsymbol{S}_t)\hat{q}(\boldsymbol{Z}_t) \tag{36}$$

where

$$\tilde{q}(\boldsymbol{Z}_t, \boldsymbol{S}_t) = \exp\left(\mathbb{E}_{q^*(\boldsymbol{\Phi})q^*(\bar{\boldsymbol{\pi}})}[\log p(\boldsymbol{X}|\boldsymbol{\Phi}, \boldsymbol{Z}_t) + \log p(\boldsymbol{Z}_t, \boldsymbol{S}_t|\bar{\boldsymbol{\pi}})]\right),$$
$$\hat{q}(\boldsymbol{Z}_t) = \exp\left(\sum_{d\in B_t} \tau_d y_d \mathbb{E}[\boldsymbol{w}]^\top \bar{\boldsymbol{z}}_d\right),$$

and $\tau_d (d \in B_t)$ are the dual variables computed in the global update. The most cumbersome point to tackle is the potentially unbounded sample space of $\boldsymbol{Z}_t$ and $\boldsymbol{S}_t$. We take the ideas from (Wang and Blei, 2012b) and adopt an approximation for $\tilde{q}(\boldsymbol{Z}_t, \boldsymbol{S}_t)$:

$$\tilde{q}(\boldsymbol{Z}_t, \boldsymbol{S}_t) \approx \mathbb{E}_{q^*(\boldsymbol{\Phi})q^*(\bar{\boldsymbol{\pi}})}\left[p(\boldsymbol{X}|\boldsymbol{\Phi}, \boldsymbol{Z}_t)p(\boldsymbol{Z}_t, \boldsymbol{S}_t|\bar{\boldsymbol{\pi}})\right]. \tag{37}$$

Computing the expectation regarding $\bar{\boldsymbol{\pi}}$ in (37) turns out to be difficult. However, imagine that the expectation operator is essentially collapsing $\bar{\boldsymbol{\pi}}$ out from the joint distribution

$$\tilde{q}(\bar{\boldsymbol{\pi}}, \boldsymbol{Z}_t, \boldsymbol{S}_t) \approx \mathbb{E}_{q^*(\boldsymbol{\Phi})}\left[q^*(\bar{\boldsymbol{\pi}})p(\boldsymbol{X}|\boldsymbol{\Phi}, \boldsymbol{Z}_t)p(\boldsymbol{Z}_t, \boldsymbol{S}_t|\bar{\boldsymbol{\pi}})\right]. \tag{38}$$

Now we propose to uncollapse $\bar{\boldsymbol{\pi}}$ and sample the local variables from

$$q^*(\bar{\boldsymbol{\pi}}, \boldsymbol{Z}_t, \boldsymbol{S}_t) \propto \tilde{q}(\bar{\boldsymbol{\pi}}, \boldsymbol{Z}_t, \boldsymbol{S}_t)\hat{q}(\boldsymbol{Z}_t). \tag{39}$$

Notice in the local updates, $\bar{\boldsymbol{\pi}}$ is only an auxilary variable. Putting all the pieces together, we have the following sampling scheme.

- **For $\boldsymbol{Z}_t$:** Let K be the current inferred number of topics. The conditional distribution of one variable z_{di} given all other local variables can be derived from (36) with $\boldsymbol{s}_d$ marginalized out for convenience.

$$q(z_{di} = k|\boldsymbol{Z}_t^{\neg di}, \bar{\boldsymbol{\pi}}) \propto \frac{(\alpha\pi_k + C_{dk}^{\neg di})(C_{kx_{di}}^{\neg di} + \Delta_{kx_{di}}^t)}{\sum_w (C_{kw}^{\neg di} + \Delta_{kw}^t)} \exp\left(\sum_{d\in B_t} n_d^{-1} y_d \tau_d \mu_k^*\right). \tag{40}$$

  Besides, for $k > K$ and symmetric Dirichlet prior $\boldsymbol{\gamma}$, (40) converge to a single rule $q(z_{di} = k|\boldsymbol{Z}_t^{\neg di}, \bar{\boldsymbol{\pi}}) \propto \alpha\pi_k/W$, and therefore the total probability of assigning a new topic is

$$q(z_{di} > K|\boldsymbol{Z}_t^{\neg di}, \bar{\boldsymbol{\pi}}) \propto \alpha\left(1 - \sum_{k=1}^{K} \pi_k\right)/W.$$

- **For $\boldsymbol{S}_t$:** The conditional distribution of s_{dk} given $(\boldsymbol{Z}_t, \bar{\boldsymbol{\pi}}, \boldsymbol{\lambda}_t)$ can be derived from the joint distribution (32):

$$q(s_{dk}|\boldsymbol{Z}_t, \bar{\boldsymbol{\pi}}) \propto S(n_d\tilde{z}_{dk}, s_{dk})(\alpha\pi_k)^{s_{dk}}. \tag{41}$$

- **For $\bar{\boldsymbol{\pi}}$:** It can be derived from (36) that given $(\boldsymbol{Z}_t, \boldsymbol{S}_t)$, each $\bar{\pi}_k$ follows the beta distribution,

$$\bar{\pi}_k \sim \text{Beta}(a_k, b_k), \tag{42}$$

  where $a_k = u_k^* + \sum_{d\in B_t} s_{dk}$ and $b_k = v_k^* + \sum_{d\in B_t}\sum_{j>k} s_{dj}$.

Similar to online MedLDA, we iterate the above steps till convergence for training. For testing, the learned model is essentially a finite MedLDA, and we use the same scheme as that of online MedLDA.

Notice that if we run online MedHDP for only one round ($T = 1$) and use the entire dataset as mini-batch ($|B| = D$), iterating the above steps till converge in fact solves the batch MedHDP problem Eq. (31). We call this batch version MedHDP$^{\text{ave}}$, and will use it as a baseline algorithm.

6.1.3 ONLINE GIBBS MEDHDP

For Gibbs MedHDP, the only difference is the loss functional ℓ_ϵ, which is reflected in the sampling of local variables. As in online Gibbs MedLDA, we can facilitate more efficient inference by adopting the same data augmentation technique with the augmented variables $\boldsymbol{\lambda}_t$. Then the local variables are $(\boldsymbol{Z}_t, \boldsymbol{S}_t, \boldsymbol{\lambda}_t)$ and the global variables are unchanged. We then use the mean field assumption $q(\boldsymbol{w}, \bar{\boldsymbol{\pi}}, \boldsymbol{\Phi}, \boldsymbol{H}_t) = q(\boldsymbol{w})q(\bar{\boldsymbol{\pi}})q(\boldsymbol{\Phi})q(\boldsymbol{H}_t)$ and compute the iterative steps as follows.

1. **Global Update:** The same as online MedHDP, except that the update rule for $\boldsymbol{w}$ is now (28) for the Gibbs classifier.

2. **Local Update:** This step involves drawing samples of the local variables. We develop a Gibbs sampler, which iteratively draws $\boldsymbol{S}_t$ from the local conditional in (41), draws $\bar{\boldsymbol{\pi}}$ from the conditional in (42), and draws the augmented variables $\boldsymbol{\lambda}_t$ from the conditional in (30). For $\boldsymbol{Z}_t$, we explain the sampling procedure in detail. Specifically, we infer $\boldsymbol{Z}_t$ through

$$q^*(\boldsymbol{Z}_t, \boldsymbol{S}_t, \boldsymbol{\lambda}_t, \bar{\boldsymbol{\pi}}) \propto \tilde{q}(\bar{\boldsymbol{\pi}}, \boldsymbol{Z}_t, \boldsymbol{S}_t)\hat{q}(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t), \tag{43}$$

where

$$\hat{q}(\boldsymbol{Z}_t, \boldsymbol{\lambda}_t) = \prod_{d \in B_t} \frac{1}{\sqrt{2\pi\lambda_d}} \exp\left(\sum_{i \in [n_d]} \Lambda_{z_{di}, x_{di}} - \mathbb{E}_{q(\boldsymbol{\Phi}, \boldsymbol{w})}\left[\frac{(\lambda_d + c\zeta_d)^2}{2\lambda_d} \right] \right),$$

The Gibbs sampling for each variable z_{di} is

$$q(z_{di} = k | \boldsymbol{Z}_t^{\neg di}, \boldsymbol{\lambda_t}, \bar{\boldsymbol{\pi}}) \propto \frac{(\alpha\pi_k + C_{dk}^{\neg di})(C_{kx_{di}}^{\neg di} + \Delta_{kx_{di}}^t)}{\sum_w (C_{kw}^{\neg di} + \Delta_{kw}^t)} \exp\left(\frac{c y_d (c\epsilon + \lambda_d)\mu_k^*}{n_d \lambda_d} - \frac{c^2(\mu_k^{*2} + \Sigma_{kk}^* + 2(\mu_k^* \boldsymbol{\mu}^* + \boldsymbol{\Sigma}_{\cdot,k}^*)^\top \boldsymbol{C}_d^{\neg di})}{2 n_d^2 \lambda_d} \right), \tag{44}$$

while the probability of sampling a new topic is

$$q(z_{di} > K | \boldsymbol{Z}_t^{\neg di}, \bar{\boldsymbol{\pi}}) \propto \alpha \left(1 - \sum_{k=1}^K \pi_k \right) / W.$$

Again, we iterate the above steps till convergence for training and the testing is the same as online MedHDP. A batch version algorithm can be attained by setting $T = 1$ and $|B| = D$, which we denote as MedHDP$^{\text{gibbs}}$.

6.2 Multi-task Learning

The above models have been presented for classification. The basic ideas can be applied to solve other learning tasks, such as regression and multi-task learning (MTL). We use multi-task learning an one example. The primary assumption of multi-task learning is that by sharing statistical strength in a joint learning procedure, multiple related tasks can be mutually enhanced or some main tasks can be improved. MTL has many applications. We consider one scenario for multi-label classification. In this task, a set of binary classifiers are trained, each of which identifies whether a document $\boldsymbol{x}_d$ belongs to a specific category $y_d^q \in \{+1, -1\}$. These binary classifiers are allowed to share common latent representations and therefore could be attained via a modified BayesPA update equation:

$$\min_{q \in \mathcal{F}_t} \mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t)\Big) + 2c \sum_{q=1}^{Q} \ell_\epsilon\Big(q(\boldsymbol{w}, \boldsymbol{\mathcal{M}}, \boldsymbol{H}_t); \boldsymbol{X}_t, \boldsymbol{Y}_t^\tau\Big),$$

where Q is the total number of tasks. We can then derive the multi-task version of Passive-Aggressive topic models, denoted by paMedLDAmt$^{\text{ave}}$ and paMedLDAmt$^{\text{gibbs}}$, in a way similar as in Section 5. We can further develop the nonparametric multi-task MedLDA topic models in a way similar as in Section 6.1 and the online PA learning algorithms. We denote the nonparametric online models by paMedHDP$^{\text{ave}}$ and paMedHDP$^{\text{gibbs}}$, according to whether the task-specific classifier is averaging or Gibbs.

7. Experiments

We demonstrate the efficiency and prediction accuracy of online MedLDA, online Gibbs MedLDA and their extensions on the 20Newsgroup (20NG) and a large Wikipedia dataset. A sensitivity analysis of the key parameters is also provided. Following the same setting in Zhu et al. (2012), we remove a standard list of stop words. All of the experiments are done on a normal computer with single-core clock rate up to 2.4 GHz.

7.1 Classification on 20Newsgroup

We perform multi-class classification on the entire 20NG dataset with all the 20 categories. The training set contains 11,269 documents, with the smallest category having 376 documents and the biggest category having 599 documents. The testing set contains 7,505 documents, with the smallest and biggest categories having 259 and 399 documents respectively. We adopt the "one-vs-all" strategy (Rifkin and Klautau, 2004) to combine binary classifiers for multi-class prediction tasks.

We use shorthand notations paMedLDA$^{\text{ave}}$ and paMedLDA$^{\text{gibbs}}$ for online MedLDA and online Gibbs MedLDA respectively. The corresponding batch learning algorithms are MedLDA (Zhu et al., 2012) and Gibbs MedLDA (MedLDA$^{\text{gibbs}}$) (Zhu et al., 2014b), which is a MedLDA model with Gibbs classifiers. We use collapsed Gibbs sampling to solve MedLDA, which is exactly the gMedLDA model proposed by Jiang et al. (2012). We also choose a state-of-the-art online unsupervised topic model as the baseline, the sparse inference for LDA (spLDA) (Mimno et al., 2012), which has been demonstrated to be superior than the stochastic variational LDA (Hoffman et al., 2013) in prediction performance. To perform the supervised tasks, we learn a linear SVM with the topic representations using LIBSVM (Chang and Lin, 2011). We refer the readers to (Zhu et al., 2012) for the performance of other batch-learning-based supervised topic models, such as sLDA

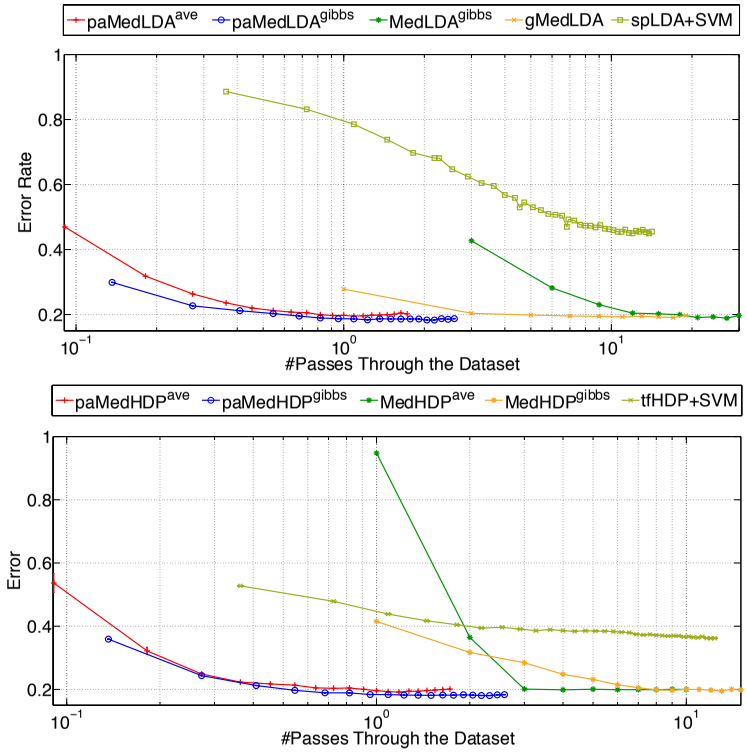

Figure 3: Test errors of different models with respect to the number of passes through the 20NG training dataset.

(Blei and McAuliffe, 2010) and DiscLDA (Lacoste-Julien et al., 2008), as well as SVM classifiers on the raw inputs, which are generally either inferior in accuracy or slower in efficiency than MedLDA. For all the LDA-based topic models, we use symmetric Dirichlet priors $\boldsymbol{\alpha} = 1/K \cdot \mathbf{1}$ and $\boldsymbol{\gamma} = 0.45 \cdot \mathbf{1}$. For BayesPA with Gibbs classifiers, the parameters were set at $\epsilon = 164$, $c = 1$, and $\sigma^2 = 1$. The models' performance is not sensitive to the choice of these parameters in wide ranges as shown in Zhu et al. (2014b). For BayesPA with averaging classifiers, the parameters determined by cross validation are $\epsilon = 16$, $c = 500$, and $\sigma^2 = 10^{-3}$. For reasons explained in section 7.3, we set the mini-batch size $|B| = 1$ for the averaging classifier and $|B| = 512$ for the Gibbs classifier.

We first analyze how many processed documents are sufficient for each model to converge. Figure 3 shows the test errors with respect to the number of passes through the 20NG training set, where the number of topics is set at $K = 80$ and the other parameters of BayesPA are set at

$(\mathcal{I}, \mathcal{J}, \beta) = (1, 2, 0)$. As we can observe, by solving a series of latent BayesPA problems, both paMedLDA$^{\text{ave}}$ and paMedLDA$^{\text{gibbs}}$ fully explore the redundancy of documents and converge in less than one pass, while their corresponding batch algorithms (i.e., MedLDA and MedLDA$^{\text{gibbs}}$) need many passes as burn-in steps. Besides, compared with the online learning algorithms for unsupervised topic models (i.e., spLDA+SVM), BayesPA topic models use supervising side information from each mini-batch, and therefore exhibit a faster convergence rate in discrimination ability. The convergence performance of BayesPA models is significantly better than that of the unsupervised spLDA.

Next, we study each model's best performance possible and the corresponding training time. To allow for a fair comparison, we train each model until the relative change of its objective is less than 10^{-4}. Figure 4 shows the prediction accuracy and training time of LDA-based models on the whole dataset with varying numbers of topics. We can see that BayesPA topic models are more than an order of magnitude faster than their corresponding batch algorithms in training time due to the power of online learning. paMedLDA$^{\text{ave}}$ is faster than paMedLDA$^{\text{gibbs}}$, because it does not need to update the covariance matrix of classifier weights $\boldsymbol{w}$. But the tradeoff is that for averaging models, they are more sensitive to the initial choice of σ^2, and therefore we need to use cross-validation to determine the best choice of variance beforehand. Furthermore, thanks to the merits of structured mean-field inference, which does not impose strict assumptions on the independence of latent variables, BayesPA topic models parallel their batch alternatives in accuracy. Moreover, all the supervised models are significantly better than the unsupervised spLDA in classification, reaching the state-of-the-art performance on the tested datasets.

Table 2 visualizes the learnt topic representation by paMedLDA$^{\text{ave}}$ and paMedLDA$^{\text{gibbs}}$. For the displayed categories, we plot the corresponding classifier's topic distribution averaged over the positive examples and top words from the topic matrix. As we can see, the average topic distributions become increasingly sparse as more and more data are observed. Eventually, the averaged topic distribution for each category contains only 1$\sim$2 non-zero entries and meanwhile different categories have quite diverse average topic distributions, therefore showing strong discriminative ability of the topic representations in distinguishing different categories. Such sparse and discriminatrive patterns are similar to what have been shown in batch settings (Zhu et al., 2012, 2014b).

7.2 Extensions

We now present the experimental results on the extensions of BayesPA topic models. We first present the results of nonparametric topic modeling on the same 20NG dataset. Then we demonstrate multi-task learning on a large Wikipedia dataset with more than 1 million documents and about 1 million unique terms.

7.2.1 NONPARAMETRIC TOPIC MODELING

Recall the nonparametric extensions of BayesPA topic models paMedHDP$^{\text{ave}}$ and paMedHDP$^{\text{gibbs}}$. To validate the advantage of online learning, we test them against their corresponding batch algorithms (i.e., the models MedHDP$^{\text{ave}}$ and MedHDP$^{\text{gibbs}}$) on the 20NG corpus. We also include an unsupervised baseline as the comparison model, the truncation-free HDP topic model (tfHDP) (Wang and Blei, 2012b), which is first used to discover the latent topic representations, and then combined with a linear SVM classifier for document categorization. For all HDP-based models, the following parameter setting is used: $\boldsymbol{\alpha} = 5 \cdot \mathbf{1}, \boldsymbol{\gamma} = 0.5 \cdot \mathbf{1}$ and $\eta = 1$. As an initial number of topic numbers

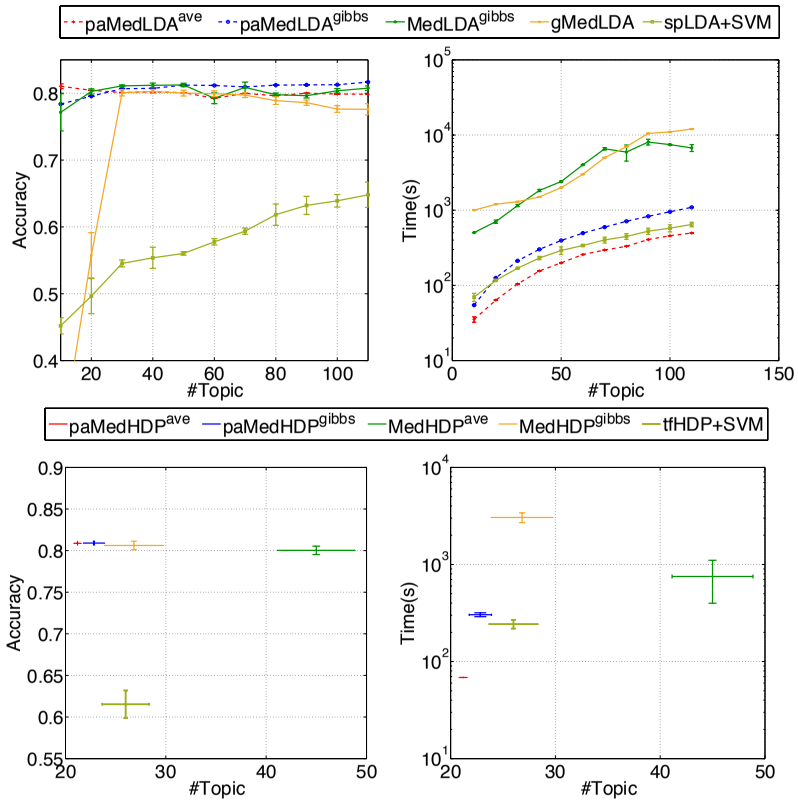

Figure 4: Classification accuracy and running time of various models with respect to the number of topics on the 20NG dataset.

for HDP to start with, we choose $K = 20$. We observed that the training time and the prediction accuracy do not depend heavily on the initial number of topics. The other parameters of BayesPA are the same.

Figure 3 shows the convergence of paMedHDP$^{\text{ave}}$ and paMedHDP$^{\text{gibbs}}$, and Figure 4 plots the accuracy and time together with the inferred topic numbers, where the length of the horizontal bars represents the variance of the inferred topic numbers. The results are summarized from five different runs. As we can see, the nonparametric extensions of BayesPA topic models also dramatically improve time efficiency and converge to corresponding batch algorithms in prediction performance. Furthermore, the averaging models are again faster to train because they do not need to update the covariance matrix of classifier weights.

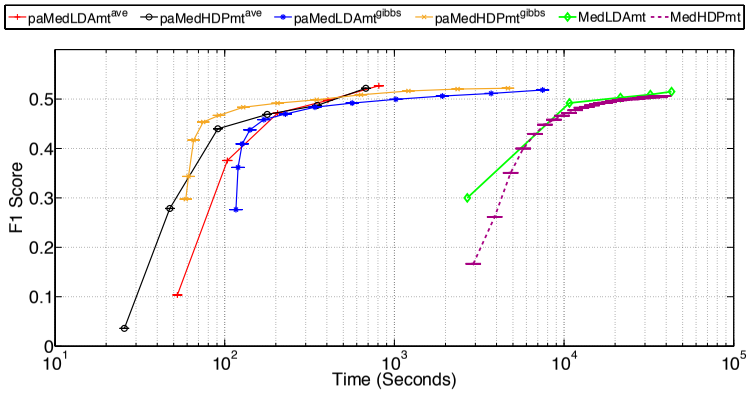

Figure 5: F1 scores of various multi-task topic models with respect to the running time on the 1.1M wikipedia dataset.

7.2.2 MULTI-TASK CLASSIFICATION

We test paMedLDAmt$^{\text{ave}}$, paMedLDAmt$^{\text{gibbs}}$ and their nonparametric exentions on a large Wiki dataset. The Wiki dataset is built from the Wikipedia set used in PASCAL LSHC challenge 2012 [6]. The Wiki dataset is a collection of documents with labels up to 20 different kinds, while the data distribution among the labels is balanced. The training set consists of 1.1 millions of wikipedia documents and the testing test consists of 5,000 documents. The vocabulary contains 917,683 unique terms. To measure performance, we use F1 score, the harmonic mean of precision and recall.

As baseline batch algorithms, we include MedLDAmt, a recent multi-task extention of Gibbs MedLDA (Zhu et al., 2013). Since MedHDP is a new model, there is no exising implementation of multi-task batch versions. So we instead extended MedHDP to support multi-task inference. We call this model MedHDPmt.

We use the same validation scheme as previous to select batchsize $|B| = 1, c = 5000, \sigma^2 = 10^{-6}$ for paMedLDAmt$^{\text{ave}}$; We choose $|B| = 512, c = 1, \sigma^2 = 1$ for paMedLDAmt$^{\text{gibbs}}$. For both models, the Dirichlet parameters are $\boldsymbol{\alpha} = 0.8 \cdot \mathbf{1}, \boldsymbol{\gamma} = 0.5 \cdot \mathbf{1}$, and $\epsilon = 1$. We use $K = 40$ topics for MedLDA models. The nonparametric extensions use exactly the same parameter settings except that $\boldsymbol{\alpha} = 5 \cdot \mathbf{1}, \eta = 1$ and we do not need to specify the topic number K.

Figure 5 shows the F1 scores of various models as a function of training time. We find that BayesPA topic models produce comparable results with their batch counterparts, but the training time is significantly less. With either Gibbs or averaging classifiers, BayesPA is about two orders of magnitude faster than their batch counterparts. Therefore, BayesPA topic models could potentially be applied to large-scale multi-class settings.

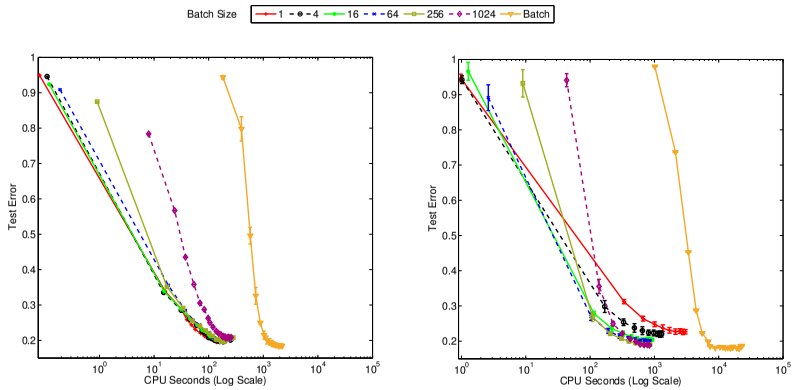

Figure 6: Test errors of paMedLDA$^{\text{ave}}$ (left) and paMedLDA$^{\text{gibbs}}$ (right) with different batch sizes on the 20NG dataset.

7.3 Sensitivity Analysis

We provide further discussions on BayesPA learning for topic models. We analyze the models' sensitivity to some key parameters.

Batch Size $|B|$: Figure 6 presents the test errors of BayesPA topic models (paMedLDA$^{\text{ave}}$, paMedLDA$^{\text{gibbs}}$) as a function of training time on the entire 20NG dataset with various batch sizes. The number of topics is fixed at $K = 40$. We can see that the convergence speeds of different algorithms vary. First of all, the batch algorithms suffer from multiple passes through the dataset and therefore are much slower than the online alternatives. Second, we could observe that algorithms with medium batch sizes ($|B| = 64$ or 256) converge faster. If we choose a batch size too small, for example, $|B| = 1$, each iteration would not provide sufficient evidence for the update of global variables; if the batch size is too large, each mini-batch becomes redundant and the convergence rate also decreases. By comparing the two figures, we find that paMedLDA$^{\text{ave}}$ runs faster than paMedLDA$^{\text{gibbs}}$. This is because for averaging classifers, we do not update the covaraince of the classifier weights, which requires frequent matrix inverse operations. Furthermore, paMedLDA$^{\text{ave}}$ appears to be more robust against change in batchsize. Similarly, Figure 7 shows the sensitivity experiment of the batchsize parameter in paMedHDP models. The results are similar to paMedLDA models, that is, a moderate batchsize leads to faster convergence.

Number of iterations $\mathcal{I}$ and samples $\mathcal{J}$: Since the time complexity of Algorithm 2 is linear in both $\mathcal{I}$ and $\mathcal{J}$, we would like to know how these parameters influence the quality of the trained models. First, we analyze which setting of $(\mathcal{I}, \mathcal{J})$ guarantees good performance. Fix $\beta = 0, K = 40$. Figure 8 presents the results. First, the number of samples $\mathcal{J}$ does not have a large effect on the accuracy. Second, the peformance of paMedLDA$^{\text{gibbs}}$ and paMedHDP$^{\text{gibbs}}$ is not sensitive the number of optimization round, but paMedLDA$^{\text{ave}}$ and paMedHDP$^{\text{ave}}$ suffers largely if $\mathcal{I} = 1$. This is because with averaging classifiers, the sampling of latent variable $\boldsymbol{Z}$ relies not only on global

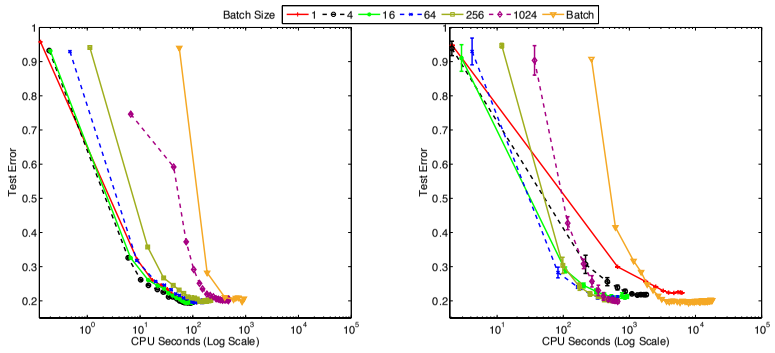

Figure 7: Test errors of paMedHDP$^{\text{ave}}$ (left) and paMedHDP$^{\text{gibbs}}$ (right) with different batch sizes on the 20NG dataset.

parameters, but also on a local variable τ, so more optimization rounds are needed. The training time of all models scale linearly in terms of $\mathcal{I}$ and $\mathcal{J}$.

$\mathcal{J}$ \ β	0	2	4
1	0.802		
3	0.803	0.803	
5	0.805	0.805	0.803

(a)

$\mathcal{J}$ \ β	0	2	4
1	0.783		
3	0.803	0.799	
5	0.808	0.803	0.792

(b)

Table 3: Effect of the number of local samples and burn-in steps for **(a).** paMedLDA$^{\text{ave}}$; and **(b).** paMedLDA$^{\text{gibbs}}$.

Notice that the first β samples are discarded as burn-in steps. To understand how large β is sufficient, we consider the settings of the pairs $(\mathcal{J}, \beta)$ and check the prediction accuracy of Algorithm 2 for $K = 40$. Based on the sensitivity analysis of $\mathcal{I}$ and $\mathcal{J}$, we fix $\mathcal{I} = 1$ for paMedLDA$^{\text{gibbs}}$, paMedHDP$^{\text{gibbs}}$ and $\mathcal{I} = 2$ for paMedLDA$^{\text{ave}}$, paMedHDP$^{\text{ave}}$. The results are shown in Table 3. We can see that accuracy scores closer to the diagonal of the table are relatively lower, while settings with the same number of kept samples, e.g. $(\mathcal{J}, \beta) = (3, 0), (5, 2), (9, 6)$, yield similar results. Therefore, the number of kept samples exhibits a more significant role in the performance of BayesPA topic models than the number of burn-in steps.

Number of Topics. Finally, we observed an accuracy degradation phenomenon when running one-pass BayesPA with a large number of topics on small datasets. To see this effect, we test on a small binary classification dataset, which consists of the documents from the two groups $alt.atheism$ and $talk.religion.misc$ in the 20 newsgroup dataset. The training set contains 1,597

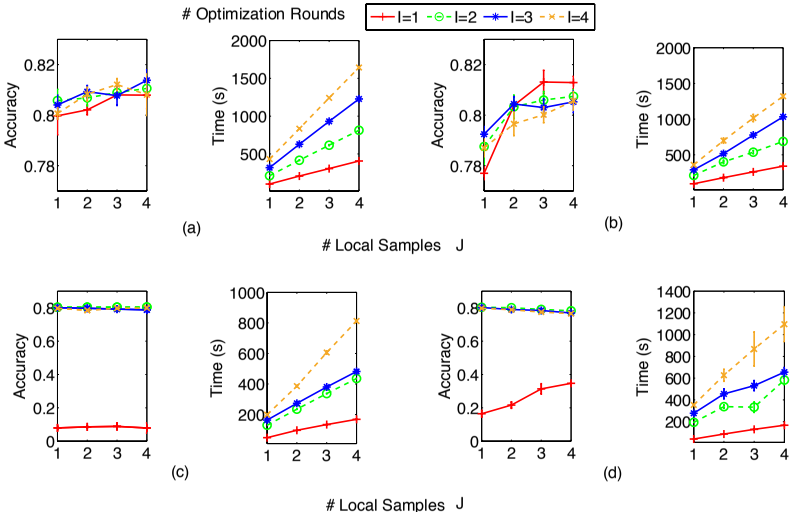

Figure 8: Classification accuracies and training time of **(a)**: paMedLDA$^{\text{gibbs}}$, **(b):** paMedHDP$^{\text{gibbs}}$, **(c)**: paMedLDA$^{\text{ave}}$, and **(d):** paMedHDP$^{\text{ave}}$, with different combinations of $(\mathcal{I}, \mathcal{J})$ on the 20NG dataset. The x-axis includes different values of $\mathcal{J}$, while different values of $\mathcal{I}$ are shown as separate lines.

documents with a split of 795/802 over the two categories and the test set contains 401 documents with a split of 204/197. For clarity, we report the results of the online BayesPA with a Gibbs MedLDA classifier, whose hyper-parameters are set as in the multi-class setting.

As shown in Figure 9 (the red curve), when the number of topics increases to relatively large, the classification accuracy drops significantly for Gibbs MedLDA with a single pass of the dataset. We believe this phenomenon is due to the fact that with a limited number of data points and a large number of parameters, the online BayesPA fails to converge in just one pass. Two possible strategies can be used to make this algorithm practically useful:

- **Multiple Scans**: In this strategy, we simply scan the dataset for multiple passes. As shown in Figure 9, this method works well — with five passes, BayesPA can learn the topic model with more than 100 topics well and lead to improved accuracy when K is in the range of $[50, 100]$. However, one disadvantage of this strategy is that it takes more computational resources, linear to the number of scans.

- **Ghost Samples**: In this strategy, we create ghost copies of the data, that is, for every data point $(\boldsymbol{x}_d, y_d)$, we make $L - 1$ exact clones. Then in our global update equation, each aggregation

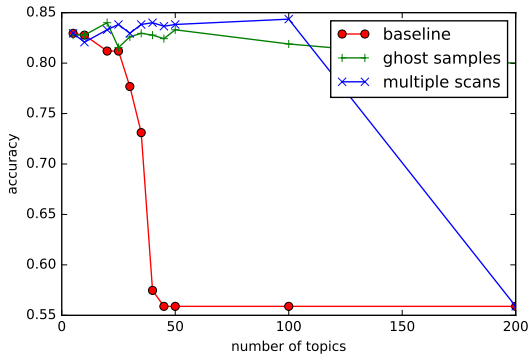

Figure 9: Solving the performance degradation issue with a couple of practical approaches: **baseline**: the model without any modifications, where degradation issues emerge. **ghost copies**: create $L = 10$ copies for every mini-batch. **multiple scan**: run the model with total of five passes over the dataset.

of sufficient statistics will be multiplied by an extra factor of L. This strategy works well too, as shown in Figure 9, although slightly worse than the strategy of multiple scans. One advantage of this strategy is that it does not increase the computation burden.

8. Conclusions and Future Work

We present online Bayesian Passive-Aggressive (BayesPA) learning as a new framework for max-margin Bayesian inference on streaming data. For fixed but large-scale datasets, online BayesPA effectively explores the statistical redundancy by repeatedly drawing samples and leads to faster convergence. We show that BayesPA subsumes the online PA, and more significantly generalizes naturally to incorporate latent variables and to perform nonparametric Bayesian inference, therefore providing great flexibility for explorative analysis. Based on the ideas of BayesPA, we develop efficient online learning algorithms for max-margin topic models as well as their nonparametric extensions which can automatically infer the unknown topic numbers. Empirical experiments on 20Newsgroups and a large-scale Wikipedia multi-label dataset demonstrate significant improvements on time efficiency, while maintaining comparable results.

As for future work, we are interested in developing highly scalable, distributed (Broderick et al., 2013) BayesPA learning paradigms, which will better meet the demand of processing massive real data available today. We are also interested in applying BayesPA to develop efficient algorithms for more sophisticated max-margin Bayesian models, such as the latent feature relational models (Zhu, 2012). Finally, a theoretical analysis of the regret bounds for BayesPA needs to be systematically carried out for both averaging and Gibbs classifiers.

Appendix A.

We show the objective in (27) is an upper bound of that in (13), that is,

$$\mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t)\Big) - \mathbb{E}_q\Big[\log(\psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t | \boldsymbol{Z}_t, \boldsymbol{w}))\Big] \geq \mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)\Big) + 2c \sum_{d \in B_t} \mathbb{E}_q\Big[(\xi_d)_+\Big], \quad (45)$$

where $\mathcal{L}(q) = \mathbf{KL}[q || q_t(\boldsymbol{w}, \boldsymbol{\Phi}) q_0(\boldsymbol{Z}_t)]$.

Proof We first have

$$\mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t, \boldsymbol{\lambda}_t)\Big) = \mathbb{E}_q\left[\log \frac{q(\boldsymbol{\lambda}_t \mid \boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t) q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)}{q_t(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)}\right],$$

and

$$\mathcal{L}\Big(q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)\Big) = \mathbb{E}_q\left[\log \frac{q(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)}{q_t(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)}\right].$$

Comparing these two equations and canceling out common factors, we know that in order for (45) to make sense, it suffices to prove

$$\mathbb{H}[q'] - \mathbb{E}_{q'}[\log(\psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t | \boldsymbol{Z}_t, \boldsymbol{w})] \geq 2c \sum_{d \in B_t} \mathbb{E}_{q'}[(\xi_d)_+] \quad (46)$$

is uniformly true for any given $(\boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)$, where $\mathbb{H}(\cdot)$ is the entropy operator and $q' = q(\boldsymbol{\lambda}_t \mid \boldsymbol{w}, \boldsymbol{\Phi}, \boldsymbol{Z}_t)$. The inequality (46) can be reformulated as

$$\mathbb{E}_{q'}\left[\log \frac{q'}{\psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t | \boldsymbol{Z}_t, \boldsymbol{w})}\right] \geq 2c \sum_{d \in B_t} \mathbb{E}_{q'}[(\xi_d)_+] \quad (47)$$

Exploiting the convexity of the function $\log(\cdot)$, i.e.

$$-\mathbb{E}_{q'}\left[\log \frac{\psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t | \boldsymbol{Z}_t, \boldsymbol{w})}{q'}\right] \geq -\log \int_{\boldsymbol{\lambda}_t} \psi(\boldsymbol{Y}_t, \boldsymbol{\lambda}_t | \boldsymbol{Z}_t, \boldsymbol{w})\, d\boldsymbol{\lambda}_t,$$

and utilizing the equality (26), we then have (47) and therefore prove (45). ■

Abstract

Obtaining labels can be costly and time-consuming. Active learning allows a learning algorithm to intelligently query samples to be labeled for a more efficient learning. Fisher information ratio (FIR) has been used as an objective for selecting queries. However, little is known about the theory behind the use of FIR for active learning. There is a gap between the underlying theory and the motivation of its usage in practice. In this paper, we attempt to fill this gap and provide a rigorous framework for analyzing existing FIR-based active learning methods. In particular, we show that FIR can be asymptotically viewed as an upper bound of the expected variance of the log-likelihood ratio. Additionally, our analysis suggests a unifying framework that not only enables us to make theoretical comparisons among the existing querying methods based on FIR, but also allows us to give insight into the development of new active learning approaches based on this objective.

Keywords: classification active learning, Fisher information ratio, asymptotic log-loss, upper-bound minimization.

1. Introduction

In supervised learning, a *learner* is a model-algorithm pair that is optimized to (semi) automatically perform tasks, such as classification, or regression using information provided by an external source (oracle). In *passive learning*, the learner has no control over the information given. In *active learning*, the learner is permitted to *query* certain types of information from the oracle (Cohn et al., 1994). Usually there is a cost associated with obtaining information from an oracle; therefore an active learner will need to maximize the information gained from queries within a fixed budget or minimize the cost of gaining a desired level of information. A majority of the existing algorithms restrict to the former problem, to get the most efficiently trained learner by querying a fixed amount of knowledge (Settles, 2012; Fu et al., 2013).

Active learning is the process of coupled querying/learning strategies. In such an algorithm, one needs to specify a query quality measure in terms of the learning method that uses the new information gained at each step of querying. For instance, information theoretic measures are commonly employed in classification problems to choose training samples whose class labels, considered as random variables, are most informative with respect to the labels of the remaining unlabeled samples. This family of measures is particularly helpful when probabilistic approaches are used for classification. Among these objectives, Fisher information criterion is very popular due to its relative ease of computation compared to other information theoretic objectives, desirable statistical properties and existence of effective optimization techniques. However, as we discuss in this manuscript, this objective is not well-studied in the classification context and there seems to be a gap between the underlying theory and the motivation of its usage in practice. *This paper is an attempt to fill this gap and also provide a rigorous framework for analyzing the existing querying methods based on Fisher information.*

From the statistical point of view, we characterize the process of constructing a classifier in three steps as follows: (1) choosing the loss and risk functions, (2) building a decision rule that minimizes the risk, and (3) modeling the discriminant functions of the decision rule. For instance, choosing the simple 0/1 loss and its a posteriori expectation as the risk, incurs the Bayes rule as the optimal decision (Duda et al., 1999), where the discriminant function is the posterior distribution of the class labels given the covariates. For this type of risk, discriminative models that directly parametrize the posteriors, such as logistic regression, are popularly used to learn the discriminant functions (Bishop, 2006). In order to better categorize the existing techniques, we break an active learning algorithm into the following sub-problems:

(i) *(Query Selection)* Sampling a set of covariates $\{\mathbf{x}_1, ..., \mathbf{x}_n\}$ from the *training* marginal[1], whose labels $\{y_1, ..., y_n\}$ are to be requested from an external source of knowledge (the *oracle*). The queried covariates together with their labels form the *training* data set.

(ii) *(Inference)* Estimating parameters of the posterior model based on the training data set formed in the previous step.

(iii) *(Prediction)* Making decisions regarding class labels of the *test* covariates sampled from the *test* marginal.

These three steps can be carried out iteratively. Note that the query selection subproblem is formulated in terms of the distribution from which the queries will be drawn.

1. Throughout this paper, marginal distribution or simply distribution refers to the distribution of covariates, while joint distribution is used for pairs of the covariates and their class labels.

Ideally, queries (or the query distribution) are chosen such that they increase the expected quality of the classification performance measured by a particular objective function. This objective can be constructed from two different perspectives: based on the accuracy of the parameter inference or the accuracy of label prediction. In the rest of the manuscript, accordingly, we refer to the algorithms that use these two types of objectives as *inference-based* or *prediction-based* algorithms, respectively.

Most of the inference-based querying algorithms in classification aim to choose queries that maximize the expected change in the objective of the inference step (Settles et al., 2008; Guo and Schuurmans, 2008) or Fisher information criterion (Hoi et al., 2006; Settles and Craven, 2008; Hoi et al., 2009; Chaudhuri et al., 2015b). On the other hand, the wide range of studies in prediction-based active learning includes a more varied set of objectives: for instance, the prediction error probability[2] (Cohn et al., 1994; Freund et al., 1997; Zhu et al., 2003; Nguyen and Smeulders, 2004; Dasgupta, 2005; Dasgupta et al., 2005; Balcan et al., 2006; Dasgupta et al., 2007; Beygelzimer et al., 2010; Hanneke et al., 2011; Hanneke, 2012; Awasthi et al., 2013; Zhang and Chaudhuri, 2014), variance of the predictions (Cohn et al., 1996; Schein and Ungar, 2007; Ji and Han, 2012), uncertainty of the learner with respect to the unknown labels as evaluated by the entropy function (Holub et al., 2008), mutual information (Guo and Greiner, 2007; Krause et al., 2008; Guo, 2010; Sourati et al., 2016), and margin of the samples with respect to the trained hyperplanar discriminant function (Schohn and Cohn, 2000; Tong and Koller, 2002).

In this paper, we focus on the Fisher information criterion used in classification active learning algorithms. These algorithms use a scalar function of the Fisher information matrices computed for parametric models of training and test marginals. In the classification context, this scalar is sometimes called *Fisher information ratio (FIR)* (Settles and Craven, 2008) and its usage is motivated by older attempts in optimal experiment design for statistical regression methods (Fedorov, 1972; MacKay, 1992; Cohn, 1996; Fukumizu, 2000).

Among the existing FIR-based classification querying methods, only the very first one proposed by Zhang and Oles (2000) approached the FIR objective from a parameter inference point of view. Using a maximum likelihood estimator (MLE), they claimed (with the proof skipped) that FIR is asymptotically equal to the expectation of the log-likelihood ratio with respect to both test and training samples (see sub-problem i above). Later on, Hoi et al. (2006) and Hoi et al. (2009), inspired by Zhang and Oles (2000), used FIR in connection with a logistic regression classifier with the motivation of decreasing the labels' uncertainty and hence the prediction error. Settles and Craven (2008) employed this objective with the same motivation, but using a different approximation and optimization technique. More recently, Chaudhuri et al. (2015b) showed that even finite-sample FIR is closely related to the expected log-likelihood ratio of an MLE-based classifier. However, their results are derived under a different and rather restricting set of conditions and assumptions: they focused on the finite-sample case where the test marginal is a uniform PMF and the proposal marginal is a general PMF (to be determined) over a finite pool of unlabeled samples. Moreover, they assumed that the conditional Fisher information matrix is assumed to be independent of the class labels. Here, in a framework similar to Zhang and Oles (2000) but with a more

2. Prediction error probability is indeed the frequentist risk function of 0/1 loss, and is also known as *generalization error*.

expanded and different derivation, we discuss a novel theoretical result based on which FIR is related to an MLE-based inference step for a large number of training data. More specifically, under certain regularity conditions required for consistency of MLE and in the absence of model mis-specification, and with no restricting assumptions on the form of test or training marginals, we show that FIR can be viewed as an upper bound for the expected variance of the asymptotic distribution of the log-likelihood ratio. Inspired by Chaudhuri et al. (2015b), we also show that under certain extra conditions, this relationship holds even in finite-sample case.

There are two practical issues in employing FIR as a query selection objective: its computation and optimization. First, computing the Fisher information matrices is usually intractable, except for very simple distributions; also FIR depends on the true marginal, which is usually unknown. Therefore, even if the computations are tractable, approximations have to be used for evaluating FIR. Second, the optimization of FIR is straightforward only if a single query is to be selected per iteration, or when the optimization has continuous domain (e.g., optimizing to get the real parameters of the query marginal as in Fukumizu, 2000). However, the optimization becomes NP-hard when multiple queries are to be selected from a countable set of unlabeled samples (*pool-based batch* active learning). Heuristics have been used to approximate such combinatorial optimization, such as greedy methods (Settles and Craven, 2008) and relaxation to continuous domains (Guo, 2010). Another strategy is to take advantage of *monotonic submodularity* of the objective set functions. If the objective is shown to be monotonically submodular, efficient greedy algorithms can be used for optimization with guaranteed tight bounds (Krause et al., 2008; Azimi et al., 2012; Chen and Krause, 2013). Regarding FIR, Hoi et al. (2006) proved that, when a logistic regression model is used, a Monte-Carlo simulation of this objective is a monotone and submodular set function in terms of the queries.

In addition to our theoretical contribution in asymptotically relating FIR to the log-likelihood ratio, we clarify the differences between some of the existing FIR-based querying methods according to the techniques that they use to address the evaluation and optimization issues. Furthermore, we show that monotonicity and submodularity of Monte-Carlo approximation of FIR can be extended from logistic regression models to *any* discriminative classifier. Here is a summary of our contributions in this paper:

- Establishing a relationship between the Fisher information matrix of the query distribution and the asymptotic distribution of the log-likelihood ratio (Section 4.1);
- Showing that FIR can be viewed as an upper bound of the expected asymptotic variance of the log-likelihood ratio, implying that minimizing FIR, as an active learning objective, is asymptotically equivalent to upper-bound minimization of the expected variance of the log-likelihood ratio, as a measure of inference performance (Section 4.2);
- Proving that under certain assumptions, the above-mentioned asymptotic relationship also holds for finite-sample estimation of FIR (Section 5.1.1);
- Discussing different existing methods for coping with practical issues in using FIR in querying algorithms (Section 5.1), and accordingly providing a unifying framework for existing FIR-based active learning methods (Section 5.2).

- Proving submodularity for the Monte-Carlo simulation of FIR under *any* discriminative classifier, assuming a pool-based active learning which enables access to approximations of Fisher information matrices of both test and training distributions (Lemma 7 and Theorem 8).

Before going through the main discussion in Section 4, we formalize our classification model assumptions, set the notations and review the basics and some of the key properties of our inference method, maximum likelihood estimation, in Sections 2 and 3. The statistical background required to follow the remaining sections is given in Appendix A.

2. The Framework and Assumptions

In this paper, we deal with classification problems, where each covariate, represented by a feature vector $\mathbf{x}$ in vector space X, is associated with a numerical class label y. Assuming that there are $1 < c < \infty$ classes, y can take any integer among the set $\{1, ..., c\}$. Suppose that the pairs $(\mathbf{x}, y)$ are distributed according to a parametric joint distribution $p(\mathbf{x}, y|\,\boldsymbol{\theta})$, with the parameter space denoted by $\Omega \subseteq \mathbb{R}^d$. Using a set of observed pairs as the training data, $\mathcal{L}_n := \{(\mathbf{x}_1, y_1), ..., (\mathbf{x}_n, y_n)\}$, we can estimate $\boldsymbol{\theta}$ and predict the class labels of the unseen test samples, e.g., by maximizing $p(y|\,\mathbf{x}, \boldsymbol{\theta})$. In active learning, the algorithm is permitted to take part in designing $\mathcal{L}_n$ by choosing a set of data points $\{\mathbf{x}_1, ..., \mathbf{x}_n\}$, for which the class labels are then generated using an external oracle.

In addition to the framework described in the last section (see subproblems i to iii), we make the following assumptions regarding the oracle, our classification model and the underlying data distribution:

(A0). The dependence of the joint distribution to the parameter $\boldsymbol{\theta}$ comes only from the class-conditional distribution and the marginal distribution does not depend on $\boldsymbol{\theta}$, that is,

$$p(\mathbf{x}, y|\,\boldsymbol{\theta}) \;=\; p(y|\,\mathbf{x}, \boldsymbol{\theta}) p(\mathbf{x}). \tag{1}$$

Zhang and Oles (2000) referred to joint distributions with such parameter dependence as type-II models, as opposed to type-I models which have parameter dependence in both class conditionals and marginal. They argue that active learning is more suitable for type-II models. Moreover, maximizing the joint with respect to the parameter vector in this model, becomes equivalent to maximizing the posterior $p(y|\,\mathbf{x}, \boldsymbol{\theta})$ (inference step in sub-problem ii).

(A1). *(Identifiability):* The joint distribution $P_{\boldsymbol{\theta}}$, whose density is given by $p(\mathbf{x}, y|\,\boldsymbol{\theta})$, is identifiable for different parameters. Meaning that for every distinct parameter vectors $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ in Ω, $P_{\boldsymbol{\theta}_1}$ and $P_{\boldsymbol{\theta}_2}$ are also distinct. That is,

$$\forall\, \boldsymbol{\theta}_1 \neq \boldsymbol{\theta}_2 \in \Omega \;\; \exists A \subseteq X \times \{1, ..., c\} \quad \text{s.t.} \quad P_{\boldsymbol{\theta}_1}(A) \neq P_{\boldsymbol{\theta}_2}(A).$$

(A2). The joint distribution $P_{\boldsymbol{\theta}}$ has common support for all $\boldsymbol{\theta} \in \Omega$.

(A3). *(Model Faithfulness):* For any $\mathbf{x} \in X$, we have access to an oracle that generates a label y according to the conditional $p(y|\,\mathbf{x}, \boldsymbol{\theta}_0)$. That is, the posterior parametric model matches the oracle distribution. We call $\boldsymbol{\theta}_0$ the true model parameter.

(A4). *(Training joint):* The set of observations in $\mathcal{L}_n := \{(\mathbf{x}_1, y_1), ..., (\mathbf{x}_n, y_n)\}$ are drawn independently from the *training/proposal/query* joint distribution of the form $p(y|\,\mathbf{x}, \boldsymbol{\theta}_0)$ $q(\mathbf{x})$, where q is the training marginal with no dependence on the parameter.

(A5). *(Test joint):* The unseen test pairs are distributed according to the *test/true* joint distribution of the form $p(y|\,\mathbf{x}, \boldsymbol{\theta}_0)p(\mathbf{x})$ where p is the test marginal with no dependence on the parameter.

(A6). *(Differentiability):* The log-conditional $\log p(y|\,\mathbf{x}, \boldsymbol{\theta})$ is of class $\mathcal{C}^3(\Omega)$ for all $(\mathbf{x}, y) \in X \times \{1, ..., c\}$, when being viewed as a funtion of the parameter.[3]

(A7). The parameter space Ω is compact and there exists an open ball around the true parameter of the model $\boldsymbol{\theta}_0 \in \Omega$.

(A8). *(Invertibility):* The Fisher information matrix (reviewed in Section 3.2) of the joint distribution is positive definite and therefore invertible for all $\boldsymbol{\theta} \in \Omega$, and for any type of marginal that is used under assumption (A0).

Regarding assumptions (A4) and (A5), note that the training and test marginals are not necessarily equal. The test marginal is usually not known beforehand and q cannot be set equal to p in practice, hence q can be viewed as a proposal distribution. Such inconsistency is what Shimodaira (2000) called *covariate shift in distribution*. In the remaining sections of the report, we use subscripts p and q for the statistical operators that consider $p(\mathbf{x})$ and $q(\mathbf{x})$ as the marginal in the joint distribution, respectively. We explicitly mention $\mathbf{x}$ as the input argument in order to refer to marginal operators. For instance, $\mathbb{E}_q$ denotes the joint expectation with respect to $q(\mathbf{x})p(y|\,\boldsymbol{\theta}, \mathbf{x})$, whereas $\mathbb{E}_{q(\mathbf{x})}$ denotes the marginal expectation with respect to $q(\mathbf{x})$.

3. Background

Here, we provide a short review of maximum likelihood estimation (MLE) as our inference method, and briefly introduce Fisher information of a parametric distribution. These two basic concepts enable us to explain some of the key properties of MLE, upon which our further analysis of FIR objective relies. Note that our focus in this section is on subproblem (ii) with the assumptions listed above.

3.1 Maximum Likelihood Estimation

Here, we review maximum likelihood estimation in the context of classification problem. Given a training data set $\mathcal{L}_n = \{(\mathbf{x}_1, y_1), ..., (\mathbf{x}_n, y_n)\}$, a maximum likelihood estimate (MLE) is obtained by maximizing the log-likelihood function over all pairs inside $\mathcal{L}_n$, with respect to the parameter $\boldsymbol{\theta}$:

$$\hat{\boldsymbol{\theta}}_n \;=\; \arg\max_{\boldsymbol{\theta}} \;\; \log p\left(\mathcal{L}_n \,|\, \boldsymbol{\theta}\right). \tag{2}$$

3. We say that a function $f : X \to Y$ is of $\mathcal{C}^p(X)$, for an integer $p > 0$, if its derivatives up to the p-th order exist and are continuous at all points of X.

Under the assumptions (A0) and (A4), the optimization in (2) can be written as

$$\hat{\boldsymbol{\theta}}_n \;=\; \arg\max_{\boldsymbol{\theta}} \;\sum_{i=1}^{n} \log p(y_i|\,\mathbf{x}_i, \boldsymbol{\theta}). \tag{3}$$

Equation (3) shows that MLE does not depend on the marginal when using type-II model. Hence, in our analysis we focus on the conditional log-likelihood as the classification objective, and simply call it the log-likelihood function when viewed as a function of the parameter vector $\boldsymbol{\theta}$, for any given pair $(\mathbf{x}, y) \in X \times \{1, ..., c\}$:

$$\ell(\boldsymbol{\theta}; \mathbf{x}, y) \;:=\; \log p(y|\,\mathbf{x}, \boldsymbol{\theta}). \tag{4}$$

Moreover, for any set of pairs independently generated from the joint distribution of the training data, such as $\mathcal{L}_n$ mentioned in (A4), the log-likelihood function will be

$$\ell(\boldsymbol{\theta}; \mathcal{L}_n) \;=\; \sum_{i=1}^{n} \ell(\boldsymbol{\theta}; \mathbf{x}_i, y_i) \;=\; \sum_{i=1}^{n} \log p(y_i|\,\mathbf{x}_i, \boldsymbol{\theta}). \tag{5}$$

Hence, the MLE can be rewritten as

$$\hat{\boldsymbol{\theta}}_n \;=\; \arg\max_{\boldsymbol{\theta}} \;\sum_{i=1}^{n} \ell(\boldsymbol{\theta}; \mathbf{x}_i, y_i). \tag{6}$$

Doing this maximization usually involves the computation of the stationary points of the log-likelihood, which requires calculating $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathcal{L}_n) = \sum_{i=1}^{n} \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathbf{x}_i, y_i)$. For models assumed in (A0), each of the derivations in the summation is equal to the *score function* defined as the gradient of the joint log-likelihood:

$$\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathbf{x}, y) \;=\; \nabla_{\boldsymbol{\theta}} \log p(y|\,\mathbf{x}, \boldsymbol{\theta}) \;=\; \nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, y|\,\boldsymbol{\theta}). \tag{7}$$

Equation (7) implies that the score will be the same no matter whether we choose the training or test distribution as our marginal. Furthermore, under regularity conditions (A6), the score is always a zero-mean random variable.[4]

Finally, using MLE to estimate $\hat{\boldsymbol{\theta}}_n$, class label of a test sample $\mathbf{x}$ will be predicted as the class with the highest log-likelihood value:

$$\hat{y}(\mathbf{x}) \;=\; \arg\max_{y} \ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y). \tag{8}$$

3.2 Fisher Information

In this section, we give a very short introduction to Fisher information. More detailed descriptions about this well-known criterion can be found in various textbooks, such as Lehmann and Casella (1998).

Fisher information of a parametric distribution is a measure of information that the samples generated from that distribution provide regarding the parameter. It owes part of its importance to the Cramér-Rao Theorem (see Appendix A.2, Theorem 19), which guarantees a lower-bound for the covariance of the parameter estimators.

Fisher information, denoted by $\mathbf{I}(\boldsymbol{\theta})$, is defined as the expected value of the outer-product of the score function with itself, evaluated at some $\boldsymbol{\theta} \in \Omega$. In our classification context, taking the expectation with respect to the training or test distributions gives us the training or test Fisher information criteria, respectively:

$$\begin{aligned} \mathbf{I}_q(\boldsymbol{\theta}) \;&:=\; \mathbb{E}_q\left[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, y|\,\boldsymbol{\theta}) \cdot \nabla_{\boldsymbol{\theta}}^{\top} \log p(\mathbf{x}, y|\,\boldsymbol{\theta})\right], \\ \mathbf{I}_p(\boldsymbol{\theta}) \;&:=\; \mathbb{E}_p\left[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x}, y|\,\boldsymbol{\theta}) \cdot \nabla_{\boldsymbol{\theta}}^{\top} \log p(\mathbf{x}, y|\,\boldsymbol{\theta})\right]. \end{aligned} \tag{9}$$

Here, we focus on $\mathbf{I}_q$ to further explain Fisher information criterion. Our descriptions can be directly generalized to $\mathbf{I}_p$ as well. First, note that from equation (7) and that the score function is always zero-mean, one can reformulate the definition as

$$\begin{aligned} \mathbf{I}_q(\boldsymbol{\theta}) \;&=\; \mathbb{E}_q\left[\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathbf{x}, y) \cdot \nabla_{\boldsymbol{\theta}}^{\top} \ell(\boldsymbol{\theta}; \mathbf{x}, y)\right] \\ &=\; \mathrm{Cov}_q\left[\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathbf{x}, y)\right]. \end{aligned} \tag{10}$$

Under the differentiability conditions (A6), it is easy to show that we can also write the Fisher information in terms of the Hessian matrix of the log-likelihood:

$$\mathbf{I}_q(\boldsymbol{\theta}) \;=\; -\mathbb{E}_q\left[\nabla_{\boldsymbol{\theta}}^2 \ell(\boldsymbol{\theta}; \mathbf{x}, y)\right]. \tag{11}$$

Recall that the subscript q in equations (10) and (11) indicates that the expectations are taken with respect to the joint distribution that uses $q(\mathbf{x})$ as the marginal, that is $p(\mathbf{x}, y|\,\boldsymbol{\theta}) = q(\mathbf{x}) p(y|\,\mathbf{x}, \boldsymbol{\theta})$. Expansion of the expectation in (11) results

$$\begin{aligned} \mathbf{I}_q(\boldsymbol{\theta}) \;&=\; -\mathbb{E}_{q(\mathbf{x})}\left[\mathbb{E}_{y|\,\mathbf{x},\boldsymbol{\theta}}\left[\nabla_{\boldsymbol{\theta}}^2 \ell(\boldsymbol{\theta}; \mathbf{x}, y)|\,\mathbf{x}, \boldsymbol{\theta}\right]\right] \\ &=\; -\int_{\mathbf{x} \in X} q(\mathbf{x}) \left[\sum_{y=1}^{c} p(y|\,\mathbf{x}, \boldsymbol{\theta}) \cdot \nabla_{\boldsymbol{\theta}}^2 \ell(\boldsymbol{\theta}; \mathbf{x}, y)\right] d\mathbf{x}\,. \end{aligned} \tag{12}$$

3.3 Some Properties of MLE

In this section, we formalize some of the key properties of MLE, which make this estimator popular in various fields. They are also very useful in the theoretical analysis of FIR, provided in the next section. More detailed descriptions of these properties, together with the proofs that are skipped here, can be found in different sources, such as Wasserman (2004) and Lehmann and Casella (1998).

Note that a full understanding of the properties described in this section requires the knowledge of different modes of statistical convergence, specifically, convergence in probability ($\xrightarrow{P}$), and convergence in law ($\xrightarrow{L}$). A brief overview of these concepts are given in Appendix A.

Theorem 1 (Lehmann and Casella (1998), Theorem 5.1) *If the assumptions (A0) to (A7) hold, then there exists a sequence of solutions* $\left\{\hat{\boldsymbol{\theta}}_n^*\right\}_{n=1}^{\infty}$ *to* $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathcal{L}_n) = 0$ *that converges to the true parameter* $\boldsymbol{\theta}_0$ *in probability.*

4. Score function is actually zero-mean even under weaker regularity conditions.

Note that Theorem 1 does not imply that convergence holds for *any* sequence of MLEs. Hence, if there are multiple solutions to equation $\nabla_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta};\mathcal{L}_n)=0$ (the equation to solve for finding the stationary points) for every n, it is not obvious which root to select as $\hat{\boldsymbol{\theta}}_n^*$ to sustain the convergence. Therefore, while consistency of the MLE is guaranteed for models with a unique root of the score function evaluated at $\mathcal{L}_n$, it is not trivial how to build a consistent sequence when multiple roots exist. Here, in order to remove this ambiguity, we assume that either the roots are unique, or become asymptotically unique, or we have access to an external procedure guiding us to select the proper roots so that $\hat{\boldsymbol{\theta}}_n \xrightarrow{P} \boldsymbol{\theta}_0$. We will denote the selected roots the same as $\hat{\boldsymbol{\theta}}_n$ from now on.

Theorem 2 (Lehmann and Casella 1998, Theorem 5.1) *Let $\hat{\boldsymbol{\theta}}_n$ be the maximum likelihood estimator based on the training data set $\mathcal{L}_n$. If the assumptions (A0) to (A8) hold, then the MLE $\hat{\boldsymbol{\theta}}_n$ has a zero-mean normal asymptotic distribution with the covariance equal to the inverse Fisher information matrix, and with the convergence rate of $1/2$:*

$$\sqrt{n}(\hat{\boldsymbol{\theta}}_n-\boldsymbol{\theta}_0) \;\xrightarrow{L}\; \mathcal{N}\left(\mathbf{0},\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\right). \tag{13}$$

Theorems 2 and Cramér-Rao bound (see Appendix A), together with the consistency assumption, i.e., $\hat{\boldsymbol{\theta}}_n \xrightarrow{P} \boldsymbol{\theta}_0$, imply that MLE is an asymptotically efficient estimator with the efficiency equal to the training Fisher information. One can rewrite (13) as

$$\sqrt{n}\cdot\mathbf{I}_q(\boldsymbol{\theta}_0)^{1/2}(\hat{\boldsymbol{\theta}}_n-\boldsymbol{\theta}_0) \;\xrightarrow{L}\; \mathcal{N}(\mathbf{0},\mathbb{I}_d). \tag{14}$$

In the following corollary, we see that if we substitute $\mathbf{I}_q(\boldsymbol{\theta}_0)$ with $\mathbf{I}_q(\hat{\boldsymbol{\theta}}_n)$, the new sequence still converges to a normal distribution:

Corollary 3 (Wasserman 2004, Theorem 9.18) *Under the assumptions given in Theorem 2, we get*

$$\sqrt{n}\cdot\mathbf{I}_q(\hat{\boldsymbol{\theta}}_n)^{1/2}(\hat{\boldsymbol{\theta}}_n-\boldsymbol{\theta}_0) \;\xrightarrow{L}\; \mathcal{N}\left(\mathbf{0},\mathbb{I}_d\right). \tag{15}$$

4. Fisher Information Ratio as an Upper Bound

In this section, we give our main theoretical analysis to relate FIR to the asymptotic distribution of the parameter log-likelihood ratio. Using the established relationship, we then show that FIR can be viewed as an asymptotic upper-bound of the expected variance of the loss function.

4.1 Asymptotic Distribution of MLE-Based Classifier

Recall that the estimated parameter $\hat{\boldsymbol{\theta}}_n$ is obtained from a given proposal distribution $q(\mathbf{x})$. The log-likelihood ratio function, at a given pair $(\mathbf{x},y)$, is defined as

$$\ell(\hat{\boldsymbol{\theta}}_n;\mathbf{x},y) \;-\; \ell(\boldsymbol{\theta}_0;\mathbf{x},y). \tag{16}$$

This ratio can be viewed as an example of the classification loss function whose expectation with respect to the test joint distribution of $\mathbf{x}$ and y, results in the *discrepancy* between the

true conditional $p(y|\mathbf{x},\boldsymbol{\theta}_0)$ and MLE conditional $p(y|\mathbf{x},\hat{\boldsymbol{\theta}}_n)$ (Murata et al., 1994). Here, we analyze this measure asymptotically as $(n\to\infty)$. Primarily, note that based on continuity of the log-likelihood function (A6) and consistency of MLE (Theorem 1), equation (16) converges in probability to zero for any $(\mathbf{x},y)$.

Furthermore, equation (16) is dependent on both the true marginal $p(\mathbf{x})$ (through the test pairs, where it should be evaluated) and the proposal marginal $q(\mathbf{x})$ (through the MLE $\hat{\boldsymbol{\theta}}_n$). In the classification context, Zhang and Oles (2000) claimed that the expected value of this ratio with respect to both marginals converges to $\mathrm{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\mathbf{I}_p(\boldsymbol{\theta}_0)]$ with the convergence rate equal to unity. In the scalar case, $\mathrm{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\mathbf{I}_p(\boldsymbol{\theta}_0)]$ is equal to the ratio of the Fisher information of the true and proposal distributions, the reason why it is sometimes referred to as the *Fisher information ratio* (Settles and Craven, 2008). This objective has been widely studied in linear and non-linear regression problems (Fedorov, 1972; MacKay, 1992; Murata et al., 1994; Cohn, 1996; Fukumizu, 2000). However, it is not as fully analyzed in classification.

Zhang and Oles (2000) and many papers following them (Hoi et al., 2006; Settles and Craven, 2008; Hoi et al., 2009), used this function as an *asymptotic* objective in active learning to be optimized with respect to the proposal q. Here, we show that this objective can also be viewed as an *upper bound* for the expected variance of the asymptotic distribution of (16).

First, we investigate the asymptotic distribution of the log-likelihood ratio in two different cases:

Theorem 4 *If the assumptions (A0) to (A8) hold, then, at any given $(\mathbf{x},y)\in X\times\{1,...,c\}$:*

(I) In case $\nabla_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\neq\mathbf{0}$, the log-likelihood ratio follows an asymptotic normality with convergence rate equal to $1/2$. More specifically,

$$\sqrt{n}\cdot\Big(\ell(\hat{\boldsymbol{\theta}}_n;\mathbf{x},y)-\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\Big) \;\xrightarrow{L}\; \mathcal{N}\Big(0,\mathrm{tr}\big[\nabla_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\cdot\nabla_{\boldsymbol{\theta}}^{\top}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\cdot\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\big]\Big). \tag{17}$$

(II) In case $\nabla_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)=\mathbf{0}$ and $\nabla^2_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)$ is non-singular, the asymptotic distribution of the log-likelihood ratio is a mixture of Chi-square distributions with one degree of freedom, and the convergence rate is one. More specifically,

$$n\cdot\Big(\ell(\hat{\boldsymbol{\theta}}_n;\mathbf{x},y) \;-\; \ell(\boldsymbol{\theta}_0;\mathbf{x},y)\Big) \;\xrightarrow{L}\; \sum_{i=1}^{d}\lambda_i\cdot\chi^2_1, \tag{18}$$

where λ_i's are eigenvalues of $\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1/2}\nabla^2_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\,\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1/2}$.

Proof Due to assumptions (A0) to (A7), Theorem 2 holds and therefore we have $\sqrt{n}\cdot(\hat{\boldsymbol{\theta}}_n-\boldsymbol{\theta}_0)\xrightarrow{L}\mathcal{N}(\mathbf{0},\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1})$. The rest of the proof is based on the Delta method in the two modes described in Appendix A (Theorems 16 and 17):

(I) $\nabla_{\boldsymbol{\theta}}\ell(\boldsymbol{\theta}_0;\mathbf{x},y)\neq\mathbf{0}$:

Since the expected log-likelihood function, evaluated at a given pair $(\mathbf{x}, y)$, is assumed to be continuously differentiable (A6) and that $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \neq \mathbf{0}$, we can apply Theorem 16 to $\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)$ to write:

$$\sqrt{n} \cdot \Big(\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) \;-\; \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \Big) \;\xrightarrow{L}\; \mathcal{N}\Big(0 \;,\; \nabla_{\boldsymbol{\theta}}^\top \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \cdot \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \Big), \tag{19}$$

where the scalar variance can also be written in a trace format.

(II) $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) = \mathbf{0}$ and $\nabla^2_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)$ non-singular :

In this case, the conditions in Theorem 17 are satisfied (with $\boldsymbol{\Sigma} = \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}$ and $g(\boldsymbol{\theta}) = \ell(\boldsymbol{\theta}; \mathbf{x}, y)$), and therefore we can directly write (18) from equations (51).

■

Theorem 4 regards the log-likelihood ratio (16) evaluated at any arbitrary pair $(\mathbf{x}, y)$. Note that if we consider the training pairs in $\mathcal{L}_n$, which are used to obtain $\hat{\boldsymbol{\theta}}_n$, it is known that the ratio evaluated at the training set converges to a single Chi-square distribution with degree one, that is,

$$\ell(\hat{\boldsymbol{\theta}}_n; \mathcal{L}_n) \;-\; \ell(\boldsymbol{\theta}_0; \mathcal{L}_n) \;\xrightarrow{L}\; \frac{1}{2}\chi^2_1. \tag{20}$$

Theorem 4 implies that variance of the asymptotic distribution of the log-likelihood ratio in case (I) is $\operatorname{tr}\big[\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \nabla_{\boldsymbol{\theta}}^\top \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\big]$, whereas in case (II), from Theorem 17 (see Appendix A), the variance is $\frac{1}{2} \left\| \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1/2} \nabla^2_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \, \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1/2} \right\|_F^2$. Therefore, it is evident that the variance of the log-likelihood ratio at any $(\mathbf{x}, y)$ is reciprocally dependent on the training Fisher information. From this point of view, one can set the training distribution such that it leads to a Fisher information that minimizes this variance. Unless the parameter and hence the Fisher information is univariate, it is not clear what objective to optimize with respect to q such that the resulting Fisher information minimizes the variance.

4.2 Establishing the Upper Bound

In the next theorem, we show that the Fisher information ratio , $\operatorname{tr}\big[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \mathbf{I}_p(\boldsymbol{\theta}_0)\big]$, is a reasonable candidate objective to minimize in order to get a training distribution q for the multivariate case.

Theorem 5 *If the assumptions (A0) to (A8) hold, then*

$$\mathbb{E}_p \Big[\operatorname{Var}_q \Big(\lim_{n\to\infty} \sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)] \Big) \Big] \;\leq\; \operatorname{tr}\Big[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \mathbf{I}_p(\boldsymbol{\theta}_0) \Big]. \tag{21}$$

The equality holds if the set of pairs $(\mathbf{x}, y)$ where we have zero score function at $\boldsymbol{\theta}_0$, i.e., $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) = \mathbf{0}$, has measure zero under the true joint distribution $P_{\boldsymbol{\theta}_0}$ in $X \times \{1, ..., c\}$.

Proof First note that $\operatorname{Var}_q \Big(\lim_{n\to\infty} \sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)] \Big)$ is well-defined for any given pair $(\mathbf{x}, y)$. We consider the two cases where the score $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)$ is non-zero and zero. In the former case, Theorem 4 shows that the sequence $\sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)]$

is asymptotically distributed according to a zero-mean normal distribution with variance shown in (17). On the other hand, when the score is zero, the rate of convergence of log-likelihood ratio is shown to be one. More specifically, Theorem 4 derives the asymptotic (non-degenerate) distribution of the sequence $n \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)]$. Based on Proposition 26, any sequence of random variables converging in law to a non-degenerate distribution is of $O_p(1)$, that is, $n \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)] = O_p(1)$ and therefore, $\sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)] = O_p\left(\frac{1}{\sqrt{n}}\right)$. Now, from Proposition 25, one can conclude that the sequence $\sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)]$ is of $o_p(1)$ and, by definition, converges in probability to zero. In other words, in case of zero score, the sequence $\sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)]$ converges in law to a degenerate distribution concentrated at zero and hence has zero asymptotic variance.

According to the analysis above, we can compute the expected value of the asymptotic variance by only considering regions with non-zero score. Define the region $R_0 \subseteq X \times \{1, ..., c\}$ as

$$R_0 \;:=\; \{(\mathbf{x}, y) | \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) = 0\}. \tag{22}$$

By this definition, the case of having zero score, $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) = 0$, happens with probability $P_{\boldsymbol{\theta}_0}(R_0)$, and non-zero score, $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \neq 0$, happens with probability $1 - P_{\boldsymbol{\theta}_0}(R_0)$. Considering these two cases and the analysis made above, variance of the asymptotic distribution of $\sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)]$ can be written as

$$\begin{aligned} &\operatorname{Var}\Big(\lim_{n\to\infty} \sqrt{n} \cdot [\ell(\hat{\boldsymbol{\theta}}_n; \mathbf{x}, y) - \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)] \Big) \\ &\quad= [1 - P_{\boldsymbol{\theta}_0}(R_0)] \cdot \operatorname{tr}\big[\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \nabla^\top_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \big] \;+\; P_{\boldsymbol{\theta}_0}(R_0) \cdot 0 \\ &\quad\leq\; \operatorname{tr}\big[\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \nabla^\top_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) \cdot \mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \big]. \end{aligned} \tag{23}$$

Taking the expectation of both sides with respect to the true joint gives the inequality (21). If the set of pairs $(\mathbf{x}, y)$ where $\nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) = \mathbf{0}$ form a zero measure set under $P_{\boldsymbol{\theta}_0}$, then $P_{\boldsymbol{\theta}_0}(R_0) = 0$ and we get equality in (23), hence an equality in (21). ■

Theorem 5 implies that minimizing the Fisher information ratio with respect to q, is indeed the upper-bound minimization of the expected variance of the asymptotic distribution of the log-likelihood ratio.

5. Fisher Information Ratio in Practice

In this section, we explain how inequality (21) can be utilized in practice as an objective function for active learning. The left-hand-side is the objective that is more reasonable to minimize from classification point of view. However, its optimization is intractable and FIR-based methods approximate it by its upper-bound minimization. Querying can be done with this objective by first learning the optimal proposal distribution q that minimizes the left-hand-side of inequality (21) and then drawing the queries from this optimal distribution:

$$q^* \;=\; \arg\min_q \;\operatorname{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \mathbf{I}_p(\boldsymbol{\theta}_0)] \tag{24a}$$

$$X_q \;\sim\; q^*(\mathbf{x}), \tag{24b}$$

where X_q is the set of queries whose samples are drawn from q^*. Note that in (24), due to the sampling process, X_q cannot be deterministically determined even by fixing all the other parameters leading to a fixed query distribution q^* (ignoring the uncertainties in the numerical optimization processes). Hence, this setting is sometimes called *probabilistic* active learning. Notice that in pool active learning, q should be constrained to be a PMF over the unlabeled pool from which the queries are to be chosen. Relaxing q to continuous distributions leads to *synthetic* active learning, since each time an unseen sample will be *synthesized* by sampling from q. We will see later that in some pool-based applications, the *objective functional* of q is approximated as a *set function* of X_q, and therefore a combinatorial optimization is performed directly with respect to the query set.

As mentioned, q^* is an upper-bound minimization of the expected asymptotic loss variance. Moreover, there are a number of unknown variables involved in FIR objective, such as $\mathbf{I}_p$ and $\boldsymbol{\theta}_0$. In practice, estimations of these unknown variables are used in the optimization process for active learning. Therefore, although the derivations in the previous section (Theorem 5) are made based on one querying of infinitely many samples, in active learning a finite-sample approximation of the cost function is used in an iterative querying process. As the number of querying iterations in active learning increases, the parameter estimates get more accurate and so does the approximate FIR objective. In the next section, we show that under certain assumptions the optimization with respect to proposal distribution in each iteration is yet another upper-bound minimization similar to (21). More specifically, Remark 6 (see Section 5.1.1) shows that although the proposal distribution is optimized separately in each iteration of an FIR-based active learning algorithm, minimizing the approximate FIR at each iteration is still an upper-bound minimization of the original cost function (i.e. left-hand-side of inequality 21).

Algorithm 0 shows steps of a general discriminative classification with active learning. We assume an initial training set $\mathcal{L}_{n_0} = \{(\mathbf{x}_1, y_1), ..., (\mathbf{x}_{n_0}, y_{n_0})\}$ is given based on which an initial MLE $\hat{\boldsymbol{\theta}}_{n_0}$ can be obtained. The initial MLE enables us to approximate the active learning objective function and therefore select queries for building the new training set. After obtaining the query set X_q, for each individual sample $\mathbf{x} \in X_q$, we request its labels $y(\mathbf{x})$ from the oracle, or equivalently, sample it from the true conditional, $y(\mathbf{x}) \sim p(y|\mathbf{x}, \boldsymbol{\theta}_0)$. These pairs are then added into the training set to get $\mathcal{L}_{n_1}$, which in turn, is used to update the parameter estimate to $\hat{\boldsymbol{\theta}}_{n_1}$. Size of the new training data is $n_1 = n_0 + |X_q|$. This procedure can be done repeatedly for a desirable number of iterations i_{max}. All different techniques that we discuss in the following sections, differ only in line 3 and the rest of the steps are common between them. Each active learning algorithm $\mathcal{A}$ takes the current estimate of the parameter $\hat{\boldsymbol{\theta}}_{n_{i-1}}$ possibly together with the unlabeled set of samples X_p, and generate a set of queries X_q to be labeled for the next iteration.

In our analysis in the subsequent sections, we focus on a specific *querying iteration* indexed by i (as a positive integer). For simplicity, we replace n_{i-1} and n_i (size of the training data set before and after iteration i) by n' and n, respectively. Hence, iteration i consists of using the available parameter estimate, $\hat{\boldsymbol{\theta}}_{n'}$, obtained through the current training data set $\mathcal{L}_{n'}$, to generate queries using a given querying algorithm $\mathcal{A}(\hat{\boldsymbol{\theta}}_{n'}, \mathcal{L}_{n'})$, and then update the classifier's parameter estimate accordingly to $\hat{\boldsymbol{\theta}}_n$.

In what follows, we first discuss practical issues in using FIR in query selection (Section 5.1) and then review existing algorithms based on this objective (Section 5.2).

Algorithm 0: Classification with Active Learning

Inputs: The initial training set $\mathcal{L}_{n_0}$; number of querying iterations i_{max}
Outputs: The trained classifier with MLE $\hat{\boldsymbol{\theta}}_{n_{i_{max}}}$

/* Initializations */
1 $\hat{\boldsymbol{\theta}}_{n_0} \leftarrow \arg\max_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathcal{L}_{n_0})$
/* Starting the Iterations */
2 **for** $i = 1 \rightarrow i_{max}$ **do**
/* Generating the query set by optimizing a querying objective */
3 $X_q \leftarrow \mathcal{A}(\mathcal{L}_{n_{i-1}}, \hat{\boldsymbol{\theta}}_{n_{i-1}})$
/* Request the queries' labels from the oracle */
4 $y(\mathbf{x}) \sim p(y|\mathbf{x}, \boldsymbol{\theta}_0) \quad \forall \mathbf{x} \in X_q$
/* Taking care of indexing */
5 $n_i \leftarrow n_{i-1} + |X_q|$
/* Update the training set and update MLE */
6 $\mathcal{L}_{n_i} \leftarrow \mathcal{L}_{n_{i-1}} \cup \left\{ \bigcup_{\mathbf{x} \in X_q} (\mathbf{x}, y(\mathbf{x})) \right\}$
7 $\hat{\boldsymbol{\theta}}_{n_i} \leftarrow \arg\max_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathcal{L}_{n_i})$
8 **return** $\hat{\boldsymbol{\theta}}_{n_{i_{max}}}$

5.1 Practical Issues

The main difficulties consist of (1) having unknown variables in the objective, such as the test marginal, $p(\mathbf{x})$, and the true parameter, $\boldsymbol{\theta}_0$, and (2) lack of closed form for Fisher information matrices for most cases. In the next two sections, we review different hacks and solutions that have been proposed to resolve these issues.

5.1.1 Replacing $\boldsymbol{\theta}_0$ by $\hat{\boldsymbol{\theta}}_{n'}$

Since $\boldsymbol{\theta}_0$ is not known, the simplest idea is to replace it by the current parameter estimate, that is $\hat{\boldsymbol{\theta}}_{n'}$ (Fukumizu, 2000; Settles and Craven, 2008; Hoi et al., 2006, 2009; Chaudhuri et al., 2015b). Clearly, as the algorithm keeps running the iterations (n' increases), the approximate objective (which contains $\boldsymbol{\theta}_{n'}$ instead of $\boldsymbol{\theta}_0$) gets closer to the original objective. This is due to the regularity and invertibility conditions assumed for the log-likelihood function and Fisher information matrices, respectively. Moreover, Chaudhuri et al. (2015b) analyzed how this approximation effects the querying performance in finite-sample case.

Their analysis is done only for pool-based active learning, and when the test marginal $p(\mathbf{x})$ is a *uniform distribution* $U(\mathbf{x})$ over the pool X_p. It is also assumed that the Hessian $\frac{\partial^2 \ell(\boldsymbol{\theta}; \mathbf{x}, y)}{\partial \boldsymbol{\theta}^2}$ is independent of the class labels y, and therefore can be viewed as the conditional Fisher information $\mathbf{I}(\boldsymbol{\theta}, \mathbf{x})$, or equivalently $\mathbf{I}_p(\boldsymbol{\theta}) = \mathbb{E}_{p(\mathbf{x})}[\mathbf{I}(\boldsymbol{\theta}, \mathbf{x})]$. Furthermore, there assumed to exist four positive constants $L_1, L_2, L_3, L_4 \geq 0$ such that the following four

inequalities hold for all $\mathbf{x} \in X_p$, $y \in \{1, ..., c\}$ and $\boldsymbol{\theta} \in \Theta$:

$$\begin{aligned} \nabla \ell(\boldsymbol{\theta}_0; \mathbf{x}, y)^\top \mathbf{I}_p(\boldsymbol{\theta}_0)^{-1} \nabla \ell(\boldsymbol{\theta}_0; \mathbf{x}, y) &\leq L_1 \\ \left\| \mathbf{I}_p(\boldsymbol{\theta}_0)^{-1/2} \mathbf{I}(\boldsymbol{\theta}_0, \mathbf{x}) \mathbf{I}_p(\boldsymbol{\theta}_0)^{-1/2} \right\| &\leq L_2 \\ \left\| \mathbf{I}_p(\boldsymbol{\theta}_0)^{-1/2} (\mathbf{I}(\boldsymbol{\theta}', \mathbf{x}) - \mathbf{I}(\boldsymbol{\theta}'', \mathbf{x})) \mathbf{I}_p(\boldsymbol{\theta}_0)^{-1/2} \right\| &\leq L_3 (\boldsymbol{\theta}' - \boldsymbol{\theta}'')^\top \mathbf{I}_p(\boldsymbol{\theta}_0) (\boldsymbol{\theta}' - \boldsymbol{\theta}'') \\ -L_4 \| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|_2 \mathbf{I}(\boldsymbol{\theta}_0, \mathbf{x}) \preceq \mathbf{I}(\boldsymbol{\theta}, \mathbf{x}) - \mathbf{I}(\boldsymbol{\theta}_0, \mathbf{x}) &\preceq L_4 \| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|_2 \mathbf{I}(\boldsymbol{\theta}_0, \mathbf{x}), \end{aligned} \tag{25}$$

where $\boldsymbol{\theta}'$ and $\boldsymbol{\theta}''$ are any two parameters in a fixed neighborhood of $\boldsymbol{\theta}_0$. Then, provided that n' is large enough, the following remark can be shown regarding the relationship between FIRs computed at $\boldsymbol{\theta}_0$ and an estimate $\hat{\boldsymbol{\theta}}_{n'}$:

Remark 6 *Let the assumptions (A0) to (A8) and those in (25) hold. Moreover, assume that the Hessian is independent of the class labels. If n' is large enough, then the following inequality holds for any $\beta \geq 10$ with high probability:*

$$\operatorname{tr}\left[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \mathbf{I}_p(\boldsymbol{\theta}_0)\right] \leq \frac{\beta+1}{\beta-1} \cdot \operatorname{tr}\left[\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})^{-1} \mathbf{I}_p(\hat{\boldsymbol{\theta}}_{n'})\right]. \tag{26}$$

The minimum value for n' that is necessary for having this inequality with probability $1-\delta$, increases quadratically with β and reciprocally with δ (Chaudhuri et al., 2015b, Lemma 2).

Proof It is shown in the proof of Lemma 2 in Chaudhuri et al. (2015a) that under assumptions mentioned in the statement, the following inequalities hold with probability $1-\delta$:

$$\frac{\beta-1}{\beta} \mathbf{I}(\mathbf{x}, \boldsymbol{\theta}_0) \preceq \mathbf{I}(\mathbf{x}, \hat{\boldsymbol{\theta}}_{n'}) \preceq \frac{\beta+1}{\beta} \mathbf{I}(\mathbf{x}, \boldsymbol{\theta}_0). \tag{27}$$

Taking expectation with respect to $p(\mathbf{x})$ and $q(\mathbf{x})$ results

$$\frac{\beta-1}{\beta} \mathbf{I}_p(\boldsymbol{\theta}_0) \preceq \mathbf{I}_p(\hat{\boldsymbol{\theta}}_{n'}) \preceq \frac{\beta+1}{\beta} \mathbf{I}_p(\boldsymbol{\theta}_0), \tag{28a}$$

$$\frac{\beta-1}{\beta} \mathbf{I}_q(\boldsymbol{\theta}_0) \preceq \mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'}) \preceq \frac{\beta+1}{\beta} \mathbf{I}_q(\boldsymbol{\theta}_0). \tag{28b}$$

Since $\mathbf{I}_q(\boldsymbol{\theta}_0)$ and $\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})$ are assumed to be positive definite, we can write (28b) in terms of inverted matrices:[5]

$$\frac{\beta}{\beta+1} \mathbf{I}_q^{-1}(\boldsymbol{\theta}_0) \preceq \mathbf{I}_q^{-1}(\hat{\boldsymbol{\theta}}_{n'}) \preceq \frac{\beta}{\beta-1} \mathbf{I}_q^{-1}(\boldsymbol{\theta}_0). \tag{29}$$

Now considering the first inequalities of (28a) and (29), multiplying both sides and taking the trace result (26). ■

Inequality (26) implies that minimizing $\operatorname{tr}\left[\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})^{-1} \mathbf{I}_p(\hat{\boldsymbol{\theta}}_{n'})\right]$ (or an approximation of it) with respect to q in each iteration of FIR-based querying algorithms, namely through the operation $\mathcal{A}(\mathcal{L}_{n'}, \hat{\boldsymbol{\theta}}_{n'})$ (line 3 of Algorithm 0), is equivalent to upper bound minimization of the original cost function, i.e. left-hand-side of (21).

