Editor: Saharon Rosset

Abstract

Large-scale data containing multiple important rare clusters, even at moderately high dimensions, pose challenges for existing clustering methods. To address this issue, we propose a new mixture model called Hidden Markov Model on Variable Blocks (HMM-VB) and a new mode search algorithm called Modal Baum-Welch (MBW) for mode-association clustering. HMM-VB leverages prior information about chain-like dependence among groups of variables to achieve the effect of dimension reduction. In case such a dependence structure is unknown or assumed merely for the sake of parsimonious modeling, we develop a recursive search algorithm based on BIC to optimize the formation of ordered variable blocks. The MBW algorithm ensures the feasibility of clustering via mode association, achieving linear complexity in terms of the number of variable blocks despite the exponentially growing number of possible state sequences in HMM-VB. In addition, we provide theoretical investigations about the identifiability of HMM-VB as well as the consistency of our approach to search for the block partition of variables in a special case. Experiments on simulated and real data show that our proposed method outperforms other widely used methods.

Keywords: Gaussian mixture model, hidden Markov model, modal Baum-Welch algorithm, modal clustering

1. Introduction

Clustering is one of the most important topics in unsupervised learning, the goal of which is to discover structures from a collection of unlabeled data. Finite mixture modeling is a major statistical framework for clustering. Without attempting to review its expansive applications, we offer instead a few examples as a glimpse at the incredibly broad usage of mixture modeling (Escobar and West (1995); Allenby et al. (1998); McLachlan et al. (2002); Kasahara and Shimotsu (2009)).

One important advantage of the mixture model is that the goodness of fit to any data can be improved by increasing the number of mixture components. The simplest approach to clustering based on a mixture model is to assign each component to an individual cluster. However, there are several drawbacks to equate clusters with mixture components, among which is that the parametric distribution of a component is too restrictive for the potentially diverse shapes of clusters (see Li et al. (2007) for a thorough discussion). Various strategies have been proposed to merge multiple mixture components so that an individual cluster can be more properly modeled (Hennig, 2010; Li, 2005; Pyne et al., 2009; Finak et al., 2009; Chan et al., 2010; Aghaeepour et al., 2011; Lin et al., 2016; Melnykov, 2016). In the statistical learning literature, a prominent method for merging multiple mixture components into one cluster is based on the modes of the mixture density, the so-called modal clustering by Li et al. (2007). We discuss this method in more detail in Section 2.

Despite their wide applications, existing mixture modeling approaches are severely challenged by high dimensional data encountered in certain research areas, for example, cell subset identification using data generated by the high-throughput single-cell technologies (Perfetto et al., 2004; Bandura et al., 2009; Maecker et al., 2012; Chattopadhyay et al., 2014; Spitzer and Nolan, 2016). These data sets contain a large number of highly unbalanced clusters. Furthermore, the most interesting clusters for scientific investigation are often of remarkably low occurrence. Even when the data dimension is not impressively large by today's standard, say in the order of tens, existing methods have much difficulty for detecting clusters of very low probabilities. Low probability mixture components tend to be "concealed" by large background clusters in the data. For the usual mixture modeling approach, in order to capture the rare clusters, we must increase the number of components dramatically. On the other hand, the curse of dimensionality prevents the use of many components; the growing computational intensity is also a concern.

Our new method is motivated by the popular manual gating analysis of single-cell cytometry data (details in Section 5.2), in which the variables are divided into groups based on prior information and examined sequentially. The key idea here is to exploit the chain-like dependence among groups of variables in the construction of a mixture model. Lin et al. (2013) used this idea to build a relatively primitive model. In this approach, the variables are partitioned into two groups, and the mixture model is estimated using the hierarchical Dirichlet process prior. This two-block model is substantially more efficient and accurate in rare clusters identification than the conventional mixture models are. The existing method, however, is unable to move beyond two variable blocks in practice due to the exponential computational complexity. The Markov chain Monte Carlo (MCMC) simulation for the two-block model is already highly intensive and is coupled by the long-standing issue of label switching when MCMC is applied to estimate mixture models (e.g., Richardson and Green (1997); Celeux et al. (2000); Stephens (2000)).

The aim of this paper is to design an effective and computationally accessible statistical model that can fit data robustly in both high and low probability regions and can identify clusters of non-Gaussian shapes. We propose a new model to exploit sequential dependence among variable groups. We also develop an algorithm to search for such a dependence structure when it is unknown. Our experiments show that even if the sequential dependence is not backed up by domain knowledge, it can still be useful as a mathematical mechanism for parsimonious modeling.

Our major contributions include: (1) We develop a *hidden Markov model on variable blocks* (*HMM-VB*) to leverage the sequential dependence structure among variable groups. To the best of our knowledge, this work is the first to exploit sequential dependence among variable groups by HMM. (2) We derive the Baum-Welch estimation algorithm for HMM-VB and the new *Modal Baum-Welch (MBW)* algorithm for finding modes of a HMM-VB, based on which clusters are formed. MBW achieves linear computational complexity without compromising optimality. (3) We develop a search algorithm to determine the grouping and ordering of the variables for a HMM-VB when variable groups are not pre-specified. (4) We

develop theorems on the identifiability of HMM-VB given the variable block structure and the identifiability of the variable blocks under certain conditions. We prove the consistency of the BIC criterion for finding the variable blocks in a special case.

The rest of the paper is organized as follows. In Section 2, we introduce notations and overview existing techniques most relevant to our proposed methods. In Section 3, we present HMM-VB and efficient algorithms for model fitting and modal clustering. In Section 4, we provide theoretical results on identifiability, consistency, and the mode search algorithm for HMM-VB. Proofs of the theorems appear in Appendix B∼D. In Section 5, experimental results are reported for both simulated and real data including mass cytometry, single-cell genomics, and image data. Comparisons are made with some competing models and popular methods. We conclude with discussions in Section 6.

2. Preliminaries

Given a random vector $X = (X_1, X_2, ..., X_d)' \in \mathcal{R}^d$, let $\mathbf{x}_i = (x_{i1}, ..., x_{id})' \in \mathcal{R}^d$ be the i-th sample of X, where $i = 1, ..., n$. Denote by $\mathbb{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n) \in \mathcal{R}^{n\times d}$ the data matrix, and we let $\mathbb{X}_j$ be the j-th column of $\mathbb{X}$ which contains the values of X_j across all the sample points. For ease of notation, we let $\mathbf{x} \in \mathcal{R}^d$ be a realization of the random vector X.

The finite Gaussian mixture model (GMM) is commonly used for clustering. A GMM with M components has the density function: $f(\mathbf{x}|\theta) = \sum_{k=1}^{M} \pi_k \phi(\mathbf{x}|\theta_k)$, where π_k is the mixture component prior probability and $\phi(\cdot \mid \theta_k)$ is the multivariate normal density parameterized by $\theta_k = (\mu_k, \Sigma_k)$, μ_k being the d-dimensional mean vector and Σ_k the $d \times d$ covariance matrix. For model estimation, a latent indicator $Z \in \{1, 2, ..., M\}$ with $P(Z = k) = \pi_k$ is used. Specifically, conditioning on $Z = k$, X follows the k-th component distribution. Z is also called the component identity of X. To perform clustering, the usual approach is to compute the posterior probability $P(Z = k|X = \mathbf{x})$ and assign $\mathbf{x}$ to the cluster with the maximum posterior. However, this approach is inadequate to model clusters with arbitrary shapes and cannot ensure that the clusters are reasonably separated. One major idea explored in the literature is to merge multiple mixture components for a better and more flexible representation of an individual cluster. We refer to Melnykov and Maitra (2010) for a thorough review on clustering based on finite mixture models.

Banfield and Raftery (1993) and Celeux and Govaert (1995) propose to decompose the covariance matrix of the mixture components in a GMM into parts that control volume, shape, and orientation respectively and allow model constraints to be imposed in these aspects either individually or by combination. A model selection criterion is then used to choose a GMM in terms of not only the number of components but also the constraints on covariance matrices. A popular R package, namely `Mclust` (Fraley and Raftery, 2006), is implemented for this method, which we will use for comparison.

The Modal EM (MEM) algorithm developed by Li et al. (2007) performs efficient merging of mixture components. It resembles the expectation-maximization (EM) algorithm (Dempster et al., 1977), as reflected by the name "modal EM". However, the objective of MEM is to find an increasing path from any data point to a local maximum of a given density. Hence, the optimization objective of MEM is to find a local maximizer over $\mathbf{x}$ for $f(\mathbf{x}|\theta)$ under a given θ, while EM is to find local maxima over θ for $f(\mathbf{x}|\theta)$ given $\mathbf{x}$. Consider a general mixture density $f(\mathbf{x}) = \sum_{k=1}^{M} \pi_k f_k(\mathbf{x})$, where $f_k(\mathbf{x})$ is the density of the k-th mixture component.

Starting from any initial value denoted by $\mathbf{x}^{[0]}$, MEM solves a local maximum of the mixture density by the following two iterative steps: (1) At iteration r, let $p_k = \frac{\pi_k f_k(\mathbf{x}^{[r]})}{f(\mathbf{x}^{[r]})}$, $k = 1$, ..., M; (2) Update $\mathbf{x}^{[r+1]} = \text{argmax}_{\mathbf{x}} \sum_{k=1}^{M} p_k \log f_k(\mathbf{x})$. MEM stops when a pre-specified stopping criterion is met. Specifically for GMM with $f(\mathbf{x}) = \sum_{k=1}^{M} \pi_k \phi(\mathbf{x}|\mu_k, \Sigma_k)$, MEM becomes

1. E-step: Solve

$$p_k = \frac{\pi_k \phi_k(\mathbf{x}^{[r]} \mid \mu_k, \Sigma_k)}{f(\mathbf{x}^{[r]})}, \quad k = 1, \ ..., \ M. \tag{1}$$

2. M-step: Solve

$$\mathbf{x}^{[r+1]} = \left(\sum_{k=1}^{M} p_k \cdot \Sigma_k^{-1}\right)^{-1} \cdot \left(\sum_{k=1}^{M} p_k \cdot \Sigma_k^{-1} \mu_k\right). \tag{2}$$

The computational efficiency of MEM enabled the development of a new clustering approach by Li et al. (2007), referred to as *modal clustering*. In Li et al. (2007), a non-parametric Gaussian kernel density estimate is used, and MEM is applied to find the mode associated with every point. Data points associated with the same mode are assigned to the same cluster. In Lee and Li (2012), modal clustering based on the general finite GMM is studied. For computational efficiency, instead of applying MEM to every data point, it is applied to the means of the mixture components. Components with mean vectors associated with the same mode are merged into one cluster. Whether a point-wise mode association or a component-wise mode association is preferred depends on the nature of the application and the computational resources. In practice, the difference in the clustering results we have observed is quite small. We refer to the clustering method based on component-wise mode association as *modal GMM* and use it as a baseline for comparison with our new method.

Under the framework of modal clustering, the purpose of a mixture component is primarily for good density estimation. We no longer rely on a one-to-one correspondence between mixture components and clusters. Mode association also ensures that different clusters of data are well separated. See Li et al. (2007) for more detailed discussion on these advantages. The flexibility provided by modal clustering for fitting data is precisely what we need for the applications we consider. In the next section, we propose a HMM-type model which can be cast as a mixture model with an enormous number of components, even exceeding the data size. This complexity causes no difficulty in clustering via mode association.

3. Hidden Markov Model on Variable Blocks

As discussed in Section 1, in some specific application domains, a sequential dependence structure among groups of variables is available. This dependence prompts us to model a subset of variables conditioning on some other subset of variables. If we view the sequential ordering of the variable blocks as a "timeline", it seems natural to employ a HMM-type model, where each variable block follows a mixture distribution and the statistical dependence among the blocks is captured by the Markov process of the underlying states (that is, the

mixture component identities). The description of a conventional HMM is provided in Appendix A. We call our new model *Hidden Markov Model on Variable Blocks (HMM-VB)*.

Suppose the d-dimensional random vector X is partitioned into T blocks indexed by $t = 1, 2, ..., T$. Let the number of variables in block t be d_t, where $\sum_{t=1}^{T} d_t = d$. Assume that the d_1 variables in block 1 have indices before the d_2 variables in block 2, and so on. In general, obviously, such an ordering of variables may not hold. But this is only a matter of naming the variables and has no effect on our results. Let $X^{(t)}$ denote the t-th variable block. Without loss of generality, let $X^{(1)} = (X_1, X_2, ..., X_{d_1})'$ and $X^{(t)} = (X_{m_t+1}, X_{m_t+2}, ..., X_{m_t+d_t})'$, where $m_t = \sum_{\tau=1}^{t-1} d_\tau$, for $t = 2, ..., T$.

Denote the underlying state of $X^{(t)}$ as s_t, $t = 1, ..., T$. Let the index set of s_t be $\mathcal{S}_t = \{1, 2, ..., M_t\}$, where M_t is the number of mixture components for variable block $X^{(t)}$, $t = 1, ..., T$. Let the set of all possible sequences be $\hat{\mathcal{S}} = \mathcal{S}_1 \times \mathcal{S}_2 \cdots \times \mathcal{S}_T$. $|\hat{\mathcal{S}}| = \prod_{t=1}^{T} M_t$. We assume:

1. $\{s_1, s_2, ..., s_T\}$ follow a Markov chain. Let $\pi_k = P(s_1 = k)$, $k \in \mathcal{S}_1$. Let the transition probability matrix $A_t = (a_{k,l}^{(t)})$ between s_t and s_{t+1} be defined by $a_{k,l}^{(t)} = P(s_{t+1} = l | s_t = k)$, $k \in \mathcal{S}_t$, $l \in \mathcal{S}_{t+1}$.

2. Given s_t, $X^{(t)}$ is conditionally independent from other $s_{t'}$ and $X^{(t')}$, for all $t' \neq t$. We also assume that given $s_t = k$, the conditional density of $X^{(t)}$ is the Gaussian distribution $\phi(X^{(t)} \mid \mu_k^{(t)}, \Sigma_k^{(t)})$.

Let $\mathbf{s} = \{s_1, ..., s_T\}$. A realization of X is $\mathbf{x}$, and a realization of $X^{(t)}$ is $x^{(t)}$. To summarize, the density of HMM-VB is given by

$$f(\mathbf{x}) = \sum_{\mathbf{s} \in \hat{\mathcal{S}}} \left(\pi_{s_1} \prod_{t=1}^{T-1} a_{s_t, s_{t+1}}^{(t)} \right) \cdot \prod_{t=1}^{T} \phi(x^{(t)} | \mu_{s_t}^{(t)}, \Sigma_{s_t}^{(t)}). \tag{3}$$

Remark 1: Figure 1 illustrates two major differences between HMM-VB and the conventional HMM. (1) The variable blocks $X^{(t)}$'s are not from the same vector space. Hence, the parameters of the distribution of $X^{(t)}$ given $s_t = k$ depend not only on k but also on t; (2) The underlying Markov chain for $\{s_1, ..., s_T\}$ is not time invariant. In fact, the state space $\mathcal{S}_t$ varies with t.

Remark 2: Although the density function of HMM-VB in Eq. (3) indicates block diagonal covariance matrices, there are important differences from a typical GMM with the same constraint on the covariance. First, the Gaussian mean vectors in Eq. (3) reside on a lattice in the Cartesian product space $\mathcal{R}^{d_1} \times \mathcal{R}^{d_2} \cdots \times \mathcal{R}^{d_T}$. Secondly, the number of components grows exponentially with T. In fact, it is often larger than the sample size. The enormous number of components cannot be handled by a typical covariance constrained GMM from either estimation or computational feasibility perspectives.

Remark 3: Since HMMs can be represented as singly connected directed acyclic graphs, HMM-VB is a special case of graphical models (e.g., Bishop (2006); Koller and Friedman (2009)). We named our model HMM-VB because we derived the estimation method based on the popular Baum-Welch algorithm for HMM. Moreover, HMM itself is a widely known model in machine learning as well as statistics.

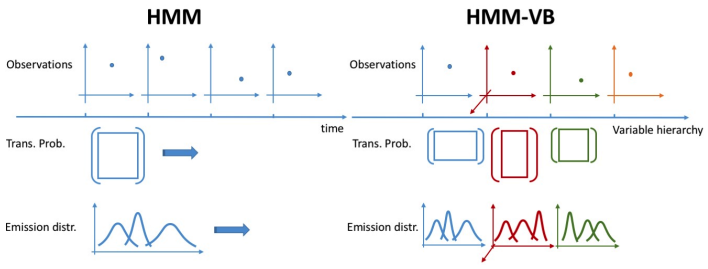

Figure 1: Comparison between HMM-VB and HMM models. The observations under HMM have to be of a fixed dimension, 2 in this illustration. Typically, only one transition probability matrix is applied through time, and the set of distributions conditioned on the states at any time spot is also fixed. HMM-VB models data across blocks of different variables, possibly of different dimensions. Both the transition probability matrix and the set of conditional distributions are defined individually at every "time" spot.