5. For any two positive definite matrices $\mathbf{A}$ and $\mathbf{B}$, we have that $\mathbf{A} \succeq \mathbf{B} \Rightarrow \mathbf{A}^{-1} \preceq \mathbf{B}^{-1}$.

5.1.2 Monte-Carlo Approximation

Computation of Fisher information matrices is intractable unless when the marginal distributions are very simple or when they are restricted to be PMFs over finite number of samples. The latter is widely used in pool-based active learning, when the samples in the pool are assumed to be generated from $p(\mathbf{x})$. In such cases, one can simply utilize a Monte-Carlo approximation to compute $\mathbf{I}_p$. More specifically, denote the set of observed instances in the pool by X_p. Then the test Fisher information at any $\boldsymbol{\theta} \in \Omega$ can be approximated by

$$\mathbf{I}_p(\boldsymbol{\theta}) \approx \hat{\mathbf{I}}(\boldsymbol{\theta}; X_p) := \frac{1}{|X_p|} \sum_{\mathbf{x} \in X_p} \sum_{y=1}^{c} p(y|\mathbf{x}, \boldsymbol{\theta}) \nabla_{\boldsymbol{\theta}} \ell(\boldsymbol{\theta}; \mathbf{x}, y) \nabla_{\boldsymbol{\theta}}^\top \ell(\boldsymbol{\theta}; \mathbf{x}, y) + \delta \cdot \mathbb{I}_d, \tag{30}$$

where δ is a small positive number and the weighted identity matrix is added to ensure positive definiteness. It is important to give the practical remark that when using equation (30), we are actually using some of the test samples in the training process, hence we cannot use those in X_p in order to evaluate the performance of the trained classifier.

Similarly, $\mathbf{I}_q$ can be estimated based on a candidate query set X_q. Let X_q be the set of samples drawn independently from $q(\mathbf{x})$. Then, for any $\boldsymbol{\theta} \in \Theta$, we can have the approximation $\mathbf{I}_q(\boldsymbol{\theta}) \approx \hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)$. Putting everything together, the best query set $X_q \subseteq X_p$ is chosen to be the one that minimizes the approximate FIR querying objective,

$$\operatorname{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'}; X_q)^{-1} \hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'}; X_p)\right]. \tag{31}$$

Note that this objective is directly written in terms of X_q, and therefore the queries can be deterministically determined by fixing all the rest (including the current parameter estimate $\hat{\boldsymbol{\theta}}_{n'}$) and optimizing with respect to X_q. Therefore, such settings are usually called *deterministic* active learning, as opposed to the probabilistic nature of (24).

5.1.3 Bound Optimization

There are other types of approximation methods occurring in the optimization side. These methods are able to remove part of the unknown variables by doing upper-bound minimization or lower-bound maximization. Recall that in active learning, the querying objective is to be optimized with respect to q (or X_q in pool-based scenario). In a very simple example, when $d = 1$, note that the $\mathbf{I}_p(\boldsymbol{\theta}_0)$ is a constant scalar in (24a) and hence can be ignored. Hence, in the scalar case, we can simply focus on maximizing the training Fisher information. In the multivariate case, though it is not clear what measure of $\mathbf{I}_q(\hat{\boldsymbol{\theta}}_n)$ to optimize, one may choose the objective to be $|\mathbf{I}_q(\hat{\boldsymbol{\theta}}_n)|$ (where $|\cdot|$ is the determinant function),[6] or $\operatorname{tr}[\mathbf{I}_q(\hat{\boldsymbol{\theta}}_n)]$.[7] The latter is worth paying more attention due to the following inequality (Yang, 2000):

$$\operatorname{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1} \mathbf{I}_p(\boldsymbol{\theta}_0)] \leq \operatorname{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}] \cdot \operatorname{tr}[\mathbf{I}_p(\boldsymbol{\theta}_0)]. \tag{32}$$

Since $\operatorname{tr}[\mathbf{I}_p(\boldsymbol{\theta}_0)]$ is a constant with respect to q, minimizing the right-hand-side of inequality (21) can itself be approximated by another upper-bound minimization:

$$\arg\min_q \ \operatorname{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}]. \tag{33}$$

6. Similar to *D-optimality* in Optimal Experiment Design (Fedorov, 1972).
7. Similar to *A-optimality* in Optimal Experiment Design (Fedorov, 1972).

Table 1: Reviewed FIR-based active learning algorithms for discriminative classifiers

This helps removing the dependence of the objective to the test distribution p. A lower bound can also be established for the FIR. Using the inequality between arithmetic and geometric means of the eigenvalues of $\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\mathbf{I}_p(\boldsymbol{\theta}_0)$, one can see that $d \cdot |\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}| \cdot |\mathbf{I}_p(\boldsymbol{\theta}_0)| \leq \mathrm{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)^{-1}\mathbf{I}_p(\boldsymbol{\theta}_0)]$. Hence, when minimizing the upper-bound in (33), one should be careful about the determinant of this matrix as a term influencing the lower-bound of the objective.

In practice, of course, the minimization in (33) can be difficult due to matrix inversion. Thus, sometimes it is further approximated by

$$\arg\max_q \ \mathrm{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)]. \tag{34}$$

Hence, algorithms that aim to maximize $\mathrm{tr}[\mathbf{I}_q(\boldsymbol{\theta}_0)]$, indeed introduce two layers of objective approximations through equations (32) to (34). As discussed before, the dependence of the objectives in all the layers (in 33 or 34) on $\boldsymbol{\theta}_0$ can be removed by replacing it with the current estimate $\boldsymbol{\theta}_{n'}$.

5.2 Some Existing Algorithms

In this section, we discuss several existing algorithms for implementing the query selection task based on minimization of FIR. We will analyze these algorithms, sorted according to date of their publication, in the context of our unifying framework.

Besides the categorizations that have already been described in previous sections, it is also useful to divide the querying algorithms into two categories based on the size of X_q: *sequential active learning*, where a single sample is queried at each iteration, i.e., $|X_q| = 1$; and *batch active learning*, where the size of the query set is larger than one. The non-singleton query batches are usually generated greedily, with the batch size $|X_q|$ fixed to a constant value.

Table 1 lists the algorithms that we reviewed in the following sections together with a summary of their properties and the approximate objective that they optimize for querying. Note that among these algorithms, the one by Chaudhuri et al. (2015b) makes extra assumptions as is described in Section 5.1.1.

Algorithm 1 (Fukumizu, 2000)

This algorithm is the classification version of the *probabilistic active learning* proposed by Fukumizu (2000) for regression problem. The assumption is that the proposal belongs to a parametric family and is of the form $q(\mathbf{x};\boldsymbol{\alpha})$, where $\boldsymbol{\alpha}$ is the parameter vector of the

Algorithm 1: Fukumizu (2000)

Inputs: Current estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$, size of the query set $|X_q|$
Outputs: The query set X_q

/* Parameter Optimization */
$\hat{\boldsymbol{\alpha}} = \arg\max_{\boldsymbol{\alpha}} \mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\sum_{y=1}^{c} p(y|\,\mathbf{x},\hat{\boldsymbol{\theta}}_{n'})\nabla_{\boldsymbol{\theta}}^{\top}\ell(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x},y)\nabla_{\boldsymbol{\theta}}\ell(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x},y)\right]$
/* Sampling from the parametric proposal */
$\mathbf{x}_i \sim q(\mathbf{x};\hat{\boldsymbol{\alpha}}) \quad , i = 1,...,|X_q|$
return $X_q = \{\mathbf{x}_1,...,\mathbf{x}_{|X_q|}\}$

family. In this *parametric* active learning, the best set of parameters $\hat{\boldsymbol{\alpha}}$ is selected using the current parameter estimate and the query set is sampled from the resulting proposal distribution $X_q \sim q(\mathbf{x};\hat{\boldsymbol{\alpha}})$.

This algorithm makes no use of the test samples and optimizes the simplified objective in (34) to obtain the query distribution $q(\mathbf{x})$. Denote the covariates of the current training data set $\mathcal{L}_{n'}$ by $X_{\mathcal{L}}$. As is described in Section (5.1), the new trace objective can be approximated by Monte-Carlo formulation using the old queried samples $X_{\mathcal{L}}$ as well as the candidate queries X_q to be selected in this iteration:

$$\mathrm{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};X_{\mathcal{L}}\cup X_q)\right]. \tag{35}$$

More specifically, the new parameter vector is obtained by maximizing the expected contribution of the queries X_q generated from $q(\mathbf{x};\boldsymbol{\alpha})$ to this objective. Taking expectation of (35) with respect to $q(\mathbf{x};\boldsymbol{\alpha})$ yields

$$\mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\mathrm{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};X_{\mathcal{L}}\cup X_q)\right]\right] = \mathrm{tr}\left[\frac{n'}{n'+|X_q|}\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};X_{\mathcal{L}}) + \frac{1}{n'+|X_q|}\mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};X_q)\right]\right]. \tag{36}$$

Recall that n' is the size of the current training data set $\mathcal{L}_{n'}$. The first term in (36) is independent of the query set X_q (assuming that the size $|X_q|$ is fixed to a constant), hence we focus only on the second term in our optimization. Noting that the queries are generated independently, we can rewrite this term (excluding the constant coefficient) as

$$\mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\mathrm{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};X_q)\right]\right] = \frac{1}{|X_q|}\mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\sum_{\mathbf{x}\in X_q}\mathrm{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x})\right]\right] \tag{37}$$

From equation (37), the parameter vector $\boldsymbol{\alpha}$ can be obtained by maximizing the expected contribution of that single query to the trace objective. That is, having fixed $|X_q|$ to a constant, the optimization for determining the parameter vector would be

$$\begin{aligned}\hat{\boldsymbol{\alpha}} &= \arg\max_{\boldsymbol{\alpha}} \ \mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\mathrm{tr}\left[\hat{\mathbf{I}}(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x})\right]\right] \\ &= \arg\max_{\boldsymbol{\alpha}} \ \mathbb{E}_{q(\mathbf{x};\boldsymbol{\alpha})}\left[\sum_{y=1}^{c} p(y|\,\mathbf{x},\hat{\boldsymbol{\theta}}_{n'})\nabla_{\boldsymbol{\theta}}^{\top}\ell(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x},y)\nabla_{\boldsymbol{\theta}}\ell(\hat{\boldsymbol{\theta}}_{n'};\mathbf{x},y)\right].\end{aligned} \tag{38}$$

Algorithm 2: Zhang and Oles (2000)

Inputs: Current estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$
Outputs: The query singleton set $X_q = \{\mathbf{x}_q\}$

$\mathbf{x}_q \leftarrow \arg\max_{\mathbf{x}} \sum_{y=1}^{c} p(y|\mathbf{x}, \hat{\boldsymbol{\theta}}_{n'}) \nabla_{\boldsymbol{\theta}}^{\top} \ell(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}, y) \nabla_{\boldsymbol{\theta}} \ell(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}, y)$

return $X_q = \{\mathbf{x}_q\}$

The optimization (38) does not depend on $X_{\mathcal{L}}$, and therefore we do not need to explicitly feed this algorithm with $\mathcal{L}$. All it needs is an estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$. The two-step procedure of generating queries from parametric query distribution is shown in Algorithm 1. This algorithm can be used in both sequential and batch modes by changing the number of samples drawn from $q(\mathbf{x}; \alpha)$.

We emphasize that Algorithm 1 is probabilistic, meaning that with any fixed parameter estimate $\hat{\boldsymbol{\theta}}_{n'}$, the next set of queries are *not* deterministically selected. The optimization is performed with respect to the parameters of the proposal distribution, which are then used to sample X_q. Fukumizu (2000) claims that introducing such randomness into active learning, which increases exploration against exploitation, may prevent the algorithm from falling into local optima. Also note that this algorithm is not pool-based, meaning that it does not select the queries from a pool of observed instances, although could be constrained to do so.

Algorithm 2 (Zhang and Oles, 2000)

Zhang and Oles (2000) started from optimization problem (34), and introduced even additional simplifications to it. They specifically considered using a binary logistic regression classifier. Here, we discuss their formulation using a general discriminate framework.

In their algorithm, a single query is selected at each iteration. Denote it by $X_q = \{\mathbf{x}_q\}$. Similar to the previous section, the Fisher information matrix $\mathbf{I}_q$ can be approximated by Monte-Carlo approximation. Zhang and Oles (2000) discarded the expectation with respect to the proposal distribution in (38) or equivalently consider q to be a uniform distribution. Therefore, the optimization with respect to parameters turned into a direct optimization with respect to the single query $\mathbf{x}_q$:

$$\mathbf{x}_q = \arg\max_{\mathbf{x} \in X} \sum_{y=1}^{c} p(y|\mathbf{x}, \hat{\boldsymbol{\theta}}_{n'}) \nabla_{\boldsymbol{\theta}}^{\top} \ell(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}, y) \nabla_{\boldsymbol{\theta}} \ell(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}, y). \tag{39}$$

This single-step deterministic approach, shown in Algorithm 2, is very similar to the probabilistic approach described above, except that there is no intermediate parameter optimization step.

It is important to note that Algorithm 2 can be used in pool-based active learning as well. This can be done by constraining $\mathbf{x}_q$ to be a member of a pool of samples, in which case it can even be extended to batch querying by sorting the unlabeled samples based on their objective values and taking the highest ones. However, such iterative optimization is not efficient, because the resulting queries will most probably be close to each other and therefore contain redundant information.

Algorithm 3: Settles and Craven (2008)

Inputs: Current estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$, the set of unlabeled samples X_p, , size of the query set $|X_q|$
Outputs: The query set X_q

/* Initializing the query set for this iteration */
$X_q \leftarrow \varnothing$
/* The loop for greedy batch querying */
for $j = 1 \rightarrow |X_q|$ **do**
  /* Query optimization and adding the result into the query set */
  $X_q \leftarrow X_q \cup \arg\min_{\mathbf{x} \in X_p} \operatorname{tr}\left[\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}\right)^{-1} \hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_p\right)\right]$
  /* Removing the selected queries from the pool */
  $X_p \leftarrow X_p - X_q$
return X_q

Algorithm 3 (Settles and Craven, 2008)

Inspired by Zhang and Oles (2000), Settles and Craven (2008) employed Fisher information ratio to develop a pool-based active learning, which can be used in either sequential or batch querying. The pool that is used here is the set of unlabeled samples, X_p, which are assumed to be drawn from the test marginal $p(\mathbf{x})$. Queries are chosen from X_p, that is $X_q \subseteq X_p$. The test Fisher information matrix can be approximated by Monte-Carlo simulation over the samples in X_p, meaning $\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_p\right)$. Similar to Algorithm 1, the updated training Fisher information matrix after querying a set X_q can be approximated by $\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_{\mathcal{L}} \cup X_q\right)$. Thus, since we do have an approximation of both Fisher information matrices, the objective to minimize is chosen to be in the form of (31).

Similar to the Zhang and Oles (2000) algorithm, the proposal distribution q is ignored in the objective (or equivalently considered as being uniform). An additional assumption Settles and Craven (2008) made to simplify the optimization task is

$$\arg\min_{X_q \subset X_p} \operatorname{tr}\left[\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_{\mathcal{L}} \cup X_q\right)^{-1} \hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_p\right)\right] \approx \arg\min_{X_q \subset X_p} \operatorname{tr}\left[\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_q\right)^{-1} \hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_p\right)\right]. \tag{40}$$

This simplified optimization is easy to implement for sequential active learning. However, the combinatorial optimization required for batch active learning can easily become intractable. As shown in Algorithm 3, Settles and Craven (2008) used a greedy approach to do this optimization (the inner loop).

Algorithm 4 (Hoi et al., 2006, 2009)

The algorithms proposed by Hoi et al. (2006) and Hoi et al. (2009) are very similar to the one developed by Settles and Craven (2008), described above, except that they use a more sophisticated optimization method. Their method shown in Algorithm 4, is different

Algorithm 4: Hoi et al. (2006, 2009)

Inputs: Current estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$, the set of unlabeled samples X_p, size of the query set $|X_q|$

Outputs: The query set X_q

/* Initializing the query set */

1 $X_q \leftarrow \varnothing$

/* The loop for greedy batch querying */

2 **for** $j = 1 \rightarrow |X_q|$ **do**

/* Query optimization */

3 $\tilde{\mathbf{x}} = \arg\min_{\mathbf{x} \in X_p} \operatorname{tr}\left[\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_q \cup \{\mathbf{x}\}\right)^{-1} \hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_p\right)\right]$

/* Add the selected query into the query set */

4 $X_q \leftarrow X_q \cup \{\tilde{\mathbf{x}}\}$

/* Remove the selected instance from the pool */

5 $X_p \leftarrow X_p - \{\tilde{\mathbf{x}}\}$

6 **return** X_q

from Algorithm 3 mainly in the way that it greedily chooses the query at each inner loop iteration of the algorithm. While Algorithm 3 exclusively considers the contribution of each $\mathbf{x} \in X_q$, ignoring the samples selected in the previous iterations and considering only $\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; \mathbf{x}\right)$ in each iteration (line 3 of Algorithm 3), Algorithm 4 takes into account all the queries chosen so far and instead considers $\hat{\mathbf{I}}\left(\hat{\boldsymbol{\theta}}_{n'}; X_q \cup \{\mathbf{x}\}\right)$ in each querying optimization (line 3 in Algorithm 4).

Hoi et al. (2006) and Hoi et al. (2009) showed that when using *binary logistic regression* classifier, their optimization (40) can be done by maximizing a *submodular* set function with respect to the query set X_q. This allowed them to use the well-known iterative algorithm proposed by Nemhauser et al. (1978), which guarantees a tight lower-bound for maximization of submodular and monotone set functions.

In the rest of this section, we show that minimizing this objective obtained from the above-mentioned assumptions, can be efficiently approximated by a monotonically submodular maximizing under *any* discriminative classifier. This is a generalization of the result derived by Hoi et al. (2006) that is obtained in case of using logistic regression classifier. As a consequence, FIR can be efficiently optimized with guaranteed tight bounds (Nemhauser et al., 1978; Nemhauser and Wolsey, 1978). First, we show in the following lemma that (40) is approximately equivalent to maximizing a simplified set function, for any unlabeled sample pool X_p:

Lemma 7 *Let $X_p, X_q \subseteq X$ be two non-empty and finite sets of samples randomly generated from $p(\mathbf{x})$ and its resample distribution $q(\mathbf{x})$, respectively, such that $X_q \subset X_p$, and the parameter $\delta \geq 0$ in (30) is a small constant. If assumptions (A0), (A4), (A6) and (A8) hold, then the following optimization problems are approximately equivalent for some function $g_{\boldsymbol{\theta}} : X \times \{1, ..., c\} \times X \rightarrow \mathbb{R}^+$, d-dimensional non-zero vector $\mathbf{v}_{\boldsymbol{\theta}}$ depending on $\mathbf{x}$ and y, and*

for all $\boldsymbol{\theta} \in \Omega$:

$$(i) \quad \arg\min_{X_q \subset X_p} \operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)^{-1} \hat{\mathbf{I}}(\boldsymbol{\theta}; X_p)\right], \tag{41a}$$

$$(ii) \quad \arg\max_{X_q \subset X_p} \sum_{\mathbf{x} \in X_p - X_q} \sum_{y=1}^{c} \frac{-1}{\delta \cdot \| \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)\|^{-2} + \sum_{\mathbf{x}' \in X_q} g_{\boldsymbol{\theta}}(\mathbf{x}, y, \mathbf{x}')}. \tag{41b}$$

The approximation is more accurate for smaller δ and well-conditioned Monte-Carlo approximation of proposal Fisher information matrix.

The proof can be found in Appendix C. Note that Lemma 7, as stated above, does not depend on the size of X_q. However, just as before, in practice it is usually assumed that $|X_q| > 0$ is fixed and therefore the optimizations in (41) should be considered with cardinality constraint. In general, combinatorial maximization problems can turn out to be intractable. Next, it is shown that the objective at hand is a monotonically submodular set function in terms of X_q and therefore can be maximized efficiently with a greedy approach such as that shown in Algorithm 4.

Theorem 8 *Suppose $f_{\boldsymbol{\theta}} : 2^{X_p} \rightarrow \mathbb{R}$ is defined as*

$$f_{\boldsymbol{\theta}}(X_q) = \sum_{\mathbf{x} \in X_p - X_q} \sum_{y=1}^{c} \frac{-1}{\delta \cdot \| \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)\|^{-2} + \sum_{\mathbf{x}' \in X_q} g_{\boldsymbol{\theta}}(\mathbf{x}, y, \mathbf{x}')}, \quad \forall X_q \subseteq X_p, \tag{42}$$

with $\mathbf{v}_{\boldsymbol{\theta}}$ a d-dimensional vector depending on $\mathbf{x}$ and y, and $g_{\boldsymbol{\theta}}$ defined in (91). Then $f_{\boldsymbol{\theta}}$ is a submodular and monotone (non-decreasing) set function for all $\boldsymbol{\theta} \in \Omega$.

The proof is in Appendix D. The result above, together with Lemma 7, imply that the objective of (41b) is a monotonically increasing set function with respect to X_q. Below we present the main result that guarantees tight bounds for greedy maximization of monotonic submodular set functions. Details of this result, which is also shown to be the optimally efficient solution to submodular maximization, can be found in the seminal papers by Nemhauser et al. (1978) and Nemhauser and Wolsey (1978).

Theorem 9 (Nemhauser et al. (1978)) *Let $f_{\boldsymbol{\theta}} : 2^{X_p} \rightarrow \mathbb{R}$ be any submodular and non-decreasing set function with $f(\varnothing) = 0$ satisfied.*[8] *If X_q is the output of a greedy maximization algorithm, and X_q^* is the optimal maximizer of $f_{\boldsymbol{\theta}}$ with a cardinality constraint (fixed $|X_q|$), then we have*

$$f_{\boldsymbol{\theta}}(X_q) \geq \left[1 - \left(\frac{|X_q| - 1}{|X_q|}\right)^{|X_q|}\right] f_{\boldsymbol{\theta}}(X_q^*) \geq \left(1 - \frac{1}{e}\right) f_{\boldsymbol{\theta}}(X_q^*). \tag{43}$$

In Algorithm 4, the inner loop (lines 2 to 5) implements the minimization in (40) greedily. We have seen above that this set minimization is approximately equivalent to maximizing a submodular and monotone set maximization, which, in turn, is shown to be efficient.

8. This can always be assumed since maximizing a general set function $f(X_q)$ is equivalent to maximizing its adjusted version $g(X_q) := f(X_q) - f(\varnothing)$, which satisfies $g(\varnothing) = 0$.

Algorithm 5 (Chaudhuri et al., 2015b)

This algorithm uses FIR for doing a probabilistic pool-based active learning. It has extra assumptions in comparison to our general framework, which are briefly explained in Section 5.1.1. Note that these assumptions are to be made as well as those listed in Section 2. In such settings, Chaudhuri et al. (2015b) gave a finite-sample theoretical analysis for FIR when applied to pool-based active learning.

More specifically, suppose $p(\mathbf{x})$ is a uniform PMF and $q(\mathbf{x})$ is a general PMF, both defined over the pool X_p. Using the notations in (25), the training Fisher information can be written as $\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'}) = \sum_{\mathbf{x}\in X_p} q(\mathbf{x})\,\mathbf{I}(\hat{\boldsymbol{\theta}}_{n'}, \mathbf{x})$. Now, assuming that $\mathbf{I}_p(\hat{\boldsymbol{\theta}}_{n'})$ has a singular decomposition of the form $\sum_{j=1}^{d} \sigma_j \mathbf{u}_j \mathbf{u}_j^\top$, FIR can be written as

$$\begin{aligned} \operatorname{tr}\Big[\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})^{-1}\,\mathbf{I}_p(\hat{\boldsymbol{\theta}}_{n'})\Big] &= \sum_{j=1}^{d} \sigma_j \operatorname{tr}\Big[\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})^{-1}\mathbf{u}_j\mathbf{u}_j^\top\Big] \\ &= \sum_{j=1}^{d} \sigma_j \mathbf{u}_j^\top\,\mathbf{I}_q(\hat{\boldsymbol{\theta}}_{n'})^{-1}\mathbf{u}_j. \end{aligned} \tag{44}$$

Minimizing the last term in (44) with respect to PMF $\{q(\mathbf{x})|\,\mathbf{x}\in X_p\}$ is equivalent to a semidefinite programming after introducing a set of auxiliary variables $t_j, j =, 1..., d$ and applying Schur complements (Vandenberghe and Boyd, 1996):

$$\begin{aligned} \underset{q(\mathbf{x}),\mathbf{x}\in X_p}{\arg\min} \quad & \sum_{j=1}^{d} \sigma_j t_j \\ \text{such that} \quad & \begin{bmatrix} t_j & \mathbf{u}_j^\top \\ \mathbf{u}_j & \sum_{\mathbf{x}\in X_p} q(\mathbf{x})\,\mathbf{I}(\hat{\boldsymbol{\theta}}_{n'}, \mathbf{x}) \end{bmatrix} \succeq 0, \\ & \sum_{\mathbf{x}\in X_p} q(\mathbf{x}) = 1. \end{aligned} \tag{45}$$

The steps for this querying method is shown in Algorithm 5. Note that the solution to (45) is slightly modified by mixing it with the uniform distribution over the pool. Such modification is mainly to establish their theoretical derivations. The mixing coefficient, $0 \le \lambda \le 1$, reciprocally depends on the number of queries. More specifically, Chaudhuri et al. (2015b) made it equal to $1 - \frac{1}{|X_q|^{1/6}}$. That is, as the number of queries increases, λ shrinks and so does the modification. Furthermore, in their analysis, they assumed that sampling from $\tilde{q}(\mathbf{x})$ (line 3 of Algorithm 5) is done *with replacement*. That is, label of a given sample might be queried multiple times.

5.2.1 Comparison with Other Information-theoretic Objectives

In the last part of this section, we compare FIR and two other common querying objectives from the field of information theory. Entropy of class labels and mutual information between labeled and unlabeled samples are two other common active learning objectives. Their goal is mainly to get the largest possible amount of information about *class labels of unlabeled samples* from each querying iteration, hence naturally pool-based.

Algorithm 5: Chaudhuri et al. (2015b)

Inputs: Current estimation of the parameter $\hat{\boldsymbol{\theta}}_{n'}$, the set of unlabeled samples X_p, size of the query set $|X_q|$

Outputs: The query set X_q

/* Solving the semidefinite programming */

1 $q(\mathbf{x}) \leftarrow$ solution to (45)

/* Modification of the solution */

2 $\tilde{q}(\mathbf{x}) \leftarrow \lambda q(\mathbf{x}) + (1-\lambda)U(\mathbf{x})$

/* Sampling with replacement from the modified proposal */

3 $\mathbf{x}_i \sim \tilde{q}(\mathbf{x}) \quad , i = 1, ..., |X_q|$

4 **return** $X_q = \{\mathbf{x}_1, ...\,\mathbf{x}_{|X_q|}\}$

Algorithm	Complexity
Entropy	$O(\lvert X_p\rvert cd)$
Mutual Information	$O\left(\lvert X_p\rvert \cdot \lvert X_q\rvert \cdot c^{\lvert X_q\rvert+1} d\right)$
Zhang and Oles (2000)	$O(\lvert X_p\rvert cd)$
Settles and Craven (2008)	$O\left(\lvert X_q\rvert \cdot \lvert X_p\rvert \cdot (cd + d^3)\right)$
Hoi et al. (2006, 2009)	$O\left(\lvert X_q\rvert \cdot \lvert X_p\rvert \cdot (cd + cd\lvert X_q\rvert + d^3)\right)$
Chaudhuri et al. (2015b)	$O\left(d^3\lvert X_p\rvert^2 + d^4\lvert X_p\rvert + d^5\right)$

Table 2: Computational complexity of different querying algorithms

Entropy-based querying, also known as uncertainty sampling, directly measures the uncertainty with respect to class label of each unlabeled sample and query those with highest uncertainty. It has been widely popular due to its simplicity and effectiveness especially in sequential active learning. However, it does not consider interaction between samples when selecting multiple queries, which can cause querying very similar samples (redundancy). Therefore, uncertainty sampling shows relatively poor performance in batch active learning. Mutual information, on the other hand, does not suffer from redundancy, however, it requires a much higher computational complexity.

These two objectives directly measure the amount of information each batch can have with respect to the class labels (hence prediction-based), as opposed to Fisher information as a measure of information regarding the distribution parameters (hence inference-based). However, there is no guarantee that by minimizing uncertainty of the class labels (or equivalently, choosing queries with highest amount of information about class labels), the prediction accuracy also increases. Whereas, as we showed earlier, FIR upper-bounds the expected asymptotic variance of a parameter inference loss function. From this point of view, FIR has a closer relationship with the performance of a classifier.

Table 2 shows computational complexity of the querying objectives. The algorithm by Fukumizu (2000) is excluded from this table since it cannot be used in pool-based sampling. Also note that the complexity reported for mutual information is for the case when it is optimized greedily. Nevertheless, it still contains an exponential term in its complexity. Entropy-based and Zhang and Oles (2000) have the lowest complexity, but in the expense of introducing redundancy into the batch of queries. Algorithms by Settles and Craven (2008), Hoi et al. (2006, 2009) and Chaudhuri et al. (2015b) become very expensive when d is large, whereas mutual information can easily get intractable for selecting batches of higher size (large $|X_q|$). Observe that algorithm by Hoi et al. (2006, 2009) is more expensive than Settles and Craven (2008). Recall that despite similarities in appearance, the former guarantees tight bound for its greedy optimization, whereas the latter does not.

The complexity for the algorithm by Chaudhuri et al. (2015b) is computed assuming that a barrier method (following path) is used as its numerical optimization (Boyd and Vandenberghe, 2004). From Table 2, this algorithm is the only one whose complexity increases quadratically with size of the pool $|X_p|$, and therefore can get significantly slow for huge pools. Furthermore, it does not depend on $|X_q|$ since the optimization in (45) as its main source of computations, only depends on $|X_p|$ and d. Furthermore, for this algorithm, computing $\mathbf{I}(\hat{\boldsymbol{\theta}}_{n'}, \mathbf{x})$ is assumed to cost $O(1)$ for each $\mathbf{x} \in X_p$ as it is taken to be independent of y.

6. Conclusion

In this paper, we focused on active learning algorithms in classification problems whose objectives are based on Fisher information criterion. As the primary result, we showed the dependency of the variance of the asymptotic distribution of log-likelihood ratio on the Fisher information of the training distribution. Then, we used this dependency to derive our novel theoretical contribution by establishing the Fisher information ratio (FIR) as the upper bound of expectation of such asymptotic variance. We also showed that replacing the true parameter by the current estimate does not remove such upper-boundedness provided that the current parameter estimate has been obtained using sufficient number of samples. Moreover, we discussed that several layers of approximations can be employed in practice to simplify FIR; simplifications, that can usually be avoided in pool-based active learning. Additionally, Monte-Carlo simulations and greedy algorithms can be used to evaluate and optimize the (simplified) FIR objective, respectively. Using this framework, we can distinguish the main differences between some of the existing FIR-based querying methods in the classification context. Such comparative analysis, not only shed light on the assumptions and simplifications of the existing algorithms, it can also be helpful for finding suitable directions in developing novel active learning algorithms based on the Fisher information criterion.

Finally, we remark that the log-likelihood ratio that is used here as the loss function is an inference-based performance metric. It naturally shows up based on the set of assumptions that are usually being made in FIR-based querying frameworks. The final goal of a classifier in machine learning is to predict labels of test samples as accurately as possible and therefore, arguably, prediction-based metrics such as 0/1 loss function better evaluate the performance of a classifier. While analyzing such metrics was out of scope of this paper,

analysis and development of querying algorithms using prediction-based metrics is definitely an exciting future research direction.

Appendix A. Statistical Background

Asymptotic analysis plays an important role in statistics. It considers extreme cases where the number of observations is increased with no bounds. In such scenarios, discussions on different notions of convergence of the sequence of random variables naturally arise. Generally speaking, there are three major types of stochastic convergence: *convergence in probability, convergence in law (distribution)* and *convergence with high probability (almost surely)*. Here, we focus on the two former modes of convergence, discuss two fundamental results based on them and formalize our notations regarding parameter estimators. Further details of the following definitions and results can be found in any standard statistical textbook such as Lehmann and Casella (1998).

A.1 Convergence of Sequence of Random Variables

Throughout this section, $\{\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, ..., \boldsymbol{\theta}_n, ...\}$, denoted simply by $\{\boldsymbol{\theta}_n\}$, is a sequence of multivariate random variables lying in $\Omega \subseteq \mathbb{R}^d$. Also suppose that $\boldsymbol{\theta}_0$ is a constant vector and $\tilde{\boldsymbol{\theta}}$ is another random variable in the same space Ω.

Definition 10 *We say that the sequence* $\{\boldsymbol{\theta}_n\}$ converges in probability *to* $\boldsymbol{\theta}_0$ *and write* $\boldsymbol{\theta}_n \xrightarrow{P} \boldsymbol{\theta}_0$, *iff for every* $\varepsilon > 0$ *we have*

$$P(|\theta_{ni} - \theta_{0i}| > \varepsilon) \;\rightarrow\; 0, \quad \textit{for all } i = 1, ..., d, \tag{46}$$

where θ_{ni} *is the* i*'th component of* $\boldsymbol{\theta}_n$.

Convergence in probability is invariant with respect to any continuous mapping:

Proposition 11 (Brockwell and Davis 1991, Proposition 6.1.4) *If* $\boldsymbol{\theta}_n \xrightarrow{P} \boldsymbol{\theta}_0$ *and* $g : \Omega \rightarrow \mathbb{R}$ *is a continuous function, then* $g(\boldsymbol{\theta}_n) \xrightarrow{P} g(\boldsymbol{\theta}_0)$.

Definition 12 *We say that a sequence* $\{\boldsymbol{\theta}_n\}$ converges in law (in distribution) *to the random variable* $\tilde{\boldsymbol{\theta}}$ *and write* $\boldsymbol{\theta}_n \xrightarrow{L} \tilde{\boldsymbol{\theta}}$, *iff the sequence of their joint CDFs,* F_n, *point-wise converges to the joint CDF of* $\tilde{\boldsymbol{\theta}}$*:*

$$F_n(\mathbf{a}) = P(\theta_{n1} \leq a_1, ..., \theta_{nd} \leq a_d) \;\rightarrow\; F(\mathbf{a}) = P(\tilde{\theta}_1 \leq a_1, ..., \tilde{\theta}_d \leq a_d) \quad \forall \mathbf{a} \in \mathcal{C}_F \subseteq \mathbb{R}^d, \tag{47}$$

where $\mathcal{C}_F$ *is the set of continuity points of the CDF* F.

Equation (47) means that for large values of n, the distribution of $\boldsymbol{\theta}_n$ can be well approximated by the distribution of $\tilde{\boldsymbol{\theta}}$. Note that throughout this paper, for simplicity, we say that a random sequence $\{\boldsymbol{\theta}_n\}$ converges to a distribution with density function $p(\boldsymbol{\theta})$, or write $\boldsymbol{\theta}_n \xrightarrow{L} p(\boldsymbol{\theta})$, instead of the full statement that $\{\boldsymbol{\theta}_n\}$ converges in law to a random variable with that distribution.

Note that $\boldsymbol{\theta}_n \xrightarrow{P} \boldsymbol{\theta}_0$ suggests that $\boldsymbol{\theta}_n - \boldsymbol{\theta}_0 \xrightarrow{L} \delta(\boldsymbol{\theta})$ where δ is the Kronecker delta function, which can be viewed as the density function of a degenerate distribution at $\boldsymbol{\theta} = \mathbf{0}$. This, however, does not give any information about the speed with which $\boldsymbol{\theta}_n$ converges to $\boldsymbol{\theta}_0$. In order to take the rate into account, we consider the convergent distribution of the sequence $\{a_n \cdot (\boldsymbol{\theta}_n - \boldsymbol{\theta}_0)\}$, where a_n is any sequence of positive integers and $a_n \to \infty$(as $n \to \infty$). In practice a_n is usually considered to have the form n^r with $r > 0$.

Definition 13 *Assume $\boldsymbol{\theta}_n \xrightarrow{P} \boldsymbol{\theta}_0$. We say that the sequence $\{\boldsymbol{\theta}_n\}$ converges to $\boldsymbol{\theta}_0$ with* rate of convergence *$r > 0$, iff $n^r(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0)$ converges in law to a random variable with non-degenerate distribution. Furthermore, the non-degenerate distribution is called the* asymptotic distribution *of $\boldsymbol{\theta}_n$.*

Next, we discuss some of the classic results in asymptotic statistics:

Theorem 14 (Law of Large Numbers, Brockwell and Davis 1991) *Let $\boldsymbol{\theta}_1, ..., \boldsymbol{\theta}_n$ be a set of independent and identically distributed (i.i.d) samples. If $\mathbb{E}[\boldsymbol{\theta}_i] = \boldsymbol{\mu}$, then*

$$\bar{\boldsymbol{\theta}}_n \;=\; \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\theta}_i \;\xrightarrow{P}\; \boldsymbol{\mu}\,. \tag{48}$$

Theorem 15 (Central Limit Theorem, Lehmann and Casella 1998) *Let $\boldsymbol{\theta}_1$,..., $\boldsymbol{\theta}_n$ be a set of i.i.d samples with mean $\mathbb{E}[\boldsymbol{\theta}_i] = \boldsymbol{\mu}$ and covariance $\mathrm{Cov}[\boldsymbol{\theta}_i] = \boldsymbol{\Sigma}$ (with a symmetric and positive semi-definite matrix $\boldsymbol{\Sigma}$), then the sequence of sample averages $\{\bar{\boldsymbol{\theta}}_n\}$ with $\bar{\boldsymbol{\theta}}_n = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{\theta}_i$ converges to the true mean with convergence rate $1/2$. Moreover, its asymptotic distribution is a zero-mean Gaussian distribution with covariance matrix $\boldsymbol{\Sigma}$, that is,*

$$\sqrt{n} \cdot (\bar{\boldsymbol{\theta}}_n - \boldsymbol{\mu}) \;\xrightarrow{L}\; \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}). \tag{49}$$

The following results are very useful when deriving the asymptotic distribution of a random sequence under a continuous mapping:

Theorem 16 (Multivariate Delta Method, first order, Lehmann and Casella 1998) *Let $\{\boldsymbol{\theta}_n\}$ be a sequence of random variables such that it converges to $\boldsymbol{\theta}_0$ with rate of convergence $1/2$ and a normal asymptotic distribution, that is, $\sqrt{n} \cdot (\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) \xrightarrow{L} \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$. If $g : \mathbb{R}^d \to \mathbb{R}$ is a continuously differentiable mapping and $\nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) \neq \mathbf{0}$, then*

$$\sqrt{n} \cdot \Big[g(\boldsymbol{\theta}_n) - g(\boldsymbol{\theta}_0) \Big] \;\xrightarrow{L}\; \mathcal{N}\Big(0, \nabla_{\boldsymbol{\theta}}^{\top} g(\boldsymbol{\theta}_0)\, \boldsymbol{\Sigma}\, \nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)\Big)\,. \tag{50}$$

Theorem 17 (Multivariate Delta Method, second order) *Let $\{\boldsymbol{\theta}_n\}$ be a sequence of random variables such that it converges to $\boldsymbol{\theta}_0$ with rate of convergence $1/2$ and a normal asymptotic distribution, that is, $\sqrt{n} \cdot (\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) \xrightarrow{L} \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$. If $g : \mathbb{R}^d \to \mathbb{R}$ is a continuously differentiable mapping where $\nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) = \mathbf{0}$ and $\nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)$ is non-singular in a neighborhood of $\boldsymbol{\theta}_0$, then the sequence $\{g(\boldsymbol{\theta}_n) - g(\boldsymbol{\theta}_0)\}$ converges in law to a mixture of random variables with degree-one Chi-square distributions, and the rate of convergence is one. More specifically,*

$$n \cdot \Big[g(\boldsymbol{\theta}_n) - g(\boldsymbol{\theta}_0) \Big] \;\xrightarrow{L}\; \sum_{i=1}^{d} \lambda_i \chi^2_1, \tag{51}$$

where λ_i's are eigenvalues of $\boldsymbol{\Sigma}^{1/2}\, \nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)\, \boldsymbol{\Sigma}^{1/2}$. Moreover, variance of this asymptotic distribution can be written as

$$\frac{1}{2} \left\| \boldsymbol{\Sigma}^{1/2}\, \nabla^2_{\mathbf{x}} g(\mathbf{x}_0)\, \boldsymbol{\Sigma}^{1/2} \right\|_F^2, \tag{52}$$

where $\| \cdot \|_F$ is the Frobenius norm.

Proof For proof see Appendix B. ■

A.2 Parameter Estimation

Now suppose that the set of independent and identically distributed (i.i.d) set of samples $\mathbf{x}_1, ... \mathbf{x}_n$ are generated from an underlying distribution that belongs to a parametric family, for which the density function $p(\mathbf{x} \,|\, \boldsymbol{\theta})$ can be represented by a multivariate parameter vector $\boldsymbol{\theta}$. Assume the true parameter is $\boldsymbol{\theta}_0$, that is $\{\mathbf{x}_i\} \sim p(\mathbf{x} \,|\, \boldsymbol{\theta}_0), i = 1, ..., n$. An *estimator* $\boldsymbol{\theta}_n = \boldsymbol{\theta}(\mathbf{x}_1, ..., \mathbf{x}_n)$ is a function that maps the observed random variables to a point in the parameter space Ω. The subscript n in $\boldsymbol{\theta}_n$ indicates its dependence on the sample size. Since the observations are generated randomly, the estimators are also random and thus $\{\boldsymbol{\theta}_n\}$ can be viewed as a sequence of random variables. There are some reserved terms for such a sequence, which we introduce in the remaining of this section:

Definition 18 (Consistency) *We say that an estimator $\boldsymbol{\theta}_n$ is* consistent *iff $\boldsymbol{\theta}_n \xrightarrow{P} \boldsymbol{\theta}_0$.*

Based on Theorem 14, sample average of the observation set is a consistent estimator of the true mean of the samples. Another important characteristic of estimators is based on the following bound over their covariance matrices:

Theorem 19 (Cramér-Rao, Lehmann and Casella 1998) *Let $\mathbf{x}_1, ..., \mathbf{x}_n \sim p(\mathbf{x} \,|\, \boldsymbol{\theta}_0)$ and $\boldsymbol{\theta}_n = \boldsymbol{\theta}(\mathbf{x}_1, ..., \mathbf{x}_n)$ be an estimator. If the first moment of $\boldsymbol{\theta}_n$ is differentiable with respect to the parameter vector and its second moment is finite, then the following inequality holds for every $\boldsymbol{\theta} \in \Omega$:*

$$\mathrm{Cov}[\boldsymbol{\theta}_n] \;\succeq\; -\left(\nabla_{\boldsymbol{\theta}} \mathbb{E}[\boldsymbol{\theta}_n]\right)^{\top} \mathbf{I}(\boldsymbol{\theta})^{-1} \nabla_{\boldsymbol{\theta}} \mathbb{E}[\boldsymbol{\theta}_n]. \tag{53}$$

The right-hand-side of (53) is called the *Cramér-Rao bound* of the estimator, where the middle term is the inverse of the *Fisher information matrix* of the parametric distribution $p(\mathbf{x} \,|\, \boldsymbol{\theta})$, defined as

$$\mathbf{I}(\boldsymbol{\theta}) \;:=\; \mathbb{E}\left[\nabla_{\boldsymbol{\theta}} \log p(\mathbf{x} \,|\, \boldsymbol{\theta}) \cdot \nabla_{\boldsymbol{\theta}}^{\top} \log p(\mathbf{x} \,|\, \boldsymbol{\theta}) \right].$$

Theorem 19 suggests that for an unbiased estimator $\boldsymbol{\theta}_n$, the inequality over the covariance matrix becomes: $\text{Cov}[\boldsymbol{\theta}_n] \succeq \mathbf{I}(\boldsymbol{\theta})^{-1}, \forall\, \boldsymbol{\theta} \in \Omega$.

Definition 20 (Efficiency) *We say that an estimator $\boldsymbol{\theta}_n$ is* efficient*, iff it attains the Cramér-Rao bound, meaning that* $\text{Cov}[\boldsymbol{\theta}_n]$ *achieves the lower-bound in (53) for every* $n = 1, 2, \ldots$ *. Furthermore, we say that $\boldsymbol{\theta}_n$ is* asymptotically efficient*, iff the lower bound is attained asymptotically (when $n \to \infty$).*

Appendix B. Proof of Second-order Multivariate Delta Method

In order to prove this theorem, we have to formulate the statistical Taylor expansion. This, in turn, needs a brief introduction of stochastic order notations.

B.1 Stochastic Order Notations

The stochastic order notations are denoted by o_p and O_p, where the former is equivalent to convergence in probability (Definition 10) and the latter implies *boundedness in probability*. In what follows, if otherwise stated, $\{\boldsymbol{\theta}_n\}$ is a sequence of multivariate random variables lying in $\Omega \subseteq \mathbb{R}^d$ and $\{a_n\}$ is a sequence of strictly positive real numbers. The skipped proofs can be found in many textbooks on asymptotic theory, such as Brockwell and Davis (1991, Chapter 6).

Definition 21 *We write $\boldsymbol{\theta}_n = o_p(a_n)$ iff*

$$\frac{\theta_{in}}{a_n} \;=\; o_p(1), \quad \textit{for all } i = 1, ..., d \tag{54}$$

Definition 22 *We write $\boldsymbol{\theta}_n = O_p(a_n)$ iff the sequence $\left\{\frac{\theta_{in}}{a_n}\right\}$ is* bounded in probability *for every $i = 1, ..., d$, that is, for every $\epsilon > 0$ there exists δ_ϵ such that*

$$P\left(\left|\frac{\theta_{in}}{a_n}\right| > \delta_\epsilon\right) \;<\; \epsilon, \quad n = 1, 2, ... \tag{55}$$

We also need the following propositions:

Proposition 23 (Brockwell and Davis, 1991) *Let $\{\theta_n\}$ and $\{\eta_n\}$ be two sequences of scalar random variables, and $\{a_n\}$ and $\{b_n\}$ be two sequences of positive real numbers. If $\theta_n = O_p(a_n)$ and $\eta_n = o_p(b_n)$, then*

(i) $\theta_n^2 = O_p(a_n^2)$

(ii) $\theta_n \eta_n = o_p(a_n b_n)$

Proposition 24 *The followings are true:*[9]

(i) $\boldsymbol{\theta}_n = o_p(a_n) \;\Leftrightarrow\; \| \boldsymbol{\theta}_n \| = o_p(a_n)$.

(ii) $\boldsymbol{\theta}_n = O_p(a_n) \;\Leftrightarrow\; \| \boldsymbol{\theta}_n \| = O_p(a_n)$.

9. Unless subscripted otherwise, $\| \cdot \|$ denotes the L_2 norm in all the equations.

Proof The proof of part (i) can be found in Brockwell and Davis (1991, Proposition 6.1.2). Here, we only prove part (ii):

$(ii, \Rightarrow)$: Since $\boldsymbol{\theta}_n = O_p(a_n)$, for every $\varepsilon > 0$ and for every $i = 1, ..., d$, there exists a coefficient $\delta_i > 0$ such that

$$P\left(|\theta_{ni}| > a_n \cdot \delta_i\right) \;<\; \frac{\varepsilon}{d} \quad , n = 1, 2, ... \tag{56}$$

Define $\delta_{\max} = \max\{\delta_1, ..., \delta_d\}$ and note that we can write

$$\begin{aligned}\left\{\boldsymbol{\theta}_n : \; \sum_{i=1}^{d} |\theta_{ni}|^2 > (d \cdot a_n \cdot \delta_{\max})^2\right\} \;&\subseteq\; \left[\bigcap_{i=1}^{d} \{\boldsymbol{\theta}_n : \; |\theta_{ni}| \le a_n \cdot \delta_{\max}\}\right]^c \\ &= \bigcup_{i=1}^{d} \{\boldsymbol{\theta}_n : \; |\theta_{ni}| > a_n \cdot \delta_{\max}\}, \end{aligned} \tag{57}$$

implying that

$$\begin{aligned} P\left(\| \boldsymbol{\theta}_n \|^2 > (d \cdot a_n \cdot \delta_{\max})^2\right) \;&\le\; P\left(\bigcup_{i=1}^{d} \{\boldsymbol{\theta}_n : \; |\theta_{ni}| > a_n \cdot \delta_{\max}\}\right) \\ &\le \sum_{i=1}^{d} P(|\theta_{ni}| > a_n \cdot \delta_{\max}). \end{aligned} \tag{58}$$

Furthermore, for every $i \in \{1, ..., d\}$, we have $\delta_{\max} \ge \delta_i$. Consequently, the interval $(a_n \delta_{\max}, \infty)$ is a subset of $(a_n \delta_i, \infty)$ and $P(|\theta_{ni}| > a_n \delta_{\max}) \le P(|\theta_{ni}| > a_n \delta_i)$. This implies that

$$P\left(\| \boldsymbol{\theta}_n \|^2 > (d \cdot a_n \cdot \delta_{\max})^2\right) \;\le\; \sum_{i=1}^{d} P(|\theta_{ni}| > a_n \cdot \delta_i) \;<\; \varepsilon. \tag{59}$$

Therefore, for every $\varepsilon > 0$, we can choose $\delta_\varepsilon = d \cdot \delta_{\max}$ such that $P\left(\frac{\| \boldsymbol{\theta}_n \|}{a_n} > \delta_\varepsilon\right) < \varepsilon$ for every $n = 1, 2, ...$ Therefore, by definition, $\| \boldsymbol{\theta}_n \| = O_p(a_n)$.
$(ii, \Leftarrow)$: Suppose $\| \boldsymbol{\theta}_n \| = O_p(a_n)$, that is for every $\varepsilon > 0$ we can find $\delta_\varepsilon > 0$ such that

$$P(\| \boldsymbol{\theta}_n \| > a_n \cdot \delta_\varepsilon) \;< \varepsilon \quad , n = 1, 2, ... \tag{60}$$

It is clear that for any given $i \in \{1, ..., d\}$ we have

$$\{\boldsymbol{\theta}_n : |\theta_{ni}| > a_n \cdot \delta_\varepsilon\} \;\subseteq\; \{\boldsymbol{\theta}_n : \| \boldsymbol{\theta}_n \| > a_n \cdot \delta_\varepsilon\}, \tag{61}$$

hence

$$P(|\theta_{ni}| > a_n \cdot \delta_\varepsilon) \;\le\; P(\| \boldsymbol{\theta}_n \| > a_n \cdot \delta_\varepsilon) \;< \epsilon \quad , n = 1, 2, ... \tag{62}$$

meaning that $\theta_{ni} = O_p(a_n), \forall i \in \{1, ..., d\}$, or equivalently $\boldsymbol{\theta}_n = O_p(a_n)$. ■

Proposition 25 *If $\boldsymbol{\theta}_n = O_p(a_n)$ and $a_n \to 0 (as\ n \to \infty)$, then $\boldsymbol{\theta}_n = o_p(1)$.*

Proof The goal is to show $\boldsymbol{\theta}_n = o_p(1)$ or equivalently $\| \boldsymbol{\theta}_n \| = o_p(1)$ by proving that $P(\| \boldsymbol{\theta}_n \| > \varepsilon) \to 0 (\text{as } n \to \infty)$ for every $\varepsilon > 0$. Fix ε to a positive real number. In order to have the sequence of probability numbers $\{P(\| \boldsymbol{\theta}_n \| > \varepsilon)\}$ converging to zero, for every $\varepsilon_0 > 0$ there should exist a positive integer $N > 0$ such that

$$P(\| \boldsymbol{\theta}_n \| > \varepsilon) < \varepsilon_0 \quad \forall n > N. \tag{63}$$

Because of the assumption of being bounded by a_n, that is $\boldsymbol{\theta}_n = O_p(a_n)$ or equivalently $\| \boldsymbol{\theta}_n \| = O_p(a_n)$, we can choose a real number $\delta_0 > 0$ such that

$$P(\| \boldsymbol{\theta}_n \| > a_n \delta_0) \;\; < \;\; \varepsilon_0 \quad n = 1, 2, ... \tag{64}$$

On the other hand, since $a_n \to 0 (\text{as } n \to \infty)$, there exists a large enough number $N_0 > 0$ such that $0 < a_n < \frac{\varepsilon}{\delta_0}$ for all $n > N_0$. Therefore, we get

$$[0, a_n \delta_0] \;\; \subseteq \;\; [0, \varepsilon] \quad \forall n > N_0, \tag{65}$$

implying that

$$P(\| \boldsymbol{\theta}_n \| \leq a_n \delta_0) \;\; \leq \;\; P(\| \boldsymbol{\theta}_n \| \leq \varepsilon) \quad \forall n > N_0. \tag{66}$$

From inequalities (64) and (66), and noticing that the latter holds for all n whereas the former is satisfied when $n > N_0$, one can write:

$$P(\| \boldsymbol{\theta}_n \| > \varepsilon) \;\; \leq \;\; P(\| \boldsymbol{\theta}_n \| > a_n \delta_0) \;\; < \;\; \varepsilon_0 \quad \forall n > N_0. \tag{67}$$

Therefore, for every $\varepsilon_0 > 0$, equation (63) is guaranteed if N is chosen to be equal to N_0 so that inequality (66) is satisfied. Similarly, this can be written for every $\varepsilon > 0$, thus the proof is complete. ■

Proposition 26 (Serfling 2002, Chapter 1) *Let $\{\boldsymbol{\theta}_n\}$ be a sequence of random variables. If there exists a random variable $\tilde{\boldsymbol{\theta}}$ such that $\boldsymbol{\theta}_n \xrightarrow{L} \tilde{\boldsymbol{\theta}}$, then $\boldsymbol{\theta}_n = O_p(1)$.*

B.2 Second-order Statistical Taylor Expansion

Now we are ready to establish the second-order statistical Taylor expansion.

Theorem 27 *Let $\{\boldsymbol{\theta}_n\}$ be a sequence of random vectors in a convex and compact set $\Omega \subseteq \mathbb{R}^d$ and $\boldsymbol{\theta}_0 \in \Omega$ be a constant vector such that $\boldsymbol{\theta}_n - \boldsymbol{\theta}_0 = O_p(a_n)$ where $a_n \to 0 (\text{as } n \to \infty)$. If $g : \Omega \to \mathbb{R}$ is a $\mathcal{C}^3$ function , then*

$$g(\boldsymbol{\theta}_n) \;\; = \;\; g(\boldsymbol{\theta}_0) \;\; + \;\; \nabla_{\boldsymbol{\theta}}^{\top} g(\boldsymbol{\theta}_0)(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) \;\; + \;\; \frac{1}{2}(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0)^{\top} \nabla_{\boldsymbol{\theta}}^2 g(\boldsymbol{\theta}_0)(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) \;\; + \;\; o_p(a_n^2). \tag{68}$$

Proof Since g is twice continuously differentiable in a neighborhood of $\boldsymbol{\theta}_0$, it can be written in terms of the Taylor expansion as

$$g(\boldsymbol{\theta}) \;\; = \;\; g(\boldsymbol{\theta}_0) \;\; + \;\; (\boldsymbol{\theta} - \boldsymbol{\theta}_0)^{\top} \nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) \;\; + \;\; \frac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)^{\top} \nabla_{\boldsymbol{\theta}}^2 g(\boldsymbol{\theta}_0)(\boldsymbol{\theta} - \boldsymbol{\theta}_0) \;\; + \;\; r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0), \tag{69}$$

where $r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0)$ is the Lagrange remainder of second order. Based on Taylor's polynomial theorem for multivariate functions, there exists a number $t \in [0, 1]$ such that $\boldsymbol{\theta}^* = t\,\boldsymbol{\theta} + (1 - t)\,\boldsymbol{\theta}_0 \in \Omega$ (due to convexity of Ω) and

$$r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0) \;\; = \;\; \frac{1}{6} \sum_{1 \leq i,j,k \leq d} \frac{\partial^3 g(\boldsymbol{\theta}^*)}{\partial \theta_i \partial \theta_j \partial \theta_k} (\theta_i - \theta_{0i})(\theta_j - \theta_{0j})(\theta_k - \theta_{0k}). \tag{70}$$

But since Ω is compact and $g \in \mathcal{C}^3$, the third derivative of g is bounded[10] and therefore there exists $M > 0$ such that

$$\left| \frac{\partial^3 g(\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j \partial \theta_k} \right| \;\; \leq \;\; M \quad , \forall \boldsymbol{\theta} \in \Omega \;\; , \forall i, j, k \in \{1, ..., d\}. \tag{71}$$

Hence, the Lagrange remainder can be bounded by

$$\begin{aligned} |r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0)| \;\; &\leq \;\; \frac{M}{6} \sum_{1 \leq i,j,k \leq 3} |\theta_i - \theta_{0i}| \cdot |\theta_j - \theta_{0j}| \cdot |\theta_k - \theta_{0k}| \\ &= \;\; \frac{M}{6} \| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|_1^3 \\ &\leq \;\; \frac{M'}{6} \| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|^3, \end{aligned} \tag{72}$$

where $M' = c_u M$ and c_u is obtained from the equivalence of norms in $\mathbb{R}^d$ vector space.[11] Now define the function $h : \Omega \to \mathbb{R}$ as below

$$h(\boldsymbol{\theta}) \;\; := \;\; \begin{cases} \dfrac{r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0)}{\| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|^2 / 2} & , \boldsymbol{\theta} \neq \boldsymbol{\theta}_0 \\ 0 & , \boldsymbol{\theta} = \boldsymbol{\theta}_0 \end{cases} \tag{74}$$

Note that $h(\boldsymbol{\theta})$ is continuous at $\boldsymbol{\theta} = \boldsymbol{\theta}_0$: due to boundedness of $r_2(\boldsymbol{\theta}, \boldsymbol{\theta}_0)$, $h(\boldsymbol{\theta})$ is also bounded by

$$|h(\boldsymbol{\theta})| \;\; \leq \;\; \frac{M'}{3} \| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \|. \tag{75}$$

Hence, for every $\varepsilon > 0$, we can select $\delta_\varepsilon = \frac{3\varepsilon}{M'}$ such that the following continuity condition holds:

$$\| \boldsymbol{\theta} - \boldsymbol{\theta}_0 \| < \delta_\varepsilon \;\; \Rightarrow \;\; |h(\boldsymbol{\theta})| \;\; \leq \;\; \varepsilon. \tag{76}$$

10. This is because of the following Theorem in real analysis:

    Theorem 28 *Let X and Y be two vector spaces. If $g : X \to Y$ is continuous and X is compact, then $f(X)$ is compact in Y.*

    In special case of this theorem, where $Y = \mathbb{R}$, compactness of $f(X)$ is equivalent to boundedness and closedness.

11. Two norm functions $\| \cdot \|_{(1)}$ and $\| \cdot \|_{(2)}$ in a vector space Ω, are called *equivalent* iff there exist constants $c_u \geq c_d > 0$ such that

$$c_d \| \boldsymbol{\theta} \|_{(2)} \;\; \leq \;\; \| \boldsymbol{\theta} \|_{(1)} \;\; \leq \;\; c_u \| \boldsymbol{\theta} \|_{(2)} \quad , \forall \boldsymbol{\theta} \in \Omega. \tag{73}$$

Continuity of $h(\boldsymbol{\theta})$ at $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ implies $\lim_{\boldsymbol{\theta}\to\boldsymbol{\theta}_0} h(\boldsymbol{\theta}) = h(\boldsymbol{\theta}_0) = 0$. Furthermore, since $\boldsymbol{\theta}_n - \boldsymbol{\theta}_0 = O_p(a_n)$ and $a_n \to 0$(as $n \to \infty$), Proposition 25 suggests that $\boldsymbol{\theta}_n - \boldsymbol{\theta}_0 = o_p(1)$. These two enable us to use Proposition 11 and write

$$h(\boldsymbol{\theta}_n) - h(\boldsymbol{\theta}_0) \;=\; h(\boldsymbol{\theta}_n) \;=\; o_p(1). \tag{77}$$

Finally, from equation (74) and Propositions 23, 24 and 25, we can write that

$$r_2(\boldsymbol{\theta}_n, \boldsymbol{\theta}_0) \;=\; h(\boldsymbol{\theta}_n) \cdot \frac{\| \boldsymbol{\theta}_n - \boldsymbol{\theta}_0 \|^2}{2} \;=\; o_p(1) \cdot O_p(a_n^2) \;=\; o_p(a_n^2) \tag{78}$$

■

B.3 Second-order Multivariate Delta Method

Finally, here is the proof of second-order multivariate Delta method (Theorem 17):

Proof From the assumption for convergence in law, i.e., $\sqrt{n}(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) \xrightarrow{L} \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$, and Proposition 26, one concludes that $\sqrt{n}(\boldsymbol{\theta}_n - \boldsymbol{\theta}_0) = O_p(1)$ and therefore $\boldsymbol{\theta}_n - \boldsymbol{\theta}_0 = O_p\left(\frac{1}{\sqrt{n}}\right)$. Thus, we can use Theorem 27 with $a_n = \frac{1}{\sqrt{n}}$ to write

$$g(\boldsymbol{\theta}) \;=\; g(\boldsymbol{\theta}_0) \;+\; (\boldsymbol{\theta} - \boldsymbol{\theta}_0)^\top \nabla_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) \;+\; \frac{1}{2}(\boldsymbol{\theta} - \boldsymbol{\theta}_0)^\top \nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)(\boldsymbol{\theta} - \boldsymbol{\theta}_0) \;+\; o_p\left(\frac{1}{n}\right), \tag{79}$$

hence

$$\begin{aligned} n\Big[g(\boldsymbol{\theta}) - g(\boldsymbol{\theta}_0)\Big] \;&=\; \frac{1}{2}\left[\sqrt{n}\cdot(\boldsymbol{\theta} - \boldsymbol{\theta}_0)\right]^\top \nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) \left[\sqrt{n}\cdot(\boldsymbol{\theta} - \boldsymbol{\theta}_0)\right] \;+\; o_p(1) \\ &\xrightarrow{L}\; \frac{1}{2}\mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})^\top \nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0) \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}) \\ &=\; \frac{1}{2}\mathcal{N}(\mathbf{0}, \mathbb{I}_d)^\top \left[\boldsymbol{\Sigma}^{1/2}\, \nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)\, \boldsymbol{\Sigma}^{1/2}\right] \mathcal{N}(\mathbf{0}, \mathbb{I}_d). \end{aligned} \tag{80}$$

Define $\boldsymbol{\Gamma} \coloneqq \boldsymbol{\Sigma}^{1/2}\, \nabla^2_{\boldsymbol{\theta}} g(\boldsymbol{\theta}_0)\, \boldsymbol{\Sigma}^{1/2}$ and rewrite the right-hand-side element-wise as

$$\frac{1}{2}\mathcal{N}(\mathbf{0}, \mathbb{I}_d)^\top \boldsymbol{\Gamma} \mathcal{N}(\mathbf{0}, \mathbb{I}_d) \;=\; \frac{1}{2}\sum_{i=1}^{d} \lambda_i \mathcal{N}(0,1)^2 \;=\; \frac{1}{2}\sum_{i=1}^{d} \lambda_i \chi^2_1, \tag{81}$$

where λ_i's are eigenvalues of $\boldsymbol{\Gamma}$. Finally, noting that the terms in the Chi-square mixture are independent, variance of the convergent random variable can be easily computed as

$$\begin{aligned} \mathrm{Var}\left[\frac{1}{2}\sum_{i=1}^{d} \lambda_i \chi^2_1\right] \;&=\; \frac{1}{4}\sum_{i=1}^{d} \lambda_i^2 \cdot \mathrm{Var}\left[\chi^2_1\right] \\ &=\; \frac{1}{2}\sum_{i=1}^{d} \lambda_i^2 \\ &=\; \frac{1}{2}\left\| \boldsymbol{\Sigma}^{1/2}\, \nabla^2_{\mathbf{x}} g(\mathbf{x}_0)\, \boldsymbol{\Sigma}^{1/2} \right\|_F^2. \end{aligned} \tag{82}$$

■

Appendix C. Proof of Lemma 7

We first substitute the score function of the classifier, i.e.,

$$\nabla_{\boldsymbol{\theta}} \log p(y|\,\mathbf{x}, \boldsymbol{\theta}) \;=\; \frac{\nabla_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta})}{p(y|\,\mathbf{x}, \boldsymbol{\theta})},$$

into Monte-Carlo approximation of $\mathbf{I}_q$ to get

$$\begin{aligned} \hat{\mathbf{I}}(\boldsymbol{\theta}; X_q) \;&=\; \frac{1}{|X_q|}\sum_{\mathbf{x}\in X_q}\sum_{y=1}^{c} p(y|\,\mathbf{x}, \boldsymbol{\theta}) \cdot \frac{\nabla_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta}) \nabla^\top_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta})}{p(y|\,\mathbf{x}, \boldsymbol{\theta})^2} \;+\; \delta\mathbb{I}_d \\ &=\; \frac{1}{|X_q|}\sum_{\mathbf{x}\in X_q}\sum_{y=1}^{c} \frac{\nabla_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta}).\nabla^\top_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta})}{p(y|\,\mathbf{x}, \boldsymbol{\theta})} \;+\; \delta\mathbb{I}_d. \end{aligned} \tag{83}$$

Define the vector $\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y) \coloneqq \nabla_{\boldsymbol{\theta}} p(y|\,\mathbf{x}, \boldsymbol{\theta}) \Big/ \sqrt{p(y|\,\mathbf{x}, \boldsymbol{\theta})}$ and rewrite $\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)$ as

$$\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q) \;=\; \frac{1}{|X_q|}\sum_{\mathbf{x}\in X_q}\sum_{y=1}^{c} \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y).\, \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)^\top + \delta \cdot \mathbb{I}_d. \tag{84}$$

On the other hand, since $X_q \subset X_p$ we can write $\hat{\mathbf{I}}(\boldsymbol{\theta}; X_p)$ in terms of $\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)$ by breaking the summation over X_p into summations over X_q and $X_p - X_q$ as follows:

$$\begin{aligned} \hat{\mathbf{I}}(\boldsymbol{\theta}; X_p) \;&=\; \frac{|X_q|}{|X_p|}\left[\frac{1}{|X_q|}\sum_{\mathbf{x}\in X_q}\sum_{y=1}^{c} \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y).\, \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)^\top + \delta \cdot \mathbb{I}_d\right] \\ &\quad\; + \frac{1}{|X_p|}\sum_{\mathbf{x}\in X_p - X_q}\sum_{y=1}^{c} \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y).\, \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)^\top \;+\; \delta\left(\frac{|X_p| - |X_q|}{|X_p|}\right)\cdot \mathbb{I}_d \\ &=\; \left(\frac{|X_q|}{|X_p|}\right)\cdot \hat{\mathbf{I}}(\boldsymbol{\theta}; X_q) \;+\; \frac{1}{|X_p|}\sum_{\mathbf{x}\in X_p - X_q}\sum_{y=1}^{c} \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y).\, \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)^\top \\ &\quad\; + \delta\left(\frac{|X_p| - |X_q|}{|X_p|}\right)\cdot \mathbb{I}_d \end{aligned} \tag{85}$$

Now that we related the Fisher information matrices to each other, we can compute the product of $\hat{\mathbf{I}}(\boldsymbol{\theta}; X_p)$ and $\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)^{-1}$ as

$$\begin{aligned} \hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)^{-1}\hat{\mathbf{I}}(\boldsymbol{\theta}; X_p) \;&=\; \left(\frac{|X_q|}{|X_p|}\right)\cdot \mathbb{I}_d \;+\; \frac{\hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)^{-1}}{|X_p|}\left[\sum_{\mathbf{x}\in X_p - X_q}\sum_{y=1}^{c} \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)\cdot \mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}, y)^\top\right] \\ &\quad\; + \delta\left(\frac{|X_p| - |X_q|}{|X_p|}\right)\cdot \hat{\mathbf{I}}(\boldsymbol{\theta}; X_q)^{-1}. \end{aligned} \tag{86}$$

Applying the trace function to both sides of the equation will result

$$\begin{aligned}\operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\hat{\mathbf{I}}(\boldsymbol{\theta};X_p)\right] &= \frac{|X_q|\cdot d}{|X_p|}+\frac{1}{|X_p|}\sum_{\mathbf{x}\in X_p-X_q}\sum_{y=1}^{c}\operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\cdot\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\right]\\ &\quad+\ \delta\left(\frac{|X_p|-|X_q|}{|X_p|}\right)\cdot\operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\right]\\ &\approx \frac{|X_q|\cdot d}{|X_p|}\ +\ \frac{1}{|X_p|}\sum_{\mathbf{x}\in X_p-X_q}\sum_{y=1}^{c}\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y),\end{aligned}\tag{87}$$

where the last term is dropped since the overloading constant, δ, is assumed to be small. Furthermore, the term including $\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}$ can be approximated by replacing the weighted harmonic mean of the eigenvalues of $\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)$ by their weighted arithmetic mean (Hoi et al., 2006)

$$\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\ \approx\ \frac{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^4}{\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)}.\tag{88}$$

Note that this approximation becomes exact when the condition number of $\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)$ is one. Substituting $\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)$ from equation (84) into the denominator of the approximation above yields

$$\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\ =\ \frac{1}{|X_q|}\sum_{\mathbf{x}'\in X_q}\sum_{y'=1}^{c}\left[\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}',y')\right]^2\ +\ \delta\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2\tag{89}$$

Assume that the value of $\boldsymbol{\theta}$ is not located at the stationary point of the conditional density $p(y|\,\mathbf{x},\boldsymbol{\theta})$, hence $\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)$ is not the zero vector. Integrating approximation (88) with equation (87) results

$$\begin{aligned}\operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\hat{\mathbf{I}}(\boldsymbol{\theta};X_p)\right] &\approx \frac{|X_q|\cdot d}{|X_p|}\\ &+\ \frac{1}{|X_p|}\sum_{\mathbf{x}\in X_p-X_q}\sum_{y=1}^{c}\frac{1}{\delta\cdot\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')},\end{aligned}\tag{90}$$

where

$$g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\ :=\ \frac{1}{|X_q|}\sum_{y'=1}^{c}\left[\frac{\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)^{\top}\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x}',y')}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^2.\tag{91}$$

Finally by removing the constants in (90), we get the optimization

$$\begin{aligned}&\operatorname*{arg\,min}_{X_q\subset X_p}\ \operatorname{tr}\left[\hat{\mathbf{I}}(\boldsymbol{\theta};X_q)^{-1}\hat{\mathbf{I}}(\boldsymbol{\theta};X_p)\right]\\ &\qquad\approx\ \operatorname*{arg\,max}_{X_q\subset X_p}\sum_{\mathbf{x}\in X_p-X_q}\sum_{y=1}^{c}\frac{-1}{\delta\cdot\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')}.\end{aligned}\tag{92}$$

Appendix D. Proof of Theorem 8

Proof of this Theorem is a generalization of the discussion by Hoi et al. (2006), with clarification of all the assumptions and approximations made.

First, note that the function $f_{\boldsymbol{\theta}}$ can be broken into simpler terms $f_{\boldsymbol{\theta}}(X_q)=\sum_{y=1}^{c}f_{\boldsymbol{\theta}}(X_q;y)$, where

$$f_{\boldsymbol{\theta}}(X_q;y)\ =\ \sum_{\mathbf{x}\in X_p-X_q}\frac{-1}{\delta\cdot\|v_{\boldsymbol{\theta}}(\mathbf{x},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')},\quad\forall X_q\subseteq X_p.\tag{93}$$

Therefore, in order to prove submodularity and monotonicity of $f_{\boldsymbol{\theta}}$, it suffices to prove these properties for $f_{\boldsymbol{\theta}}(\cdot;y)$ for all $y\in\{1,...,c\}$. Fix y and take any subset $X_q\subseteq X_p$ and $\boldsymbol{\xi}\in X_p-X_q$. Then, we can write

$$\begin{aligned}f_{\boldsymbol{\theta}}(X_q\cup\{\boldsymbol{\xi}\};y) &= \sum_{\mathbf{x}\in X_p-(X_q\cup\{\boldsymbol{\xi}\})}\frac{-1}{\delta\cdot\|v_{\boldsymbol{\theta}}(\mathbf{x},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')}\\ &= \sum_{\mathbf{x}\in X_p-X_q}\frac{-1}{\delta\cdot\|v_{\boldsymbol{\theta}}(\mathbf{x},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')}\\ &\quad+\ \frac{1}{\delta\cdot\|v_{\boldsymbol{\theta}}(\boldsymbol{\xi},y)\|^{-2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')}.\end{aligned}$$

We then form the discrete derivative of $f_{\boldsymbol{\theta}}(\cdot;y)$ at X_q to get

$$\begin{aligned}\rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_q;\boldsymbol{\xi}) &= f_{\boldsymbol{\theta}}(X_q\cup\{\boldsymbol{\xi}\};y)\ -\ f_{\boldsymbol{\theta}}(X_q;y)\\ &= \sum_{\mathbf{x}\in X_p-X_q}\left[\frac{-1}{\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')}+\frac{1}{\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')}\right]\\ &\quad+\ \frac{1}{\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')}.\end{aligned}$$

The right-hand-side can be rewritten as

$$\begin{aligned}&\sum_{\mathbf{x}\in X_p-X_q}\left[\frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q}g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)}\right]\\ &\quad+\ \frac{1}{\frac{\delta}{\|\,\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}+\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}}g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')}.\end{aligned}\tag{94}$$

Since by definition $g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\geq 0,\forall\,\mathbf{x},y,\mathbf{x}'$, all of the terms in (94) are non-negative and therefore $\rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_q;\boldsymbol{\xi})\geq 0$. This is true for any $X_q\subseteq X_p$, hence monotonicity of $f_{\boldsymbol{\theta}}(\cdot;y)$ is obtained. Now let us take any superset $X_{q'}$ such that $X_q\subseteq X_{q'}\subseteq X_p$ and $\boldsymbol{\xi}\in X_p-X_{q'}$, and form the difference between their corresponding discrete derivatives. From (94), we will

have

$$\begin{aligned}
&\rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_q;\boldsymbol{\xi}) - \rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_{q'};\boldsymbol{\xi}) \\
&= \sum_{\mathbf{x}\in X_p - X_q} \left[\frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)} \right] \\
&+ \frac{1}{\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\boldsymbol{\xi},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')} \\
&- \sum_{\mathbf{x}\in X_p - X_{q'}} \left[\frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_{q'}\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_{q'}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)} \right] \\
&- \frac{1}{\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\boldsymbol{\xi},y)\|^2} + \sum_{\mathbf{x}'\in X_{q'}\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')}. \qquad (95)
\end{aligned}$$

From non-negativity of $g_{\boldsymbol{\theta}}$ and that $X_q \subseteq X_{q'}$, we can conclude that for any $\mathbf{x} \in X$ and $y \in \{1,...,c\}$,

$$\begin{aligned}
&\sum_{\mathbf{x}'\in X_{q'}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') \;\geq\; \sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') \\
\Leftrightarrow\quad &\left[\sum_{\mathbf{x}'\in X_{q'}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \;\leq\; \left[\sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \\
\Leftrightarrow\quad &-\left[\sum_{\mathbf{x}'\in X_{q'}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \;\geq\; -\left[\sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \qquad (96)
\end{aligned}$$

Similarly, since $X_q \cup \{\boldsymbol{\xi}\} \subseteq X_{q'} \cup \{\boldsymbol{\xi}\}$ we will get

$$-\left[\sum_{\mathbf{x}'\in X_{q'}\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \geq -\left[\sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}') + \frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2}\right]^{-1} \qquad (97)$$

Applying the inequalities (96) and (97) into euqation (95) results

$$\begin{aligned}
&\rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_q;\boldsymbol{\xi}) - \rho_{f_{\boldsymbol{\theta}}(\cdot;y)}(X_{q'};\boldsymbol{\xi}) \\
&\geq \sum_{\mathbf{x}\in X_p - X_q} \left[\frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)} \right] \\
&- \sum_{\mathbf{x}\in X_p - X_{q'}} \left[\frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)} \right] \\
&+ \frac{1}{\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\boldsymbol{\xi},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')} - \frac{1}{\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\boldsymbol{\xi},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\boldsymbol{\xi},y,\mathbf{x}')}, \qquad (98)
\end{aligned}$$

which yields[12]

$$\sum_{\mathbf{x}\in X_{q'} - X_q} \frac{g_{\boldsymbol{\theta}}(\mathbf{x},y,\boldsymbol{\xi})}{\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q\cup\{\boldsymbol{\xi}\}} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)\left(\frac{\delta}{\|\mathbf{v}_{\boldsymbol{\theta}}(\mathbf{x},y)\|^2} + \sum_{\mathbf{x}'\in X_q} g_{\boldsymbol{\theta}}(\mathbf{x},y,\mathbf{x}')\right)} \;\geq\; 0. \qquad (99)$$

Inequality (99) holds for any $X_q \subseteq X_p$; hence submodularity of $f_{\boldsymbol{\theta}}(\cdot;y)$ stands for all $y \in \{1,...,c\}$ and $\boldsymbol{\theta} \in \Omega$.

12. The inequality in (98) is obtained by the fact that, for every four positive real numbers a, a_0, b and b_0, if we have $-a \geq -a_0$ and $-b \geq -b_0$ (similar to equations 96 and 97), then

$$-a \cdot b \;=\; (-a)\cdot b \;\geq\; (-a_0)\cdot b \;=\; a_0 \cdot (-b) \;\geq\; a_0 \cdot (-b_0) \;=\; -a_0 \cdot b_0.$$

Abstract

Hidden semi-Markov models (HSMMs) are latent variable models which allow latent state persistence and can be viewed as a generalization of the popular hidden Markov models (HMMs). In this paper, we introduce a novel spectral algorithm to perform inference in HSMMs. Unlike expectation maximization (EM), our approach correctly estimates the probability of given observation sequence based on a set of training sequences. Our approach is based on estimating moments from the sample, whose number of dimensions depends only logarithmically on the maximum length of the hidden state persistence. Moreover, the algorithm requires only a few matrix inversions and is therefore computationally efficient. Empirical evaluations on synthetic and real data demonstrate the advantage of the algorithm over EM in terms of speed and accuracy, especially for large data sets.

Keywords: Graphical models, hidden semi-Markov model, spectral algorithm, tensor analysis, aviation safety

1. Introduction

Hidden semi-Markov models (HSMMs) are discrete latent variable models which allow temporal persistence of latent states, and can be viewed as a generalization of the popular hidden Markov models (HMMs) (Chiappa, 2014; Murphy, 2002; Yu, 2010). In HSMMs, the stochastic model for the unobservable process is defined by a semi-Markov chain: latent state at the next time step is determined by the current latent state as well as time elapsed since the entry into the current state. The ability to flexibly model such latent state persistence turns out to be useful in many application areas, including anomaly detection (Tan and Xi, 2008; Xie and Yu, 2009), activity recognition (van Kasteren et al., 2010), and speech synthesis (Zen et al., 2007). Such state persistence is in contrast to HMMs, which use a Markov chain over latent state transitions and hence have an implicit geometric distribution for the state duration (Rabiner, 1989).

Given a set of training sequences, one can formulate two distinct but related problems: *learning*, i.e., estimating model parameters and *inference*, i.e., computing the probability of an observed and/or latent variable sequence. The methods proposed for learning HSMMs usually follow the initial idea due to Rabiner (Rabiner, 1989) based on the modifications of the Baum-Welch algorithm (Baum and Petrie, 1966), which are all variants of the expectation maximization (EM) framework, presented in (Dempster et al., 1977). Once the parameters are estimated, we can then perform inference using, e.g., the forward-backward algorithm of (Yu and Kobayashi, 2003). However, since EM, in general, has no global guarantees in estimating the parameters correctly and can suffer from slow convergence, such methods can be inefficient and/or inconsistent.

Bayesian nonparametric approaches based on hierarchical Dirichlet processes have also been proposed for HMMs (Fox et al., 2008) and HSMMs (Johnson and Willsky, 2013). Such models avoid the need to specify the number of latent states and can, in principle, learn it from data. However, in practice, inference algorithms for such models are often sensitive to initialization and may suffer from slow convergence.

In recent years, there has been an increased interest in spectral algorithms, which provide computationally efficient, local-minimum-free, provably consistent inference and/or parameter estimation algorithms for latent variable models. For example, (Anandkumar et al., 2013a, 2014b, 2013c) have proposed spectral methods for learning the parameters of a wide class of tree-structured latent graphical models, including Gaussian mixture models, topic models, and latent Dirichlet allocation. The main idea is based on a tensor decomposition of certain low order moments, computable directly from data, in order to extract the model parameters.

In many problems, however, the end goal is not the recovery of model parameters but statistical inference, i.e., computing the probability of a given test sequence, which may be doable without estimating the canonical model parameters. In this regard, (Hsu et al., 2012) have proposed an efficient spectral algorithm for inference in HMMs. It is based on the idea of expressing the probability of the observed sequence in a representation which does not depend on the model parameters and uses easily computable second and third order sample moments to perform inference. Although their work has been used in models on sequences and trees used in Natural Language Processing (NLP) and Reinforcement Learning (RL) (Boots and Gordon, 2010; Dhillon et al., 2011; Balle et al., 2011; Cohen et al., 2014), their approach is not easily extendable to general latent variable models. The work of (Parikh et al., 2011), on the other hand, introduced a spectral algorithm to perform inference in latent tree graphical models with arbitrary topology, and later in (Parikh et al., 2012) a general spectral inference framework for latent junction trees.

In this paper, we utilize the framework of (Parikh et al., 2012) and introduce a novel spectral algorithm for inference in HSMMs. Since we address a more specific problem than (Parikh et al., 2012), our results shed more light into the details of the spectral framework for HSMMs, allow for a sharper analysis, and yield a significantly more efficient algorithm than the general framework in (Parikh et al., 2012). There are two main technical contributions in this work:

- By exploiting the *homogeneity* of HSMMs we make our proposed algorithm more efficient and accurate than the algorithm which directly follows from the recipe in (Parikh et al., 2012) for general graphs. In particular, our approach ensures that during the training phase the number of matrix multiplications and inverses is fixed and independent of the sequence length of the observations.

- Through careful analysis we show that the number of dimensions in the sample moments (represented as a multidimensional matrix or a tensor) in estimated observable representation depends only *logarithmically* on the maximum length of latent state persistence (this is in contrast to a standard implementation, which would have a linear dependence).

In experiments, comparing our method with EM on both synthetic and real data sets, two observations stand out: (i) the spectral method gets similar or better performance than EM as the number of samples increases, and (ii) the spectral method is orders of magnitude faster than EM for the datasets we consider.

Few remarks are in order about the proposed algorithm. Note that our method does not estimate model parameters explicitly but rather learns alternative representation to perform inference on observable variables. The idea of the observable representations was first introduced with the name 'observable operators models' by (Jaeger, 2000) in the context of constructing learning algorithm for the identification of linearly dependent processes. Our formulation cannot be directly used to infer hidden states, although methods such as in (Mossel and Roch, 2005) can be potentially utilized to recover original HSMM parameters from the learned representation. Finally, we note that the similar ideas of using homogeneity of HMMs to improve algorithm's efficiency has also been utilized in other related works, e.g., (Siddiqi et al., 2010; Hsu et al., 2012).

The rest of the paper is organized as follows: We introduce notation in Section 2. In Section 3, we present HSMM inference from a tensor product perspective and in Section 4 introduce the spectral algorithm for inference. In Section 5, we present a careful technical analysis to establish logarithmic dependence of the number of modes in the tensor on maximum latent state persistence. We present experimental results in Section 6 and conclude in Section 7.

2. Notation and Preliminaries

In this section, we cover basic facts about tensor algebra. Detailed tutorials on tensors can be found in (Kiers, 2000) or (Kolda and Bader, 2009). A tensor is defined as a multidimensional array of data, which will be denoted by boldface Euler script letters, e.g., $\underset{m_1,\ldots,m_N}{\mathcal{X}} \in \mathbb{R}^{I_{m_1}\times\cdots\times I_{m_N}}$, which is N-mode tensor of dimensions $I_{m_1}\times\cdots\times I_{m_N}$. A specific mode is denoted by the subscript variable m_i, whose dimension is I_{m_i}.

Any tensor can be matrisized (or flattened) into a matrix. This mapping can be done in multiple ways, the only requirement is that the number of elements is preserved and the mapping is one-to-one. If we split the modes into two disjoint sets, one corresponding to rows and the other to columns, e.g., $\{m_1,\ldots,m_N\}=\{p_1,\ldots,p_K\}\cup\{q_1,\ldots,q_L\}$, then a matrisization of $\mathcal{X}$ is denoted by a corresponding capital boldface letter, e.g., $\underset{p_1,\ldots,p_K q_1,\ldots,q_L}{\mathbf{X}} \in \mathbb{R}^{I_{p_1}\cdots I_{p_K}\times I_{q_1}\cdots I_{q_L}}$.

Tensor Multiplication. Multiplication of two tensors is performed along specific modes. For this, we flatten each tensor to a matrix, perform the usual matrix multiplication and transform the result back to a tensor. The multiplication is denoted by a symbol $\times$ with an optional subscript representing the modes along which the operation is performed, e.g.,:

$$\underset{p_1,\ldots,p_K,r_1,\ldots,r_M}{\mathcal{Z}} = \underset{p_1,\ldots,p_K,q_1,\ldots,q_L}{\mathcal{X}} \times_{q_1,\ldots,q_L} \underset{q_1,\ldots,q_L,r_1,\ldots,r_M}{\mathcal{Y}},$$

where $\underset{q_1,\ldots,q_L,r_1,\ldots,r_M}{\mathcal{Y}} \in \mathbb{R}^{I_{q_1}\times\cdots\times I_{q_L}\times I_{r_1}\times\cdots\times I_{r_M}}$ and the resulting tensor on the left hand side is of the form $\underset{p_1,\ldots,p_K,r_1,\ldots,r_M}{\mathcal{Z}} \in \mathbb{R}^{I_{p_1}\times\cdots\times I_{p_K}\times I_{r_1}\times\cdots\times I_{r_M}}$. Observe that in the above, we can flatten the tensors $\mathcal{X}$ and $\mathcal{Y}$ in multiple different ways as long as the matrix multiplication remains valid. For example, we could assign the multiplication modes in both tensors to columns, in this case the matrix product becomes $\mathbf{Z}=\mathbf{X}\mathbf{Y}^T$. Alternatively, the tensor $\mathcal{Y}$ could be matrisized with the multiplication modes corresponding to rows, resulting in the product $\mathbf{Z}=\mathbf{X}\mathbf{Y}$.

$\underset{p,q,r}{\mathcal{X}} \in \mathbb{R}^{I_p\times I_q\times I_r}$	N-mode tensor of dimensions $I_p\times I_q\times I_r$
$\underset{p,q,r}{\mathbf{X}} \in \mathbb{R}^{I_pI_q\times I_r}$	Matricization of tensor $\underset{p,q,r}{\mathcal{X}}$ with I_pI_q rows and I_r columns
$\underset{p,q,r}{\mathcal{X}} \times_r \underset{r,s,t}{\mathcal{Y}}$	Multiplication of tensor $\underset{p,q,r}{\mathcal{X}}$ and tensor $\underset{r,s,t}{\mathcal{Y}}$ along mode r
$\underset{p,q,r}{\mathcal{X}} \times_{q,r} \underset{p,q,r}{\mathcal{X}}^{-1} = \underset{p,p}{\mathcal{I}} = \underset{p}{\mathcal{I}}$	Inversion of tensor $\underset{p,q,r}{\mathcal{X}}$ with respect to modes q and r
$\mathbb{X}_t$	Representation of a clique in a Junction tree
$o_t \in \{1,\ldots,n_o\}$	Observation variable in HSMM
$x_t \in \{1,\ldots,n_x\}$	Latent state variable in HSMM
$d_t \in \{1,\ldots,n_d\}$	Latent duration variable in HSMM
$\mathbf{O}_{R_t} := \{o_{t+1}, o_{t+2},\ldots\}$	Set of observations to the right of time step t
$\mathbf{O}_{L_t} := \{\ldots, o_{t-2}, o_{t-1}\}$	Set of observations to the left of time step t

Table 1: Summary of some of the key notations used throughout the paper.

An important fact about tensor multiplication is that in a series of tensor multiplications the order is irrelevant (i.e., it is an associative operation) as long as the multiplication is performed along the matching modes, e.g,

$$\underset{sp}{\mathcal{X}} \times_s \left(\underset{tr}{\mathcal{Y}} \times_r \underset{rs}{\mathcal{Z}}\right) = \left(\underset{sp}{\mathcal{X}} \times_s \underset{rs}{\mathcal{Z}}\right) \times_r \underset{tr}{\mathcal{Y}}.$$

If we let the matrisized tensors to be $\mathbf{X}\in\mathbb{R}^{I_p\times I_s}$, $\mathbf{Y}\in\mathbb{R}^{I_t\times I_r}$ and $\mathbf{Z}\in\mathbb{R}^{I_r\times I_s}$, then the above can be verified to be true since

$$\mathbf{X}\left(\mathbf{Y}\mathbf{Z}\right)^T = \left(\mathbf{X}\mathbf{Z}^T\right)\mathbf{Y}^T.$$

To reduce clutter, in many places we will drop the multiplication subscripts. The implied modes of multiplication can then be inferred from the subscripts of the tensors. Specifically, when two tensors are multiplied, we first check their modes and then multiply along the modes which are common to both of them. For example, in the product $\underset{pqr}{\mathcal{X}} \times \underset{qsr}{\mathcal{Y}}$, the implied multiplication is performed along the common modes, i.e., q and r.

Tensor Inversion. We also discuss the operation of tensor inversion. Tensor inverse $\mathcal{X}^{-1}$ is always defined with respect to a certain subset of modes and can be written as follows:

$$\underset{p_1,\ldots,p_K,q_1,\ldots,q_L}{\mathcal{X}} \times_{q_1,\ldots,q_L} \underset{p_1,\ldots,p_K,q_1,\ldots,q_L}{\mathcal{X}^{-1}} = \underset{p_1,\ldots,p_K,p_1,\ldots,p_K}{\mathcal{I}},$$

where the inversion is performed along the modes $q_1,\ldots,q_L$, and $\underset{p_1,\ldots,p_K,p_1,\ldots,p_K}{\mathcal{I}}$ denotes an identity tensor, whose elements are everywhere zero, except $\mathcal{I}(i_1,\ldots,i_K,i_1,\ldots,i_K)=1$. To perform inversion, we first convert tensor to a matrix, i.e., matrisized tensor. If the modes to be inverted along are associated with columns of the matrix, we compute the right matrix inverse, so that these modes get eliminated after the product. Otherwise, if those modes associated with rows, we compute left matrix inverse. Obviously, for the full rank square matrices both choices would produce the same result. For example, in the above equation the matrisized tensor might be of the form $\underset{p_1,\ldots,p_K q_1,\ldots,q_L}{\mathbf{X}} \in \mathbb{R}^{I_{p_1}\cdots I_{p_K}\times I_{q_1}\cdots I_{q_L}}$, therefore, we would compute the right matrix inverse so that

the modes $q_1, \ldots, q_L$ are eliminated. If the matrisized $\mathbf{X}$ has full row rank, then the inverse can be computed, otherwise we could only compute its pseudo-inverse. Tensorizing the matrix $\mathbf{X}^{-1}$ gives us the desired tensor inverse.

Mode Duplication. Observe that in the above, the tensor $\underset{p_1,\ldots,p_K,p_1,\ldots,p_K}{\mathcal{I}}$ has duplicate modes. In general, if a tensor has duplicate modes, the corresponding sub-tensor can be interpreted as a hyper-diagonal. For example, if for a tensor $\underset{pq}{\mathcal{X}}$ we construct a tensor $\underset{pppq}{\overline{\mathcal{X}}}$, which has its mode p duplicated three times, then for a fixed index i, the sub-tensor $\overline{\mathcal{X}}(:,:,:,i)$ is a hypercube with elements $\mathcal{X}(:,i)$ on the diagonal.

Mode duplication enables us to multiply several tensors along the same mode. For example, if we need to multiply tensors $\underset{sp}{\mathcal{X}}$, $\underset{pr}{\mathcal{Y}}$ and $\underset{tp}{\mathcal{Z}}$ along the mode p, then a simple product of the form

$$\underset{sp}{\mathcal{X}} \times_p \underset{pr}{\mathcal{Y}} \times_p \underset{tp}{\mathcal{Z}}$$

cannot be done since any product of two tensors along the mode p would eliminate it, preventing any further multiplications. In general, if there are N multiplications along the specific mode, then there are must be cumulatively $2N$ number of times such a mode is encountered in the participating tensors. In our example, we might duplicate the mode p in, say, tensor $\mathcal{Z}$ to have

$$\underset{sp}{\mathcal{X}} \times_p \left(\underset{pr}{\mathcal{Y}} \times_p \underset{tpp}{\mathcal{Z}} \right) = \underset{sp}{\mathcal{X}} \times_p \underset{prt}{\mathcal{W}} = \underset{srt}{\mathcal{V}},$$

so that there are two multiplications over mode p and cumulatively there are four times such a mode is encountered in the participating tensors. To reduce clutter, we sometimes do not explicitly show the duplicated variables in the subscripts; the implied mode repetition will be evident from the context or explicitly stated in cases when there is a confusion. For example, the identity tensor will often be written as $\underset{p_1,\ldots,p_K}{\mathcal{I}}$.

Tensor rank Finally, we discuss the meaning of a tensor rank. A tensor can have multiple ranks and each of them is defined based on the rank of a particular matricization. For example, consider a tensor $\underset{pqs}{\mathcal{X}}$. If we flatten it to a matrix $\mathbf{X} \in \mathbb{R}^{I_p \times I_q I_s}$ then it can have a rank r_1. On the other hand, a matricization of the form $\mathbf{X} \in \mathbb{R}^{I_p I_q \times I_s}$ can have a rank r_2, and so on. In our derivations, the particular rank we are referring to will be evident from the context.
In Table 2 we summarized some of the key notations used throughout the paper.

3. Problem Formulation

In this paper, we consider the problem of inference in HSMM[1] (see Figure 1). Unlike the popular HMM, which has a geometric probability for state persistence, i.e., the probability of persisting in the same state over t time steps decreases as π^t, where π is the probability of persistence for one time step, HSMM explicitly models state persistence. From a graphical model perspective, HSMM has three sets of variables: the observations $o_t \in \{1, \ldots, n_o\}$, the latent states $x_t \in \{1, \ldots, n_x\}$, and another latent variable $d_t \in \{1, \ldots, n_d\}$ which determines the length of state persistence. HSMM

1. To reduce clutter, in the main paper we only consider the model for a general time stamp t and ignore the initial ($t = 0$) and final ($t = T$) steps of the model, whose representation differs slightly from what is shown in Figure 1. The details for these parts are presented separately in Appendix B.

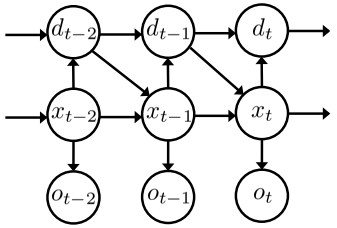

Figure 1: Hidden Semi-Markov Model (HSMM) depicted as a dynamic Bayesian network. Here $o_t \in \{1, \ldots, n_o\}$ denotes an observation at time step t, $x_t \in \{1, \ldots, n_x\}$ is a latent state and $d_t \in \{1, \ldots, n_d\}$ is the length of state persistence at time step t.

is specified by three conditional probability tables (CPTs): the observation/emission probability $p(o_t|x_t)$ and the state transition and the duration probabilities given by

$$p(d_t|x_t, d_{t-1}) = \begin{cases} p(d_t|x_t) & \text{if } d_{t-1} = 1 \\ \delta(d_t, d_{t-1} - 1) & \text{if } d_{t-1} > 1 \,, \end{cases} \tag{1}$$

$$p(x_t|x_{t-1}, d_{t-1}) = \begin{cases} p(x_t|x_{t-1}) & \text{if } d_{t-1} = 1 \\ \delta(x_t, x_{t-1}) & \text{if } d_{t-1} > 1 \,, \end{cases} \tag{2}$$

where $\delta(a, b)$ denotes the Dirac delta function: $\delta(a, b) = 1$ if $a = b$ and 0 otherwise. In addition, one can consider suitable prior probabilities $p(x_0)$ and $p(d_0)$. In essence, d_t works as a down counter for state persistence. When $d_{t-1} > 1$, the model remains in the same state $x_t = x_{t-1}$, while when $d_{t-1} = 1$, one samples a new state x_t and the new duration in that state $d_t|x_t$. For our analysis, we assume $p(d_t|x_t, d_{t-1} = 1)$ to be a discrete distribution over $\{1, \ldots, n_d\}$ where n_d denotes the largest duration of state persistence.

The considered inference problem can be posed as follows: given a set of discrete sequences $\{\mathbf{S}^1, \ldots, \mathbf{S}^N\}$ drawn independently from the HSMM model, where each sequence is defined as $\mathbf{S}^i = \{o_1^i, \ldots, o_{T_i}^i\}, i = 1, \ldots, N$, our goal is to compute the probability $p(\mathbf{S}^{test})$ of any given test sequence $\mathbf{S}^{test} = (o_1^{test}, \ldots, o_T^{test})$. A traditional approach would be to estimate the CPTs using the EM algorithm, and use the estimates to compute $p(\mathbf{S}^{test})$. However, the EM algorithm is not guaranteed to estimate the parameters optimally, and hence the computation of $p(\mathbf{S}^{test})$ may be incorrect. The focus of our work is to develop a provably correct spectral algorithm for computing the probability $p(\mathbf{S}^{test})$.

3.1 HSMM in Tensor Notations

We start by considering the matrix forms of the HSMM parameters and writing the computations in tensor notation, as introduced in Section 2. Specifically, $p(d_t|x_t, d_{t-1} = 1)$ is denoted as $D \in \mathbb{R}^{n_d \times n_x}$, $p(x_t|x_{t-1}, d_{t-1} = 1)$ is denoted as $X \in \mathbb{R}^{n_x \times n_x}$, and $p(o_t|x_t)$ as $O \in \mathbb{R}^{n_o \times n_x}$. We make the following assumptions on the HSMM parameters:

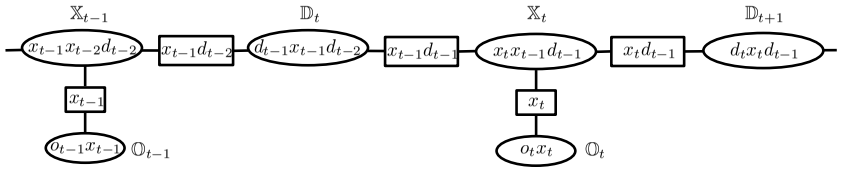

Figure 2: Junction Tree for Hidden Semi-Markov Model. The ovals represent cliques, which are denoted by capital blackboard bold variables; the rectangles denote separators. Symbols within the shapes represent the variables on which the corresponding potentials depend.

Assumptions

$A1$. X is full rank and has non-zero probability of visiting any state from any other state.

$A2$. D has a non-zero probability of any duration in any state.

$A3$. O is full column rank and, as a consequence, $n_x \leq n_o$.

We provide some comments on the above assumptions. We note that the assumption $A1$ can be relaxed to allow zero entries (while still ensuring full rank structure) and thus prevent certain states to be directly reachable from other states; however, this would require more involved analysis based on the mixing time of the corresponding Markov chain (Levin et al., 2009), and is not pursued in this work. Also, observe that the assumption of $n_x \leq n_o$ is needed in order to ensure that hidden states are identifiable, although recent work is showing that such an assumption can be relaxed in some cases (Bailly et al., 2009; Anandkumar et al., 2013b). Intuitively, it means that the number of different observations coming from each state is large enough, so that one hidden state can be differentiated from the other.

To express the joint probability $p(o_1, \ldots, o_T)$ for any possible observation sequence in tensor form, we utilize the junction tree algorithm (Barber, 2012). The resulting tree is shown in Figure 2 and it corresponds to the graphical model of HSMM in Figure 1. Recall, that the junction tree is a tree-structured representation of an arbitrary graph enabling efficient inference. It can be constructed by forming a maximal spanning tree from the cliques of the graph. The cliques then represent vertices in the junction tree and the edges connecting the vertices are labeled with variables common to two cliques it connects. The set of variables on the edges are referred to as separators. For example, in Figure 2 the cliques $\mathbb{X}_t$ and $\mathbb{D}_t$ have two variables in common, x_{t-1} and d_{t-1}, and which define the sepatator between $\mathbb{X}_t$ and $\mathbb{D}_t$.

We proceed by representing the clique CPTs of the junction tree as tensors. For example, the clique $\mathbb{X}_t$, containing the CPT of $p(x_t|x_{t-1}, d_{t-1})$ is represented as tensor $\underset{x_t|x_{t-1}d_{t-1}}{\mathcal{X}}$. For ease of exposition, the tensor's modes are named based on the variables on which the tensor depends. We also keep the conditioning symbol $|$ for clarity. Similarly, we represent the clique $\mathbb{D}_t$ with its CPT $p(d_t|x_t, d_{t-1})$ as tensor $\underset{d_t|x_td_{t-1}}{\mathcal{D}}$, and $\mathbb{O}_t$ containing $p(o_t|x_t)$ as tensor $\underset{o_t|x_t}{\mathcal{O}}$.

If we denote the joint probability of the observed sequence $p(o_1, \ldots, o_T)$ as $\underset{o_1,..,o_T}{\mathcal{P}}$ then the message passing for the junction tree algorithm in Figure 2 can be represented as tensor multiplications:

$$\underset{o_1,\ldots,o_T}{\mathcal{P}} = \prod_t \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_tx_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{o_t|x_t}{\mathcal{O}} \right), \tag{3}$$

where, for simplicity, we denoted by $\prod_t$ the tensor product over multiple time steps.

Note that in (3) the neighboring tensors are multiplied along the modes which are the separator variables between two corresponding neighboring cliques in Figure 2. Therefore, as we discussed in Section 2, if a certain mode of a tensor is to participate multiple times in products with other tensor, the mode must be duplicated for the expression to remain correct. It can easily be seen from the junction tree that the number of times the mode is duplicated depends on the number of times such a variable appears in separators adjacent to the clique. For example, the tensor $\underset{x_tx_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}}$ has a mode x_{t-1} appearing once in the separator connecting $\mathbb{X}_t$ and $\mathbb{D}_t$ in Figure 2, while x_t appears a total of two times, once in the separator connecting $\mathbb{X}_t$ and $\mathbb{O}_t$, and once in the separator connecting $\mathbb{X}_t$ and $\mathbb{D}_{t+1}$. Finally, d_{t-1} appears in the separator between $\mathbb{D}_t$ and $\mathbb{X}_t$, and between $\mathbb{D}_{t+1}$ and $\mathbb{X}_t$. Applying the same reasoning to tensors $\mathcal{D}$ and $\mathcal{O}$ results in the expression (3).

3.2 Summary of Technical Results

In this work, we represent expression (3), which is defined in terms of unknown model parameters, in a different *observable form*, where all the factors can be estimated directly from data using certain sample moments without knowledge of model parameters. Such an observable form is derived in Sections 4.1 and 4.2. Based on the observable form, in Section 4.3 we propose a simple spectral algorithm which requires estimating $\mathcal{X}$, $\mathcal{D}$ and $\mathcal{O}$ for all the time stamps t. This estimation process is expensive as it involves costly tensor operations to be performed at each time index t. Moreover, the accurate estimation of these tensors requires large number of training sequences which might not be available, leading to inaccurate and unstable computations. However, exploiting the homogeneity property of HSMMs, i.e., the probability distributions represented by the above tensors are the same across all time t, we derive a computationally efficient and accurate spectral algorithm in Section 4.4 which requires the estimation of only three tensors for all the time stamps t. Although the computational complexity of the inference, i.e., the evaluation of expression (3), is not affected by the introduced modifications, the overall algorithm becomes faster and more accurate.

In Section 5 we return to the results of Sections 4.1 and establish the conditions under which the derived observable form can be computed from data. In particular, our analysis shows that the number of dimensions of the required sample moments (in the form of tensors, estimated from data and representing the co-occurrence frequency of certain observable variables), has logarithmic dependence on the longest state persistence n_d. Such conclusion is in contrast to the analysis, which would follow from the work of (Parikh et al., 2012), in which case the required number of dimensions in the estimated sample moments would have had linear dependence on n_d. The exponential reduction in the size of the estimated tensors represents significant improvement in algorithm's efficiency and accuracy since the multidimensional matrices are of smaller size and consequently more data is available to estimate each of its entry.

4. Spectral Algorithm for Inference in HSMM

In this Section we present the details of the spectral inference approach. In particular, in Sections 4.1 and 4.2 we derive observable tensor representation and show how to estimate each of its factors directly from data. Practical algorithms implementing these ideas are then derived in Sections 4.3 and 4.4.

4.1 Observable Tensor Representation

Observe that the computation of the joint probability in (3) requires knowledge of the unknown model parameters. Our goal is to change the tensor representation such that $\underset{o_1,\ldots,o_T}{\mathcal{P}}$ can be written in terms of the quantities directly computable from data. To that end, we follow (Parikh et al., 2012) and between every two factors in (3) introduce an identity tensor with the modes corresponding to the modes along which the multiplication is performed. For example, consider a part of (3) after introducing identity tensors:

$$\times \underset{x_{t-1}d_{t-2}}{\mathcal{I}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{x_{t-1}d_{t-1}}{\mathcal{I}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_t x_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{x_t}{\mathcal{I}} \times_{x_t} \underset{o_t x_t}{\mathcal{O}} \right) \times_{x_t d_{t-1}} \underset{x_t d_{t-1}}{\mathcal{I}} \times, \quad (4)$$

where all the identity tensors have duplicated modes which are not shown.

Now rewrite each of the identity tensors in (4) as a multiplication of some factor times its inverse. For example,

$$\underset{x_t}{\mathcal{I}} = \underset{\omega_{x_t}x_t}{\mathcal{F}} \times_{\omega_{x_t}} \underset{\omega_{x_t}x_t}{\mathcal{F}^{-1}},$$

for some invertible factor $\underset{\omega_{x_t}x_t}{\mathcal{F}}$, whose modes are x_t and ω_{x_t}. Note that the choice of mode x_t is fixed and is determined by the modes of the identity tensor $\underset{x_t}{\mathcal{I}}$, while the mode ω_{x_t} is not fixed and we have freedom in selecting it as convenient. Moreover, observe that since the tensor inversion is done along the mode ω_{x_t} and the matrix $\mathbf{F}$ has its rows associated with mode ω_{x_t}, we need to ensure such a matrix has full column rank for the inverse to exist and for the product $\mathbf{F}^{-1}\mathbf{F}$ to be the identity matrix (see Section 2 for more details on tensor inversion). Based on the above discussion, we choose tensor $\mathcal{F}$ such that (i) ω_{x_t} are the observed variables, (ii) $\underset{\omega_{x_t}x_t}{\mathcal{F}}$ is invertible, i.e., matrix $\mathbf{F}$, whose columns correspond to x_t, has full column rank, and (iii) we interpret the factor $\underset{\omega_{x_t}x_t}{\mathcal{F}}$ as corresponding to a conditional probability distribution, i.e., $p(\omega_{x_t}|x_t)$ and therefore write $\underset{\omega_{x_t}|x_t}{\mathcal{F}}$.

After expanding each of the identity tensors, regrouping the factors and recalling that in a series of tensor multiplication the order is irrelevant, we can identify three modified tensors:

$$\begin{aligned}
\underset{\omega_{x_{t-1}d_{t-2}}\omega_{x_{t-1}d_{t-1}}}{\tilde{\mathcal{D}}} &= \underset{\omega_{x_{t-1}d_{t-2}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\omega_{x_{t-1}d_{t-1}}|x_{t-1}d_{t-1}}{\mathcal{F}} \\
\underset{\omega_{x_{t-1}d_{t-1}}\omega_{x_t}\omega_{x_t d_{t-1}}}{\tilde{\mathcal{X}}} &= \underset{\omega_{x_{t-1}d_{t-1}}|x_{t-1}d_{t-1}}{\mathcal{F}^{-1}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_t x_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{\omega_{x_t}|x_t}{\mathcal{F}} \right) \times_{x_t d_{t-1}} \underset{\omega_{x_t d_{t-1}}|x_t d_{t-1}}{\mathcal{F}} \\
\underset{\omega_{x_t}o_t}{\tilde{\mathcal{O}}} &= \underset{\omega_{x_t}|x_t}{\mathcal{F}^{-1}} \times_{x_t} \underset{o_t|x_t}{\mathcal{O}}.
\end{aligned}$$

Note that although each of the above tensors depends only on certain observed variables ω, for a concrete algorithm one has to decide what these ω are, and also how to estimate the associated

tensors from data. The right hand side in the above expressions depend on the unknown model parameters, whereas the tensors on the left do not correspond to valid probability distributions (due to the presence of inverses $\mathcal{F}^{-1}$), and so cannot be estimated from data using sample moments. For example, $\underset{\omega_{x_{t-1}d_{t-2}}\omega_{x_{t-1}d_{t-1}}}{\tilde{\mathcal{D}}}$ is not a tensor form of $p(\omega_{x_{t-1}d_{t-2}}, \omega_{x_{t-1}d_{t-1}})$.

Next, we discuss the choice of the observable set ω in the factors $\mathcal{F}$. From Figure 2 we can see that there are three types of separators which depend on $x_{t-1}d_{t-1}$, $x_t d_{t-1}$ and x_t, consequently, there are three types of identity tensors which we introduced in (4), i.e., $\underset{x_{t-1}d_{t-1}}{\mathcal{I}}$, $\underset{x_t d_{t-1}}{\mathcal{I}}$ and $\underset{x_t}{\mathcal{I}}$. Therefore, we need to define three types of observable sets $\omega_{x_{t-1}d_{t-1}}$, $\omega_{x_t d_{t-1}}$ and ω_{x_t}. There are multiple choices for these sets, one of them is $\omega_{x_{t-1}d_{t-1}} = \omega_{x_t d_{t-1}} = \{o_{t+1}, o_{t+2}, \ldots\}$ for all t (see Figure 3 for an illustration). Ideally, we want these sets to be of minimal size, since they need to be estimated from observations. The detailed description of how many and which of these observations to select to get a minimal set is deferred until Section 5, where we also show that we can set $\omega_{x_t} = o_t$.

In what follows, we define $\mathbf{O}_{R_t} := \{o_{t+1}, o_{t+2}, \ldots, o_{t+\tau}\}$ (see Figure 3) to emphasize that this is a fixed set of observations whose length τ is yet to be determined, starting after time stamp t and going to the right (or forward in time) in the graphical model in Figure 1. With these definitions, setting $\omega_{x_{t-1}d_{t-1}} = \mathbf{O}_{R_t}$, $\omega_{x_t d_{t-1}} = \mathbf{O}_{R_t}$, $\omega_{x_{t-1}d_{t-2}} = \mathbf{O}_{R_{t-1}}$ and $\omega_{x_t} = o_t$, we can now rewrite (3) in the form:

$$\underset{o_1,\ldots,o_T}{\mathcal{P}} = \prod_t \underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} \times_{\mathbf{O}_{R_t}} \left(\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} \times_{o_t} \underset{o_t o_t}{\tilde{\mathcal{O}}} \right). \quad (5)$$

Comparing (3) and (5) we see that the above equation expresses the joint probability distribution in the observable form. As noted above, we cannot yet use this formula in practice since we do not know how to compute the transformed tensors. In what follows, we show how to estimate such tensors directly from data, without the need for the model parameters.

4.2 Estimation of Observable Tensors

In this Section we express each of the tensors in (5) in forms which can be directly estimated from the observed sequences.

4.2.1 COMPUTATION OF TENSOR $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}}$

Consider the tensor from Section 4.1

$$\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} = \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}, \quad (6)$$

whose modes are the observable variables $\mathbf{O}_{R_{t-1}}$ and $\mathbf{O}_{R_t}$. To estimate this tensor from data, consider $\mathbf{O}_{L_{t-1}}$, a set of the observed variables such that $\mathbf{O}_{L_{t-1}}$ and $\mathbf{O}_{R_{t-1}}$ are independent, conditioned on $x_{t-1}d_{t-2}$ (see Figure 3):

$$p(\mathbf{O}_{L_{t-1}}, \mathbf{O}_{R_{t-1}}) = \sum_{x_{t-1}d_{t-2}} p(\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}) p(\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}) p(x_{t-1}d_{t-2}). \quad (7)$$

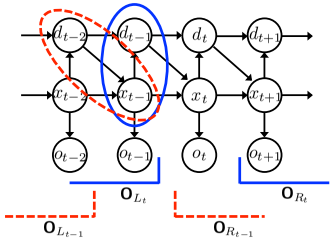

Figure 3: Conditional independence in HSMM. The figure depicts two sets of relationships: $\mathbf{O}_{L_t}$ and $\mathbf{O}_{R_t}$ are independent conditioned on $x_{t-1}d_{t-1}$, similarly, $\mathbf{O}_{L_{t-1}}$ and $\mathbf{O}_{R_{t-1}}$ are conditionally independent given $x_{t-1}d_{t-2}$. We defined $\mathbf{O}_{L_t} = \{\ldots, o_{t-2}, o_{t-1}\}$ and $\mathbf{O}_{R_t} = \{o_{t+1}, o_{t+2}, \ldots\}$.

The above conditional independence relationship can be written in tensor form:

$$\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}} = \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}}, \tag{8}$$

where tensor $\mathcal{K}$ represents the marginal $p(x_{t-1}, d_{t-2})$. Note that, though not shown, the modes x_{t-1} and d_{t-2} need to appear twice in $\mathcal{K}$, since it interacts with both other terms (see the discussion on mode duplication in Section 2). The set $\mathbf{O}_{L_{t-1}}$ is defined in a way similar to $\mathbf{O}_{R_t}$ but with the set of observations starting at time stamp $t-2$ and going to the left (or backward in time), i.e., $\mathbf{O}_{L_{t-1}} := \{\ldots, o_{t-3}, o_{t-2}\}$ (see Figure 3).

Next, we express the inverse of the tensor $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ from (8) and substitute back to (6). For this, we observe that in (6) the tensor $\mathcal{F}^{-1}$ is inverted with respect to mode $\mathbf{O}_{R_{t-1}}$, therefore, we do the following:

$$\begin{aligned}
\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}} \times_{\mathbf{O}_{R_{t-1}}} \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} &= \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{I}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \\
\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} &= \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_{t-1}}} \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}},
\end{aligned} \tag{9}$$

where $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}^{-1}}$ is inverted with respect to mode $\mathbf{O}_{L_{t-1}}$. Next, substituting (9) back to (6), we get

$$\begin{aligned}
\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} &= \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_{t-1}}} \overline{\underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}} \\
&= \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_{t-1}}} \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathcal{M}},
\end{aligned} \tag{10}$$

where we have eliminated all the latent variables by multiplying the last four terms on the first line.

Observe that the tensors $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}}$ and $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathcal{M}}$ represent valid joint probability distributions over a subset of observations $p(\mathbf{O}_{L_{t-1}}, \mathbf{O}_{R_{t-1}})$ and $p(\mathbf{O}_{L_{t-1}}, \mathbf{O}_{R_t})$, respectively, and though they are

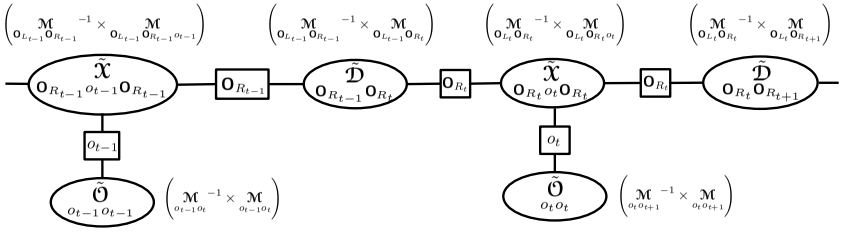

Figure 4: Graphical representation of the HSMM spectral algorithm for inference in Algorithm 1. As compared to junction tree in Figure 2, the cliques and separators are now defined in terms of the tensors, which are defined with respect to the observed data. The expressions in the parenthesis show the observable representation of the corresponding tensors.

defined with respect to unknown model parameters (as, for example, in (7)), we can readily estimate them from data. For example, $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathcal{M}}$ is a tensor, where each entry is computed from the frequency of co-occurrence of tuples of the observations $\{\ldots, o_{t-3}, o_{t-2}, o_{t+1}, o_{t+2}, \ldots\}$. Ideally, we want a small number of observations since we need to estimate their co-occurrence frequency from the training data. A precise characterization of how many and which of these observations suffices for the analysis will be done in Section 5.

4.2.2 COMPUTATION OF TENSOR $\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}}$

The form of this tensor was established at the beginning of Section 4.2 to be:

$$\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} = \underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}^{-1}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_tx_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{o_t|x_t}{\mathcal{F}}\right) \times_{x_td_{t-1}} \underset{\mathbf{O}_{R_t}|x_td_{t-1}}{\mathcal{F}}. \tag{11}$$

Consider the following conditional independence relationship (see Figure 3):

$$\underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}} = \underset{\mathbf{O}_{L_t}|x_{t-1}d_{t-1}}{\mathcal{F}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}} \times_{x_{t-1}d_{t-1}} \underset{x_{t-1}d_{t-1}}{\mathcal{K}}, \tag{12}$$

where $\underset{x_{t-1}d_{t-1}}{\mathcal{K}} = \underset{x_{t-1}d_{t-1}x_{t-1}d_{t-1}}{\mathcal{K}}$ and we omitted the duplicated modes.

We express the inverse of tensor $\underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$ from the above equation

$$\underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}^{-1}} = \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_t}} \underset{\mathbf{O}_{L_t}|x_{t-1}d_{t-1}}{\mathcal{F}} \times_{x_{t-1}d_{t-1}} \underset{x_{t-1}d_{t-1}}{\mathcal{K}},$$

where tensor $\underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$ is inverted with respect to mode $\mathbf{O}_{R_t}$, while $\underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}}$ is inverted with respect to mode $\mathbf{O}_{L_t}$. Substituting back to (11), we get

$$\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} = \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_t}} \underset{\mathbf{O}_{L_t}|x_{t-1}d_{t-1}}{\mathcal{F}} \times_{x_{t-1}d_{t-1}} \underset{x_{t-1}d_{t-1}}{\mathcal{K}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_tx_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{o_t|x_t}{\mathcal{F}}\right) \times_{x_td_{t-1}} \underset{\mathbf{O}_{R_t}|x_td_{t-1}}{\mathcal{F}}.$$

Considering the last five factors and multiplying them together, we obtain

$$\underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}o_t}{\mathcal{M}} = \underset{\mathbf{O}_{L_t}|x_{t-1}d_{t-1}}{\mathcal{F}} \times_{x_{t-1}d_{t-1}} \underset{x_{t-1}d_{t-1}}{\mathcal{K}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_tx_t|x_{t-1}d_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{o_t|x_t}{\mathcal{F}} \right) \times_{x_td_{t-1}} \underset{\mathbf{O}_{R_t}|x_td_{t-1}}{\mathcal{F}}.$$

Finally, (11) can now be written as

$$\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} = \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}}^{-1} \times_{\mathbf{O}_{L_t}} \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}o_t}{\mathcal{M}}, \tag{13}$$

where the right hand side can now be estimated directly from data, without the need for the model parameters.

4.2.3 COMPUTATION OF TENSOR $\tilde{\mathcal{O}}_{o_to_t}$

Finally, we consider the tensor

$$\underset{o_to_t}{\tilde{\mathcal{O}}} = \underset{o_t|x_t}{\mathcal{F}}^{-1} \times_{x_t} \underset{o_t|x_t}{\mathcal{O}}. \tag{14}$$

The conditional independence relationship can take the form

$$\underset{o_to_{t+1}}{\mathcal{M}} = \underset{o_t|x_t}{\mathcal{F}} \times_{x_t} \underset{o_{t+1}|x_t}{\mathcal{F}} \times_{x_t} \underset{x_t}{\mathcal{K}}.$$

Expressing the inverse of $\underset{o_t|x_t}{\mathcal{F}}$

$$\underset{o_t|x_t}{\mathcal{F}}^{-1} = \underset{o_to_{t+1}}{\mathcal{M}}^{-1} \times_{o_{t+1}} \underset{o_{t+1}|x_t}{\mathcal{F}} \times_{x_t} \underset{x_t}{\mathcal{K}},$$

and substituting in (14), we get

$$\begin{aligned} \underset{o_to_t}{\tilde{\mathcal{O}}} &= \underset{o_to_{t+1}}{\mathcal{M}}^{-1} \times_{o_{t+1}} \underset{o_{t+1}|x_t}{\mathcal{F}} \times_{x_t} \underset{x_t}{\mathcal{K}} \times_{x_t} \underset{o_t|x_t}{\mathcal{O}} \\ &= \underset{o_to_{t+1}}{\mathcal{M}}^{-1} \times_{o_{t+1}} \underset{o_to_{t+1}}{\mathcal{M}}. \end{aligned} \tag{15}$$

4.3 Basic Version of Spectral Algorithm

The basic version of the spectral HSMM algorithm to compute $\underset{o_1,\ldots,o_T}{\mathcal{P}}$ entirely using the observed variables can be described as a two step process: in the learning step, compute tensors $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}}$, $\underset{\mathbf{O}_{R_{t-1}}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}}$, and $\underset{o_to_t}{\tilde{\mathcal{O}}}$ for each t using (10), (13) and (15) from the training data. In the inference step, use (5) to compute $p(\mathbf{S}^{test})$. Algorithm 1 shows its basic version and Figure 4 shows the graphical representation of this algorithm in terms of the transformed junction tree of Figure 2.

As an example, consider the learning step of the algorithm and the computation of tensor in (10), i.e.,

$$\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} = \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}}^{-1} \times_{\mathbf{O}_{L_{t-1}}} \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathcal{M}}.$$

Algorithm 1 Basic Spectral Algorithm for HSMM inference

Input: Training sequences: $\mathbf{S}^i = \{o_1^i, \ldots, o_{T_i}^i\}, i = 1, \ldots, N$.
Testing sequence: $\mathbf{S}^{test} = \{o_1^{test}, \ldots, o_T^{test}\}$.
Output: $p(\mathbf{S}^{test})$

Learning phase:
for all t **do**
  Estimate $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}}$, $\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}}$ and $\underset{o_to_t}{\tilde{\mathcal{O}}}$ from data $\{\mathbf{S}^1, \ldots, \mathbf{S}^N\}$ using equations (10), (13) and (15).
end for

Inference phase:
$p(\mathbf{S}^{test}) = 1$
for $t = T$ **down to** $t = 1$ **do**
  $p(\mathbf{S}^{test}) = p(\mathbf{S}^{test}) \times \underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} \times_{\mathbf{O}_{R_t}} \left(\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} \times_{o_t} \underset{o_to_t}{\tilde{\mathcal{O}}}\Big|_{o_t=o_t^{test}} \right)$
end for

For a fixed t, we estimate each entry of $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}}$ from the frequency of co-occurrence of tuples of the observed symbols $\{\ldots, o_{t-3}, o_{t-2}, o_{t+1}, o_{t+2}, \ldots\}$ in the given data set (the sets $\mathbf{O}_{L_{t-1}}$ and $\mathbf{O}_{R_{t-1}}$ were defined at the beginning of Section 4.2). Next, following our discussion after (9), we invert $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathcal{M}}^{-1}$ along the modes $\mathbf{O}_{L_{t-1}}$. For this, we matrisize the tensor so that the modes $\mathbf{O}_{L_{t-1}}$ are associated with columns and $\mathbf{O}_{R_{t-1}}$ with rows in matrix $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{L_{t-1}}}{\mathbf{M}}$ (see Section 2 for the discussion on tensor matrisization and inversion). Finally, we compute the right inverse of the matrix to obtain $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{L_{t-1}}}{\mathbf{M}}^{-1}$, so that $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{L_{t-1}}}{\mathbf{M}} \cdot \underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{L_{t-1}}}{\mathbf{M}}^{-1} = \mathbf{I}$

Similarly, we estimate the tensor $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathcal{M}}$ using the corresponding co-occurrences of the observed symbols. Matrisizing the result, so that the rows correspond to the modes $\mathbf{O}_{L_{t-1}}$ and the columns to $\mathbf{O}_{R_t}$, we get the matrix $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathbf{M}}$. The multiplication $\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{L_{t-1}}}{\mathbf{M}}^{-1} \cdot \underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_t}}{\mathbf{M}} = \underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathbf{D}}}$ produces a matrix, which is then converted to a tensor to get the final result in (10).

In the inference step we perform tensor multiplications for each t running along the length of the testing sequence. The only nuance here is that before multiplying the tensor $\underset{o_to_t}{\tilde{\mathcal{O}}}$ with others, the second mode o_t, whose dimension is n_o is collapsed into a scalar. This operation is denoted as $\underset{o_to_t}{\tilde{\mathcal{O}}}\Big|_{o_t=o_t^{test}}$, which means that based on the value of the tth symbol in testing sequence, we select the column corresponding to the element o_t^{test}. For example, if $\underset{o_to_t}{\tilde{\mathcal{O}}} \in \mathbb{R}^{10\times10}$ and $o_t^{test} = 3$ then $\underset{o_to_t}{\tilde{\mathcal{O}}}\Big|_{o_t=o_t^{test}} \in \mathbb{R}^{10\times1}$, a third column in the original matrix.

Analyzing (10), (13) and (15), we see that the computational complexity of the learning phase of the algorithm is determined by the tensor inverses and multiplications. For example, if in (10) we denote $|\mathbf{O}_R| = |\mathbf{O}_L| = \ell$ (in Section 5 we will show that $\ell = \lceil 1 + \frac{\log n_d}{\log n_x} \rceil$), then $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathbf{M}} \in \mathbb{R}^{n_o^\ell \times n_o^\ell}$

and $\underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_t}}{\mathbf{M}} \in \mathbb{R}^{n_o^\ell \times n_o^\ell}$. The computational complexity of the multiplications and inversions would then be $\mathcal{O}(n_o^{3\ell})$. Performing this computations for all t and assuming that the length of the sequences is T, would result in $\mathcal{O}\left(n_o^{3\ell}T\right)$. Additionally, with N training examples there will be a cost of $\mathcal{O}\left(\ell NT\right)$ to estimate the sample moments $\mathfrak{M}$, which is based on counting the co-occurrences of certain observable symbols. In the inference phase of the algorithm, we perform a series of tensor multiplications with the cost of $\mathcal{O}(n_o^{3\ell}T)$.

4.4 Efficient Version of Spectral Algorithm

Note that for large ℓ the accurate estimation of tensors $\mathfrak{M}$ for each t will require large number of training sequences which might not be available, leading to inaccurate and unstable computations. Observe, however, that for example the estimated sample-based tensors $\underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_t}}{\mathbf{M}}$ in (10) for each t estimate the same population quantity due to homogeneity of HSMM. Thus, a novel aspect of our work is the improvement of the accuracy and efficiency of the basic Algorithm 1 by exploiting the homogeneity property of HSMM and estimating the tensors $\tilde{\mathfrak{X}}$, $\tilde{\mathfrak{D}}$ and $\tilde{\mathfrak{O}}$ using all time steps, i.e., by pooling samples across different t and averaging the estimates. Thus, we compute only three tensors across all t, as opposed to computing these tensors separately for each t.

We show the details for computing the tensors $\tilde{\mathfrak{D}}$ in the batch form. The derivations for other tensors $\tilde{\mathfrak{X}}$ and $\tilde{\mathfrak{O}}$ can be computed in a similar manner. Recall from (10) the form of $\underset{\mathbf{o}_{R_{t-1}}\mathbf{o}_{R_t}}{\tilde{\mathfrak{D}}}$, and consider the following alternative expression, based on the sum over all t:

$$\tilde{\mathfrak{D}} = \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_{t-1}}}{\mathbf{M}}\right)^{-1} \times_{\mathbf{o}_L} \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_t}}{\mathbf{M}}\right), \tag{16}$$

where $\mathbf{o}_L$ denotes a generic mode of the averaged tensor $\mathfrak{M}$, corresponding to $\mathbf{o}_{L_{t-1}}$ for all t. Note that in practice, instead of summation, we use averaging to avoid numerical overflow problems, and the average is equivalent to the expression in (16) since the term $\frac{1}{T}$ cancels out. Since

$$\underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_{t-1}}}{\mathbf{M}} = \underset{\mathbf{o}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{\mathbf{o}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}}, \tag{17}$$

the first term inside brackets can be rewritten as:

$$\sum_t \underset{\mathbf{o}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{\mathbf{o}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \overset{(a)}{=} \sum_t \underset{\mathbf{o}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}$$
$$\overset{(b)}{=} \underset{\mathbf{o}_{R_2}|x_2d_1}{\mathcal{F}} \times \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}\right), \tag{18}$$

where in (a) we combined the two factors, i.e., $\underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}} = \underset{\mathbf{o}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}x_{t-1}d_{t-2}}{\mathcal{K}}$ and in (b) we used the homogeneity property of HSMM, i.e., the fact that $\underset{\mathbf{o}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ does not depend on time stamp t, and extracted one of the common factors, in fact, the first factor. Note that the term $\underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}$, on the other hand, does depend on t since the factor $\underset{x_{t-1}d_{t-2}}{\mathcal{K}}$, which represents the probability $p(x_{t-1}, d_{t-2})$, changes as the time stamp t changes.

Similarly, since

$$\underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_t}}{\mathbf{M}} = \underset{\mathbf{o}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{o}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}, \tag{19}$$

rewrite the second term in (16) as

$$\sum_t \underset{\mathbf{o}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{o}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$$
$$= \sum_t \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}} \times_{x_{t-1}d_{t-2}} \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \underset{\mathbf{o}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$$
$$= \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}\right) \times \underset{d_2|x_2x_2d_1}{\mathcal{D}} \times_{x_2d_2} \underset{\mathbf{o}_{R_3}|x_2d_2}{\mathcal{F}}, \tag{20}$$

where we used the transformations similar as in (18), i.e., the fact that the factors $\underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}}$ and $\underset{\mathbf{o}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$ are homogeneous, independent of t. Now if we multiply the inverse of (18) with (20), we get

$$\underset{\mathbf{o}_{R_2}|x_2d_1}{\mathcal{F}}^{-1} \times \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}\right)^{-1} \times \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}x_{t-1}d_{t-2}}{\overline{\mathcal{F}}}\right) \times \underset{d_2|x_2x_2d_1}{\mathcal{D}} \times \underset{\mathbf{o}_{R_3}|x_2d_2}{\mathcal{F}} \tag{21}$$
$$= \underset{\mathbf{o}_{R_2}|x_2d_1}{\mathcal{F}}^{-1} \times_{x_2d_1} \underset{d_2|x_2x_2d_1}{\mathcal{D}} \times_{x_2d_2} \underset{\mathbf{o}_{R_3}|x_2d_2}{\mathcal{F}}$$
$$= \underset{\mathbf{o}_{R_2}\mathbf{o}_{R_3}}{\tilde{\mathfrak{D}}} = \underset{\mathbf{o}_{R_{t-1}}\mathbf{o}_{R_t}}{\tilde{\mathfrak{D}}}, \tag{22}$$

where in (21) we used the fact that the order in which tensors are multiplied is irrelevant and also the fact that the terms in parenthesis are invertible. This is due to the fact that the set of observations $\mathbf{o}_{L_{t-1}}$ for all t is selected so as to make each of the summand invertible (see Section 5 for the details about the choice of $\mathbf{o}_{L_{t-1}}$). Moreover, in (22) we used the definition of $\underset{\mathbf{o}_{R_{t-1}}\mathbf{o}_{R_t}}{\tilde{\mathfrak{D}}}$

$$\underset{\mathbf{o}_{R_{t-1}}\mathbf{o}_{R_t}}{\tilde{\mathfrak{D}}} = \underset{\mathbf{o}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}^{-1} \times \underset{d_{t-1}|x_{t-1}d_{t-2}}{\mathcal{D}} \times \underset{\mathbf{o}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}},$$

together with the homogeneity property of HSMM. We note that although the above derivations rely on the assumption of the existence of the matrix summation inverse in equation (21), the idea of aggregating observations from multiple time steps has also been utilized by other works, e.g., (Siddiqi et al., 2010; Anandkumar et al., 2014a) and shown to be very effective in practice, significantly improving the accuracy of corresponding algorithms.

We can conclude that the batch form of the tensor takes the form:

$$\tilde{\mathfrak{D}} = \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_{t-1}}}{\mathbf{M}}\right)^{-1} \times_{\mathbf{o}_L} \left(\sum_t \underset{\mathbf{o}_{L_{t-1}}\mathbf{o}_{R_t}}{\mathbf{M}}\right). \tag{23}$$

Algorithm 2 Efficient Spectral Algorithm for HSMM inference

Input: Training sequences: $\mathbf{S}^i = \{o_1^i, \ldots, o_{T_i}^i\}, i = 1, \ldots, N$.
Testing sequence: $\mathbf{S}^{test} = \{o_1^{test}, \ldots, o_T^{test}\}$.
Output: $p(\mathbf{S}^{test})$

Learning phase:
Estimate $\tilde{\mathcal{D}}, \tilde{\mathfrak{X}}$ and $\tilde{\mathfrak{O}}$ from data $\{\mathbf{S}^1, \ldots, \mathbf{S}^N\}$ using equations (23), (24) and (25).

Inference phase:
$p(\mathbf{S}^{test}) = 1$
for $i = T$ **down to** $i = 1$ **do**
$p(\mathbf{S}^{test}) = p(\mathbf{S}^{test}) \times \tilde{\mathcal{D}} \times \left(\tilde{\mathfrak{X}} \times \tilde{\mathfrak{O}}|_{o=o_i^{test}}\right)$
end for

Similar derivations can be carried out to obtain the rest of the tensors in the batch form:

$$\tilde{\mathfrak{X}} = \left(\sum_t \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathfrak{M}}\right)^{-1} \times_{\mathbf{O}_L} \left(\sum_t \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t} o_t}{\mathfrak{M}}\right), \tag{24}$$

$$\tilde{\mathfrak{O}} = \left(\sum_t \underset{o_t o_{t+1}}{\mathfrak{M}}\right)^{-1} \times_o \left(\sum_t \underset{o_t o_{t+1}}{\mathfrak{M}}\right). \tag{25}$$

where in the last expression the mode o corresponds to the mode $o_{t_{t+1}}$ after averaging of tensor $\underset{o_t o_{t+1}}{\mathfrak{M}}$ for all t.

Analyzing (23), (24) and (25), we see that the computational complexity of the learning phase of the Algorithm 2 is now $\mathcal{O}\left((n_o^{2\ell} + \ell N)T\right)$, mainly determined by the tensor additions and the estimation of the sample moments $\mathfrak{M}$. The number of inverses and multiplications is now fixed and independent of sequence length T. Specifically, there will be only three tensor multiplications and inversions for a total cost of $\mathcal{O}(n_o^{3\ell})$ (as opposed to T tensor multiplications and inversions as in Algorithm 1). The computational complexity of the inference phase is $\mathcal{O}(n_o^{3\ell}T)$, which is the same as for Algorithm 1.

Note that such a batch tensor computation significantly improves the accuracy of the resulting spectral algorithm. In part, this is due to the fact that we now use more data to estimate the tensors as compared to the original form (5). The estimates obtained in this form have lower variance, which in turn ensures that the inverses we compute in (23), (24) and (25) are more stable and accurate.

5. Rank Analysis of Observable Tensors

In Section 4.2.1, when we derived the equations (10), (13) and (15), we glossed over the question of the existence of tensor inverses $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathfrak{M}^{-1}}$, $\underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathfrak{M}^{-1}}$ and $\underset{o_t o_{t+1}}{\mathfrak{M}^{-1}}$. In this section, our task is to analyze the rank structure of these tensors and impose restrictions on the sets $\mathbf{O}_L$ and $\mathbf{O}_R$ to ensure that the rank conditions are satisfied. For example, consider equation (10) and expand all its terms using (8)

to get

$$\underset{\mathbf{O}_{R_{t-1}}\mathbf{O}_{R_t}}{\tilde{\mathcal{D}}} = \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times \overbrace{\underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times \underbrace{\underset{x_{t-1}d_{t-2}}{\mathcal{K}^{-1}} \times \underset{x_{t-1}d_{t-2}}{\mathcal{K}}}} \times \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times \underset{d_{t-1}|x_{t-1}x_{t-1}d_{t-2}}{\mathcal{D}} \times \underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}},$$

where we dropped the multiplication subscripts and some of the duplicated modes, which can be inferred from the context. Observe that in order for the above equation to produce (6), the terms in the middle must multiply out into identity tensor

$$\underset{x_{t-1}d_{t-2}}{\mathcal{I}} = \underset{x_{t-1}d_{t-2}}{\mathcal{K}^{-1}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \qquad \underset{x_{t-1}d_{t-2}}{\mathcal{I}} = \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times_{\mathbf{O}_{L_{t-1}}} \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}. \tag{26}$$

Moreover, recall that $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ was originally introduced as part of the identity tensor

$$\underset{x_{t-1}d_{t-2}}{\mathcal{I}} = \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}^{-1}} \times_{\mathbf{O}_{R_{t-1}}} \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}, \tag{27}$$

therefore, we can conclude that for (10) to exist, the identity statements in (26) and (27) must be satisfied. These statements have implications for the ranks of $\underset{x_{t-1}d_{t-2}}{\mathcal{K}}$, $\underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ and $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$, which in turn determine the length of the observation sequences $\mathbf{O}_{L_{t-1}}$ and $\mathbf{O}_{R_{t-1}}$.

Since $\underset{x_{t-1}d_{t-2}}{\mathcal{K}}$ represents a distribution $p(x_{t-1}d_{t-2})$, its matrisized version is a diagonal matrix with $p(x_{t-1}d_{t-2})$ on the diagonal. Using assumptions $A1$ and $A2$, it can be concluded that the diagonal elements in this matrix are non-zero and it has rank $n_x n_d$, it is thus invertible and so the first equation in (26) is satisfied.

Next, consider the second equation in (26) and recall from Section 2 that if we matrisize the tensor as $\underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathbf{F}} \in \mathbb{R}^{n_o^{|\mathbf{O}_{L_{t-1}}|} \times n_x n_d}$ then $\mathbf{F}$ must have full column rank $n_x n_d$ for the proper inverse to exist, implying $n_o^{|\mathbf{O}_{L_{t-1}}|} \geq n_x n_d$. Similarly, $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ in (27) must have rank $n_x n_d$. As a consequence of the above, the tensor

$$\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathfrak{M}} = \underset{\mathbf{O}_{L_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times \underset{x_{t-1}d_{t-2}}{\mathcal{K}} \tag{28}$$

will have rank $n_x n_d$ and, in general, is rank-deficient.

The argument above can also be used to show that $\underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathfrak{M}}$ has rank $n_x n_d$ since in (12) the tensors $\underset{x_{t-1}d_{t-1}}{\mathcal{K}}$, $\underset{\mathbf{O}_{L_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$ and $\underset{\mathbf{O}_{R_t}|x_{t-1}d_{t-1}}{\mathcal{F}}$ all have rank $n_x n_d$. Similarly, $\underset{o_t o_{t+1}}{\mathfrak{M}}$ will have rank n_x because in (15) the rank of the participating tensors $\underset{x_t}{\mathcal{K}}$, $\underset{o_{t+1}|x_t}{\mathcal{F}}$ and $\underset{o_t|x_t}{\mathcal{F}}$ is n_x. In particular, note that the tensor $\underset{o_t|x_t}{\mathcal{F}}$ is the observation matrix $O \in \mathbb{R}^{n_o \times n_x}$ of the model and it has rank n_x according to assumption $A3$. This conclusion also justifies our choice for $\omega_{x_t} = o_t$ at the end of Section 4.1.

The key unknowns now are the sets of the observed variables $\mathbf{O}_R$ and $\mathbf{O}_L$ that must be appropriately selected for the corresponding tensors to have rank $n_x n_d$. Recall that we defined $\mathbf{O}_{R_{t-1}} = \{o_t, o_{t+1}, \ldots\}$. As one of the new key results of our work, we established that if we select the observations o_t non-sequentially with gaps that grow exponentially with the state size n_x then the following result holds for all t:

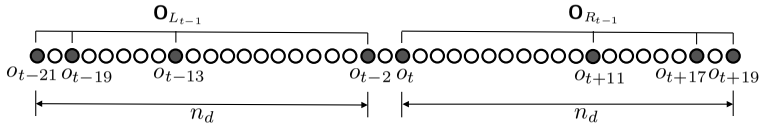

Figure 5: Observations required to estimate $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathfrak{M}}$ from data for HSMM with $n_x = 3$ and $n_d = 20$.

Theorem 1 *Let the number of observations be $|\mathbf{O}_{R_{t-1}}| = \ell$ and define the set of indices $\mathcal{S} = \{\max\{t,\ t+(n_d-1)-(n_x^i-1)\} \mid i = 0,\dots,\ell-1\}$, such that $\mathbf{O}_{R_{t-1}} = \{o_k | k \in \mathcal{S}\}$ then the rank of tensor $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$ is $\min[n_x^\ell,\ n_x n_d]$.*

As a consequence of this result, to achieve the rank $n_x n_d$ we will require $\ell = \lceil 1 + \frac{\log n_d}{\log n_x} \rceil$ observations, since we need to ensure $n_x^\ell \geq n_x n_d$ and we want the minimal ℓ which satisfies this. The span of the selected observations is n_d, while their number is only logarithmic in n_d. For example, consider the estimation of tensor $\underset{\mathbf{O}_{L_{t-1}}\mathbf{O}_{R_{t-1}}}{\mathfrak{M}}$ for an HSMM with $n_x = 3$ and $n_d = 20$. In this case $\ell = 4$ and $\mathbf{O}_{R_{t-1}} = \{o_t, o_{t+11}, o_{t+17}, o_{t+19}\}$ and $\mathbf{O}_{L_{t-1}} = \{o_{t-21}, o_{t-19}, o_{t-13}, o_{t-2}\}$, where the set $\mathbf{O}_{L_{t-1}}$ is defined similar to $\mathbf{O}_{R_{t-1}}$ in Theorem 1 but for the indices to the left of time stamp $t-1$. Figure 5 illustrates this example. We note that the requirement for the span of the selected observations to be n_d, which is a maximum state persistence, is to ensure that for a given time stamp t, we select the observations far enough to the right and left of it so that those observations are likely to be sampled from different hidden states.

In order to prove the above Theorem, we will focus our analysis on the tensor $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$ instead of $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$. This specific choice was only done to ensure the compactness in our notations, however the HSMM homogeneity property enables us to transfer this result for tensors for any t. Note that

$$\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}} = \underset{\mathbf{O}_{R_{t-1}}|x_{t-2}d_{t-2}}{\mathcal{F}} = \underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}} \times_{x_{t-1}d_{t-2}} \underset{x_{t-1}d_{t-2}|x_{t-2}d_{t-2}}{\mathcal{X}},$$

where the first equality is due to the homogeneity property of the model and in the second equality we embedded the HSMM transition matrix into tensor $\underset{x_{t-1}d_{t-2}|x_{t-2}d_{t-2}}{\mathcal{X}}$ with mode d_{t-2} duplicated. It can be shown that the matricized tensor $\underset{x_{t-1}d_{t-2}|x_{t-2}d_{t-2}}{\mathbf{X}} \in \mathbb{R}^{n_x n_d \times n_x n_d}$ has rank $n_x n_d$, i.e., it is full rank. Therefore, the rank structure of $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$ determines the rank structure of $\underset{\mathbf{O}_{R_{t-1}}|x_{t-1}d_{t-2}}{\mathcal{F}}$.

The rest of Section 5 is devoted to the proof of Theorem 1. We first establish the rank structure of tensor $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$ for sequential set of observations $\mathbf{O}_{R_{t+1}}$ and then analyze the rank structure for the observations which were selected non-sequentially.

5.1 Rank Structure of Tensor $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$

Define by $\mathbf{X}_{R_{t+1}} = \{x_{t+2}, x_{t+3}, \dots\}$, the sequence of hidden states corresponding to observations $\mathbf{O}_{R_{t+1}} = \{o_{t+2}, o_{t+3}, \dots\}$. Then using conditional independence property of the graphical model in Figure 1, namely, that the variables $\mathbf{O}_{R_{t+1}}$ and $x_t d_t$ are independent given $\mathbf{X}_{R_{t+1}}$, we can write:

$$\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}} = \underset{\mathbf{O}_{R_{t+1}}|\mathbf{X}_{R_{t+1}}}{\mathcal{Q}} \times \underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathcal{T}}, \tag{29}$$

for some tensors $\mathcal{Q}$ and $\mathcal{T}$, representing the appropriate probability distributions.

Denoting $\ell = |\mathbf{O}_{R_{t+1}}| = |\mathbf{X}_{R_{t+1}}|$, it can be verified, that the matrisized form of $\mathcal{Q}$ in (29) can be written as $\mathbf{Q} = \otimes_\ell O \in \mathbb{R}^{n_o^\ell \times n_x^\ell}$, i.e., a Kronecker product of the observation matrix O with itself ℓ times. According to the assumption $A3$, $rank(O) = n_x$ and $n_x \leq n_o$, and using the rank property of the Kronecker product, we infer that $rank(\mathbf{Q}) = n_x^\ell$.

Combining the above conclusion with the fact that the matrisized form of the other two tensors in (29) is $\mathbf{F} \in \mathbb{R}^{n_o^\ell \times n_x n_d}$ and $\mathbf{T} \in \mathbb{R}^{n_x^\ell \times n_x n_d}$, to ensure invertibility of $\mathcal{F}$, we need to select a set of variables $\mathbf{X}_{R_{t+1}}$ so that $rank\left(\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}\right) = n_x n_d$ with the condition that $n_x^\ell \geq n_x n_d$. Thus, the problem of the analysis of the rank structure of tensor $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$ translates to the problem of rank structure of matrix $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$. In what follows, we assume that $\mathbf{X}_{R_{t+1}} = \{x_{t+2}, \dots, x_{t+\ell+1}\}$ are sequential and so we would be interested in determining ℓ which makes $rank\left(\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}\right) = n_x n_d$. Later, the sequential assumption will be removed and we show how to select such variables in a more efficient way.

5.1.1 COMPUTATION OF FACTOR T

In order to study the rank structure of $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ we will have to understand the mechanism how this matrix is constructed and how the rank changes as the size of $\mathbf{X}_{R_{t+1}}$ increases. We start by considering the following conditional independence relationships from the model in Figure 1:

$$p(x_{t+3}, x_{t+2}|x_{t+1}, d_{t+1}) = \sum_{d_{t+2}} p(x_{t+3}|x_{t+2}, d_{t+2}) \underline{p(d_{t+2}|x_{t+2}, d_{t+1}) p(x_{t+2}|x_{t+1}, d_{t+1})} \tag{30}$$

$$p(x_{t+3}, x_{t+2}, x_{t+1}|x_t, d_t) = \sum_{d_{t+1}} p(x_{t+3}, x_{t+2}|x_{t+1}, d_{t+1}) \underline{p(d_{t+1}|x_{t+1}, d_t) p(x_{t+1}|x_t, d_t)}. \tag{31}$$

Using the model's homogeneity property, we see that the quantity underlined in expression (30) is the same as the one in (31). Moreover, equation (30) can then be thought of as transforming $p(x_{t+1}|x_t, d_t)$ into $p(x_{t+2}, x_{t+1}|x_t, d_t)$, while the expression in (31), in effect, transforms probability $p(x_{t+2}, x_{t+1}|x_t, d_t)$ into $p(x_{t+3}, x_{t+2}, x_{t+1}|x_t, d_t)$. Thus (30) and (31) encode the following chain of transformations:

$$p(x_{t+1}|x_t, d_t) \to p(x_{t+2}, x_{t+1}|x_t, d_t) \to p(x_{t+3}, x_{t+2}, x_{t+1}|x_t, d_t).$$

Based on the above considerations, we can rewrite (30) and (31) in the tensor form as follows:

$$\underset{x_{t+3},x_{t+2}|x_{t+1},d_{t+1}}{\mathcal{T}} = \underset{x_{t+3},x_{t+2}|x_{t+2},d_{t+2}}{\mathcal{T}} \times_{x_{t+2}d_{t+2}} \underset{x_{t+2},d_{t+2}|x_{t+1}d_{t+1}}{\mathcal{V}} \tag{32}$$

$$\underset{x_{t+3},x_{t+2},x_{t+1}|x_t,d_t}{\mathcal{T}} = \underset{x_{t+3},x_{t+2},x_{t+1}|x_{t+1},d_{t+1}}{\mathcal{T}} \times_{x_{t+1}d_{d+1}} \underset{x_{t+1},d_{t+1}|x_td_t}{\mathcal{V}}, \tag{33}$$

where $\underset{x_{t+2},d_{t+2}|x_{t+1},d_{t+1}}{\mathcal{V}} = \underset{x_{t+1},d_{t+1}|x_t,d_t}{\mathcal{V}} = \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathcal{D}} \times_{x_{t+1}d_t} \underset{x_{t+1},d_t|x_t,d_t}{\mathcal{X}}$. The homogeneity property allows us to rewrite the above as

$$\underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathcal{T}} = \underset{x_{t+1},x_t|x_t,d_t}{\mathcal{T}} \times \mathcal{V} \tag{34}$$

$$\underset{x_{t+3},x_{t+2},x_{t+1}|x_t,d_t}{\mathcal{T}} = \underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathcal{T}} \times \mathcal{V}. \tag{35}$$

Our next step is to represent the above tensor equations in the matrix form. First, consider tensor $\mathcal{V}$, its matricized form can be written as:

$$\mathbf{V} = \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}} \ \underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}} \tag{36}$$

where $\underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}} \in \mathbb{R}^{n_x n_d \times n_x n_d}$ and $\underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}} \in \mathbb{R}^{n_x n_d \times n_x n_d}$. Next, consider the equations (34) and (35), its matrix version is of the form:

$$\underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} = \underset{x_{t+1},x_t|x_t,d_t}{\mathbf{T}} \ \mathbf{V} \tag{37}$$

$$\underset{x_{t+3},x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} = \underset{x_{t+2},x_{t+1},x_t|x_t,d_t}{\mathbf{T}} \ \mathbf{V}, \tag{38}$$

here the sizes of the matrices are $\underset{x_{t+1},x_t|x_t,d_t}{\mathbf{T}} \in \mathbb{R}^{n_x^2 \times n_x n_d}$, $\underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} \in \mathbb{R}^{n_x^2 \times n_x n_d}$, and similarly $\underset{x_{t+2},x_{t+1},x_t|x_t,d_t}{\mathbf{T}} \in \mathbb{R}^{n_x^3 \times n_x n_d}$, and matrix $\underset{x_{t+3},x_{t+2},x_t|x_t,d_t}{\mathbf{T}} \in \mathbb{R}^{n_x^3 \times n_x n_d}$.

Summarizing the above derivations, we can describe the following algorithmic approach for analyzing $\underset{\mathbf{X}_{R_{t+1}}|x_td_t}{\mathbf{T}}$ as $\mathbf{X}_{R_{t+1}}$ increases. We begin with $\underset{x_{t+1}|x_t,d_t}{\mathbf{T}} = [\mathcal{X}\ \mathbf{I} \cdots \mathbf{I}] \in \mathbb{R}^{n_x \times n_x n_d}$, where the first block $\mathcal{X} \in \mathbb{R}^{n_x \times n_x}$ corresponds to $d_t = 1$, and the subsequent $(n_d - 1)$ blocks of $\mathbf{I} \in \mathbb{R}^{n_x \times n_x}$ correspond to $d_t > 1$ for which $x_{t+1} = x_t$. We then use (37) to get $\underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}}$. However, notice that in (37) the matrix $\underset{x_{t+1},x_t|x_t,d_t}{\mathbf{T}}$ has a duplicated mode x_t, therefore, we need to restructure $\underset{x_{t+1}|x_t,d_t}{\mathbf{T}}$, which can be accomplished with:

$$\underset{x_{t+1},x_t|x_t,d_t}{\mathbf{T}'} = \underset{x_{t+1}|x_t,d_t}{\mathbf{T}} \odot \ \mathbf{E},$$

where $\mathbf{E} = [\mathbf{I} \cdots \mathbf{I}] \in \mathbb{R}^{n_x \times n_x n_d}$ and $\odot$ denotes a Khatri-Rao product (row-wise Kronecker product)[2]. Then, we use (38) to transform $\underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}}$ into $\underset{x_{t+3},x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}}$ where, again a

2. Let $\mathbf{P} = \begin{bmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \\ \vdots \\ \mathbf{p}_n \end{bmatrix} \in \mathbb{R}^{m \times n}$ and $\mathbf{Q} \in \mathbb{R}^{k \times n}$ then $\mathbf{P} \odot \mathbf{Q} = \begin{bmatrix} \mathbf{p}_1 \otimes \mathbf{Q} \\ \mathbf{p}_2 \otimes \mathbf{Q} \\ \vdots \\ \mathbf{p}_n \otimes \mathbf{Q} \end{bmatrix} \in \mathbb{R}^{mk \times n}$, where $\otimes$ is a Kronecker product.

Algorithm 3 Computation of $\underset{\mathbf{X}_{R_{t+1}}|x_td_t}{\mathbf{T}}$

Input: $p(d_t|x_t, d_{t-1})$ and $p(x_t|x_{t-1}, d_{t-1})$ - duration and transition distributions, ℓ - the number of sequential hidden states represented by $\mathbf{X}_{R_{t+1}}$.
Initialization:

$$p(x_{t+1}|x_t, d_t) \rightarrow \underset{x_{t+1}|x_t,d_t}{\mathbf{T}}$$
$$p(d_{t+1}|x_{t+1}, d_t) \rightarrow \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}}$$
$$p(x_{t+1}|x_t, d_t) \rightarrow \underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}}$$
$$\mathbf{V} = \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}} \ \underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}}, \quad \mathbf{E} = [\mathbf{I} \cdots \mathbf{I}]$$

for $i = 1$ **to** $\ell - 1$ **do**

$$\underset{x_{t+i},\ \ldots\ ,x_{t+1},x_t|x_t,d_t}{\mathbf{T}'} = \underset{x_{t+i},\ \ldots\ ,x_{t+1}|x_t,d_t}{\mathbf{T}} \odot \mathbf{E} \tag{39}$$

$$\underset{x_{t+i+1},\ \ldots\ ,x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} = \underset{x_{t+i},\ \ldots\ ,x_{t+1},x_t|x_t,d_t}{\mathbf{T}'} \mathbf{V} \tag{40}$$

end for

preliminary step is to restructure the matrix as follows:

$$\underset{x_{t+2},x_{t+1},x_t|x_t,d_t}{\mathbf{T}'} = \underset{x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} \odot \ \mathbf{E}.$$

Algorithm 3 summarizes the above constructions for a general case.

The following Theorem characterizes the rank structure of matrix $\underset{\mathbf{X}_{R_{t+1}}|x_td_t}{\mathbf{T}}$ in the output of the Algorithm 3. The proof can be found in Appendix A.1.

Theorem 2 *The rank of the output matrix* $\underset{\mathbf{X}_{R_{t+1}}|x_td_t}{\mathbf{T}}$ *in Algorithm 3 is* $\min(\ell n_x, n_x n_d)$.

Applying now Theorem 2 to equation (29) in matrix form

$$\underset{\mathbf{O}_{R_{t+1}}|x_td_t}{\mathbf{F}} = \underset{\mathbf{O}_{R_{t+1}}|\mathbf{X}_{R_{t+1}}}{\mathbf{Q}} \times \underset{\mathbf{X}_{R_{t+1}}|x_td_t}{\mathbf{T}},$$

where $rank(\mathbf{Q}) = n_x^\ell$ we can now conclude the following result:

Corollary 3 *To achieve the full column rank for* $\underset{\mathbf{O}_{R_{t+1}}|x_td_t}{\mathbf{F}} \in \mathbb{R}^{n_o^\ell \times n_x n_d}$, *i.e. to ensure that the rank of tensor* $\underset{\mathbf{O}_{R_{t+1}}|x_td_t}{\mathcal{F}}$ *is* $n_x n_d$, *the number of observations* ℓ *in* $\mathbf{O}_{R_{t+1}} = \{o_{t+2}, o_{t+3}, \ldots, o_{t+\ell+1}\}$ *must be equal to the maximum state persistence i.e.,* $\ell = n_d$.

Algorithm 4 Efficient computation of $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$

Input: $p(d_t|x_t, d_{t-1})$ and $p(x_t|x_{t-1}, d_{t-1})$ - duration and transition distributions, ℓ - the number of sequential hidden states represented by $\mathbf{X}_{R_{t+1}}$
Initialization:

$$p(x_{t+1}|x_t, d_t) \rightarrow \underset{x_{t+1}|x_t,d_t}{\mathbf{T}}$$
$$p(d_{t+1}|x_{t+1}, d_t) \rightarrow \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}}$$
$$p(x_{t+1}|x_t, d_t) \rightarrow \underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}}$$
$$\mathbf{V} = \underset{x_{t+1},d_{t+1}|x_{t+1},d_t}{\mathbf{D}} \underset{x_{t+1},d_t|x_t,d_t}{\mathbf{X}}, \quad \mathbf{E} = [\mathbf{I} \cdots \mathbf{I}]$$

$c = 1$
for $i = 1$ **to** $\ell - 1$ **do**

$$\mathbf{T} = \mathbf{T}\ \mathbf{V} \tag{41}$$

if $i == (n_x)^c - 1$ **or** $i == \ell - 1$ **do**

$$\mathbf{T} = \mathbf{T} \odot \mathbf{E} \tag{42}$$

end if
$c = c + 1$
end for

5.1.2 EFFICIENT COMPUTATION OF FACTOR $\mathbf{T}$

In Corollary 3 we established that the number of observations in $\mathbf{O}_{R_{t+1}} = \{o_{t+2}, o_{t+3}, \ldots, o_{t+\ell+1}\}$ is $\ell = n_d$. Therefore, the sizes of the estimated quantities $\tilde{\mathcal{D}} \in \mathbb{R}^{n_o^{n_d} \times n_o^{n_d}}$ and $\tilde{\mathcal{X}} \in \mathbb{R}^{n_o^{n_d} \times n_o^{n_d} \times n_o}$ in Algorithm 3 will have exponential dependency on n_d. When maximum state persistence is large, the estimation of such quantity becomes impractical. Fortunately, we can modify Algorithm 3 to significantly reduce the number of observations. The idea is to apply the step (40) multiple times in-between the applications of step (39). Recall that in the previous construction we established that $\ell = n_d$ consecutive observations are sufficient, e.g., $\mathbf{O}_{R_{t+1}} = \{o_{t+2}, \ldots, o_{t+\ell+1}\}$. In contrast, in the proposed approach, every time we add an observation, say $o_{t+\tau}$, we skip certain number δ of time steps before adding another observation $o_{t+\tau+\delta}$, so that the observations are non-consecutive. As we illustrate next, the span of these non-consecutive observations is still n_d but the number of them is only logarithmic in n_d. The proposed approach still achieves the full rank structure of $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathbf{F}}$ but with smaller number of data points. Algorithm 4, which is a simple modification of Algorithm 3, summarizes the above procedure.

The following result establishes the rank structure of the matrix $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ in the output of the Algorithm 4. The proof can be found in Appendix A.2.

Theorem 4 *The rank of the output matrix* $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ *in Algorithm 4 is* $\min(n_x^\ell, n_x n_d)$.

Note that based on the above theorem, Algorithm 4 increases the rank at every step exponentially rather than linearly. In order for $\underset{\mathbf{X}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ to achieve the rank $n_x n_d$ we will now require $\ell = \lceil 1 + \frac{\log n_d}{\log n_x} \rceil$ observations, since we need to ensure $n_x^\ell = n_x n_d$. Observe that the span of the selected observations is still n_d, while the number of the observations is only logarithmic in n_d. The following Corollary summarizes the above conclusions.

Corollary 5 *To achieve the full column rank for* $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathbf{F}} \in \mathbb{R}^{n_o^\ell \times n_x n_d}$*, i.e. to ensure that the rank of tensor* $\underset{\mathbf{O}_{R_{t+1}}|x_t d_t}{\mathcal{F}}$ *is* $n_x n_d$*, the number of observations* ℓ *in* $\mathbf{O}_{R_{t+1}}$ *must be equal to* $\ell = \lceil 1 + \frac{\log n_d}{\log n_x} \rceil$*, since we need to ensure* $n_x^\ell = n_x n_d$.

Theorem 4 together with Corollary 5 now proves the Theorem 1 stated earlier.

6. Experiments

In this section we evaluated the performance of the proposed algorithm both on synthetic as well as real data sets and compared its performance to a standard EM algorithm.

6.1 Synthetic Data

Using synthetic data, we compared the estimation accuracy and the runtime of the proposed spectral algorithm with EM. For this, we defined two HSMMs, one with $n_o = 3, n_x = 2, n_d = 2$ and another with $n_o = 5, n_x = 4, n_d = 6$. For each model, we generated a set of $N_{train} = \{500, 1000, 5000, 10^4, 10^5\}$ training and $N_{test} == 1000$ testing sequences, each of length $T = 100$. The accuracy of estimating likelihood for each testing sequence was measured using the relative deviation from the true likelihood, i.e., $\epsilon_i = \frac{|\hat{p}(\mathbf{S}_i^{test}) - p(\mathbf{S}_i^{test})|}{p(\mathbf{S}_i^{test})}$ for $i = 1, \ldots, 1000$. Given 1000 such values, we then computed the final score, which is the root-mean-square error (RMSE) across all the testing sequences, RMSE $= \sqrt{\frac{1}{N_{test}} \sum_{i=1}^{N_{test}} \epsilon_i^2}$.

Figure 6 shows results, where the top row of graphs corresponds to the model with $n_o = 3, n_x = 2, n_d = 2$ and the bottom row is for model with $n_o = 5, n_x = 4, n_d = 6$. The left column of graphs shows the progression of RMSE across EM iterations for both models; the middle column shows the dependence of testing error on the number of training samples and the right column shows the running times. It can be observed from plots (b) and (e) in Figure 6 that with the small training set, EM achieves smaller errors, while as the number of training samples increases, the spectral method becomes more accurate, outperforming EM. Also, comparing the plots (a), (b) with (d) and (e), we can conclude that for larger models, i.e., whose n_o, n_x and n_d are larger, the spectral method requires more data in order to achieve same or better accuracy than EM. This is expected since the sizes of estimated tensors grow with the model size. Moreover, the plots (c) and (f) in Figure 6 show that spectral method is several orders of magnitude faster than EM.

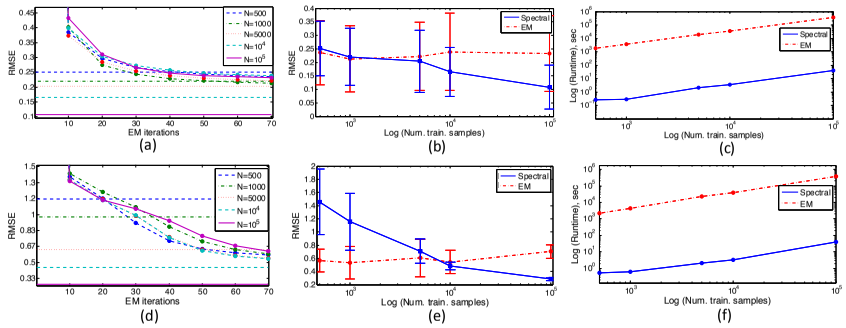

Figure 6: Performance of the spectral algorithm and EM on synthetic data generated from HSMM with $n_o = 3, n_x = 2, n_d = 2$ (top row) and $n_o = 5, n_x = 4, n_d = 6$ (bottom row). (a), (d): Error for EM across different iterations for various training data sets. The straight lines show the performance for spectral method. (b), (e): Average error and one standard deviation over 100 runs for EM after convergence and spectral algorithm across different number of training data. (c), (f): Runtime, in seconds, for both methods.

Given the above results, we can conclude that (i) for small data sets EM is a preferable algorithm, (ii) for large data, the spectral algorithm is a better choice, since it achieves higher accuracy and (iii) across all data sets the spectral algorithm requires significantly less computations as compared to EM.

6.2 Application to Aviation Safety Data

We also compared the performance of the spectral algorithm and EM on real NASA flight data set (NASA), containing over $180,000$ flights of 35 aircrafts from a defunct mid-western airline company. For each flight, the data has a record of 186 parameters, sampled at 1 Hz, including sensor readings and pilot actions. We considered a problem of anomaly detection in aviation systems (Budalakoti et al., 2009; Gorinevsky et al., 2012; Matthews et al., 2013) and used HSMM to detect abnormal flights based on pilot actions. Our idea is based on the observation that a flight can be partitioned into a number of phases, e.g., initial descent, touch down, or braking on the runway, and where within each phase the pilot performs certain actions. For example, during the initial descent, the pilot reduces throttle, lowers the flaps, and uses the ailerons and elevator to stabilize the aircraft. On the other hand, in the braking stage, the pilot uses brakes as well as rudder to keep the aircraft in the middle of the runway. Using HSMM as a model, we represented the flight phases as hidden states and the pilot actions as the observations from these states (see Melnyk et al. (2013) and Melnyk et al. (2016) for more details).

In our experiments, we focused on a part of flight related to the landing phase, which typically lasts 15-60 minutes in duration from when the flight crosses 10,000 ft while approaching an airport

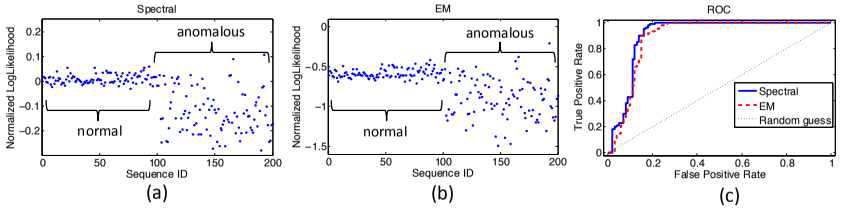

Figure 7: Evaluation of the spectral algorithm and EM on aviation safety data. (a) and (b): Normalized joint loglikelihood computed by spectral algorithm (a) and EM (b) for a set of 200 test flights, with 100 normal and 100 anomalous. HSMM parameters: $n_o = 9, n_x = 8, n_d = 40$ (c): The Receiver Operating Characteristic (ROC) curve, illustrating classification accuracy of the algorithms. Area Under Curve (AUC) for spectral algorithm is 0.91 and for EM is 0.89.

to the touch down on the runway. Our experiments are run on a subset of flights landing at the same airport. We chose 9 pilot commands, which include "selected altitude", "selected heading", "selected throttle level", etc. A simple data filter, based on the histogram of the pilot actions, was applied to select $10,020$ normal flights for training. The test set contained 200 flights, with 100 of them being similar to the training set and the rest were selected from the flights rejected by the filter. Most of anomalous flights contained low occurrence or rare events, such as fast descent, unusual usage of air brakes, etc., and few significant anomalies, e.g., aborted descent in order to delay the flight when the runway is not available. The length of the considered flight sequences varied from 500 to 4000 seconds.

For each flight in the testing set, we applied EM and spectral algorithm to compute the normalized joint log-likelihood

$$\frac{1}{T_i} \log p(o_1, o_2, \ldots, o_{T_i}),$$

where o_i are the observed pilot actions for test flight i, and T_i is the length of the test flight i, with $i = 1, \ldots, 200$. Figure 7 shows the results. The high-likelihood sequences were considered normal and low-likelihood ones classified as anomalous (see plots (a) and (b) in Figure 7). Both algorithms achieved similar detection accuracy, with the spectral algorithm having the Area Under Curve (AUC) score of 0.91 and the EM had AUC $= 0.89$ (see plot (c) on Figure 7). On the other hand, the computational time of the spectral algorithm was orders of magnitude smaller as compared to EM. We also compared performance of both algorithm on the same flight data while varying the dimensionality of the HSMM parameters (see Figure 8 and Table 2). We can see that although the performance of EM and spectral algorithm is similar across many models, the latter offers significant computational savings.

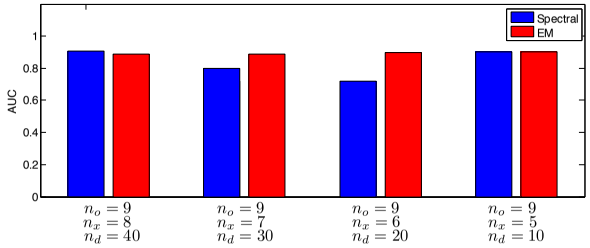

Figure 8: Comparison of AUC scores for EM and spectral algorithm for various model parameters when evaluated on aviation safety data. Both algorithms achieve similar high accuracy across different models.

Parameters		$n_o = 9$ $n_x = 8$ $n_d = 40$	$n_o = 9$ $n_x = 7$ $n_d = 30$	$n_o = 9$ $n_x = 6$ $n_d = 20$	$n_o = 9$ $n_x = 5$ $n_d = 10$
Running Time	Spectral	6.8 hours	6.4 hours	6.4 hours	6.3 hours
	EM	> 2 days	> 2 days	> 2 days	> 2 days

Table 2: Comparison of running time for EM and spectral algorithm for multiple model parameters on the flight data. Spectral algorithm is several orders of magnitude faster as compared to EM, offering significant computational savings.

7. Conclusion

In this paper, we presented a novel spectral algorithm to perform inference in HSMM. We derived an observable representation of the model which can be computed from the data sample moments of size logarithmic in the maximum length of latent state persistence. Based on the representation and exploiting the homogeneity of the model, we presented an efficient approach to inference, which ensures that during the training phase the number of matrix multiplications and inverses is fixed and independent of the sequence length of the observations. Empirical evaluation on synthetic and real flight data sets were presented to illustrate the promise of the proposed spectral algorithm. In particular, the spectral method gets similar or better performance than EM as the size of the training data set increases, and at the same time the spectral method is orders of magnitude faster than EM providing significant computational savings. Going forward, we plan to explore if similar spectral methods can be developed for inference in more general dynamic Bayesian networks.

Appendix A. Analysis of Tensor Rank Structure

A.1 Analysis of Algorithm 3

In this Section, we provide analysis of the Algorithm 3 and study the rank structure of matrix $\mathbf{T}$ in order to prove Theorem 2. To understand the analysis, it is important to know how the structure of matrix $\underset{\mathbf{x}_{R_{t+1}|x_t d_t}}{\mathbf{T}}$ evolves across iterations. For this, we present in Figure 9 a schematic description of a few steps of the algorithm. For the analysis we will need to establish certain auxiliary results.

Lemma 6 *Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a matrix which has no all-zero columns, then the $rank\,(\mathbf{I} \odot \mathbf{A}) = rank\,(\mathbf{A} \odot \mathbf{I}) = n$, where $\odot$ denotes Khatri-Rao product and $\mathbf{I} \in \mathbb{R}^{n \times n}$.*

Proof Let $\mathbf{K} = (\mathbf{I} \odot \mathbf{A}) \in \mathbb{R}^{mn \times n}$. By definition of Khatri-Rao product, $\mathbf{K}(:, j) = \mathbf{e}_j \otimes \mathbf{A}(:, j)$, for $j = 1, \ldots, n$, which consists of zeros, except for rows $(j-1)m+1, \ldots, (j-1)m+m$, containing the column $\mathbf{A}(:, j)$. Here $\otimes$ denotes Kronecker product and $\mathbf{e}_j$ is everywhere zero except for

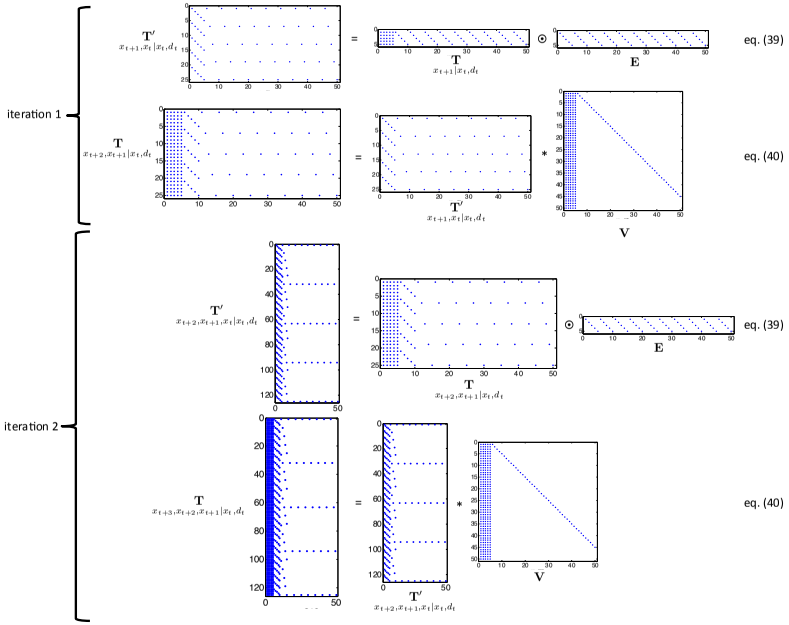

Figure 9: Schematic representation of Algorithm 3. This example illustrates the HSMM with $n_x = 5$ and $n_d = 10$. The non-zero matrix elements are displayed as dots.

position j which is 1. As long as there is no all-zero columns in $\mathbf{A}$, each column of $\mathbf{K}$ is independent of each other and therefore the rank is n. Moreover, since the matrix $\mathbf{A} \odot \mathbf{I}$ is a row-permuted version of $\mathbf{A} \odot \mathbf{I}$, their ranks are the same. ■

Lemma 7 *Define a block-row matrix $\mathbf{M} = [\mathbf{A}_1\ \mathbf{A}_2\ \cdots\ \mathbf{A}_k] \in \mathbb{R}^{m \times kn}$, where each $\mathbf{A}_i \in \mathbb{R}^{m \times n}$. Define by $r_j,\ j = 1, \ldots, n$ the rank of matrix $[\mathbf{A}_1(:, j)\ \cdots\ \mathbf{A}_k(:, j)]$ composed of jth columns of $\mathbf{A}$'s, and let $\mathbf{E} = [\mathbf{I}\,\mathbf{I}\,\cdots\,\mathbf{I}] \in \mathbb{R}^{n \times kn}$, where $\mathbf{I} \in \mathbb{R}^{n \times n}$. Then the rank of matrix $\mathbf{W} = \mathbf{M} \odot \mathbf{E} \in \mathbb{R}^{mn \times kn}$, obtained using a Khatri-Rao product, is $\min(mn, \sum_j r_j)$.*

Proof First note that $\mathbf{M} \odot \mathbf{E}$ and $\mathbf{E} \odot \mathbf{M}$ are row permuted version of each other, so they have the same rank. Therefore, consider $\mathbf{W}' = \mathbf{E} \odot \mathbf{M} = [\mathbf{I} \odot \mathbf{A}_1 \cdots \mathbf{I} \odot \mathbf{A}_k]$. Also, note that $\mathbf{e}_j \otimes [\mathbf{A}_1(:, j) \cdots \mathbf{A}_k(:, j)]$, $j = 1, \ldots, n$ is a matrix which consists of zeros except for rows $(j-1)m+1, \ldots, (j-1)m+m$ where it contains the columns $[\mathbf{A}_1(:, j)\ \cdots\ \mathbf{A}_k(:, j)]$. The rank of these columns is r_j and all other columns in $\mathbf{W}$ are independent of them due to the structure of the Khatri-Rao product. Therefore, each set of such columns adds r_j to the total rank. Since the overall rank of $\mathbf{W}$ cannot exceed either the number of rows or columns, we conclude that $rank(\mathbf{W}) = \min(mn, \sum_j r_j)$. ■

Lemma 8 *Let $V = \{\mathbf{v}_1, \ldots, \mathbf{v}_n\}$ be a set of linearly independent vectors. Define $\mathbf{u} = \sum_{i=1}^{n} c_i \mathbf{v}_i$, where coefficients $c_i \neq 0, i = 1, \ldots, n$. Define U to be a strict subset of V, i.e., $U \subset V$, then a set of vectors $\mathbf{u} \cup U$ is independent.*

Proof Define $\{1, \ldots, n\} = \alpha \cup \bar{\alpha}$, where α denotes a subset of indices for vectors corresponding to U. Then we can write $\mathbf{u} = \sum_{i:i \in \alpha} c_i \mathbf{v}_i + \sum_{j:j \in \bar{\alpha}} c_j \mathbf{v}_j$.