3.1 Maximum Likelihood Estimation

HMM is usually estimated by the EM algorithm. However, because the cardinality of $\bar{\mathcal{S}}$ grows exponentially with the sequence length, the computational complexity of a direct application of EM is of exponential complexity. This technical hurdle was overcome by the *Baum-Welch (BW) algorithm* which achieves complexity of linear order in the sequence length and quadratic in the number of states without compromising optimality. The BW algorithm, a special instance of EM, was developed in the 1960's before the general EM algorithm was developed in the 1970's. As a result, we still call the estimation algorithm Baum-Welch, following the convention of the literature on HMM. We present the BW algorithm for HMM model estimation in Appendix A. For a detailed exposure to HMM, we refer to Young et al. (1997).

We now present the corresponding BW algorithm for HMM-VB. It can be proved that the BW algorithm for HMM is an exact EM algorithm. The derivation of the BW algorithm for HMM-VB is similar to the derivation of BW for the usual HMM. We thus omit it here. Clearly, it is not meaningful to estimate HMM-VB using a single sequence, which is essentially a single data point in this case. HMM-VB is after all a model for $X \in \mathcal{R}^d$.

Denote by $\mathbf{x}_i = (x_i^{(1)}, x_i^{(2)}, ..., x_i^{(T)})'$ the ordered and grouped i-th sample according to the given variable blocks. We denote the original i-th sample before ordering by $\breve{\mathbf{x}}_i$. Consider estimation of HMM-VB based on a data set $\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$. We define $L_k(\mathbf{x}_i, t)$ and $H_{k,l}(\mathbf{x}_i, t)$ similarly as in Eq. (8) and Eq. (9) in Appendix A. For $i = 1, ..., n$,

$$L_k(\mathbf{x}_i, t) = P(s_{i,t} = k \mid \mathbf{x}_i), \ k \in \mathcal{S}_t, \tag{4}$$

$$H_{k,l}(\mathbf{x}_i, t) = P(s_{i,t} = k, s_{i,t+1} = l \mid \mathbf{x}_i), \ k \in \mathcal{S}_t, l \in \mathcal{S}_{t+1}. \tag{5}$$

The BW algorithm iterates the following two steps:

1. E-step: Under the current set of parameters, compute $L_k(\mathbf{x}_i, t)$, $i = 1, ..., n$, $k \in \mathcal{S}_t$, $t = 1, ..., T$, and $H_{k,l}(\mathbf{x}_i, t)$, $i = 1, ..., n$, $k \in \mathcal{S}_t$, $l \in \mathcal{S}_{t+1}$, $t = 1, ..., T-1$.

2. M-step: Update parameters by

$$\mu_k^{(t)} = \frac{\sum_{i=1}^n L_k(\mathbf{x}_i, t) x_i^{(t)}}{\sum_{i=1}^n L_k(\mathbf{x}_i, t)}, \quad k \in \mathcal{S}_t,\ t = 1, ..., T,$$

$$\Sigma_k^{(t)} = \frac{\sum_{i=1}^n L_k(\mathbf{x}_i, t) \left(x_i^{(t)} - \mu_k^{(t)}\right) \left(x_i^{(t)} - \mu_k^{(t)}\right)'}{\sum_{i=1}^n L_k(\mathbf{x}_i, t)}, \quad k \in \mathcal{S}_t,\ t = 1, ..., T,$$

$$a_{k,l}^{(t)} = \frac{\sum_{i=1}^n H_{k,l}(\mathbf{x}_i, t)}{\sum_{i=1}^n L_k(\mathbf{x}_i, t)}, \quad k \in \mathcal{S}_t,\ l \in \mathcal{S}_{t+1},\ t = 1, ..., T-1,$$

$$\pi_k \propto \sum_{i=1}^n L_k(\mathbf{x}_i, 1),\ k \in \mathcal{S}_1,\ s.t. \sum_{k \in \mathcal{S}_1} \pi_k = 1.$$

The above equations can be easily extended to the case of weighted sample points. It can occur in practice that each sample point is assigned with a weight. For instance, quantization is often used to reduce the data size significantly. Instead of using the original data, one may use the quantized points, each of which can represent a different number of original points and hence is assigned with a weight proportional to that number. Suppose weight w_i is assigned to sample $\mathbf{x}_i$. The E-step is not affected. In the M-step, we can simply multiply w_i in front of each summand appeared in the equations above.

The forward-backward algorithm for computing $L_k(\mathbf{x}_i, t)$ and $H_{k,l}(\mathbf{x}_i, t)$ is essentially the same as the forward-backward algorithm for the usual HMM. The fact that the variable blocks are not from the same vector space and the state spaces vary with t does not cause any intrinsic difference. Suppress the sample index i and consider one sample point $\mathbf{x}$.

Define the forward probability $\alpha_k(\mathbf{x}, t)$ as the joint probability of observing the first t variable blocks $x^{(\tau)}$, $\tau = 1, ..., t$, and being in state k at time t:

$$\alpha_k(\mathbf{x}, t) = P(x^{(1)}, x^{(2)}, ..., x^{(t)}, s_t = k), \quad k \in \mathcal{S}_t.$$

This probability can be evaluated by the following recursive formula:

$$\begin{aligned} \alpha_k(\mathbf{x}, 1) &= \pi_k \phi(x^{(1)} \mid \mu_k^{(1)}, \Sigma_k^{(1)}), \quad k \in \mathcal{S}_1, \\ \alpha_k(\mathbf{x}, t) &= \phi(x^{(t)} \mid \mu_k^{(t)}, \Sigma_k^{(t)}) \sum_{l \in \mathcal{S}_{t-1}} \alpha_l(\mathbf{x}, t-1) a_{l,k}^{(t-1)}, \quad 1 < t \le T,\ k \in \mathcal{S}_t. \end{aligned}$$

Define the backward probability $\beta_k(\mathbf{x}, t)$ as the conditional probability of observing the variable blocks after time t, $x^{(\tau)}$, $\tau = t+1, ..., T$, given the state at block t is k:

$$\begin{aligned} \beta_k(\mathbf{x}, t) &= P(x^{(t+1)}, ..., x^{(T)} \mid s_t = k), \quad 1 \le t \le T-1,\ k \in \mathcal{S}_t, \\ &\quad \text{Set } \beta_k(\mathbf{x}, T) = 1, \quad \text{for all } k \in \mathcal{S}_T. \end{aligned}$$

The backward probability can be evaluated using the following recursion:

$$\begin{aligned} \beta_k(\mathbf{x}, T) &= 1, \quad k \in \mathcal{S}_T, \\ \beta_k(\mathbf{x}, t) &= \sum_{l \in \mathcal{S}_{t+1}} a_{k,l}^{(t)} \phi(x^{(t+1)} \mid \mu_l^{(t+1)}, \Sigma_l^{(t+1)}) \beta_l(\mathbf{x}, t+1), \quad 1 \le t < T, \quad k \in \mathcal{S}_t. \end{aligned}$$

The probabilities $L_k(\mathbf{x}, t)$ and $H_{k,l}(\mathbf{x}, t)$ are solved by

$$L_k(\mathbf{x}, t) = P(s_t = k \mid \mathbf{x}) = \frac{P(\mathbf{x}, s_t = k)}{P(\mathbf{x})} = \frac{\alpha_k(\mathbf{x}, t) \beta_k(\mathbf{x}, t)}{P(\mathbf{x})}, \quad k \in \mathcal{S}_t,$$

$$\begin{aligned} H_{k,l}(\mathbf{x}, t) &= P(s_t = k, s_{t+1} = l \mid \mathbf{x}) = \frac{P(\mathbf{x}, s_t = k, s_{t+1} = l)}{P(\mathbf{x})} \\ &= \frac{1}{P(\mathbf{x})} \alpha_k(\mathbf{x}, t) a_{k,l}^{(t)} \phi(x^{(t+1)} \mid \mu_l^{(t+1)}, \Sigma_l^{(t+1)}) \beta_l(\mathbf{x}, t+1), \quad k \in \mathcal{S}_t,\ l \in \mathcal{S}_{t+1}. \end{aligned}$$

The normalizing factor $P(\mathbf{x}) = \sum_{k \in \mathcal{S}_t} \alpha_k(\mathbf{x}, t) \beta_k(\mathbf{x}, t)$ holds for any t.