Assuming the opposite, i.e., $\mathbf{u} \cup U$ are dependent, we can write $k_0 \mathbf{u} + \sum_{i:i \in \alpha} k_i \mathbf{v}_i = 0$ where $k_0 \neq 0$ and some of $k_i, i \in \alpha$ are also must be non-zero. Substituting the definition of $\mathbf{u}$ and rearranging the terms, we get:

$$k_0 \sum_{i:i \in \alpha} (c_i + k_i) \mathbf{v}_i + k_0 \sum_{j:j \in \bar{\alpha}} c_j \mathbf{v}_j = 0.$$

Since $c_j \neq 0, j \in \bar{\alpha}$, the above equation claims the linear dependence of vectors in V, which is a contradiction of our assumption and so $\mathbf{u} \cup U$ are independent. ■

We are now ready to analyze Algorithm 3. It can be verified that (36) is of the form:

$$\mathbf{V} = \begin{bmatrix} \Psi \begin{bmatrix} \mathbf{I} & & \\ & \ddots & \\ & & \mathbf{I} \\ \hline \mathbf{0} & \cdots & \mathbf{0} \end{bmatrix} \end{bmatrix} \in \mathbb{R}^{n_x n_d \times n_x n_d} \quad \text{where} \quad \Psi = \begin{bmatrix} \text{diag}\,[D(1,:)]\,\mathcal{X} \\ \text{diag}\,[D(2,:)]\,\mathcal{X} \\ \vdots \\ \text{diag}\,[D(n_d,:)]\,\mathcal{X} \end{bmatrix} \in \mathbb{R}^{n_x n_d \times n_x}, \tag{43}$$

where $\text{diag}\,[D(i,:)]$ is the diagonal matrix with ith row from D on the diagonal. Note that we can also write $\Psi = (D \odot \mathbf{I})\,\mathcal{X}$. Observe that the rank of $\mathbf{V}$ is $n_x n_d$ because the $n_x(n_d-1) \times n_x(n_d-1)$

block diagonal matrix delineated in (43) and the last $n_x \times n_x$ block matrix diag $[D(n_d,:)]\,\mathcal{X}$ in Ψ together comprising $n_x n_d$ independent columns of $\mathbf{V}$. Note that diag $[D(n_d,:)]\,\mathcal{X}$ has rank n_x because $\mathcal{X}$ is full rank and $D(n_d,:)$ is non-zero, which follows from assumptions $A1$ and $A2$. As a side note observe that the requirement to have $D(n_d,:)$ non-zero implies that there is a non-zero probability of maximum state persistence.

In analyzing the Algorithm 3, it would be useful to denote the matrices at iteration i in (39) and (40) as

$$\begin{aligned}\underset{x_{t+i},\ldots,x_{t+1}|x_t,d_t}{\mathbf{T}} &= [\mathbf{A}_1^{(i)} \cdots \mathbf{A}_{n_d}^{(i)}]\\ \underset{x_{t+i},\ldots,x_{t+1},x_t|x_t,d_t}{\mathbf{T}'} &= [\mathbf{B}_1^{(i)} \cdots \mathbf{B}_{n_d}^{(i)}]\\ \underset{x_{t+i+1},\ldots,x_{t+2},x_{t+1}|x_t,d_t}{\mathbf{T}} &= [\mathbf{C}_1^{(i)} \cdots \mathbf{C}_{n_d}^{(i)}].\end{aligned}$$

Moreover, utilizing the structure of matrix $\mathbf{V}$ from (43), the operations involved in step (40) are as follows:

$$\left[\mathbf{C}_1^{(i)}\ \mathbf{C}_2^{(i)}\ \mathbf{C}_3^{(i)}\ \cdots\ \mathbf{C}_{n_d}^{(i)}\right] = \left[[\mathbf{B}_1^{(i)} \cdots \mathbf{B}_{n_d}^{(i)}]\Psi\ \ \mathbf{B}_1^{(i)}\ \mathbf{B}_2^{(i)}\ \cdots\ \mathbf{B}_{n_d-1}^{(i)}\right]. \tag{44}$$

With the above information we can now present the proof of Theorem 2:

Proof of Theorem 2 At the start of the algorithm $\underset{x_{t+1}|x_t,d_t}{\mathbf{T}} = [\mathcal{X}\ \mathbf{I} \cdots \mathbf{I}] = [\mathbf{A}_1^{(1)} \cdots \mathbf{A}_{n_d}^{(1)}]$, which has rank n_x. The rank of matrix $\left[\mathbf{A}_1^{(1)}(:,l) \cdots \mathbf{A}_{n_d}^{(1)}(:,l)\right]$ for $l = 1,\ldots,n_x$ is $r_l = 2$ since among all the columns only two of them are independent. Therefore, according to Lemma 7, the result of operations in (39), has rank $\sum_l r_l = 2n_x$. Moreover, we note that since $[\mathbf{B}_1^{(1)}\ \mathbf{B}_2^{(1)}\ \cdots\ \mathbf{B}_{n_d}^{(1)}] = [\mathcal{X}\odot\mathbf{I}\ \mathbf{I}\odot\mathbf{I} \cdots \mathbf{I}\odot\mathbf{I}]$, it can be seen that its $2n_x$ independent vectors can be formed by the columns $[\mathbf{B}_1^{(1)}\ \mathbf{B}_2^{(1)}]$, so that the rank of $\left[\mathbf{B}_1^{(1)}(:,l) \cdots \mathbf{B}_{n_d}^{(1)}(:,l)\right]$ for $l = 1,\ldots,n_x$ is 2.

Next, since the rank of $\mathbf{V}$ is $n_x n_d$, the operations in (40) produce matrix $[\mathbf{C}_1^{(1)}\ \mathbf{C}_2^{(1)}\ \cdots\ \mathbf{C}_{n_d}^{(1)}]$ with the rank still being $2n_x$. Moreover, the columns of $\mathbf{C}_1^{(1)}$ are linearly dependent on the rest of the columns, $[\mathbf{C}_2^{(1)}\ \cdots\ \mathbf{C}_{n_d}^{(1)}]$, due to (44). However, the rank of $\left[\mathbf{C}_1^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right]$ is now $r_l = 3$ for $l = 1,\ldots,n_x$. To understand this, note that

$$\begin{aligned}[\mathbf{B}_1^{(1)}\ \mathbf{B}_2^{(1)}\ \cdots\ \mathbf{B}_{n_d}^{1}] &= [\mathcal{X}\odot\mathbf{I}\ \mathbf{I}\odot\mathbf{I} \cdots \mathbf{I}\odot\mathbf{I}]\\ [\mathbf{C}_1^{(1)}\ \mathbf{C}_2^{(1)}\ \mathbf{C}_3^{(1)}\ \cdots\ \mathbf{C}_{n_d}^{(1)}] &= [\mathbf{C}_1^{(1)}\ \mathcal{X}\odot\mathbf{I}\ \mathbf{I}\odot\mathbf{I} \cdots \mathbf{I}\odot\mathbf{I}],\end{aligned}$$

where, according to (44), $\mathbf{C}_1^{(1)} = [\mathbf{B}_1^{(1)} \cdots \mathbf{B}_{n_d}^{(1)}]\Psi$. As we established before, the rank of the matrix $\left[\mathbf{C}_2^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right] = \left[\mathbf{B}_1^{(1)}(:,l) \cdots \mathbf{B}_{n_d-1}^{(1)}(:,l)\right]$ is $r_l = 2$. Moreover, it can also be checked that $\mathbf{C}_1^{(1)}(:,l)$ is independent of $\left[\mathbf{C}_2^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right]$ due to Lemma 8. Clearly, then the cumulative rank of $\left[\mathbf{C}_1^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right]$ is 3 for $l = 1,\ldots,n_x$.

To generalize the above, if at the iteration i the rank of matrix $\left[\mathbf{A}_1^{(i)} \cdots \mathbf{A}_{n_d}^{(i)}\right]$ is in_x while the rank of $\left[\mathbf{A}_1^{(i)}(:,l) \cdots \mathbf{A}_{n_d}^{(i)}(:,l)\right]$ is $(i+1)$, then the operations in step (39) produce $\left[\mathbf{B}_1^{(i)} \cdots \mathbf{B}_{n_d}^{(i)}\right]$

having rank $(i+1)n_x$ due to Lemma 7. The step in (40) keeps the rank of $\left[\mathbf{C}_1^{(i)} \cdots \mathbf{C}_{n_d}^{(i)}\right]$ at $(i+1)n_x$ due to the full rank structure of $\mathbf{V}$. At the same time, this step increases the rank of matrix $\left[\mathbf{C}_1^{(i)}(:,l) \cdots \mathbf{C}_{n_d}^{(i)}(:,l)\right]$ to $(i+2)$ due to Lemma 8, i.e., independence of $\mathbf{C}_1^{(i)}(:,l)$ from $\left[\mathbf{C}_2^{(i)}(:,l) \cdots \mathbf{C}_{n_d}^{(i)}(:,l)\right]$ with the latter having the rank $(i+1)$. Therefore, each iteration increases the rank of matrix $\mathbf{T}$ by n_x and so after $2 \le \ell \le n_d$ steps the rank of the resulting matrix $\underset{\mathbf{x}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ is ℓn_x.

Note that if $\ell = 1$ then the Algorithm 3 is not executed and returns the trivial $\underset{x_{t+1}|x_t,d_t}{\mathbf{T}}$ with rank n_x. On the other hand, if $\ell > n_d$ then the rank of $\underset{\mathbf{x}_{R_{t+1}}|x_t d_t}{\mathbf{T}}$ is $n_x n_d$ since this is the number of columns in that matrix and so is the maximum achievable rank. ■

A.2 Analysis of Algorithm 4

In this Section we analysis of the Algorithm 4 in order to prove Theorem 4. Similarly as in Section A.1, it is instructive to visualize the progress of Algorithm 4. Figure 10 shows a schematic description of a few steps of the algorithm.

We are now ready to present the proof of Theorem 4.

Proof of Theorem 4 For the proof, we refer back to Algorithm 3 and the proof of Theorem 2. Recall, that at iteration $i = 1$, the result of step (39) is a matrix $[\mathbf{B}_1^{(1)} \cdots \mathbf{B}_{n_d}^{(1)}] \in \mathbb{R}^{n_x^2 \times n_x n_d}$, whose rank is $2n_x$, since $\left[\mathbf{A}_1^{(1)}(:,l) \cdots \mathbf{A}_{n_d}^{(1)}(:,l)\right] = [\mathcal{X}\,\mathbf{I} \cdots \mathbf{I}] \in \mathbb{R}^{n_x \times n_x n_d}$ for $l = 1,\ldots,n_x$ had two independent columns. Then, the transformations in step (40) produced $\left[\mathbf{C}_1^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right]$ for $l = 1,\ldots,n_x$ with rank $3n_x$.

Note that if $n_x > 2$ then $\left[\mathbf{A}_1^{(1)}(:,l) \cdots \mathbf{A}_{n_d}^{(1)}(:,l)\right]$ potentially can have a rank up to n_x, while in Algorithm 3 we only have it equal to 2. It turns out that if we apply step (40) multiple times and use Lemma 8, we can increase the rank of $\left[\mathbf{C}_1^{(1)}(:,l) \cdots \mathbf{C}_{n_d}^{(1)}(:,l)\right]$ for $l = 1,\ldots,n_x$ to n_x.

Specifically, consider step (41). At iteration $i = 1$ we have $[\mathbf{A}_1^{(1)} \cdots \mathbf{A}_{n_d}^{(1)}] = [\mathbf{B}_1^{(1)} \cdots \mathbf{B}_{n_d}^{(1)}]$ and for $l = 1,\ldots,n_x$ the two independent columns are $\left[\mathbf{B}_1^{(1)}(:,l)\ \mathbf{B}_2^{(1)}(:,l)\right] = [\mathcal{X}(:,l)\ \mathbf{I}(:,l)]$. The result of step (41) gives us then three independent columns

$$\left[\mathbf{C}_1^{(1)}(:,l)\ \mathbf{C}_2^{(1)}(:,l)\ \mathbf{C}_3^{(1)}(:,l)\right] = \left[\mathbf{C}_1^{(1)}(:,l)\ \mathcal{X}(:,l)\ \mathbf{I}(:,l)\right],$$

where $\mathbf{C}_1^{(1)} = [\mathcal{X}\,\mathbf{I}\ \cdots\ \mathbf{I}]\Psi$. The independence follows from Lemma 8. The repeated application of step (41) one more time gives four independent columns

$$\left[\mathbf{C}_1^{(2)}(:,l)\ \mathbf{C}_2^{(2)}(:,l)\ \mathbf{C}_3^{(2)}(:,l)\ \mathbf{C}_4^{(2)}(:,l)\right] = \left[\mathbf{C}_1^{(2)}(:,l)\ \mathbf{C}_1^{(1)}(:,l)\ \mathcal{X}(:,l)\ \mathbf{I}(:,l)\right],$$

where $\mathbf{C}_1^{(2)} = [\mathbf{C}_1^{(1)} \cdots \mathbf{C}_{n_d}^{(1)}]\Psi$. Observe that since the number of rows is n_x, we can increase the rank at most up to n_x. Therefore, if in the beginning we had two independent columns and we want to get n_x independent columns, we would need to apply the step (41) $n_x - 2$ times, so as to have the matrix $[\mathbf{C}_1^{(n_x-2)}(:,l)\ \cdots\ \mathbf{C}_{n_d}^{(n_x-2)}(:,l)]$ with rank n_x.

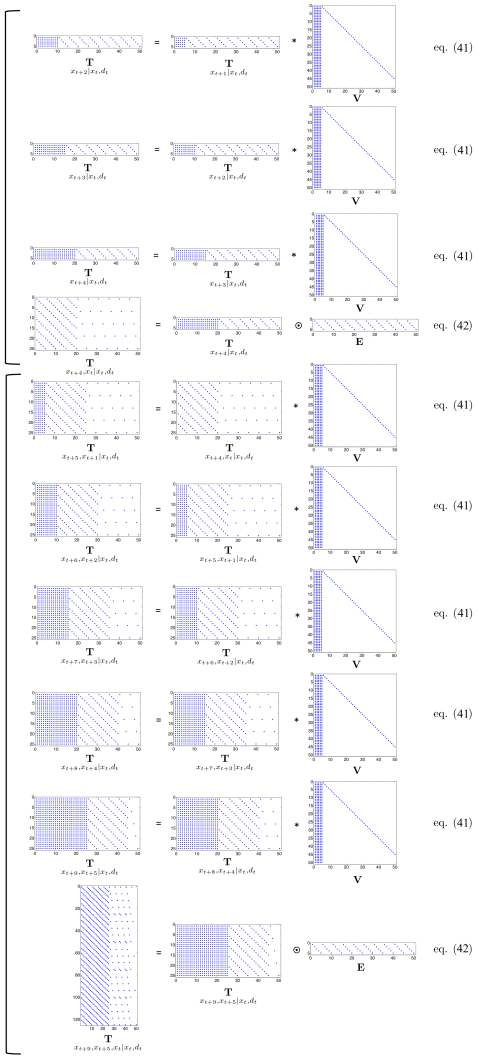

Figure 10: Schematic representation of Algorithm 4. This example illustrates the HSMM with $n_x = 5$ and $n_d = 10$. The non-zero matrix elements are displayed as dots.

If we now apply step (42) it will give us $[\mathbf{A}_1^{(1)} \ \cdots \ \mathbf{A}_{n_d}^{(1)}] \in \mathbb{R}^{n_x^2 \times n_x n_d}$ with rank n_x^2 due to Lemma 7. Continuing in this manner, we can again repeatedly apply the step (41) to create a matrix with a rank at most n_x^2, since there are n_x^2 rows and assuming that $n_x n_d \geq n_x^2$. The number of times we need to apply (41) is now $n_x^2 - n_x$ since we need to go from n_x to n_x^2 independent columns.

In general, the step (41) needs to be applied $n_x^c - n_x^{c-1}$, in order to obtain n_x^c independent columns. The application of step (42) then creates $\mathbf{T}$ with rank n_x^{c+1}. Note, that since $\mathbf{T}$ has $n_x n_d$ columns, the maximum achievable rank is $n_x n_d$. ■

Observe that the above proof also provided the method for selecting the non-sequential observations $\mathbf{X}_{R_{t+1}}$. Specifically, since the set of observations $\mathbf{X}_{R_{t+1}} = \{o_{t+2}, \ldots\}$ must start from observation o_{t+2} and $|\mathbf{X}_{R_{t+1}}| = \ell$, we denote $s = t+2$. Then, ith added observation is $o_{s+(n_d-1)-(n_x^i-1)}$ for $i = 0, \ldots, \ell-2$ and the ℓth observation is $o_s = o_{t+2}$. For tensor $\mathcal{F}_{\mathbf{O}_{R_{t+1}}|x_t d_t}$ to achieve rank $n_x n_d$ we need to add $\ell = \lceil 1 + \frac{\log n_d}{\log n_x} \rceil$ observations.

Appendix B. Initial and Final Parts of HSMM

In this Section we present the derivations for the initial and final steps of HSMM, which were omitted from the main text. Specifically, this amounts to computing the factor $\mathcal{X}$ for two parts of the model, corresponding to $\mathbb{X}_{root}$ and $\mathbb{X}_T$ in Figures 11 and 12. The derivations for all other parts of HSMM were presented in the main text and this supplement.

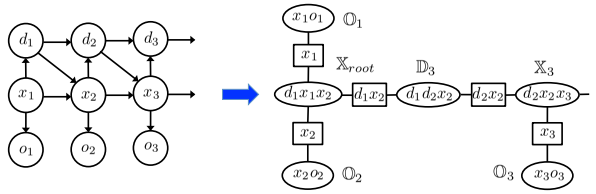

Figure 11: Part of HSMM corresponding to the initial time stamps and the related part of junction tree.

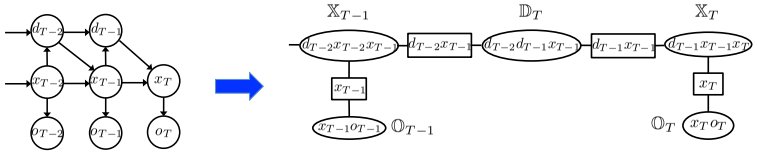

Figure 12: Part of HSMM corresponding to the final time stamps and the related part of junction tree.

To begin, recall the expression for the joint likelihood of the observed sequence:

$$\underset{o_1,\ldots,o_T}{\mathcal{P}} = \prod_t \underset{d_{t-1}|x_{t-1}d_{t-2}}{\mathcal{D}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_t|x_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{o_t|x_t}{\mathcal{O}} \right)$$

and rewrite the above expression by keeping only the initial and final factors:

$$\underset{o_1,\ldots,o_T}{\mathcal{P}} = \left(\underset{o_1|x_1}{\mathcal{O}} \times_{x_1} \left(\underset{x_2x_2|x_1d_1}{\mathcal{X}} \times_{x_2} \underset{o_2|x_2}{\mathcal{O}} \right) \right) \times_{x_2d_1} \underset{d_2|x_2x_2d_1}{\mathcal{D}} \times \cdots$$
$$\cdots \times \underset{d_{T-1}|x_{T-1}x_{T-1}d_{T-2}}{\mathcal{D}} \times_{x_{T-1}d_{T-1}} \left(\underset{x_T|x_{T-1}d_{T-1}}{\mathcal{X}} \times_{x_T} \underset{o_T|x_T}{\mathcal{O}} \right). \tag{45}$$

Introduce the identity tensors into (45), regroup the terms and extract the factors $\mathcal{X}$:

$$\underset{\omega_{x_1}\omega_{x_2}\omega_{x_2d_1}}{\tilde{\mathcal{X}}} = \underset{\omega_{x_1}|x_1}{\mathcal{F}} \times_{x_1} \left(\underset{x_2x_2|x_1d_1}{\mathcal{X}} \times_{x_2} \underset{\omega_{x_2}|x_2}{\mathcal{F}} \right) \times_{x_2d_1} \underset{\omega_{x_2d_1}|x_2d_1}{\mathcal{F}} \tag{46}$$

$$\underset{\omega_{x_{T-1}d_{T-1}}\omega_{x_T}}{\tilde{\mathcal{X}}} = \underset{\omega_{x_{T-1}d_{T-1}}|x_{T-1}d_{T-1}}{\mathcal{F}^{-1}} \times_{x_{T-1}d_{T-1}} \left(\underset{x_T|x_{T-1}d_{T-1}}{\mathcal{X}} \times_{x_T} \underset{\omega_{x_T}|x_T}{\mathcal{F}} \right). \tag{47}$$

Defining the observable sets $\omega_{x_1} = o_1$, $\omega_{x_2} = o_2$ and $\omega_{x_2d_1} = \mathbf{O}_{R_3}$ we can rewrite (46) as follows:

$$\underset{o_1o_2\mathbf{O}_{R_3}}{\tilde{\mathcal{X}}} = \underset{o_1|x_1}{\mathcal{F}} \times_{x_1} \left(\underset{x_2x_2|x_1d_1}{\mathcal{X}} \times_{x_2} \underset{o_2|x_2}{\mathcal{F}} \right) \times_{x_2d_1} \underset{\mathbf{O}_{R_3}|x_2d_1}{\mathcal{F}}. \tag{48}$$

Note that since all the factors participating in (48) are valid probability distributions, the resulting factor, i.e., $\underset{o_1o_2\mathbf{O}_{R_3}}{\tilde{\mathcal{X}}}$ is also a valid probability distribution, so it can be estimated directly from data. This is in contrast to the derivations we made for other parts of the model, where we had to perform additional transformations such as, for example in (10), in order to bring to the form, which could be estimated from the data samples.

In order to estimate (47), we compare it to the similar factor we considered in the main paper:

$$\underset{\omega_{x_{t-1}d_{t-1}}\omega_{x_t}\omega_{x_td_{t-1}}}{\tilde{\mathcal{X}}} = \underset{\omega_{x_{t-1}d_{t-1}}|x_{t-1}d_{t-1}}{\mathcal{F}^{-1}} \times_{x_{t-1}d_{t-1}} \left(\underset{x_tx_t|x_{t-1}x_{t-1}d_{t-1}}{\mathcal{X}} \times_{x_t} \underset{\omega_{x_t}|x_t}{\mathcal{F}} \right) \times_{x_td_{t-1}} \underset{\omega_{x_td_{t-1}}|x_td_{t-1}}{\mathcal{F}}, \tag{49}$$

and observe that the last factor $\underset{\omega_{x_td_{t-1}}|x_td_{t-1}}{\mathcal{F}}$ in (49) is a conditional probability distribution, which has the following marginalization property

$$\underset{\omega_{x_td_{t-1}}|x_td_{t-1}}{\mathcal{F}} \times_{\omega_{x_td_{t-1}}} \underset{\omega_{x_td_{t-1}}}{\mathbf{1}} = \underset{x_td_{t-1}}{\mathbf{1}}, \tag{50}$$

where $\mathbf{1}$ is the tensor, which has all elements equal to 1. The above can also be written in the scalar notations, $\sum_{\omega_{x_td_{t-1}}} p(\omega_{x_td_{t-1}}|x_td_{t-1}) = 1$ for each value of x_td_{t-1}. Therefore, if we apply (50) to (49), we get $\underset{\omega_{x_{t-1}d_{t-1}}\omega_{x_t}}{\tilde{\mathcal{X}}}$, which is the time-shifted version of $\underset{\omega_{x_{T-1}d_{T-1}}\omega_{x_T}}{\tilde{\mathcal{X}}}$. Therefore, to compute (47), we estimate the tensor in (13), i.e.,

$$\underset{\mathbf{O}_{R_t}o_t\mathbf{O}_{R_t}}{\tilde{\mathcal{X}}} = \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}^{-1}} \times_{\mathbf{O}_{L_t}} \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}o_t}{\mathcal{M}},$$

and marginalize out the right set of modes, corresponding to $\mathbf{O}_{R_t}$. Alternatively, we can use the batch estimate

$$\tilde{\mathcal{X}} = \left(\sum_t \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}}{\mathcal{M}} \right)^{-1} \times_{\mathbf{O}_L} \left(\sum_t \underset{\mathbf{O}_{L_t}\mathbf{O}_{R_t}o_t}{\mathcal{M}} \right),$$

and similarly perform the marginalization. This concludes our derivations.

Editor: Peter Spirtes

Abstract

Obtaining a non-parametric expression for an interventional distribution is one of the most fundamental tasks in causal inference. Such an expression can be obtained for an identifiable causal effect by an algorithm or by manual application of do-calculus. Often we are left with a complicated expression which can lead to biased or inefficient estimates when missing data or measurement errors are involved.

We present an automatic simplification algorithm that seeks to eliminate symbolically unnecessary variables from these expressions by taking advantage of the structure of the underlying graphical model. Our method is applicable to all causal effect formulas and is readily available in the R package causaleffect.

Keywords: simplification, probabilistic expression, causal inference, graphical model, graph theory

1. Introduction

Symbolic derivations resulting in complicated expressions are often encountered in many fields working with mathematical notation. These expressions can be derived manually or they can be outputs from a computer algorithm. In both cases, the expressions may be correct but unnecessarily complex in a sense that some unrecognized identities or properties would lead to simpler expressions.

We will consider simplification in the context of causal inference in graphical models (Pearl, 2009). Advances in causal inference have led to algorithmic solutions to problems such as identifiability of causal effects and conditional causal effects (Huang and Valtorta, 2006; Shpitser and Pearl, 2006a,b), z-identifiability (Bareinboim and Pearl, 2012), transportability and meta-transportability (Bareinboim and Pearl, 2013b,a) among others. The aforementioned algorithmic solutions operate symbolically on the joint distribution of the variables of interest and return expressions for the desired queries. These algorithms have been previously implemented in the R package causaleffect (Tikka and Karvanen, 2017). Another implementation of an identifiability algorithm can be found in the CIBN software by Jin Tian and Lexin Liu freely available from `http://web.cs.iastate.edu/~jtian/Software/CIBN.htm`. However, the algorithms themselves are imperfect in a sense that they often output an expression that is complicated and far from ideal. The question is whether there exists a simpler expression that is still a solution to the original problem.

Simplification of expressions may provide significant benefits. First, a simpler expression can be understood and reported more easily. Second, evaluating a simpler expression will be less of a computational burden due to reduced dimensionality of the problem. Third, in situations where estimation of causal effects is of interest and missing data is a concern, eliminating variables with missing data from the expression has clear advantages. The same applies to variables with measurement error.

We begin with presenting in Section 2 a general form of probabilistic expressions that are often encountered in causal inference. In this paper probabilistic expressions are formed by products of non-parametric conditional distributions of some variables and summations over the possible values of these variables. Simplification in this case is the process of eliminating terms from these expressions by carrying out summations. As our expressions correspond to causal effects, the expressions themselves take a specific form.

Causal models are typically associated with a directed acyclic graph (DAG) which represents the functional relationships between the variables of interest. In situations where the joint distribution is faithful, meaning that no additional conditional independences are generated by the joint distribution (Spirtes et al., 2000), the conditional independence properties of the variables can be read from the graph itself through a concept known as d-separation (Geiger et al., 1990). We will use d-separation as our primary tool for operating on the probabilistic expressions. The reader is assumed to be familiar with a number of graph theoretic concepts that are explained for example in (Koller and Friedman, 2009) and used throughout the paper.

Our simplification procedure is built on the definition of simplification sets, which is presented in Section 3. We continue by introducing a sound and complete simplification algorithm for probabilistic expressions defined in Section 2 for which these simplification sets exist. The algorithm takes as an input the expression to be simplified and the graph induced by the underlying causal model, and proceeds to construct a joint distribution of the variables contained in the expression by using the d-separation criteria. Higher level algorithms that use this simplification procedure are presented in Section 4. These include an algorithm for the simplification of a nested expression and an algorithm for the simplification of a quotient of two expressions. Section 5 contains examples on the application of these algorithms. We have also updated the causaleffect R-package to automatically apply these simplification procedures to causal effect expressions.

As a motivating example we present an expression of a causal effect given by the ID algorithm of Shpitser and Pearl (2006a) that can be simplified. The complete derivation of this effect can be found in Appendix C. The causal effect of X on Z_1, Z_2, Z_3 and Y is identifiable in the graph of Figure 1 and application of the ID algorithm gives

$$P(Z_1|Z_2,X)P(Z_3|Z_2)\frac{\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)}{\sum_{X,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)}\times \sum_{X,Z_3,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2).$$

It turns out that there exists a significantly simpler expression,

$$P(Z_1|Z_2,X)P(Z_2)\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2), \quad (1)$$

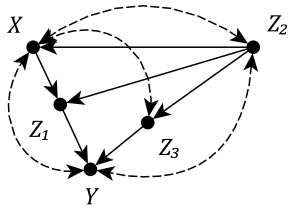

Figure 1: A graph for the introductory example on simplification.

for the same causal effect. This expression can be obtained without any knowledge of the underlying model by using standard probability manipulations. However, this requires that a favorable choice is made for the ordering of the nodes of the graph in the ID algorithm. In the case that we had chosen an ordering where Z_1 precedes Z_3, the term for Z_3 would instead be $P(Z_3|Z_2, Z_1, X)$ and simplification would require knowledge about the underlying graph. We will take another look at this example later in Section 5 where we describe in detail how our procedure can be used to find expression (1).

Our simplification procedure is different from the well-known exact inference method of minimizing the amount of numerical computations when evaluating expressions for conditional and marginal distributions by changing the order of summations and multiplications in the expression. Variants of this method are known by different names depending on the context, such as Bayesian variable elimination (Koller and Friedman, 2009) and the sum-product algorithm (Bishop, 2006) which is a generalization of belief propagation (Pearl, 1988; Lauritzen and Spiegelhalter, 1988). Efficient computational methods exist for causal effects as well, such as (Shpitser et al., 2011). The general principle is the same in all of the variants, and no symbolic simplification is performed.

In our setting simplification can be defined explicitly but in general it is difficult to say what makes one expression simpler than another. Carette (2004) provides a formal definition for simplification in the context of Computer Algebra Systems (CAS) that operate on algebraic expressions. Modern CAS systems such as Mathematica (Wolfram Research Inc., 2015) and Maxima (Maxima, 2014) implement techniques for symbolic simplification. Bailey et al. (2014) and references therein discuss simplification techniques in CAS systems further. However to the best of our knowledge, the symbolic simplification procedures for probabilistic expressions described in this paper have neither been given previous attention nor implemented in any existing system.

2. Probabilistic Expressions

Every expression that we consider is defined in terms of a set of variables $\mathbf{W}$. As we are interested in probabilistic expressions, we also assume a joint probability distribution P for the variables of $\mathbf{W}$. The most basic of expressions are called atomic expressions which will be the main focus of this paper.

Definition 1 (Atomic expression) *Let $\mathbf{W}$ be a set of p discrete random variables and let P be any joint distribution of $\mathbf{W}$. An atomic expression is a pair*

$$A = A[\mathbf{W}] = \langle \mathbf{T}, \mathbf{S} \rangle,$$

where

1. *$\mathbf{T}$ is a set of pairs $\{\langle V_1, \mathbf{C}_1 \rangle, \ldots, \langle V_n, \mathbf{C}_n \rangle\}$ such that for each V_i and $\mathbf{C}_i$ it holds that $V_i \in \mathbf{W}$, $\mathbf{C}_i \subseteq \mathbf{W}$, $V_i \notin \mathbf{C}_i$ and $V_i \neq V_j$ for $i \neq j$.*
2. *$\mathbf{S}$ is a set $\{S_1, \ldots, S_m\} \subseteq \mathbf{W}$ such that for each $i = 1, \ldots, m$ it holds that $S_i = V_j$ for some $j \in \{1, \ldots, n\}$.*

The value of an atomic expression A is

$$P_A = \sum_{\mathbf{S}} \prod_{i=1}^{n} P(V_i|\mathbf{C}_i).$$

The probabilities $P(V_i|\mathbf{C}_i)$ are referred to as the terms of the atomic expression. A term $P(V_i|\mathbf{C}_i)$ is said to contain a variable V if $V_i = V$ or $V \in \mathbf{C}_i$. A term for a variable V refers to a term $P(V|\cdot)$. We also use the shorthand notation $V[A] := \{V_1, \ldots V_n\}$. As $\mathbf{S}$ is a set, we will only sum over a certain variable once. All variables are assumed to be univariate and discrete for clarity, but we may also consider multivariates and situations where some of the variables are continuous and the respective sums are interpreted as integrals instead.

As an example we will construct an atomic expression describing the following formula

$$\sum_{X} P(Y|Z_2, X, Z_3, Z_1)P(Z_3|Z_2, X)P(X|Z_2)P(Z_2),$$

which is a part of the motivating example in the introduction. We let $\mathbf{W} = \{X, Y, Z_1, Z_2, Z_3\}$, which is the set of nodes of the graph of Figure 1. The sets $\mathbf{T}$ and $\mathbf{S}$ can now be defined as

$$\{\langle Y, \{Z_2, X, Z_3, Z_1\}\rangle, \langle Z_3, \{Z_2, X\}\rangle, \langle X, \{Z_2\}\rangle, \langle Z_2, \emptyset\rangle\} \quad \text{and} \quad \{X\},$$

respectively. Next we define a more general probabilistic expression.

Definition 2 (Expression) *Let $\mathbf{W}$ be a set of p variables and let P be the joint distribution of $\mathbf{W}$. An expression is a triple*

$$B = B[\mathbf{W}, n, m] = \langle \mathbf{B}, \mathbf{A}, \mathbf{S} \rangle,$$

where

1. *$\mathbf{S}$ is a subset of $\mathbf{W}$.*
2. *For $m > 0$, $\mathbf{A}$ is a set of atomic expressions*

$$\{\langle \mathbf{T}_1, \mathbf{S}_1 \rangle, \ldots, \langle \mathbf{T}_m, \mathbf{S}_m \rangle\}.$$

If $m = 0$ then $\mathbf{A} = \emptyset$.

3. For $n > 0$, $\mathbf{B}$ is a set of expressions

$$\{B_1[\mathbf{W}_1, n_1, m_1], \ldots, B_n[\mathbf{W}_n, n_n, m_n]\}$$

such that $\mathbf{W}_i \subseteq \mathbf{W}$, $n_i < n, m_i < m$ for all $i = 1, \ldots, n$. If $n = 0$ then $\mathbf{B} = \emptyset$.

The value of an expression B is

$$P_B = \sum_{\mathbf{S}} \prod_{i=1}^{n} P_{B_i} \prod_{j=1}^{m} P_{A_j},$$

where an empty product should be understood as being equal to 1.

The recursive definition ensures the finiteness of the resulting expression by requiring that each sub-expression has fewer sub-expressions of their own than the expression above it. A single value might be shared by multiple expressions, as the terms of the product in the value of the expression are exchangeable. Expressions $B_1[\mathbf{W}, n_1, m_1]$ and $B_2[\mathbf{W}, n_2, m_2]$ are equivalent if their values P_{B_1} and P_{B_2} are equal for all P. Equivalence is defined similarly for atomic expressions. Every expression is formed by nested atomic expressions by definition. Because of this, we focus on the simplification of atomic expressions.

As an example we construct an expression for the causal effect formula (1). We define $\mathbf{W} := \{X, Y, Z_1, Z_2, Z_3\}$ and let the sets $\mathbf{B}$ and $\mathbf{S}$ be empty. We define the set $\mathbf{A}$ to consist of three atomic expressions A_1, A_2 and A_3 defined as follows

$$\begin{aligned}
A_1 &= \langle\{\langle Z_1, \{Z_2, X\}\rangle\}, \emptyset\rangle, \\
A_2 &= \langle\{\langle Z_2, \emptyset\}\rangle\}, \emptyset\rangle, \\
A_2 &= \langle\{\langle Y, \{Z_2, X, Z_3, Z_1\}\rangle, \langle Z_3, \{Z_2, X\}\rangle, \langle X, \{Z_2\}\rangle, \langle Z_2, \emptyset\rangle\}, \{X\}\rangle.
\end{aligned}$$

In the context of probabilistic graphical models, we are provided additional information about the joint distribution of the variables of interest in the form of a DAG. As we are concerned on the simplification of the results of causal effect derivations in such models, the general form of the atomic expressions can be further narrowed down by using the structure of the graph and the ordering of vertices called a topological ordering.

Definition 3 (Topological ordering) *Topological ordering π of a DAG $G = \langle \mathbf{W}, \mathbf{E}\rangle$ is an ordering of its vertices, such that if X is an ancestor of Y in G then $X < Y$ in π.*

The symbol V_j^π is used to denote the subset of vertices of G that are less than V_j in π. For sets we may define $\mathbf{V}^\pi$ to contain those vertices of G that are less than every vertex of $\mathbf{V}$ in π. Consider a DAG $G = \langle \mathbf{W}, \mathbf{E}\rangle$ and a topological ordering π of its vertices. We use the notation $\pi(\cdot)$ to denote indexing over the vertex set $\mathbf{W}$ of G in the ordering given by π, that is $V_{\pi(1)} > V_{\pi(2)} > \cdots > V_{\pi(m)}$ where $m = |\mathbf{W}|$. For any atomic expression $A[\mathbf{V}] = \langle \mathbf{T}, \mathbf{S}\rangle$ such that $\mathbf{V} \subseteq \mathbf{W}$ we also define the induced ordering ω. This ordering is an ordering of the variables in $\mathbf{V}$ such that if $X > Y$ in ω then $X > Y$ also in π. From now on in this paper, any indexing over the variables of an atomic expression will refer to the induced ordering of the set $\mathbf{V}$ when π is given, i.e $V_1 > V_2 > \cdots > V_n$ in ω. In other words, ω is obtained from π by leaving out variables that are not contained in A.

The ID algorithm performs the so-called C-component factorization. These components are subgraphs of the original graph where every node is connected by a path consisting entirely of bidirected edges. The resulting expressions of these factors serve as the basis for our simplification procedure.

Definition 4 (Topological consistency) *Let G' be a DAG with a subgraph $G = \langle \mathbf{W}, \mathbf{E}\rangle$ and let π be a topological ordering of the vertices of G. An atomic expression $A[\mathbf{W}] = \langle \mathbf{T}, \mathbf{S}\rangle$ is topologically consistent (or π-consistent for short) if*

$$An(V_i)_G \subseteq \mathbf{C}_i \subseteq V_i^\pi \text{ for all } i = 1, \ldots, n.$$

Here $An(V_i)_G$ denotes the ancestors of V_i in G. To motivate this definition we note that the outputs of the algorithms of Shpitser and Pearl (2006a,b) can always be represented by using products and quotients of topologically consistent atomic expressions. An expression is topologically consistent when every atomic expression contained by it is topologically consistent with respect to a topological ordering of a subgraph. We provide a proof for this statement in Appendix A. This also shows that any manual derivation of a causal effect can always be represented by a topologically consistent expression. The assumption that $An(V_i)_G \subseteq \mathbf{C}_i$ is not necessary for the simplification to be successful. This assumption is used to speed up the performance of our procedure in Section 3.

3. Simplification

Simplification in our context is the procedure of eliminating variables from the set of variables that are to be summed over in expressions. In atomic expressions, a successful simplification in terms of a single variable should result in another expression that holds the same value, but with the respective term eliminated and the variable removed from the summation. As we are interested in causal effects, we consider only simplification of topologically consistent atomic expressions.

Our approach to simplification is that the atomic expression has to represent a joint distribution of the variables present in the expression to make the procedure feasible. The question is whether the expression can be modified to represent a joint distribution. Before we can consider simplification, we have to define this property explicitly.

Definition 5 (Simplification sets) *Let G' be a DAG and let G be a subgraph of G' over a vertex set $\mathbf{W}$ with a topological ordering π. Let $A[\mathbf{W}] = \langle \mathbf{T}, \mathbf{S}\rangle$, where $\mathbf{T} = \{\langle V_1, \mathbf{C}_1, \rangle, \ldots, \langle V_n, \mathbf{C}_n\rangle\}$, be a π-consistent atomic expression and let $V_j \in \mathbf{S}$. Suppose that $V_{\pi(p)} = V_j$ and that $V_{\pi(q)} = V_1$ and let $\mathbf{M}$ be the set*

$$\{U \in \mathbf{W} \mid U \notin V[A], V_{\pi(q)} > U > V_{\pi(p)}\}.$$

If there exists a set $\mathbf{D} \subset V_j^\pi$ and the sets $\mathbf{E}_U \subseteq \mathbf{W}$ for all $U \in \mathbf{M}$ such that the conditional distribution of the variables $V_{\pi(p)}, \ldots, V_{\pi(q)}$ can be factorized as

$$P(V_{\pi(p)}, \ldots, V_{\pi(q)} | \mathbf{D}) = \prod_{U \in \mathbf{M}} P(U | \mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i | \mathbf{C}_i), \tag{2}$$

and

$$(U \perp\!\!\!\perp V_j | \mathbf{E}_U \setminus \{V_j\})_{G'} \text{ for all } U \in \mathbf{M}. \quad (3)$$

then the sets $\mathbf{D}$ *and* $\mathbf{E}_U, U \in \mathbf{M}$ *are the simplification sets of* A *with respect to* V_j.

This definition is tailored for the next result that can be used to determine the existence of a simpler expression when simplification sets exist. Afterwards we will show how this result can be applied in practice via an example. The definition characterizes π-consistent atomic expressions that represent joint distributions. It is apparent that simplifications sets are not always unique, which can lead to different but still simpler expressions. Henceforth the next result considers simplification in terms of a single variable. The proof is available in Appendix B.

Theorem 6 (Simplification) *Let* G' *be a DAG and let* G *be a subgraph of* G' *over a vertex set* $\mathbf{W}$ *with a topological ordering* π. *Let* $A[\mathbf{W}] = \langle \mathbf{T}, \mathbf{S} \rangle$ *be a* π*-consistent atomic expression and let* $\mathbf{D}$ *and* $\mathbf{E}_U, U \in \mathbf{M}$ *be its simplification sets with respect to a variable* $V_j \in \mathbf{S}$. *Then there exist an expression* $A'[\mathbf{W} \setminus \{V_j\}] = \langle \mathbf{T}', \mathbf{S}' \rangle$ *such that* $V_j \notin \mathbf{S}'$, $P_A = P_{A'}$ *and no term in* A' *contains* V_j.

Note that even if $\mathbf{M} = \emptyset$ in Definition 5, the existence of simplification sets still requires that $\prod_{V_i \geq V_j} P(V_i | \mathbf{C}_i) = P(V_j, \ldots, V_1 | \mathbf{D})$. In many cases there exists variables $U \in \mathbf{M}$ such that the expression does not contain a term for U. Condition (2) of Definition 5 guarantees that if these terms were contained in the expression it would represent a joint distribution. Our goal is thus to introduce these terms into the original expression temporarily, carry out the desired summation, and finally remove the added terms. This can only be achieved if the variables in the set $\mathbf{M}$ are conditionally independent of the variable currently being summed over, hence the assumption $(U \perp\!\!\!\perp V_j | \mathbf{E}_U \setminus \{V_j\})_{G'}$ of condition (3) of Definition 5.

We show how simplification sets can be used in practice to derive a simpler expression via an example. We consider the causal effect of $\{X, Z, W\}$ on Y in the graph G of Figure 2.

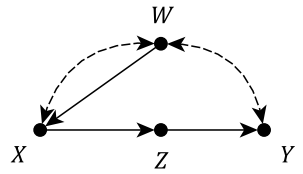

Figure 2: A graph G for the example on the use of simplification sets.

The effect in question is identifiable and the ID algorithm readily gives atomic expression

$$\sum_{X,W} P(Y | X, W, Z) P(X | W) P(W).$$

We consider simplification sets with respect to $V_j = W$. The topological order is $W < X < Z < Y$. The atomic expression does not contain a term for Z so we have $\mathbf{M} = \{Z\}$. By noting that $(Z \perp\!\!\!\perp W | X)_G$ we are able to satisfy condition (3) of Definition 5. We can write

$$P(Y, Z, X, W) = P(Z | X, W) P(Y | X, W, Z) P(X | W) P(W),$$

as required by condition (2) of Definition 5 by setting $\mathbf{E}_Z = \{X, W\}$. Thus, the simplification sets $\mathbf{D}$ and $\mathbf{E}_Z$ for the atomic expression with respect to W are $\emptyset$ and $\{X, W\}$, respectively. Finally, we obtain the simpler atomic expression by carrying out the summation over W:

$$\sum_X P(Y | X, Z) P(X).$$

Neither Definition 5 nor Theorem 6 provide a method to obtain simplification sets or to determine whether they exist in general. To solve this problem we present a simplification algorithm for π-consistent atomic expressions that operates by constructing simplification sets iteratively for each variable in the summation set.

Algorithm 1 always attempts to perform maximal simplification, meaning that as many variables of the set $\mathbf{S}$ are removed as possible. If the simplification in terms of the entire set $\mathbf{S}$ can not be completed, the intermediate result with as many variables simplified as possible is returned. If simplification in terms of specific variables or a subset is preferred, the set $\mathbf{S}$ should be defined accordingly.

The function SIMPLIFY takes three arguments: an atomic expression $A[\mathbf{W}]$ that is to be simplified, a graph G and a topological ordering π of its vertices. A is assumed to be π-consistent.

On line 10 the function INDEX.OF returns the corresponding index i of the term containing S_j. Since A is π-consistent, we only have to iterate through the variables $V_1, \ldots, V_j$ as the terms outside this range contain no relevant information about the simplification of V_j. The variables without a corresponding term in the atomic expression A are retrieved on line 11 by the function GET.MISSING. This function returns the set $\mathbf{M}$ of Definition 5 with respect to the current variable to be summed over.

In order to show that the term of A represent some joint distribution, we proceed in the order dictated by the topological ordering of the vertices. The sets $\mathbf{J}$ and $\mathbf{D}$ keep track of the variables that have been successfully processed and of the conditioning set of the joint term that was constructed on the previous iteration. Similarly, the sets $\mathbf{R}$ and $\mathbf{I}$ keep track of the variables and conditioning sets of the corresponding variables that the atomic expression does not originally contain a term for. Iteration through relevant terms begins on line 13. Next, we take a closer look at the function JOIN which is called next on line 14.

Here $\mathcal{P}(\cdot)$ denotes the power set, $\triangle$ denotes the symmetric difference and $An^*(\cdot)_G$ denotes the ancestors with the argument included. The function JOIN attempts to combine the joint term $P(\mathbf{J} | \mathbf{D})$, obtained from the previous iteration steps, with the term $P(V | \mathbf{C}) := P(V_k | \mathbf{C}_k)$ of the current iteration step. d-separation statements of G are evaluated to determine whether this can be done. In practice this means finding a suitable subset $\mathbf{P}_i$ of $\mathbf{G}$, where $\mathbf{G} \cup An(V)_G$ is the largest possible conditioning set of the new combined term. The set $\mathbf{G}$ is computed on line on line 4 of Algorithm 2. A valid subset $\mathbf{P}_i$ satisfies $P(\mathbf{J} | \mathbf{D}) = P(\mathbf{J} | An^*(V)_G, \mathbf{P}_i)$ and $P(V | \mathbf{C}) = P(V | An(V)_G, \mathbf{P}_i)$ which allow us to write the product $P(\mathbf{J} | \mathbf{D}) P(V | \mathbf{C})$ as $P(\mathbf{J}, V | An(V)_G, \mathbf{P}_i)$.

25:                     k ← k + 1
26:         if k = i + 1 then
27:             A_new ← FACTORIZE(J, D, R, I, A)
28:             if A_new = A then
29:                 A ← B
30:             else
31:                 A ← A_new
32:                 S ← S \ {S_j}
33:                 j ← 0
34:     return A
```

In order to find this valid subset, we compute the sets $\mathbf{A}$ and $\mathbf{B}$ for each candidate on lines 8 and 9. These sets characterize the necessary change in the conditioning sets of the terms $P(\mathbf{J}|\mathbf{D})$ and $P(V|\mathbf{C})$ that would enable a joint term to be formed by these two terms. The validity of the candidate set is finally checked on line 10 which determines if the necessary change is allowed by d-separation criteria in the graph G. If no valid subset $\mathbf{P}_i$ can be found, we can still attempt to insert a missing variable of $\mathbf{M}$ by calling INSERT. If this

Algorithm 2 Construction of the joint distribution of the set $\mathbf{J}$ and a variable V given their conditional sets $\mathbf{D}$ and $\mathbf{C}$ using d-separation criteria in G. S is the current summation variable, $\mathbf{M}$ is the set of variables not contained in the expression and π is a topological ordering.

```
1:  function JOIN(J, D, V, C, S, M, G, π)
2:      if J = ∅ then
3:          return ⟨{V}, C, ∅⟩
4:      G ← J^π \ An*(V)_G
5:      P ← P(G)
6:      n ← |P|
7:      for i = 1 : n do
8:          A ← (An*(V)_G ∪ P_i) △ D
9:          B ← (An(V)_G ∪ P_i) △ C
10:         if (J ⫫ A|D \ A)_G and (V ⫫ B|C \ B)_G then
11:             return ⟨J ∪ {V}, (An(V)_G ∪ P_i), ∅⟩
12:     if M ≠ ∅ then
13:         for M' ∈ M do
14:             if M' ∈ D, M' ∉ C then
15:                 ⟨J_new, D_new, R⟩ ← INSERT(J, D, M', S, G, π)
16:                 if J ⊂ J_new then
17:                     return ⟨J_new, D_new, R⟩
18:     return ⟨J, D, ∅⟩
```

does not succeed either, the original sets $\mathbf{J}$ and $\mathbf{D}$ are returned, which instructs SIMPLIFY to terminate simplification in terms of V_j and attempt simplification in the next variable.

A special case where the first variable of the joint distribution forms $P(\mathbf{J}, \mathbf{D})$ alone is processed on line 2 of Algorithm 2. In this case, we have an immediate result without having to iterate through the subsets of $\mathbf{G}$. The formulation of the set $\mathbf{G}$ ensures that the resulting factorization is π-consistent if it exists. Knowing that the ancestral set $An(V)_G$ has to be a subset of the new conditioning set also greatly reduces the amount of subsets we have to iterate through. In a typical situation, the size of $\mathbf{P}$ is not very large. Let us now inspect the insertion procedure in greater detail.

In essence, the function INSERT is a simpler version of JOIN, because the only restriction on the conditioning set of M' is imposed by the conditioning set of $\mathbf{J}$ and the fact that M' has to be conditionally independent of the current variable S to be summed over. If JOIN or INSERT was unsuccessful in forming a new joint distribution, we have that $\mathbf{J}_{\text{new}} \subset \mathbf{J}$. In this case simplification in terms of the current variable cannot be completed. If we have that $\mathbf{J}_{\text{new}} \not\subset \mathbf{J}$ the iteration continues.

Together the functions JOIN and INSERT capture the two conditions of Definition 5. They are essentially two variations of the underlying procedure of determining whether the terms of the atomic expression actually represent a joint distribution. The only difference is that JOIN is called when we are processing terms that already exist in the expression, and INSERT

Algorithm 3 Insertion of variable M' into the joint term $P(\mathbf{J}|\mathbf{D})$ using d-separation criteria in G. S is the current summation variable and π is a topological ordering.

1: **function** INSERT($\mathbf{J}, \mathbf{D}, M', S, G, \pi$)
2: $\quad\mathbf{G} \leftarrow \mathbf{J}^{\pi} \setminus An^*(M')_G$
3: $\quad n \leftarrow |\mathbf{G}|$
4: $\quad$**for** $i = 1 : n$ **do**
5: $\quad\quad\mathbf{A} \leftarrow (An^*(M')_G \cup \mathbf{P}_i) \triangle \mathbf{D}$
6: $\quad\quad\mathbf{B} \leftarrow (An(M')_G \cup \mathbf{P}_i)$
7: $\quad\quad$**if** $(\mathbf{J} \perp\!\!\!\perp \mathbf{A}|\mathbf{D} \setminus \mathbf{A})_G$ **and** $(M' \perp\!\!\!\perp \mathbf{S}|\mathbf{B} \setminus \mathbf{S})_G$ **then**
8: $\quad\quad\quad$**return** $\langle \mathbf{J} \cup \{M'\}, (An^*(M')_G \cup \mathbf{P}_i), \{M'\}\rangle$
9: $\quad$**return** $\langle \mathbf{J}, \mathbf{D}, \emptyset\rangle$

is called when there are variables without corresponding terms in the expression, that is the set $\mathbf{M}$ of Definition 5 is not empty.

If the innermost while-loop of Algorithm 1 succeeded in iterating through the relevant variables, we are ready to complete the simplification process in terms of S_j. We carry out the summation over S_j which results in $P(\mathbf{J} \setminus \{V_i\}|\mathbf{D})$. This is done on line 27 by calling FACTORIZE($\mathbf{J}, \mathbf{D}, \mathbf{R}, \mathbf{I}, A$) which checks whether the joint term $P(\mathbf{J} \setminus \{V_i\}|\mathbf{D})$ can be factorized back into a product of terms. In practice this means that if the function succeeds, it will return an atomic expression obtained by removing each inserted term $P(R|\mathbf{I}_R)$ such that $R \in \mathbf{R}$ and $\mathbf{I}_R \in \mathbf{I}$ from atomic expression A. The status of the atomic expression is updated on lines 31 and 32 to reflect this. If the function fails, it will return A unchanged.

If the innermost while-loop did not iterate completely through the relevant variables, the simplification was not successful in terms of S_j at this point. In this case we reset A to its original state on line 29 and attempt simplification in terms of the next variable. If there are no further variables to be eliminated, the outermost while-loop will also terminate. In the next theorem, we show that Algorithm 1 is both sound and complete in terms of simplification sets. The proof for the theorem can be found in Appendix D.

Theorem 7 *Let G' be a DAG and let G be a subgraph of G' over a vertex set $\mathbf{W}$ with a topological ordering π. Let $A[\mathbf{W}] = \langle \mathbf{T}, \{V_j\}\rangle$ be a π-consistent atomic expression. Then if* SIMPLIFY(A, G, π) *succeeds, it has constructed a collection of simplification sets of A with respect to V_j. Conversely, if there exists a collection of simplifications sets of A with respect to V_j, then* SIMPLIFY(A, G, π) *will succeed.*

4. High Level Algorithms

In this section, we present an algorithm to simplify all atomic expressions in the recursive stack of an expression. We will also provide a simple procedure to simplify quotients defined by two expressions: one representing the numerator and another representing the denominator. In some cases it is also possible to eliminate the denominator by subtracting common terms. First, we present a general algorithm to simplify topologically consistent expressions.

Algorithm 4 Recursive wrapper for the simplification of an expression $B = \langle \mathbf{B}, \mathbf{A}, \mathbf{S}\rangle$ given graph G and topological ordering π.

1: **function** DECONSTRUCT(B, G, π)
2: $\quad\mathbf{R} \leftarrow \emptyset$
3: $\quad$**for** $Y \in \mathbf{A}$ **do**
4: $\quad\quad\langle\{\langle V_1, \mathbf{C}_1\rangle, \ldots, \langle V_n, \mathbf{C}_n\rangle\}, \mathbf{S}_Y\rangle \leftarrow$ SIMPLIFY(Y, G, π)
5: $\quad\quad$**if** $\mathbf{S}_Y = \emptyset$ **then**
6: $\quad\quad\quad\mathbf{A} \leftarrow \mathbf{A} \cup (\bigcup_{i=1}^{n} \{\langle\{\langle V_i, \mathbf{C}_i\rangle\}, \emptyset\rangle\})$
7: $\quad$**for** $\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle \in \mathbf{B}$ **do**
8: $\quad\quad\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle \leftarrow$ DECONSTRUCT($\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle, G$)
9: $\quad\quad$**if** $\mathbf{B}_X = \emptyset$ **and** $\mathbf{S}_X = \emptyset$ **then**
10: $\quad\quad\quad\mathbf{R} \leftarrow \mathbf{R} \cup \{\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle\}$
11: $\quad\quad\quad\mathbf{A} \leftarrow \mathbf{A} \cup \mathbf{A}_X$
12: $\quad\mathbf{B} \leftarrow \mathbf{B} \setminus \mathbf{R}$
13: $\quad$**return** $\langle \mathbf{B}, \mathbf{A}, \mathbf{S}\rangle$

Algorithm 4 begins by simplifying all atomic expressions contained in the expressions. If an atomic expression contains no summations after the simplification but does contain multiple terms, each individual term is converted into an atomic expression of their own. After this, we iterate through all sub-expressions contained in the expression. The purpose of this is to carry out the simplification of every atomic expression in the stack and collect the results into as few atomic expressions as possible. First, we traverse to the bottom of the stack on line 8 by deconstructing sub-expressions until they have no sub-expressions of their own. Afterwards, it must be the case that $\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle$ consists of atomic sub-expressions only.

If $\langle \mathbf{B}_X, \mathbf{A}_X, \mathbf{S}_X\rangle$ contains no summations on line 9 then the atomic expressions contained in this expression do not require an additional expression to contain them, but can instead be transferred to be a part of the expression above the current one in the recursive stack. On line 6 we lift the atomic expressions contained in the atomic sub-expressions up to the current recursion stage.

There is no guarantee, that the resulting atomic expression is still π-consistent after this procedure. The function DECONSTRUCT operates on the principle of simplifying as many atomic expressions as possible, combining the results into new atomic expressions and simplifying them once more. We do not claim that this procedure is complete in a sense that Algorithm 4 would always find the simplest representation for a given expression. This method in nonetheless sound and finds drastically simpler expressions in almost every situation where such an expression exists.

We may also consider quotients often formed by deriving conditional distributions. For this purpose we need a subroutine to extract terms from atomic sub-expression that are independent of the summation index, that is $V_i \notin \mathbf{S}$ and $\mathbf{C}_i \cap \mathbf{S} = \emptyset$.

The procedure of Algorithm 5 is rather straightforward. First, we attempt to simplify B by using DECONSTRUCT on line 2. Next, we simply recurse as deep as possible without encountering a sum in an expression. If a sum is encountered, extraction is attempted. On any stage where a sum was not encountered, we may still have atomic sub-expression

Algorithm 5 Extraction of terms independent of the summation indices from a expression $B = \langle \mathbf{B}, \mathbf{A}, \mathbf{S} \rangle$ given graph G and topological ordering π.

```
1:  function EXTRACT(B, G, π)
2:      B ← DECONSTRUCT(B, G, π)
3:      if S = ∅ then
4:          for X ∈ B do
5:              X ← EXTRACT(X, G, π)
6:          for ⟨T_A, S_A⟩ ∈ A do
7:              if S_A ≠ ∅ then
8:                  A_E ← ∅
9:                  R ← ∅
10:                 for ⟨V, C⟩ ∈ T_A do
11:                     if V ∉ S_A and C ∩ S_A = ∅ then
12:                         A_E ← A_E ∪ {⟨{⟨V, C⟩}, ∅⟩}
13:                         R ← R ∪ {⟨V, C⟩}
14:                 A ← A ∪ A_E
15:                 T_A ← T_A \ R
16:     else
17:         A_E ← ∅
18:         R ← ∅
19:         for ⟨T_A, S_A⟩ ∈ A do
20:             if S_A = ∅ then
21:                 T_A^(1) ← ∅
22:                 T_A^(2) ← ∅
23:                 for ⟨V, C⟩ ∈ T_A do
24:                     T_A^(1) ← T_A^(1) ∪ {V}
25:                     T_A^(2) ← T_A^(2) ∪ C
26:                 if T_A^(1) ∩ S = ∅ and T_A^(2) ∩ S = ∅ then
27:                     A_E ← A_E ∪ {⟨T_A, S_A⟩}
28:                     R ← R ∪ {⟨T_A, S_A⟩}
29:         A ← A \ R
30:         B_E ← {B}
31:         return ⟨B_E, A_E, ∅⟩
```

that contain sums. Because the recursion had reached this far, we know that there are no summations above them in the stack, so we can attempt extraction on them as well.

Algorithm 6 takes two expressions, B_1 and B_2, and removes any sub-expressions and atomic sub-expressions that are shared by B_1 and B_2. This is of course only feasible when the summation sets are empty for both B_1 and B_2. This condition is checked on line 4.

Algorithm 6 Simplification of a quotient P_{B_1}/P_{B_2} given by the values of two expressions $B_1 = \langle \mathbf{B}_1, \mathbf{A}_1, \mathbf{S}_1 \rangle$ and $B_2 = \langle \mathbf{B}_2, \mathbf{A}_2, \mathbf{S}_2 \rangle$ given graph G and topological ordering π.

```
1:  function q-SIMPLIFY(B_1, B_2, G, π)
2:      B_1 ← EXTRACT(B_1, G, π)
3:      B_2 ← EXTRACT(B_2, G, π)
4:      if S_1 ≠ ∅ or S_2 ≠ ∅ then
5:          return ⟨B_1, B_2⟩
6:      i ← 1
7:      while i ≤ |B_1| and |B_1| > 0 and |B_2| > 0 do
8:          for j = 1 : |B_2| do
9:              if B_1i = B_2j then
10:                 B_1 ← B_1 \ {B_1i}
11:                 B_2 ← B_2 \ {B_2j}
12:                 i ← 0
13:                 break
14:         i ← i + 1
15:     i ← 1
16:     while i ≤ |A_1| and |A_1| > 0 and |A_2| > 0 do
17:         for j = 1 : |A_2| do
18:             if A_1i = A_2j then
19:                 A_1 ← A_1 \ {A_1i}
20:                 A_2 ← A_2 \ {A_2j}
21:                 i ← 0
22:                 break
23:         i ← i + 1
24:     return ⟨B_1, B_2⟩
```

5. Examples

In this section we present examples of applying the algorithms of the previous sections. We denote line number y of algorithm x with Ax:y. We begin with a simple example on the necessity of the INSERT procedure in graph G of Figure 3.

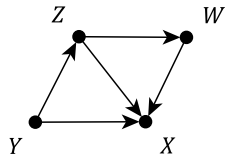

Figure 3: A graph G for the example on the necessity of the insertion procedure.

The causal effect of W on X is identifiable in this graph, and expression

$$\sum_{Z,Y} P(Y)P(Z|Y)P(X|W,Z,Y)$$

is obtained by direct application of the ID algorithm or by the truncated factorization formula for causal effects in Markovian models (Pearl, 2009). We let A be this atomic expression. The topological ordering π is $X > W > Z > Y$ and $\mathbf{M} = \{W\}$. The call to SIMPLIFY(A, G, π) will first attempt simplification in terms of Z, by calling

$$\text{JOIN}(\emptyset, \emptyset, X, \{W, Z, Y\}, Z, \{W\}, G, \pi),$$

which results in $\langle X, \{W, Z, Y\}, \emptyset\rangle$. At the second call

$$\text{JOIN}(\{X\}, \{W, Z, Y\}, Z, Y, Z, \{W\}, G, \pi)$$

we already run into trouble since we cannot find a conditioning set that would allow Z to be joined with $\{X\}$. However, since $\mathbf{M}$ is non-empty and $W \in \{W, Z, Y\}$ and $W \notin \{Z\}$ this means that the next call is

$$\text{INSERT}(\{X\}, \{W, Z, Y\}, W, Z, G, \pi).$$

Insertion fails in this case, as one can see from the fact that no conditioning set exists that would make W conditionally independent of Z. Thus we recurse back to JOIN and back to SIMPLIFY and end up on line A1:15 which breaks out of the while-loop. Thus A cannot be simplified in terms of Z. Simplification is attempted next in terms of Y. The first two calls are in this case

$$\text{JOIN}(\emptyset, \emptyset, X, \{W, Z, Y\}, Y, \{W\}, G, \pi),$$
$$\text{JOIN}(\{X\}, \{W, Z, Y\}, Z, \{Y\}, Y, \{W\}, G, \pi),$$

and in the second call we run into trouble again and have to attempt insertion

$$\text{INSERT}(\{X\}, \{W, Z, Y\}, W, Y, G, \pi).$$

This time we find that we can add a term for W which is $P(W|Z,Y)$ because $(W \perp\!\!\!\perp Y|Z)_G$. The other calls to JOIN also succeed and we can write the value of A as

$$\frac{\sum_{Z,Y} P(Y)P(Z|Y)P(W|Y,Z)P(X|W,Z,Y)}{P(W|Z)}.$$

and complete the summation in terms of Y. After the call to FACTORIZE we are left with the final expression

$$\sum_{Z} P(X|W,Z)P(Z).$$

We continue by considering again graph G depicted in Figure 1. The topological ordering π is $Y > Z_1 > Z_3 > X > Z_2$. Atomic expression A_1 given by

$$\sum_{X,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2),$$

is a part of the expression to be simplified.

We will first simplify A_1 and take a closer look at how the function JOIN operates. The call to SIMPLIFY(A_1, G, π) will attempt simplification in terms of the set $\{X, Y\}$ in the ordering that agrees with the topological ordering π, which is (Y, X). After initializing the required sets, we find the index of the term with Y as a variable on line 10. There is one missing variable, Z_1, so $\mathbf{M} = \{Z_1\}$ as returned by GET.MISSING on line A1:11. The first call to JOIN results in $\langle Y, \{Z_2, X, Z_3, Z_1\}, \emptyset\rangle$, because line A2:3 is triggered. Condition on line A1:15 is not satisfied since $\mathbf{J}_{\text{new}} = \{Y\} \not\subseteq \emptyset = \mathbf{J}$. Thus we update the status of $\mathbf{J}$ and $\mathbf{D}$ on lines A1:18 and A1:19. Since $\mathbf{R}_{\text{new}} = \emptyset$ on line A1:20 we do not have to update the status of $\mathbf{R}$, $\mathbf{I}$ and $\mathbf{M}$ on lines A1:21, A1:22 and A1:23. The innermost while-loop is now complete and we call FACTORIZE on line A1:27 which succeeds in removing the term $P(Y|Z_2, X, Z_3, Z_1)$ by completing the sum. Now we update the status of the atomic expression on line A1:31 and remove Y from the set of variables to be summed over on line A1:32. The resulting value of the expression at this point is

$$\sum_{X} P(Z_3|Z_2,X)P(X|Z_2)P(Z_2).$$

Next, the summation in terms of X is attempted. JOIN is once again successful, because Z_3 is the first variable to be joined and line A2:3 is triggered. Next we attempt to join the terms $P(Z_3|Z_2, X)$ and $P(X|Z_2)$. Computation of the set $\mathbf{G}$ on line A2:4 results in

$$\{Z_3\}^{\pi} \setminus An^*(X)_G = \{X, Z_2\} \setminus \{X, Z_2\} = \emptyset.$$

The power set computed on line A2:5 contains only the empty set. For $\mathbf{P}_1 = \emptyset$ we have

$$A = (An(X)^*_G \cup \mathbf{P}_1) \triangle \mathbf{D} = (\{X, Z_2\} \cup \emptyset) \triangle \{X, Z_2\} = \emptyset$$

on line 8, and

$$B = (An(X)_G \cup \mathbf{P}_1) \triangle \mathbf{C} = (\{Z_2\} \cup \emptyset) \triangle \{Z_2\} = \emptyset$$

on line 9. The condition on line A2:10 evaluates to true and we return with $\langle \{Z_3, X\}, \{Z_2\}, \emptyset\rangle$. The innermost while-loop terminates allowing the summation over X to be performed. The function FACTORIZE provides us with the final expression

$$P(Z_3|Z_2)P(Z_2). \tag{4}$$

Next, we will consider the full example and see how q-SIMPLIFY is applied. Using the ID algorithm we obtain the causal effect of X on Z_1, Z_2, Z_3 and Y in graph G of Figure 1 and it is

$$P(Z_1|Z_2,X)P(Z_3|Z_2)\frac{\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)}{\sum_{X,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)} \times \sum_{X,Z_3,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2).$$

We will represent this as a quotient of expression using Definition 2. Let A_1 be the atomic expression of the previous example and let A_2 also be an atomic expression given by

$$\sum_{X} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2),$$

which is essentially the same as A_1, but with the variable Y removed from the summation set $\mathbf{S}$. Similarly, we let A_3 be an atomic expression given by

$$\sum_{X,Z_3,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2).$$

We also define the atomic expressions A_4 with the value $P(Z_3|Z_2)$ and A_5 with the value $P(Z_1|Z_2,X)$. Now, we define two expressions B_1 and B_2 for the quotient P_{B_1}/P_{B_2} as follows:

$$B_1 = \langle \emptyset, \{A_2, A_3, A_4, A_5\}, \emptyset \rangle, \quad B_2 = \langle \emptyset, \{A_1\}, \emptyset \rangle.$$

We now call q-SIMPLIFY(B_1, B_2, G, π). First, we must trace the calls to EXTRACT for both expressions on lines A6:2 and A6:3. For B_1 and B_2 this immediately results in a call to DECONSTRUCT on line A5:2. First, the function applies SIMPLIFY to each atomic expression contained in the expressions on line A4:4.

Let us first consider the simplification of A_2. As before with A_1, we have that JOIN first succeeds in forming $\langle Y, \{Z_2, X, Z_3, Z_1\}, \emptyset \rangle$, but this time Y is not in the summation set, so we continue. Next, the algorithm attempts to join $P(Y|Z_2,X,Z_3,Z_1)$ with $P(Z_3|Z_2,X)$. The set $\mathbf{G}$ is defined as

$$\{Y\}^\pi \setminus An^*(Z_3)_G = \{Z_3, Z_1, X, Z_2\} \setminus \{Z_3, Z_2\} = \{Z_1, X\}$$

and its subsets are $\{Z_1, X\}$, $\{Z_1\}$, $\{X\}$ and $\emptyset$. For the first subset $\mathbf{P}_1 = \emptyset$ we have that

$$A = (An^*(Z_3) \cup \mathbf{P}_1) \triangle \mathbf{D} = \{Z_2, Z_3\} \triangle \{Z_2, X, Z_3, Z_1\} = \{X, Z_1\}$$

and since $(Y \not\perp\!\!\!\perp X, Z_1 | Z_3, Z_2)_G$ the condition on line A2:10 is not satisfied. We continue with $\mathbf{P}_2 = \{X\}$ and obtain

$$A = (An^*(Z_3) \cup \mathbf{P}_2) \triangle \mathbf{D} = \{X, Z_2, Z_3\} \triangle \{Z_2, X, Z_3, Z_1\} = \{Z_1\}$$

and since $(Y \not\perp\!\!\!\perp Z_1 | X, Z_3, Z_2)_G$ the condition on line A2:10 is still not satisfied. Next, for $\mathbf{P}_3 = \{Z_1\}$ we have

$$A = (An^*(Z_3) \cup \mathbf{P}_3) \triangle \mathbf{D} = \{Z_2, Z_3, Z_1\} \triangle \{Z_2, X, Z_3, Z_1\} = \{X\}$$

and since $(Y \not\perp\!\!\!\perp X | Z_1, Z_3, Z_2)_G$ the condition on line A2:10 is again, not satisfied. Finally, for $\mathbf{P}_4 = \{Z_1, X\}$ we have

$$A = (An^*(Z_3) \cup \mathbf{P}_4) \triangle \mathbf{D} = \{Z_2, X, Z_3, Z_1\} \triangle \{Z_2, X, Z_3, Z_1\} = \{X\}$$

and

$$B = (An(Z_3) \cup \mathbf{P}_4) \triangle \mathbf{C} = \{Z_2, X, Z_1\} \triangle \{Z_2, X\} = \{Z_1\}.$$

Both conditions on line A2:10 are now satisfied ny noting that $(Z_3 \perp\!\!\!\perp Z_1 | X, Z_2)_G$. Afterwards we obtain

$$P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X) = P(Y,Z_3|Z_1,Z_2,X)$$

and continue in an attempt to join the term $P(X|Z_2)$ with this result. The set $\mathbf{G}$ is now defined as

$$\{Y, Z_3\}^\pi \setminus An^*(X)_G = \{Z_1, X, Z_2\} \setminus \{X, Z_2\} = \{Z_1\}$$

and its subsets are $\{Z_1\}$ and $\emptyset$. Starting with $\mathbf{P}_1 = \emptyset$ we have that

$$A = (An^*(X) \cup \mathbf{P}_1) \triangle \mathbf{D} = \{X, Z_2\} \triangle \{Z_1, Z_2, X\} = \{Z_1\}$$

and since $(Y, Z_3 \not\perp\!\!\!\perp Z_1 | X, Z_2)_G$ the condition on line A2:10 is not satisfied. Continuing with $\mathbf{P}_2 = \{Z_1\}$ we have

$$B = (An(X) \cup \mathbf{P}_2) \triangle \mathbf{C} = \{Z_2, Z_1\} \triangle \{Z_2\} = \{Z_1\}.$$

Again, the condition on line A2:10 is not satisfied by noting that $(X \not\perp\!\!\!\perp Z_1 | Z_2)_G$. We have exhausted the possible subsets, which means that we enter the loop on line A2:13 since the set $\mathbf{M} = \{Z_1\}$ is not empty of line A2:12.

In this case INSERT is called to bring Z_1 into the expression because $Z_1 \in \mathbf{D} = \{Z_1, Z_2, X\}$ and $Z_1 \notin \mathbf{C} = \{Z_2\}$. The set $\mathbf{G}$ is constructed on line A3:2 and it is

$$\mathbf{J}^\pi \setminus An^*(Z_1)_G = \{Y, Z_3\}^\pi \setminus \{X, Z_1, Z_2\} = \emptyset.$$

For the only subset $\mathbf{P}_1 = \emptyset$ we have

$$B = (An(Z_1)_G \cup \mathbf{P}_1) = \{X, Z_2\}$$

on line A3:6, and since $(Z_1 \not\perp\!\!\!\perp X | Z_2)_G$ the condition on line A3:7 is not satisfied and we return with $\langle \mathbf{J}, \mathbf{D}, \emptyset \rangle$ unchanged on line 9 of Algorithm 3, which causes JOIN to also return with the same output on line A3:18. The condition on line A1:15 is now satisfied and we cannot simplify A_2.

The atomic expression A_3 can be simplified. First, Y is eliminated exactly as it was removed from A_1. Following the same principle we can see that whenever a variable in the summation set is the largest one in the topological order of the variables contained in the atomic expression, it will be removed successfully. From this we obtain that the value of A_3 is in fact simply $P(Z_2)$. Let us call the atomic expression with this value E, that is $P_E = P(Z_2)$. The atomic expression A_1 can also be simplified, and its value is given by (4). Furthermore, since this value is made of two product terms, it is split into two atomic expressions respectively. Let these be called D_1 and D_2 such that $P_{D_1} = P(Z_3|Z_2)$ and $P_{D_2} = P(Z_2)$.

Applying SIMPLIFY to A_4 and A_5 simply returns the original expressions, since they do not contain any summations and the loop on line A1:3 is never entered. The set of atomic expressions is afterwards updated on line A4:6. Neither B_1 nor B_2 contain any sub-expressions or summations on line A4:9, so DECONSTRUCT(B_1, G, π) returns $\langle \emptyset, \{A_2, E, A_4, A_5\}, \emptyset \rangle$ and DECONSTRUCT(B_2, G, π) returns $\langle \emptyset, \{D_1, D_2\}, \emptyset \rangle$. The lack of summations on line A5:3 of causes EXTRACT to iterate through the atomic expression contained in B_1 and B_2 directly on line A5:6, since neither of them have any sub-expressions of their own.

Only A_2 contains a sum at this point. The iteration over the terms of A_2 on line A5:10 finds that the only term that does not contain X is $P(Z_2)$ on line A5:11. Let us denote the atomic expression with the value $P(Z_2)$ as C_1 and the atomic expression resulting from the extraction as C_2 which now has the value

$$\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2).$$

This completes the extraction and results in an expression B_1' such that

$$B_1' = \langle \emptyset, \{C_1, C_2, E, A_4, A_5\}, \emptyset \rangle.$$

The expression B_2 remains unchanged.

q-SIMPLIFY is now able to proceed. Neither B_1' nor B_2 contain sub-expression so the loop on line A6:7 is not entered, and we are only subtracting their common atomic expressions in the loop on line A6:16. It is easy to see that $A_4 = D_1$ and $C_1 = D_2$, so they are removed from both B_1' and B_2. Finally, the expressions corresponding to the numerator and denominator are returned.

To summarize, we began with the expression

$$P(Z_1|Z_2,X)P(Z_3|Z_2)\frac{\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)}{\sum_{X,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2)} \times \sum_{X,Z_3,Y} P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2)P(Z_2).$$

and successfully simplified it into

$$P(Z_1|Z_2,X)P(Z_2)\sum_X P(Y|Z_2,X,Z_3,Z_1)P(Z_3|Z_2,X)P(X|Z_2).$$

6. Discussion

We have presented a formal definition of topologically consistent atomic expressions and simplification sets and provided a sound and complete algorithm to find these sets for a given expression. We also discussed some general techniques that apply to a more general class of these expressions. Algorithm 7 and Algorithm 8, presented in Appendix A, have been previously implemented in the R package causaleffect (Tikka and Karvanen, 2017). We have updated the package to include all of the simplification procedures presented in this paper and they can be applied to all causal effect and conditional causal effect expressions derived from identification procedures. Our definition of topologically consistent atomic expressions is similar to g-functionals that can be used to characterize identifiability results under special conditions (Shpitser and Tchetgen Tchetgen, 2016).

It is plausible that these procedures could also be extended into other causal inference results, such as formulas for z-identifiability, transportability and meta-transportability of causal effects. The extensions are non-trivial however, since transportability formulas contain terms with distributions from multiple domains and z-identifiable causal effects contain do-operators in the conditioning sets which would require the implementation of the rules of do-calculus into Algorithm 1. Do-calculus consists of three inference rules that can be used to manipulate probabilities involving the do-operator (Pearl, 2009). Currently, we operate only on expressions that do not involve the do-operator. In fact, in our procedure it is not required to know the original causal query that produced the result.

Simpler expressions have many useful properties. They can help in understanding and communicating results and evaluating them saves computational resources. Estimation accuracy can also be improved in some cases when variables that are present in the original expression suffer from missing data or measurement error. One example where the benefits

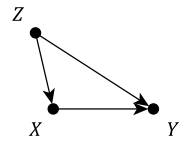

Figure 4: A graph G for a situation where simplification fails

of simplification are realized can be found in (Hyttinen et al., 2015), where expressions of causal effects are derived and repeatedly evaluated for a large number of causal models.

Our approach to simplification stems from the nature of causal effect expressions. In our setting, a question still remains whether simplification sets completely characterize all situations where a variable can be eliminated from an atomic expression. One might also consider simplification in a general setting, where we do not assume topological consistency or any other constraints for the atomic expressions. In this case a 'black box' definition for simplification could be considered, where we simply require that when the sum over a variable of interest is completed we are again left with another atomic expression without this variable in the summation set. This framework is theoretically interesting but we are not aware of any potential applications.

The worst case time complexity of Algorithm 1 is difficult to gauge and is a topic for further research. One can observe that the performance of the algorithm is highly dependent on the size of the differences of the conditioning sets between adjacent terms. Both Algorithm 2 and Algorithm 3 iterate through the subsets of these differences and check d-separation criteria for each subset. Thus dynamic programming solutions could be implemented to further improve performance by collecting the results of these checks. Previously determined conditional independences would not need to be checked again and could be retrieved from memory instead.

In some cases, simplification has some apparent connections to identifiability. Consider the graph G of Figure 4. In this graph the causal effect of X on Y is identifiable, and its expression is

$$\sum_Z P(Y|Z,X)P(Z).$$

If we let Z be an unobserved variable instead, then G depicts the well-known bow-arc graph, where the same causal effect is unidentifiable. This corresponds to an unsuccessful attempt to remove Z from the expression of the causal effect. However, we cannot know beforehand whether an expression for a causal effect is going to be atomic or not, so we cannot use our algorithm to derive identifiability in general.

A reviewer suggested a simplification algorithm where the ID algorithm would be applied to latent projections (Pearl and Verma, 1991) onto the variables to be marginalized. This algorithm would be able to solve many, but not all, simplification tasks. Importantly, in the example presented in Figure 1, we cannot make any variables latent, as we are interested in the causal effect of X on all of the other variables. A reviewer also suggested that simplified

expressions could be categorized into those that are obtained through latent projections and those that are not. This categorization might give additional insight into the topic.

Acknowledgments

We thank the anonymous reviewers for their constructive feedback that greatly helped us to improve this paper. We also thank Lasse Leskelä for his comments.

Appendix A. Topological Consistency of Causal Effect Formulas

We prove the statement that every causal effect formula returned by the algorithms of Shpitser and Pearl (2006a,b) can be represented by using products and quotients of π-consistent atomic expressions such that π is a topological ordering of G.

We use the notation $G[\mathbf{X}]$ to denote an induced subgraph, which is obtained from G by removing all vertices not in $\mathbf{X}$ and by keeping all edges between the vertices of $\mathbf{X}$ in G. Here $G_{\overline{\mathbf{X}},\underline{\mathbf{Z}}}$ means the graph that is obtained from G by removing all incoming edges of $\mathbf{X}$ and all outgoing edges of $\mathbf{Z}$. We say that G is an *I-map* of P if P admits the causal Markov factorization with respect to $G = \langle \mathbf{V}, \mathbf{E} \rangle$, which is

$$P = \prod_{i=1}^{n} P(V_i | Pa^*(V_i)_G) \prod_{j=1}^{k} P(U_j),$$

where $Pa^*(\cdot)$ contains unobserved parents as well.

Consider first lines 2, 3, 4 and 7 of Algorithm 7 where recursive calls occur and let π_r be the topological ordering of the graph in the previous recursion step. Line 2 limits the identification procedure to the ancestors of $\mathbf{Y}$ so we can still obtain an expression that topologically consistent with respect to a topological ordering obtained from π_r by removing non-ancestors. Lines 3 and 4 make no changes to the distribution P and the graph G. On line 7 the induced subgraph $G[\mathbf{S}']$ in the next call is a C-component, but the joint distribution in this case is a π_r-consistent expression

$$P(\mathbf{S}') = \prod_{V_i \in \mathbf{S}'} P(V_i | V_i^{\pi_r} \cap \mathbf{S}', v_i^{\pi_r} \setminus \mathbf{s}'),$$

since every conditioning set is of the form $V_i^{\pi_r}$ when we only consider variables instead of their values, so we obtain

$$P(\mathbf{S}') = \prod_{V_i \in \mathbf{S}'} P(V_i | V_i^{\pi_r}),$$

Furthermore, any expression returned from line 7 will now be π_r-consistent. Thus all recursive calls retain topological consistency with respect to π.

Consider now the non-recursive terminating calls on lines 1 and 6. Consider line 1 first. If line two was triggered previously, we can factorize $P(\mathbf{V})$ in such a way that each variable is conditioned by its ancestors, since the ancestors of ancestors of $\mathbf{Y}$ are by definition ancestors of $\mathbf{Y}$. If line 7 was triggered previously we already know that the joint distribution was previously factorized in a π_r-consistent fashion. If line 3 or 4 was triggered previously, we

know that they have not imposed any changes on P of G. Line 6 clearly produces a π_r consistent end result. Lines 4, 6 and 7 can only produce either products of quotients. By noting that π_r-consistency implies π-consistency, we have that the result of the algorithm can always be represented by using products and quotients of π-consistent atomic expressions.

Algorithm 7 The causal effect of intervention $do(\mathbf{X} = \mathbf{x})$ on $\mathbf{Y}$ (Shpitser and Pearl, 2006a).

INPUT: Value assignments $\mathbf{x}$ and $\mathbf{y}$, joint distribution $P(\mathbf{v})$ and a DAG $G = \langle \mathbf{V}, \mathbf{E} \rangle$. G is an I-map of P.

OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y})$ in terms of $P(\mathbf{v})$ or **FAIL**(F, F').

function ID$(\mathbf{y}, \mathbf{x}, P, G)$
1: **if** $\mathbf{x} = \emptyset$, **then**
  return $\sum_{v \in \mathbf{v} \setminus \mathbf{y}} P(\mathbf{v})$.
2: **if** $\mathbf{V} \neq An(\mathbf{Y})_G$, **then**
  return ID$(\mathbf{y}, \mathbf{x} \cap An(\mathbf{Y})_G, P(An(\mathbf{Y})_G), G[An(\mathbf{Y})_G])$.
3: **Let** $\mathbf{W} = (\mathbf{V} \setminus \mathbf{X}) \setminus An(\mathbf{Y})_{G_{\overline{\mathbf{X}}}}$.
  if $\mathbf{W} \neq \emptyset$, **then**
  return ID$(\mathbf{y}, \mathbf{x} \cup \mathbf{w}, P, G)$.
4: **if** $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}_1], \ldots, G[\mathbf{S}_k]\}$, **then**
  return $\sum_{v \in \mathbf{v} \setminus (\mathbf{y} \cup \mathbf{x})} \prod_{i=1}^{k}$ **ID**$(\mathbf{s}_i, \mathbf{v} \setminus \mathbf{s}_i, P, G)$.
  if $C(G[\mathbf{V} \setminus \mathbf{X}]) = \{G[\mathbf{S}]\}$, **then**
5: **if** $C(G) = \{G\}$, **then**
  throw FAIL$(G, G[\mathbf{S}])$.
6: **if** $G[\mathbf{S}] \in C(G)$, **then**
  return $\sum_{v \in \mathbf{s} \setminus \mathbf{y}} \prod_{V_i \in \mathbf{S}} P(v_i | v_i^{\pi})$.
7: **if** $(\exists \mathbf{S}') \mathbf{S} \subset \mathbf{S}'$ such that $G[\mathbf{S}'] \in C(G)$, **then**
  return ID$(\mathbf{y}, \mathbf{x} \cap \mathbf{s}', \prod_{V_i \in \mathbf{S}'} P(V_i | V_i^{\pi} \cap \mathbf{S}', v_i^{\pi} \setminus \mathbf{s}'), G[\mathbf{S}'])$.

The claim is now apparent for Algorithm 8 since line 2 is eventually called for every conditional causal effect.

Algorithm 8 The causal effect of intervention $do(\mathbf{X} = \mathbf{x})$ on $\mathbf{Y}$ given $\mathbf{Z}$ (Shpitser and Pearl, 2006b).

INPUT: Value assignments $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$, joint distribution $P(\mathbf{v})$ and a DAG $G = \langle \mathbf{V}, \mathbf{E} \rangle$. G is an I-map of P.

OUTPUT: Expression for $P_{\mathbf{x}}(\mathbf{y}|\mathbf{z})$ in terms of $P(\mathbf{v})$ or **FAIL**(F, F').

function IDC$(\mathbf{y}, \mathbf{x}, \mathbf{z}, P, G)$
1: **if** $\exists Z \in \mathbf{Z}$ such that $(\mathbf{Y} \perp\!\!\!\perp Z | \mathbf{X}, \mathbf{Z} \setminus \{Z\})_{G_{\overline{\mathbf{X}},\underline{\mathbf{Z}}}}$ **then**
  return IDC$(\mathbf{y}, \mathbf{x} \cup \{z\}, \mathbf{z} \setminus \{z\}, P, G)$.
2: **else let** $P' =$ **ID**$(\mathbf{y} \cup \mathbf{z}, \mathbf{x}, P, G)$.
  return $P' / \sum_{y \in \mathbf{y}} P'$

Appendix B. Proof of Theorem 6

Proof By direct calculation we obtain

$$\begin{aligned}
P_A &= \sum_{V_j} \prod_{i=1}^{n} P(V_i|\mathbf{C}_i) \\
&= \prod_{V_i<V_j} P(V_i|\mathbf{C}_i) \sum_{V_j} \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i) \\
&= \prod_{V_i<V_j} P(V_i|\mathbf{C}_i) \sum_{V_j} \frac{P(V_{\pi(p)}, \ldots, V_{\pi(q)}|\mathbf{D})}{\prod_{U\in\mathbf{M}} P(U|\mathbf{E}_U)} \\
&= \prod_{V_i<V_j} P(V_i|\mathbf{C}_i) \frac{P(V_{\pi(p+1)}, \ldots, V_{\pi(q)}|\mathbf{D})}{\prod_{U\in\mathbf{M}} P(U|\mathbf{E}_U)} \\
&= \prod_{V_i<V_j} P(V_i|\mathbf{C}_i) \prod_{V_i>V_j} P(V_i|\mathbf{D}_i) := P_{A'},
\end{aligned}$$

where the sets $\mathbf{D}_i$ are obtained from the factorization of the joint term such that A' is a π^*-consistent where π^* is obtained from π by removing V_j from the ordering. To justify the equalities, we first note that terms of variables $V_i < V_j$ do not contain V_j and can be brought outside the sum.

To obtain the third equality, we multiply by $[\prod_{U\in\mathbf{M}} P(U|\mathbf{E}_U)]/[\prod_{U\in\mathbf{M}} P(U|\mathbf{E}_U)]$ and apply condition (2) of Definition 5 on the right-hand side as licensed by condition (3) of the definition. To obtain the fourth equality, we simply carry out the summation in terms of V_j. Conditions (2) and (3) of Definition 5 make it possible to refactorize the joint term into product terms so that the terms corresponding to variables $U \in \mathbf{M}$ remain unchanged and can be divided out once more. Thus we obtain the last equality, and an expression that no longer contains V_j and has the same value as A. ■

Appendix C. Derivation of the Causal Effect in the Introductory Example

We present the derivation of the causal effect of X on Y, Z_3, Z_2, Z_1 in the graph G of Figure 1 using Algorithm 7. We fix topological ordering of G as $Z_2 < X < Z_1 < Z_3 < Y$. The original call $\mathrm{ID}(\{Y, Z_1, Z_2, Z_3\}, \{X\}, P(\mathbf{V}), G)$ fires line 4 and results in three new recursive calls. We have

$$P_X(Y, Z_3, Z_1, Z_2) = P_{Y,Z_3,X,Z_2}(Z_1) P_{Y,Z_1,X,Z_2}(Z_3) P_{Z_3,Z_1,X}(Y, Z_2), \tag{5}$$

as the graph $G[\mathbf{V}\setminus\{X\}]$ has three C-components formed by the sets $\{Z_1\}$, $\{Z_3\}$ and $\{Y, Z_2\}$, respectively.

The first recursive call $\mathrm{ID}(\{Z_1\}, \{Y, Z_3, X, Z_2\}, P(\mathbf{V}), G)$ fires line 2 because Z_3 and Y are not ancestors of Z_1. The next call $\mathrm{ID}(\{Z_1\}, \{X, Z_2\}, P(Z_1, X, Z_2), G[\{Z_1, X, Z_2\}])$ fires line 6 because $C(G[\{Z_1\}])$ contains only one C-component and it is not part of a larger

C-component in the graph of the current recursion stage. We have

$$P_{Y,Z_3,X,Z_2}(Z_1) = P_{X,Z_2}(Z_1) = P(Z_1|X, Z_2). \tag{6}$$

To obtain $P_{Y,Z_1,X,Z_2}(Z_3)$ we call $\mathrm{ID}(\{Z_3\}, \{Y, Z_1, X, Z_2\}, P(\mathbf{V}), G)$ which also fires line 2 because X, Z_1 and Y and not ancestors of Z_3. Calling $\mathrm{ID}(\{Z_3\}, \{Z_2\}, P(Z_3, Z_2), G[\{Z_3, Z_2\}])$ fires line 6 $C(G[\{Z_3\}])$ contains only one C-component and it is not part of a larger C-component in the graph of the current recursion stage. We have

$$P_{Y,Z_1,X,Z_2}(Z_3) = P_{Z_2}(Z_3) = P(Z_3|Z_2). \tag{7}$$

To obtain the last term we call $\mathrm{ID}(\{Y, Z_2\}, \{Z_3, Z_1, X\}, P(\mathbf{V}), G)$. The subgraph $G[\mathbf{V}\setminus\{Z_3, Z_1, X\}] = G[\{Y, Z_2\}]$ has only one C-component, but it is part of a larger C-component formed by the set $\mathbf{S}' = \{Y, Z_3, X, Z_2\}$ in the current graph G. Line 7 is fired resulting in

$$\mathrm{ID}(\{Y, Z_2\}, \{Z_3, X\}, P(Y|Z_3, Z_1, X, Z_2) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2), G[\mathbf{S}']). \tag{8}$$

This call fires line 2 since X is not an ancestor of Y in the graph $G[\mathbf{S}']$. Letting $\mathbf{T} = \mathbf{S}'\setminus\{X\} = \{Y, Z_3, Z_2\}$ the next call is

$$\mathrm{ID}(\{Y, Z_2\}, \{Z_3\}, \sum_X P(Y|Z_3, Z_1, X, Z_2) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2), G[\mathbf{T}]). \tag{9}$$

This time we trigger line 6 because $G[\mathbf{T}\setminus\{Z_3\}]$ has only one C-component and there is no larger C-component of $G[\mathbf{T}]$ that would contain it. We obtain

$$\begin{aligned}
P_{Z_3,Z_1,X}(Y, Z_2) &= P_{Z_3,Z_1,X}(Y, Z_2) \\
&= P_{Z_3,X}(Y, Z_2) \\
&= P_{Z_3}(Y, Z_2) \\
&= P^*(Y|Z_3, Z_2) P^*(Z_2),
\end{aligned} \tag{10}$$

where P^* is the distribution of the current recursion stage, that is

$$P^*(Y, Z_3, Z_2) = \sum_X P(Y|Z_3, Z_1, X, Z_2) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2).$$

In order to represent the conditional probability on the last line of (10), we write

$$\begin{aligned}
P^*(Y|Z_3, Z_2) P^*(Z_2) &= \frac{P^*(Y, Z_3, Z_2)}{P^*(Z_3, Z_2)} P^*(Z_2) \\
&= \frac{P^*(Y, Z_3, Z_2)}{\sum_Y P^*(Y, Z_3, Z_2)} \sum_{Y,Z_3} P^*(Y, Z_3, Z_2) \\
&= \frac{\sum_X P(Y|Z_2, X, Z_3, Z_1) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2)}{\sum_{X,Y} P(Y|Z_2, X, Z_3, Z_1) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2)} \times \\
&\quad \sum_{X,Z_3,Y} P(Y|Z_2, X, Z_3, Z_1) P(Z_3|Z_2, X) P(X|Z_2) P(Z_2).
\end{aligned} \tag{11}$$

Finally, we gather the results of our subproblems in (6), (7) and (11), and insert them back into the equation in (5) which yields

$$P_X(Y, Z_3, Z_1, Z_2) = P(Z_1|Z_2, X)P(Z_3|Z_2)\times \frac{\sum_X P(Y|Z_2, X, Z_3, Z_1)P(Z_3|Z_2, X)P(X|Z_2)P(Z_2)}{\sum_{X,Y} P(Y|Z_2, X, Z_3, Z_1)P(Z_3|Z_2, X)P(X|Z_2)P(Z_2)}\times \sum_{X,Z_3,Y} P(Y|Z_2, X, Z_3, Z_1)P(Z_3|Z_2, X)P(X|Z_2)P(Z_2)$$

as the formula for the causal effect.

Appendix D. Proof of Theorem 7

Proof (i) Suppose that SIMPLIFY(A, G, π) has returned an expression with variable V_j eliminated. Because the computation completed successfully, we have that each application of JOIN and INSERT succeed. We can rewrite the value of A as

$$\prod_{V_i<V_j} P(V_i|\mathbf{C}_i)\sum_{V_j}\prod_{V_i\geq V_j} P(V_i|\mathbf{C}_i),$$

where the terms $P(V_i|\mathbf{C}_i)$ such that $V_i < V_j$ can be brought outside the sum over V_j, because they cannot contain V_j. The functions JOIN and INSERT use only standard rules of probability calculus, which can be seen on line 10 of Algorithm 2 and line 7 of Algorithm 3, and thus every new formation of a joint distribution $P(\mathbf{J}|\mathbf{D})$ has been valid. Once again we rewrite the value of A as

$$\prod_{V_i<V_j} P(V_i|\mathbf{C}_i)\sum_{V_j} P(\mathbf{J}|\mathbf{D}),$$

which means that condition (2) of Definition 5 is now satisfied, as we have obtained a joint term from the original product terms.Because $V_j \in \mathbf{J}$ we can carry out the summation which yields

$$\prod_{V_i<V_j} P(V_i|\mathbf{C}_i)\cdot P(\mathbf{J}\setminus\{V_j\}|\mathbf{D}),$$

Because Algorithm 1 succeeds, we know that every insertion is canceled out by FACTORIZE. To complete the procedure we obtain a new factorization without V_j resulting in an atomic expression A' that no longer contains V_j. Condition (3) of Definition 5 is satisfied by the definition of INSERT, because the function always checks the conditional independence with the current summation variable on line 7. Both conditions for simplification sets have been satisfied by construction.

(ii) Suppose that there exists a collection of simplification sets of A with respect to V_j. For the sake of clarity, assume further that $V_n = V_j$. This assumption lets us only consider those terms that are relevant to the simplification of V_j, as we can always move conditionally independent terms outside the summation and consider only the expression remaining inside the sum. Let us first assume that $\mathbf{M} = \emptyset$. In this case condition (2) simply reads

$$\prod_{V_i\geq V_j} P(V_i|\mathbf{C}_i) = P(V_j, \ldots, V_1|\mathbf{D}),$$

and that the product terms are a factorization of the joint term. However, we want to show that they also provide a factorization that agrees with the topological ordering. Because A is $\pi-$consistent, for any two variables $V > W$ we have that $\mathbf{C}_W \subseteq V^\pi$ which enables us to consider the summations from V_k up to V_1 for $k = 1, \ldots, j-1$, which results in

$$\sum_{V_k,\ldots,V_1}\prod_{V_i\geq V_j} P(V_i|\mathbf{C}_i) = \sum_{V_k,\ldots,V_1} P(V_j, \ldots, V_1|\mathbf{D}) = P(V_j, \ldots, V_{k+1}|\mathbf{D}).$$

We obtain for $k = j-1, \ldots, 1$

$$\begin{aligned} P(V_j|\mathbf{C}_j) &= P(V_j|\mathbf{D}) \\ P(V_j|\mathbf{C}_j)P(V_{j-1}|\mathbf{C}_{j-1}) &= P(V_j, V_{j-1}|\mathbf{D}) \\ &\vdots \\ P(V_j|\mathbf{C}_j)\cdots P(V_2|\mathbf{C}_2) &= P(V_j, \ldots, V_2|\mathbf{D}) \\ P(V_j|\mathbf{C}_j)\cdots P(V_2|\mathbf{C}_2)P(V_1|\mathbf{C}_1) &= P(V_j, \ldots, V_1|\mathbf{D}). \end{aligned} \tag{12}$$

From the last and second to last equation we can obtain

$$P(V_j, \ldots, V_2|\mathbf{D})P(V_1|\mathbf{C}_1) = P(V_j, \ldots, V_1|\mathbf{D}),$$

and by dividing with the first term from the left hand side we obtain

$$P(V_1|\mathbf{C}_1) = P(V_1|V_j, \ldots, V_2, \mathbf{D}).$$

In fact, we can do this for any two subsequent equations in (12) to obtain

$$P(V_i|\mathbf{C}_i) = P(V_i|V_j, \ldots, V_{i+1}, \mathbf{D}), \quad i = 1, \ldots, j-1$$

Algorithm 1 operates by starting from V_1, so we still have to show it succeeds in constructing the joint term. Using the previous results we can rewrite the original equation as

$$\prod_{V_i\geq V_j} P(V_i|\mathbf{C}_i) = \prod_{V_i\geq V_j} P(V_i|\mathbf{C}_i^*),$$

where $\mathbf{C}_i^* = \mathbf{D}\cup\{V_j, \ldots, V_{i+1}\}$ for $i < j$ and $\mathbf{C}_j^* = \mathbf{D}$. From this we obtain

$$\begin{aligned} P(V_1|\mathbf{C}_1) &= P(V_1|\mathbf{C}_1^*) \\ P(V_1|\mathbf{C}_1^*)P(V_2|\mathbf{C}_2) &= P(V_1, V_2|\mathbf{C}_2^*) \\ &\vdots \\ P(V_1, \ldots, V_{j-1}|\mathbf{C}_{j-1}^*)P(V_j|\mathbf{C}_j) &= P(V_j, \ldots, V_1|\mathbf{C}_j^*). \end{aligned} \tag{13}$$

The function JOIN will succeed every time since the for-loop starting on line 7 of Algorithm 2 will discover the conditional independence properties allowing the previous equalities in (13) to take place. Thus Algorithm 1 will return an atomic expression with the variable V_j eliminated from the summation set.

Assume now that $\mathbf{M} \neq \emptyset$ and let $\mathbf{V} = V[A]$ and. In this case condition (2) allows us to write

$$\prod_{U \in \mathbf{M}} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i) = P(\mathbf{V}, \mathbf{M}|\mathbf{D}),$$

and furthermore, we have that these product terms are a factorization of the joint term. First, we aim to reduce the number of variables in $\mathbf{M}$ to be considered. This is done because Algorithm 1 always starts and finishes the construction of the joint term with a variable in $\mathbf{V}$. We categorize each $U \in \mathbf{M}$ into three disjoint sets. We define

$$\mathbf{M}^- := \{U \in \mathbf{M} \mid U \notin \bigcup_{k=1}^{j} \mathbf{C}_k\}, \mathbf{M}^+ := \{U \in \mathbf{M} \mid U \in \bigcap_{k=1}^{j} \mathbf{C}_k\} \text{ and}$$

$$\mathbf{M}^* := \mathbf{M} \setminus (\mathbf{M}^- \cup \mathbf{M}^+).$$

First, we show that we can ignore variables in $\mathbf{M}^-$ by obtaining a new factorization without them. It follows from the definition of $\mathbf{M}^-$ and (2) that we can compute the marginalization as follows

$$\begin{aligned} P(\mathbf{V}, \mathbf{M} \setminus \mathbf{M}^-|\mathbf{D}) &= \sum_{U \in \mathbf{M}^-} P(\mathbf{V}, \mathbf{M}|\mathbf{D}) \\ &= \sum_{U \in \mathbf{M}^-} \prod_{U \in \mathbf{M}} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i) \\ &= \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i) \sum_{U \in \mathbf{M}^-} \prod_{U \in \mathbf{M}} P(U|\mathbf{E}_U) \\ &= \prod_{U \in \mathbf{M} \setminus \mathbf{M}^-} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i). \end{aligned}$$

We have a new factorization without any variables in $\mathbf{M}^-$. Similarly, we can eliminate the variables in $\mathbf{M}^+$ from our factorization. It follows from the definition of $\mathbf{M}^+$ that for all $U \in \mathbf{M}^+$ we have that $\mathbf{E}_U \subseteq \mathbf{D}$. From this we obtain

$$\prod_{U \in \mathbf{M}^+} P(U|\mathbf{E}_U) = P(\mathbf{M}^+|\mathbf{D}).$$

We can now write

$$\begin{aligned} P(\mathbf{V}, \mathbf{M}^*|\mathbf{D}, \mathbf{M}^+) &= \frac{P(\mathbf{V}, \mathbf{M} \setminus \mathbf{M}^-)}{P(\mathbf{M}^+|\mathbf{D})} \\ &= \frac{\prod_{U \in \mathbf{M} \setminus \mathbf{M}^-} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i)}{\prod_{U \in \mathbf{M}^+} P(U|\mathbf{E}_U)} \\ &= \prod_{U \in \mathbf{M}^*} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i). \end{aligned}$$

Thus it suffices to consider the factorization given by

$$\prod_{U \in \mathbf{M}^*} P(U|\mathbf{E}_U) \prod_{V_i \geq V_j} P(V_i|\mathbf{C}_i) = P(\mathbf{V}, \mathbf{M}^*|\mathbf{D}^*), \tag{14}$$

where $\mathbf{D}^* = \mathbf{D} \cup \mathbf{M}^+$.

Next, we will order the variables in $\mathbf{M}^*$. For each $U \in \mathbf{M}^*$ we find the largest index $u \in \{1, \ldots, j-1\}$ such that $U \in \mathbf{C}_u$. This choice is well defined, since by definition at least one such index exists. Furthermore, as the product terms in (14) are a factorization of the joint term, the conditioning sets are increasing and we have that $U \notin \mathbf{C}_i$ for all $i \geq u+1$. In the case that multiple variables $U_i \in \mathbf{M}^*$ for some set of indices $i \in \mathbf{I}$ share the same index u, we may redefine M^* such that $U_i, i \in \mathbf{I}$ are replaced by a single variable U_I such that $\prod_{i \in I} P(U_i|\mathbf{E}_{U_i}) = P(U_I|\mathbf{E}_{U_I})$, where $\mathbf{E}_{U_I} = \cap_{i \in \mathbf{I}} \mathbf{E}_{U_i}$. Thus we can assume that for any two variables $U_1, U_2 \in \mathbf{M}^*$ we have that $u_1 \neq u_2$. We can now order the variables in $\mathbf{M}^*$ by their respective indices u such that $U_1 > U_2 > \ldots > U_m$ and $u_1 < u_2 < \ldots < u_m$.

Nest we will extend the ordering to include all of the variables in the set $\mathbf{V}$. We let $\mathbf{Q} := \mathbf{V} \cup \mathbf{M}^*$ and find an ordering of this set such that it agrees with induced ordering ω of the variables in $\mathbf{V}$ and with the ordering of the indices $u_1, \ldots, u_m$. A new factorization given by this ordering can be defined as follows:

$$Q_k = \begin{cases} V_{k-m} & k > u_m, \\ V_{k-l} & u_l < k < u_{l+1}, \\ V_k & k < u_1, \\ U_l & k = u_l. \end{cases} \quad \mathbf{D}_k = \begin{cases} \mathbf{C}_{k-m} & k > u_m, \\ \mathbf{C}_{k-l} & u_l < k < u_{l+1}, \\ \mathbf{C}_k & k < u_1, \\ \mathbf{E}_{U_l} & k = u_l. \end{cases}$$

We can now rewrite the factorization of (14) as

$$\prod_{k=1}^{n+m} P(Q_k|\mathbf{D}_k) = P(\mathbf{Q}|\mathbf{D}^*), \tag{15}$$

We can now apply the same procedures as in the case of $\mathbf{M} = \emptyset$ with the exception that INSERT succeeds where JOIN fails with terms containing Q_k and Q_{k+1} when $k = l - 1$ for all $l = 1, \ldots, m$. The success of INSERT is guaranteed by condition (3), as the function will find this conditional independence on line 10 of Algorithm 3. Also, FACTORIZE will remove all additional terms that were introduced in the process, which is made possible by condition (3) and the definition of the factorization of $P(\mathbf{Q}|\mathbf{D}^*)$. After the summation over V_j is carried out, the conditional independence between V_j and the variables $U \in \mathbf{M}^*$ ensures that their respective terms are equal to the original factorization before the summation was carried out when the new factorization is constructed so that it agrees with the ordering of the set $\mathbf{Q}$. Thus an atomic expression is returned with the variable V_j eliminated with the same value as the original atomic expression. ■

Abstract

We initiate the rigorous study of classification in semimetric spaces, which are point sets with a distance function that is non-negative and symmetric, but need not satisfy the triangle inequality. We define the *density dimension* dens and discover that it plays a central role in the statistical and algorithmic feasibility of learning in semimetric spaces. We compute this quantity for several widely used semimetrics and present nearly optimal sample compression algorithms, which are then used to obtain generalization guarantees, including fast rates.

Our claim of near-optimality holds in both computational and statistical senses. When the sample has radius R and margin γ, we show that it can be compressed down to roughly $d = (R/\gamma)^{\mathsf{dens}}$ points, and further that finding a significantly better compression is algorithmically intractable unless P=NP. This compression implies generalization via standard Occam-type arguments, to which we provide a nearly matching lower bound.

Keywords: semimetric, classification, compression, generalization

1. Introduction

The problem of learning in non-metric spaces has been of significant recent interest, being the subject of a 2010 COLT workshop and a central topic of all three SIMBAD conferences. In this paper, we initiate the study of efficient statistical learning in *semimetric* spaces, which are point sets endowed with a distance function that is non-negative and symmetric but may not satisfy the triangle inequality (Wilson, 1931)[1]. Without the latter, quite a bit of structure is lost — for example, semimetric spaces admit convergent sequences without a Cauchy subsequence (Burke, 1972). We are not aware of any rigorous learning results in semimetric spaces prior to this work.

Background and motivation. Much of the existing machinery for classification algorithms, as well as generalization bounds, depends strongly on the data residing in a Hilbert space. For some important applications, this structural constraint severely limits the applicability of existing methods. Indeed, it is often the case that the data is naturally endowed with some distance function strongly dissimilar to the familiar Euclidean norm.

Consider images, for example. Although these can be naively represented as coordinate-vectors in $\mathbb{R}^d$, the Euclidean (or even ℓ_p) distance between the representative vectors does not correspond well to the one perceived by human vision. Instead, the earthmover distance is commonly used in vision applications (Rubner et al., 2000). Yet representing earthmover distances using any fixed ℓ_p norm unavoidably introduces very large interpoint distortion (Naor and Schechtman, 2007), potentially corrupting the data geometry before the learning process has even begun. Nor is this issue mitigated by kernelization, as kernels necessarily embed the data in a Hilbert space, again incurring the aforementioned distortion. A similar issue arises for strings: These can be naively treated as vectors endowed with different ℓ_p metrics, but a much more natural metric over strings is the edit distance, which is similarly known to be strongly non-Euclidean (Andoni and Krauthgamer, 2010). Additional limitations of kernel methods are articulated in Balcan et al. (2008b).

These concerns have led researchers to seek out algorithmic and statistical approaches that apply in greater generality. A particularly fruitful recent direction has focused on metric spaces, which are point sets endowed with a distance function that is non-negative and symmetric, and also satisfies the triangle equality. While metric spaces are significantly more general than Hilbertian ones, they still do not capture many common distance functions used by practitioners. These non-metric distances include the Jensen-Shannon divergence, which appears in statistical applications (Fuglede and Topsøe, 2004; Goodfellow et al., 2014), the k-median Hausdorff distances, and the ℓ_p distances with $0 < p < 1$, which appear in vision applications (M. Dubuisson, A. Jain, 1994; Jacobs et al., 2000) — all of which are semimetrics. An additional line of work (M. Dubuisson, A. Jain, 1994; Jacobs et al., 2000, 1998; Weinshall et al., 1998) underscored the effectiveness of non-metric distances in various applications (mainly vision), and among these, semimetrics again play a prominent role (Basri et al., 1995; Cox et al., 1996; Gdalyahu and Weinshall, 1999; Huttenlocher et al., 1993; Jain and Zongker, 1997; J. Puzicha, J. Buhmann, Y. Rubner, C. Tomasi, 1999).

Main results. We initiate the rigorous study of classification for semimetric spaces. We define the *density dimension* ($\mathsf{dens} = \mathsf{dens}(\mathcal{X})$) of a semimetric space $\mathcal{X}$ as the logarithm of the *density constant* $\mu = \mu(\mathcal{X})$, which intuitively is the smallest number such that any r-radius open ball in $\mathcal{X}$ contains at most μ points at mutual interpoint distance at least $r/2$; a formal definition is given in Equation (2). We then demonstrate that dens plays a central role in the statistical and algorithmic feasibility of learning in this setting by showing that it controls the packing numbers of $\mathcal{X}$. Crucially for learning, this insight implies that there is

1. Some authors use the term "semimetric" to mean *pseudometrics*. These preserve much of the structure of metrics, the only difference being that they allow distinct points to have distance 0. Our usage appears to be more standard.

one standard technique that survives violations of the triangle inequality — namely, sample compression. Denoting by R and γ the sample radius and margin, respectively, we can achieve the latter by extracting a γ-net from the sample (Theorem 2). This compresses the sample from size n to $(R/\gamma)^{O(\mathsf{dens})}$, which is nearly optimal unless P=NP (Theorem 4).

On the statistical front, we give a compression-based generalization bound that smoothly interpolates between the consistent $(R/\gamma)^{O(\mathsf{dens})}/n$ and agnostic $\sqrt{(R/\gamma)^{O(\mathsf{dens})}/n}$ decay regimes (Theorem 8). This "fast rate" holds for general compression schemes. Applied to margin-based semimetric sample-compression schemes, it becomes amenable to efficient Structural Risk Minimization. The lower bound in Theorem 11 shows that even under margin assumptions, there exist adversarial distributions forcing the sample complexity to be exponential in dens.

To demonstrate the applicability of our framework, we compute the density dimension of the three popular semimetrics enumerated above: Jensen-Shannon divergence, ℓ_p distances with $0 < p < 1$, and k-median Hausdorff distances (Theorem 13). Along the way, we discover that the latter (for $k = 1$) is in fact universal for *all* semimetrics; this surprising fact may be of independent interest (Lemma 12).

Related work. In a series of papers, Balcan et al. (2008c,a,b) developed a theory of learning with similarity functions, which resemble kernels but relax the requirement of being positive definite. Learning is accomplished by embedding the data into an appropriate Euclidean space and performing large-margin separation. Hence, this approach effectively extracts the implicit Euclidean structure encoded in the similarity function, but does not seem well-suited for inherently non-Euclidean data. In Wang et al. (2007) this framework was extended to dissimilarity functions, obtaining analogous results.

For metric spaces, it is known that a sample of size exponential in the doubling dimension (ddim) suffices to achieve low generalization error (von Luxburg and Bousquet, 2004; Gottlieb et al., 2014a; Shalev-Shwartz and Ben-David, 2014; Kontorovich and Weiss, 2014), and that exponential dependence on ddim is in general unavoidable (Shalev-Shwartz and Ben-David, 2014). As for algorithmic runtimes, the naive nearest-neighbor classifier evaluates queries in $O(n)$ time (where n is the sample size); however, an approximate nearest neighbor can be found in time $2^{O(\mathsf{ddim})} \log n$. If one desires runtimes depending not on n but on the geometry (say, margin γ) of the data, one may achieve a sample compression scheme of size $\gamma^{-O(\mathsf{ddim})}$, and it is NP-hard to achieve a significantly better compression (Gottlieb et al., 2014b).

As we show in the Appendix, the above results characterizing learning in metric space do not carry over to semimetrics. More precisely, the doubling dimension of a semimetric does not control its packing numbers, as it does in metric spaces. Although we succeed in showing that the density constant does indeed control the packing numbers even in semimetrics, this does not necessarily imply portability of learning algorithms for metric spaces into semimetrics. For example, although the nearest-neighbor classifier is still well-defined in semimetric spaces, and may naively be evaluated on queries in $O(n)$ time, relaxing to approximate nearest neighbors no longer provides the exponential speedup in query time that it does in metric spaces (Lemma 17). Simply put, without the triangle inequality, the hierarchy-based search methods, such as Beygelzimer et al. (2006); Gottlieb et al. (2014a) and related approaches, all break down.

Paper outline. After presenting our basic definitions in Section 2, we give packing bounds and net-construction algorithms in Section 3. In Section 4 we give upper and lower bounds on sample complexity for learning in semimetrics. The density dimension of some common semimetircs is computed in Section 5. The Appendix contains a detailed discussion demonstrating the inapplicability of existing metric-space techniques to the semimetric case.

2. Preliminaries

Semimetric spaces. Throughout this paper, our instance space $\mathcal{X}$ will be endowed with a semimetric $\rho : \mathcal{X} \times \mathcal{X} \to [0, \infty)$, which is a non-negative symmetric function verifying $\rho(x, x') = 0 \iff x = x'$ for all $x, x' \in \mathcal{X}$. If the semimetric space $(\mathcal{X}, \rho)$ additionally satisfies the triangle inequality, $\rho(x, x') \leq \rho(x, x'') + \rho(x'', x')$ for all $x, x', x'' \in \mathcal{X}$, then ρ is a *metric*. The distance between two sets A, B in a semimetric space is defined by $\rho(A, B) = \inf_{x \in A, x' \in B} \rho(x, x')$. For $x \in \mathcal{X}$ and $r > 0$, denote by $B_r(x) = \{y \in \mathcal{X} : \rho(x, y) < r\}$ the open r-ball about x. The *radius* of a set is the radius of the smallest ball containing it, $\mathrm{rad}(A) = \inf\{r > 0 : \exists x \in A, A \subseteq B_r(x)\}$ and $\mathrm{diam}(A) := \sup_{x,x' \in A} \rho(x, x')$.

Doubling and density dimensions. Let $\lambda = \lambda(\mathcal{X})$ be the smallest number such that every open ball in $\mathcal{X}$ can be covered by λ open balls of half the radius, where all balls are centered at points of $\mathcal{X}$. Formally,

$$\lambda(\mathcal{X}) = \min\{\lambda \in \mathbb{N} : \forall x \in \mathcal{X}, r > 0 \; \exists x_1, \ldots, x_\lambda \in \mathcal{X} : B_r(x) \subseteq \cup_{i=1}^{\lambda} B_{r/2}(x_i)\}.$$

Then λ is the *doubling constant* of $\mathcal{X}$, and the *doubling dimension* of $\mathcal{X}$ is $\mathsf{ddim}(\mathcal{X}) = \log_2 \lambda$.

An r-*net* of a set $A \subseteq \mathcal{X}$ is any *maximal* subset A having mutual interpoint distance at least r. The r-packing number $\mathcal{M}(r, A)$ of A is the maximum size of any r-net of A:

$$\mathcal{M}(r, A) = \max\{|E| : E \subseteq A, (x, y \in E) \wedge (x \neq y) \implies \rho(x, y) \geq r\}. \tag{1}$$

The *density constant* $\mu(\mathcal{X})$ was defined in Gottlieb and Krauthgamer (2013) as the smallest number such that any open r-radius ball in $\mathcal{X}$ contains at most μ points at mutual interpoint distance at least $r/2$:

$$\mu(\mathcal{X}) = \min\{\mu \in \mathbb{N} : (x \in \mathcal{X}) \wedge (r > 0) \implies \mathcal{M}\left(\frac{r}{2}, B_r(x)\right) \leq \mu\}, \tag{2}$$

and we define the *density dimension* of $\mathcal{X}$ by $\mathsf{dens}(\mathcal{X}) = \log_2 \mu(\mathcal{X})$. A closely related notion was introduced by Vol'berg and Konyagin (1987) under the term *uniform metric dimension*.

An important property of the density dimension is that it is *hereditary*: for $S \subset \mathcal{X}$, we have $\mu(S) \leq \mu(\mathcal{X})$; the doubling dimension is only approximately hereditary (Gottlieb and Krauthgamer, 2013).

It will be convenient to define $\mathrm{Log}\,(x) := \log_2 \lceil x \rceil$, and we will make frequent use of the identity

$$\mu(S)^{\mathrm{Log}(\alpha)} = \lceil \alpha \rceil^{\mathsf{dens}(S)}. \tag{3}$$

Learning model. We work in the standard *agnostic* learning model (Mohri et al., 2012; Shalev-Shwartz and Ben-David, 2014), whereby the learner receives a sample S consisting of n labeled examples (X_i, Y_i), drawn iid from an unknown distribution over $\mathcal{X} \times \{-1, 1\}$. All subsequent probabilities and expectations will be with respect to this distribution. Based on the training sample S, the learner produces a *hypothesis* $h : \mathcal{X} \to \{-1, 1\}$, whose *empirical error* is defined by $\widehat{\mathrm{err}}(h) = n^{-1} \sum_{i=1}^{n} \mathbf{1}_{\{h(X_i) \neq Y_i\}}$ and whose *generalization error* is defined by $\mathrm{err}(h) = \mathbb{P}(h(X) \neq Y)$.

Sub-sample, margin, and induced 1-NN. In a slight abuse of notation, we will blur the distinction between $S \subset \mathcal{X}$ as a collection of points in a semimetric space and $S \in (\mathcal{X} \times \{-1, 1\})^n$ as a sequence of labeled examples. Thus, the notion of a *sub-sample* $\tilde{S} \subset S$ partitioned into its positively and negatively labeled subsets as $\tilde{S} = \tilde{S}_+ \cup \tilde{S}_-$ is well-defined. The *margin* of $\tilde{S}$, defined by $\mathrm{marg}(\tilde{S}) = \rho(\tilde{S}_+, \tilde{S}_-)$, is the minimum distance between a pair of opposite-labeled points (see Fig. 1). In degenerate cases where one of $\tilde{S}_+, \tilde{S}_-$ is empty, $\mathrm{marg}(\tilde{S}) = \infty$. (For ease of presentation, we assume that the margin is strictly less than $\mathrm{rad}(S)$, and so $\mathrm{rad}(S)/\mathrm{marg}(S) > 1$. In the case of equality, substituting any value less than the margin will cause the relevant claim to hold.) A sub-sample $\tilde{S}$ naturally induces the 1-NN classifier $h_{\tilde{S}}$, via $h_{\tilde{S}}(x) = \mathrm{sign}(\rho(x, \tilde{S}_-) - \rho(x, \tilde{S}_+))$.

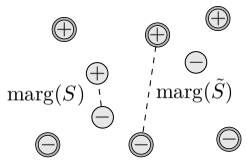

Figure 1: In this example, the sub-sample $\tilde{S} \subset S$ is indicated by double circles. It is always the case that $\mathrm{marg}(\tilde{S}) \geq \mathrm{marg}(S)$.

The problem of *nearest-neighbor condensing* is to produce the minimal subsample $\tilde{S} \subset S$ so that the 1-NN classifier $h_{\tilde{S}}$ is *consistent* with S, i.e. has zero training error. In the *inconsistent* version of this problem, one is given a parameter $\varepsilon > 0$ and tasked with producing a minimal subsample $\tilde{S} \subset S$ whose induced $h_{\tilde{S}}$ has training error at most ε.

3. Packing bounds and algorithms

The central contribution of this section is the following lemma, which demonstrates that for a semimetric space, a bound on its density dimension implies one on its packing numbers.

Lemma 1 *For any point set S in a semimetric space $\mathcal{X}$ and $r > 0$, the size of any r-net of S is $k = \lceil \mathrm{rad}(S)/r \rceil^{\mathsf{dens}(S)}$, and furthermore, such an r-net can be computed in time $O(k|S|)$.*

Proof To bound the size of a maximal r-net $C \subset S$, suppose its radius is R. Partition C into clusters by extracting from C an arbitrary net D with minimum interpoint distance $R/2$, and assigning each point $p \in C$ to a cluster centered at the nearest neighbor of p in

D. Then apply the procedure recursively to each cluster, halving the previous radius, until reaching point sets with minimum interpoint distance at least r. By repeatedly applying the definition of the density constant, the size of C is bounded by $\mu(S)^{\mathrm{Log}(\mathrm{rad}(S)/r)} = \lceil \mathrm{rad}(S)/r \rceil^{\mathsf{dens}(S)}$.

The actual r-net is constructed in a greedy fashion. Initialize set $C = \emptyset$, and for every point in S, add it to C if its closest neighbor in C is at distance r or greater. Since $|C| \leq k$, the total runtime is $O(k|S|)$. See Algorithm 1. ■

Algorithm 1 Brute-force net construction

Require: sample S, margin r
Ensure: C is an r-net for S
  for $x \in S$ **do**
    if $\rho(x, C) \geq r$ **then**
      $C = C \cup \{x\}$
    end if
  end for

Having demonstrated the existence of a small r-net, we can now consider the problems of producing both consistent (lossless) and inconsistent (lossy) 1-NN classifiers for the sample (see Section 2).

Consistent case. For a labeled sample S, recall that the *margin* of S is the minimum distance between oppositely labeled points in S, as defined formally in Section 2. The margin of a given sample can be computed in time $\Theta(|S|^2)$ by considering all pairs of points. We begin with a consistent classifier, whose generalization performance with explicit constants is analyzed in Theorem 7(i). Informally, the latter states that a 1-nearest neighbor classifier induced by a sub-sample of size k has generalization error $O\left(\frac{k \log n + \log \frac{1}{\delta}}{n}\right)$.

Theorem 2 *Let S be a sample set equipped with a semimetric distance function, and let the margin $\gamma = \mathrm{marg}(S)$ be given. In time $O(k|S|)$ we can construct a nearest-neighbor classifier that achieves zero training error on S, where $k = (\mathrm{rad}(S)/\gamma)^{O(\mathsf{dens}(S))}$. The evaluation on a test point requires $\Theta(k)$ distance computations, and with probability $1 - \delta$, the resulting classifier has generalization error $O\left(\frac{k \log n + \log \frac{1}{\delta}}{n}\right)$.*

Proof We build a γ-net C for S in time $O(k|S|)$, as in Lemma 1. Since γ is the margin, by construction every point in S has the same label as its nearest neighbor in C, and so the nearest neighbor classifier with respect to C has zero sample error.

Given a test point x, we assign it the same label as its nearest neighbor in C. Then the generalization bounds follow from Theorem 7(i). For the runtime, $O(k)$ operations are clearly sufficient to find the nearest neighbor (see also Lemmas 16 and 17). ■

Remark 3 *If the margin is not known in advance, then it must be computed, and the runtime in Theorem 2 grows to $O(n^2)$. In this case we can give an alternate construction*

that achieves the runtime of $O(k|S|)$ of the Theorem. Extract sets $S_+, S_- \in S$ of oppositely labeled points in S, and for each set build a subset in a manner similar to the proof of Lemma 1: Let R be the maximum among the radii of S_+, S_-. Partition S_+ into clusters by extracting from S_+ an arbitrary net D with minimum interpoint distance $R/2$, and assigning each point $p \in S_+$ to a cluster centered at the nearest neighbor of p in D. Then apply the procedure recursively to each cluster in D, halving the previous radius. This construction is done to S_- in parallel, and terminates when the union of the subsets for S_+ and S_- is consistent with S. This must occur within $O(\log(\text{rad}(S)/\text{marg}(S)))$ iterations, producing a consistent set of size k in time $O(kn \log(\text{rad}(S)/\text{marg}(S))) = O(kn)$ (where equality follows from the $\log(\text{rad}(S)/\text{marg}(S))$ term being subsumed in the definition of k).

The procedure in Theorem 2 compresses S, producing a consistent sub-sample C. Immediate from the theorem is that the smaller the compressed set C, the better the generalization bounds of the classifier. However, as Gottlieb et al. (2014b) recently demonstrated, even in metric spaces, it is NP-hard to approximate the size of the minimum consistent subset to within a factor $2^{O(\mathsf{ddim}(S)\log(\text{rad}(S)/\text{marg}(S)))^{1-o(1)}} = 2^{O(\mathsf{dens}(S)\log(\text{rad}(S)/\text{marg}(S)))^{1-o(1)}}$ (where the equality follows from Lemma 15). This means that choosing the net of Lemma 1 is close to the optimal construction for a consistent subset of S.

Inconsistent case. It is natural to ask whether allowing the classifier nonzero sample error results in improved generalization bounds. This is indeed generally the case, as the bound in Theorem 8 indicates. Informally, the latter shows that a 1-nearest neighbor classifier induced by a sub-sample of size k with sample error ε has generalization error $Q(k,\varepsilon) = O\left(\varepsilon + \frac{1}{n}\log\frac{n^k}{\delta} + \sqrt{\frac{\varepsilon}{n}\log\frac{n^k}{\delta}}\right)$. Optimizing this bound is an instance of Structural Risk Minimization (SRM). Unfortunately, we can show SRM to be infeasible for this problem, and that the generalization guarantees of Theorem 2 are nearly the best that can be obtained by way of Theorem 8:

Theorem 4 *Given a set S equipped with a metric or semimetric distance function, let $S^* \subset S$ be a sub-sample for which the generalization bound $Q(k,\varepsilon)$ in Theorem 8 (for a fixed constant δ) is minimized. Then it is NP-hard to compute any subset of S achieving a generalization bound within factor $2^{O((\mathsf{dens}(S)\log(\text{rad}(S)/\text{marg}(S)))^{1-o(1)}}$ of the generalization bound induced by S^*.*

Proof The proof is via reduction from the minimum consistent subset problem mentioned above. Fix the confidence level δ in the bound, let T be an instance of the minimum consistent subset problem, and put $m = |T|$. For some large value p, replace each point $t_i \in T$ with a (similarly labeled) set of p points $s_{i,1}, \ldots, s_{i,p}$ obeying the line metric, with $\rho(s_{i,a}, s_{i,b}) = \phi|a-b|$ for an infinitesimally small ϕ. Put $\rho(s_{i,a}, s_{j,b}) = \rho(t_i, t_j)$. The new set is S, with $n = |S| = pm$.

Consider a subset $S' \subset S$. If the 1-NN rule on S' misclassifies a point of S, say $s_{i,a}$, then in fact it must misclassify all p points $s_{i,b}$, $b \in [1,p]$. So an inconsistent subset of S achieves a value of $Q(|S'|, p/n) = \Omega(p/n)$ in the generalization bound.

Now consider the consistent subset of S consisting of $m = n/p$ points $s_{i,1}$ for $i \in [1,m]$. By Theorem 7(i), this classifier achieves a generalization bound of $O\left(\frac{m\log n}{n}\right) = O\left(\frac{\log n}{p}\right)$.

So when $p = \Omega(\sqrt{n\log n})$, this consistent classifier is better than any inconsistent classifier. Now a consistent subset of size $d \le m$ has generalization bound $O\left(\frac{d\log n}{n}\right)$. As it is NP-hard to find a subset whose size is within a factor $2^{O(\mathsf{dens}(S)\log(\text{rad}(S)/\text{marg}(S)))^{1-o(1)}}$ of the smallest consistent subset, it is NP-hard to find a consistent subset with generalization bound within a factor $2^{O(\mathsf{dens}(S)\log(\text{rad}(S)/\text{marg}(S)))^{1-o(1)}}$ of the optimal consistent subset, and the theorem follows. ■

In light of the hardness result established in Theorem 4, we specialize the goal from one of seeking a small nearly consistent sub-sample to one where the sub-sample must be a γ-net. In this case, the relevant generalization bound is provided by Theorem 10. As before, we wish to perform SRM for this bound. Fortunately, we are able to compute the latter exactly in polynomial time, and even more efficiently if we are willing to settle for a solution within a constant factor of the optimal. The proof of the following theorem follows the lines of Gottlieb et al. (2014a).

Theorem 5 *Given a sample set S equipped with a semimetric:*

(a) A nearest-neighbor classifier minimizing the generalization bound of Theorem 10 can be computed in randomized time $O(|S|^{4.373})$.

(b) A nearest-neighbor classifier whose generalization bound is within factor 2 of optimal can be computed in deterministic time $O(|S|^2 \log|S|)$.

Each of these classifiers can be evaluated on test points in time $\left(\frac{\text{rad}(S)}{\gamma}\right)^{O(\mathsf{dens}(S))}$, where γ is the margin imposed by the SRM procedure.

Proof For each of these solutions, we enumerate and sort in increasing order the distances between all oppositely labeled point pairs in S, in total time $O(|S|^2\log|S|)$. Each distance constitutes a separate guess for the optimal margin to "impose" on S. That is, for each distance γ, we will remove from S some points to ensure that all opposite labeled pairs are more than γ far apart.

To accomplish this, we iteratively build a new graph G. We initialize G with vertices representing the points of S. At each round we add to G an edge between the next closest pair of opposite labeled points, as given by the sorted enumeration above. This distance is the margin of the current round: Points connected by an edge in G represent pairs that are too close together for the current margin, and we need to compute how many points would need to be removed from G in order for no edge to remain in the graph. (However, no points or edges will actually removed from G.) As observed by Gottlieb et al. (2014a), this task is precisely the problem of bipartite vertex cover. By König's theorem, the minimum vertex cover problem in bipartite graphs is equivalent to the maximum matching problem, and a maximum matching in bipartite graphs can be computed in randomized time $O(n^{2.373})$ (Mucha and Sankowski, 2004; Williams, 2012). So for each candidate margin, we can compute in $O(n^{2.373})$ time the number of points that must be removed from the current graph G in order to remove all edges. For $O(n^2)$ possible margins, this amounts to $O(n^{4.373})$ time. Having computed for each interpoint distance the number of points required to be

deleted to achieve this distance, we choose the distance-number pair which minimizes the bound of Theorem 10. We then remove the corresponding points from S, and use the algorithm of Lemma 1 to construct a net satisfying the margin bound.

The runtime improvement in (b) comes from a faster vertex-cover computation. It is well known that a 2-approximation to vertex cover can be computed (in arbitrary graphs) by a greedy algorithm in time linear in the graph size $O(|V^+ \cup V^-| + |E|) = O(n^2)$, see e.g. Bar-Yehuda and Even (1981). This algorithm simply chooses any edge and removes both endpoints, until no edges remain. We apply this algorithm to our setting: A new edge is added to G only if both endpoints survive in the already computed cover, and then both endpoints are marked as removed in the solution to the new graph. Having computed for each interpoint distance the number of points required to be deleted to achieve this distance, we choose the distance-number pair which minimizes the bound of Theorem 10. We then remove the corresponding points from S, and use the algorithm of Lemma 1 to construct a net satisfying the margin bound. The runtime is dominated by the time required to sort the distances.

For both algorithms, a new point is classified by finding its nearest neighbor in the extracted net. ■

Remark 6 *It is worth asking whether a succesful learner in (semi)metric space must necessarily perform some type of compression. Moran and Yehudayoff (2016) recently demonstrated that for classifiers of finite VC-dimension, learning and compression are in fact equivalent. However, no such result is known — or even conjectured — for infinite VC-dimension classifiers such as 1-NN and its variants.*

If a (semi)metric learner does choose to learn by compression, he is not necessarily restricted to learning via 1-NN, but can make use of any proximity-based function. But even then, Theorems 10 and 11 below demonstrate that from an information-theoretic standpoint, roughly $(\mathrm{rad}(S)/\mathrm{marg}(S))^{\mathsf{dens}(\mathcal{X})}$ *examples are both necessary in the worst case and always sufficient. One could still hope to exhibit a learning problem in a (semi)metric space where* any *learner achieving small generalization must solve some hard problem. Results of this type are known for finite automata under cryptographic assumptions (Kearns and Vazirani, 1997, Section 1.4); could something similar be shown for proximity-based learning?*

4. Generalization guarantees

In this section, we provide general sample compression bounds, which then will be specialized to the nearest-neighbor classifier proposed above. Theorem 8 presents a smooth interpolation between two classic bounds: the consistent case with rate $\tilde{O}(1/n)$, and the agnostic case with rate $\tilde{O}(1/\sqrt{n})$. Applied to margin-based semimetric sample-compression schemes, this result yields the efficiently computable and optimizable bound in Theorem 10, which is nearly optimal (as shown in Theorem 4). Finally, the lower bound in Theorem 11 shows that even under margin assumptions, there exist adversarial distributions forcing the sample complexity to be exponential in dens.

4.1 Sample compression schemes

We use the notion of a *sample compression scheme* in the sense of Graepel et al. (2005), where it is treated in full rigor. Informally, a learning algorithm maps a sample S of size n to a hypothesis h_S. It is a d-sample compression scheme if a sub-sample of size d suffices to produce a hypothesis that agrees with the labels of all the n points. It is an ε-*lossy* d-sample compression scheme if a sub-sample of size d suffices to produce a hypothesis that disagrees with the labels of at most εn of the n sample points. At this stage, we are not assuming anything about the computational efficiency of a compression scheme.

The algorithm need not know d and ε in advance. We say that the sample S is (d, ε)-*compressible* if the algorithm succeeds in finding an ε-lossy d-sample compression scheme for this particular sample. In this case:

Theorem 7 (Graepel et al. (2005)) *For any distribution over $\mathcal{X} \times \{-1, 1\}$, any $n \in \mathbb{N}$ and any $0 < \delta < 1$, with probability at least $1 - \delta$ over the random sample S of size n, the following holds:*

(i) If S is $(d, 0)$-compressible, then $\mathrm{err}(h_S) \leq \dfrac{1}{n-d}\left((d+1)\log n + \log\dfrac{1}{\delta}\right)$.

(ii) If S is (d, ε)-compressible, then $\mathrm{err}(h_S) \leq \dfrac{\varepsilon n}{n-d} + \sqrt{\dfrac{(d+1)\log n + \log\frac{1}{\delta}}{2(n-d)}}$.

The generalizing power of sample compression was independently discovered by Littlestone and Warmuth (1986); Devroye et al. (1996), and later elaborated upon by Graepel et al. (2005). The bounds above are already quite usable, but they feature an abrupt transition from the $(\log n)/n$ decay in the lossless ($\varepsilon = 0$) regime to the $\sqrt{(\log n)/n}$ decay in the lossy regime. We now provide a smooth interpolation between the two (such results are known in the literature as "fast rates" (Boucheron et al., 2005); see also a related result in Shalev-Shwartz and Ben-David (2014)):

Theorem 8 *Fix a distribution over $\mathcal{X} \times \{-1, 1\}$, an $n \in \mathbb{N}$ and $0 < \delta < 1$. With probability at least $1 - \delta$ over the random sample S of size n, the following holds for all $0 \leq \varepsilon \leq \frac{1}{2}$: If S is (d, ε)-compressible, then, putting $\tilde{\varepsilon} = \varepsilon n/(n-d)$, we have*

$$\begin{aligned} \mathrm{err}(h_S) &\leq \tilde{\varepsilon} + \frac{2}{3(n-d)}\log\frac{n^{d+1}}{\delta} + \sqrt{\frac{9\tilde{\varepsilon}(1-\tilde{\varepsilon})}{2(n-d)}\log\frac{n^{d+1}}{\delta}} \\ &=: Q(d, \varepsilon). \end{aligned} \tag{4}$$

Proof We closely follow the argument in Graepel et al. (2005, Theorem 2), with the twist that instead of Hoeffding's inequality, we use Bernstein's. The particular form of the latter is due to Dasgupta and Hsu (2008, Lemma 1): if $\hat{p} \sim \mathrm{Bin}(n, p)/n$ and $\delta > 0$, then the following holds with probability at least $1 - \delta$:

$$p \leq \hat{p} + \frac{2}{3n}\log\frac{1}{\delta} + \sqrt{\frac{9\hat{p}(1-\hat{p})}{2n}\log\frac{1}{\delta}}. \tag{5}$$

Now suppose that S is $(d, k/n)$-compressible, as witnessed by some sub-sample $\tilde{S} \subset S$ of size d. In particular, the hypothesis $h_{\tilde{S}}$ induced by the sub-sample $\tilde{S}$ makes k or fewer mistakes on the $n-d$ points in $S \setminus \tilde{S}$. Substituting $p = \mathrm{err}(h_{\tilde{S}})$ and

$$\hat{p} = \widehat{\mathrm{err}}_{S \setminus \tilde{S}}(h_{\tilde{S}}) := \frac{1}{|S \setminus \tilde{S}|} \sum_{x \in S \setminus \tilde{S}} \mathbf{1}_{\{h_{\tilde{S}} \text{ errs on } x\}} \leq \frac{k}{n-d} = \tilde{\varepsilon}$$

into (5) yields that for fixed $\tilde{S}$ and random $S \setminus \tilde{S}$, with probability at least $1-\delta$,

$$\mathrm{err}(h_{\tilde{S}}) \quad \leq \quad \widehat{\mathrm{err}}_{S \setminus \tilde{S}}(h_{\tilde{S}}) + \frac{2}{3(n-d)} \log \frac{1}{\delta} + \sqrt{\frac{9\tilde{\varepsilon}(1-\tilde{\varepsilon})}{2(n-d)} \log \frac{1}{\delta}}, \tag{6}$$

where we used the monotonicity of $t \mapsto t(1-t)$ on $[0, \frac{1}{2}]$. To see that (6) follows from (5), note that when $\tilde{S}$ of size d is fixed and $S \setminus \tilde{S}$ is drawn iid $\sim \mathbb{P}$, we have $(n-d)\widehat{\mathrm{err}}_{S \setminus \tilde{S}}(h_{\tilde{S}}) \sim \mathrm{Bin}(n-d, \mathrm{err}(h_{\tilde{S}}))$. To make (6) hold simultaneously for all $\tilde{S} \subseteq S$, divide δ by n^d — the number of ways to choose a (multi)set $\tilde{S}$ of size d. To make the claim hold for all $d \in [n]$ and all $0 \leq \varepsilon < 1$, stratify (as in Graepel et al. (2005, Lemma 1)) over the n possible choices of d, which amounts to dividing δ by an additional factor of n. Unlike in Graepel et al. (2005), there is no need to stratify over the possible values of ε, since (5) holds for random (and not just fixed) $\hat{p}$. ■

4.2 Margin-based nearest neighbor compression

We now specialize the general sample compression result of Theorem 8 to our setting, where $h_{S'}$ induced by a sub-sample $S' \subset S$ is given by the 1-NN classifier defined in Section 2. Any sample S of size n is trivially $(n, 0)$-compressible and $(0, \frac{1}{2})$-compressible — the former is achieved by not compressing at all, and the latter by a constant predictor. Now d and ε cannot simultaneously be made arbitrarily small, and for non-degenerate samples S, the bound Q in Theorem 8 will have a nontrivial minimal value Q^*. Theorem 4 shows that computing Q^* is intractable and the algorithm in Theorem 5 solves a tractable modification of this problem. For $k \in \mathbb{N}$ and $\gamma > 0$, let us say that the sample S is (k, γ)-*separable* if it admits a sub-sample $S' \subset S$ such that $|S \setminus S'| \leq k$ and $\mathrm{marg}(S') > \gamma$, and observe that separability implies compressibility:

Lemma 9 *If S is (k, γ)-separable then it is $\left(\lceil \mathrm{rad}(S)/\gamma \rceil^{\mathsf{dens}(S)}, k/|S|\right)$-compressible.*

Proof Suppose $S' \subset S$ is a witness of (k, γ)-separability. Being pessimistic, we will allow our lossy sample compression scheme to mislabel all of $S \setminus S'$, but not any of S', giving it a sample error $\varepsilon \leq k/|S|$. Now by construction, S' is $(0, \gamma)$-separable, and thus a γ-net $\tilde{S} \subset S'$ suffices to recover the correct labels of S' via 1-nearest neighbor. Lemma 1 provides the estimate

$$|\tilde{S}| \leq \mu(S)^{\mathrm{Log}(\mathrm{rad}(S)/\gamma)} = \lceil \mathrm{rad}(S)/\gamma \rceil^{\mathsf{dens}(S)},$$

whence the compression bound. ■

These observations culminate in an efficiently optimizable margin-based generalization bound:

Theorem 10 *Fix a distribution over $\mathcal{X}$, an $n \in \mathbb{N}$ and $0 < \delta < 1$. With probability at least $1-\delta$ over the random sample S of size n, the following holds for all $0 \leq k \leq n/2$: If S is (k, γ)-separable with witness S', then*

$$\mathrm{err}(h_{S'}) \leq Q(d, k/n) =: R(k, \gamma),$$

where Q is defined in (4) and

$$d = \mu(S')^{\mathrm{Log}(\mathrm{rad}(S')/\gamma)} = \lceil \mathrm{rad}(S')/\gamma \rceil^{\mathsf{dens}(S)}.$$

Furthermore, the minimizer (k^*, γ^*) of $R(\cdot, \cdot)$ is efficiently computable.

4.3 Sample complexity lower bound

The following result shows that even under margin assumptions, a sample of size exponential in dens will be required for some distributions. (See also the recent agnostic lower bound for passive 1-NN, Kontorovich et al. (2016, Theorem 5), based on (Berend and Kontorovich, 2015, Equation (25)) an exact PAC lower bound (Kontorovich and Pinelis, 2016, Theorem 2.1).)

Theorem 11 *There are universal constants $c, \delta > 0$ such that for every semimetric space $(\mathcal{X}, \rho)$ with $\mathsf{dens}(\mathcal{X}) > 6$ and any learning algorithm mapping samples S of size n to hypotheses $h_n : \mathcal{X} \to \{-1, 1\}$, there is a distribution $\mathbb{P}$ over $\mathcal{X}$ and a target concept $f : \mathcal{X} \to \{-1, 1\}$, such that $\mathrm{err}(f) = 0$ yet*

$$\mathbb{P}\left(\mathrm{err}(h_n) \geq \frac{c \lceil \mathrm{rad}(S)/\mathrm{marg}(S) \rceil^{\mathsf{dens}(\mathcal{X})}}{n} \right) \geq \delta.$$

Proof The definition of the density constant implies the existence of an $r > 0$ and an $M \subseteq \mathcal{X}$ satisfying

(a) $m := |M| = \mu(\mathcal{X}) = 2^{\mathsf{dens}(\mathcal{X})}$

(b) M is contained in a ball of radius $2r$

(c) $\rho(x, x') \geq r$ for $x \neq x' \in M$

The assumption $\mathsf{dens}(\mathcal{X}) > 6$ implies $m \geq 65$. Taking $0 < \varepsilon < \frac{1}{8}$, recall the standard VC lower bound argument (Blumer et al., 1989; A. Ehrenfeucht, D. Haussler, M. Kearns, L. Valiant, 1989), which constructs a distribution $\mathcal{D}$ over M by putting a mass of $1 - 8\varepsilon$ on $x_1 \in M$ and distributing the remaining mass uniformly over the other $m-1$ points. Suppose the target $f : M \to \{-1, 1\}$ is drawn uniformly at random from $F = \{-1, 1\}^M$, and some learning algorithm is given a sample $S = (X_1, \ldots, X_n) \sim \mathcal{D}^n$, where $n = (m-1)/(32\varepsilon)$.

First, we argue that with probability $\Omega(1)$, S will contain exactly 2 distinct points. Let E_1 be the event that S consists of 1 point; then

$$\mathbb{P}(E_1) = (1-8\varepsilon)^n + (m-1)\left(\frac{8\varepsilon}{m-1}\right)^n. \tag{7}$$

Since $n = (m-1)/(32\varepsilon)$ and $m \geq 65$, the first term in the right-hand side of (7) is at most $e^{-(m-1)/32} \leq e^{-2} < 0.1353354$. The second term therein is (i) monotonically decreasing in m (for $m \geq 65$) and (ii) monotonically increasing in ε; at $m = 65$ and $\varepsilon = 1/8$, we have the upper bound $65/64^{16} < 10^{-27}$. Thus $\mathbb{P}(E_1) < 0.1353355$.

Let E_2 be the event that S has more than 2 points. We decompose E_2 into two cases: E_2', where $x_1 \in S$ and E_2'', where $x_1 \notin S$. Clearly, $\mathbb{P}(E_2'') \leq (8\varepsilon/(m-1))^3 < 0.000004$. To analyze E_2', define $\xi_i = \mathbf{1}_{\{X_i \neq x_1\}}$ and note that under E_2', the random quantity $1 + Z := \sum_{i=1}^m \xi_i$ upper-bounds the number of distinct points in S. Hence, $\mathbb{P}(E_2') \leq \mathbb{P}(Z \geq 2)$. Now $\mathbb{E}[Z] = n(8\varepsilon/(m-1)) = 1/4$, and by the multiplicative Chernoff's bound,

$$\mathbb{P}(Z \geq 2) = \mathbb{P}(Z \geq 4\mathbb{E}Z) \leq e^{-\mathbb{E}Z} = e^{-1/4}.$$

We conclude that $\mathbb{P}(E_2) < 0.0003 + e^{-1/4} < 0.7789$ and hence $\mathbb{P}(\mathbb{E}_1 \cup E_2) < 0.91415$.

Let E_3 be the event that S will consist exacly of 2 distinct points x, x', and furthermore, that the randomly drawn f has $f(x) \neq f(x')$; then $\mathbb{P}(E_3) \geq \frac{1}{2}(1 - \mathbb{P}(\mathbb{E}_1 \cup E_2)) > 0.04$. Conditioned on E_3, the labels assigned by f to the remaining $m-2$ points in M are iid Bernoulli(1/2) and their total mass under $\mathcal{D}$ is at least $(m-2)(8\varepsilon/(m-1)) > 7.875\varepsilon$, since $m \geq 65$. Since the labels are random, no learning algorithm can do better than flipping a coin, and the algorithm will be correct on $\frac{1}{2}(m-2)$ of the unseen points, in expectation. The probability of being correct on more than $\frac{3}{4}(m-2)$ of the points is bounded by $e^{-(m-2)/8} < 0.000381$. Thus, with probability at least $\delta := 0.039$, any learning algorithm that observes n labeled examples sampled from $\mathcal{D}$ will achieve an error of at least $(7.875/4)\varepsilon > 1.95\varepsilon$.

The above argument proves a sample complexity lower bound of $\Omega(m/\varepsilon)$. Inverting the bound for $\varepsilon = \mathrm{err}(h_n)$ implies that with probability at least δ, the following events occur:

(i) $\mathrm{err}(h_n) > 1.95 \cdot \frac{m-1}{32n} > \frac{0.05m}{n}$

(ii) the sample S contains exactly two distinct points, x, x'

(iii) the randomly chosen f has $f(x) \neq f(x')$.

To finish the proof, it remains to establish the requisite relationship between the deterministic quantity $m = |M|$ and the random quantity

$$\mu(\mathcal{X})^{\mathrm{Log}(\mathrm{rad}(S)/\mathrm{marg}(S))} = \lceil \mathrm{rad}(S)/\mathrm{marg}(S) \rceil^{\mathsf{dens}(\mathcal{X})},$$

where $S \sim \mathcal{D}^n$. By construction, $\mathrm{rad}(M) \leq 2r$, and by (ii,iii), $r \leq \mathrm{marg}(S) \leq 2r$, whence $\mathrm{Log}\,(\mathrm{rad}(S)/\mathrm{marg}(S)) = 1$ and

$$m = \mu(\mathcal{X})^{\mathrm{Log}(\mathrm{rad}(S)/\mathrm{marg}(S))}.$$

and the claimed lower bound follows. ■

5. Density dimension of some common semimetrics

In this section we demonstrate the utility of the density dimension by calculating its value under some common semimetric distance functions on d-dimensional vectors. The first of these functions is the Jensen-Shannon divergence, equivalent (Fuglede and Topsøe, 2004) to the ℓ_2-squared distance function $\ell_2^2(x,y) = \sum_{i=1}^d |x_i - y_i|^2$. We also consider the non-metric ℓ_p-spaces for $0 < p < 1$, $\ell_p(x,y) = (\sum_{i=1}^d |x_i - y_i|^p)^{1/p}$. Finally, we consider the k-median Hausdorff distance.

Recall that the usual Hausdorff distance is a metric defined on any two point sets A and B, and we shall make the simplifying assumption that $|A| = |B| = m$. Let $l(a,b)$ for all $a \in A$ and $b \in B$ be a vector distance function — for simplicity we shall assume the Euclidean ℓ_2 distance — and $l(a,B)$ be the distance from $a \in A$ to its nearest neighbor in B. The Hausdorff distance is the maximum distance between a point in A (or B) and its nearest neighbor in B (respectively, in A): $\max\{\max_{a\in A} l(a,B), \max_{b\in B} l(b,A)\}$. Huttenlocher et al. (1993) define the k-median Hausdorff distance (in the terminology of Jacobs et al. (2000), but perhaps more aptly termed the k-rank Hausdorff distance) by setting $h_k(A,B)$ to be the k-th smallest value in the vector $v = (l(a_1,B), \ldots, l(a_d,B))$, and then the k-rank Hausdorff distance is $H_k(A,B) = \max\{h_k(A,B), h_k(B,A)\}$. Note that $H_m(A,B)$ recovers the classic metric Hausdorff distance (and we require $k \leq m$). On the other hand, we can show that $H_1(A,B)$ is sufficiently robust to be *universal* for all semimetrics — that is, any semimetric can be realized by the distance function $H_1(A,B)$:

Lemma 12 *If ρ is a semimetric on a point set X of size n, then ρ can be realized as the H_1 distance (induced by $l = \ell_2$ as above) over subsets of $\mathbb{R}$ of size n.*

Proof Put $D = \mathrm{diam}(X)$ and replace each point $x_i \in X$ with a set $A_i \subset \mathbb{R}$ of size n as follows. For $a_{i,j} \in A_i$, if $j \geq i$, then set $a_{i,j} = 2D((i+1)n + j)$, and otherwise set $a_{i,j} = a_{j,i} + \rho(x_i, x_j)$.

Consider any pair $x_i, x_j \in X$ for $i < j$. Clearly $\ell_2(a_{i,j} - a_{j,i}) = \ell_2(a_{i,j} - a_{i,j} - \rho(x_i,x_j)) = \rho(x_i,x_j)$, so $H_1(A_i,A_j)$ is at most this value. On the other hand, for any k,p we can show that $\ell_2(a_{i,k} - a_{j,p}) \geq D$ whenever $k \neq j$ or $p \neq i$): If $i \leq k$, we have $a_{i,k} = 2D((i+1)n+k)$, and otherwise $2D((k+1)n+i) \leq a_{i,k} \leq 2D((k+1)n+i) + D$. Similarly, if $j \leq p$ we have $a_{j,p} = 2D((j+1)n+p)$, and otherwise $2D((p+1)n+j) \leq a_{j,p} \leq 2D((p+1)n+j) + D$. Since by assumption $i \neq j$, the two terms differ by at least D unless both $j = k$ and $i = p$. ■

We bound the density dimension under these three distance functions.

Theorem 13 *A set of m d-dimensional vectors has density dimension: $O(d)$ under ℓ_2-squared, $O(d/p^2)$ under ℓ_p $(0 < p < 1)$, and $O(k(d + \log m))$ under H_k.*

Proof We begin with a standard proof that a set of d-dimension Euclidean vectors has density dimension $O(d)$. Take any radius 4 ball, and we bound the size of a 2-net of points within this ball. By the triangle inequality, 1-radius balls centered at the 2-net points do not intersect, and so the density constant of the space is bounded by the number of 1-radius balls whose centers can be packed into the 4-radius ball. Since a piece of a 1-radius ball may escape the 4-radius ball, by the triangle inequality this term is bounded by the number of

1-radius balls that can be packed into a 5-radius ball. The ratio of the volume of a 5-radius ball to that of a 1-radius ball is 5^d, which bounds the density constant of d-dimensional Euclidean space.

For ℓ_2^2, we embed this space into ℓ_2 by simply retaining the vectors and changing only the distance function. In other words, we take the square root of all the distances, which is known as a *snowflake* operator. To bound the number of 2-net points within a ball of radius 4 in ℓ_2^2, consider instead a larger 1-net in the 4-radius ball. After the embedding, it is a 2-radius Euclidean ball containing a 1-net, and so the density constant of ℓ_2^2 is $2^{O(d)}$ as well.

For ℓ_p $(0 < p < 1)$, let us consider a snowflake of this function, that is $\ell_p^{p/2}(x, y) = (\sum_{i=1}^d |x_i - y_i|^p)^{1/2}$. We can show that the vectors under this distance function can be embedded into $O(d/p^2)$-dimensional Euclidean space with only constant distortion: Considering each coordinate separately, the distance operator $|x_i - y_i|^{p/2}$ on a single coordinate has the effect of embedding all points on a line into a helix. It is known that this embedding can be realized in $O(1/p^2)$-dimensional Euclidean space with arbitrarily small distortion (see Talagrand (1992) for $\frac{1}{2} < p < 1$, and Gottlieb and Krauthgamer (2011); Bartal et al. (2011) for $0 < p \leq \frac{1}{2}$). We create such an embedding for each coordinate and then concatenate the coordinate embeddings into a single vector. This yields an embedding from d-dimensional $\ell_p^{p/2}$ into $O(d/p^2)$-dimensional Euclidean space with arbitrarily small distortion. Then a 1-net inside a $2^{2/p}$-radius ball in the original ℓ_p-space is a 1-net inside a $(2+\varepsilon)$-radius ball in the target Euclidean space (for arbitrarily small ε), and so its density dimension is $O(d/p^2)$.

For the k-rank Hausdorff distance, first note that since h_k is non-decreasing under deletions, we have for all vector sets A, B and subsets $A' \subset A$ and $B' \subset B$ that $H_k(A', B') \geq H_k(A, B)$. Also, we can show there always exist A', B' each of size exactly k that satisfy $H_k(A', B') = H_k(A, B)$: To see this, assume without loss of generality that $h_k(A, B) \geq h_k(B, A)$. Let $h_k(A, B)$ be determined by a set $A_1 \subset A$ of size exactly k, along with a set $B_1 \subset B$ of size $k_1 \leq k$, where the points of B_1 are the nearest neighbors of A_1. Similarly, let $h_k(B, A)$ be determined by set $B_2 \subset B$ of size exactly k, along with nearest-neighbor set $A_2 \subset A$ of size $k_2 \leq k$. Now add to B' the k_1 vectors of B_1, and for each $b \in B_1$, add to A' a distinct vector $a \in A_1$ for which b is its nearest neighbor. Further add to A' $\min\{k_2, k - k_1\}$ vectors of A_2, and add to B' $\min\{k_2, k - k_1\}$ distinct vectors of B_2 that are the nearest neighbors of the relevant vectors in A_2. If the resulting sets A', B' are of size k then we are done, and have $H_k(A', B') = H_k(A, B)$. Otherwise, we add to A' and B' additional points of A_1 and B_2, respectively, until both sets are of size k – as A', B' already contain the respective nearest neighbors of B_2, A_1, the additional points do not affect the distance.

Now consider a set $\mathcal{A}$ of vector sets all within distance 2 of some center set $A_c \in \mathcal{A}$ and at mutual inter-set distance at least 1. We will show that $|\mathcal{A}| = 2^{O(kd)}m^k$, from which the item follows. To prove this, take in turn each subset $A_c' \subset A_c$ of size k (there are $\binom{m}{k} < m^k$ such subsets), and let $\mathcal{A}'$ contain all sets $A_i' \subset A_i$ of size k for which $H_k(A_c', A_i') = H_k(A_c, A_i)$. $\mathcal{A}'$ has radius 2 and inter-set distance at least 1. To complete the proof, we will show that $n = |\mathcal{A}'| \leq 2^{O(kd)}$, from which it follows that $|\mathcal{A}| < |\mathcal{A}'|m^k = 2^{O(kd)}m^k$:

Since $H_k(A_c', A_i') \leq 2$ for all $A_i' \in \mathcal{A}'$, we have that $h_k(A_i', A_c') \leq 2$, and so every vector of A_i' is within Euclidean distance 2 of one of the k vectors of A_c'. Let each vector of A_c' be the center of a 2-radius Euclidean ball. Clearly, the vectors of each A_i' fall into at most

k different Euclidean balls, and so there are at most 2^k different sets of k balls (i.e., ball configurations) into which A_i' may fall. Let $C \subset \mathcal{A}'$ $(p = |C|)$ include all vertex sets falling into some specific ball configuration. For each pair of vertex sets in C, there must be a pair of vectors at distance at least 2 falling into the same 2-radius Euclidean ball. Then $p = 2^{O(kd)}$ and $n \leq 2^k p = 2^{O(kd)}$. ■

We leave it as an open problem to improve on the dependence of k in our bound of the density dimension of the Hausdorff distance.

We conclude this section with an illustration of how the theory developed in this paper explains the success of the greedy net-based compression algorithm, even in the case of semimetrics. We present results for the Hausdorff semimetric applied to the Covertype dataset, found in the UCI Machine Learning Repository.[2] This dataset contains 7 different label types, which we treated as 21 separate binary classification problems; we report representative results below.

data set	**original size**	**% compressed down to**
Covertype 2 vs. 5	2000	97
Covertype 1 vs. 4	2000	25
Covertype 4 vs. 7	2000	2

Figure 2: Summary of the performance of semimetric sample compression algorithm.

Acknowledgments

Thanks to Daniel Hsu for bringing Equation (5) to our attention and Shay Moran for pointing out the analogous result of Shalev-Shwartz and Ben-David (2014). A special thanks to Yevgeni Korsunsky for carefully reading the manuscript and providing very helpful comments.

Appendix A. Inapplicability of metric techniques to semimetrics

Our proof that the density constant controls the size of a net in semimetric spaces (Lemma 1) is non-constructive, and as a result the construction times for nets in semimetrics are necessarily inferior to those of metric spaces. Likewise, estimating a margin of a point set is more challenging for semimetrics and requires a more sophisticated approach than for metric spaces (see Remark 3).

Unlike in metric spaces, where the covering numbers $\mathcal{N}(\cdot)$ and the packing numbers $\mathcal{M}(\cdot)$ are related via $\mathcal{M}(2\varepsilon) \leq \mathcal{N}(\varepsilon) \leq \mathcal{M}(\varepsilon)$ (see e.g., Alon et al. (1997)), violating the triangle inequality breaks this connection between covering and packing. Particularly, for

semimetrics, a doubling constant (while well-defined) does not imply a packing property such as that of Lemma 1. As a consequence, the bounds in the host of results constituting the theory of learning in doubling metric spaces are not applicable to semimetrics. This fact is captured in the following lemma:

Lemma 14 *In semimetric spaces, a bound on the doubling constant does not imply a packing number. In particular, There exist semimetric spaces $\mathcal{X}$ of arbitrary cardinality with a universally bounded doubling constant $\lambda(\mathcal{X}) = O(1)$, such that $\mathcal{X}$ contains a* $\mathrm{rad}(\mathcal{X})$*-net C of size $\Theta(|\mathcal{X}|)$.*

Proof Let $\mathcal{X}$ be composed of two sets, A and A'. Put $A = \{a_1, \ldots, a_n\}$, endowed with the line metric $\rho(a_i, a_j) = |i-j|$, so the maximum distance in A is $n-1$. Note that $\lambda(A) = O(1)$. Define A' to consist of n points, such that

$$\rho(a'_i, a_j) = \rho(a_i, a_j) + \phi \mathbf{1}_{\{i=j\}}, \qquad (\phi > 0 \text{ infinitesimal}),$$

while $\rho(a'_i, a'_j) = n - 1$. This defines a semimetric on $\mathcal{X}$.

Clearly, A' forms a $\mathrm{rad}(\mathcal{X})$-net of size $|\mathcal{X}|/2$, and yet we can show that $\lambda(\mathcal{X}) = O(1)$. Indeed, consider any ball $B_r(x)$ in $\mathcal{X}$. Then all points in $B_r(x)$ can be covered by the same $\lambda(A) = O(1)$ balls of radius $\frac{r}{2}$ that cover $A \cap B_r(x)$. The claim follows. ■

In fact, a deeper principle underlies the results above: In metric spaces, the doubling and density constants are almost the same, while in semimetric spaces there may be a large gap between them. This is captured in the following lemma, which delineates the relationship between the doubling constant and density constant. (The first half of the lemma is due to Gottlieb and Krauthgamer (2013).)

Lemma 15 *Let $\mathcal{X}$ be point set endowed with a metric distance function. Then*

(a) $\lambda(\mathcal{X}) \leq \mu(\mathcal{X})$,

(b) $\sqrt{\mu(\mathcal{X})} \leq \lambda(\mathcal{X})$.

Let $\mathcal{Y}$ be a point set endowed with a semimetric distance function. Then

(c) $\lambda(\mathcal{Y}) \leq \mu(\mathcal{Y})$,

(d) $\mu(\mathcal{Y})$ *may be as large as* $\Theta(|\mathcal{Y}|)$*, even when* $\lambda(\mathcal{Y}) = O(1)$.

Proof To prove (a) and (c), that $\lambda \leq \mu$: Consider any open ball $B_r(x) \in \mathcal{X}$. Let C be a maximal collection of points at mutual interpoint distance at least $\frac{r}{2}$, and note that by definition $|C| \leq \mu(\mathcal{X})$. By the maximality of C, $|C|$ balls of radius $\frac{r}{2}$ centered at points of C cover all of $B_r(x)$, so $\lambda(\mathcal{X}) \leq |C| \leq \mu(\mathcal{X})$. For (b): again, consider any open ball $B_r(x) \in \mathcal{X}$, and let C be a maximal collection of points at mutual interpoint distance at least $\frac{r}{2}$. Now, by definition $\mathcal{X}$ may be covered by $\lambda(\mathcal{X})$ balls of radius $\frac{r}{2}$, and each of these smaller balls may be covered by $\lambda(\mathcal{X})$ balls of radius $\frac{r}{4}$, so there exists a set of $\lambda^2(\mathcal{X})$ balls of radius $\frac{r}{4}$ covering all of X, and in particular C. By the triangle inequality, each ball of radius $\frac{r}{4}$ can cover at most one point of C, and so $|C| \leq \lambda^2(\mathcal{X})$. Finally, (d) follows

immediately from Lemma 14. ■

In metric spaces, the following bounds on exact and approximate nearest neighbor search are well-known.

Lemma 16 *Given a point set S equipped with a metric distance function, and a query point x:*

(a) Locating the exact nearest neighbor of x in S requires $\Theta(|S|)$ comparisons in the worst case.

(b) A $(1+\varepsilon)$-approximate nearest neighbor of x in S can be found in time $2^{\mathsf{ddim}(S)} \log |S| + \varepsilon^{-O(\mathsf{ddim}(S))}$.

Proof To prove (a), let S be a set of points obeying the line metric, i.e. the distance between $s_i, s_j \in S$ is $|i-j|$. Suppose x is at distance $n = |S|$ from s_i, and at distance $n+1$ from all other points of S. Then s_i can be any point of S, and cannot be located without inspecting each point. The claim in (b) is the result of Krauthgamer and Lee (2004). ■

For semimetric spaces, we demonstrate that the situation is much worse:

Lemma 17 *Given a point set S equipped with a semimetric distance function, discovering an exact or approximate nearest neighbor requires $\Theta(|S|)$ comparisons in the worst case.*

Proof For the upper bound, trivially $O(|S|)$ time is sufficient to consider every point in S.

For the lower bound, suppose the query point q is at an infinitesimally small distance from a single point $s_0 \in S$, and at distance $\mathrm{rad}(S)$ from all other points of S. Then s_0 can be any point in S, and cannot be located without inspecting each point: Without the triangle inequality, the distance between one pair of points has no bearing on any other distance. ■

Abstract

This paper takes a close look at the important commonalities and subtle differences between the well-established field of supervised learning and the much younger one of co-optimization. It explains the relationships between the problems, algorithms and views on cost and performance of the two fields, all throughout providing a two-way dictionary for the respective terminologies used to describe these concepts. The intent is to facilitate advancement of both fields through transfer and cross-pollination of ideas, techniques and results. As a proof of concept, a theoretical study is presented on the connection between existence / lack of free lunch in the two fields, showcasing a few ideas for improving computational complexity of certain supervised learning approaches.

Keywords: supervised learning, active learning, co-optimization, free lunch, optimal algorithms

1. Introduction

It is not uncommon in science that separate fields independently develop similar ideas but describe them with different language, or that they need to solve similar problems but approach them from different perspectives and thus derive different methods of solving them. Either field would benefit from learning about the latest and greatest in the other, but achieving such benefits requires overcoming a couple of barriers: lack of awareness of the existence of another field concerned with similar issues and lack of understanding of its language and perspective. The goal of this paper is to break such barriers between the fields of supervised learning and co-optimization.

Supervised learning has been around for a long time, thus knowledge and understanding of it has permeated other disciplines. Loosely speaking, it is concerned with generalizing from given examples to unseen ones. Co-optimization is a much newer area, not widely known outside its community. The term has been introduced by Service and Tauritz (2008a), though the ideas had already been floating around in the field of coevolution (Popovici et al., 2010), a sub-field of evolutionary computation (De Jong, 2006) that has been around since the early 90's (Hillis, 1990). There are multiple possible goals in co-optimization, of which a common one is finding solutions that would perform well in many different situations (tests), given the ability to do only a limited number of performance assessments. This type of goal is the focus of *test-based co-optimization*. To draw a quick parallel to supervised learning, un-assessed situations are similar in nature to unseen examples, but their space can and must be explored. The present work delves into this parallel in much greater detail.

We start in Section 2.1 with a handful of examples of problems from both fields, first presented in natural language and then formalized to highlight both the commonalities and the differences between them. Then in Section 2.2 we discuss the relationship between the typical algorithmic approaches applied to solve such problems in their respective fields. Two themes thread through both sections: how much and what kind of information is available to the problem-solver, and what are the various kinds of cost the problem-solver might incur. The performance-versus-cost issue is further detailed in Section 2.3, highlighting how both fields lack a performance-evaluation approach encompassing all cost types.

Thus Section 2 should provide a useful guide to those newcomers to one of the fields that already have a background in the other, but it is *not a detailed survey* of either field; many books and review papers are available for that purpose, e.g., by Abu-Mostafa et al. (2012) for supervised learning, Popovici et al. (2010) for co-optimization. Rather, it presents a *mapping between the core issues and concepts* that researchers in the two fields concern themselves with and the language they use in the process (summarized in Table 3). State-of-the-art approaches in either field should be describable in terms of such core notions; while not the main focus, a couple of supervised learning examples, such as deep learning (LeCun et al., 2015) and the reusable holdout (Dwork et al., 2015), are mentioned in sections 2.3.1 and 2.3.2.

The motivation behind this type of presentation is to enable researchers in the two fields to better understand each other and provide a bridge over which methods, ideas and results can travel both ways and contribute to the advancement of both fields. In particular, for machine learning researchers, the co-optimization paradigm should reveal the formalization of new and non-trivial learning tasks and of methods for assessing performance on those tasks which offer interesting free lunches. To illustrate the potential, in Section 3 we derive the counterpart for binary classification of a recent line of work in co-optimization concerning the exploitation of free lunch to design algorithms that have optimal performance with respect to a particular type of cost. We discuss the implications for the other cost types described in Section 2.3 and also point out how this new paradigm suggests alternative approaches to instance selection and active learning.

2. Parallel Between Fields

There are three main aspects of any computer science field: the problems to be solved, the algorithms used to solve them and the paradigms used to assess and compare different algorithms' performance with respect to the problem-solving goal. For each of these aspects, we explain what's common and what's different between supervised learning and co-optimization. In the process, we also build a two-way dictionary between the terminologies of these two fields, summarized in Table 3.

2.1 Problems

We first present some problem examples through their real-world formulations, but explaining or replacing domain jargon with simple words. This should make it easier to spot both commonalities and differences, which are then formalized later in Section 2.1.3.

2.1.1 Examples of Co-optimization Problems

Resilient Piping – Automated design of robust physical systems (Co-optimization). Consider the problem of placing valves in a network of water-carrying pipes so as to maximize the resilience of the network in case of damage. Such piping networks carry water from pumps to a number of usage sites; this could be for human consumption, for equipment cooling or for putting out fires (Popovici et al., 2007). Should damage occur somewhere in the network, such as broken pipes causing local leaks and global pressure drop, the damaged areas need to be isolated by automatically closing nearby "smart" valves, so as to stop the leak and restore pressure to as much of the network as possible. Smart valves are expensive and can only be placed sparingly throughout the network. Where they are placed has a big impact on how tightly we can isolate a given damage, i.e., how resilient the network is to that damage. For any given placement of valves and any given damage, we can compute this resilience value using graph-traversal algorithms to identify the valves closest to damaged spots and to determine, once these valves are closed, how many usage sites still have an unobstructed path to a pump and thus can get water. The goal is to find, for a given piping network and number of smart valves, a placement that provides as good as possible resilience across many/all damage scenarios. More broadly, the problem described here is that of automating the design of physical systems that perform well under many different circumstances.

Sorting Networks – Automated algorithm design (Co-search). Consider the task of sorting in increasing order a sequence of numbers by repeatedly comparing pairs of numbers and, if the first is bigger than the second, swapping them. An algorithm performing such sorting is called a sorting network, because it can be represented as a network of compare-and-swap gates. Sorting networks have both software and hardware applications. Each gate incurs a cost, either computational or actual, so one would like to use as few of them as possible. For a given number of available gates and a given length of input sequences, the goal is to find a network with that number of gates that correctly sorts all input sequences of that length (Hillis, 1990). More broadly, the problem described here is that of automating the design of computer programs that for any possible input produce the correct output, where correctness is according to the computational task at hand (e.g., sorting).

2.1.2 Examples of Supervised Learning Problems

Photo Labeling – Automated item classification (Supervised binary classification). Consider the problem of automating the labeling of photos as to whether or not they contain a particular thing, say a balloon. We are provided with a set of examples of photos that have been manually labeled by humans as 'yes' if they contain a balloon or 'no' if they don't. The goal is to find a computer program that outputs the correct label for any possible photo.

Protein Structure – Outcome prediction (Discrete regression). Consider the problem of predicting higher-level protein structure. The primary structure of a protein is specified by a chain of amino-acids of 20 possible types. In nature, this chain folds into a convoluted shape, such that neighboring amino-acids become part of local formations of three different types: coil, helix and beta-strand. Determining this secondary-structure sequence of a given protein (i.e., what type of formation each amino-acid becomes part of) requires lab experiments and it is known only for a small percentage of all known proteins. The goal is to find a computer program that outputs the correct secondary-structure sequence for any amino-acid sequence (Cheng et al., 2008).

More broadly, these two problems are about learning from samples in order to generalize to new, as yet unseen cases.

2.1.3 Problem Comparisons and Formalisms

While these problems span a varied set of domains and at first glance may not appear particularly related, closer inspection reveals common aspects as well as key differentiators.

All of the descriptions above state that the problem-solving goal is finding something (a placement of valves, a network of compare-and-swap gates, a computer program). This 'object' of interest needs to 'perform' in a certain way (or have some desirable properties) across all/many 'contexts' (damages, number sequences, photos, proteins). While not explicitly stated in the above descriptions, for each of these problems the number of contexts of interest can be very large: there are millions of proteins with known amino-acid sequence but unknown structure; there is an infinite number of photos, or at least a combinatorial number of them if we restrict the size; there is an exponential number of sorting-relevant sequences;[1] and the number of possible damage locations in a water-delivery network can also be significant, with the number of damage scenarios increasing in combinatorial fashion if we account for co-occurrences at different locations (which can happen for instance in case of earthquakes).

Additionally, for each of these problems, the set of objects of interest can also be very large: if there are n possible locations where we could place valves, but we can only afford $m < n$ valves, then the number of possible placements is $\binom{n}{m}$; the number of possible networks with n compare-and-swap gates is also combinatorial in n; and the number of input-output mappings for the computer programs predicting photo labels or protein structures is exponential.

The descriptions above also hint at differences in the information available to help us solve the respective problem. To see this better, we turn to formalisms. Table 1 provides a summary of the notation. Throughout the rest of Section 2 we underline key terminology which is then collated in Table 3.

Co-optimization Formalisms. Consider the problem of designing resilient piping networks. Let S denote the set of all possible placements of a given number of valves in a given piping network. Let T denote the set of all possible/likely damages to that piping network. For any valve placement $s \in S$ and any damage $t \in T$ we can compute the resilience of s to t, as described earlier. Let this computation be denoted by a metric $M : S \times T \to V \subset \mathbb{R}$. The goal is to find a valve placement $s \in S$ that maximizes, say, the *average* resilience over all damages $t \in T$, $g(s) = avg_{t \in T} M(s,t)$.[2] We call this goal the maxiavg solution concept (i.e., definition of what constitutes a solution) and we call g the quality function; $g(s)$ is the quality of potential solution s. Equivalently, we could be concerned with the *total* resilience over all damages, $g(s) = \sum_{t \in T} M(s,t)$, a solution concept called maxisum. Other interpretations of 'as good as possible resilience across many/all