To initialize the model, we design several schemes. In our experiments, models from different initializations are estimated and the one with the maximum likelihood is chosen. In our baseline initialization scheme, k-means clustering is applied individually to each variable block using all the data instances. Based on the clustering result of k-means, we take every cluster as one mixture component and compute the sample mean and sample covariance matrix of data in that cluster. To reduce the sensitivity to the initial clustering result, we also compute the pooled common sample covariance matrix for the clusters. The initial covariance matrix of a component is then set as a convex combination of the cluster-specific sample covariance and the common sample covariance. The transition probabilities are always initialized to be uniform. Under the second initialization scheme, we randomly sample a subset from the whole data and apply the baseline initialization to the subset. Under the third initialization scheme, we randomly pick a subset from the data and treat points in this subset as the cluster centroids of the k-means. These centroids will induce a cluster partition of the whole data, based on which we initialize the component means and covariance matrices in the same way as the baseline method. Both the second and the third initialization schemes are repeated several times with different random starts.

3.2 Modal Baum-Welch Algorithm

HMM-VB can be viewed as a special case of a GMM where each component of the GMM corresponds to a particular sequence of states $\mathbf{s} = \{s_1, ..., s_T\}$, that is, a combination of states for all the variable blocks. We call this equivalent GMM the *GMM mapped from HMM-VB*. Each component is a Gaussian distribution with mean $\mu_{\mathbf{s}} = (\mu_{s_1}^{(1)}, \mu_{s_2}^{(2)}, ..., \mu_{s_T}^{(T)})$ (column-wise stack of vectors) and a covariance matrix, denoted by $\Sigma_{\mathbf{s}}$, that is block diagonal. The t-th diagonal block in $\Sigma_{\mathbf{s}}$ is $\Sigma_{s_t}^{(t)}$ with dimension $d_t \times d_t$. We can thus readily apply the modal clustering framework for GMM to data modeled by HMM-VB. However, the number of components in the mapped GMM is $M = \prod_{t=1}^T M_t$, which grows exponentially with T assuming similar M_t's. A direct application of the MEM algorithm (see Eq. (1) and (2)) is computationally infeasible. We discover that because of the block diagonal structure of the

covariance matrix of the GMM mapped from HMM-VB, we can in fact avoid computing the posterior of $\mathbf{x}$ belonging to each component (exponentially many of them!). Instead, we only need $L_k(\mathbf{x}, t)$ for all k and t when updating $\mathbf{x}$ in the M-step of MEM. Because the BW algorithm solves $L_k(\mathbf{x}, t)$ at a complexity linear in T, we can achieve linear complexity for solving the modes of HMM-VB as well. We call this new algorithm *Modal Baum-Welch (MBW)* Algorithm.

We denote by $x^{(t),r}$ the value of the t-th variable block at iteration r, and let $\mathbf{x}^{[r]} = (x^{(1),r}, x^{(2),r}, ..., x^{(T),r})$ be the concatenated and properly ordered full vector at iteration r. The equivalence of MBW and the Modal EM algorithm is ensured by Theorem 7 in Section 4.3, which is proved in Appendix D.

The MBW algorithm iterates the following two steps:

1. E-step: Compute $L_k(\mathbf{x}^{[r]}, t)$, for $k \in \mathcal{S}_t$, $t = 1, ..., T$.
2. M-step: For $t = 1, ..., T$,

$$x^{(t),r+1} = \left(\sum_{k \in \mathcal{S}_t} L_k(\mathbf{x}^{[r]}, t) \cdot \left(\Sigma_k^{(t)} \right)^{-1} \right)^{-1} \left(\sum_{k \in \mathcal{S}_t} L_k(\mathbf{x}^{[r]}, t) \cdot \left(\Sigma_k^{(t)} \right)^{-1} \cdot \mu_k^{(t)} \right).$$

The clustering method based on MBW is straightforward. We first find the state sequence $\mathbf{s}_i^{(*)}$ with maximum posterior given $\mathbf{x}_i$ by the Viterbi algorithm (Young et al., 1997):

$$\mathbf{s}_i^* = \arg\max_{\mathbf{s} \in \hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}_i),\ i = 1, ..., n.$$

Since different $\mathbf{x}_i$'s may yield the same sequence, we then identify the collection of distinct $\mathbf{s}_i^*$. For each distinct sequence, say $\mathbf{s}^*$, find $\mu_{\mathbf{s}^*} = (\mu_{s_1^*}^{(1)}, \mu_{s_2^*}^{(2)}, ..., \mu_{s_T^*}^{(T)})$. Use $\mu_{\mathbf{s}^*}$ as an initialization for MBW to find the mode associated with it. If $\mu_{\mathbf{s}_i^*}$ and $\mu_{\mathbf{s}_j^*}$ are brought to the same mode by MBW, the corresponding data vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ are put into the same cluster. When $|\hat{\mathcal{S}}|$ is very large, the number of different $\mathbf{s}_i^*$'s can become close to the data size. Hence, the amount of computation we can save by seeking modes starting from $\mu_{\mathbf{s}_i^*}$'s instead of the original data diminishes. As a result, in such cases, we recommend seeking modes directly from the original data.

3.3 Computational Complexity

For both the BW estimator of HMM-VB and the MBW algorithm, the vast majority of the computation is on obtaining $L_k(\mathbf{x}_i, t)$ and $H_{k,l}(\mathbf{x}_i, t)$, $i = 1, ..., n$, $t = 1, ..., T$, $k \in \mathcal{S}_t$, $l \in \mathcal{S}_{t+1}$. For clarity of discussion, suppose the number of states in each block, $|\mathcal{S}_t|$, is a constant. Then the complexity for computing the two quantities is $O(nT|\mathcal{S}_t|^2)$.

The two quantities $L_k(\mathbf{x}_i, t)$ and $H_{k,l}(\mathbf{x}_i, t)$ can be computed separately for each sample $\mathbf{x}_i$. Thus the E-step in both the BW and the MBW algorithms are easily parallelizable by simply dividing the data among multiple processors. For the MBW algorithm, since we search for the mode separately starting from each sample point, the M-step is also naturally parallelizable. For the BW estimation algorithm, in the M-step, some quantities need to be

transmitted to a central processor to update the parameters, which will then be broadcast to the distributed processors. However, an inspection of the M-step shows that we do not need to communicate $L_k(\mathbf{x}_i, t)$ and $H_{k,l}(\mathbf{x}_i, t)$ for every sample point $\mathbf{x}_i$ to the central processor. Suppose the first processor treats a data segment containing points 1, 2, ..., n_1. It only needs to send $\sum_{i=1}^{n_1} L_k(\mathbf{x}_i, t)$, $\sum_{i=1}^{n_1} L_k(\mathbf{x}_i, t) x_i^{(t)}$, $\sum_{i=1}^{n_1} L_k(\mathbf{x}_i, t) x_i^{(t)} x_i^{(t)'}$, $\sum_{i=1}^{n_1} H_{k,l}(\mathbf{x}_i, t)$, $k \in \mathcal{S}_t$, $l \in \mathcal{S}_{t+1}$, $t = 1, ..., T$, to the central processor. Thus the communication load from a processor treating one data segment to the central processor does not depend on the data size and is nearly as low as the number of parameters in the model (the negligible relative difference shrinks quickly when $|\mathcal{S}_t|$ grows). The central processor can then update the parameters precisely according to the formula in the M-step. Since the design of the parallel algorithm of BW is simple, we hereby skip the details for brevity.

3.4 Constructing Variable Dependence Structure

We refer to the grouping and ordering of the variable blocks, that is, the formation of $X^{(t)}$, $t = 1, ..., T$, as the dependence structure or variable block structure. We have so far assumed that the dependence structure of HMM-VB is given. To complete our new framework for clustering, we now address how to determine such a dependence structure when it is not pre-specified. We propose to seek a dependence structure that yields the HMM-VB with the minimum BIC for the data. We use the following definition of BIC:

$$BIC = -2\log(\hat{L}) + k\log(n),$$

where $\hat{L}$ is the maximum value of the likelihood function, n is the sample size, and k is the number of free parameters to be estimated. The challenge lies in the computational complexity of the combinatorial optimization problem. An exhaustive search is intractable even for moderate dimensions (the number of possible groupings and orderings is much larger than that of variable permutations). To achieve computational feasibility, we design a greedy local search scheme.

We first generate an ordering of the variables based on some prior knowledge or on a random permutation, which we call raw ordering hereafter. The raw ordering is not necessarily the final ordering of the variables after the grouping is decided, although the former indeed strongly influences the latter. We may generate several random raw orderings of the variables. Given any raw ordering, the variables are grouped by a step-wise optimization procedure. Based on the likelihoods of the corresponding HMM-VBs, the dependence structure will be chosen under each raw ordering. We then compare structures found from all the raw orderings and select the best from them.

Denote the raw ordering of the variables by Q, with $Q(j) \in \{1, ..., d\}$, for $j = 1, ..., d$. Note that $Q(j)$ is a bijection between $\{1, ..., d\}$ and itself. Denote by G the grouping for the original variable vector. For example, if $Q = (3, 2, 1)$, with $d = 3$, then the specified ordering of the input data for HMM-VB is $(X_{Q(1)}, X_{Q(2)}, X_{Q(3)}) = (X_3, X_2, X_1)$. Suppose that there are two variable blocks, where X_2 and X_3 form the first variable block and X_1 belongs to the second block. Then $G(Q(1)) = 1$, $G(Q(2)) = 1$ and $G(Q(3)) = 2$, or equivalently $G(1) = 2$, $G(2) = 1$, and $G(3) = 1$.

Next, we determine how the variables are grouped based on a step-wise selection process. The variables are treated one by one in the order given by Q. The algorithm ensures that

$G(Q(1))$, ..., $G(Q(j-1))$ have been determined when solving $G(Q(j))$. Specifically, suppose $G(Q(1)), ..., G(Q(j-1)) \in \{1, 2, ..., g\}$. That is, the first $j-1$ ordered variables have been put into g non-empty groups. Note that $g \leq j-1$. The possible value for $G(Q(j))$ is 1, ..., g, or $g+1$. If the $Q(j)$-th variable is put in any existing group, then $G(Q(j)) \leq g$; otherwise it forms by itself a new group with identity number $g+1$. In order to determine $G(Q(j))$, we compare exhaustively the structures with $G(Q(j)) = 1, 2, ..., g, g+1$, which means experimenting with putting the $Q(j)$-th variable in each existing group as well as forming a new group by the $Q(j)$-th variable alone. We use each structure to estimate a HMM-VB for the first j ordered variables: $X_{Q(1)}, X_{Q(2)}, ..., X_{Q(j)}$ (note that this is not the full dimensional data). These HMM-VBs are compared by BIC using the j-dimensional data, and the one with the optimal BIC is chosen, which in turn determines $G(Q(j))$. The process is repeated to sweep through all the variables until the full dimension $j = d$.

Note that we need to specify the number of components for each variable block. After extensive numerical experiments, we set $M_t = 10$ if $d_t \leq 5$, $M_t = 15$ if $d_t \in [6, 10]$, otherwise, $M_t = d_t + 10$ for t being any variable block. In addition, the greedy local search algorithm is quite robust to the change in the number of mixture components.

We denote the BIC of the estimated HMM-VB under raw ordering Q and grouping $G(Q(1))$, ..., $G(Q(j))$ for the partial data containing the first j ordered variables by $\mathcal{L}_{BIC}(\mathbb{X}_{Q(1),...,Q(j)}, G(Q(1)), ..., G(Q(j)), \theta)$, where θ denotes the parameters of HMM-VB. Recall that $\mathbb{X}_{Q(j)}$ denotes the $Q(j)$-th column of the data matrix $\mathbb{X}$. Our step-wise selection algorithm under a given raw ordering Q is as follows:

1. Input data matrix $\mathbb{X}$ and the ordering structure $\{Q(1), ..., Q(d)\}$.
2. Set $j = 1$, $g = 1$, $G(Q(1)) = 1$.
3. For $j = 2$, ..., d
   (a) For each $k = 1$, ..., g, $g+1$, obtain the maximum likelihood estimation of HMM-VB for partial data composed of $\mathbb{X}_{Q(1)}, \mathbb{X}_{Q(2)}, ..., \mathbb{X}_{Q(j)}$ under structure Q and $(G(Q(1)), ..., G(Q(j-1)), G(Q(j)) = k)$. Let the estimated parameter at k be $\theta^{*,k}$.
   (b) Compute
   $$G^*(Q(j)) = \underset{k \in \{1,...,g,g+1\}}{\operatorname{argmin}} \mathcal{L}_{BIC}(\mathbb{X}_{Q(1),...,Q(j)}, G(Q(1)), ..., G(Q(j)) = k, \theta^{*,k}).$$
   (c) Set $G(Q(j)) \longleftarrow G^*(Q(j))$.
   (d) If $G(Q(j)) = g+1$, set $g \longleftarrow g+1$.

Note that if the prior knowledge of the ordering structure is unknown, we randomly generate the raw ordering $\{Q(j)\}_{j=1}^d$ multiple times and adopt the one achieving the optimal BIC. We find that this approach performs well empirically as illustrated in the experiment section. It is also not difficult to see that this algorithm runs on the order of $O(d^2)$, which is efficient in practice.

4. Theoretical Properties

We study the identifiability of HMM-VB, prove the consistency of using BIC for model selection in a special case, and prove the optimality of MBW algorithm for HMM-VB.

4.1 Identifiability

Since HMM-VB can be viewed as a special case of a GMM, we need to ensure model identifiability, which is a necessary condition for estimating the parameters of a mixture model consistently. Specifically, we need to make sure that no two essentially different mixture parameters define the same distribution. We now introduce a type of GMM that includes HMM-VB as a special case and prove some results that help establish the identifiability of HMM-VB. A list of new definitions and notations is provided first.

The variable blocks $X^{(t)}$, $t = 1, ..., T$ are mutually exclusive and collectively exhaustive (that is, their union is the set of all the variables). For brevity, with a slight abuse of notation, using $X^{(t)}$ to mean both a subvector of X as well as a set of variables, but ensure that the specific meaning is clear from context. Denote a *variable partition* by $\mathcal{P} = \{X^{(1)}, X^{(2)}, ..., X^{(T)}\}$.

1. *Lattice GMM*: Denote the Gaussian parameter of a mixture component for variable block $X^{(t)}$ by $\theta_{i_t}^{(t)} = (\mu_{i_t}^{(t)}, \Sigma_{i_t}^{(t)})$, $i_t = 1, ..., M_t$. We define a *lattice GMM* on a variable partition $\mathcal{P}$ as a GMM that bears the form
$$f(\mathbf{x}) = \sum_{i_1=1}^{M_1} \sum_{i_2=1}^{M_2} \cdots \sum_{i_T=1}^{M_T} \pi(i_1, ..., i_T) \cdot \prod_{t=1}^{T} \phi(x^{(t)} \mid \theta_{i_t}^{(t)}). \tag{6}$$
   For a lattice GMM, a component is indexed by a T-tuple $(i_1, ..., i_T)$. Denote the number of components for each variable block collectively by $\mathbb{M} = \{M_1, ..., M_t\}$. We introduce latent state variables s_t for each block $X^{(t)}$, $s_t \in \{1, ..., M_t\}$, $t = 1, ..., T$. The joint pmf of s_t's is given by $\pi(i_1, ..., i_T)$. We use $\Pi(s_1, ..., s_T)$ to denote the joint pmf of $s_1, ..., s_T$ and $\Pi(s_{t_1}, s_{t_2}, ..., s_{t_k})$ to denote the marginal pmf of any subset of the latent states.
   $\Theta^{(t)} = \{\theta_{i_t}^{(t)}, i_t = 1, ..., M_t\}$ is the *grid* of parameters for variable block $X^{(t)}$. Clearly, a lattice-GMM is a mixture of components whose parameters are points from the Cartesian product of the grid of each variable block: $\Theta = \Theta^{(1)} \times \Theta^{(2)} \cdots \times \Theta^{(T)}$. We call Θ the *lattice* of parameters for the full dimensional vector X.
   We say $\theta_{i_t}^{(t)} \in \Theta^{(t)}$ *exists* if $P(s_t = i_t) > 0$, or equivalently there is at least one set of i_1, ..., i_{t-1}, i_{t+1}, ..., i_T such that $\pi(i_1, i_2, ..., i_T) > 0$. We say that the grid $\Theta^{(t)}$ is *distinct* if $\theta_{i_t}^{(t)} \neq \theta_{i'_t}^{(t)}$ for any $i_t \neq i'_t$. The grid $\Theta^{(t)}$ is *non-redundant* if it is distinct and every $\theta_{i_t}^{(t)} \in \Theta^{(t)}$, $i_t = 1, ..., M_t$, exists. If $\Theta^{(t)}$ is not non-redundant, then we can shrink the grid $\Theta^{(t)}$ by eliminating some θ_{i_t}'s and/or merging identical θ_{i_t}'s in the set. Lattice Θ is *non-redundant* if all $\Theta^{(t)}$, $t = 1, ..., T$ are non-redundant.
2. *Tight variable partition*: $\mathcal{P}$ is a *tight variable partition* (or simply tight partition) for a lattice GMM if by Eq. (6), the component prior $\pi(i_1, ..., i_T) > 0$ for all the T-tuples $(i_1, ..., i_T)$.