1. Specifically, 2^n, where n is the length of the sequence, since any network which correctly sorts all binary sequences of length n also correctly sorts any arbitrary numeric sequence of length n.
2. Assuming such average (or perhaps an expectation) is well defined and that g has a maximum.

damage scenarios' include, for instance, aggregating over damages by taking the worst value rather than the average (worst-case optimization, also called maximin solution concept) or requiring Pareto-dominance, like in multi-objective optimization with the damages playing the role of objectives (Popovici et al., 2010).

Thus, resilient piping design is clearly an optimization problem: we have a set of potential solutions S and we are searching for the element of S that maximizes a function $g : S \to \mathbb{R}$. More specifically, in the field of optimization, this type of problem is called a test-based co-optimization problem. This is because the function g is in fact defined via the metric M, whose definition involves an additional set of entities T. The elements of T are called tests: they do not contribute to the definition of the set of potential solutions S, but they help test which elements of S are solutions and which are not, via the metric M. For brevity, from here on we will use just the word co-optimization when we actually mean test-based co-optimization; co-optimization problems that are not test-based exist, but are outside the scope of this paper.[3]

Note also that we do not have a closed-form mathematical formula for M. Rather, the resilience of a design to a damage is determined through a computational procedure (this could involve graph-traversal algorithms as mentioned above, or, in some cases, a fluid dynamics simulation). While we might know what this procedure is, this knowledge does not easily (or even at all) provide us with a roadmap for solving the problem. What we *can* always do though is to evaluate M to get its output for one input-pair $\langle s, t\rangle$ at a time; $\langle s, t\rangle$ is typically called an interaction or event and determining $M(s, t)$ is referred to as performing a metric evaluation or M-evaluation or, for short, an evaluation; we also say that s has seen t (and t has seen s). For each such evaluation we incur the computational cost of running M (ranging from milliseconds for graph-traversal algorithms to minutes or hours for hydraulics simulations); this is the basic unit of cost for co-optimization algorithms. We say that M is accessible in black-box fashion. In some domains, M may in fact be the outcome of a real-world experiment which we do not know how to simulate computationally, in which case M is truly black-box and even more costly (e.g., days and dollars).

A key point in co-optimization is that the function whose maximum we are trying to find is not the black-box M, but g, which is an aggregate of $|T|$ values of M. As previously discussed, the size of T can be such that computing the actual value of g for even a single $s \in S$ can be very costly or completely infeasible. Even estimating $g(s)$ will typically require evaluating multiple interactions involving s. This is in contrast with traditional black-box optimization, where the quality of a potential solution is given by a single evaluation, since it is potential solutions that are the object of black-box evaluation, not interactions. It is also in contrast with multi-objective optimization, where the number of objectives is so small that evaluating each potential solution on *all* objectives is not an issue and may in fact be considered the basic unit of cost; in co-optimization the set T is something that needs to be explored. Single- and multi-objective optimization could also be seen as instantiations of the more generic framework of co-optimization.[4]

3. In particular, the field of co-optimization also comprises a subfield concerned with so-called *compositional* co-optimization problems (Popovici et al., 2010), some of which have been approached via cooperative coevolutionary algorithms (Potter, 1997).
4. But see also work mapping test-based co-optimization to multi-objective optimization with fewer *underlying* objectives than the size of T (Bucci et al., 2004).

With a bit of reshaping, the sorting network problem can similarly be cast. Let S denote the set of all possible networks made up of a fixed number of compare-and-swap gates and taking as inputs sequences of a fixed length. Let T denote the set of all binary sequences of that length (see footnote 1 on page 4). For any network $s \in S$ and any input sequence $t \in T$, we can determine sorting correctness by running the sequence through the network, then checking if the output is in fact sorted. Let $M : S \times T \to \{0, 1\} \subset \mathbb{R}$ be a metric such that $M(s, t) = 1$ if s correctly sorts t and 0 otherwise. Like for the piping network design problem, M is not given by a closed-form mathematical formula, but for any input-pair $\langle s, t\rangle$ we can compute $M(s, t)$ via the above procedure. As originally stated, the goal for sorting network design is to find a network $s \in S$ such that $M(s, t) = 1$ for all $t \in T$. This is an example of a test-based co-search problem, in that we are searching for an element with a particular property. A co-optimization problem is a co-search problem in which the property of the element we're looking for is that the element optimizes some function. The sorting network problem can be re-phrased as a test-based co-optimization problem, since an s satisfying the above property also maximizes $g : S \to \mathbb{R}$, $g(s) = \sum_{t \in T} M(s, t)$. Also note that for this problem an M-evaluation has fairly modest cost (linear in the number of compare-and-swap gates and likely measured in milliseconds), but the size of T is exponential (2^n, where n is the length of the input sequence).

A subtle difference between the resilient piping problem and the re-stated sorting networks problem is that for the latter it is really important that we find a maximum of g and we might be able to tell whether or not we have, whereas for the former we would not recognize a maximum even if we found one, so we're really looking for as high a value of g as we can find. Nonetheless, any method we can apply to the generic, black-box formulation of the resilient piping problem we can also apply to the sorting networks problem. Problems like these are the object of study in the field of co-optimization (Service and Tauritz, 2008a; Popovici et al., 2010; Popovici and Winston, 2015).

Supervised Learning Formalisms and Mapping to Co-optimization. We now turn our attention to the latter two problems, which come from the field of supervised machine learning (Abu-Mostafa et al., 2012). For the photo labeling problem, let X be the set of all possible photos (up to a certain size limit). Let $Y = \{yes, no\}$ be the set of labels, denoting presence or absence of balloons. Let $f : X \to Y$ denote the correct assignment of labels to photos, where correctness can always be judged by humans. This is often referred to as the target function to be learned. We are provided with a set of n labeled examples $\mathrm{D} = (x_i, y_i = f(x_i))_{i=1..n} \subset X \times Y$ and the goal is to find the full f, or, more precisely, to find a computer program that implements f. Such a program is often referred to as a classifier or predictor, the examples D are also referred to as data points or simply as data or a data set, and the problem solving goal is also referred to as (binary) classification.

We can map this problem to a test-based co-optimization problem as follows. Let S be the set of all computer programs that take as input a photo $x \in X$ and output a label $y \in Y$. For any $s \in S$ and any $x \in X$ we denote by $s(x)$ the output of program s for input photo x. Note $|S|$ is larger than $|Y^X|$, since multiple programs can implement the same functionality. Let $T = X$ (i.e., photos constitute tests) and define $M : S \times T \to \mathbb{R}$ via $M(s, t) = \delta(s(t), f(t))$, where δ is the Kronecker delta function or some other function measuring the agreement between $s(t)$ and $f(t)$. Then the photo labeling goal is to find a program $s \in S$ such that $M(s, t) = 1$ for all $t \in T$. This is essentially the same goal as

for sorting network design and can be restated as maxisum, which is useful since for this particular application we do not actually expect to find a perfect program. Equivalently and more commonly, M is defined as $1 - \delta(s(t), f(t))$ and called error, which is then to be minimized.

The problem of predicting secondary protein structure is similar: X is the set of all possible primary-structure amino-acid sequences, Y is the set of all possible secondary-structure sequences and f represents the real-world mapping of primary to secondary structure sequences. When mapping to co-optimization, S is the set of all computer programs that take as input a primary-structure amino-acid sequence and output a secondary-structure sequence, $T = X$ and $M(s, t)$ is defined to measure agreement between $s(t)$, the secondary-structure sequence output by program s for amino-acid sequence t, and the true secondary-structure sequence given by $f(t)$; agreement could be binary (1 if sequences are identical, 0 otherwise) or it could give partial credit for those positions that do match between the two sequences. The problem-solving goal, especially for the second choice of M, is once again maxisum.

Comparison. While these formalisms show us how we can express the problem-solving goals of typical supervised learning tasks in a similar fashion to those of co-optimization, they also expose subtle but important differences in the information available to any algorithm attempting to solve such problems. One such difference is the access we have to the function M. For generic co-optimization problems like resilient piping and sorting network design, we can evaluate M for any $\langle s, t\rangle$, thus the main concern is with the cost of each such evaluation and, consequently, with the number of evaluations that can be afforded and how good a potential solution (as judged via g) we can find given such an evaluation budget. For supervised learning problems like photo labelling and protein structure prediction, we can only get at the value of M for pairs $\langle s, x_i\rangle_{i\in 1..n}$ corresponding to the data set D (which is provided as input to the algorithm for free) and the main concern is how good a potential solution we can find given only those n specific labeled examples. Note how n does not impose a hard limit on the number of $\langle s, x_i\rangle$ pairs for which we can compute M, but see more on cost in Section 2.3.1.

Having made this difference explicit, we can now see that the related field of supervised active learning (Settles, 2012) concerns itself with problems whose information availability lies on a spectrum between the above two extremes.

2.1.4 Active Learning Problems

For instance, consider the following slight variation of the photo labeling problem. The goal is the same as before, but instead of a set of labeled photos we have a much larger set of unlabeled photos (obtained, for instance, via internet crawling). With the advent of the Amazon Mechanical Turk (Amazon, 2005) obtaining a label for a photo can be relatively cheap and prompt, though it is not completely free, and the time required to get it is not computational in nature, but rather depends on human availability (Maji, 2011). Both to save money and to speed up the process, it would be beneficial if we could ask for a label only for those images most useful for the learning task. This is referred to as a pool-based active learning problem. Formally, we are given X the set of all possible photos, Y the set

Symbol	Description
S	Space of potential solutions.
T	Space of tests.
$V \subseteq \mathbb{R}$	Space of metric values.
$M : S \times T \to V$	Interaction metric; $M(s, t)$ is the result of evaluating potential solution s with test t; it can be completely black box or based on labels in supervised learning.
$g : S \to \mathbb{R}$	Quality function that is the target of optimization; $g(s)$ gives quality of potential solution $s \in S$; examples include taking the average, sum or minimum of M over T.
X	Space of inputs, from which data is sampled.
Y	Space of outputs (labels for inputs).
$f : X \to Y$	Target function from Y^X, labeling inputs; it defines M when viewing supervised learning as co-optimization.
$\mathrm{D} \subset X \times Y$ $\mathrm{D} = (x_i, f(x_i))_{i=1..n}$	Data set of size n from which f must be inferred.
$\mathcal{H}$	In supervised learning, set of hypotheses considered (also called a model). In co-optimization, set of potential solutions actually being searched. Its mapping to Y^X or, respectively, S is typically not one-to-one.

Table 1: Notation summary for Section 2.1 (Problems) and Section 2.2 (Algorithms).

of labels, a strict subset $X' = (x_i)_{i=1..n}$ of X and access to f in black-box fashion with the restriction that we can only query f for $x_i \in X'$.

If mapping this to co-optimization, the restriction on access to f means in turn that we can only get the value of M for pairs $\langle s, x_j\rangle$ for those $x_j \in X'$ for which we have obtained a label. However, while in generic co-optimization one metric evaluation is the basic unit of cost, in active learning if we perform multiple $M(s, x_j)$ evaluations with different s but the same x_j we incur the cost of obtaining the label $f(x_j)$ only once overall and the costs for $s(x_j)$ and $\delta(s(x_j), f(x_j))$ multiple times, once for each s.

This is true for two additional flavours of active learning. One further variation of the above problem consists of the case when we are not provided with a set $X' \subset X$, but with a stream of elements from X: each element is available only for a limited time, during which the algorithm can ask for a label for that element, thus it must decide quickly whether or not to do so—and we cannot ask for all labels. This setup is of interest for domains such as part-of-speech tagging (Dagan and Engelson, 1995).

Let us also revisit the protein structure problem and relax the requirement that we use only data previously generated by lab experiments. Rather, we are allowed to perform further experiments for any existing amino-acid chain to determine its secondary structure, though for any such experiment we incur costs both in money and in time required to perform the experiment. Note that for this setting f is truly black-box and we have no restrictions as to for which examples $x \in X$ we can obtain the label $f(x)$—examples

can be generated de-novo. Consequently, if we model this as co-optimization, we have no restrictions in terms of which pairs $\langle s, x\rangle$ we can compute M for. Thus, this problem is the most similar to the co-optimization problems of resilient piping design and sorting network design. The difference is that for those problems it was M directly that was given in black-box fashion, whereas for the de-novo active learning problem we have that M is defined through f and it is f that we have black-box access to. The impact of this difference will be discussed in Section 3.

For all active learning problems there may be a budget constraining how many labels the algorithm can obtain.

2.2 Algorithms

We now turn to discussing the various types of algorithms that have historically been used to approach supervised learning and co-optimization problems. Even state-of-the art algorithms tend to fall under these broad types or employ as components the core approaches described here and hybrids thereof; when they don't, this framework should make it easy to express how they differ. Our categorization is mainly driven by the way algorithms make use of the information available to them. Sections 2.2.1 and 2.2.2 will read familiar to the machine learning researcher; we review some basic notions so that: 1) whenever possible, we can directly describe them using co-optimization terminology; and 2) we can refer back and contrast with them the co-optimization-specific notions we introduce later in Section 2.2.3 and thus build towards the vocabulary mapping in Table 3.

2.2.1 Supervised Learning Algorithms

Recall from the formalization of supervised learning in Section 2.1.2 that we are looking for an element $s \in S$ that minimizes $g(s) = \sum_{t\in T} M(s,t) = \sum_{t\in T}(1 - \delta(s(t), f(t)))$, but we only have access to the value of $f(t)$ for $t \in (x_i)_{i=1..n}$ from the data D. Thus, a first issue to be addressed is that we *cannot* actually compute $g(s)$ for any s. Supervised learning algorithms deal with this by working with restrictions of the sum inside g to subsets of the data. State-of-the-art methods employ meta-approaches such as regularization or cross-validation (discussed at the end of this section), but at their core they incorporate and expand upon the following procedure. Data is randomly partitioned into a training set and a test set. An $s \in S$ is identified that minimizes g^{tr}, the variant of g obtained by summing $M(s,t)$ only over the t in the training set, also called in-sample error or training error. It is hoped that $g^{tr}(s)$ will correlate with the actual value of $g(s)$, though of course the former is an optimistically-biased estimator of the latter. For that reason, for the best s *only*, an unbiased estimator is computed by summing $M(s,t)$ only over the t in the test set. Overfitting or over-training is said to have occurred if an s was chosen that had low training error, but high test set error. The term generalization error is used to refer either to the actual value of $g(s)$ or to the out-of-sample error defined as the sum of $M(s,t)$ only over the $t \in T \setminus (x_i)_{i=1..n}$ (the symbol '$\setminus$' stands for set difference).

In minimizing g^{tr}, the next issue concerns the set S. For supervised learning problems, the true space of all potential solutions S is the set of all computer programs implementing a function from X to Y. In practice though, supervised learning algorithms only consider a subset $\mathcal{H} \subset S$ of programs, but one with a structure that facilitates finding a program that implements f or a good approximation of f. The elements of $\mathcal{H}$ are referred to as hypotheses. For instance, $\mathcal{H}$ could be the set of neural networks of a particular size and shape, or the set of decision trees of a certain depth, etc. Such a set $\mathcal{H}$ is typically called a model.[5] There may be multiple elements of $\mathcal{H}$ that implement the same function from X to Y and there may be functions from X to Y that no element of $\mathcal{H}$ implements (i.e., the mapping from $\mathcal{H}$ to Y^X is not one-to-one). The choice of $\mathcal{H}$ (and an algorithm to search it) has a strong bearing on the expected generalization error and carries with it a so-called bias-variance tradeoff (Geman et al., 1992), where bias and variance represent two different sources of said error that are difficult to minimize simultaneously. Bias is the average, over possible data sets, of the distance between the target function and the best hypothesis found by the algorithm for that data set. The variance measures how much this best hypothesis varies with the data set. Larger, more *complex* sets $\mathcal{H}$ tend to have lower bias but higher variance and be prone to high generalization error via overfitting. Smaller and simpler sets $\mathcal{H}$ tend to have lower variance but be prone to high generalization error due to high bias (underfitting).

For many supervised learning approaches, the choice of $\mathcal{H}$ requires that the data is either directly given as or can be transformed into tabular form, i.e., the set X can be written as $X^{\mathrm{f}} = X_1^{\mathrm{f}} \times X_2^{\mathrm{f}} \times ... \times X_k^{\mathrm{f}}$ where the sets X_i^{f} are numeric, ordinal or categorical in nature (the superscript 'f' stands for 'feature'). These sets represent so-called variables or features or (in statistics) covariates. In certain domains the elements of X in fact have richer structure, which cannot be represented in tabular form. When mapping such an X into an X^{f} there will inevitably be information loss; additionally, the choice of mapping could have an impact on the difficulty of the problem.

At the core of even sophisticated machine learning methods there are two main ways in which the structure of $\mathcal{H}$ helps locate an element of $\mathcal{H}$ that minimizes g^{tr} and they differ in the way they make use of the training data: constructive versus exploratory.[6]

Constructive approaches rely on a mapping of X to X^{f} and define $\mathcal{H}$ in such a way that the training data can be used to directly construct a *single* element $s \in \mathcal{H}$ with a good g^{tr}-value (low training error). From a co-optimization standpoint, this constructive process used during training does not involve any $M(s,t)$ evaluations. For instance, for decision trees (Rokach and Maimon, 2014) this is done by repeatedly partitioning the examples based on one feature X_i^{f} at a time, by using the relationship between the feature's values for the training data points and the respective labels of those data points; a new node is added to the tree with each partition until a maximum depth is reached. For support vector machines (SVMs, Cristianini and Shawe-Taylor, 2000), $\mathcal{H}$ is a set of polynomials which, along with some constraints, makes the problem of minimizing training error into a quadratic programming problem.

Exploratory approaches work by computing the training error g^{tr} for *multiple* elements of $\mathcal{H}$ in order to find one with a good value. In co-optimization lingo, they perform a series of $M(s,t)$ evaluations for various $s \in \mathcal{H}$ and various t in the training set portion of $(x_i)_{i=1..n}$ in order to decide which s to pick. This search process can be strongly or loosely guided.

5. In some works, the word 'model' is used to mean a single hypothesis. To avoid confusion, in this paper 'model' only refers to a set of hypotheses $\mathcal{H}$.
6. These have also been referred by De Jong (2006) as bottom-up and, respectively, top-down.

One way to provide strong guidance to the search is to map X to X^{f} and define the space $\mathcal{H}$ so that the error g^{tr} has a closed form with easily computable derivative that allows gradient descent techniques to be used for minimization. Neural networks are an example of this (Rumelhart et al., 1986): the X_i^{f} are mapped to the input nodes of the network, $\mathcal{H}$ is the set of all possible weight combinations for the edges and the error function is linear in these weights. Forward propagation constitutes performing one M-evaluation.[7] Back-propagation of the error to update the weights via gradient descent generates a new network $s' \in \mathcal{H}$. Using a single example for each back-propagation step generates a series of evaluations of the type $M(s_1, t^1), M(s_2, t^2), M(s_3, t^3), \ldots$. Using multiple examples and aggregating the error before propagating it back leads to a series of evaluations of the type $M(s_1, t_1^1), M(s_1, t_2^1), \ldots, M(s_1, t_i^1), M(s_2, t_1^2), M(s_2, t_2^2), \ldots, M(s_2, t_j^2),\ M(s_3, t_1^3), \ldots$. In either case, the s with best g^{tr}-value (often last in the series) is output. Choosing the order in which to use the examples is typically done stochastically and orderings resulting from different random seeds lead to different exploratory paths through $\mathcal{H}$.

An example of a loosely-guided exploratory approach is the application of genetic programming (Koza et al., 2006) to supervised learning. Genetic programming is a set of techniques from the field of evolutionary computation (De Jong, 2006) that draw inspiration from the principle of evolution by natural selection to search for computer programs achieving some task. Programs can take various shapes, such as rule-sets in the field of learning classifier systems (Lanzi et al., 2003), expression trees in symbolic regression (Icke and Bongard, 2013), even neural networks with variable structure in neuro-evolution (Floreano et al., 2008), etc. The set X, representing inputs to the programs, need not necessarily take tabular X^{f} form and the space $\mathcal{H}$ of programs is not constrained to lead to a closed-form error function. Instead, $\mathcal{H}$ is endowed with a topology such that neighboring points (programs) in $\mathcal{H}$ have close error values. This topology is induced by so-called genetic operators that generate new programs in $\mathcal{H}$ from previous programs, in a manner inspired by how mutation and crossover work on DNA. A program $s \in \mathcal{H}$ is evaluated by computing $M(s, t)$ for some (usually all) t from the training-set portion of $(x_i)_{i=1..n}$ and aggregating these measurements into one value, often referred to as fitness. Programs with good fitness (low error) are selected and operators are applied to them to produce a population of new programs; the process then repeats for multiple iterations called generations. These techniques are slower at climbing any given local optima than pure-gradient methods—since they essentially have to indirectly estimate the gradient by performing $M(s, t)$ evaluations—but better at avoiding getting stuck in one. Note also that they are general optimization techniques applicable to other tasks besides supervised learning and therefore not tuned to it.

Meta-approaches. Both exploratory and constructive approaches need to be concerned about over-/under-fitting. One heuristic is to try out sets $\mathcal{H}$ of different complexities: for example, put a hard constraint on the degree of the polynomials or the depth of the trees considered, then investigate what happens when varying the value of the constraint. Another heuristic is to use "soft" constraints, i.e., allow an all-encompassing $\mathcal{H}$, but include in the training error g^{tr} a penalty term for the complexity of individual hypotheses in that $\mathcal{H}$; examples include: allowing trees of high maximum depth, but including a penalty term that grows with the depth; or allowing polynomials of high degree, but including a penalty term that is low when most weights are close to 0 and high otherwise. This latter heuristic is generally referred to as regularization; in genetic programming, penalizing tree depth is called parsimony pressure. Different levels must be tried out for the relative contribution of the penalty term versus the main error term.

7. Feeding example t through network s computes $s(t)$ and determining disagreement between the network's output and the example's label computes $M(s, t) = 1 - \delta(s(t), f(t))$.

In the above, the expression 'try out' refers to the fact that the overall algorithm applies multiple basic methods (either exploratory or constructive), or applies a parameterized basic method multiple times with different parameter values, then selects one of the variants for producing the final output—a process known as model selection. To perform the selection, (semi)unbiased empirical estimates are computed for the output of each variant by performing additional $M(s, t)$ evaluations with tests not used during the training of that variant—a process known as (cross-)validation (Refaeilzadeh et al., 2009; Geisser, 1975; Stone, 1974). Thus, during this process, what was originally designated as a training set gets further split (possibly multiple times for cross-validation) into an *actual* training set and a validation set. The term holdout set has also been used in the literature, but with inconsistent meaning, referring sometimes to a validation set and sometimes to a true test set. The test set is still to be used only once to get an unbiased estimate for the quality of the final output. Such uses of estimates for output selection and performance evaluation are relevant for co-optimization algorithms as well, as discussed in sections 2.2.3 and 2.3.2.

2.2.2 Active Learning Algorithms

Typical approaches to active learning treat the problem as an extension of supervised learning. As such, they use a query strategy to decide for which points $x \in X$ to obtain a label, then apply one of the supervised learning methods described above on the labeled data accumulated so far, then re-iterate these two steps. Some query strategies are generic and could be used with any supervised learning approach, whereas others are specific to the supervised learning algorithm used (Settles, 2012). Whether the core supervised learning approach is constructive or exploratory, *the query strategy of active learning algorithms can be thought of as exploring the set X*. The resemblance of active learning to co-optimization suggests there may be approaches that are more direct than the standard iterative one. We will revisit this at the end of Section 3.

2.2.3 Co-optimization Algorithms

Because in co-optimization it is the metric M that is given in black-box fashion (as opposed to an f that further defines M), it is not obvious if or how one could find a good element of S through a constructive approach. Therefore, co-optimization algorithms (Service and Tauritz, 2008a) are exploratory by necessity and involve adaptations of stochastic search and optimization heuristics (Luke, 2013) like simulated annealing (SA), hill-climbing (HC) and evolutionary algorithms (EAs)—the genetic programming described in Section 2.2.1 being an example of the latter.

Note that in this case the search space S does not necessarily contain computer programs, but possibly other kinds of objects or structures (e.g., subsets of valves in the case of resilient piping design or, often, simply vectors of parameter values characterizing a structure or design). Recall that supervised learning algorithms actually search a hypothesis set $\mathcal{H}$ that does not have a one-to-one mapping with Y^X; similarly, in co-optimization, the

way the space S is represented in the computer often means that what's actually being explored by the algorithm is a set other than S and whose mapping to S is not one-to-one. To limit notation, we'll denote this set by the same symbol $\mathcal{H}$. In the field of evolutionary computation (De Jong, 2006), the choice of $\mathcal{H}$ is called a representation and the mapping from $\mathcal{H}$ to S is called the genotype-to-phenotype mapping. One still needs to consider the tradeoff between the ability of $\mathcal{H}$ to represent many/all the elements of S and the ease of searching $\mathcal{H}$ (which may decrease as the size of $\mathcal{H}$ increases). This can be considered a counterpart concept to supervised learning's bias-variance tradeoff.

As in supervised learning, an important issue is the fact that we might not be able to compute the actual value of the quality function g that we are to optimize, because $g(s)$ is defined as the sum of $M(s,t)$ for *all* $t \in T$ and T is very large and/or M is very expensive.

In contrast to supervised learning, there are no restrictions as to which elements $t \in T$ we can use in $M(s,t)$ evaluations. Consequently, *co-optimization algorithms explore not just the space S but also the space T, as well as the cross-product of the two.* Thus, a co-optimization algorithm can be formalized as having two components: 1) the exploration mechanism,[8] deciding which interaction between a potential solution $s \in S$ and a test $t \in T$ should be evaluated next via the metric M, given the sequence of interactions previously evaluated and their M-values, also referred to as the history[9]; and 2) the output mechanism,[10] deciding, based on such a history, which potential solution s to output. This formalism can be used to describe exploratory approaches to supervised learning as well; and most meta approaches perform some kind of output selection even when incorporating constructive components.

Exploration mechanisms. A basic but sometimes successful approach is to use any of the previously-mentioned stochastic search heuristics for exploring S, by evaluating any considered $s \in S$ with a random sample of tests $t \in T$ and using as fitness an aggregation of the resulting M-values, a placeholder for the true quality of s. This sample may contain a portion that is fixed throughout the entire algorithm, a portion that is regenerated for each iteration and a portion that is regenerated for each s.

Another popular approach is to apply the evolutionary metaphor to both spaces. The resulting *coevolutionary* algorithms (Popovici et al., 2010) maintain a population of potential solutions $s \in S$ and a population of tests $t \in T$. Elements in the former population are paired with elements in the latter and the resulting interactions are evaluated via the metric M. Various interaction methods can be used to determine who is paired (interacts) with whom (Popovici, 2006). For the maxiavg/maxisum solution concepts, fitness is typically assigned to each element s in the S-population by averaging $M(s,t)$ for all the interactions that particular s was involved in; such fitness represents a subjective quality, internal to the algorithm. Much research has gone into how to assign fitness to the elements of T, leading to two main paradigms: 1) if high values of M are good for the elements of S, then reward tests in T for low values of M (i.e., for being *difficult* tests)—a paradigm traditionally

8. This has also been called just an *algorithm* (Wolpert and Macready, 2005; Service and Tauritz, 2008b) or a *search heuristic* (Service and Tauritz, 2008b; Service, 2009a,b; Popovici and De Jong, 2009; Popovici et al., 2011).
9. This has also been called a *sample* (Wolpert and Macready, 2005) or simply a *sequence* (Service and Tauritz, 2008b).
10. This has also been called a *champion-selection rule* (Wolpert and Macready, 2005), a *champion selection function* (Service and Tauritz, 2008b), a *candidate selection function* (Service and Tauritz, 2008b; Service, 2009a,b) or *output selection* (Popovici and De Jong, 2009; Popovici et al., 2011).

referred to as *competitive* coevolution (Angeline and Pollack, 1993; Popovici et al., 2010); and 2) reward elements of T for their ability to differentiate between elements of S, that is for being *informative* tests (Bucci, 2007). In addition to the tests in the current population, archives of hard/informative tests can be kept and used in evaluations (Rosin and Belew, 1997; de Jong, 2005). Co-optimization problems emerged as a formalization of the kinds of problems coevolutionary algorithms were being applied to.

Both approaches (random sampling of tests versus coevolution) typically use the same *number* of tests to evaluate all potential solutions considered; these potential solutions are called *partially evaluated*, as said number of tests is usually much smaller than $|T|$.

Output mechanisms. A typical approach is *greedy*, which outputs the partially-evaluated potential solution with the best average of M-values over the tests it was evaluated with. It is also common to maintain archives of promising potential solutions (as identified by the greedy method) and then do another round of M-evaluation for them, with either freshly sampled or similarly archived tests, and pick the output based on the resulting *empirical* g-estimates (Panait and Luke, 2002); this is similar to the process of validation for model selection used in supervised learning. Newer work (Wolpert and Macready, 2005) has introduced optimal output mechanisms whose definition makes use of *theoretical* (Bayes) estimates of g consisting of aggregations (e.g., averages) over all possible values that yet-unperformed metric evaluations could result in. Interestingly—and unlike greedy—such output mechanisms even consider outputting *completely-unevaluated* potential solutions, i.e., ones for which the algorithm hasn't yet performed any M-evaluations, if their Bayes estimates are better. We will discuss these in more detail in sections 2.3.2 and 3.

Estimates of g, whether empirical or theoretical, can also be used to judge the quality of the outputted potential solution. In particular, using freshly sampled tests to obtain an unbiased empirical estimate (Chong et al., 2008) is similar to the way a test set is used in supervised learning; such an estimate represents an objective quality and is external to the algorithm itself. As with over/under-training in supervised learning, this is necessary because a disconnect can occur between internal and external quality measurements (Popovici and De Jong, 2005; de Jong, 2007).

2.3 Cost and Performance

In computer science the terms cost and performance are sometimes used interchangeably, especially when algorithms are acceptable only if they produce correct output and differentiating between them is done by measuring their execution speed. In supervised learning and co-optimization the notion of correctness is replaced by as-good-as-possible, thus we have to differentiate between two terms. We use the word 'performance' to refer to quantities having to do with the quality of potential solutions outputted by the algorithm. We use the word 'cost' to refer to time or money. Performance and cost are typically inter-related, since the performance of an algorithm may vary with the cost expended. We start by formalizing the various types of cost encountered in co-optimization and supervised learning, and hint at possible tradeoffs between different types. Then we review ways of assessing performance, which may itself incur costs.

The study in Section 3 relies upon and provides examples for several of the notions of cost and performance introduced here.

2.3.1 Cost

In general, costs can take several high-level forms: 1) computational time, that is the time required by a computer to perform a calculation; it can vary from one hardware to another, but may be expressible in terms of basic operations via the big-O notation of traditional computational complexity—this tends to be more difficult to achieve when the calculation is in fact a complex simulation; 2) real-world time, for instance time required to run a physical or chemical experiment, or time required to get a human to provide a label; and 3) money, for instance to pay for a lab, materials and people.

Algorithms for supervised learning and co-optimization problems can incur these kinds of costs while carrying out various activities. Some are directly driven by the problem specification: obtaining labels for active learning and evaluating $M(s,t)$ for co-optimization; all algorithms attacking these problems will necessarily incur the associated costs. Other cost-incurring activities are dependent on the specific choice of algorithm and include: exploration decisions, construction, output selection. Last but not least, in supervised learning and co-optimization evaluating the performance of any algorithm often incurs additional costs. Table 2 provides an overview in concise form.

Labeling costs are relevant only for *active learning* and are discussed extensively in Section 2.1.4, so we only re-summarize them on the top of Table 2. The only additional note is that while for all the problem examples in Section 2.1.4 labeling costs were in the form of real-world time or money, they can occasionally be measured in computational time: for instance, trying to find a quick-to-compute approximation for a very-slow-to-compute simulation (Sacks et al., 1989), such as one involving computational fluid dynamics or a weather model.

Metric-evaluation costs are part of the problem specification in *co-optimization*, as detailed in Section 2.1.1; their type and magnitude can vary, but even when computational and small it is a concern due to the very large sizes of S and T (often combinatorial or exponential) requiring a lot of M-evaluations to find good potential solutions.

Metric-evaluation costs are also relevant in *supervised learning*. They are a key concern for all exploratory algorithms, since exploration decisions are made based on the outcome of such evaluations. Additionally, incurring $M(s,t)$ evaluation costs may also be necessary for two other algorithmic activities discussed later in this section, namely output selection and performance assessment, which are relevant even for constructive approaches to supervised learning. The cost of evaluating $M(s,t)$ is always computational time and has two components: 1) cost of computing $s(t)$, that is the computational time required to run example t through program s (e.g., forward-propagation through a neural network, or top-down propagation through a decision tree, or evaluation of a polynomial for a support vector machine); and 2) cost of computing the agreement $\delta(s(t), f(t))$. The latter cost is typically small, e.g., constant when simply comparing photo labels or linear in the number of amino-acids when comparing protein structures. The cost of computing $s(t)$ varies with the size of individual hypotheses, e.g., number of edges in a neural network, levels in a decision tree (and trees in a random forest, Ho, 1995) or terms in a polynomial; it has grown in recent years for models such as deep learning's convolutional neural networks with millions of connections (LeCun et al., 2015). Using models with a low cost of computing $s(t)$ is desirable because this cost is also always incurred once a solution is deployed in the real world.

Table 2: Summary of the various types of costs encountered in test-based co-optimization and supervised learning.

		Supervised learning				Test-based Co-optimization
		Passive	Active			
			Pool-based	Stream-based	De-novo	
Labeling costs		Free ("gift" from someone else)	Pay for label Type: usually money or time, occasionally computational. Magnitude: varies widely across domains			Not applicable (N/A), there are no labels
Label availability	*How many ...*	Restricted by problem specification	Restricted mainly by labeling budget, then by pb. spec.	Restricted by labeling budget		
	... and which examples we can get labels for:	Restricted			Unrestricted	
Metric-evaluation (M(s,t)) costs		Type: always computational, two components *s(t)* and *δ(s(t), f(t))*; exclusive of cost of obtaining label *f(t)* Incurred during training by exploratory algorithms Incurred during testing and validation by all algorithms Magnitude: *s(t)* varies with hypothesis size, *δ* with label size Cost of s(t) always incurred in the real world by deployed solution				Main cost of interest, all algorithms incur it Type: usually computational, sometimes real-world time and/or money Magnitude: varies widely, a concern even if small due to extremely large *S* and *T*
		May also be incurred as part of ouput-selection and performance-assessment				
		Restricted by metric-evaluation budget				
M(s,t) availability	*How many ...*					
	... and which interactions <s,t>:	Restricted to *t* in training data	Restricted to *t* that we have chosen to obtain a label for (see label availability)			Unrestricted
Exploration-decision costs	*... to decide which interactions to evaluate next:*	Magnitude: negligible when picking the output of core training components; multiple of metric-evaluation costs when performing (cross-)validation for model selection				Always incurred, as all approaches are exploratory Magnitude: negligible compared to metric-evaluation costs for traditional approaches (EAs, SA, HCs), not so for newer ones (CMA-ES, EDAs, Bayes-optimal)
		Magnitude: for backprop, at most as much as metric-evaluation costs; for others, see co-opt. box to the right				
	... to decide which examples to label next:	N/A	Incurred by query strategy			N/A
Construction costs		Incurred by constructive approaches Magnitude: big-O complexity as function of data size				N/A
		Incurred many times if full retraining is required				
Output-selection costs		Magnitude: negligible for greedy methods; multiple of metric-evaluation costs when using empirical estimates; negligible to prohibitive for theoretical Bayes estimates				
		Incurred to determine which of the considered potential solutions to output as the algorithm's best guess for a solution				
Performance-evaluation costs		Magnitude: metric-evaluation costs over a single-use test set				Magnitude: multiple of metric-evaluation costs when using empirical estimates; negligible to prohibitive for theoretical Bayes estimates
		Incurred to estimate the actual, "true" quality of the outputted potential solution				

Type: usually computational, unless we collect new data or perform new experiments

Type: always computational

For *active learning*, note that the cost of obtaining the label $f(t)$ is not included in the cost of $M(s,t)$, because a label can be used for multiple computations of $M(s,t)$ for the same t but different s.

Exploration-decision costs are incurred to decide which problem-specification costs to incur next (e.g., which evaluations $M(s,t)$ an exploratory approach would perform, or, in the case of active learning, which labels a query strategy would request). They are always computational.

Back-propagation in neural networks for supervised learning is an example of an exploration decision incurring a cost: it produces a new network s for which to then evaluate $M(s,t)$ via forward propagation. The cost of one backward propagation has similar magnitude to that of one forward propagation and both vary with the size of the network, as described earlier. If multiple rounds of forward propagation are performed for each backward propagation, then, overall, exploration-decision costs are accordingly smaller than metric-evaluation costs.

Evolutionary approaches, whether used for *supervised learning* or *co-optimization*, usually incur exploration-decision costs while performing selection and breeding to produce a new generation of potential solutions, which will then be involved in $M(s,t)$ evaluations. Similarly, simulated annealing and hill-climbers incur exploration costs when generating and sampling from a local neighborhood. Historically, these costs have been considered much lower than $M(s,t)$ costs. But newer stochastic black-box optimization heuristics tend to have non-negligible exploration costs, such as: quadratic matrix computations for covariance-matrix adaptation evolutionary strategies (CMA-ES, Hansen and Ostermeier, 2001), estimating distributions for estimation of distribution algorithms (EDAs, Larranaga and Lozano, 2002), recursive optimization for optimal exploration mechanisms (Popovici and Winston, 2015; Popovici, 2017).

In *active learning*, exploration-decision costs are also incurred via the query strategy used to decide the next $x \in X$ for which to obtain a label. Such costs vary widely with the strategy (Settles, 2012) and have to be weighted against the costs of obtaining labels, since reducing the latter is the main goal of sophisticated query strategies .

Construction costs, as the name suggests, are incurred by constructive approaches to supervised learning, whether passive or active; examples include the construction of a decision tree and solving quadratic programming equations for support vector machines. They are computational costs, usually measured in basic operations and expressed via big-O complexity as a function of properties of the problem, such as size of data. They are of particular concern for the increasingly more common "big data", as well as in active learning, where these costs are incurred multiple times if full retraining is necessary each time new labels are obtained.

Output-selection costs are incurred in order to decide which potential solution to output out of the possibly multiple ones considered. This activity is closely-related to performance assessment, since the performance of an algorithm always relies in some manner on the quality of potential solutions it outputs. As discussed in Section 2.2, one distinguishing feature—and potential difficulty—of co-optimization and supervised learning problems is the inability to compute the actual quality of any potential solution for the problem instance at hand. Consequently, assessing quality of potential solutions must be done by means of estimation, which carries a cost.

In co-optimization, simple output selection methods just side-step the issue, by using the greedy heuristic of outputting the potential solution with the best average over only the tests seen so far, a highly-biased empirical estimate of g. Keeping track of this potential solution is trivial, so output selection costs have historically been considered negligible compared to metric-evaluation costs. As described in Section 2.2.3, there are also approaches that acknowledge the issue. Some compute new empirical estimates of g for a handful of potential solutions identified via the greedy method, then use these estimates (which could be unbiased or at least less biased) to select which one to output; this requires performing additional $M(s,t)$ evaluations and incurring the respective metric-evaluation costs. Others use theoretical g-estimates whose computation does not involve performing additional metric evaluations, but rather aggregating (e.g., averaging) over all possible values that such evaluations could result in. These aggregates can be computationally-prohibitive; but output selection only relies on comparisons between them, the outcome of which can sometimes be determined without actually computing the aggregates themselves (Popovici and De Jong, 2009; Popovici et al., 2011; Popovici, 2017), in which case the costs are minimal.

Unless we collect new data or perform new experiments for the purpose of additional $M(s,t)$ evaluations, output selection costs are only computational. This is the case for supervised learning as well. Here too, output selection costs can be negligible if the algorithm simply outputs the outcome of the training process for a particular method, for example, the decision tree constructed, or the final set of weights for a neural network (which is often the greedy best-so-far, given the gradient-based nature of exploration via back-propagation). More commonly though, a model is selected first via (cross-)validation, as described in Section 2.2.1. To compute the empirical estimates involved in validation, $M(s,t)$ costs are incurred by performing additional metric evaluations for the outputs of the models to be selected amongst.

2.3.2 Performance

By performance of an algorithm we mean the quality of the algorithm's outputted potential solutions with respect to the problem solving goal. But because in supervised learning and often in co-optimization as well exact quality is not actually computable, assessing algorithmic performance is an uncertainty-laced, more difficult task in these fields compared to traditional function optimization.

Perhaps the simplest performance question one can answer—and one that is quite important to answer in practice—is: on the problem instance at hand, what is the quality of the potential solution that constitutes our algorithm's final choice as *the solution* to be deployed in the real-world?

This is a quality-estimation question, so it can be answered the same way as when part of the output selection process (see previous section). But subtle care must be taken. Computing unbiased empirical estimates (by performing additional $M(s,t)$ evaluations and incurring the associated costs) must be done with fresh tests in co-optimization (Chong et al., 2008) or, in supervised learning, with labeled data points (a test set) not used for any other purpose.[11] Moreover, the resulting estimate *should not* be used for any further

11. Note the different usage of the word 'test' in the two parts of this sentence.

tweaking of the chosen potential solution, or else it ceases to be an unbiased estimate; in other words, a true test set is always single-use—but see the work of Dwork et al. (2015) for a novel technique where the bias resulting from reuse is small and quantifiable as a function of the amount of reuse.

We may also wish to know how performance of an algorithm varies as a function of given resources/cost expended, so we can determine how we may be able to boost performance. Ideally, such characterizations would take into account *all costs* listed in the previous section. In reality, different approaches have focused on different aspects of the performance-cost dependence.

In passive supervised learning, the main concern is with performance as a function of resources, in the form of size of available data. However, the cost of acquiring data is not counted as a cost incurred by the learning algorithm. Indirectly, this dependency on data size does describe a relationship between performance and algorithmic cost, because making use of more data takes more time, whether it is done in constructive or exploratory fashion. Because of this, a whole subfield of supervised learning concerns itself with instance selection, that is determining a subset of the labeled examples that is small, yet using it would result in similar output quality as using the whole set (Reinartz, 2002). In co-optimization, the main concern is with performance as a function of metric-evaluation costs. In active learning, the main concern is with performance as a function of labeling costs. Unlike passive supervised learning, the latter two fields *do* concern themselves with the dependency of performance on the cost of acquiring data, whether the data consists of values of M or values of f.

Algorithms often have one or more parameters whose values must be set. Thus another important issue is how performance varies with changes in parameters. In supervised learning, a common example of this comes from binary classification in the form of receiver operating characteristic (ROC) curves (Spackman, 1989) which plot how the error for one class changes as a function of the error for the other class while varying the value of the algorithm parameter investigated.

Being able to compare the performance obtained for two different values of one parameter of an algorithm is akin to being able to compare two different algorithms. While empirical quality estimates allow us to do that and to determine if one one algorithm is better than another for the one problem instance at hand, the question that immediately arises is whether some algorithms are better than others in a general sense (i.e., across all, or a large class of problem instances). This is important because designing or tuning a new algorithm for each problem instance is a time-consuming manual activity that might not be feasible in practice. For instance, imagine a factory that must schedule jobs on a set of machines susceptible to various breakdowns (Jensen, 2001) and must produce a new schedule every day for the jobs of that day. One cannot re-tune with such high frequency.

To answer the above question, one must make precise the meaning of 'better' and of 'general'. Theoretical Bayes estimates are intrinsically about performance on multiple problem instances. By definition, they are aggregations (e.g., expectations) over all possible hypotheses f or metrics M, assuming a certain probability distribution over such functions. Wolpert (1992, 1996) first introduced this view of algorithmic performance and argued that, to the extent that the goal of supervised learning is to generalize to *unseen* examples, the meaning of 'better' should really be based on out-of-sample error (off-training set (OTS) error)

Supervised Learning	**Co-optimization**
labeled example data point data set data	 test interaction event
data size	budget
training set	history
test set	fresh tests
hypotheses classifiers predictors	potential solutions population
model variables features covariates	representation search space
bias-variance tradeoff	genotype-to-phenotype mapping
unknown target	black-box metric
forward propagation labeling	evaluation
IID error generalization error out-of-sample, off-training set (OTS) error	quality function external, objective quality
in-sample error validation error	fitness internal, subjective quality
overfitting (over-training) underfitting	internal-external quality disconnect
regularization	parsimony pressure
gradient descent back-propagation query strategy instance selection	exploration mechanism genetic operators (e.g., mutation, crossover) interaction methods generation
model selection (cross-)validation	output mechanism
supervised learning (binary) classification active learning (pool-based, stream, de novo)	solution concept (e.g., maxiavg, maxisum, maximin) test-based co-optimization problem co-search problem
no free lunch (NFL)	

Table 3: Terminology map. Terms in respective cells for the two fields are not synonymous, but represent concepts that are similar or related (e.g., back-propagation can be thought of as being a type of exploration mechanism).

rather than on the overall error g (IID error, where IID stands for independently identically distributed). For the OTS notion, he showed that there is no free lunch (NFL), meaning that for any given data set: 1) if all hypotheses consistent with that data set are equally likely (i.e., uniformly distributed), then all algorithms have the exact same aggregated performance; and 2) for any two algorithms, there are as many distributions over hypotheses for which one algorithm is aggregately-better than the other for that data set, as there are distributions where the opposite relation between algorithms holds. If by 'better' we mean better actual g value (i.e., over all tests in T), then there is free lunch, but of a rather unsatisfying type: the only aggregate-performance differences between algorithms come from their in-sample error. And while overall error is non-increasing as a function of the data set size n, out-of-sample error can actually increase with n (Wolpert, 1992). All of this holds regardless of the amount of computation expended by the algorithms.

Wolpert and Macready (2005) adapted and applied this approach to co-optimization. Since in co-optimization there is no given data set, the meaning of 'better' *must* rely on the actual value of g over all tests in T and the "fair ground" on which we compare algorithms is not a data set but the budget of $M(s,t)$ evaluations they are allowed to perform. Under this setup, there is free lunch (i.e., some algorithms are aggregately-better than others) *even if* all metrics M are equally likely.[12]

Active learning has not been studied to a similar extent from a free lunch perspective. Cursory treatment by Wolpert (1996) claims negative implications of no free lunch theorems apply just as they do for passive supervised learning. The details of this are unclear though, as there are several different NFL theorems for passive supervised learning and they are conditioned on a given data set (or its size) and are generally concerned with error outside this data set, whereas in active learning there is no data set given upfront, generating data is a key part of the algorithms. The claim is also intriguing given active learning's similarities with co-optimization and the existence of free lunch in that field. Investigating this issue is subject for future work and the treatment in Section 3 should provide a base towards that: it uses the common ground built in Section 2 to get a deeper understanding of the commonalities and differences between the two fields from a free lunch perspective.

3. Free Lunch Study

Having laid out the various concerns and approaches to measuring performance and cost, we now use them to present a proof-of-concept method transfer from co-optimization to supervised learning. Specifically, we focus on the free lunch view of performance versus cost, where quality is measured by means of theoretical Bayes estimates and metric-evaluation costs are constrained by a budget. We show how optimal *exploratory* algorithms can be designed within this framework, but also emphasize how they might incur significant costs in some of the other categories listed in Section 2.3.1, such as exploration-decision costs and output-selection costs, thus arguing for the need of a more encompassing view on costs to be developed.

12. Wolpert and Macready (2005) originally showed this for the worst-case (maximin) solution concept, but similar results have later been shown for other solution concepts (Service and Tauritz, 2008b; Service, 2009a,b), including the maxisum that most resembles supervised learning (Popovici and De Jong, 2009; Popovici, 2017).

We structure the presentation in 3 incremental steps with respect to metric-evaluation costs: in Section 3.1 we describe the small-scale case of only one or two M-evaluations in total at most one of which is remaining in the budget; in Section 3.2 we progress to histories of arbitrarily-many already-evaluated interactions, but still at most one remaining to be evaluated; finally, in Section 3.3 we discuss the most general case of arbitrarily-large spent budgets and arbitrarily-large remaining budgets. In each section we first review the co-optimization perspective and results pertaining to free lunch and optimality, then derive and contrast their counterparts for supervised learning. We focus specifically on binary classification, but many of the ideas presented would apply in a multi-class situation. Throughout, we differentiate between the nature of free lunches for output mechanisms versus exploration mechanisms. We keep the presentation as informal as possible and support it with small but concrete examples; precise mathematical definitions of all concepts involved and proofs of the results can be found in the accompanying Online Appendix A.

3.1 Small Overall Budget

In this section we look at a spent budget of 0 or 1 evaluations and a remaining budget of 1.

3.1.1 Co-optimization

Consider a domain with $S = \{a, b, c\}$, $T = \{t_1, t_2\}$, $V = \{0, 1\}$ and $M : S \times T \to V$, meaning there are 3 potential solutions, 2 tests and binary outcomes for interactions between solutions and tests. To ease comparison with supervised learning, suppose the values in V represent some kind of penalty, such that lower values are better and we're trying to find the potential solution minimizing the sum of M over the tests (i.e., a minisum solution concept rather than maxisum). The total number of interactions is $|S| \cdot |T| = 3 \cdot 2 = 6$ and therefore the total number of possible metrics M for this domain is $|V|^{|S|\cdot|T|} = 2^6 = 64$. These are shown in columns 1–7 of Table 4, one per row, numbered from 0 to 63.

Output mechanisms concern themselves with which potential solution to output given the history of interactions evaluated so far and their M-values; this history reflects the budget spent so far; the remaining budget is not a concern. If the current history is an empty sequence H = [] (i.e., we haven't yet performed any evaluations, spent budget is 0) and we have no other information, then all 64 metrics are possible and, we assume, equally likely (more on this in Section 3.4). Columns 8–10 in the table show, for each metric, the actual value of g (i.e., the sum of M over all tests) for each of the 3 potential solutions. At the bottom, the expected value of g, averaged over all metrics, shows that in the absence of any data or information all 3 potential solutions are equally promising, with an expected g-value of 1. Due to the equal likelihood of all metrics, this can also be thought of as follows: the expected M-value for a potential solution on a test it hasn't yet seen is the average of the values in V, which is 0.5; summing that over two tests gives $2 \cdot 0.5 = 1$.

Consider now the situation where an algorithm has evaluated the interaction $\langle a, t_1 \rangle$ and observed value $M(a, t_1) = 1$, so now the history is H = $[\langle \langle a, t_1 \rangle, 1 \rangle]$ (spent budget is 1). What should the algorithm output as the most promising potential solution? As we can see from the columns 11–13 in Table 4, metrics from 0 to 31 are no longer possible, since they have $M(a, t_1) = 0$. Averaging g only over the remaining metrics (which we say are *consistent* with the history) yields a different expected value for potential solution a (1.5)

Table 4: Examples of co-optimization free lunch in domain with $S = \{a, b, c\}$, $T = \{t_1, t_2\}$, $V = \{0, 1\}$. Output mechanism free lunch (columns 11–28): for history $\mathrm{H} = [\langle\langle s, t\rangle, 1\rangle]$ with $s \in \{a, b, c\}$ and $t \in \{t_1, t_2\}$, outputting a new potential solution $s' \neq s$ yields strictly better expected performance (1) than outputting s (1.5). Exploration mechanism free lunch (right half of table): for history $\mathrm{H} = [\langle\langle s, t\rangle, 1\rangle]$, instantiated with $s = a$ and $t = t_1$, testing a new potential solution $s' \neq s$ with either the same test t or a new test $t' \neq t$ yields strictly better expected performance (0.75) than further testing s (1). Font style indicates which values were averaged to compute an expectation, green cell shading indicates where the minimum value is coming from and orange cell shading highlights the expected performance for each exploration choice.

than for b or c (1). Given these estimates, it follows that outputting one of b or c is the strictly best choice from the perspective of the algorithm's aggregated performance. This is an example of existence of *output mechanism free lunch* in co-optimization. Note this does not mean that outputting b or c is the best thing to do for each and every metric; for instance, if M happens to be M_{47}, outputting a would be the better choice.

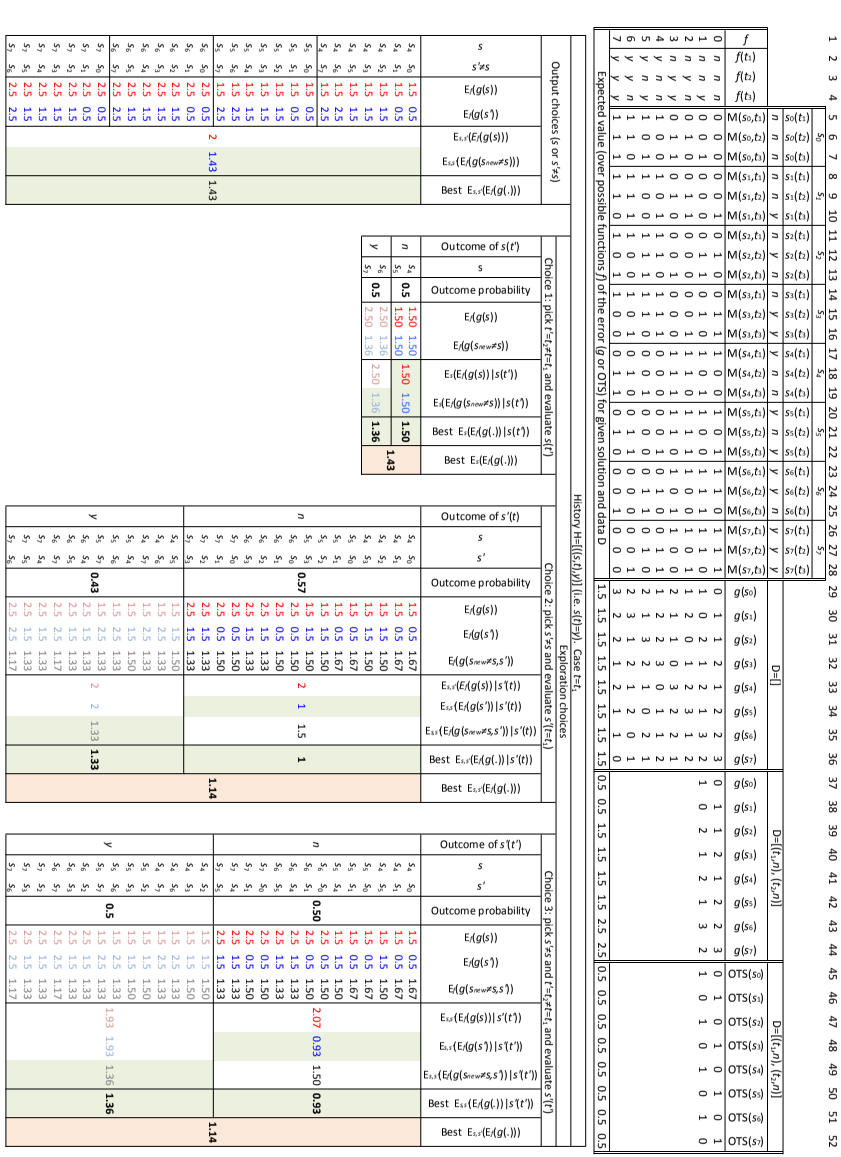
Often, an algorithm might not be able to pick a specific potential solution and/or a specific test, rather it picks at random from a set of previously unexplored possibilities. Consider for instance a history $\mathrm{H} = [\langle\langle s, t\rangle, 1\rangle]$, where s is any of a, b or c and t is either t_1 or t_2, but we do not know which. There are 6 possible cases, depicted in columns 11–28 of Table 4. In each of these cases, the expected g-value of s is 1.5, so overall the expectation is also 1.5 and the expected g-value of any $s' \neq s$ is 1, thus outputting s' is the better choice. These values can also be arrived at with the kind of reasoning described a few paragraphs back: for s, the expected g-value is the sum of the actual M-value observed for t, which is 1, plus the expected value of M on the remaining test, 0.5; for $s' \neq s$, since it hasn't seen any tests yet, the expected g-value is the same as before: we simply multiply the expected M-value on a given test, 0.5, by the total number of tests, 2.

Exploration mechanisms concern themselves with which interaction to evaluate next given the history; this decision may be influenced by the remaining budget of M-evaluations. Suppose that the algorithm having produced history $\mathrm{H} = [\langle\langle s, t\rangle, 1\rangle]$ (spent budget of 1) is now allowed one additional evaluation (remaining budget of 1). It is the job of the exploration mechanism to decide which of the remaining 5 interactions to run through the metric M. And to determine the performance expected to result from a given interaction choice (exploration decision), we must aggregate over the potential outcomes of evaluating that interaction (0 or 1) the expected value of g for the best output for the ensuing lengthened history for that outcome. The exploration decision can be thought of as having two parts: choosing which potential solution to evaluate and choosing which test to evaluate it with. If s is chosen, then there is only one test it hasn't seen yet, $T \setminus \{t\}$. If an $s' \neq s$ is chosen, then there is a choice between evaluating s' with t or with the other test, $t' \neq t$. These choices are shown in columns 29–58 of Table 4, instantiated only with with $s = a$ and $t = t_1$, due to space constraints; the other instantiations yield the same kind of results. We can see that once an interaction is chosen and its M-value observed, the number of consistent metrics is further cut in half: there are as many metrics producing an M-value of 1 as of 0. Thus aggregating over outcomes is simply by averaging. And within each outcome, for each potential solution we average over the consistent metrics the g-value for that solution, then choose the potential solution with the best average. We see that the choice of evaluating an $s' \neq s$, regardless of whether with test t or t', leads to a better expected g-value (0.75) than evaluating s again with the remaining test t' (expected g-value 1). This is an example of existence of *exploration mechanism free lunch* in co-optimization.

3.1.2 Supervised Learning

Consider now a small binary classification domain with inputs $X = \{t_1, t_2, t_3\}$ and outputs $Y = \{y, n\}$ (short-hand for *yes*, *no*). There are a total of $|Y|^{|X|} = 2^3 = 8$ possible functions $f : X \to Y$. These are shown on the top left side of Table 5 (columns 1–4), one per row, numbered from 0 to 7. The problem is to guess f given some data D in the form

of pairs from $X \times Y$. Columns 5–28 in Table 5 show how this problem can be mapped to a co-optimization problem. We've already denoted the elements of X via the letter t because from a co-optimization perspective they serve as tests. For simplicity, let the space of potential solutions S have a one-to-one mapping with Y^X—though in practice this will often not be the case, as discussed in Section 2.1.3. So let $S = \{s_0, ..., s_7\}$ where s_i corresponds to f_i. Typically, an algorithm attempting to find an $s \in S$ that approximates f would know there is some mapping between S and Y^X, but may not be able to pick $s \in S$ guaranteeing specific outputs for given inputs (e.g., we don't know how to directly set the weights of a neural network to guarantee a certain error for a certain input). We have $T = X = \{t_1, t_2, t_3\}$ and $M : S \times T \to V = \{0, 1\}$, $M(s, t) = 1 - \delta(s(t), f(t))$ where δ is the Kronecker delta function. There are $|S| \cdot |T| = 8 \cdot 3 = 24$ possible interactions. In generic co-optimization, there would be $|V|^{|S| \cdot |T|} = 2^{24}$ possible metrics M, but since here M is fully determined by f, there are only 8 possible metrics M, fully-specified, one per row, in columns 5–28 of Table 5.



One way to think about it is that supervised learning with an unrestricted set of functions f maps to co-optimization with a restricted set of metrics M; the specifics of this restriction lead to differences in the design of optimal algorithms that we point out throughout the entire Section 3. Note also that in supervised learning there is a dependence between the number of tests and the number of theoretically-possible distinct potential solutions, as $|Y^X| = |Y|^{|X|}$, whereas that's typically not the case in co-optimization (for instance, in the piping network problem, the set S of possible valve placements would be the same whether tests consist of pairs of co-occurring damages or triples thereof, the latter of which are more numerous).

Output mechanisms. If we have no data (D = {}), then all these metrics (functions) are possible and, we assume, equally likely. We discuss this assumption in more detail in Section 3.4. Columns 29–36 in the table show, for each metric, the actual value of g (i.e., the sum of errors over all tests) for each of the 8 potential solutions. At the bottom, the expected value of g, averaged over all metrics, shows that in the absence of information all potential solutions are equally promising, with an expected g-value of 1.5.

Consider being given 2 data points, namely D = $\{(t_1, n), (t_2, n)\}$. Columns 37–44 in Table 5 show that only 2 out of the 8 functions f (metrics M) are still possible (consistent with the data D). Averaging the expected value of g over only these functions shows that potential solutions s_0 and s_1 look more promising than the rest. So any algorithm that would output one of them, by whatever means, would be better overall than an algorithm outputting one of the other six potential solutions. This constitutes *free lunch with respect to g*. By contrast, the *no free lunch* that Wolpert (1992) showed was *for off-training-set (OTS) error*. This is exemplified in columns 45–52 of Table 5, where OTS(s_i) is simply equal to the error over the remaining test t_3, which is $M(s_i, t_3)$. Averaging this over the two possible functions shows that all potential solutions have the same expected error outside of the sample D.

Nonetheless, one question is: how might we exploit the free lunch with respect to g? Answering this for the equal-likelihood case can provide a base from which to then study non-uniform distributions over problems, where there should be free lunch with respect to OTS as well. We can approach this question in a manner similar to co-optimization by considering only algorithms that use an exploratory approach, where they can sample

Table 5: Examples of binary classification free lunch in domain with $X = \{t_1, t_2, t_3\}$, $Y = \{y, n\}$. Font style indicates which values and probabilities were aggregated, green cell shading indicates where the minimum value is coming from and orange cell shading highlights the expected performance for each exploration choice.

$s \in S$ and $t \in T$ that are present in the data and pay for each $M(s,t)$ evaluation. While traditional exploratory approaches to supervised learning always perform *full evaluation*, i.e., for each s considered they evaluate $M(s,t)$ for all t in the data, there is no constraint to do so. In fact, as we shall see later in this section, full evaluation can be suboptimal.

Consider the history $\mathrm{H} = [\langle\langle s,t\rangle, y\rangle]$, meaning the algorithm randomly selected an $s \in S$ and a $t \in \{t_1, t_2\}$, evaluated $s(t)$ and observed value y (spent budget is 1). The output mechanism has two choices: output the partially-evaluated s or output a randomly selected, completely-unevaluated potential solution $s' \neq s$. These choices are shown in the bottom left part of Table 5 (instantiated only with with $t = t_1$, due to space constraints; the other instantiation yields the same kind of results). Since $s(t) = y$, s can only be one of s_4, s_5, s_6, s_7, with respective expected g-values of 1.5, 1.5, 2.5, 2.5. For each possible s, there are seven possibilities for $s' \neq s$, of which four (s_0, s_1, s_2, s_3) have expected g less than or equal to 1.5 and three $(\{s_4, s_5, s_6, s_7\} \setminus \{s\})$ have expected g greater than or equal to 1.5. Averaging over all situations yields an overall expectation of 2 for $g(s)$ and ≈ 1.43 for $g(s')$, thus outputting s' is the strictly better choice and we have *output mechanism free lunch*.

Exploration mechanisms. Suppose now that the algorithm having produced history $\mathrm{H} = [\langle\langle s,t\rangle, y\rangle]$ (spent budget of 1) is allowed one additional M-evaluation (remaining budget of 1). It is the job of the exploration mechanism to decide which interaction to run through the metric M. The rest of Table 5 outlines the three exploration choices: 1) evaluate s again with the remaining test present in the data (in this case, $t' = t_2$); 2) pick a random $s' \neq s$ and evaluate it with the test already seen by s (that is $t = t_1$); and 3) pick a random $s' \neq s$ and evaluate it with the other test ($t' = t_2$). And to determine the expected performance for a given exploration choice, we must: consider each of the two potential outcomes, y or n, that could be observed when evaluating the chosen interaction; determine the best (minimum) g-value estimate for the history resulting from that outcome; then aggregate the estimates for the two outcomes. This aggregate is a *weighted* average, since the two outcomes might not be equally likely; for instance, if we choose to evaluate $s'(t = t_1)$, there are 16 cases with outcome n and only 12 with outcome y, so the respective probabilities are $16/28 \approx 0.57$ and $12/28 \approx 0.43$. The calculations reveal that evaluating an interaction involving s', whether with t or t', yields a strictly better expected g-value (1.14) than further evaluating s (1.43). This constitutes *exploration mechanism free lunch*.

It is insightful to look more closely at these calculations so as to understand how the estimates for the various potential solutions involved change when a new interaction is evaluated. Recall that after having evaluated $s(t)$ and observing y the expected $g(s)$ is 2 and the expected $g(s')$ for any completely-unevaluated potential solution $s' \neq s$ is 1.43. The outcome of evaluating $s(t')$ changes the estimate for s: if we observe $s(t') = n$, the new estimate goes down to 1.5 (we've just observed a match between s and f, so s looks more promising now), whereas if we observe $s(t') = y$, then the estimate goes up to 2.5. This is not surprising, since by evaluating $s(t')$ we are, after all, learning more about s. What is interesting is that the estimate of g for a completely-unevaluated potential solution also changes: either to 1.5 if $s(t') = n$ or to 1.36 if $s(t') = y$. This is pointedly different from generic co-optimization. Referring back to Table 4, for history $\mathrm{H} = [\langle\langle a, t_1\rangle, 1\rangle]$ the expected g-value of b or c is 1 and it does not change when we evaluate $M(a, t_2)$ no matter what outcome we observe. Similar impacts can be noted in Table 5 for the other two exploration choices: evaluating $s'(t)$ for $s' \neq s$ changes the expected value for a random

remaining completely-unevaluated potential solution, but not for s, which has already seen t; evaluating $s'(t')$ for $s' \neq s, t' \neq t$ changes both expectations. In contrast, for co-optimization solution concepts like maxisum and maximin the outcome of evaluations involving one potential solution never changes the expectation for any other potential solutions (and this is independent of which test is used in the evaluation).

This difference can be explained through the prism of the possible metrics M, which in the case of supervised learning are much fewer than $|V|^{|S|\cdot|T|}$. Note for instance how in Table 5 we have no metric M assigning 0 to all interactions, nor one assigning 1 to all interactions. In fact, each of the metrics induced by possible functions f has the property that half the interactions get assigned a 0 and half get assigned a 1; and this is also true at the test level: for any test $t \in T$, there are $|S|/2$ potential solutions $s \in S$ such that $M(s,t) = 0$ and just as many for which $M(s,t) = 1$. Thus for any given test t, the expected value of M for a random potential solution that hasn't seen t yet depends on how many other potential solutions have seen t and what the outcomes were. We provide a generic characterization of this in the following section.

3.2 Large Spent Budget, Small Remaining Budget

When the budget spent so far consists of more than a couple of M-evaluations, the structure of the resulting histories can become more complex in terms of which potential solutions have interacted with which tests. We extend the treatment from the small examples above to these more generic cases; when discussing exploration mechanisms we still keep the remaining budget at just one M-evaluation.

3.2.1 Co-optimization

The issue of free lunch and optimality for the maxisum solution concept of co-optimization has first been investigated by Popovici and De Jong (2009), for output mechanisms only. As shown there and alluded to in the simple example of Section 3.1.1, given a history of evaluated interactions H, the expected value of g for a potential solution s is obtained by adding two components: 1) the sum of actual $M(s,t)$ values over those tests t seen by s as part of H; and 2) the sum of *expected* $M(s,t)$ values over tests t not seen by s. Due to the assumption of equally-likely metrics, the later is simply the product of the number of unseen tests and the average of V. To express this formally, assume T and V are finite, $|T| = m$, $T = \{t_1, \ldots, t_m\}$, $|V| = p$, $V = \{v_1, \ldots, v_p\}$. Given a history H and a potential solution s, let $0 \leq k \leq m$ denote the number of *distinct* interactions in H involving s: $\langle\langle s, t_{i_1}\rangle, v_{j_1}\rangle, \ldots \langle\langle s, t_{i_k}\rangle, v_{j_k}\rangle$, where $i_1, \ldots, i_k \in 1..m$, all distinct, and $j_1, \ldots, j_k \in 1..p$, $v_{j_\ell} = M(s, t_{i_\ell})$. Let the *current sum* of s given H, $g_{\mathrm{H}}(s) = v_{j_1} + \cdots + v_{j_k}$. Then the expected g-value of s given H is $\mathbb{E}(g(s)|\,\mathrm{H}) = g_{\mathrm{H}}(s) + (m-k)\cdot \mathrm{avg}(V)$. For brevity, we sometimes leave H implicit and simply write $\mathbb{E}(g(s))$. Notably, this value does not depend on any interactions involving potential solutions other than s. It also does not depend on which specific distinct k tests s has interacted with as part of H, only how many and what the outcomes of those interactions were. For a potential solution that is completely unevaluated (i.e., $k = 0$), the expectation is simply $m \cdot avg(V)$.

Output mechanisms are optimal if for any given H they output the potential solution s with the best $\mathbb{E}(g(s)|\,\mathrm{H})$ value; this may be a partially-evaluated potential solution ($k > 0$)

or a completely-unevaluated one. The computational cost of this, alluded to in Section 2.3.1, is small[13] : updating $\mathbb{E}(g(s))$ after each new M-evaluation involving s is trivial, as is determining the potential solution with the best $\mathbb{E}(g(\cdot))$-value; the cost of optimal output-selection is at most $O(|\,\mathrm{H}\,|)$. But the feasibility of implementation is dependent on knowing $\mathrm{avg}(V)$. Note that we do not need to know the actual value of m, since the the term $m \cdot \mathrm{avg}(V)$ is common to all estimates and thus doesn't impact the outcome of comparisons between them.

Exploration mechanisms have the nature of choices available to them influenced by the above-mentioned lack of dependencies, as follows. To assess an interaction choice, for each possible outcome in V we assess the resulting history and determine the potential solution with the best g-value estimate for that history, using the $\mathbb{E}(g(s)|\,\mathrm{H})$ formula in the previous paragraph; then we aggregate these values over the possible outcomes; under the assumption of all possible and equally-probable metrics, all outcomes for a given interaction are also equally likely, so the aggregation is via uniform averaging. These mathematical derivations reveal that for any interaction $\langle s,t\rangle$ that is new with respect to history H, the expected performance after evaluating $\langle s,t\rangle$ is independent of the specific t used, as long as s has not previously seen it (Popovici, 2017). Thus the only actual choice to be made is which potential solution to evaluate; the test can be picked randomly amongst those yet unseen by that solution (can be one seen by other potential solutions). For a history containing measured interactions involving α distinct potential solutions, the number of choices is $\alpha+1$: one of α partially-evaluated potential solutions or a random completely-unevaluated one. And the computational cost of assessing one choice is the sum of p optimal output mechanism costs (as described in the previous paragraph), one for each possible outcome in V. This is considerably more expensive than the optimal output mechanism, though explicitly implementing it could still be tractable for small values of p and α. Furthermore, such explicit implementation might not be necessary in some situations: for domains where V is symmetric around 0, if the history H does not contain any fully-evaluated potential solutions (ones that have seen all m tests), then the best choice is mathematically-provable to be evaluating a new interaction for a still-testable potential solution with the best $\mathbb{E}(g(\cdot))$ (Popovici, 2017)—and the ensuing exploration-decision cost is as small as described above for the optimal output mechanism.

3.2.2 Supervised Learning

Let us now return to the case of binary classification. Given a history of evaluated interactions H, the expected value of g for a potential solution s is still obtained by adding the same two components as in co-optimization: the sum of $M(s,t)$ values known from the history ($g_{\mathrm{H}}(s)$) and the sum of expected $M(s,t)$ values. The difference is that for the second component, the expected value of $M(s,t)$ varies with t.

To see this, consider the example in Table 6. For a binary classification domain with $|X| = m$, assuming a one-to-one relationship between S and Y^X, the total number of potential solutions is 2^m. For any test and any metric M, half of these potential solutions will produce an M-value of 1, while the other half will produce an M-value of 0. As part of the history H, test t has interacted with potential solutions s and s', both times resulting

13. For other co-optimization solution concepts, like maximin, output-selection cost can be much larger.

	M(,.)									
	t	t'	t''

E(.) = $\frac{2^{m-1}-\beta 1}{2^m-\beta}$	$\frac{2^{m-1}-2}{2^m-2}$	$\frac{2^{m-1}}{2^m-1}$	$\frac{2^{m-1}-1}{2^m-1}$									

Table 6: Examples of computing expected g-values for potential solutions for a given history. Binary classification domain with $|X| = m > 4$, $|Y| = 2$ and $3 \leq |D| < m$, with $\mathrm{D} \supseteq \{(t,n),(t',n),(t'',y)\}$ and history $\mathrm{H} = [\langle\langle s,t\rangle,y\rangle, \langle\langle s',t\rangle,y\rangle, \langle\langle s',t'\rangle,n\rangle, \langle\langle s'',t''\rangle,n\rangle]$. $\mathbb{E}(\cdot)$ is shorthand notation for $\mathbb{E}(\cdot|\,\mathrm{D},\mathrm{H})$, whether applied to tests or to g-values for potential solutions.

in value 1. Thus of the remaining 2^m-2 potential solutions that have not been evaluated with t yet, there are only $2^{m-1}-2$ left that can produce a value of 1, while the other 2^{m-1} give a value of 0. So the expected value of $M(\cdot,t)$ for any potential solution other than s and s' is $\mathbb{E}(t|\,\mathrm{D},\mathrm{H}) = \mathbb{E}(t) = \frac{(2^{m-1}-2)\cdot 1+2^{m-1}\cdot 0}{2^m-2} = \frac{2^{m-1}-2}{2^m-2}$. In general, if as part of H a test has interacted with β other potential solutions, of which β_1 produced an outcome of 1, then the probability of observing 1 upon evaluating another potential solution with this test is $\frac{2^{m-1}-\beta_1}{2^m-\beta}$ and the probability of observing 0 is $\frac{2^{m-1}-(\beta-\beta_1)}{2^m-\beta}$; so the expected value for evaluating a new interaction with that test is $\frac{2^{m-1}-\beta_1}{2^m-\beta}\cdot 1 + \frac{2^{m-1}-(\beta-\beta_1)}{2^m-\beta}\cdot 0 = \frac{2^{m-1}-\beta_1}{2^m-\beta}$. $\mathbb{E}(t')$ and $\mathbb{E}(t'')$ in Table 6 were also derived using this formula. The expected value for any test not seen by any potential solution is still $\mathrm{avg}(V) = 0.5$, which can also be derived as $\frac{2^{m-1}-0}{2^m-0}$. This is regardless of whether such a test is part of the data D or not. Then the g-value estimates for potential solutions are $\mathbb{E}(g(s)|\,\mathrm{D},\mathrm{H}) = \mathbb{E}(g(s)) = M(s,t)+\mathbb{E}(t')+\mathbb{E}(t'')+(m-3)\cdot 0.5$ and respectively $\mathbb{E}(g(s'))$, $\mathbb{E}(g(s''))$ and $\mathbb{E}(g(s_{new}))$ shown in Table 6. More thorough mathematical derivations of these quantities can be found in Online Appendix A.2.

Output mechanisms are optimal if they output the potential solution with minimum $\mathbb{E}(g(\cdot))$. To implement that, the estimates are inexpensive to compute, albeit more involved than for co-optimization: for each new $M(s,t)$ evaluation, first update the expected value for $\mathbb{E}(t)$, then update $\mathbb{E}(g(s))$ as well as $\mathbb{E}(g(\cdot))$ for any other potential solutions that haven't yet seen t (including a representative completely-unevaluated one) then re-determine the potential solution with the best g-value estimate, for a total output-selection cost of $O(|\,\mathrm{H}\,|)$. However, these computations do require knowing the value of m and care must be taken to avoid potential computer precision errors for large m.

Exploration mechanisms are exemplified in Table 7, which shows how Table 5's performance estimates for the various exploration choices can be re-derived using a more compact computation approach: for a given choice, for each of the two possible outcomes, consider the resulting history and compute $\mathbb{E}(g(\cdot))$ for all potential solutions involved, using

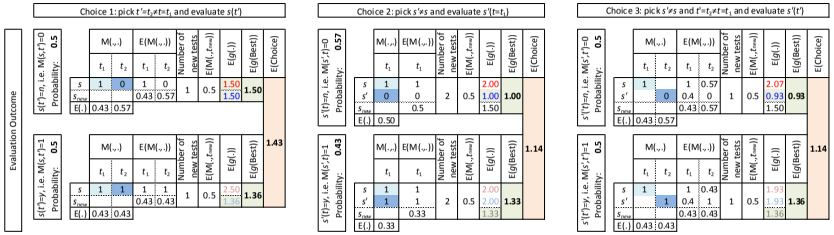

Table 7: Examples of computing expected g-values for potential solutions after various exploration choices and outcomes. Binary classification domain with $X = \{t_1, t_2, t_3\}$, $Y = \{y, n\}$, data $\mathrm{D} = \{(t_1, n), (t_2, n)\}$ and history $\mathrm{H} = [\langle\langle s, t_1\rangle, y\rangle]$. Font style and green & orange cell shading link to the respective cells in Table 5. Light blue shading corresponds to the current history and dark blue shading shows the next interaction chosen for evaluation and its M-outcome. $\mathbb{E}(\cdot)$ is shorthand notation for $\mathbb{E}(\cdot \,|\, \mathrm{D}, \mathrm{H})$. For a given s and t, the expected value $\mathbb{E}(M(s,t))$ is equal either to the actual value of $M(s,t)$, if it has been evaluated, or to $\mathbb{E}(t)$ otherwise.

formulas like the ones in Table 6; then take the best (minimum) estimate; then use the probabilities of the two outcomes to compute a weighted average of the best estimates.

For example, consider the middle panel of Table 7, where $m = 3$ and we choose to evaluate a new potential solution s' with the test $t = t_1$, which has previously interacted only with s (so $\beta = 1$) and produced a value $M(s,t) = 1$ (so $\beta_1 = 1$). The probability of outcome 1 for $M(s', t_1)$ is $\frac{2^2-1}{2^3-1} = \frac{3}{7} \approx 0.43$ and the probability of outcome 0 is $\frac{2^2-0}{2^3-1} = \frac{4}{7} \approx 0.57$. For outcome 1 the best g-value estimate is 1.33 for s_{new} and for outcome 0 it is 1 for s', resulting in an expected performance of $1.14 = 1.33 \cdot 0.43 + 1 \cdot 0.57$ for the $\langle s', t_1\rangle$ exploration choice.

For this particular example, the expected performance for evaluating a new potential solution s' was the same whether using the test t_1 already seen by s or the new test t_2. This is not the case in general, as exemplified in Table 8 for a slightly larger domain and history. When choosing to evaluate a new potential solution s'', we get different expected performance whether we use the test t previously seen by s and s', the test t' previously seen by s' only or a new test t'' not previously seen by any potential solution. Similarly, if choosing to further evaluate s, we get different expected performance whether we use the test t' previously seen by s' or a new test t''.

Thus for binary classification the number of relevant choices available for the exploration mechanism for a given history is considerably larger than in co-optimization. If a history H contains η distinct interactions involving α distinct potential solutions and γ distinct tests ($\eta \leq \alpha \cdot \gamma$), then there could be as many as $(\alpha+1) \cdot (\gamma+1) - \eta$ relevant choices, as opposed to at most $\alpha + 1$ in co-optimization. The computational cost of assessing one choice is the sum of two optimal output mechanism costs, one for each of the possible outcomes $\{y, n\}$. Consequently, the total exploration-decision cost is significantly larger than the optimal output mechanism cost, though still polynomial with a naive explicit implementation of $\mathrm{O}(|\,\mathrm{H}\,|^3)$, which could be tractable for moderate-size histories.

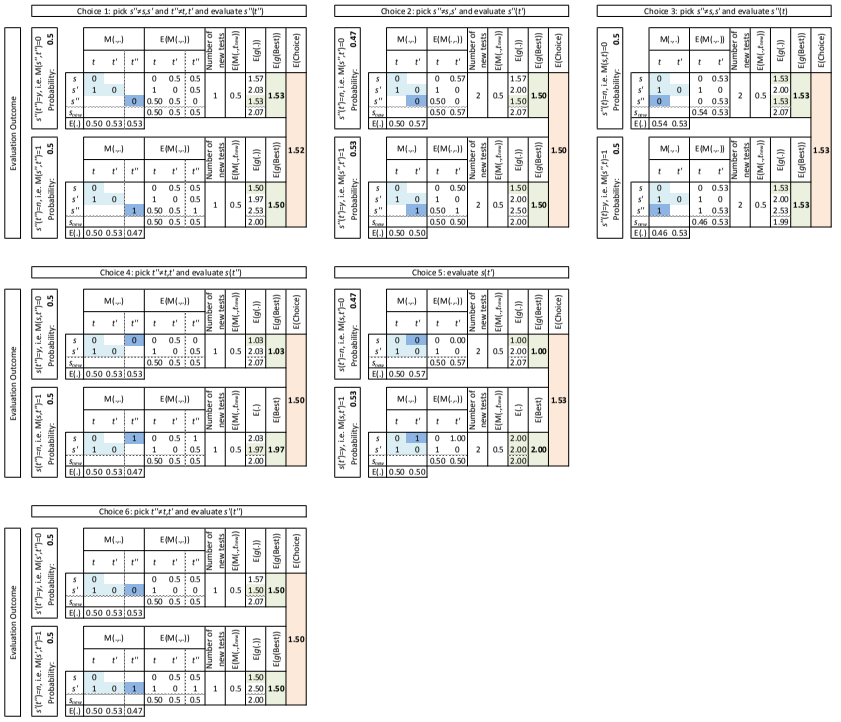

Table 8: Examples of how the choice of test impacts the expected resulting performance. Binary classification domain with $|X| = m = 4$, $Y = \{y, n\}$, data $\mathrm{D} = \{(t, n), (t', n), (t'', y)\}$ and history $\mathrm{H} = [\langle\langle s, t\rangle, n\rangle, \langle\langle s', t\rangle, y\rangle, \langle\langle s', t'\rangle, n\rangle]$. Bold font shows which values and probabilities were aggregated. Green cell shading indicates where the best (minimum) value is coming from, orange cell shading highlights the expected performance for each exploration choice, light blue shading corresponds to the current history and dark blue shading shows the next interaction chosen for evaluation and its M-outcome. $\mathbb{E}(\cdot)$ is shorthand notation for $\mathbb{E}(\cdot \,|\, \mathrm{D}, \mathrm{H})$. For a given s and t, the expected value $\mathbb{E}(M(s,t))$ is equal either to the actual value of $M(s,t)$, if it has been evaluated, or to $\mathbb{E}(t)$ otherwise. $\mathbb{E}(g(s))$ is equal to the sum of the $\mathbb{E}(M(s,t))$ over tests seen by any potential solution plus the number of new tests times $\mathbb{E}(M(\cdot, t_{new})) = \mathbb{E}(t_{new}) = 0.5$.

Since math-based reductions of exploration-decision costs have been proven for co-optimization, we did a preliminary analysis to see if the same were possible for binary classification. We were able to prove a couple of ways to analytically prune the set of relevant exploration choices while maintaining optimality. Specifically, if t_{new} is a test present in the data but previously unseen by any potential solution, then out of the exploration choices $\langle s, t_{new}\rangle, s \in S$ we only need to assess the expected performance for $\langle s^{best}, t_{new}\rangle$, where s^{best} is the potential solution with the best expectation $\mathbb{E}(g(\cdot))$ for the current H (Theorem 1 in Appendix A.3). Moreover, if s^{best} is a completely-unevaluated potential solution, then out of all choices of type $\langle s^{best}, t\rangle, t \in T$ we only need to assess $\langle s^{best}, t^*\rangle$ for a t^* easily-identifiable as maximizing the quantity $\mathbb{E}(t) \cdot \big(1 - \mathbb{E}(t)\big) \cdot \frac{2^{m-\beta}}{2^{m-\beta}-1}$, where β is as in Section 3.2.2, the number of potential solutions seen by t (Theorem 2 in Appendix A.3).

While helpful, these results allow us to prune at most $\alpha + \gamma$ exploration choices, which in the worst case (if $\alpha \cdot \gamma \gg \eta$) could still leave us with $\mathrm{O}(|\,\mathrm{H}\,|^2)$ interaction choices to be assessed, each costing $\mathrm{O}(|\,\mathrm{H}\,|)$. Further research is needed to determine if additional analytical pruning can be performed. Moreover, these results only concern the interaction choice optimizing the expected g-value for the best output right after evaluating that interaction, i.e., a remaining budget of $n = 1$. Which interaction choice is optimal could vary with n and we briefly discuss this case in the next section; the pruning results above were obtained by first generalizing to the formulas below and then instantiating them with $n = 1$.

3.3 Large Remaining Budget

Since output mechanisms are not impacted by remaining budgets and we have already studied large spent budgets in Section 3.2, in this section we focus on exploration mechanisms. Their optimality and free lunch for large remaining budgets was previously investigated in co-optimization for the maxisum (Popovici, 2017) and maximin (Popovici and Winston, 2015) solutions concepts. Following the reasoning from those works, exemplified for $n = 1$ in the previous section, the expected performance for an optimal exploratory algorithm for binary classification, given data D, current history H and remaining budget n, denoted by $\Phi_{\mathrm{a}}^{\min}(\mathrm{D}, \mathrm{H}, n)$, can be recursively expressed as:

$$\Phi_{\mathrm{a}}^{\min}(\mathrm{D}, \mathrm{H}, 0) = \min_{s \in S} \mathbb{E}(g(s)|\,\mathrm{D}, \mathrm{H}),$$

$$\begin{aligned}\Phi_{\mathrm{a}}^{\min}(\mathrm{D}, \mathrm{H}, n) &= \min_{\langle s,t\rangle \in \mathcal{E}'(\mathrm{D},\mathrm{H})} \mathop{\mathbb{E}}_{v \in \{0,1\}} \Phi_{\mathrm{a}}^{\min}(\mathrm{D}, \mathrm{H} \oplus \langle\langle s, t\rangle, v\rangle, n-1) \\ &= \min_{\langle s,t\rangle \in \mathcal{E}'(\mathrm{D},\mathrm{H})} \sum_{v \in \{0,1\}} P(M(s,t) = v|\,\mathrm{D}, \mathrm{H}) \cdot \Phi_{\mathrm{a}}^{\min}(\mathrm{D}, \mathrm{H} \oplus \langle\langle s, t\rangle, v\rangle, n-1)\end{aligned}$$

where

- $\mathcal{E}'(\mathrm{D}, \mathrm{H})$ represents the set of all new interactions that could be evaluated next;
- the probabilities $P(M(s,t) = v|\,\mathrm{D}, \mathrm{H})$ of outcomes 0 and 1 are as described at the beginning of Section 3.2.2;
- $\oplus$ denotes adding a measured interaction to a history; and
- the subscript 'a' refers to 'algorithms'.

In words, the optimal performance for a given history and budget is dependent on the optimal performance for histories lengthened by one and budgets decreased by one; it is obtained by optimizing over interaction choices the expected value, aggregated over possible outcomes for the interaction, of the optimal performance for the resulting lengthened history and reduced budget.

Going back to the expression of $\mathbb{E}(g(s))$ from Table 6, note that it can be re-written as $M(s,t) + \mathbb{E}(t') + \mathbb{E}(t'') + (|D| - 3) \cdot 0.5) + (m - |D|) \cdot 0.5$. The last term is the expected out-of-sample (OTS) error and is the same for all potential solutions: this is the no free lunch of Wolpert (1992). The sum of the other terms represents the *expected* in-sample error. Note this differs from traditional exploratory approaches to supervised learning, where each considered potential solution is evaluated with all tests in the data and therefore the actual in-sample error is known. Such an approach can still be used if the budget n is large in relation to the size of the data D, but given the existence of exploration mechanism free lunch, this could conceivably be a suboptimal approach.

To show that this can indeed happen, we apply the above recursive formula to a small example. Consider a domain with 3 inputs ($|X| = m = 3$) and a situation where we are given 2 data points ($|\,\mathrm{D}\,| = 2$) and a budget of 2 M-evaluations. Whenever output needs to be produced, we use the optimal output mechanism, which chooses the potential solution with minimum $\mathbb{E}(g(\cdot))$ given the history at that point. The optimal exploration mechanism takes into account the outcome of the first interaction in order to determine what the second interaction should be; the respective aggregate performance, given by the above formula, is ≈ 1.071. Full evaluation simply evaluates a potential solution with the two available tests and there are 4 equally-likely combinations of outcomes (11, 01, 10, 00); averaging the respective minimum $\mathbb{E}(g(\cdot))$ values (1.357, 1.5, 1.5, 0.5) yields an aggregate performance of ≈ 1.214, which is strictly worse.

However, implementing the optimal exploration mechanism appears daunting for large budgets n, as it seemingly involves solving a very time-consuming recursive optimization problem. Interestingly, the co-optimization studies of optimal exploration mechanisms for maxisum (Popovici, 2017) and maximin (Popovici and Winston, 2015) showed that for some situations an analytical solution to this recursive optimization can be proven, making the optimal algorithm straightforward to implement, with low exploration-decision and output-selection costs of $\mathrm{O}(|\,\mathrm{H}\,|)$.

The preliminary analysis we performed for binary classification so far only yielded the pruning results for $n = 1$ presented in the previous section, which could still leave us with more than one choice, requiring recursing down to $n = 0$. This is not an issue for such a small n, but for large n the exponential cost of recursive optimization can be infeasible. The additional complexity introduced in binary classification by the interdependence between different potential solutions makes it unclear at the moment whether a full analytical solution for the recursive optimization (or at least some amount of pruning) can be proven for large remaining budgets—and thus whether the costs of the optimal exploration mechanism are feasible or not. This serves to highlight the importance of acknowledging *all* types of costs, as optimizing with respect to one type (e.g., metric-evaluation costs) can incur another (e.g., exploration-decision costs).

3.4 Discussion

The above analysis made two core assumptions: 1) that all functions in Y^X are equally likely; and 2) that there is a of one-to-one mapping between S and Y^X. Additionally, algorithms were constrained to use only a limited budget of M-evaluations; such algorithms might not know the actual in-sample error (error on the data D) for all/any of the potential solutions considered and thus must decide what to output given only such incomplete information.

For this setup, given a certain budget n of M-evaluations, an optimal algorithm is one that has the smallest average over all functions in Y^X of the error on the data D (in-sample error) for the potential solution outputted after using up the budget; and there is free lunch, in that some algorithms produce strictly smaller such average values than others. Unfortunately, this is not useful for generalization, since under the above assumptions, all potential solutions have the same average over functions of OTS-error (error outside the data D): $(m - |\,\mathrm{D}\,|) \cdot 0.5$.

In practice though, we often have reason to believe that the first assumption is not true, rather that there is a non-uniform P on Y^X. But if we do not know anything more specific about P besides its existence, this in itself is not sufficient reason for dismissing OTS no free lunch, as there are as many distributions over metrics for which one algorithm is aggregately-better than the other as there are distributions where the opposite relation holds (Wolpert, 1992). On the other hand, if the knowledge we have about P and the way we choose S allow us to express theoretical Bayes estimates, then we can perform the same type of analysis as presented here to derive and investigate algorithms that are aggregately-optimal from a generalization perspective as well.

Here are several ways in which this could become useful. First, it could be used in passive supervised learning to provide a new approach for dealing with data sets so large that it is too costly to perform evaluation with their entire contents for every potential solution considered. Rather than performing instance selection (Reinartz, 2002) and then performing full evaluation using the selected subset of examples, computational resources could be used more effectively by selecting at a more granular level, namely that of interactions $\langle s, t\rangle$ rather than that of examples (tests) t.

Second, it could be extended for usage in active learning, as a direct exploratory approach instead of the current methods which perform retraining after new labels are observed. To achieve this, the analysis will have to be adapted to take into account labeling costs; whether a new interaction $\langle s, t\rangle$ will incur both an M-evaluation cost and a labeling cost or only the former depends on whether or not the test t has been previously seen by other potential solutions and thus already labeled. This could be formalized as having two different budgets, one for labeling and one for M-evaluations, or, if both costs are in fact measured in the same "currency", have a single budget and allow the algorithm to determine the best way to allocate it to the two activities.

Last but not least, recall from the discussion on page 11 that some exploratory approaches do not rely on the error function having a closed form with easily computable derivative and therefore they also do not require that the data be in (or transformed into) tabular form. The optimal algorithms described in Section 3 have this desirable property and thus would be applicable to supervised learning for more complex data structures.

4. Conclusions

Metaphorically speaking, this paper laid out a deciphered Rosetta Stone for the languages of supervised learning and co-optimization, then used it to translate free lunch research from the latter field to the former. While practical optimal algorithms based on free lunch are still a ways away, the hope of this presentation is that the different perspective provided by co-optimization could spark ideas for new types of heuristics for supervised learning (promising directions were described in Section 3.4) and also that this translation will become only one of many, the beginning of cross-pollination of ideas between the fields.

Several paths for future research have already been pointed out: reducing the time complexity of optimal exploration mechanisms in the base setup comprising uniformity assumptions, expanding to non-uniform distributions and adapting to the multiple types of costs incurred in active learning. Additionally, there are yet more fields concerned with similar problems and constructing similar mappings for them could lead to further advances; the most obvious ones are reinforcement learning, design of experiments and statistical learning in general.

Editor: Mohammad Emtiyaz Khan

Abstract

The R package GFA provides a full pipeline for factor analysis of multiple data sources that are represented as matrices with co-occurring samples. It allows learning dependencies between subsets of the data sources, decomposed into latent factors. The package also implements sparse priors for the factorization, providing interpretable biclusters of the multi-source data.

Keywords: Bayesian latent variable modelling, biclustering, data integration, factor analysis, multi-view learning

1. Introduction

The need for intelligent data integration and analysis methods is getting increasingly common. We often encounter connected measurements from multiple data sources, possessing complex shared variation and structured noise. Modelling the relationships within this kind of a data collection, and using them for prediction, is a challenging problem. Two existing R packages, CCAGFA (Klami et al., 2015) and CMF (Klami et al., 2014), provide good tools for this[1], but remain limited in their use for two reasons: the packages do not provide a complete data analysis pipeline, and they assume the structure present within data sources to be dense, that is, present in all the samples and the features. This assumption is often unrealistic, and we provide package GFA to allow sparse factorization of multi-source data, along with tools from data preprocessing to model interpretation.

Extending from the classical Bayesian matrix factorization work, *group factor analysis* (GFA) (Virtanen et al., 2012; Klami et al., 2015) assumes that data matrix $\mathbf{Y}^{(m)} \in \mathbb{R}^{N \times D_m}$ can be approximated with $\mathbf{X}\mathbf{W}^{(m)\top}$, where the latent variable matrix $\mathbf{X} \in \mathbb{R}^{N \times K}$ describes the observed data in a lower dimensional space, and the projection matrix $\mathbf{W}^{(m)} \in \mathbb{R}^{D_m \times K}$ gives a mapping between the latent space and the data space of the mth source. A key aspect of the model definition is a group sparse prior for the $\mathbf{W}$ matrices: the association of a data matrix to component k is based on evidence in the data. Allowing only a subset of the components to explain a data matrix results in the posterior identifying relationships between any subset of the data sources. The spike-and-slab sparsity priors used to achieve this are described by Bunte et al. (2016). Alternative priors aiming for similar goals have been presented by Zhao et al. (2016)[2], though not containing any tools for preprocessing or model interpretation.

1. Available at `https://cran.r-project.org/package=CCAGFA` and `https://cran.r-project.org/package=CMF` .

2. The GFA Package

GFA implements a Gibbs sampling scheme for inferring the posterior of group factor analysis, and it is available for R at `https://cran.r-project.org/package=GFA`. It has been designed to contain the key elements needed for the data analysis task of factorization of multiple data sources.

2.1 Model Options and Initialization

The package includes a variety of model options for the user to choose from, depending on the application requirement. The default priors assume latent factors that are dense along the sample space, and group sparsity along the feature space (Klami et al., 2015). Using them, the posterior given data `Y` can be inferred by:

```
opts <- getDefaultOpts()
res <- gfa(Y,opts)
```

Another main use of the package is biclustering of multiple data sources, which is done by using element-wise sparse priors for the matrices $\mathbf{X}$ and $\mathbf{W}$. This approach has been presented in Bunte et al. (2016), and is usable via `getDefaultOpts(bicluster=TRUE)`.

The input data `Y` given to function `gfa()` is a list of matrices (that is, data sources) that each have an equal number of rows. Alternatively, if there are several data sources with the same columns, it is possible to input a list with two elements: the sources with paired rows, and the sources with paired columns. Other important options include which parts of the data collection share the scale of each component or the strength of the residual noise (by default each data source for both), and whether the convergence of the sampling chain should be estimated (based on the Geweke diagnostic of its reconstruction). A full description of the possible options is given in the documentation of the function `getDefaultOpts()`.

2.2 Missing Value Prediction

GFA can be used for prediction by simply including the missing matrix elements as `NA`s. The model parameters are sampled based on the observed data only, and the missing values are predicted with the function `reconstruction()`. If the data samples are acquired in a sequential manner, it is alternatively possible to i) infer the models parameters on the first batch, and ii) using fixed projections, quickly predict missing data sources of the second batch based on the observed data sources. Both the approaches use learned relationships between the data sources (shared components) to predict from one to other, and provide predictive distributions along with point estimates.

JMLR 18(39):1-5, 2017

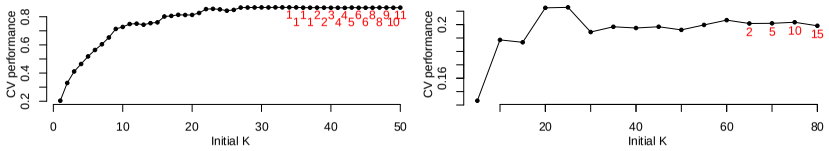

Figure 1: Illustrating model complexity selection with GFA on synthetic data (left) and GDSC data set (right), showing the cross-validated predictive performance (Spearman correlation), and the number of empty components (red numbers) as a function of initial model complexity K. High initial K allows the components to produce a flexible noise model, as opposed to low initial K.

3. Usage

In addition to inferring model parameters and predicting missing values, the data analysis pipeline typically needs additional steps presented here.

3.1 Preprocessing

The input data can be normalized in different ways with `normalizeData(Y)`. As GFA aims to explain maximal variance with a compact set of parameters, and has no separate assumptions for the bias (mean) of features, centering the data is advised. Furthermore, the higher the variance of features (or data sources), the larger their effect to the model parameters. If the user considers this to be desired behavior, no scaling should be done. On the other hand, if the features (or data sources) are deemed approximately equally important, they should be scaled accordingly.

3.2 Model Complexity Selection

The priors of GFA are able to infer the model complexity. This is achieved by initializing the model with a high number of components K (default $\min(N, \sum_m D_m)/2$) and allowing the sparsity prior to prune out excessive components (explaining only little variance). As complexity selection is a difficult task in general, we recommend using any prior information of the data, if available, when selecting the initial K. Here it should be noted that the components can model (structured) noise in addition to the signal of interest, inducing a flexible noise model. If this is not desired, `informativeNoisePrior()` can be used to specify how large proportion of variance is expected to be explained with the components; in effect causing weaker (structured noise) components to be explained by the simple residual noise. The package issues a warning if the automatic model complexity selection does not seem to work as intended, for example if no components are pruned.

We demonstrate model complexity selection with two examples in Figure 1: a synthetic data set, and a cancer cell line data set by Genomics of Drug Sensitivity in Cancer project (GDSC) (Yang et al., 2013). The complexity of the synthetic data set is overestimated slightly, resulting in accurate predictions as long as initial K is above the true $K = 32$. With the GDSC data set, where the true model complexity is unknown, initial K at 20 or 25 gives the best predictions, but the full model is not far behind.

3.3 Interpreting the Model

The inferred factorization explains dependencies in the data collection through K components. The factorization can be visualized using function `visualizeComponents()`, which shows the component activities in the data sources. Shared components imply predictability from a data source to another. The function can also show the full parameter matrices $\mathbf{X}$ and $\mathbf{W}$, as well as their effect, and the effect of individual components, in the data space.

3.4 Robustness Analysis

As in factor analysis in general, the factorization GFA aims to infer is unidentifiable, resulting in an extremely multi-modal posterior.[3] Thus consideration is needed if a user wishes to analyze multiple factorizations (in this case sampling chains) jointly, as they are not likely to be identical. To the best of our knowledge, there are no sampling methods that would in practice converge to the true multi-modal posterior with high-dimensional data. To this end, we provide function `robustComponents()` which uses a correlation-based procedure to analyze which components occur frequently in different GFA sampling chains. This approach can be used to obtain robust factorizations for noisy data collections, where the components explain only small parts of the variation, resulting in uncertain estimates.

3.5 Examples

The package manual contains simplified examples demonstrating function usage. Besides this, we provide the following three demonstrations:

- demo(GFApipeline): Simple illustration of the GFA pipeline.
- demo(GFAexample): Elaborate illustration of the GFA model on simulated data.
- demo(GFAdream): Replication of Bunte et al. (2016) results (requiring data download, which is instructed).

4. Discussion

GFA allows inferring the relationships between multiple co-occurring data matrices by reconstructing them with group sparse priors for the projection matrices. It finds a decomposition with components that are specific to the data sources, shared between them all, or shared between any subset of them. This kind of sparsity is beneficial for exploratory data analysis and integration. Our GFA package covers essential tools ranging from preprocessing to modelling assumptions and from robustness analysis to interpreting the model.

Acknowledgments

This work was financially supported by the Academy of Finland (Finnish Center of Excellence in Computational Inference Research COIN; grants 295503 and 292337 to MA and SK). We acknowledge the computational resources provided by Aalto Science-IT project.

3. Unimodal posterior could be achieved in special cases, given limiting identifiability constraints.

Abstract

GPflow is a Gaussian process library that uses TensorFlow for its core computations and Python for its front end.[1] The distinguishing features of GPflow are that it uses variational inference as the primary approximation method, provides concise code through the use of automatic differentiation, has been engineered with a particular emphasis on software testing and is able to exploit GPU hardware.

1. GPflow and TensorFlow are available as open source software under the Apache 2.0 license.

1. Existing Gaussian Process Libraries

Gaussian processes (GPs) are versatile Bayesian nonparametric models using a prior on functions (Rasmussen and Williams, 2006). There are now many publicly available GP libraries ranging in scale from personal projects to major community tools. We do not here give detailed consideration to all libraries, regrettably neglecting, for instance, those that only support Gaussian likelihoods (Ambikasaran et al., 2014) or do not make provision for scalability (Pedregosa et al., 2011). The influential GPML toolbox (Rasmussen and Nickisch, 2010) uses *MATLAB*. It has been widely forked. A key reference for our particular contribution is the GPy library (GPy, since 2012), which is written primarily using Python and Numeric Python (NumPy). GPy has an intuitive object-oriented interface. Another relevant GP library is GPstuff (Vanhatalo et al., 2013) which is also a *MATLAB* library.

2. Objectives for a new library

GPflow is motivated by a set of goals. The software is designed to be fast, particularly at scale. Where approximation inference is necessary we want it to be accurate. We aim to support a variety of kernel and likelihood functions. Another goal is that the implementations are well tested. The software should be made easy to use by an intuitive user interface. Finally it should be easy to extend the software. We argue that there is a way to better meet these simultaneous objectives than existing packages and that it is realised in GPflow.

3. Key features for meeting the objectives

To best meet the key goals of our library, we were led to a project that had all of the following distinguishing features:

(i) The use of variational inference as the primary approximation method to meet the twin challenges of non-conjugacy and scale (Matthews, 2016).

(ii) Relatively concise code which uses automatic differentiation to remove the burden of gradient implementations.

(iii) The ability to leverage GPU hardware for fast computation.

(iv) A clean object-oriented Python front end.

(v) A dedication to testing and open source software principles.

Table 1 gives a summary of which GP libraries possess the distinguishing features we have highlighted. The GPflow interface and Python architecture are heavily influenced by GPy. An important difference between GPflow and GPy is that GPflow uses TensorFlow for its core computations rather than numeric Python. This difference significantly affects the general requirements of the architecture. The GPU functionality in GPy is currently limited to CUDA code for the GPLVM (Dai et al., 2014). By contrast the GPflow implementation is targeted at a broad variety of GPU capability.

Library	Sparse variational inference	Automatic differentiation	GPU demonstrated	OO Python front end	Test coverage
GPML	✓	✗	✗	✗	N\R
GPstuff	Partial	✗	✗	✗	N\R
GPy	✓	✗	GPLVM	✓	49%
GPflow	✓	✓	SVI	✓	99%

Table 1: A summary of the features possessed by existing GP libraries at the time of writing. OO stands for object-oriented. In the GPU column GPLVM denotes GP latent variable model and SVI is Stochastic variational inference. N\R denotes not reported.

Having established a desirable set of key design features, the question arises as how best to engineer a GP library to achieve them. A central insight here is that many of the features we highlight are well supported in neural network libraries. Of the available libraries we use TensorFlow (Abadi et al.), as discussed in the next section.

4. Contributing GP Requirements to TensorFlow

In TensorFlow (Abadi et al.) a computation is described as a directed graph where the nodes represent *Operations* (*Ops* for short) and the edges represent *Tensors*. As a directed edge, a Tensor represents the flow of some data between computations. Ops are recognisable mathematical functions such as addition, multiplication etc. *Kernels* (in an unfortunate collision in terminology with the GP literature) are implementations of a given Op on a specific device such as a CPU or GPU. Like almost all modern neural network software, TensorFlow comes with the ability to automatically compute the gradient of an objective function with respect to some parameters. The TensorFlow open source implementation comes with a wealth of GPU kernels for the majority of Ops.

Although we gained significantly from using TensorFlow within GPflow, there were some capabilities that were not yet present in the software which were required for our purposes. We therefore added this functionality to TensorFlow. GP software needs the ability to solve systems of linear equations using common linear algebra algorithms. The differentiation of computational graphs that used the Cholesky decomposition required a new Op, which we contributed. The main part of the code was a C++ implementation of the blocked Cholesky algorithm proposed by Murray (2016). We also contributed code that enabled GPU solving of matrix triangular systems, which in some cases is the bottleneck for approximate inference.

5. Details of GPflow

GPflow supports exact inference where possible, as well as a variety of approximation methods. One source of intractability is non-Gaussian likelihoods, so it is helpful to categorize the available likelihood functionality on this basis. Another major source of intractability is the adverse scaling of GP methods with the number of data points. To this end we support 'variationally sparse' methods which ensure that the approximation is scalable and close

	Gaussian likelihood	Non-Gaussian likelihood (variational)	Non-Gaussian likelihood (MCMC)
Full covariance	GPR	VGP	GPMC
Variational sparsity	SGPR	SVGP	SGPMC

Table 2: A table showing the inference classes in GPflow. Relevant references are VGP (Opper and Archambeau, 2009), SGPR (Titsias, 2009), SVGP (Hensman et al., 2013, 2015b) and SGPMC (Hensman et al., 2015a).

in a Kullback-Leibler sense to the posterior (Matthews et al., 2016). Whether or not a given inference method uses variational sparsity is another useful way to categorize it. The inference options, which are implemented as classes in GPflow, are summarized in Table 2. Note that all the MCMC based inference methods support a Bayesian prior on the hyper-parameters, whereas all other methods assume a point estimate. Our main MCMC method is Hamiltonian Monte Carlo (Neal, 2010).

We now discuss some architectural considerations. The whole Python component of GPflow is intrinsically objected-oriented. The code for the various inference methods in Table 2 is structured in a class hierarchy, where common code is pulled out into a shared base class. The object-oriented paradigm, whilst very natural for the Python layer of the code, has a different emphasis to that of a computational graph which is arguably closer to a functional concept. The largely functional computational graph, and a object-oriented interface need to live cleanly together in GPflow. This is achieved through the Param class that allows parameters to be both properties of an object that can be manipulated as such and Variables in a TensorFlow graph that can be optimized.

A number of steps have been taken to ensure project quality and usability. All GPflow source code is openly available on GitHub at `http://github.com/GPflow/GPflow`. The web page uses continuous integration to run an automated test suite. The test code coverage for GPflow is higher than similar packages where the code coverage statistics are published, achieving a level of 99% (Table 1). A user manual can be found at `http://gpflow.readthedocs.io`.

6. Timed Experiments

As a scenario, we studied training a multiclass GP classifier on MNIST using stochastic variational inference (Hensman et al., 2015b,a).[2] We compared against GPy. None of the other libraries discussed support this algorithm. Functionally, the algorithms are nearly identical in GPflow and GPy. We did a series of trials measuring the time each package took to perform 50 iterations of the algorithm. The trials included a set of CPU experiments, where we varied the number of threads available to the two packages. For GPflow, we also measured the effect of adding a GPU on top of the maximal number of CPU threads considered. GPy does not presently have a GPU implementation of this algorithm. We

2. Code for these timing experiments can be found at `http://github.com/gpflow/GPflowBenchmarks`

used a Linux workstation Intel Core I7-4930K CPU clocked at 3.40GHz an NVIDIA GM200 Geforce GTX Titan X GPU.

The results of the timing experiments are shown in Figure 1. For the CPU experiments, the speeds for GPflow and GPy are similar. It can be seen that the increase in speed from adding a GPU is considerable. These gains could make a significant difference to the work flow of a researcher on this topic. Based on the measurements we have made, training using GPflow with 6 CPU threads would take approximately 41 hours or just under 2 days. Adding a GPU would currently reduce the training time to about 5 hours.

Abstract

Information diffusion in online social networks is affected by the underlying network topology, but it also has the power to change it. Online users are constantly creating new links when exposed to new information sources, and in turn these links are alternating the way information spreads. However, these two highly intertwined stochastic processes, information diffusion and network evolution, have been predominantly studied *separately*, ignoring their co-evolutionary dynamics.

We propose a temporal point process model, COEVOLVE, for such joint dynamics, allowing the intensity of one process to be modulated by that of the other. This model allows us to efficiently simulate interleaved diffusion and network events, and generate traces obeying common diffusion and network patterns observed in real-world networks such as Twitter. Furthermore, we also develop a convex optimization framework to learn the parameters of the model from historical diffusion and network evolution traces. We experimented with both synthetic data and data gathered from Twitter, and show that our model provides a good fit to the data as well as more accurate predictions than alternatives.

Keywords: social networks, information diffusion, network structure, co-evolutionary dynamics, point processes, Hawkes process, survival analysis

1. Introduction

Online social networks, such as Twitter or Weibo, have become large information networks where people share, discuss and search for information of personal interest as well as breaking news (Kwak et al., 2010). In this context, users often forward to their *followers* information they are exposed to via their *followees*, triggering the emergence of information *cascades* that travel through the network (Cheng et al., 2014), and constantly create new links to information sources, triggering changes in the network itself over time. Importantly, recent empirical studies with Twitter data have shown that both information diffusion and network evolution are coupled and network changes are often triggered by information diffusion (Antoniades and Dovrolis, 2015; Weng et al., 2013; Myers and Leskovec, 2014).

While there have been many recent works on modeling information diffusion (Gomez-Rodriguez et al., 2010; Du et al., 2013; Cheng et al., 2014; Farajtabar et al., 2015a) and network evolution (Chakrabarti et al., 2004; Leskovec et al., 2008, 2010), most of them treat these two stochastic processes independently and separately, ignoring the influence one may have on the other over time. More notably, Weng et al. (2013) were the first to show experimental evidence that information diffusion influences network evolution in microblogging sites both at system-wide and individual levels. In particular, they studied *Yahoo! Meme*, a social micro-blogging site similar to Twitter, which was active between 2009 and 2012, and showed that information diffusion causes about 24 % of the new links, and that the likelihood of a new link from a user to another increases with the number of posts by the second user seen by the first one. Also, Antoniades and Dovrolis (2015) studied the temporal characteristics of retweet-driven connections within the Twitter network and realized that the number of retweets is an important factor to infer such connections. They showed that links created due to information diffusion account for 42 % of new links, and are rather infrequent, compared to tweets and retweets, but they are responsible for a large percentage of the new links in Twitter.

However, there are a few limitations in the above-mentioned studies. First, they only characterize the effect that information diffusion has on the network dynamics, or the vice versa, but not the bidirectional influence. Second, previous studies are mostly empirical and only make binary predictions on link creation events without precise timing. For example, the work of (Weng et al., 2013; Antoniades and Dovrolis, 2015) predict whether a new link will be created based on the number of retweets; and, Myers and Leskovec (2014) predict whether a burst of new links will occur based on the number of retweets and users' similarity. Thus, to better understand information diffusion and network evolution, there is an urgent need for joint probabilistic models of the two processes, which are largely inexistent to date.

In this paper, we propose a probabilistic generative model, COEVOLVE, for the joint dynamics of information diffusion and network evolution on Twitter-like networks. Our

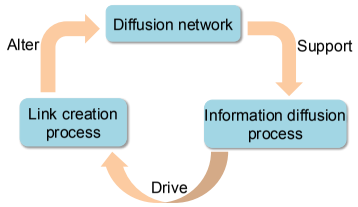

Figure 1: Illustration of how information diffusion and network structure processes interact

model is able to learn parameters from real world data, and predict the precise timing of both diffusion and new link events. The proposed model is based on the framework of temporal point processes, which explicitly characterizes the continuous time interval between events, and it consists of two interwoven and interdependent components, as shown in Figure 1:

I. **Information diffusion process.** We design an "identity revealing" multivariate Hawkes process (Farajtabar et al., 2014) to capture the mutual excitation behavior of retweeting events, where the intensity of such events in a user is boosted by previous events from her time-varying set of followees. Although Hawkes processes have been used for information diffusion before (Farajtabar et al., 2016; Blundell et al., 2012; Iwata et al., 2013; Zhou et al., 2013a; Farajtabar et al., 2014; Linderman and Adams, 2014; Valera and Gomez-Rodriguez, 2015), the key innovation of our approach is to explicitly model the excitation due to a particular source node, hence revealing the identity of the source. Such design reflects the reality that information sources are explicitly acknowledged, and it also allows a particular information source to acquire new links in a rate according to her "informativeness".

II. **Network evolution process.** We model link creation as an "information driven" survival process, and couple the intensity of this process with retweeting events. Although survival processes have been used for link creation before (Hunter et al., 2011; Vu et al., 2011), the key innovation in our model is to incorporate retweeting events as the driving force for such processes. Since our model has captured the source identity of each retweeting event, new links will be targeted toward information sources, with an intensity proportional to their degree of excitation and each source's influence.

Our model is designed in such a way that it allows the two processes, information diffusion and network evolution, unfold simultaneously in the same time scale and exercise bidirectional influence on each other, allowing sophisticated coevolutionary dynamics to be generated, as illustrated in Figure 2.

Importantly, the flexibility of our model does not prevent us from efficiently simulating diffusion and link events from the model and learning its parameters from real world data:

- **Efficient simulation.** We design a scalable sampling procedure that exploits the sparsity of the generated networks. Its complexity is $O(nd \log m)$, where n is the number of events, m is the number of users and d is the maximum number of followees per user.

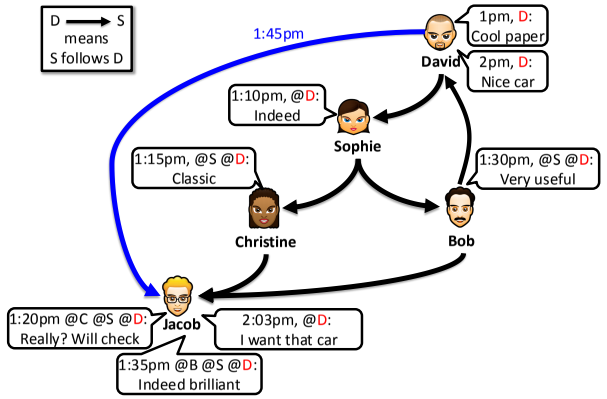

Figure 2: Illustration of information diffusion and network structure co-evolution.
Information diffusion → network structure: David's tweet at 1:00 pm about a paper is retweeted by Sophie and Christine respectively at 1:10 pm and 1:15 pm to reach out to Jacob. Jacob retweets about this paper at 1:20 pm and 1:35 pm and then finds David a good source of information and decides to follow him directly at 1:45 pm.
Information diffusion → network structure: As a result new path of information from David to Jacob (and his downstream followers) is created. Consequently, a subsequent tweet by David about a car at 2:00 pm directly reaches out to Jacob without need to Sophie and Christine retweet.

- **Convex parameters learning.** We show that the model parameters that maximize the joint likelihood of observed diffusion and link creation events can be efficiently found via convex optimization.

Then, we experiment with our model and show that it can produce coevolutionary dynamics of information diffusion and network evolution, and generate retweet and link events that obey common information diffusion patterns (*e.g.*, cascade structure, size and depth), static network patterns (*e.g.*, node degree) and temporal network patterns (*e.g.*, shrinking diameter) described in related literature (Leskovec et al., 2005, 2010; Goel et al., 2012). Finally, we show that, by modeling the coevolutionary dynamics, our model provides significantly more accurate link and diffusion event predictions than alternatives in large scale Twitter data set (Antoniades and Dovrolis, 2015).

The remainder of this article is organized as follows. We first proceed by building sufficient background on the temporal point processes framework in Section 2. Then, we introduce our joint model of information diffusion and network structure co-evolution in Section 3. Sections 4 and 5 are devoted to answer two essential questions: how can we generate data from the model? and how can we efficiently learn the model parameters from historical event data? Any generative model should be able to answer the above questions.

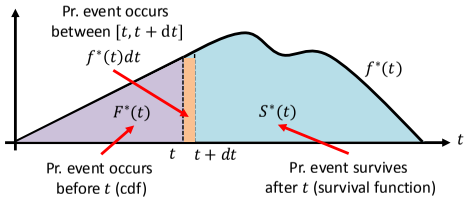

Figure 3: Illustration of three inter-related quantities in point processes framework: conditional density function, conditional cumulative density function, and survival function.

In Sections 6, 7, and 8 we perform empirical investigation of the properties of the model, we evaluate the accuracy of the parameter estimation in synthetic data, and we evaluate the performance of the proposed model in the real-world data set, respectively. Section 9 reviews the related work, and finally, the paper is concluded in Section 10. Proofs, more detailed contents and experimental results, and some extensions are left to the appendices.

2. Background on Temporal Point Processes

A temporal point process is a random process whose realization consists of a list of discrete events localized in time, $\{t_i\}$ with $t_i \in \mathbb{R}^+$ and $i \in \mathbb{Z}^+$. Many different types of data produced in online social networks can be represented as temporal point processes, such as the times of retweets and link creations. A temporal point process can be equivalently represented as a counting process, $N(t)$, which records the number of events before time t. Let the history $\mathcal{H}(t)$ be the list of times of events $\{t_1, t_2, \ldots, t_n\}$ up to but not including time t. Then, the number of observed events in a small time window $[t, t + dt)$ of length dt is

$$dN(t) = \sum_{t_i \in \mathcal{H}(t)} \delta(t - t_i)\, dt, \tag{1}$$

and hence $N(t) = \int_0^t dN(s)$, where $\delta(t)$ is a Dirac delta function. More generally, given a function $f(t)$, we can define the convolution with respect to $dN(t)$ as

$$f(t) \star dN(t) := \int_0^t f(t - \tau)\, dN(\tau) = \sum\nolimits_{t_i \in \mathcal{H}(t)} f(t - t_i). \tag{2}$$

The point process representation of temporal data is fundamentally different from the discrete time representation typically used in social network analysis. It directly models the time interval between events as random variables, avoids the need to pick a time window to aggregate events, and allows temporal events to be modeled in a fine grained fashion. Moreover, it has a remarkably rich theoretical support (Aalen et al., 2008).

An important way to characterize temporal point processes is via the conditional intensity function—a stochastic model for the time of the next event given all the times of previous events. Formally, the conditional intensity function $\lambda^*(t)$ (intensity, for short) is

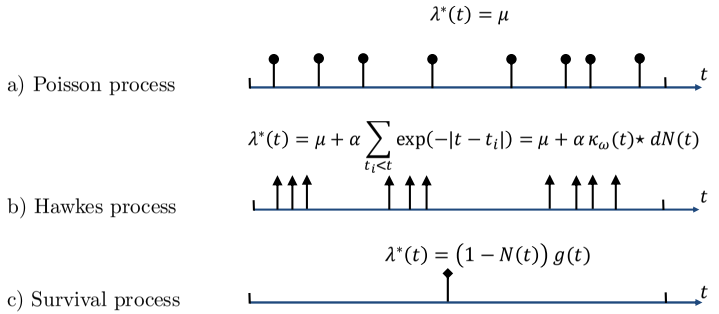

Figure 4: Three types of point processes with a typical realization

the conditional probability of observing an event in a small window $[t, t + dt)$ given the history $\mathcal{H}(t)$, *i.e.*,

$$\lambda^*(t)dt := \mathbb{P}\left\{\text{event in } [t, t + dt) | \mathcal{H}(t)\right\} = \mathbb{E}[dN(t) | \mathcal{H}(t)], \tag{3}$$

where one typically assumes that only one event can happen in a small window of size dt and thus $dN(t) \in \{0, 1\}$. Then, given the observation until time t and a time $t' \geqslant t$, we can also characterize the conditional probability that no event happens until t' as

$$S^*(t') = \exp\left(-\int_t^{t'} \lambda^*(\tau)\, d\tau\right), \tag{4}$$

the (conditional) probability density function that an event occurs at time t' as

$$f^*(t') = \lambda^*(t')\, S^*(t'), \tag{5}$$

and the (conditional) cumulative density function, which accounts for the probability that an event happens before time t':

$$F^*(t') = 1 - S^*(t') = \int_t^{t'} f^*(\tau)\, d\tau. \tag{6}$$

Figure 3 illustrates these quantities. Moreover, we can express the log-likelihood of a list of events $\{t_1, t_2, \ldots, t_n\}$ in an observation window $[0, T)$ as

$$\mathfrak{L} = \sum_{i=1}^{n} \log \lambda^*(t_i) - \int_0^T \lambda^*(\tau)\, d\tau, \quad T \geqslant t_n. \tag{7}$$

This simple log-likelihood will later enable us to learn the parameters of our model from observed data. Finally, the functional form of the intensity $\lambda^*(t)$ is often designed to capture the phenomena of interests. Some useful functional forms we will use are (Aalen et al., 2008):

(i) **Poisson process.** The intensity is assumed to be independent of the history $\mathcal{H}(t)$, but it can be a nonnegative time-varying function, *i.e.*,

$$\lambda^*(t) = g(t) \geqslant 0. \tag{8}$$

(ii) **Hawkes process.** The intensity is history dependent and models a mutual excitation between events, *i.e.*,

$$\lambda^*(t) = \mu + \alpha\kappa_\omega(t) \star dN(t) = \mu + \alpha \sum_{t_i \in \mathcal{H}(t)} \kappa_\omega(t - t_i), \tag{9}$$

where,

$$\kappa_\omega(t) := \exp(-\omega t)\mathbb{I}[t \geqslant 0] \tag{10}$$

is an exponential triggering kernel and $\mu \geqslant 0$ is a baseline intensity independent of the history. Here, the occurrence of each historical event increases the intensity by a certain amount determined by the kernel and the weight $\alpha \geqslant 0$, making the intensity history dependent and a stochastic process by itself. In our work, we focus on the exponential kernel, however, other functional forms, such as log-logistic function, are possible, and the general properties of our model do not depend on this particular choice.

(iii) **Survival process.** There is only one event for an instantiation of the process, *i.e.*,

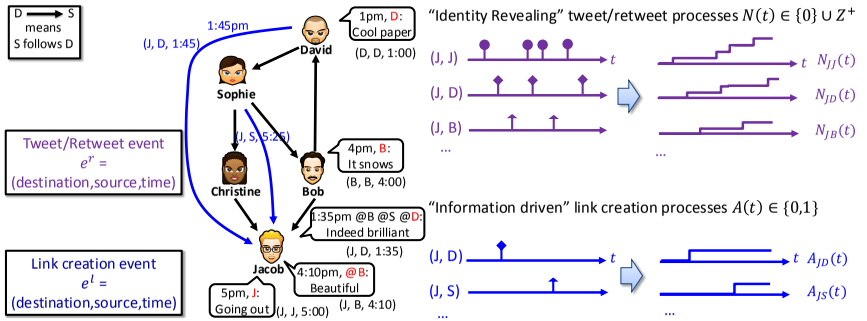
$$\lambda^*(t) = (1 - N(t))g(t), \tag{11}$$

where $g(t) \geqslant 0$ and the term $(1 - N(t))$ makes sure $\lambda^*(t)$ is 0 if an event already happened before t.

Figure 4 illustrates these processes. Interested reader should refer to Aalen et al. (2008) for more details on the framework of temporal point processes.

Point process models have been applied to many tasks in networks such as fake news mitigation (Farajtabar et al., 2017), recommendation systems (Hosseini et al., 2017), outlier detection (Li et al., 2017), activity shaping in social networks (Farajtabar et al., 2014), verifying crowd-generated data (Tabibian et al., 2017), sequence modeling using deep recurrent neural networks (Xiao et al., 2017), and campaigning in networks (Farajtabar et al., 2016).

3. Generative Model of Information Diffusion and Network Evolution



In this section, we use the above background on temporal point processes to formulate Coevolve, our probabilistic model for the joint dynamics of information diffusion and network evolution.

3.1 Event Representation

We model the generation of two types of events: tweet/retweet events, e^r, and link creation events, e^l. Instead of just the time t, we record each event as a triplet, as illustrated in Figure 5(a):

$$e^r \quad \text{or} \quad e^l \quad := \quad (\underset{\text{destination}}{u}, \overset{\text{source}}{s}, \underset{\text{time}}{t}). \tag{12}$$

For retweet event, the triplet means that the destination node u retweets at time t a tweet originally posted by source node s. Recording the source node s reflects the real world scenario that information sources are explicitly acknowledged. Note that the occurrence of event e^r does *not* mean that u is directly retweeting from or is connected

(a) Event representation (b) Point and counting processes

Figure 5: Events of point processes and their associated counting processes for link creation and information diffusion; (a) Trace of events generated by a tweet from David followed by new links Jacob creates to follow David and Sophie; (b) The associated points in time and the counting process realizations.

to s. This event can happen when u is retweeting a message by another node u' where the original information source s is acknowledged. Node u will pass on the same source acknowledgement to its followers (*e.g.*, "I agree @a @b @c @s"). Original tweets posted by node u are allowed in this notation. In this case, the event will simply be $e^r = (u, u, t)$. Given a list of retweet events up to but not including time t, the history $\mathcal{H}^r_{us}(t)$ of retweets by u due to source s is

$$\mathcal{H}^r_{us}(t) = \{e^r_i = (u_i, s_i, t_i) | u_i = u \text{ and } s_i = s\}. \tag{13}$$

The entire history of retweet events is denoted as

$$\mathcal{H}^r(t) := \cup_{u,s \in [m]} \mathcal{H}^r_{us}(t). \tag{14}$$

For link creation event, the triplet means that destination node u creates at time t a link to source node s, *i.e.*, from time t on, node u starts following node s. To ease the exposition, we restrict ourselves to the case where links cannot be deleted and thus each (directed) link is created only once. However, our model can be easily augmented to consider multiple link creations and deletions per node pair, as discussed in Section E. We denote the link creation history as $\mathcal{H}^l(t)$.

3.2 Joint Model with Two Interwoven Components

Given m users, we use two sets of counting processes to record the generated events, one for information diffusion and another for network evolution. More specifically,

I. Retweet events are recorded using a matrix $\boldsymbol{N}(t)$ of size $m \times m$ for each fixed time point t. The (u, s)-th entry in the matrix, $N_{us}(t) \in \{0\} \cup \mathbb{Z}^+$, counts the number of retweets of u due to source s up to time t. These counting processes are "identity revealing", since they keep track of the source node that triggers each retweet. The

matrix $\boldsymbol{N}(t)$ is typically less sparse than $\boldsymbol{A}(t)$, since $N_{us}(t)$ can be nonzero even when node u does not directly follow s. We also let $d\boldsymbol{N}(t) := (\, dN_{us}(t)\,)_{u,s\in[m]}$.

II. Link events are recorded using an adjacency matrix $\boldsymbol{A}(t)$ of size $m \times m$ for each fixed time point t. The (u, s)-th entry in the matrix, $A_{us}(t) \in \{0, 1\}$, indicates whether u is directly following s. Therefore, $A_{us}(t) = 1$ means the directed link has been created before t. For simplicity of exposition, we do not allow self-links. The matrix $\boldsymbol{A}(t)$ is typically sparse, but the number of nonzero entries can change over time. We also define $d\boldsymbol{A}(t) := (\, dA_{us}(t)\,)_{u,s\in[m]}$.

Then, the interwoven information diffusion and network evolution processes can be characterized using their respective intensities

$$\mathbb{E}[d\boldsymbol{N}(t) \,|\, \mathcal{H}^r(t) \cup \mathcal{H}^l(t)] = \boldsymbol{\Gamma}^*(t)\, dt \tag{15}$$

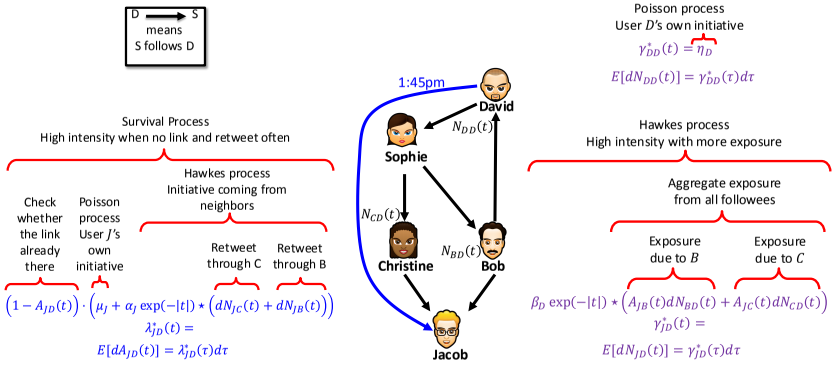
$$\mathbb{E}[d\boldsymbol{A}(t) \,|\, \mathcal{H}^r(t) \cup \mathcal{H}^l(t)] = \boldsymbol{\Lambda}^*(t)\, dt, \tag{16}$$

where,

$$\boldsymbol{\Gamma}^*(t) = (\, \gamma^*_{us}(t)\,)_{u,s\in[m]} \tag{17}$$

$$\boldsymbol{\Lambda}^*(t) = (\, \lambda^*_{us}(t)\,)_{u,s\in[m]}. \tag{18}$$

The sign * means that the intensity matrices will depend on the joint history, $\mathcal{H}^r(t) \cup \mathcal{H}^l(t)$, and hence their evolution will be coupled. By this coupling, we make: (i) the counting processes for link creation to be "information driven" and (ii) the evolution of the linking structure to change the information diffusion process. In the next two sections, we will specify the details of these two intensity matrices.



3.3 Information Diffusion Process

We model the intensity, $\boldsymbol{\Gamma}^*(t)$, for retweeting events using multivariate Hawkes process:

$$\gamma^*_{us}(t) = \mathbb{I}[u = s]\, \eta_u + \mathbb{I}[u \neq s]\, \beta_s \sum_{v\in\mathcal{F}_u(t)} \kappa_{\omega_1}(t) \star (A_{uv}(t)\; dN_{vs}(t))\,, \tag{19}$$

where $\mathbb{I}[\cdot]$ is the indicator function and $\mathcal{F}_u(t) := \{v \in [m] : A_{uv}(t) = 1\}$ is the current set of followees of u. The term $\eta_u \geqslant 0$ is the intensity of original tweets by a user u on his own initiative, becoming the source of a cascade, and the term $\beta_s \sum_{v\in\mathcal{F}_u(t)} \kappa_{\omega_1}(t) \star (A_{uv}(t)\; dN_{vs}(t))$ models the propagation of peer influence over the network, where the triggering kernel $\kappa_{\omega_1}(t)$ models the decay of peer influence over time.

Note that the retweeting intensity matrix $\boldsymbol{\Gamma}^*(t)$ is by itself a stochastic process that depends on the time-varying network topology, the non-zero entries in $\boldsymbol{A}(t)$, whose growth is controlled by the network evolution process in Section 3.4. Hence the model design captures the influence of the network topology and each source's influence, β_s, on the information diffusion process. More specifically, to compute $\gamma^*_{us}(t)$, one first finds the current set $\mathcal{F}_u(t)$ of followees of u, and then aggregates the retweets of these followees that are due to source s. Note that these followees may or may not *directly* follow source s. Then, the more frequently node u is exposed to retweets of tweets originated from source s via her followees, the more likely she will also retweet a tweet originated from source s. Once node u retweets due to source s, the corresponding $N_{us}(t)$ will be incremented, and this in turn will increase the likelihood of triggering retweets due to source s among the followers of u. Thus, the source does *not* simply broadcast the message to nodes directly following her but her influence

(a) Link creation process (b) Social network (c) Information diffusion process

Figure 6: Our hypothetical social network where the information diffusion paths make Jacob follow David: (a) The breakdown of conditional intensity function for the link creation process of Jacob following David $A_{JD}(t)$; (b) The information paths between Jacob and David; (c) The information diffusion processes for David tweeting on his own initiative $N_{DD}(t)$ and Jacob retweeting posts originated from David $N_{JD}(t)$.

propagates through the network even to those nodes that do not directly follow her. Finally, this information diffusion model allows a node to repeatedly generate events in a cascade, and is very different from the independent cascade or linear threshold models (Kempe et al., 2003) which allow at most one event per node per cascade.

3.4 Network Evolution Process

In our model, each user is exposed to information through a time-varying set of neighbors. By doing so, information diffusion affects network evolution, increasing the practical application of our model to real-world network data sets. The particular definition of exposure (*e.g.*, a retweet's neighbor) depends on the type of historical information that is available. Remarkably, the flexibility of our model allows for different types of diffusion events, which we can broadly classify into two categories.

In the first category, events corresponds to the times when an information cascade hits a person, for example, through a retweet from one of her neighbors, but she does not explicitly like or forward the associated post. Here, we model the intensity, $\boldsymbol{\Lambda}^*(t)$, for link creation using a combination of survival and Hawkes process:

$$\lambda^*_{us}(t) = (1 - A_{us}(t)) \left(\mu_u + \alpha_u \sum_{v\in\mathcal{F}_u(t)} \kappa_{\omega_2}(t) \star dN_{vs}(t) \right), \tag{20}$$

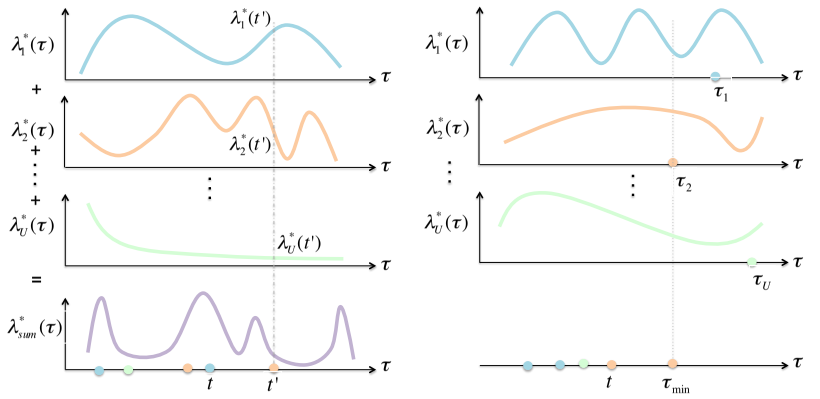
where the term $1 - A_{us}(t)$ effectively ensures a link is created only once, and after that, the corresponding intensity is set to zero. The term $\mu_u \geqslant 0$ denotes a baseline intensity, which models when a node u decides to follow a source s spontaneously at her own initiative. The term $\alpha_u \kappa_{\omega_2}(t) \star dN_{vs}(t)$ corresponds to the retweets by node v (a followee of node u) which are originated from source s. The triggering kernel $\kappa_{\omega_2}(t)$ models the decay of interests over time.

In the second category, the person decides to explicitly like or forward the associated post and influencing events correspond to the times when she does so. In this case, we model the intensity, $\mathbf{\Lambda}^*(t)$, for link creation as:

$$\lambda^*_{us}(t) = (1 - A_{us}(t))(\mu_u + \alpha_u \kappa_{\omega_2}(t) \star dN_{us}(t)), \tag{21}$$

where the terms $1 - A_{us}(t)$, $\mu_u \geqslant 0$, and the decaying kernel $\kappa_{\omega_2}(t)$ play the same role as the corresponding ones in Equation (20). The term $\alpha_u \kappa_{\omega_2}(t) \star dN_{us}(t)$ corresponds to the retweets of node u due to tweets originally published by source s. The higher the corresponding retweet intensity, the more likely u will find information by source s useful and will create a *direct* link to s.

In both cases, the link creation intensity $\mathbf{\Lambda}^*(t)$ is also a stochastic process by itself, which depends on the retweet events, be it the retweets by the neighbors of node u or the retweets by node u herself, respectively. Therefore, it captures the influence of retweets on the link creation, and closes the loop of mutual influence between information diffusion and network topology. Figure 6 illustrates these two interdependent intensities.



Intuitively, in the latter category, information diffusion events are more prone to trigger new connections, because, they involve the target and source nodes in an explicit interaction, however, they are also less frequent. Therefore, it is mostly suitable to large event data sets, as the ones we generate in our synthetic experiments. In contrast, in the former category, information diffusion events are less likely to inspire new links but found in abundance. Therefore, it is more suitable for smaller data sets, as the ones we use in our real-world experiments. Consequently, in our synthetic experiments we used the latter and in our real-world experiments, we used the former.

More generally, the choice of exposure event should be made based on the type and amount of available historical information. Note that, these are two realizations, among the many others, of the link formation process in the Coevolve framework. Many other extensions can be found in appendix E. In practice, these different forms can be utilized depending on the conditions and constraints of the networks and the data in hand. More importantly, in this section, we make one example on how to tailor the model to fit the application best.

Finally, note that creating a link is more than just adding a path or allowing information sources to take shortcuts during diffusion. The network evolution makes fundamental changes to the diffusion dynamics and stationary distribution of the diffusion process in Section 3.3. As shown in Farajtabar et al. (2014), given a fixed network structure $\boldsymbol{A}$, the expected retweet intensity $\boldsymbol{\mu}_s(t)$ at time t due to source s will depend of the network structure in a nonlinear fashion, *i.e.*,

$$\boldsymbol{\mu}_s(t) := \mathbb{E}[\mathbf{\Gamma}^*_{:s}(t)] = (e^{(\boldsymbol{A}-\omega_1 \boldsymbol{I})t} + \omega_1 (\boldsymbol{A} - \omega_1 \boldsymbol{I})^{-1} (e^{(\boldsymbol{A}-\omega_1 \boldsymbol{I})t} - \boldsymbol{I}))\, \boldsymbol{\eta}_s, \tag{22}$$

where $\boldsymbol{\eta}_s \in \mathbb{R}^m$ has a single nonzero entry with value η_s and $e^{(\boldsymbol{A}-\omega_1 \boldsymbol{I})t}$ is the matrix exponential. When $t \to \infty$, the stationary intensity $\bar{\boldsymbol{\mu}}_s = (\boldsymbol{I} - \boldsymbol{A}/\omega)^{-1} \boldsymbol{\eta}_s$ is also nonlinearly

(a) Ogata's algorithm (b) Proposed algorithm

Figure 7: Ogata's algorithm vs our simulation algorithm in simulating U interdependent point processes characterized by intensity functions $\lambda_1(t), \ldots, \lambda_U(t)$; (a) Illustrating Ogata's algorithm, which first takes a sample from the process with intensity equal to sum of individual intensities and then assigns it to the proper dimension proportionally to its contribution to the sum of intensities; (b) Illustrating our proposed algorithm, which first draws a sample from each dimension independently and then takes the minimum time among them.

related to the network structure. Thus, given two network structures $\boldsymbol{A}(t)$ and $\boldsymbol{A}(t')$ at two points in time, which are different by a few edges, the effect of these edges on the information diffusion is not just an additive relation. Depending on how these newly created edges modify the eigen-structure of the sparse matrix $\boldsymbol{A}(t)$, their effect on the information diffusion dynamics can be very significant.

4. Efficient Simulation of Coevolutionary Dynamics

We could simulate samples (link creations, tweets and retweets) from our model by adapting Ogata's thinning algorithm (Ogata, 1981), originally designed for multidimensional Hawkes processes. However, a naive implementation of Ogata's algorithm would scale poorly, *i.e.*, for each sample, we would need to re-evaluate $\mathbf{\Gamma}^*(t)$ and $\mathbf{\Lambda}^*(t)$. Thus, to draw n sample events, we would need to perform $O(m^2 n^2)$ operations, where m is the number of nodes. Figure 7(a) schematically demonstrates the main steps of Ogata's algorithm. Please refer to Appendix B for further details.

Here, we design a sampling procedure that is especially well-fitted for the structure of our model. The algorithm is based on the following key idea: if we consider each intensity function in $\mathbf{\Gamma}^*(t)$ and $\mathbf{\Lambda}^*(t)$ as a separate point process and draw a sample from each, the minimum among all these samples is a valid sample for the multidimensional point process.

Algorithm 1 Simulation Algorithm for Coevolve

Initialization:
Initialize the priority queue Q
for $\forall\ u, s \in [m]$ **do**
  Sample next link event e^l_{us} from A_{us} (Algorithm 3)
  $Q.insert(e^l_{us})$
  Sample next retweet event e^r_{us} from N_{us} (Algorithm 3)
  $Q.insert(e^r_{us})$
end for
General Subroutine:
$t \leftarrow 0$
while $t < T$ **do**
  $e \leftarrow Q.extract_min()$
  if $e = (u, s, t')$ is a retweet event **then**
    Update the history $\mathcal{H}^r_{us}(t') = \mathcal{H}^r_{us}(t) \cup \{e\}$
    for $\forall\ v$ *s.t.* $u \rightsquigarrow v$ **do**
      Update event intensity: $\gamma_{vs}(t') = \gamma_{vs}(t'^{-}) + \beta$
      Sample retweet event e^r_{vs} from γ_{vs} (Algorithm 3)
      $Q.update_key(e^r_{vs})$
      if NOT $s \rightsquigarrow v$ **then**
        Update link intensity: $\lambda^*_{vs}(t') = \lambda^*_{vs}(t'^{-}) + \alpha$
        Sample link event e^l_{vs} from λ_{vs} (Algorithm 3)
        $Q.update_key(e^l_{vs})$
      end if
    end for
  else
    Update the history $\mathcal{H}^l_{us}(t') = \mathcal{H}^l_{us}(t) \cup \{e\}$
    $\lambda^*_{us}(t) \leftarrow 0\ \ \forall\ t > t'$
  end if
  $t \leftarrow t'$
end while

As the results of this section are general and can be applied to simulate any multi-dimensional point process model we abuse the notation a little bit and represent U (possibly inter-dependent) point processes by U intensity functions $\lambda^*_1, \ldots, \lambda^*_U$. In the specific case of simulating coevolutionary dynamics we have $U = m^2 + m(m-1)$ were the first and second terms are the number information diffusion and link creation processes, respectively. Figure 7 illustrates the way in which both algorithms differ. The new algorithm has the following steps:

1. Initialization: Simulate each dimension separately and find their next sampled event time.

2. Minimization: Take the minimum among all the sampled times and declare it as the next event of the multidimensional process.

Algorithm 2 Efficient Intensity Computation

Global Variabels:
Last time of intensity computation: t
Last value of intensity computation: I
Initialization:
$t \leftarrow 0$
$I \leftarrow \mu$
function $get_intensity(t')$
  $I' \leftarrow (I - \mu)\exp(-\omega(t' - t)) + \mu$
  $t \leftarrow t'$
  $I \leftarrow I'$
  return I
end function

Algorithm 3 1-D next event sampling

Input: Current time: t
Output: Next event time: s
$s \leftarrow t$
$\hat{\lambda} \leftarrow \lambda^*(s)$ (Algorithm 2)
while $s < T$ **do**
  $g \sim Exponential(\hat{\lambda})$
  $s \leftarrow s + g$
  $\bar{\lambda} \leftarrow \lambda^*(s)$ (Algorithm 2)
  Rejection test:
  $d \sim Uniform(0, 1)$
  if $d \times \hat{\lambda} < \bar{\lambda}$ **then**
    return s
  else
    $\hat{\lambda} = \bar{\lambda}$
  end if
end while
return s

3. Update: Recalculate the intensities of the dimensions that are affected by this approved sample and re-sample only their next event. Then go to step 2.

Note that, events are sampled one by one; After each event, the intensities of affected dimensions are recomputed and fixed. This means that, the history is fixed and the dimensions of the Hawkes process become independent (just until the next event). We take next sample. Then, we make the necessary updates in the intensity functions to capture the influence of dimensions on each other. Therefore, each dimension can be thought independent until next sample is drawn because the intensity function is known.

To prove that the new algorithm generates samples from the same distribution as Ogata's algorithm does we need the following Lemma. It justifies step 2 of the above outline.

Lemma 1 *Assume we have U independent non-homogeneous Poisson processes with intensity $\lambda_1^*(\tau), \ldots, \lambda_U^*(\tau)$. Take random variable τ_u equal to the time of process u's first event after time t. Define $\tau_{min} = \min_{1\le u\le U}\{\tau_u\}$ and $u_{min} = \operatorname{argmin}_{1\le u\le U}\{\tau_u\}$. Then,*

(a) τ_{min} is the first event after time t of the Poisson process with intensity $\lambda_{sum}^*(\tau)$. In other words, τ_{min} has the same distribution as the next event (t') in Ogata's algorithm.

(b) u_{min} follows the conditional distribution $\mathbb{P}(u_{min} = u|\tau_{min} = x) = \frac{\lambda_U^*(x)}{\lambda_{sum}^*(x)}$. I.e. the dimension firing the event comes from the same distribution as the one in Ogata's algorithm.

Given the above Lemma, we can now prove that the distribution of the samples generated by the proposed algorithm is identical to the one generated by Ogata's method.

Theorem 2 *The sequence of samples from Ogata's algorithm and our proposed algorithm follow the same distribution.*

It's noteworthy that the dimensions are not independent, but their dependency is considered in the update stage. Until the next update happens they can be considered independent because their intensity function is determined and fixed.

This new algorithm is specially suitable for the structure of our inter-coupled processes. Since social and information networks are typically sparse, every time we sample a new node (or link) event from the model, only a small number of intensity functions in the local neighborhood of the node (or the link), will change. This number is of $O(d)$ where d is the maximum number of followers/followees per node. As a consequence, we can reuse most of the individual samples for the next overall sample. Moreover, we can find which intensity function has the minimum sample time in $O(\log m)$ operations using a heap priority queue. The heap data structure will help maintain the minimum and find it in logarithmic time with respect to the number of elements therein. Therefore, we have reduced an $O(nm)$ factor in the original algorithm to $O(d \log m)$.

Finally, we exploit the properties of the exponential function to update individual intensities for each new sample in $O(1)$. For simplicity consider a Hawkes process with intensity $\lambda^*(t) = \mu + \sum_{t_i\in\mathcal{H}_t} \alpha \exp(-\omega(t-t_i))$. Note that both link creation and information diffusion processes have this structure. Now, let $t_i < t_{i+1}$ be two arbitrary times, we have

$$\lambda^*(t_{i+1}) = (\lambda^*(t_i) - \mu)\exp(-\omega(t_{i+1} - t_i)) + \mu. \tag{23}$$

It can be readily generalized to the multivariate case too. Therefore, we can compute the current intensity without explicitly iterating over all previous events. As a result we can change an $O(n)$ factor in the original algorithm to $O(1)$. Furthermore, the exponential kernel also facilitates finding the upper bound of the intensity since it always lies at the beginning of one of the processes taken into consideration. Algorithm 2 summarizes the procedure to compute intensities with exponential kernels, and Algorithm 3 shows the procedure to sample the next event in each dimension making use of the special property of exponential triggering kernel.

The simulation algorithm is shown in Algorithm 1. By using this algorithm we reduce the complexity from $O(n^2m^2)$ to $O(nd\log m)$, where d is the maximum number of followees per node. That means, our algorithm scales logarithmically with the number of nodes and linearly with the number of edges at any point in time during the simulation. Moreover, events for new links, tweets and retweets are generated in a temporally intertwined and

Algorithm 4 MM-type parameter learning for Coevolve

Input: Set of retweet events $\mathcal{E} = \{e_i^r\}$ and link creation events $\mathcal{A} = \{e_i^l\}$ observed in time window $[0, T)$
Output: Learned parameters $\{\mu_u\}, \{\alpha_u\}, \{\eta_u\}, \{\beta_s\}$
Initialization:
for $u \leftarrow 1$ to m **do**
  Initialize μ_u and α_u randomly
end for
for $u \leftarrow 1$ to m **do**
  $\eta_u = \frac{\sum_{e_i^r\in\mathcal{E}} \mathbb{I}[u=u_i=s_i]}{T}$
end for
for $s \leftarrow 1$ to m **do**
  $\beta_s = \frac{\sum_{e_i^r\in\mathcal{E}} \mathbb{I}[s=s_i\neq u_i]}{\sum_{u\in[m]} \mathbb{I}[u\neq s] \sum_{v\in\mathcal{F}_u(t)} \int_0^T \kappa_{\omega_1}(t) \star (A_{uv}(t)\, dN_{vs}(t))\, dt}$
end for
while not converged **do**
  for $i \leftarrow 1$ to n_l **do**
    $\nu_{i1} = \frac{\mu_{u_i}}{\mu_{u_i} + \alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\Big|_{t=t_i}}$
    $\nu_{i2} = \frac{\alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\Big|_{t=t_i}}{\mu_{u_i} + \alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\Big|_{t=t_i}}$
  end for
  for $u \leftarrow 1$ to m **do**
    $\mu_u = \frac{\sum_{e_i^l\in\mathcal{A}} \mathbb{I}[u=u_i]\, \nu_{i1}}{\sum_{s\in[m]} \int_0^T (1 - A_{us}(t))\, dt}$
    $\alpha_u = \frac{\sum_{e_i^l\in\mathcal{A}} \mathbb{I}[u=u_i] \nu_{i2}}{\sum_{s\in[m]} \int_0^T (1 - A_{us}(t))(\kappa_{\omega_2}(t) \star dN_{us}(t))\, dt}$
  end for
end while

interleaving fashion, since every new retweet event will modify the intensity for link creation and vice versa.

5. Efficient Parameter Estimation from Coevolutionary Events

In this section, we first show that learning the parameters of our proposed model reduces to solving a convex optimization problem and then develop an efficient, parameter-free Minorization-Maximization algorithm to solve such problem.

5.1 Concave Parameter Learning Problem

Given a collection of retweet events $\mathcal{E} = \{e_i^r\}$ and link creation events $\mathcal{A} = \{e_i^l\}$ recorded within a time window $[0, T)$, we can easily estimate the parameters needed in our model using maximum likelihood estimation. To this aim, we compute the joint log-likelihood $\mathfrak{L}$

of these events using Equation (7), *i.e.*,

$$\mathfrak{L}(\{\mu_u\},\{\alpha_u\},\{\eta_u\},\{\beta_s\}) = \underbrace{\sum_{e_i^r\in\mathcal{E}} \log\left(\gamma^*_{u_i s_i}(t_i)\right) - \sum_{u,s\in[m]} \int_0^T \gamma^*_{us}(\tau)\, d\tau}_{\text{tweet / retweet}} + \underbrace{\sum_{e_i^l\in\mathcal{A}} \log\left(\lambda^*_{u_i s_i}(t_i)\right) - \sum_{u,s\in[m]} \int_0^T \lambda^*_{us}(\tau)\, d\tau}_{\text{links}}. \tag{24}$$

For the terms corresponding to retweets, the log term sums only over the actual observed events while the integral term actually sums over all possible combination of destination and source pairs, even if there is no event between a particular pair of destination and source. For such pairs with no observed events, the corresponding counting processes have essentially survived the observation window $[0, T)$, and the term $-\int_0^T \gamma^*_{us}(\tau)d\tau$ simply corresponds to the log survival probability. The terms corresponding to links have a similar structure.

Once we have an expression for the joint log-likelihood of the retweet and link creation events, the parameter learning problem can be then formulated as follows:

$$\begin{array}{ll} \text{minimize}_{\{\mu_u\},\{\alpha_u\},\{\eta_u\},\{\beta_s\}} & -\mathfrak{L}(\{\mu_u\},\{\alpha_u\},\{\eta_u\},\{\beta_s\}) \\ \text{subject to} & \mu_u \geq 0, \quad \alpha_u \geq 0, \quad \eta_u \geq 0, \quad \beta_s \geq 0 \quad \forall\, u, s \in [m]. \end{array} \tag{25}$$

Theorem 3 *The optimization problem defined by Equation* (25) *is jointly convex.*

5.2 Efficient Minorization-Maximization Algorithm

Since the optimization problem is jointly convex with respect to all the parameters, one can simply take any convex optimization method to learn the parameters. However, these methods usually require hyper parameters like step size or initialization, which may significantly influence the convergence. Instead, the structure of our problem allows us to develop an efficient algorithm inspired by previous work (Zhou et al., 2013a,b; Xu et al., 2016), which leverages Minorization Maximization (MM) (Hunter and Lange, 2004) and is parameter free and insensitive to initialization.

Our algorithm utilizes Jensen's inequality to provide a lower bound for the second log-sum term in the log-likelihood given by Equation (24). More specifically, consider a set of arbitrary auxiliary variable ν_{ij}, where $1 \leq i \leq n_l$, $j = 1, 2$ and n_l is the number of link events, *i.e.*, $n_l = |\mathcal{A}|$. Further, assume these variables satisfy

$$\forall\ 1 \leq i \leq n_l : \quad \nu_{i1}, \nu_{i2} \geq 0, \quad \nu_{i1} + \nu_{i2} = 1. \tag{26}$$

The following lemma is preliminary to find a closed form update formula for the parameters.

Lemma 4 *The log-likelihood in Equation* (24) *is lower-bounded as follows:*

$$\begin{aligned} \mathfrak{L} \geq \mathfrak{L}' = & \sum_{e_i^r\in\mathcal{E}} \mathbb{I}[u_i = s_i]\, \log\left(\eta_{u_i}\right) + \sum_{e_i^r\in\mathcal{E}} \mathbb{I}[u_i \neq s_i]\, \log(\beta_{s_i}) \\ & + \sum_{e_i^r\in\mathcal{E}} \mathbb{I}[u_i \neq s_i]\, \log\Big(\sum\nolimits_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_1}(t) \star (A_{u_i v}(t)\, dN_{v s_i}(t))\right)\Big|_{t=t_i}\Big) \\ & - \sum_{u,s\in[m]} \eta_u T + \beta_s \sum\nolimits_{v\in\mathcal{F}_u(t)} \int_0^T \kappa_{\omega_1}(t) \star (A_{uv}(t)\, dN_{vs}(t))\, dt \\ & + \sum_{e_i^l\in\mathcal{A}} \nu_{i1} \log(\mu_{u_i}) + \nu_{i2} \log(\alpha_{u_i}) + \nu_{i2} \log\Big(\sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\Big|_{t=t_i}\Big) \\ & - \sum_{e_i^l\in\mathcal{A}} \nu_{i1} \log(\nu_{i1}) + \nu_{i2} \log(\nu_{i2}) \\ & - \sum_{u,s\in[m]} \mu_u \int_0^T (1 - A_{us}(t))\, dt + \alpha_u \int_0^T (1 - A_{us}(t))(\kappa_{\omega_2}(t) \star dN_{us}(t))\, dt. \end{aligned} \tag{27}$$

Given the above lemma, by taking the gradient of the lower-bound with respect to the parameters, we can find the closed form updates to optimize the lower-bound:

$$\eta_u = \frac{\sum_{e_i^r\in\mathcal{E}} \mathbb{I}[u = u_i = s_i]}{T} \tag{28}$$

$$\beta_s = \frac{\sum_{e_i^r\in\mathcal{E}} \mathbb{I}[s = s_i \neq u_i]}{\sum_{u\in[m]} \mathbb{I}[u \neq s] \sum_{v\in\mathcal{F}_u(t)} \int_0^T \kappa_{\omega_1}(t) \star (A_{uv}(t)\, dN_{vs}(t))\, dt} \tag{29}$$

$$\mu_u = \frac{\sum_{e_i^l\in\mathcal{A}} \mathbb{I}[u = u_i]\, \nu_{i1}}{\sum_{s\in[m]} \int_0^T (1 - A_{us}(t))\, dt} \tag{30}$$

$$\alpha_u = \frac{\sum_{e_i^l\in\mathcal{A}} \mathbb{I}[u = u_i]\, \nu_{i2}}{\sum_{s\in[m]} \int_0^T (1 - A_{us}(t))(\kappa_{\omega_2}(t) \star dN_{us}(t))\, dt}. \tag{31}$$

Finally, although the lower bound is valid for every choice of ν_{ij} satisfying Equation (26), by maximizing the lower bound with respect to the auxiliary variables we can make sure that the lower bound is tight:

$$\begin{array}{lll} \text{maximize}_{\{\nu_{ij}\}} & \mathcal{L}'(\{\mu_u\},\{\alpha_u\},\{\eta_u\},\{\beta_s\},\{\nu_{ij}\}) & \\ \text{subject to} & \nu_{i1} + \nu_{i2} = 1 & \forall\, i : 1 \leq i \leq n_l \\ & \nu_{i0}, \nu_{i1} \geq 0 & \forall\, i : 1 \leq i \leq n_l. \end{array} \tag{32}$$

Fortunately, the above constrained optimization problem can be solved easily via Lagrange multipliers, which leads to closed form updates:

$$\nu_{i1} = \frac{\mu_{u_i}}{\mu_{u_i} + \alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\big|_{t=t_i}} \tag{33}$$

$$\nu_{i2} = \frac{\alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\big|_{t=t_i}}{\mu_{u_i} + \alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \left(\kappa_{\omega_2}(t) \star dN_{vs}(t)\right)\big|_{t=t_i}}. \tag{34}$$

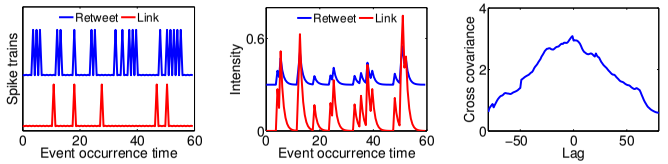
Algorithm 4 summarizes over the learning procedure, which is guaranteed to converge to a global optimum (Hunter and Lange, 2004; Zhou et al., 2013a)

It's notable that, the maximum likelihood is prone to fall into overfitting, therefore, there is a wealth of research on how to add sparsity constraints like low rank or group sparsity regularizers (Zhou et al., 2013a) or via suitable conjugate prior (Linderman and Adams, 2014). The ideas on the next section are applicable with some modification to the case that the aforementioned ideas are utilized to improve the naive solution of the maximum likelihood.

6. Properties of Simulated Co-evolution, Networks and Cascades

In this section, we perform an empirical investigation of the properties of the networks and information cascades generated by our model. In particular, we show that our model can generate co-evolutionary retweet and link dynamics and a wide spectrum of static and temporal network patterns and information cascades.

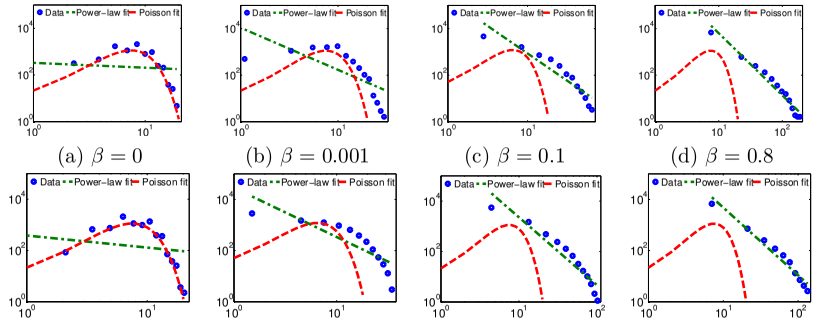
6.1 Simulation Settings



Throughout this section, if not said otherwise, we simulate the evolution of a 8,000-node network as well as the propagation of information over the network by sampling from our model using Algorithm 1. We set the exogenous intensities of the link and diffusion events to $\mu_u = \mu = 4 \times 10^{-6}$ and $\eta_u = \eta = 1.5$ respectively, and the triggering kernel parameter to $\omega_1 = \omega_2 = 1$. The parameter μ determines the independent growth of the network—roughly speaking, the expected number of links each user establishes spontaneously before time T is μT. Whenever we investigate a static property, we choose the same sparsity level of 0.001. The specific range of values we utilized in the current and the next section are such that the process remains stationary and doesn't blow up (Hawkes, 1971). Furthermore, the range of parameters are chosen such that all the results could be reported in a unified scale.

6.2 Retweet and Link Coevolution

Figures 8(a,b) visualize the retweet and link events, aggregated across different sources, and the corresponding intensities for one node and one realization, picked at random. Here, it is already apparent that retweets and link creations are clustered in time and often follow each other. Further, Figure 8(c) shows the cross-covariance of the retweet and link creation intensity, computed across multiple realizations, for the same node, *i.e.*, if $f(t)$ and $g(t)$ are two intensities, the cross-covariance is a function $h(\tau) = \int f(t+\tau)g(t)\,dt$. It can be seen that the cross-covariance has its peak around 0, *i.e.*, retweets and link creations are highly correlated and co-evolve over time. For ease of exposition, we illustrated co-evolution using one node, however, we found consistent results across nodes.



6.3 Degree Distribution

Empirical studies have shown that the degree distribution of online social networks and microblogging sites follow a power law (Chakrabarti et al., 2004; Kwak et al., 2010), and argued that it is a consequence of the rich get richer phenomena. The degree distribution of a network is a power law if the expected number of nodes m_d with degree d is given by $m_d \propto d^{-\gamma}$, where $\gamma > 0$. Intuitively, the higher the values of the parameters α and β, the closer the resulting degree distribution follows a power-law. This is because the network

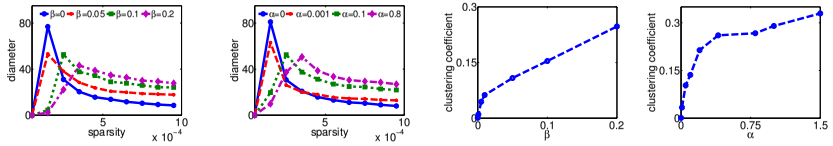
(a) $\beta = 0$ (b) $\beta = 0.001$ (c) $\beta = 0.1$ (d) $\beta = 0.8$



(a) $\alpha = 0$ (b) $\alpha = 0.05$ (c) $\alpha = 0.1$ (d) $\alpha = 0.2$

Figure 9: Degree distributions when network sparsity level reaches 0.001 for different β (α) values and fixed $\alpha = 0.1$ ($\beta = 0.1$) are shown in top (bottom) row. By varying the value of β (α) the degree distributions spans from random to scale-free networks illustrating the flexibility of the framework to model real-world networks.

grows more locally. Interestingly, the lower their values, the closer the distribution to an Erdos-Renyi random graph (Erdos and Rényi, 1960), because, the edges are added almost uniformly and independently without influence from the local structure. Figure 9 confirms this intuition by showing the degree distribution for different values of β and α.

6.4 Small (shrinking) Diameter

There is empirical evidence that the diameter of online social networks and microblogging sites exhibit relatively small diameter and shrinks (or flattens) as the network grows (Backstrom et al., 2012; Chakrabarti et al., 2004; Leskovec et al., 2005). Figures 10(a-b) show the diameter on the largest connected component (LCC) against the sparsity of the network

(a) Diameter, $\alpha = 0.1$ (b) Diameter, $\beta = 0.1$ (c) CC, $\alpha = 0.1$ (d) CC, $\beta = 0.1$

Figure 10: Diameter and clustering coefficient for network sparsity 0.001; (a,b) The diameter against sparsity over time for fixed $\alpha = 0.1$, and for fixed $\beta = 0.1$ respectively; (c,d) The clustering coefficient (CC) against β and α, respectively.

over time for different values of α and β. Although at the beginning, there is a short increase in the diameter due to the merge of small connected components, the diameter decreases as the network evolves. Moreover, larger values of α or β lead to higher levels of local growth in the network and, as a consequence, slower shrinkage. Here, nodes *arrive* to the network when they follow (or are followed by) a node in the largest connected component.

6.5 Clustering Coefficient

Triadic closure (Granovetter, 1973; Leskovec et al., 2008; Romero and Kleinberg, 2010) has been often presented as a plausible link creation mechanism. However, different social networks and microblogging sites present different levels of triadic closure (Ugander et al., 2013). Importantly, our method is able to generate networks with different levels of triadic closure, as shown by Figure 10(c-d), where we plot the clustering coefficient (Watts and Strogatz, 1998), which is proportional to the frequency of triadic closure, for different values of α and β.

6.6 Cascade Patterns

Our model can produce the most commonly occurring cascades structures as well as heavy-tailed cascade size and depth distributions, as observed in historical Twitter data (Goel et al., 2012). Figure 11 summarizes the results, which provide empirical evidence that the higher the α (β) value, the shallower and wider the cascades.

7. Experiments on Model Estimation and Prediction on Synthetic Data

In this section, we first show that our model estimation method can accurately recover the true model parameters from historical link and diffusion events data and then demonstrate that our model can accurately predict the network evolution and information diffusion over time, significantly outperforming two state of the art methods (Weng et al., 2013; Antoniades and Dovrolis, 2015; Myers and Leskovec, 2014) at predicting new links, and a baseline Hawkes process that does not consider network evolution at predicting new events.

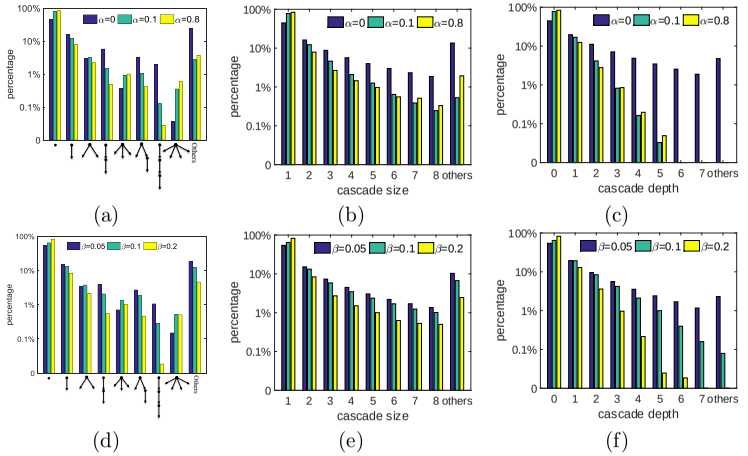


Figure 11: Distribution of cascade structure, size and depth for different values of α (β) and fixed $\beta = 0.2$ ($\alpha = 0.8$) on the top (bottom) row. The commom motifs of propagation are shown in (a) and (d).

7.1 Experimental Setup

Throughout this section, we experiment with our model considering m=400 nodes. We set the model parameters for each node in the network by drawing samples from $\mu \sim U(0, 0.0004)$, $\alpha \sim U(0, 0.1)$, $\eta \sim U(0, 1.5)$ and $\beta \sim U(0, 0.1)$. We then sample up to 60,000 link and information diffusion events from our model using Algorithm 1 and average over 8 different simulation runs.

7.2 Model Estimation

We evaluate the accuracy of our model estimation procedure via two measures: (i) the relative mean absolute error (*i.e.*, $\mathbb{E}[|x - \hat{x}|/x]$, MAE) between the estimated parameters (x) and the true parameters ($\hat{x}$), (ii) the Kendall's rank correlation coefficient between each estimated parameter and its true value, and (iii) test log-likelihood. Tables 1 and 2, and Figure 12 show the rank correlation, relative error, and the log likelihood on the test data, respectively. They show that as we feed more events into the estimation procedure, the estimation becomes more accurate.

7.3 Link Prediction

We use our model to predict the identity of the source for each test link event, given the historical events before the time of the prediction, and compare its performance with two

Table 1: Parameter Estimation Results (Rank Correlation)

# Events	α	β	η	μ
5×10^4	0.66 ± 0.05	0.82 ± 0.05	0.81 ± 0.05	0.72 ± 0.03
4×10^4	0.58 ± 0.03	0.79 ± 0.04	0.72 ± 0.05	0.65 ± 0.03
3×10^4	0.49 ± 0.05	0.76 ± 0.04	0.66 ± 0.04	0.58 ± 0.05
2×10^4	0.38 ± 0.05	0.65 ± 0.05	0.54 ± 0.05	0.47 ± 0.05
1×10^4	0.24 ± 0.03	0.43 ± 0.05	0.29 ± 0.04	0.26 ± 0.04

Table 2: Parameter Estimation Results (Relative Error)

# Events	α	β	η	μ
5×10^4	0.25 ± 0.05	0.1 ± 0.04	0.16 ± 0.05	0.18 ± 0.05
4×10^4	0.31 ± 0.05	0.17 ± 0.05	0.24 ± 0.03	0.28 ± 0.06
3×10^4	0.47 ± 0.04	0.32 ± 0.04	0.35 ± 0.04	0.39 ± 0.05
2×10^4	0.65 ± 0.05	0.49 ± 0.04	0.55 ± 0.04	0.57 ± 0.05
1×10^4	0.86 ± 0.05	0.71 ± 0.04	0.75 ± 0.06	0.79 ± 0.05

state of the art methods, which we denote as TRF (Antoniades and Dovrolis, 2015) and WENG (Weng et al., 2013).

Central to TRF model is the notion of TRF event: When a follower $L \in \mathcal{F}(R)$ receives a retweet of S through R, L can decide to follow S directly. They call this sequence a *Tweet-Retweet-Follow* (TRF) event, and refer to its three main actors as Speaker S, Repeater R, and Listener L. In addition to characterizing and identifying such events, TRF measures the probability of creating a link from a source at a given time by simply computing the proportion of new links created from the source over all total created links up to the given time. More specifically, it estimates the probability of new link as follows. Consider a tweet of Speaker S at time t_s . Suppose that this tweet is not retweeted by any of the followers of S in the period $[t_s, t_s + \Delta]$. Let $\Phi(S, t_s)$ be the set of followers of followers of S that are not directly following S at t_s. The exogenous probability of of following S is:

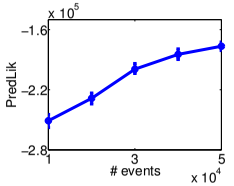
$$P_{EXO} = \frac{|L : L \in \Phi(S, t_s), L \in \mathcal{F}(S, t_s + \Delta|}{|\Phi(S, t_s)|}. \tag{35}$$

Similarly, consider a tweet of Speaker S at time t_s that has been retweeted by a follower of S, referred to as Repeater R, at time $t_r > t_s$. Let $\Phi_R(S, t_r)$ be the subset of $\Phi(S, t_r)$ that includes only followers of R. The endogenous probability of following S is:

$$P_{END} = \frac{|L : L \in \Phi_R(S, t_r), L \in \mathcal{F}(S, t_r + \Delta|}{|\Phi_R(S, t_r)|}. \tag{36}$$

And the probability of following S is simply $P_{EXO} + P_{END}$.

Weng et al. (2013) analyzed the complete graph and activity of Yahoo! Meme, to identify the effect of information diffusion on the evolution of the underlying network. WENG considers several link creation strategies and makes a prediction by combining these strategies. More specifically, they consider five link creation mechanisms and their combinations: Random: follow a randomly selected user who is not yet followed; Triadic closure: follow a randomly selected triadic node; Grandparent: follow a randomly selected grandparent;



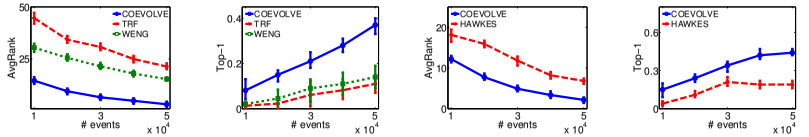


Figure 12: Performance of model estimation for the synthetic network reported in Log-likelihood on unseen test data.

(a) Links: AR (b) Links: Top-1 (c) Activity: AR Activity: Top-1

Figure 13: Prediction performance of future links and activities for a 400-node synthetic network on the test unseen data. The accuracy is reported by means of average rank (AR) and success probability that the true events rank among the top-1 events (Top-1).

Origin: follow a randomly selected origin; Traffic shortcut: follow a randomly selected grandparent or origin. Then, they parameterize the the probability of using a strategy and learned the it using maximum likelihood. Because of the contribution of multiple terms in the log-likelihood expression (due to the mixed effects of strategies) they numerically explore the values of parameters in the unit square to maximize the log-likelihood.

Here, we evaluate the performance by computing the probability of all potential links using our model, TRF and WENG. In our model, the intensity gives us a measure of how likely a link will be created at a specific point of time. The higher the intensity, the more likely the connection. Therefore, we can sort the future events based on the likelihood of happening. Then, we compute (i) the average rank of all true (test) events in our sorted list (AvgRank) and, (ii) the success probability that the true (test) events rank among the top-1 potential events at each test time (Top-1). Figure 13 summarizes the results, where we trained our model with an increasing number of events. Our model outperforms both TRF and WENG for a significant margin.

7.4 Activity Prediction

We use our model to predict the identity of the node that generates each test diffusion event, given the historical events before the time of the prediction, and compare its performance with a baseline consisting of a multi-dimensional Hawkes process without network evolution

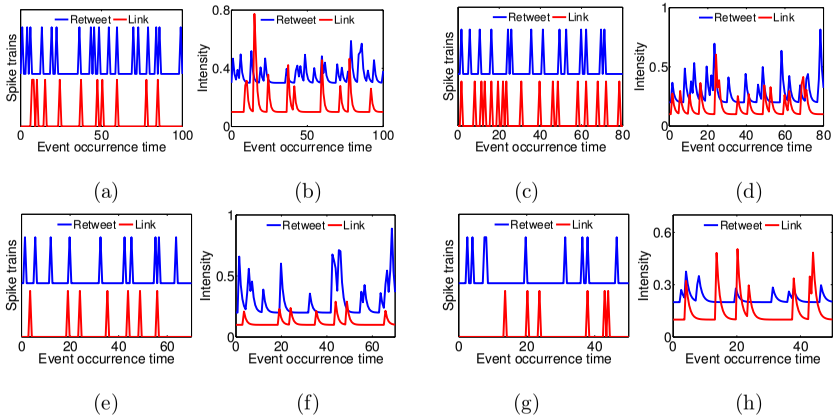

Figure 14: Link and retweet behavior of 4 typical users in the real-world data set. Panels (a,c,e,g) show the spike trains of link and retweet events and Panels (b,d,f,h) show the estimated link and retweet intensities with exponential decaying kernel.

part. For the Hawkes baseline, we take a snapshot of the network right before the prediction time, and use all historical retweeting events to fit the model and finding $(a_{uv})_{u,v\in[m]}$ and $(\eta_u)_{u\in[m]}$ similar to previous works (Farajtabar et al., 2014). Here, each user u performs activity with intensity

$$\gamma_u(t) = \eta_u + \sum_{v\in\mathcal{F}_u(t)} a_{uv}\ \kappa_{\omega_1}(t) \star dN_v(t). \tag{37}$$

Now, we have two Hawkes process based models, Coevolve, which considers information propagation coevolved with the link creation process, and the baseline Hawkes model which only contains the information propagation part to model activities. Similar to the link prediction we used the intensity to measure how likely is an event. We can sort future events according to their probability. Then, we evaluate the performance via the same two measures as in the link prediction task and summarize the results in Figure 13 against an increasing number of training events. Please refer to the previous subsection to learn about the measures used here. The results show that, by modeling the network evolution, our model performs significantly better than the baseline.

8. Experiments on Coevolution and Prediction on Real Data

In this section, we validate our model using a large Twitter data set containing nearly 550,000 tweet, retweet and link events from more than 280,000 users (Antoniades and Dovrolis, 2015). We will show that our model can capture the co-evolutionary dynamics

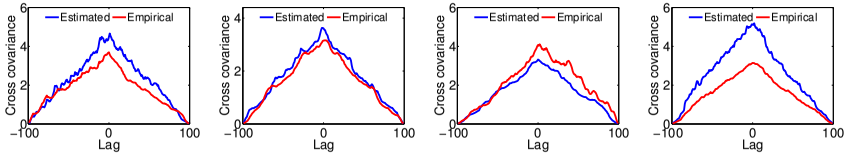

Figure 15: Empirical and simulated cross covariance of link and retweet intensities for four typical users.

and, by doing so, it predicts retweet and link creation events more accurately than several alternatives.

8.1 Data Set Description & Experimental Setup

We use a data set that contains both link events as well as tweets/retweets from millions of Twitter users (Antoniades and Dovrolis, 2015). In particular, the data set contains data from three sets of users in 20 days; nearly 8 million tweet, retweet, and link events by more than 6.5 million users. The first set of users (8,779 users) are source nodes s, for whom all their tweet times were collected. The second set of users (77,200 users) are the followers of the first set of users, for whom all their retweet times (and source identities) were collected. The third set of users (6,546,650 users) are the users that start following at least one user in the first set during the recording period, for whom all the link times were collected.

In our experiments, we focus on all events (and users) during a 10-day period (Sep 21 2012 - 30 Sep 2012) and used the information before Sep 21 to construct the initial social network (original links between users). We model the co-evolution in the second 10-day period using our framework. More specifically, in the coevolution modeling, we have 5,567 users in the first layer who post 221,201 tweets. In the second layer 101,465 retweets are generated by the whole 77,200 users in that interval. And in the third layer we have 198,518 users who create 219,134 links to 1978 users (out of 5567) in the first layer.

We split events into a training set (covering 85% of the retweet and link events) and a test set (covering the remaining 15%) according to time, *i.e.*, all events in the training set occur earlier than those in the test set. We then use our model estimation procedure to fit the parameters from an increasing proportion of events from the training data.

8.2 Retweet and Link Coevolution

Figures 14 visualizes the retweet and link events, aggregated across different targets, and the corresponding intensities given by our trained model for four source nodes, picked at random. Here, it is already apparent that retweets (of his posts) and link creations (to him) are clustered in time and often follow each other, and our fitted model intensities successfully track such behavior. Further, Figure 15 compares the cross-covariance between the empirical retweet and link creation intensities and between the retweet and link creation intensities given by our trained model, computed across multiple realizations, for the same nodes. For all nodes, the similarity between both cross-covariances is striking and both has