3. *Maximum variable partition*: A variable partition $\mathcal{P}_1$ is *nested* in partition $\mathcal{P}_2$, denoted by $\mathcal{P}_1 \succ \mathcal{P}_2$ or $\mathcal{P}_2 \prec \mathcal{P}_1$, if every variable block of $\mathcal{P}_1$ is a subset of a variable block of $\mathcal{P}_2$. That is, the partition $\mathcal{P}_1$ can be obtained from $\mathcal{P}_2$ by further dividing a variable block into smaller blocks. $\mathcal{P}$ is a *maximum variable partition* (or simply maximum partition) for a lattice GMM if $\mathcal{P}$ is a tight variable partition and there exists no other tight partition $\mathcal{P}'$ for the GMM such that $\mathcal{P}' \succ \mathcal{P}$.

We let $\mathcal{M}$ to denote the collection of parameters that specify a lattice GMM on the variable partition $\mathcal{P}$. $\mathcal{M} = \{\mathbb{M}, \Theta, \Pi(s_1, ..., s_T)\}$. We also use $\mathcal{M}_{X^{(t)}}$ to denote the marginal GMM for $X^{(t)}$ derived from $\mathcal{M}$. For instance, $\mathcal{M}_{X^{(t)}} = \{M_t, \Theta^{(t)}, \Pi(s_t)\}$. Similarly, we can have marginal GMM for multiple variable blocks, e.g., $\mathcal{M}_{X^{(t)}, X^{(t+1)}}$.

Suppose $\mathcal{O}$ is a permutation function from one index set to another and Γ is a set of indexed parameters. We denote the permuted parameters by $\mathcal{O}(\Gamma)$. For instance, if $\Gamma = \{\mu_1, \mu_2, \mu_3\}$ and $\mathcal{O}$ permutes $\{1, 2, 3\}$ to $\{3, 2, 1\}$, then $\mathcal{O}(\Gamma) = \{\mu_3, \mu_2, \mu_1\}$. Consider an index given by a T-tuple $(i_1, ..., i_T)$ and $\mathcal{O}_t$ is a permutation function on the tth position i_t. We use $\mathcal{O}_{1:T} = \mathcal{O}_1 \times \mathcal{O}_2 \cdots \times \mathcal{O}_T$ to denote the permutation on the T-tuple: $(i_1, i_2, ..., i_T) \to (\mathcal{O}_1(i_1), \mathcal{O}_2(i_2), ..., \mathcal{O}_T(i_T))$.

Lemma 1 *The identifiability of GMM gives that* $\sum_{k=1}^{M} \pi_k \phi(X|\mu_k, \Sigma_k) = \sum_{l=1}^{M^*} \pi_l^* \phi(X|\mu_l^*, \Sigma_l^*)$ *with distinct* (μ_k, Σ_k)*'s, distinct* (μ_l^*, Σ_l^*)*'s, and all the priors* $\pi_k > 0$ *and* $\pi_l^* > 0$, $k = 1, ..., M$, $l = 1, ..., M^*$ *implies* $M = M^*$ *and up to a permutation of mixture components,* $\pi_k = \pi_k^*$, $\mu_k = \mu_k^*$ *and* $\Sigma_k = \Sigma_k^*$.

See for instance Yakowitz and Spragins (1968); Titterington et al. (1985).

Theorem 2 *Let* $\mathcal{M}$ *and* $\mathcal{M}'$ *be two sets of parameters for a lattice GMM on the same variable partition* $\mathcal{P}$. *Assume that* $\mathcal{M}$ *and* $\mathcal{M}'$ *specify the same density function and their lattices* Θ *and* Θ' *are both non-redundant. Then the number of components for each variable block* $M_t = M_t'$, $t = 1, ..., T$. *There exists a unique permutation* $\mathcal{O}_t : i_t \to i_t'$ *for each variable block* $X^{(t)}$ *such that* $\mathcal{M}'_{X^{(t)}} = \mathcal{O}_t(\mathcal{M}_{X^{(t)}})$ *and* $\mathcal{M}' = \mathcal{O}_{1:T}(\mathcal{M})$.

Remark: $M_t = M_t'$ and $\mathcal{M}'_{X^{(t)}} = \mathcal{O}_t(\mathcal{M}_{X^{(t)}})$ are simple results of Lemma 1. The assumption that Θ and Θ' are non-redundant does not imply every prior in Eq. (6) is positive. Hence Lemma 1 cannot be directly applied to prove $\mathcal{M}$ and $\mathcal{M}'$ are identical up to permutation. We provide the proof for Theorem 2 in Appendix B.

The generic HMM-VB density in Eq. (3), given a pre-determined variable block structure can be re-written as

$$f(\mathbf{x}) = \sum_{i_1=1}^{M_1} \sum_{i_2=1}^{M_2} \cdots \sum_{i_T=1}^{M_T} \left(\pi_{i_1} a^{(1)}_{i_1, i_2} a^{(2)}_{i_2, i_3} \cdots a^{(T-1)}_{i_{T-1}, i_T} \right) \cdot \prod_{t=1}^{T} \phi(x^{(t)}|\mu^{(t)}_{i_t}, \Sigma^{(t)}_{i_t}). \tag{7}$$

It is clear that HMM-VB is a lattice GMM on partition $\mathcal{P}$. Specifically, the parameter set $\mathcal{M}$ for a HMM-VB is $\mathcal{M} = \{\mathbb{M}, \Theta, \pi_{i_1}, a^{(t-1)}_{i_{t-1}, i_t}, i_1 = 1, ..., M_1, i_t = 1, ..., M_t, t = 2, ..., T\}$.

We prove the following lemma in Appendix B which specifies the conditions under which a HMM-VB has non-redundant lattice.

Lemma 3 *The HMM-VB in Eq.* (7) *has non-redundant lattice* Θ *if and only if* Θ *is distinct and* $\pi_{i_1} > 0$, *for* $\forall i_1 \in \{1, ..., M_1\}$ *and for* $\forall t = 2, ..., T$ *and* $i_t \in \{1, ..., M_t\}$, *there exists at least one* $i_{t-1} \in \{1, ..., M_{t-1}\}$ *such that* $a^{(t-1)}_{i_{t-1}, i_t} > 0$.

Corollary 4 *For a given variable block structure, if two HMM-VBs,* $\mathcal{M}$ *and* $\mathcal{M}'$, *both have non-redundant lattices* Θ *and* Θ', *and define the same density function, then there exists a unique permutation* $\mathcal{O}_t$ *for the mixture components of every variable block* $X^{(t)}$, $t = 1, ..., T$, *such that* $\mathcal{M}' = \mathcal{O}_{1:T}(\mathcal{M})$.

Remark: Corollary 4 establishes the identifiability of HMM-VB under a given variable block structure. By Theorem 2, it is obvious that $\mathbb{M}' = \mathcal{O}_{1:T}(\mathbb{M})$, $\Theta' = \mathcal{O}_{1:T}(\Theta)$, and $\Pi'(s_1, ..., s_T) = \mathcal{O}_{1:T}(\Pi(s_1, ..., s_T))$. We only need to show that the last equation implies that the transition probabilities are identical up to permutation $\mathcal{O}_{1:T}$. We prove this in Appendix B.

We have so far assumed that the partition $\mathcal{P}$ for the lattice GMM is given. A natural question is whether $\mathcal{P}$ is identifiable. To answer the question, we assume $\mathcal{P}$ is a tight variable partition. Without this constraint, we can express any GMM with M components as a lattice GMM with every block containing a single variable and every block being assigned with M components. The number of components for the lattice GMM will be M^d with only M components assigned with non-zero priors. If we restrict to tight variable partitions, the maximum partition will not be trivial. Furthermore, we can prove that the the maximum partition always exists and is unique. Thus the identifiability of a GMM (according to Lemma 1) ensures that the maximum partition is identifiable. That is, the variable block structure, in its most refined partition, is identifiable.

Theorem 5 *The maximum variable partition of a GMM exists and is unique.*

The proof is given in Appendix B.

Suppose $\mathcal{M}$ is a HMM-VB on a tight partition $\mathcal{P}$. It is obvious that $\mathcal{P}$ is a tight partition for a HMM-VB if and only if $\pi_{i_1} > 0$, $\forall i_1 \in \{1, ..., M_1\}$, and all the transition probabilities are positive. If $\mathcal{P}$ is a maximum partition for the equivalent lattice GMM of $\mathcal{M}$, $\mathcal{P}$ is identifiable once $\mathcal{M}$ is given (by Theorem 5). However, because the latent states s_1, ..., s_T of the HMM-VB follow a Markov chain (an extra constraint), even if $\mathcal{P}$ cannot be further refined for the HMM-VB, it is not necessarily the maximum partition for the corresponding lattice GMM. In other words, a lattice GMM that is not a HMM-VB on its maximum partition can be an HMM-VB on a coarser partition. Another subtlety with HMM-VB is that even when $\mathcal{P}$ is identifiable, the order of the variable blocks is not for the simple reason that a reversed Markov chain is still Markov. The fact that the order of the variable blocks is not identifiable is also clear from the extreme case when the latent states s_1, ..., s_T are independent and therefore any order of them is valid. On the other hand, because our mode-based clustering method for HMM-VB searches for the modes of the joint density, the modes are not affected as long as the equivalent lattice GMM is the same. Hence regardless of the order of the variable blocks (e.g., forward chain or backward chain), if the HMM-VB is a correct model, the modes will not change, and neither will the clustering result.

4.2 Consistency of BIC for Model Selection

In this section, we prove a special case that the probability of selecting the true variable block structure by minimizing BIC approaches 1 as $n \to \infty$ under some assumptions and the conditions that the true variable structure is among the candidates and the number of components for each variable block is known.

Let the number of variable blocks be T and its true value be T^0. Denote the true number of components in each block by M_t^0, $t = 1, ..., T^0$. Also let $\mathbb{M}^{0^{T^0}} = \{M_1^0, ..., M_{T^0}^0\}$. Denote the variable index sets of the true ordered blocks by $\mathbf{C^0}^{T^0} = (C_1^0, C_2^0, ..., C_{T^0}^0)$. For example, C_1^0 contains the indices of the variables in the first block. For a particular sequence of variable blocks $\mathbf{C}^T = (C_1, C_2, ..., C_T)$, we use the notation $X^{(C_t)}$ to denote the tth block of variables according to $\mathbf{C}^T$. Denote the parameters of a model collectively by $\gamma_{(\mathbf{C}^T, \mathbb{M}^T)} \in \Gamma_{(\mathbf{C}^T, \mathbb{M}^T)}$, where $\Gamma_{(\mathbf{C}^T, \mathbb{M}^T)}$ is the space of the parameters.

Denote by g the true density function of X. Let $D_{KL}(g||f) = \int g(x) \log(g(x)/f(x))dx$ be the Kullback-Leibler divergence from density f to g. We define the following two notations:

$$\begin{aligned}\gamma^*_{(\mathbf{C}^T, \mathbf{M}^T)} &= \underset{\gamma_{(\mathbf{C}^T, \mathbf{M}^T)} \in \Gamma_{(\mathbf{C}^T, \mathbf{M}^T)}}{\operatorname{argmin}} D_{KL}(g||f(.|\gamma_{(\mathbf{C}^T, \mathbf{M}^T)})) \\ &= \underset{\gamma_{(\mathbf{C}^T, \mathbf{M}^T)} \in \Gamma_{(\mathbf{C}^T, \mathbf{M}^T)}}{\operatorname{argmax}} E_X\{\log f(X|\gamma_{(\mathbf{C}^T, \mathbf{M}^T)})\}, \\ \hat{\gamma}_{(\mathbf{C}^T, \mathbf{M}^T)} &= \underset{\gamma_{(\mathbf{C}^T, \mathbf{M}^T)} \in \Gamma_{(\mathbf{C}^T, \mathbf{M}^T)}}{\operatorname{argmax}} \frac{1}{n} \sum_{i=1}^{n} \log\{f(\mathbf{x}_i|\gamma_{(\mathbf{C}^T, \mathbf{M}^T)})\}.\end{aligned}$$

Consider the case where the true model contains finite T^0 variable blocks and all the models in consideration are restricted to have the same number of variable blocks ($T = T^0$). To simplify the notation, all the dependence over T^0 and T is omitted below. We make two assumptions:

A1 There exists a unique $(\mathbf{C}^0, \mathbb{M}^0)$ such that $g = f(.|\gamma^*_{(\mathbf{C}^0, \mathbb{M}^0)})$ for some parameter value γ^*.

As discussed previously, when the order of the variable blocks is reversed, we obtain a HMM-VB that yields the same density function for X although parameterized differently. Hence, the order is not identifiable. Thus, the uniqueness in assumption **A1** is implicitly up to a reverse ordering. To further simplify the notation, the dependency over $\mathbb{M}^0$ is omitted below.

A2 $\gamma^*_{(\mathbf{C})}$ and $\hat{\gamma}_{(\mathbf{C})}$ are assumed to belong to a compact subspace $\Gamma'_{(\mathbf{C})}$:

$$\Gamma'_{(\mathbf{C})} = (\Lambda \times \mathcal{A} \times \mathcal{B}(\eta, |C_1|)^{M_1^0} \times \mathcal{D}_{|C_1|}^{M_1^0} \times \mathcal{B}(\eta, |C_2|)^{M_2^0} \times \mathcal{D}_{|C_2|}^{M_2^0} \times \cdots \times \mathcal{D}_{|C_T|}^{M_T^0} \times \mathcal{B}(\eta, |C_T|)^{M_T^0}) \cap \Gamma_{(\mathbf{C})},$$

where

[1] $\Lambda = \{(\pi_1, ..., \pi_{M_1^0}) \in [0,1]^{M_1^0}; \sum_{k=1}^{M_1^0} \pi_k = 1\}$ denotes the set of possible proportions,

[2] $$\mathcal{A} = \left\{ \begin{pmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,M_{t+1}^0} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,M_{t+1}^0} \\ \vdots & \vdots & \cdots & \vdots \\ a_{M_t^0,1} & a_{M_t^0,2} & \cdots & a_{M_t^0,M_{t+1}^0} \end{pmatrix} \in [0,1]^{M_t^0 \times M_{t+1}^0}; \forall j \in 1 : M_t^0, \textstyle\sum_{k=1}^{M_{t+1}^0} a_{j,k} = 1 \right\}_{t=1}^{T-1},$$

[3] $\mathcal{B}(\eta, d) = \{\mathbf{x} \in \mathcal{R}^d, ||\mathbf{x}|| \leq \eta\}$, where $\forall \mathbf{x} \in \mathcal{R}^d$, $||\mathbf{x}|| = \sqrt{\sum_{i=1}^d x_i^2}$,

[4] $|C|$ denotes the cardinality of the set C,

[5] $\mathcal{D}_d$ is the set of $d \times d$ positive definite matrices with eigenvalues in $[a, b]$ with $0 < a < b$.

Theorem 6 *Under the special case that $T = T^0 < \infty$, and assumptions* **A1**, **A2**, *the ordered variable block structure $\hat{\mathbf{C}}$ that minimizes BIC under a given $\mathbb{M}^0$ is consistent in the sense that $P(\hat{\mathbf{C}} = \mathbf{C}^0) \to 1$ as $n \to \infty$.*

The proof is given in Appendix C.

Remark: We point out that the proved consistency in the asymptotic setting as stated above holds for marginal likelihood approaches as well. We observe empirically, however, that BIC performs better for model selection when the sample size is only modestly large. This is expected as BIC addresses overfitting, which has been discussed extensively in literature (e.g., Burnham and Anderson (2003)). Our simulation study in Section 5.1.1 further confirms the advantage of BIC when the sample size is modestly large.

4.3 Modal Baum-Welch Algorithm and Its Optimality

Recall the definition for probability $L_k(\mathbf{x}, t) = P(s_t = k \mid \mathbf{x})$, $k \in \mathcal{S}_t$, $t = 1, ..., T$.