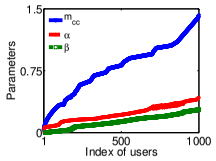

Figure 16: Empirical cross covariance and learned model parameters for 1,000 users, picked at random. The x-axis indexes the users while their α, β and the empirical cross covariance are shown in different colors on the y-axis.

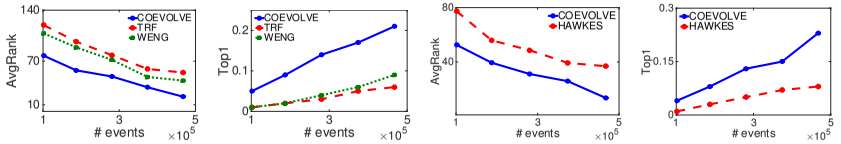
their peak around 0, *i.e.*, retweets and link creations are highly correlated and co-evolve over time. For ease of exposition, as in Section 6, we illustrated co-evolution using four nodes, however, we found consistent results across nodes.

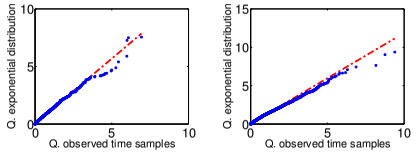
To further verify that our model can capture the coevolution, we compute the average value of the empirical cross covariance function, denoted by m_{cc}, per user. Intuitively, one could expect that our model estimation method should assign higher α and/or β values to users with high m_{cc}. Figure 16 confirms this intuition on 1,000 users, picked at random. Whenever a user has high α and/or β value, she exhibits a high cross covariance between her created links and retweets.



8.3 Link Prediction

We use our model to predict the identity of the source for each test link event, given the historical (link and retweet) events before the time of the prediction, and compare its performance with the same two state of the art methods as in the synthetic experiments, TRF (Antoniades and Dovrolis, 2015) and WENG (Weng et al., 2013).

We evaluate the performance by computing the probability of all potential links using different methods, and then compute (i) the average rank of all true (test) events (AvgRank) and, (ii) the success probability (SP) that the true (test) events rank among the top-1 potential events at each test time (Top-1). We summarize the results in Figure 17(a-b), where we consider an increasing number of training retweet/tweet events. Our model outperforms TRF and WENG consistently. For example, for $8 \cdot 10^4$ training events, our model achieves a SP 2.5x times larger than TRF and WENG.



8.4 Activity Prediction

We use our model to predict the identity of the node that generates each test diffusion event, given the historical events before the time of the prediction, and compare its performance with a baseline consisting of a Hawkes process without network evolution. For the Hawkes baseline, we take a snapshot of the network right before the prediction time, and use all historical retweeting events to fit the model. Here, we evaluate the performance the via the same two measures as in the link prediction task and summarize the results in Figure 17(c-d) against an increasing number of training events. The results show that, by modeling the co-evolutionary dynamics, our model performs significantly better than the baseline.

(a) Links: AR (b) Links: Top-1 (c) Activity: AR Activity: Top-1

Figure 17: Prediction performance in the Twitter data set by means of average rank (AR) and success probability that the true (test) events rank among the top-1 events (Top-1).

(a) Link process (b) Retweet process

Figure 18: Quantile plots of the intensity integrals from the real link and retweet event time. The alignment of blue dots (empirical) and red ones (theoretical) shows the suitability of our model in representing observed traces of activities in Twitter.

8.5 Model Checking

Given all the subsequent event times generated using a Hawkes process, *i.e.*, t_i and t_{i+1}, according to the time changing theorem (Daley and Vere-Jones, 2007), the intensity integrals $\int_{t_i}^{t_{i+1}} \lambda(t)\, dt$ should conform to the unit-rate exponential distribution. Figure 18 presents the quantiles of the intensity integrals computed using intensities with the parameters estimated from the real Twitter data against the quantiles of the unit-rate exponential distribution. It clearly shows that the points approximately lie on the same line, giving empirical evidence that a Hawkes process is the right model to capture the real dynamics.

9. Related Work

In this section, we survey related works in modeling temporal networks followed by a subsection on co-evolution dynamics. Next, we review the literature on information diffusion models. Finally, we conclude this section by works that are closely related and are developed for almost the same goal.

Temporal Networks. Much effort has been devoted to modeling the evolution of social networks (Phan and Airoldi, 2015; Doreian and Stokman, 2013; Wang et al., 2011). Of the proposed methods in characterizing link creation, triadic closure (Granovetter, 1973) is a simple but powerful principle to model the evolution based on shared friends. Modeling timing and rich features of social interactions has been attracting increasing interest

in the social network modeling community (Goldenberg et al., 2010). However, most of these models use timing information as discrete indices. The dynamics of the resulting time-discretized model can be quite sensitive to the chosen discretization time steps; Too coarse a discretization will miss important dynamic features of the process, and too fine a discretization will increase the computational and inference costs of the algorithms. In contrast, the events we try to model tend to be asynchronous with a number of different time scales. Recently, Snijders and Luchini (2006) used a Cox-intensity Poisson model with exponential random graphs to model friendship dynamics. Brandes et al. (2009) extended this model to the temporal sequence of interactions that take place in the social network, but with insufficient model flexibility, and limited scalability. However, these works largely fail to model the interdependency between events generated by different users, which is one of the focuses of our proposed framework. Most of this line of work is summarized in a recent survey (Holme, 2015), with a short section devoted to point process based approaches.

Co-evolution Dynamics. In machine learning and several other communities, both the dynamics on the network and the dynamics of the network have been extensively studied, and combining the two is a natural next step. For example, Bhattacharya et al. (2015) claimed that content generation in social networks is influenced not just by their personal features like age and gender, but also by their social network structure. Furthermore, research has been done to address the co-evolution problems, for example, in the complex network literature, under the name of *adaptive system* (Gross and Blasius, 2008). The main premise is that the evolution of the topology depends on the dynamics of the nodes in the network, and a feedback loop can be created between the two, which allows dynamical exchange of information. In a different context, epidemiologists have found that nodes may rewire their links to try to avoid contact with the infected ones (Gross et al., 2006). Co-evolutionary models have been also developed for collective opinion formation, investigating whether the coevolutionary dynamics will eventually lead to consensus or fragmentation of the population (Zschaler et al., 2012). However, this line of research tends to be less data-driven.Moreover, although the general nonlinear dynamic-system based methods usually address co-evolutionary phenomena that are macroscopic in nature, they lack the inference power of statistical generative models which are more adapted to teasing out microscopic details from the data. Finally, we would also like to mention a different line of research exemplified by the actor-oriented models developed by Snijders (2014), where a continuous-time Markov chain on the space of directed networks is specified by local node-centric probabilistic link change rules, and MCMC and method of moments are used for parameter estimation. Hawkes processes we used are generally non-Markovian and making use of event history far into the past.

Information Diffusion. The presence of timing information in event data and the ability to model such information bring up the interesting question of how to use the learned model for time-sensitive inference or decision making. Furthermore, the development of online social networks has attracted a lot of empirical studies of the online influence patterns of online communities (Guo et al., 2015), micro blogs (Bakshy et al., 2011) and so on. However, these works usually consider only relatively simple models for the influence, which may not be very predictive. For more mathematically oriented works, based on information cascades (a special case of asynchronous event data) from social networks, discrete-time

diffusion models have been fitted to the cascades (Goyal et al., 2010a) and used for decision making, such as identifying influencer (Agarwal et al., 2008), maximizing information spread (Rodriguez and Schölkopf, 2012), and marketing planing (Richardson and Domingos, 2002; Bhagat et al., 2012). Several recent experimental comparisons on both synthetic and real world data showed that continuous-time models yield significant improvement in settings such as recovering hidden diffusion network topologies from cascade data (Du et al., 2012; Gomez-Rodriguez et al., 2011; Yang and Zha, 2013; Zarezade et al., 2015), predicting the timings of future events (Rodriguez et al., 2013), finding source of information cascades (Farajtabar et al., 2015a). Besides this, Point process modeling of activity in network is becoming increasingly popular (Parikh et al., 2012; Hall and Willett, 2016; Farajtabar et al., 2017). These time-sensitive modeling and decision making problems can usually be framed into optimization problems and are usually difficult to solve. This brings up interesting optimization problems, such as efficient submodular function optimization with provable guarantees (Goyal et al., 2010b; Kempe et al., 2003), sampling methods (Lian et al., 2014; Gunawardana et al., 2011) for inference and prediction, and convex framework proposed in (Farajtabar et al., 2014; Karimi et al., 2016) to make decisions to shape the activity to a variety of objectives and intervene in networks (Farajtabar et al., 2017). Furthermore, the high dimensional nature of modern event data makes the evaluation of objective function of the optimization problem even more expensive. Therefore, more accurate modeling and sophisticated algorithm needed to be designed to tackle the challenges posed by modern event data applications.

The work most closely related to ours is the empirical study of information diffusion and network evolution (Gross and Blasius, 2008; Singer et al., 2012; Weng et al., 2013; Antoniades and Dovrolis, 2015; Myers and Leskovec, 2014). Among them, (Weng et al., 2013) was the first to show experimental evidence that information diffusion influences network evolution in microblogging sites both at system-wide and individual levels. In particular, they studied *Yahoo! Meme*, a social micro-blogging site similar to Twitter, which was active between 2009 and 2012, and showed that the likelihood that a user u starts following a user s increases with the number of messages from s seen by u. Antoniades and Dovrolis (2015) investigated the temporal and statistical characteristics of retweet-driven connections within the Twitter network and then identified the number of retweets as a key factor to infer such connections, in agreement with (Weng et al., 2013). Besides link prediction, they argue about which potential network motifs TRF events can lead to in the network structure. Myers and Leskovec (2014) showed that the Twitter network can be characterized by steady rates of change, interrupted by sudden bursts of new connections, triggered by retweet cascades. They also developed a method to predict which retweets are more likely to trigger these bursts. Finally, Tran et al. (2015) utilized multivariate Hawkes process to establish a connection between temporal properties of activities and the structure of the network. In contrast to our work they studied the static properties, *e.g.*, community structure and inferred the latent clusters using the observed activities.

However, there are fundamental differences between the above-mentioned studies and our work. First, they only characterize the effect that information diffusion has on the network dynamics, but not the bidirectional influence. In contrast, our probabilistic generative model takes into account the bidirectional influence between information diffusion and network dynamics. Second, previous studies are mostly empirical and only make binary

predictions on link creation events. For example, the work of (Weng et al., 2013; Antoniades and Dovrolis, 2015) predict whether a new link will be created based on the number of retweets; and, (Myers and Leskovec, 2014) predict whether a burst of new links will occur based on the number of retweets and users' similarity. However, our model is able to learn parameters from real world data, and predict the precise timing of both diffusion and new link events.

10. Conclusion and Future Works

In this work, we proposed a joint continuous-time model of information diffusion and network evolution, which can capture the coevolutionary dynamics, can mimic the most common static and temporal network patterns observed in real-world networks and information diffusion data, and can predict the network evolution and information diffusion more accurately than previous state-of-the-arts. Using point processes to model intertwined events in information and social networks opens up many interesting venues for future. Our current model is just a show-case of a rich set of possibilities offered by a point process framework, which have been rarely explored before in large scale social network modeling. There are quite a few directions that remain as future work and are very interesting to explore. For example:

- A large and diverse range of point processes can also be used instead in the framework and augment the current model without changing the efficiency of simulation and the convexity of parameter estimation.
- We can incorporate features from previous state of the diffusion or network structure. For example, one can model information overload by adding a nonlinear transfer function on top of the diffusion intensity, or model peer pressure by adding a nonlinear transfer function depending on the number of neighbors.
- There are situations that the processes are naturally evolve in different time scales. For example, link dynamics is meaningful in the scale of days, however, the resolution in which information propagation occurs is usually in hours or even minutes. Developing an efficient mechanism to account for heterogeneity in time resolution would improve the model's ability to predict.
- We may augment the framework to allow time-varying parameters. The simulation would not be affected and the estimation of time-varying interaction can still be carried out via a convex optimization problem (Zhou et al., 2013b).
- Alternatively, one can use different triggering kernels for the Hawkes processes and learn them to capture finer details of temporal dynamics.

Acknowledgments

The authors would like to thank Demetris Antoniades and Constantine Dovrolis for providing them with the data set. The research was supported in part by NSF/NIH BIGDATA 1R01GM108341, ONR N00014-15-1-2340, NSF IIS-1218749, NSF CAREER IIS-1350983.

Appendix A. Notations

Table 3: Table of Notations of the COEVOLVE framework

Notation	Description
m	number of nodes in the network
$e^r = (u, s, t)$	retweet event: node u retweets at time t a tweet by source node s
$e^l = (u, s, t)$	link event: node u create at time t a link to source node s
$\mathcal{H}^r_{us}(t)$	history of retweet events by node u up to time t due to source s
$\mathcal{H}^r(t)$	history of all retweet events up to time t
$\mathcal{H}^l(t)$	history of all link events up to time t
$N_{us}(t)$	count process of the number of retweets of u due to source s up to time t
$\boldsymbol{N}(t)$	count process matrix of all pairs $\boldsymbol{N}(t) := (\ N_{us}(t)\ )_{u,s\in[m]}$
$d\boldsymbol{N}(t)$	differential of retweet process matrix $d\boldsymbol{N}(t) := (\ dN_{us}(t)\ )_{u,s\in[m]}$
$A_{us}(t)$	survival process indicating whether u is directly following s at time t
$\boldsymbol{A}(t)$	survival process matrix of all paris $\boldsymbol{A}(t) := (\ A_{us}(t)\ )_{u,s\in[m]}$
$d\boldsymbol{A}(t)$	differential of link creation process matrix $d\boldsymbol{A}(t) := (\ dA_{us}(t)\ )_{u,s\in[m]}$
$\gamma^*_{us}(t)$	conditional intensity function of user u retweet an event due to source s
$\boldsymbol{\Gamma}^*(t)$	matrix of information diffusion intensity functions $\Gamma(t) = (\ \gamma^*_{us}(t)\ )_{u,s\in[m]}$
$\mathbb{I}[\cdot]$	indicator function
$\mathcal{F}_u(t)$	set of followers of u at time t
η_u	intensity of original tweets by a user u on his own initiative
β_s	amount of increase in retweeting intensity when a tweet by source s hits
$\kappa_\omega(t)$	decaying kernel with bandwidth ω; $\kappa_\omega(t) = e^{-\omega t}$
$\lambda^*_{us}(t)$	conditional intensity function for user u follows source s at time t
$\boldsymbol{\Lambda}^*(t)$	matrix of link creation intensity functions $\boldsymbol{\Lambda}^*(t) = (\ \lambda^*_{us}(t)\ )_{u,s\in[m]}$
μ_u	intensity of node u deciding to follow a source at her own initiative
α_u	amount of increase in linking intensity when a tweet by the source hits
$\mathcal{E}$	collection of retweet events observed
$\mathcal{A}$	collection of link creation events
$\mathfrak{L}$	likelihood of observation
ν_{ij}	auxiliary variable for lower-bounding the log-likelihood

Appendix B. Basic Simulation Algorithm

In this section, we revisit Ogata's algorithm in more details. Consider a U-dimensional point process in which each dimension u is characterized by a conditional intensity function $\lambda_u^*(t)$.

Ogata's algorithm starts with summing the intensities, $\lambda_{sum}^*(\tau) = \sum_{u=1}^{U} \lambda_u^*(\tau)$. Then, assuming we have simulated up to time t, the next sample time, t', is the first event drawn from the non-homogenous Poisson process with intensity $\lambda_{sum}^*(\tau)$ which begins at time t. Here, the algorithm exploits that, given a fixed history, the Hawkes Process is a non-homogenous Poisson process, which runs until the next event happens. Then, the new event will result in an update of the intensities and a new non-homogenous Poisson process starts until the next event.

It can be shown that the waiting time of a non-homogeneous Poisson process is an exponentially distributed random variable with rate equal to integral of the intensity (Ross, 2011), *i.e.* $s \sim Exponential\left(\int_t^{t+s} \lambda_{sum}^*(\tau)\, d\tau\right)$. Thus, the next sample time can be computed as

$$t' = \underbrace{t}_{\text{current time}} + \underbrace{s.}_{\text{waiting time for the first event}} \tag{38}$$

Sampling from a non-homogenous Poisson process is not straight-forward, therefore, Ogata's algorithm uses rejection sampling with a homogenous Poisson process as the proposal distribution. More in detail, given $\hat{\lambda} = \max_{t \le \tau \le T} \lambda_{sum}^*(\tau)$, t' is the time of first event of homogenous Poisson Process with rate $\hat{\lambda}$. Then, we accept the sample time with probability $\lambda_{sum}^*(t')/\hat{\lambda}$. Finally, the dimension firing the event is determined by sampling proportionally to the contribution of the intensity of that user to the total intensity, *i.e.*, $\lambda_u^*(t')/\lambda_{sum}^*(t')$ for $1 \le u \le U$. This procedure is iterated until we reach the end of simulation time T. Algorithm 5 presents the complete procedure.

Ogata's algorithm would scale poorly with the dimension of the process, because, after each sample, we would need to re-evaluate the affected intensities and find the upper bound. As a consequence, a naive implementation to draw n samples require $O(Un^2)$ time complexity, where U is the number of dimensions. This is because for each sample we need to find the new summation of intensities, which involves $O(U)$ individual ones, each taking $O(n)$ time to accumulate over this history. In our social networks application, we have $m^2 - m$ point processes for link creation and m^2 ones for retweeting, *i.e.*, $U = O(m^2)$. Therefore, Ogata's algorithm takes $O(m^2 n^2)$ time complexity.

Algorithm 5 Ogata's Algorithm

Input: U dimensional Hawkes process $\{\lambda_u^*(t)\}_{u=1\ldots U}$, Due time: T
Output: Set of events: $\mathcal{H} = \{(t_1, u_1), \ldots, (t_n, u_n)\}$
$t \leftarrow 0$
$i \leftarrow 0$
while $t < T$ **do**
  $\lambda_{sum}^*(\tau) \leftarrow \sum_{u=1}^{U} \lambda_u^*(\tau)$ — Sampling next event time
  $\hat{\lambda} \leftarrow \max_{t \le \tau \le T} \lambda_{sum}^*(\tau)$ — Sampling next event time
  $s \sim Exponential(\hat{\lambda})$ — Sampling next event time
  $t' \leftarrow t + s$ — Sampling next event time
  if $t' \ge T$ **then** — Sampling next event time
    break — Sampling next event time
  end if — Sampling next event time
  $\bar{\lambda} \leftarrow \lambda_{sum}^*(t')$ — Rejection test
  $d \sim Uniform(0, 1)$ — Rejection test
  if $d \times \hat{\lambda} > \bar{\lambda}$ **then** — Rejection test
    $t \leftarrow t'$ — Rejection test
    Goto 6 — Rejection test
  end if — Rejection test
  $S \leftarrow 0$ — Attribution test
  $d \sim Uniform(0, 1)$ — Attribution test

Appendix C. Proofs

Lemma 1 *Assume we have U independent non-homogeneous Poisson processes with intensity $\lambda_1^*(\tau), \ldots, \lambda_U^*(\tau)$. Take random variable τ_u equal to the time of process u's first event after time t. Define $\tau_{min} = \min_{1\le u\le U}\{\tau_u\}$ and $u_{min} = \operatorname{argmin}_{1\le u\le U}\{\tau_u\}$. Then,*

(a) τ_{min} is the first event after time t of the Poisson process with intensity $\lambda_{sum}^*(\tau)$. In other words, τ_{min} has the same distribution as the next event (t') in Ogata's algorithm.

(b) u_{min} follows the conditional distribution $\mathbb{P}(u_{min} = u|\tau_{min} = x) = \frac{\lambda_U^*(x)}{\lambda_{sum}^*(x)}$. I.e. the dimension firing the event comes from the same distribution as the one in Ogata's algorithm.

Proof (a) The waiting time of the first event of a dimension u is exponentially distributed[1] random variable (Ross, 2011); *i.e.*, $\tau_u - t \sim Exponential\left(\int_t^{t+\tau_u}\lambda_u^*(\tau)\,d\tau\right)$. We have:

$$\begin{aligned}\mathbb{P}(\tau_{min}\le x|x>t) &= 1-\mathbb{P}(\tau_{min}>x|x>t) = 1-\mathbb{P}(\min(\tau_1,\ldots,\tau_U)>x|x>t)\\ &= 1-\mathbb{P}(\tau_1>x,\ldots,\tau_U>x|x>t) = 1-\prod_{u=1}^{U}\mathbb{P}(\tau_u>x|x>t)\\ &= 1-\prod_{u=1}^{U}\exp\left(-\int_t^{t+x}\lambda_u^*(\tau)\,d\tau\right) = 1-\exp\left(-\int_t^{t+x}\lambda_{sum}^*(\tau)\,d\tau\right).\end{aligned} \tag{39}$$

Therefore, $\tau_{min}-t$ is exponentially distributed with parameter $\int_t^{\tau_{min}}\lambda_{sum}^*(\tau)\,d\tau$ which can be seen as the first event of a non-homogenous poisson process with intensity $\lambda_{sum}^*(\tau)$ after time t.

(b) To find the distribution of u_{min} we have

$$\begin{aligned}\mathbb{P}(u_{min}=u|\tau_{min}=x) &= \lambda_u^*(x)\exp\left(-\int_t^{t+x}\lambda_u^*(\tau)\,d\tau\right)\prod_{v\ne u}\exp\left(-\int_t^{t+x}\lambda_v^*(\tau)\,d\tau\right)\\ &= \lambda_u^*(x)\prod_{v}\exp\left(-\int_t^{t+x}\lambda_v^*(\tau)\,d\tau\right).\end{aligned} \tag{40}$$

After normalization we get $\mathbb{P}(u_{min}=u|\tau_{min}=x) = \frac{\lambda_U^*(x)}{\lambda_{sum}^*(x)}$. ∎

Theorem 2 *The sequence of samples from Ogata's algorithm and our proposed algorithm follow the same distribution.*

Proof Using the chain rule the probability of observing $\mathcal{H}_T = \{(t_1,u_1),\ldots,(t_n,u_n)\}$ is written as:

$$\mathbb{P}\{(t_1,u_1),\ldots,(t_n,u_n)\} = \prod_{i=1}^{n}\mathbb{P}\{(t_i,u_i)|(t_{i-1},u_{i-1}),\ldots,(t_1,u_1)\} = \prod_{i=1}^{n}\mathbb{P}\{(t_i,u_i)|\mathcal{H}_{t_i}\}.$$

By fixing the history up to some time, say t_i, all dimensions of multivariate Hawkes process become independent of each other (until next event happens). Therefore, the above lemma can be applied to show that the next sample time from Ogata's algorithm and the proposed one come from the same distribution, *i.e.*, for every i, $\mathbb{P}\{(t_i,u_i)|\mathcal{H}_{t_i}\}$ is the same for both algorithms. Thus, the multiplication of individual terms is also equal for both. This will prove the theorem. ∎

1. If random variable X is exponentially distributed with parameter r, then $f_X(x) = r\exp(-rx)$ is its probability distribution function and $F_X(x) = 1-\exp(-rx)$ is the cumulative distribution function.

Theorem 3 *The optimization problem defined by Equation (25) is jointly convex.*

Proof We expand the likelihood by replacing the intensity functions into Equation (24):

$$\begin{aligned}\mathfrak{L} = &\sum_{e_i^r\in\mathcal{E}}\log\left(\mathbb{I}[u_i=s_i]\,\eta_{u_i}+\mathbb{I}[u_i\ne s_i]\,\beta_{s_i}\sum\nolimits_{v\in\mathcal{F}_{u_i}(t_i)}\left(\kappa_{\omega_1}(t)\star(A_{u_iv}(t)\,dN_{vs_i}(t))\right)\Big|_{t=t_i}\right)\\ &-\sum_{u,s\in[m]}\mathbb{I}[u=s]\,\eta_u\int_0^T dt+\mathbb{I}[u\ne s]\,\beta_s\sum\nolimits_{v\in\mathcal{F}_u(t)}\int_0^T\kappa_{\omega_1}(t)\star(A_{uv}(t)\,dN_{vs}(t))\,dt\\ &+\sum_{e_i^l\in\mathcal{A}}\log\left(\mu_{u_i}+\alpha_{u_i}\sum_{v\in\mathcal{F}_{u_i}(t_i)}\left(\kappa_{\omega_2}(t)\star dN_{vs}(t)\right)\Big|_{t=t_i}\right)\\ &-\sum_{u,s\in[m]}\mu_u\int_0^T(1-A_{us}(t))\,dt+\alpha_u\int_0^T(1-A_{us}(t))\Big(\sum_{v\in\mathcal{F}_u(t)}\kappa_{\omega_2}(t)\star dN_{vs}(t)\Big)\,dt.\end{aligned} \tag{41}$$

If we stack all parameters in a vector $\boldsymbol{x} = (\{\mu_u\},\{\alpha_u\},\{\eta_u\},\{\beta_s\})$, one can easily notice that the log-likelihood $\mathfrak{L}$ can be written as $\sum_j\log(\boldsymbol{a}_j^\top\boldsymbol{x}) - \sum_k\boldsymbol{b}_k^\top\boldsymbol{x}$, which is clearly a concave function with respect to $\boldsymbol{x}$ (Boyd and Vandenberghe, 2004), and thus $-\mathfrak{L}$ is convex. Moreover, the constraints are linear inequalities and thus the domain is a convex set. This completes the proof for convexity of the optimization problem. ∎

Lemma 4 *The log-likelihood in Equation (24) is lower-bounded as follows:*

$$\begin{aligned}\mathfrak{L}\ge\mathfrak{L}' = &\sum_{e_i^r\in\mathcal{E}}\mathbb{I}[u_i=s_i]\,\log(\eta_{u_i})+\sum_{e_i^r\in\mathcal{E}}\mathbb{I}[u_i\ne s_i]\,\log(\beta_{s_i})\\ &+\sum_{e_i^r\in\mathcal{E}}\mathbb{I}[u_i\ne s_i]\,\log\Big(\sum\nolimits_{v\in\mathcal{F}_{u_i}(t_i)}\left(\kappa_{\omega_1}(t)\star(A_{u_iv}(t)\,dN_{vs_i}(t))\right)\Big|_{t=t_i}\Big)\\ &-\sum_{u,s\in[m]}\eta_uT+\beta_s\sum\nolimits_{v\in\mathcal{F}_u(t)}\int_0^T\kappa_{\omega_1}(t)\star(A_{uv}(t)\,dN_{vs}(t))\,dt\\ &+\sum_{e_i^l\in\mathcal{A}}\nu_{i1}\log(\mu_{u_i})+\nu_{i2}\log(\alpha_{u_i})+\nu_{i2}\log\Big(\sum_{v\in\mathcal{F}_{u_i}(t_i)}\left(\kappa_{\omega_2}(t)\star dN_{vs}(t)\right)\Big|_{t=t_i}\Big)\\ &-\sum_{e_i^l\in\mathcal{A}}\nu_{i1}\log(\nu_{i1})+\nu_{i2}\log(\nu_{i2})\\ &-\sum_{u,s\in[m]}\mu_u\int_0^T(1-A_{us}(t))\,dt+\alpha_u\int_0^T(1-A_{us}(t))(\kappa_{\omega_2}(t)\star dN_{us}(t))\,dt.\end{aligned} \tag{42}$$

Proof We can lower-bound the logarithm in the log-likelihood (Equation (41)) using Jensen's inequality as follows:

$$\begin{aligned}
&\log\left(\mu_{u_i} + \alpha_{u_i} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \big(\kappa_{\omega_2}(t) \star dN_{vs}(t)\big)\big|_{t=t_i}\right) \\
&= \log\left(\nu_{i1}\frac{\mu_{u_i}}{\nu_{i1}} + \nu_{i2}\frac{\alpha_{u_i}}{\nu_{i2}} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \big(\kappa_{\omega_2}(t) \star dN_{vs}(t)\big)\big|_{t=t_i}\right) \\
&\geq \nu_{i1}\log\left(\frac{\mu_{u_i}}{\nu_{i1}}\right) + \nu_{i2}\log\left(\frac{\alpha_{u_i}}{\nu_{i2}} \sum_{v\in\mathcal{F}_{u_i}(t_i)} \big(\kappa_{\omega_2}(t) \star dN_{vs}(t)\big)\big|_{t=t_i}\right) \\
&\geq \nu_{i1}\log(\mu_{u_i}) + \nu_{i2}\log(\alpha_{u_i}) + \nu_{i2}\log\left(\sum_{v\in\mathcal{F}_{u_i}(t_i)} \big(\kappa_{\omega_2}(t) \star dN_{vs}(t)\big)\big|_{t=t_i}\right) \\
&\quad - \nu_{i1}\log(\nu_{i1}) - \nu_{i2}\log(\nu_{i2}).
\end{aligned} \tag{43}$$

■

Replacing the logarithm with the lower-bound gets the result.

Appendix D. More Properties of the Coevolution Model

In this section we complement the properties of simulated coevolved networks and cascades by visualizing the outcomes, *i.e.*, the networks and cascades.

D.1 Network Visualization

Figure 19 visualizes several snapshots of the largest connected component (LCC) of two 300-node networks for two particular realizations of our model, under two different values of β. In both cases, we used $\mu = 2 \times 10^{-4}$, $\alpha = 1$, and $\eta = 1.5$. The top two rows correspond to $\beta = 0$ and represent one end of the spectrum, *i.e.*, Erdos-Renyi random network. Here, the network evolves uniformly. The bottom two rows correspond to $\beta = 0.8$ and represent the other end, *i.e.*, scale-free networks. Here, the network evolves locally, and clusters emerge naturally as a consequence of the local growth. They are depicted using a combination of forced directed and Fruchterman Reingold layout with Gephi[2]. Moreover, the figure also shows the retweet events (from others as source) for two nodes, A and B, on the bottom row. These two nodes arrive almost at the same time and establish links to two other nodes. However, node A's followees are more central, therefore, A is being exposed to more retweets. Thus, node A performs more retweets than B does. It again shows how information diffusion is affected by network structure. Overall, this figure clearly illustrates that by careful choice of parameters we can generate networks with a very different structure.

2. http://gephi.github.io/

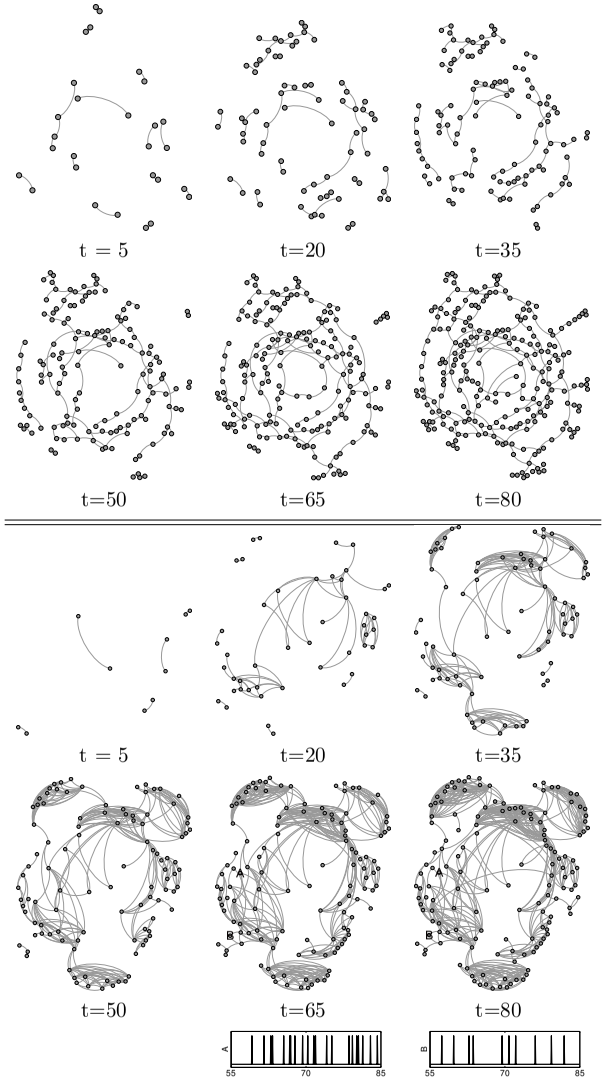

Figure 19: Evolution of two networks: one with $\beta = 0$ (1st and 2nd rows) and another one with $\beta = 0.8$ (3rd and 4th rows), and spike trains of nodes A and B (5th row).

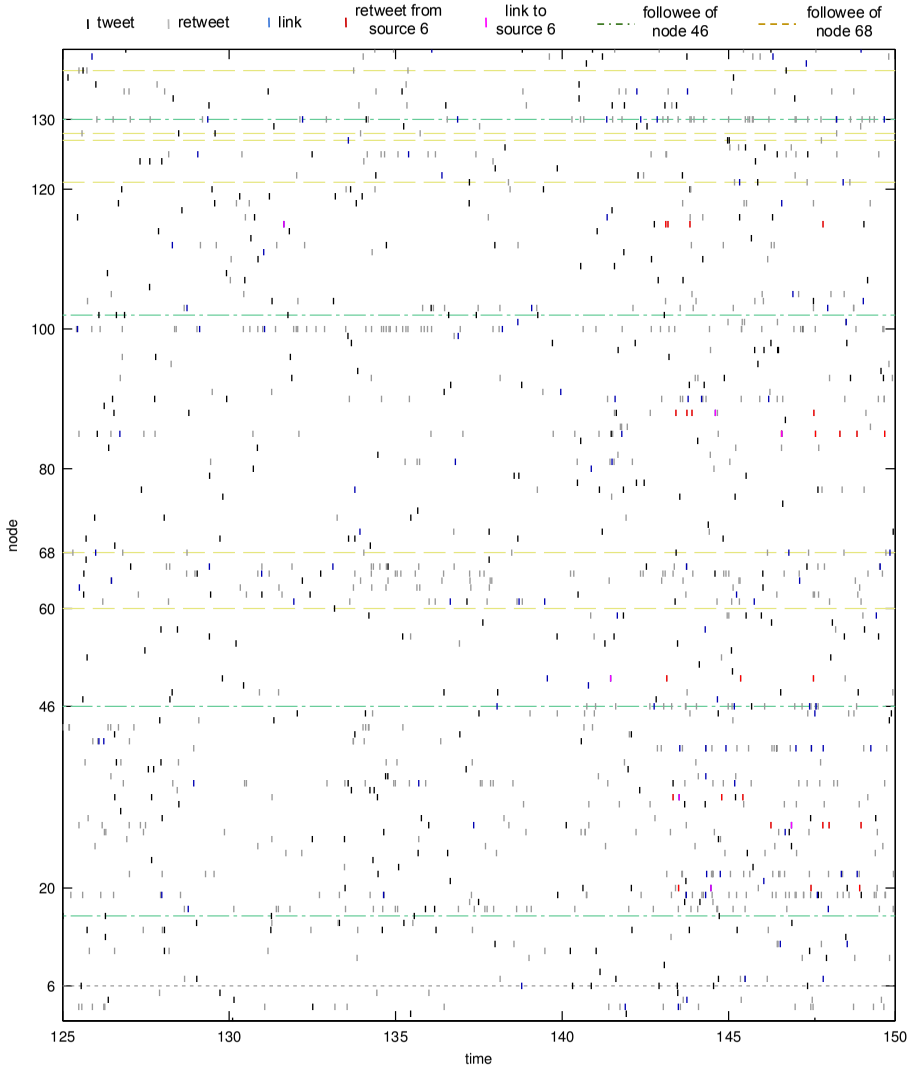

Figure 20: Coevolutionary dynamics of events for the network shown in Figure 21. Explanation is provided in section D.2.

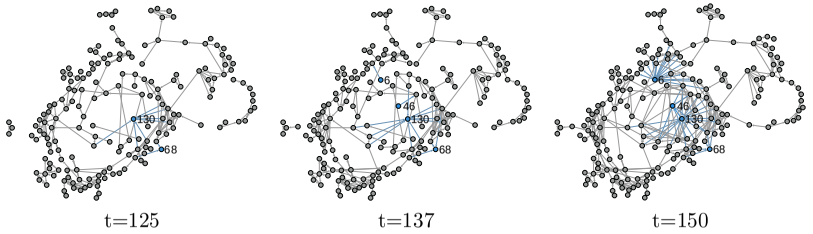

Figure 21: Network structure in which events from Figure 20 take place shown at different time points with the important nodes and links higlighted.

D.2 Cascade Visualization

Figure 20 illustrates the spike trains (tweet, retweet, and link events) for the first 140 nodes of a network simulated with a similar set of parameters as above and Figure 21 shows three snapshots of the network at different times. First, consider node 6 in the network. After she joins the network, a few nodes begin to follow him. Then, when she starts to tweet, her tweets are retweeted many times by others (red spikes) in the figure and these retweets subsequently boost the number of nodes that link to her (Magenta spikes). This clearly illustrates the scenario in which information diffusion triggers changes on the network structure. Second, consider nodes 46 and 68 and compare their associated events over time. After some time, node 46 becomes much more active than node 68. To understand why, note that soon after time 137, node 46 followed node 130, which is a very central node (*i.e.* following a lot of people), while node 68 did not. This clearly illustrates the scenario in which network evolution triggers changes on the dynamics of information diffusion.

Appendix E. Extensions

The basic model presented in Section 3 is just a show-case of the potential of point processes in modeling networks and processes over them. In this section, we extend our model in a variety of ways. More specifically, we explain how the model can be augmented to support link removal, node birth and death, and connection specific parameters. We did not perform experiments with these extensions because our real-world data set does not contain information regarding to link removal and node birth and death. Curating a comprehensive data set that can be used in modeling all these aspects of networks is left as interesting future work.

E.1 Link Deletion

We can generalize our model to support link deletion by introducing an intensity matrix $\boldsymbol{\Xi}^*(t) = (\boldsymbol{\xi}^*_{us}(t))_{u,s\in[m]}$ and model each individual intensity as a survival process. Assume $\boldsymbol{A}^+(t)$ is the previously defined counting matrix $\boldsymbol{A}(t)$, which indicates the existence of an edge at time t. Then, we introduce a new counting matrix $\boldsymbol{A}^-(t) = (A^-_{us}(t))_{u,s\in[m]}$, which

indicates the lack of an edge at time t, and we define it via its intensity function as

$$\mathbb{E}[d\boldsymbol{A}^{-}(t) \,|\, \mathcal{H}^{r}(t) \cup \mathcal{H}^{l}(t)] = \boldsymbol{\Xi}^{*}(t)\, dt, \tag{44}$$

Then, we define the intensity as

$$\boldsymbol{\xi}^{*}_{us}(t) = A^{+}_{us}(t)(\zeta_u + \nu_s \sum_{v \in \mathcal{F}u} \kappa_{\omega_3}(t) \star dA^{-}_{vs}(t)), \tag{45}$$

where the term $A^{+}_{us}(t)$ guarantees that the link has positive intensity to be removed only if it already exists, just like the term $1 - A_{us}(t)$ in Equation (21), the parameter ζ_u is the base rate of link deletion and $\nu_s \sum_{v \in \mathcal{F}u} \kappa_{\omega_3}(t) \star dA^{-}_{vs}(t)$ is the increased link deletion intensity due to increased number of followees of u who decided to unfollow s. This is an excitation term due to deleted links to source s; given s is unfollowed by some followees of u, then u may find s not a good source of information too.

Given a pair of nodes (u, s), the process starts with $A^{+}_{us}(t) = 0$. Whenever a link is created this process ends and a removal process $A^{-}_{us}(t)$ starts. Similarly, when the removal process fires, the connection is removed and a new link creation process is instantiated. These two processes interleave until the end.

E.2 Node Birth and Death

We can augment our model to consider the number of nodes $m(t)$ to change over time:

$$m(t) = m_b(t) - m_d(t) \tag{46}$$

where $m_b(t)$ and $m_d(t)$ are counting processes modeling the numbers of nodes that join and left the network till time t, respectively. The way we construct $m_b(t)$ and $m_d(t)$ guarantees that $m(t)$ is always non-negative.

The birth process, $m_b(t)$, is characterized by a conditional intensity function $\phi^{*}(t)$:

$$\mathbb{E}[dm_b(t) \,|\, \mathcal{H}^{r}(t) \cup \mathcal{H}^{l}(t)] = \phi^{*}(t)\, dt, \tag{47}$$

where

$$\phi^{*}(t) = \epsilon + \theta \sum_{u,s \in [m(t)]} \kappa_{\omega_4}(t) \star dN_{us}(t). \tag{48}$$

Here, ϵ is the constant rate of arrival and $\theta \sum_{u,s \in [m(t)]} \kappa_{\omega_4}(t) \star dN_{us}(t)$ is the increased rate of node arrival due to the increased activity of nodes. Intuitively, the higher the overall activity in the existing network, the larger the number of new users.

The construction of the death process, $m_d(t)$, is more involved. Every time a new user joins the network, we start a survival process that controls whether she leaves the network. Thus, we can stack all these survival processes in a vector, $\boldsymbol{l}(t) = (l_u(t))_{u \in [m]}$, characterized by a multidimensional conditional intensity function $\boldsymbol{\sigma}^{*}(t) = (\sigma_u(t))_{u \in [m_b(t)]}$:

$$\mathbb{E}[d\boldsymbol{l}(t) | \mathcal{H}^{r}(t) \cup \mathcal{H}^{l}(t)] = \boldsymbol{\sigma}^{*}(t)\, dt. \tag{49}$$

Intuitively, we expect the nodes with lower activity to be more likely to leave the network and thus its conditional intensity function to adopt the following form:

$$\sigma^{*}_{u}(t) = (1 - l_u(t)) \left[\sum_{j=1}^{J} \pi_j g_j(t) + \left(h(t) - \sum_{s \in [m(t)]} \kappa_{\omega_5}(t) \star dN_{us}(t) \right)_{+} \right], \tag{50}$$

where the term $(1 - l_u(t))$ ensures that a node is deleted only once, $\sum_{j=1}^{J} \pi_j g_j(t)$ is the history-independent typical rate of death, shared across nodes, which we represent by a grid of known temporal kernels, $\{g_j(t)\}$ with unknown coefficients, $\{\pi_j\}$, and the second term is capturing the effect of activity on the probability of leaving the network. More specifically, if a node is not active, we assume its intensity is upper bounded by $h(t)$ and the most active she becomes, the lower its probability of leaving the network and the larger the term $\sum_{s \in [m(t)]} \kappa_{\omega_5}(t) \star dN_{us}(t)$. The hinge function $(\cdot)_{+}$ guarantees the intensity is always positive.

Then, given the individual death processes the total death process is

$$m_d(t) = \sum_{u=1}^{m_b(t)} l_u(t), \tag{51}$$

which completes the modeling of the time-varying number of nodes.

E.3 Incorporating Features

One can simply enrich the model by taking into account the longitudinal or static information of the networked data, *e.g.*, by conditioning the intensity on additional external features, such as node attributes or edge types (Li and Zha, 2014; Tran et al., 2015). Let us assume each user u comes with a K-dimensional feature vector $\boldsymbol{x}_u$ including properties such as her age, job, location, number of followers, number of tweets, and more generally structural features (Fadaee et al., 2015). A good feature set can represent the local and global structure of the networks. For example, when the feature set includes number of followers or location information, the link creation process can be reduced to Barabasi-Albert model (Barabási and Albert, 1999), Watts-Strogatz model(Watts and Strogatz, 1998), or their many variations depending on the coefficients.

Interestingly, we can augment the information diffusion intensity as follows. We introduce a K-dimensional link intensity parameter $\boldsymbol{\eta}_u$ in which each dimension reflects the contribution of the corresponding element in the feature vector to the intensity and replace the baseline rate η_u by $\boldsymbol{\eta}_u^{\top} \boldsymbol{x}_u$. Similarly, we introduce a K-dimensional vector $\boldsymbol{\beta}_s$ where each dimension has a corresponding element in the feature vector $\boldsymbol{x}_s$ and substitute β_s by $\boldsymbol{\beta}_s \boldsymbol{x}_s$. Therefore, one can rewrite the original information diffusion intensity given by Equation (19) as:

$$\gamma^{*}_{us}(t) = \mathbb{I}[u = s]\, \boldsymbol{\eta}_u^{\top} \boldsymbol{x}_u + \mathbb{I}[u \neq s]\, \boldsymbol{\beta}_s^{\top} \boldsymbol{x}_s \sum\nolimits_{v \in \mathcal{F}_u(t)} \kappa_{\omega_1}(t) \star (A_{uv}(t)\; dN_{vs}(t))\,. \tag{52}$$

Similarly, we can parameterize the coefficients of the link creation intensity by a K-dimensional vector and write the counter-part of Equation (20) incorporating features of the node for computing the intensity:

$$\lambda^{*}_{us}(t) = (1 - A_{us}(t))(\boldsymbol{\mu}_u^{\top} \boldsymbol{x}_u + \boldsymbol{\alpha}_u^{\top} \boldsymbol{x}_u \sum_{v \in \mathcal{F}_u(t)} \kappa_{\omega_2}(t) \star dN_{vs}(t)). \tag{53}$$

Through this extension we can easily incorporate content quality of events as well; Tweets containing interesting ideas, hot news, or specific language will be retweeted more. Furthermore, these high quality tweets can increase the likelihood of new connections. All these contextual features can be easily incorporated.

Another important feature that can be used is the time. The framework can handle situations that the base rates are time dependent, *i.e.*, $\eta_u(t)$ or $\mu_u(t)$. Please refer to (Tabibian et al., 2017; Du et al., 2015) for good instances of time dependent base rates. For example, where there are seasonal increase or decrease in the follow or retweet processes, we can write the base rate as $\mu_u(t) = \sum_{k=1}^{K} r_k h_k(t)$ where $h_k(t)$'s are sinusoidal kernels with different width and r_k's are the coefficients to be learned.

Surprisingly enough, all the results for convexity for parameter learning, and efficient simulation techniques are still valid for this case too. As far as the features contribute to the intensity linearly, the log-likelihood is concave and we can simulate the model as efficiently as the original model (Li and Zha, 2014; Tran et al., 2015).

E.4 Connection Specific Parameters

Up to this point, the parameters of the link creation and removal, node birth and death and the information diffusion intensities depend on one end point of the interactions. For example β_s and η_u in the information diffusion intensity given by Equation (19) only depend on the source and the actor, respectively. However, proceeding with this example, parameters can be made connection specific, *i.e.*, Equation (19) can be restated as

$$\gamma^*_{us}(t) = \mathbb{I}[u = s]\, \eta_{us} + \mathbb{I}[u \neq s]\, \beta_{us} \sum\nolimits_{v \in \mathcal{F}_u(t)} \kappa_{\omega_1}(t) \star (A_{uv}(t)\ dN_{vs}(t))\,, \tag{54}$$

where η_{us} is the base intensity of u retweeting a tweet originated by s and β_{us} is the coefficient of excitement of u to retweet s when one of her followees retweets something from s.

Given enough computational resources and large amounts of historical data, one can take into account more complex scenarios and larger and more flexible models. For example, the middle user, say v, who is along the path of diffusion and forwards the tweet originated from s to u can also be taking into consideration, *i.e.*, defining β_{svu} as the amount of increase in intensity of user u retweeting from s when user v has just retweeted a post from s. All desirable properties of simulation algorithm and parameter estimation method still hold.

E.5 Source-oblivious Information Propagation

Our framework, Coevolve, relies on the assumption that the identity of the original source is preserved through the information propagation process. However, some platforms may only keep the last hop in the propagation. Furthermore, this assumption may be violated when users copy the content of the posts rather than reshare or retweet it. The current framework, can be easily extended to handle such cases. Basically, the source-oblivious problem can be posed as a missing (or noisy) data problem which amounts to model and infer the propagation process via incomplete observation and has been studied recently (Zipkin et al., 2016; Du et al., 2015; Stomakhin et al., 2011). Furthermore, the unobserved identity of the source can be modeled as a latent variable and inferred simultaneously with the Hawkes diffusion network (Yang and Zha, 2013).

Abstract

In many applications, data come with a natural ordering. This ordering can often induce local dependence among nearby variables. However, in complex data, the width of this dependence may vary, making simple assumptions such as a constant neighborhood size unrealistic. We propose a framework for learning this local dependence based on estimating the inverse of the Cholesky factor of the covariance matrix. Penalized maximum likelihood estimation of this matrix yields a simple regression interpretation for local dependence in which variables are predicted by their neighbors. Our proposed method involves solving a convex, penalized Gaussian likelihood problem with a hierarchical group lasso penalty. The problem decomposes into independent subproblems which can be solved efficiently in parallel using first-order methods. Our method yields a sparse, symmetric, positive definite estimator of the precision matrix, encoding a Gaussian graphical model. We derive theoretical results not found in existing methods attaining this structure. In particular, our conditions for signed support recovery and estimation consistency rates in multiple norms are as mild as those in a regression problem. Empirical results show our method performing favorably compared to existing methods. We apply our method to genomic data to flexibly model linkage disequilibrium. Our method is also applied to improve the performance of discriminant analysis in sound recording classification.

Keywords: Local dependence, Gaussian graphical models, precision matrices, Cholesky factor, hierarchical group lasso

1. Introduction

Estimating large inverse covariance matrices is a fundamental problem in modern multivariate statistics. Consider a random vector $X = (X_1, \ldots, X_p)^T \in \mathbb{R}^p$ with mean zero and covariance matrix $E(XX^T) = \Sigma$. Unlike the covariance matrix, which captures marginal correlations among variables in X, the inverse covariance matrix $\Omega = \Sigma^{-1}$ (also known as the precision matrix) characterizes conditional correlations and, under a Gaussian model, $\Omega_{jk} = 0$ implies that X_j and X_k are conditionally independent given all other variables. When p is large, it is common to regularize the precision matrix estimator by making it sparse (see, e.g., Pourahmadi, 2013). This paper focuses on the special context in which variables have a natural ordering, such as when data are collected over time or along a genome. In such a context, it is often reasonable to assume that random variables that are far away in the ordering are less dependent than those that are close together. For example, it is known that genetic mutations that occur close together on a chromosome are more likely to be coinherited than mutations that are located far apart. We propose a method for estimating the precision matrix based on this assumption while also allowing each random variable to have its own notion of closeness.

In general settings where variables do not necessarily have a known ordering, two main types of convex methods with strong theoretical results have been developed for introducing sparsity in Ω. The first approach, known as the *graphical lasso* (Yuan and Lin, 2007; Banerjee et al., 2008; Friedman et al., 2008; Rothman et al., 2008), performs penalized maximum likelihood, solving $\min_{\Omega \succ 0, \Omega = \Omega^T} \mathcal{L}(\Omega) + \lambda P(\Omega)$, where $\mathcal{L}(\Omega) = -\log\det\Omega + n^{-1}\sum_{i=1}^n x_i^T \Omega x_i$ is, up to constants, the negative log-likelihood of a sample of n independent Gaussian random vectors and $P(\Omega)$ is the (vector) ℓ_1-norm of Ω. Zhang and Zou (2014) introduce a new convex loss function called the *D-trace loss* and propose a positive definite precision matrix estimator by minimizing an ℓ_1-penalized version of this loss. The second approach is through penalized pseudo-likelihood, the most well-known of which is called *neighborhood selection* (Meinshausen and Bühlmann, 2006). Estimators in this category are usually solved by a column-by-column approach and thus are more amenable to theoretical analysis (Yuan, 2010; Cai et al., 2011; Liu and Luo, 2012; Liu and Wang, 2012; Sun and Zhang, 2013; Khare et al., 2014). However they are not guaranteed to be positive definite and do not exploit the symmetry of Ω. Peng et al. (2009) propose a partial correlation matrix estimator that develops a symmetric version of neighborhood selection; however, positive definiteness is still not guaranteed.

In the context of variables with a natural ordering, by contrast, almost no work uses convex optimization to flexibly estimate Ω while exploiting the ordering structure. Sparsity is usually induced via the Cholesky decomposition of Σ, which leads to a natural interpretation of sparsity. Consider the Cholesky decomposition $\Sigma = QQ^T$, which implies $\Omega = L^T L$ for $L = Q^{-1}$ for lower triangular matrices Q and L with positive diagonals. The assumption that $X \sim N(0, \Sigma)$ is then equivalent to a set of linear models in terms of rows of L, i.e., $L_{11}X_1 = \varepsilon_1$ and

$$L_{rr}X_r = -\sum_{k=1}^{r-1} L_{rk}X_k + \varepsilon_r \quad r = 2, \ldots, p, \tag{1}$$

where $\varepsilon \sim N(0, I_p)$. Thus, $L_{rk} = 0$ (for $k < r$) can be interpreted as meaning that in predicting X_r from the previous random variables, one does not need to know X_k. This observation has motivated previous work, including Pourahmadi (1999); Wu and Pourahmadi (2003); Huang et al. (2006); Shojaie and Michailidis (2010); Khare et al. (2016). While these methods assume sparsity in L, they do not require local dependence because each variable is allowed to be dependent on predecessors that are distant from it (compare the upper left to the upper right panel of Figure 10).

The assumption of "local dependence" can be expressed as saying that each variable X_r can be best explained by exactly its K_r closest predecessors:

$$L_{rr}X_r = -\sum_{k=r-K_r}^{r-1} L_{rk}X_k + \varepsilon_r, \quad \text{for} \quad L_{rk} \neq 0, \quad r - K_r \leq k \leq r-1, \quad r = 2, \ldots, p. \quad (2)$$

Note that this does not describe all patterns of a variable depending on its nearby variables. For example, X_r can be dependent on X_{r-2} but not on X_{r-1}. In this case, the dependence is still local, but would not be captured by (2). We focus on the restricted class (2) since it greatly simplifies the interpretation of the learned dependence structure by capturing the extent of this dependence in a single number K_r, the neighborhood size.

Another desirable property of model (2) is that it admits a simple connection between the sparsity pattern of L and the sparsity pattern of the precision matrix Ω in the Gaussian graphical model. In particular, straightforward algebra shows that for $j < k$,

$$L_{kj} = \cdots = L_{pj} = 0 \implies \Omega_{jk} = 0. \quad (3)$$

Statistically, this says that if none of the variables $X_k, \ldots, X_p$ depends on X_j in the sense of (1), then X_j and X_k are conditionally independent given all other variables.

Bickel and Levina (2008) study theoretical properties in the case that all bandwidths, K_r, are equal, in which case model (2) is a K_r-ordered antedependence model (Zimmerman and Nunez-Anton, 2009). A banded estimate of L then induces a banded estimate of Ω. The *nested lasso* approach of Levina et al. (2008) provides for "adaptive banding", allowing K_r to vary with r (which corresponds to variable-order antedependence models in Zimmerman and Nunez-Anton, 2009); however, the nested lasso is non-convex, meaning that the proposed algorithm does not necessarily minimize the stated objective and theoretical properties of this estimator have not been established.

In this paper, we propose a penalized likelihood approach that provides the flexibility of the nested lasso but is formulated as a convex optimization problem, which allows us to prove strong theoretical properties and to provide an efficient, scalable algorithm for computing the estimator. The theoretical development of our method allows us to make clear comparisons with known results for the graphical lasso (Rothman et al., 2008; Ravikumar et al., 2011) in the non-ordered case. Both methods are convex penalized likelihood approaches, so this comparison highlights the similarities and differences in the ordered and non-ordered problems.

There are two key choices we make that lead to a convex formulation. First, we express the optimization problem in terms of the Cholesky factor L. The nested lasso and other methods (starting with Pourahmadi 1999) use the modified Cholesky decomposition, $\Omega = T^T D^{-1} T$, where T is a lower-triangular matrix with ones on its diagonal and D is a diagonal matrix with positive entries. While $\mathcal{L}(\Omega)$ is convex in Ω, the negative log-likelihood $\mathcal{L}(T^T D^{-1} T)$ is not jointly convex in T and D. By contrast,

$$\mathcal{L}\left(L^T L\right) = -\log\det\left(L^T L\right) + \frac{1}{n}\sum_{i=1}^{n} x_i^T L^T L x_i = -2\sum_{r=1}^{p}\log L_{rr} + \frac{1}{n}\sum_{i=1}^{n}\|Lx_i\|_2^2 \quad (4)$$

is convex in L. This parametrization is considered in Aragam and Zhou (2015), Khare et al. (2014), and Khare et al. (2016). Maximum likelihood estimation of L preserves the regression interpretation by noting that

$$\mathcal{L}\left(L^T L\right) = -2\sum_{r=1}^{p}\log L_{rr} + \frac{1}{n}\sum_{r=1}^{p}\sum_{i=1}^{n} L_{rr}^2\left(x_{ir} + \sum_{k=1}^{r-1} L_{rk}x_{ik}/L_{rr}\right)^2.$$

This connection has motivated previous work with the modified Cholesky decomposition, in which $T_{rk} = -L_{rk}/L_{rr}$ are the coefficients of a linear model in which X_r is regressed on its predecessors, and $D_{rr} = L_{rr}^{-2}$ corresponds to the error variance. The second key choice is our use of a hierarchical group lasso in place of the nested lasso's nonconvex penalty.

We introduce here some notation used throughout the paper. For two sequences of constants $a(n)$ and $b(n)$, the notation $a(n) = o\left(b(n)\right)$ means that for every $\varepsilon > 0$, there exists a constant $N > 0$ such that $|a(n)/b(n)| \leq \varepsilon$ for all $n \geq N$. And the notation $a(n) = \mathcal{O}\left(b(n)\right)$ means that there exists a constant $N > 0$ and a constant $M > 0$ such that $|a(n)/b(n)| \leq M$ for all $n \geq N$. For a sequence of random variables $A(n)$, the notation $A(n) = \mathcal{O}_P\left(b(n)\right)$ means that for every $\varepsilon > 0$, there exists a constant $M > 0$ such that $\mathrm{P}\left(|A(n)/b(n)| > M\right) \leq \varepsilon$ for all n.

For a vector $v = (v_1, \ldots, v_p) \in \mathbb{R}^p$, we define $\|v\|_1 = \sum_{j=1}^p |v_j|$, $\|v\|_2 = (\sum_{j=1}^p v_j^2)^{1/2}$ and $\|v\|_\infty = \max_j |v_j|$. For a matrix $M \in \mathbb{R}^{n\times p}$, we define the element-wise norms by two vertical bars. Specifically, $\|M\|_\infty = \max_{jk}|M_{jk}|$ and Frobenius norm $\|M\|_F = (\sum_{j,k} M_{jk}^2)^{1/2}$. For $q \geq 1$, we define the matrix-induced (operator) q-norm by three vertical bars: $|||M|||_q = \max_{\|v\|_q=1}\|Mv\|_q$. Important special cases include $|||M|||_2$, also known as the spectral norm, which is the largest singular value of M, as well as $|||M|||_1 = \max_k \sum_{j=1}^p |M_{jk}|$ and $|||M|||_\infty = \max_j \sum_{k=1}^p |M_{jk}|$. Note that $|||M|||_1 = |||M|||_\infty$ when M is symmetric.

Given a p-vector v, a $p \times p$ matrix M, and an index set T, let $v_T = (v_i)_{i\in T}$ be the $|T|$-subvector and M_T the $p \times |T|$ submatrix with columns selected from T. Given a second index set T', let $M_{TT'}$ be the $|T| \times |T'|$ submatrix with rows and columns of M indexed by T and T', respectively. Specifically, we use $L_{r\cdot}$ to denote the r-th row of L.

2. Estimator

For a given tuning parameter $\lambda \geq 0$, we define our estimator $\hat{L}$ to be a minimizer of the following penalized negative Gaussian log-likelihood

$$\hat{L} \in \underset{\substack{L:L_{rr}>0 \\ L_{rk}=0 \text{ for } r<k}}{\arg\min} \left\{-2\sum_{r=1}^{p}\log L_{rr} + \frac{1}{n}\sum_{i=1}^{n}\|Lx_i\|_2^2 + \lambda\sum_{r=2}^{p} P_r\left(L_{r\cdot}\right)\right\}. \quad (5)$$

The penalty P_r, which is applied to the r-th row, is defined by

$$P_r\left(L_{r\cdot}\right) = \sum_{\ell=1}^{r-1}\left\|W^{(\ell)} * L_{g_{r,\ell}}\right\|_2 = \sum_{\ell=1}^{r-1}\left(\sum_{m=1}^{\ell} w_{\ell m}^2 L_{rm}^2\right)^{1/2}, \quad (6)$$

where $W^{(\ell)} = (w_{\ell 1}, \ldots, w_{\ell\ell}) \in \mathbb{R}^\ell$ is a vector of weights, $*$ denotes element-wise multiplication, and $L_{g_{r,\ell}}$ denotes the vector of elements of L from the group $g_{r,\ell}$, which corresponds

to the first ℓ elements in the r-th row (for $1 \leq \ell \leq r-1$):

$$g_{r,\ell} = \left\{(r, \ell') : \ell' \leq \ell\right\}.$$

Since $g_{r,1} \subset g_{r,2} \subset \cdots \subset g_{r,r-1}$, each row r of L is penalized with a sum of $r-1$ nested, weighted ℓ_2-norm penalties. This is a hierarchical group lasso penalty (Yuan and Lin, 2007; Zhao et al., 2009; Jenatton et al., 2011; Yan and Bien, 2015) with group structure conveyed in Figure 1.

With $w_{\ell m} > 0$, this nested structure always puts more penalty on those elements that are further away from the diagonal. Since the group lasso has the effect of setting to zero a subset of groups, it is apparent that this choice of groups ensures that whenever the elements in $g_{r,\ell}$ are set to zero, elements in $g_{r,\ell'}$ are also set to zero for all $\ell' \leq \ell$. In other words, for each row of $\hat{L}$, the non-zeros are those elements within some (row-specific) distance of the diagonal. This is in contrast to the ℓ_1-penalty as used in Khare et al. (2016), which produces sparsity patterns with no particular structure (compare the top-left and top-right panels of Figure 10).

The choice of weights, $w_{\ell m}$, affects both the empirical and theoretical performance of the estimator. We focus primarily on a quadratically decaying set of weights,

$$w_{\ell m} = \frac{1}{(\ell - m + 1)^2}, \tag{7}$$

but also consider the unweighted case (in which $w_{\ell m} = 1$). The decay counteracts the fact that the elements of L appear in differing numbers of groups (for example L_{r1} appears in $r-1$ groups whereas $L_{r,r-1}$ appears in just one group). In a related problem, Bien et al. (2016) choose weights that decay more slowly with $\ell - m$ than (7). Our choice makes the enforcement of hierarchy weaker so that our penalty behaves more closely to the lasso penalty (Tibshirani, 1996). The choice of weight sequence in (7) is more amenable to theoretical analysis; however, in practice the unweighted case is more efficiently implemented and works well empirically.

Problem (5) is convex in L. While $-\log\det(\cdot)$ is strictly convex, $-\sum_r \log(L_{rr})$ is not strictly convex in L. Thus, the arg min in (5) may not be unique. In Section 4, we provide sufficient conditions to ensure uniqueness with high probability.

In Appendix A, we show that (5) decouples into p independent subproblems, each of which estimates one row of L. More specifically, let $\mathbf{X} \in \mathbb{R}^{n \times p}$ be a sample matrix with independent rows $x_i \sim N(0, \Sigma)$, $\hat{L}_{11} = n^{1/2}(\mathbf{X}_1^T \mathbf{X}_1)^{-1/2}$ and for $r = 2, \ldots, p$,

$$\hat{L}_{r,1:r} = \underset{\beta \in \mathbb{R}^r; \beta_r > 0}{\arg\min} \left\{ -2\log\beta_r + \frac{1}{n}\left\|\mathbf{X}_{1:r}\beta\right\|_2^2 + \lambda \sum_{\ell=1}^{r-1} \left(\sum_{m=1}^{\ell} w_{\ell m}^2 \beta_m^2 \right)^{1/2} \right\}. \tag{8}$$

This observation means that the computation can be easily parallelized, which potentially can achieve a linear speed up with the number of CPU cores. Theoretically, to analyze the properties of $\hat{L}$ it is easier to start by studying an estimator of each row, i.e., a solution to (8). We will see in Section 4 that problem (8) has connections to a penalized regression problem, meaning that both the assumptions and results we can derive are better than if we were working with a penalty based on Ω.

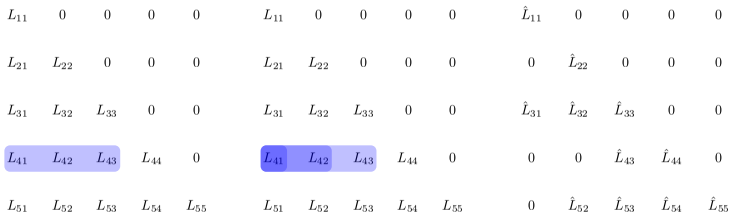

Figure 1: There are $\binom{p}{2}$ groups used in the penalty, with each row r having $r-1$ nested groups $g_{r,1} \subset g_{r,2} \subset \cdots \subset g_{r,r-1}$. Left: the group $g_{4,3}$. Middle: the nested group structure $g_{4,1} \subset g_{4,2} \subset g_{4,3}$. Right: A possible sparsity pattern in $\hat{L}$, where elements in $g_{2,1}, g_{4,2}$ (and thus $g_{4,1}$) and $g_{5,1}$ are set to zero.

In light of the regression interpretation of (1), $\hat{L}$ provides an interpretable notion of local dependence; however, we can of course also use our estimate of L to estimate Ω: $\hat{\Omega} = \hat{L}^T\hat{L}$. By construction, this estimator is both symmetric and positive definite. Unlike a lasso penalty, which would induce unstructured sparsity in the estimate of L and thus would not be guaranteed to produce a sparse estimate of Ω, the adaptively banded structure in our estimator of L can yield a generally banded $\hat{\Omega}$ with sparsity pattern determined by (3) (See the top-left and bottom-left panels in Figure 10 for an example).

3. Computation

As observed above, we can compute $\hat{L}$ by solving (in parallel across r) problem (8). Consider an alternating direction method of multipliers (ADMM) approach that solves the equivalent problem

$$\min_{\beta, \gamma \in \mathbb{R}^r; \beta_r > 0} \left\{ -2\log\beta_r + \frac{1}{n}\left\|\mathbf{X}_{1:r}\beta\right\|_2^2 + \lambda \sum_{\ell=1}^{r-1} \left(\sum_{m=1}^{\ell} w_{\ell m}^2 \gamma_m^2 \right)^{1/2} \quad \text{s.t.} \quad \beta = \gamma \right\}.$$

Algorithm 1 presents the ADMM algorithm, which repeatedly minimizes this problem's augmented Lagrangian over β, then over γ, and then updates the dual variable $u \in \mathbb{R}^r$. The main computational effort in the algorithm is in solving (9) and (10). Note that (9) has a smooth objective function. Straightforward calculus gives the closed-form solution (see Appendix B for detailed derivation),

$$\begin{aligned}
\beta_r^{(t+1)} &= \frac{-B - \sqrt{B^2 - 8A}}{2A} > 0 \\
\beta_{-r}^{(t+1)} &= -\left(2S_{-r,-r}^{(r)} + \rho I\right)^{-1} \left(2S_{-r,r}^{(r)}\beta_r^{(t+1)} + u_{-r}^{(t)} - \rho\gamma_{-r}^{(t)}\right),
\end{aligned}$$

Algorithm 1 ADMM algorithm to solve (8)

Require: $\beta^{(0)}$, $\gamma^{(0)}$, $u^{(0)}$, $\rho > 0$, $t = 1$.

repeat

$$\beta^{(t)} \leftarrow \underset{\beta \in \mathbb{R}^r : \beta_r > 0}{\arg\min} \left\{ -2 \log \beta_r + \frac{1}{n} \left\| \mathbf{X}_{1:r} \beta \right\|_2^2 + \left(\beta - \gamma^{(t-1)} \right)^T u^{(t-1)} + \frac{\rho}{2} \left\| \beta - \gamma^{(t-1)} \right\|_2^2 \right\} \tag{9}$$

$$\gamma^{(t)} \leftarrow \underset{\gamma \in \mathbb{R}^r}{\arg\min} \left\{ \frac{\rho}{2} \left\| \gamma - \beta^{(t)} - \rho^{-1} u^{(t-1)} \right\|_2^2 + \lambda \sum_{\ell=1}^{r-1} \left(\sum_{m=1}^{\ell} w_{\ell m}^2 \gamma_m^2 \right)^{1/2} \right\} \tag{10}$$

$u^{(t)} \leftarrow u^{(t-1)} + \rho \left(\beta^{(t)} - \gamma^{(t)} \right)$

$t \leftarrow t + 1$

until convergence

return $\gamma^{(t)}$

where

$$\begin{aligned} S^{(r)} &= \frac{1}{n} \mathbf{X}_{1:r}^T \mathbf{X}_{1:r} \\ A &= 4 S_{r,-r}^{(r)} \left(2 S_{-r,-r}^{(r)} + \rho I \right)^{-1} S_{-r,r}^{(r)} - 2 S_{r,r}^{(r)} - \rho < 0 \\ B &= 2 S_{r,-r}^{(r)} \left(2 S_{-r,-r}^{(r)} + \rho I \right)^{-1} \left(u_{-r}^{(t)} - \rho \gamma_{-r}^{(t)} \right) - u_r^{(t)} + \rho \gamma_r^{(t)}. \end{aligned}$$

The closed-form update above involves matrix inversion. With $\rho > 0$, the matrix $2S_{-r,-r}^{(r)} + \rho I$ is invertible even when $r > n$. Since determining a good choice for the ADMM parameter ρ is in general difficult, we adapt the dynamic ρ updating scheme described in Section 3.4.1 of Boyd et al. (2011).

Solving (10) requires evaluating the proximal operator of the hierarchical group lasso with general weights. We adopt the strategy developed in Bien et al. (2016) (based on a result of Jenatton et al. 2011), which solves the dual problem of (10) by performing Newton's method on at most $r - 1$ univariate functions. The detailed implementation is given in Algorithm 3 in Appendix C. Each application of Newton's method corresponds to performing an elliptical projection, which is a step of blockwise coordinate ascent on the dual of (10) (see Appendix D for details). Finally we observe in Algorithm 2 that for the unweighted case ($w_{\ell m} = 1$), solving (10) is remarkably efficient.

The `R` package `varband` provides `C++` implementations of Algorithms 1 and 2.

4. Statistical Properties

In this section we study the statistical properties of our estimator. In what follows, we consider a lower triangular matrix L having row-specific bandwidths, K_r. The first $J_r = r - 1 - K_r$ elements of row r are zero, and the band of non-zero off-diagonals (of size K_r) is denoted $\mathcal{I}_r = \{J_r + 1, \ldots, r-1\}$. We also denote $\mathcal{I}_r^c = \{1, 2, \ldots, r\} \setminus \mathcal{I}_r$. See Figure 2 for a graphical example of $K_5, J_5, \mathcal{I}_4$, and $\mathcal{I}_4^c$.

Algorithm 2 Algorithm for solving (10) for unweighted estimator

Require: $\beta^{(t)}, u^{(t-1)} \in \mathbb{R}^r$, $\lambda, \rho > 0$.

Initialize $\gamma^{(t)} = \beta^{(t)} + u^{(t-1)}/\rho$ and $\tau = \lambda/\rho$

for $\ell = 1, \ldots, r-1$ **do**

$$\left(\gamma^{(t)} \right)_{1:\ell} \leftarrow \left(1 - \frac{\tau}{\left\| \left(\gamma^{(t)} \right)_{1:\ell} \right\|_2} \right)_+ \left(\gamma^{(t)} \right)_{1:\ell}$$

return $\gamma^{(t)}$.

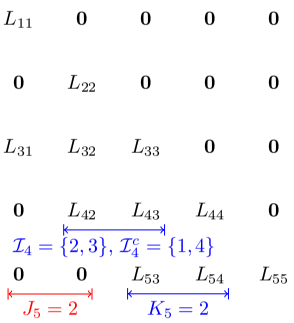

Figure 2: Schematic showing $J_r, K_r, \mathcal{I}_r$, and $\mathcal{I}_r^c$.

Our theoretical analysis is built on the following assumptions:

A1 *Gaussian assumption*: The sample matrix $\mathbf{X} \in \mathbb{R}^{n \times p}$ has n independent rows with each row x_i drawn from $N(\mathbf{0}, \Sigma)$.

A2 *Sparsity assumption*: The true Cholesky factor $L \in \mathbb{R}^{p \times p}$ is the lower triangular matrix with positive diagonal elements such that the precision matrix $\Omega = \Sigma^{-1} = L^T L$. The matrix L has row-specific bandwidths K_r such that $L_{rj} = 0$ for $0 < j < r - K_r$.

A3 *Irrepresentable condition*: There exists some $\alpha \in (0, 1]$ such that

$$\max_{2 \le r \le p} \max_{\ell \in \mathcal{I}_r^c} \left\| \Sigma_{\ell \mathcal{I}_r} \left(\Sigma_{\mathcal{I}_r \mathcal{I}_r} \right)^{-1} \right\|_1 \le \frac{6}{\pi^2} (1 - \alpha)$$

A4 *Bounded singular values*: There exists a constant κ such that

$$0 < \kappa^{-1} \le \sigma_{\min}(L) \le \sigma_{\max}(L) \le \kappa$$

When $\max_r K_r < n$, the Gaussianity assumption **A1** implies that $\mathbf{X}_{\mathcal{I}_r}$ has full column rank for all r with probability one. Our analysis applies to the general high-dimensional scaling scheme where $K_r = K_r(n)$ and $p = p(n)$ can grow with n.

For $r = 2, \ldots, p$ and $\ell \in \mathcal{I}_r^c = \{1, \ldots, J_r, r\}$, let

$$\theta_r^{(\ell)} := \mathrm{Var}\left(X_\ell | X_{\mathcal{I}_r}\right) \quad \text{and} \quad \theta_r := \max_{\ell \in \mathcal{I}_r^c} \theta_r^{(\ell)}.$$

By Assumption **A1**, $\theta_r^{(\ell)} = \Sigma_{\ell\ell} - \Sigma_{\ell\mathcal{I}_r} \left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1} \Sigma_{\mathcal{I}_r\ell}$ represents the noise variance when regressing X_ℓ on $X_{\mathcal{I}_r}$, i.e., for $\ell = 1, \ldots, J_r, r$,

$$X_\ell = \Sigma_{\ell\mathcal{I}_r} (\Sigma_{\mathcal{I}_r\mathcal{I}_r})^{-1} X_{\mathcal{I}_r}^T + E_\ell \qquad \text{with} \qquad E_\ell \sim N\left(0, \theta_r^{(\ell)}\right). \tag{11}$$

In words, $\theta_r^{(\ell)}$ measures the degree to which X_ℓ cannot be explained by the variables in the support and θ_r is the maximum such value over all ℓ outside of the support $\mathcal{I}_r$ in the r-th row. Intuitively, the difficulty of the estimation problem increases with θ_r. Note that for $r = 1, \ldots, p$, (1) implies $\theta_r^{(r)} = 1/L_{rr}^2$.

Assumption **A3** (along with the $\beta_{\min}$ condition) is essentially a necessary and sufficient condition for support recovery of lasso-type methods (see, e.g., Zhao and Yu, 2006; Meinshausen and Bühlmann, 2006; Wainwright, 2009; Van de Geer and Bühlmann, 2009; Ravikumar et al., 2011). The constant $\alpha \in (0, 1]$ is usually referred to as the irrepresentable (incoherence) constant (Wainwright, 2009). Intuitively, the irrepresentable condition requires low correlations between signal and noise predictors, and thus a value of α that is close to 1 implies that recovering the support is easier to achieve. The constant $6\pi^{-2}$ is determined by the choice of weight (7) and can be eliminated by absorbing its reciprocal into the definition of the weights $w_{\ell m}$. Doing so, one finds that our irrepresentable condition is essentially the same as the one found in the regression setting (Wainwright, 2009) despite the fact that our goal is estimating a precision matrix.

Assumption **A4** is a bounded singular value condition. Recalling that $\Omega = L^T L$,

$$0 < \kappa^{-2} \leq \sigma_{\min}(\Sigma) \leq \sigma_{\max}(\Sigma) \leq \kappa^2, \tag{12}$$

which is equivalent to the commonly used bounded eigenvalue condition in other literatures.

4.1 Row-Specific Results

We start by analyzing support recovery properties of our estimator for each row, i.e., the solution to the subproblem (8). For $r > n$, the Hessian of the negative log-likelihood is not positive definite, meaning that the objective function may not be strictly convex in β and the solution not necessarily unique. Intuitively, if the tuning parameter λ is large, the resulting row estimate $\hat{L}_{r\cdot}$ is sparse and thus includes most variation in a small subset of the r variables. More specifically, for large λ, $\hat{\mathcal{I}}_r \subseteq \mathcal{I}_r$ and thus by Assumption **A1**, $\mathbf{X}_{\hat{\mathcal{I}}_r}$ has full rank, which implies that $\hat{L}_{r\cdot}$ is unique. The series of technical lemmas in Appendix E precisely characterizes the solution.

The first part of the theorem below shows that with an appropriately chosen tuning parameter λ the solution to (8) is sparse enough to be unique and that we will not overestimate the true bandwidth. Knowing that the support of the unique row estimator $\hat{L}_{r\cdot}$ is

contained in the true support reduces the dimension of the parameter space, and thus leads to a reasonable error bound. Of course, if our goal were simply to establish the uniqueness of $\hat{L}_{r\cdot}$ and that $\hat{K}_r \leq K_r$, we could trivially take $\lambda = \infty$ (resulting in $\hat{K}_r = 0$). The latter part of the theorem thus goes on to provide a choice of λ that is sufficiently small to guarantee that $\hat{K}_r = K_r$ (and, furthermore, that the signs of all non-zeros are correctly recovered).

Theorem 1 *Consider the family of tuning parameters*

$$\lambda = \frac{8}{\alpha} \sqrt{\frac{\theta_r \log r}{n}} \tag{13}$$

and weights given by (7)*. Under Assumptions **A1**–**A4**, if the tuple (n, J_r, K_r) satisfies*

$$n > \alpha^{-2} \left(3\pi^2 K_r + 8\right) \theta_r \kappa^2 \log J_r, \tag{14}$$

then with probability greater than $1 - c_1 \exp\{-c_2 \min(K_r, \log J_r)\} - 7\exp(-c_3 n)$ for some constants c_1, c_2, c_3 independent of n and J_r, the following properties hold:

1. *The row problem* (8) *has a unique solution $\hat{L}_{r\cdot}$ and $\hat{K}_r \leq K_r$.*
2. *The estimate $\hat{L}_{r\cdot}$ satisfies the element-wise ℓ_∞ bound,*

$$\left\| \hat{L}_{r\cdot} - L_{r\cdot} \right\|_\infty \leq \lambda \left(4 \left\| \left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1} \right\|_\infty + 5\kappa^2 \right). \tag{15}$$

3. *If in addition,*

$$\min_{j \geq J_r + 1} |L_{rj}| > \lambda \left(4 \left\| \left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1} \right\|_\infty + 5\kappa^2 \right), \tag{16}$$

then exact signed support recovery holds: For all $j \leq r$, $\mathrm{sign}(\hat{L}_{rj}) = \mathrm{sign}(L_{rj})$.

Proof See Appendix F. ■

In the classical setting where the ambient dimension r is fixed and the sample size n is allowed to go to infinity, $\lambda \to 0$ and the above scaling requirement is satisfied. By (15) the row estimator $\hat{L}_{r\cdot}$ is consistent as is the classical maximum likelihood estimator. Moreover, it recovers the true support since (16) holds automatically. In high-dimensional scaling, however, both n and r are allowed to change, and we are interested in the case where r can grow much faster than n. Theorem 1 shows that, if $\left\| \left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1} \right\|_\infty = \mathcal{O}(1)$ and if n can grow as fast as $K_r \log J_r$, then the row estimator $\hat{L}_{r\cdot}$ still recovers the exact support of $L_{r\cdot}$ when the signal is at least $\mathcal{O}(\sqrt{\frac{\log r}{n}})$ in size, and the estimation error $\max_j |\hat{L}_{rj} - L_{rj}|$ is $\mathcal{O}(\sqrt{\frac{\log r}{n}})$. Intuitively, for the row estimator to detect the true support, we require that the true signal be sufficiently large. The condition (16) imposes limitations on how fast the signal is allowed to decay, which is the analogue to the commonly known "$\beta_{\min}$ condition" that is assumed for establishing support recovery of the lasso.

Remark 2 *Both the choice of tuning parameter* (13) *and the error bound* (15) *depend on the true covariance matrix via* θ_r*. This quantity can be bounded by* κ^2 *as in* (12) *using the fact that* $(\Sigma_{\mathcal{I}_r\mathcal{I}_r})^{-1}$ *is positive definite:*

$$\theta_r = \max_{\ell \in \mathcal{I}_r^c} \theta_r^{(\ell)} = \max_{\ell \in \mathcal{I}_r^c} \left\{ \Sigma_{\ell\ell} - \Sigma_{\ell\mathcal{I}_r} \left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1} \Sigma_{\mathcal{I}_r\ell} \right\} \leq \max_{\ell \in \mathcal{I}_r^c} \Sigma_{\ell\ell} \leq \kappa^2.$$

The proof of Theorem 1 shows that the results in this theorem still hold true if we replace θ_r *by* κ^2*. This observation leads to the fact that we can select a tuning parameter having the properties of the theorem that does not depend on the unknown sparsity level* K_r*. Therefore, our estimator is adaptive to the underlying unknown bandwidths.*

4.1.1 Connections to the regression setting

In (1) we showed that estimation of the r-th row of L can be interpreted as a regression of X_r on its predecessors. It is thus very interesting to compare Theorem 1 to the standard high-dimensional regression results. Consider the following linear model of a vector $\mathbf{y} \in \mathbb{R}^n$ of the form

$$\mathbf{y} = \mathbf{Z}\eta + \omega \qquad \omega \sim N(\mathbf{0}, \sigma^2 I_n) \tag{17}$$

where $\eta \in \mathbb{R}^p$ is the unknown but fixed parameter to estimate, $\mathbf{Z} \in \mathbb{R}^{n\times p}$ is the design matrix with each row an observation of p predictors, σ^2 is the variance of the zero-mean additive noise ω. A standard approach in the high-dimensional setting where $p \gg n$ is the lasso (Tibshirani, 1996), which solves the convex optimization problem,

$$\min_{\eta\in\mathbb{R}^p} \frac{1}{2n} \|\mathbf{y} - \mathbf{Z}\eta\|_2^2 + \lambda \|\eta\|_1 , \tag{18}$$

where $\lambda > 0$ is a regularization parameter. In the setting where η is assumed to be sparse, the lasso solution is known to be able to successfully recover the signed support of the true η with high probability when λ is of the scale $\sigma\sqrt{\frac{\log p}{n}}$ and certain technical conditions are satisfied (Wainwright, 2009).

Despite the added complications of working with the log term in the objective of (8), Theorem 1 gives a clear indication that, in terms of difficulty of support recovery, the row estimate problem (8) is essentially the same as a lasso problem with random design, i.e., with each row $z_i \sim N(\mathbf{0}, \Sigma)$ (Theorem 3, Wainwright, 2009). Indeed, a comparison shows that the two irrepresentable conditions are equivalent. Moreover, θ_r plays the same role as Wainwright (2009)'s $\max_i \left(\Sigma_{S^cS^c} - \Sigma_{S^cS}\left(\Sigma_{SS}\right)^{-1}\Sigma_{SS^c}\right)_{ii}$, a threshold constant of the conditional covariance, where S is the support of the true η.

Städler et al. (2010) introduce an alternative approach to the lasso, in the context of penalized mixture regression models, that solves the optimization problem,

$$(\hat{\phi}, \hat{\rho}) = \arg\min_{\phi,\rho} \left\{ -2\log\rho + \frac{1}{n}\|\rho\mathbf{y} + \mathbf{Z}\phi\|_2^2 + \lambda\|\phi\|_1 \right\}, \tag{19}$$

where $\hat{\sigma} = \hat{\rho}^{-1}$ and $\hat{\eta} = -\hat{\phi}/\hat{\rho}$. Note that (19) basically coincides with (8) except for the penalty.

In Städler et al. (2010), the authors study the asymptotic and non-asymptotic properties of the ℓ_1-penalized estimator for the general mixture regression models where the loss functions are non-convex. The theoretical properties of (19) are studied in Sun and Zhang (2010), which partly motivates the scaled lasso (Sun and Zhang, 2012).

The theoretical work of Sun and Zhang (2010) differs from ours both in that they study the ℓ_1 penalty (instead of the hierarchical group lasso) and in their assumptions. The nature of our problem requires the sample matrix to be random (as in **A1**), while Sun and Zhang (2010) considers the fixed design setting, which does not apply in our context. Moreover, they provide prediction consistency and a deviation bound of the regression parameters estimation in ℓ_1 norm. We give exact signed support recovery results for the regression parameters as well as estimation deviation bounds in various norm criteria. Also, they take an asymptotic point of view while we give finite sample results.

4.2 Matrix Bandwidth Recovery Result

With the properties of the row estimators in place, we are ready to state results about estimation of the matrix L. The following theorem gives an analogue to Theorem 1 in the matrix setting. Under similar conditions, with one particular choice of tuning parameter, the estimator recovers the true bandwidth for all rows adaptively with high probability.

Theorem 3 *Let* $\theta = \max_r \theta_r$ *and* $K = \max_r K_r$*, and take*

$$\lambda = \frac{8}{\alpha}\sqrt{\frac{2\theta\log p}{n}} \tag{20}$$

and weights given by (7)*. Under Assumptions* ***A1****–****A4****, if* (n, p, K) *satisfies*

$$n > \alpha^{-2}\theta\kappa^2\left(12\pi^2 K + 32\right)\log p, \tag{21}$$

then with probability greater than $1 - cp^{-1}$ *for some constant* c *independent of* n *and* p*, the following properties hold:*

1. *The estimator* $\hat{L}$ *is unique, and it is at least as sparse as* L*, i.e.,* $\hat{K}_r \leq K_r$ *for all* r*.*
2. *The estimator* $\hat{L}$ *satisfies the element-wise* ℓ_∞ *bound,*

$$\left\|\hat{L} - L\right\|_\infty \leq \lambda\left(4\max_r \left\|\left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1}\right\|_\infty + 5\kappa^2\right). \tag{22}$$

3. *If in addition,*

$$\min_r \min_{j\geq J_r+1} |L_{rj}| > \lambda\left(4\max_r \left\|\left(\Sigma_{\mathcal{I}_r\mathcal{I}_r}\right)^{-1}\right\|_\infty + 5\kappa^2\right), \tag{23}$$

then exact signed support recovery holds: $\operatorname{sign}(\hat{L}_{rj}) = \operatorname{sign}(L_{rj})$ *for all* r *and* j*.*

Proof See Appendix G. ∎

As discussed in Remark 2, we can replace θ with its upper bound κ^2, and the results remain true. This theorem shows that one can properly estimate the sparsity pattern across all rows

exactly using only one tuning parameter chosen without any prior knowledge of the true bandwidths. In Section 4.1.1, we noted that the conditions required for support recovery and the element-wise ℓ_∞ error bound for estimating a row of L is similar to those of the lasso in the regression setting. A union bound argument allows us to translate this into exact bandwidth recovery in the matrix setting and to derive a reasonable convergence rate under conditions as mild as that of a lasso problem with random design. This technique is similar in spirit to neighborhood selection (Meinshausen and Bühlmann, 2006), though our approach is likelihood-based.

Comparing (21) to (14), we see that the sample size requirement for recovering L is determined by the least sparse row. While intuitively one would expect the matrix problem to be harder than any single row problem, we see that in fact the two problems are basically of the same difficulty (up to a multiplicative constant).

In the setting where variables exhibit a natural ordering, Shojaie and Michailidis (2010) proposed a penalized likelihood framework like ours to estimate the structure of directed acyclic graphs (DAGs). Their method focuses on variables which are standardized to have unit variance. In this special case, penalized likelihood does not involve the log-determinant term and under similar assumptions to ours, they proved support recovery consistency. However, they use lasso and adaptive lasso (Zou, 2006) penalties, which do not have the built-in notion of local dependence. Since these ℓ_1-type penalties do not induce structured sparsity in the Cholesky factor, the resulting precision matrix estimate is not necessarily sparse. By contrast, our method does not assume unit variances and learns an adaptively banded structure for $\hat{L}$ that leads to a sparse $\hat{\Omega}$ (thereby encoding conditional dependencies).

To study the difference between the ordered and non-ordered problems, we compare our method with Ravikumar et al. (2011), who studied the graphical lasso estimator in a general setting where variables are not necessarily ordered. Let $\mathcal{S}$ index the edges of the graph specified by the sparsity pattern of $\Omega = \Sigma^{-1}$. The sparsity recovery result and convergence rate are established under an irrepresentable condition imposed on $\Gamma = \Sigma \otimes \Sigma \in \mathbb{R}^{p^2 \times p^2}$:

$$\max_{e \in \mathcal{S}^c} \left\| \Gamma_{e\mathcal{S}} \left(\Gamma_{\mathcal{S}\mathcal{S}} \right)^{-1} \right\|_1 \leq (1 - \alpha) \tag{24}$$