Theorem 7 *For a HMM-VB, suppose the solution of the M-step in the MEM algorithm provided by Eq. (2) is divided into blocks $\mathbf{x}^{[r+1]} = (x^{(1),r+1}, ..., x^{(T),r+1})$. Then*

$$x^{(t),r+1} = \left(\sum_{k \in \mathcal{S}_t} L_k(\mathbf{x}^{[r]}, t) \cdot \left(\Sigma_k^{(t)}\right)^{-1} \right)^{-1} \left(\sum_{k \in \mathcal{S}_t} L_k(\mathbf{x}^{[r]}, t) \cdot \left(\Sigma_k^{(t)}\right)^{-1} \cdot \mu_k^{(t)} \right), \ t = 1, ..., T.$$

This theorem ensures that the MBW algorithm is the exact special case of the MEM algorithm when the GMM is a HMM-VB. The proof is provided in Appendix D.

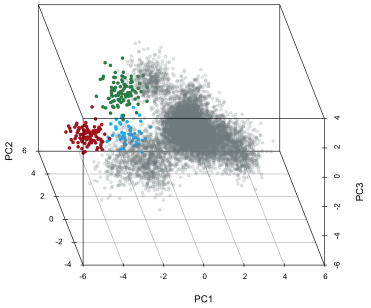
5. Experiments

In this section, we present experimental results on several simulated data sets (Section 5.1), one mass cytometry data (Section 5.2), and two data sets with very high dimensions (Section 5.3). For each data set, the BW algorithm was run repeatedly starting from multiple initial models. In Section 3.1, the different ways of initialization are described. Among the final models, we choose the one yielding the maximum likelihood.

5.1 Simulation with Various Types of Variable Block Structures

We first conduct simulation studies to examine the effectiveness of HMM-VB at capturing small clusters, the overall clustering performance, and its robustness against different parameter settings.

5.1.1 Two variable blocks



Using a similar set-up as in Lin et al. (2013), a sample of size $10,000$ with dimension $d = 8$ is drawn from a hierarchical mixture model. There are two variable blocks. Following the notations in the previous section, $\mathbf{x}_i$ is divided into two variable blocks, also called subvectors, $x_i^{(1)}$ and $x_i^{(2)}$. The first subvector contains the first 5 dimensions: $x_i^{(1)} = (x_{i,1}, ..., x_{i,5})$, with $d_1 = 5$. The second subvector contains the last 3 dimensions: $x_i^{(2)} = (x_{i,6}, x_{i,7}, x_{i,8})$, with $d_2 = 3$. In particular, $x_i^{(1)}$'s are generated from a mixture of 7 normal distributions such that the last two normal distributions (assigned with component priors 0.01 and 0.02 respectively) have high mean values for the second and third dimensions. The other normal components have very different proportions and mean vectors. The second subvector, $x_i^{(2)}$'s, are generated from a mixture of 10 normal distributions, where only two of them have high mean values across all three dimensions. The component proportions of $x_i^{(2)}$ vary according to which normal component $x_i^{(1)}$ was generated from, as in the assumption of HMM-VB. A detailed description of the data generation mechanism is in Appendix E. The data is designed to have at least one distinct cluster after standardization (subtract mean and divided by the standard error). In particular, the standardized data have a well-separated region that the five dimensions x_2, x_3, x_6, x_7, x_8 are of high positive values, and the rest are negative. The particular designed data region contains 100 data points, which account for only 1% of the data.

We also run the MBW algorithm to find modes of the true density (see Appendix E). The result serves two purposes: 1) to validate the effectiveness of MBW for finding small clusters when there is no model estimation error; 2) to be used as a ground truth for comparison with our HMM-VB method. MBW identifies perfectly that particular cluster of size 100. In addition, it finds in total 16 modes (clusters). Among them, there are two additional small clusters of size 54 and 98 respectively. Figure 5.1.1 (Left) shows the three smallest clusters.

To fit HMM-VB given the dependence structure among the 8 variables, we only need to specify M_1 and M_2, the numbers of mixture components for the two variable blocks. If casted as a GMM, the HMM-VB has $M_1 \times M_2$ components for the full dimensional data. Model selection by BIC is conducted to select the optimal M_1 and M_2. Summaries on various model specifications are listed in Figure 5.1.1 (Right). The model with $M_1 = 7$ and $M_2 = 10$ has the lowest BIC and is thus chosen.

Recall that we search modes by MBW starting from the mean of every component that has been chosen by a data vector according to the maximum a posteriori rule. We call the components that have not been chosen by any data point the empty mixture components, while the others are nonempty. Figure 5.1.1 (Right) shows that even though the total number of nonempty mixture components increases with M_1 and M_2, the number of clusters after modal clustering remains relatively stable.

In Table 1, we compare clustering results of HMM-VB with four baseline methods: K-means, agglomerative hierarchical clustering on a set of dissimilarities, Mclust, and modal GMM. We also tried other methods, such as spectral clustering using R `kernlab` package, pdfCluster (Azzalini and Menardi, 2014) using R `pdfCluster` package, and the mean-shift algorithm (Fukunaga and Hostetler, 1975; Cheng, 1995) using R `MeanShift` package. R `pdfCluster` program was aborted by the computer system when applied to the data. R `kernlab` and `MeanShift` packages failed to obtain results after several hours, while the

(M_1, M_2)	BIC	# nonempty components	# clusters
$(3, 3)$	$183,687.4$	8	2
$(3, 5)$	$176,134.6$	9	7
$(7, 10)$	$163,486.1$	35	16
$(8, 10)$	$163,724.0$	37	16
$(10, 10)$	$164,245.1$	45	16
$(10, 15)$	$164,822.9$	70	17
$(15, 10)$	$165,338.6$	56	16

$(20, 15)$	$167,761.7$	121	17
$(20, 20)$	$206,478.6$	158	19

Figure 2: (Left): Visualization of the simulated data in Section 5.1.1 based on the first three principal components (PC). The smallest three clusters are plotted in blue (54 observations), green (98), red (100), and the rest are in grey. (Right): Comparisons of BIC, total number of nonempty components and clusters under various model specifications (M_1 and M_2).

methods in Table 1 take less than one minute. For K-means, hierarchical clustering, and Mclust, we used the three R functions `kmeans` (with 20 starting points), `hclust` and `Mclust`. In this analysis, we treat the 16 clusters found by MBW applied to the true mixture density as the ground truth. Hence, for K-means and hierarchical clustering, we manually set 16 as the number of clusters. The number of normal mixture components and the covariance structure are determined by BIC in the `Mclust` package (the package version is 5.2.3). More specifically, we let `Mclust` search a maximum of 20 mixture components and then used the BIC to choose among all the default covariance matrix models, as computational errors were generated when searching over all the models. For this data set, the optimal number of clusters chosen by Mclust is 15. The modal GMM analysis is performed using the same C codes for fitting the HMM-VB model. We simply specified a single variable block containing all the 8 variables. The HMM-VB model is then reduced to a usual GMM. In addition, we let the total number of mixture components be $7 \times 10 = 70$.

The first column of Table 1 shows the 16 true clusters and their cluster sizes. Let us call the true clusters E_1^*, ..., E_{16}^*. Results about each true cluster occupy one row in the table, while results obtained from every clustering method are reported in one column. Take the first row for cluster E_1^* as an example. E_1^* has $5,098$ data points. A cluster generated by any method is described by a pair of numbers, the one outside the parenthesis being the size of the cluster and the one inside being the number of points shared with the true cluster. For instance, HMM-VB generates a cluster containing $5,096$ points, among which $5,088$ are shared with E_1^*. This cluster is the best match with E_1^*. In comparison, modal GMM yields a cluster of size $4,695$ overlapping E_1^* by $4,467$. By K-means, hierarchical clustering or Mclust, E_1^* is split roughly into three clusters. Thus three pairs of cluster sizes are recorded in the first row under each method. For clarity of presentation, if the overlap between a

cluster and any E_i^* is too small, the cluster is not listed in the ith row. Reversely, a cluster generated by a certain method may also cover a substantial portion of points from multiple true clusters. For instance, hierarchical clustering yields one small cluster of size 257, which contains both part of E_1^* and E_2^*. A cluster of size 154 generated by K-means contains E_5^* and E_8^*. Therefore, a single cluster generated by a certain method may be reported in multiple rows. To indicate clearly such a case, the same color (except for black) is used to mark out a single cluster in any column. If a cluster is reported only once in any column, the result is shown in black (in other words, black is not a color code).

True cluster	HMM-VB	K-means	HC	Mclust	Modal GMM

Table 1: Comparisons of clustering performance among HMM-VB, K-means, hierarchical clustering (HC), Mclust, and modal GMM for the simulation data in Section 5.1.1.

Table 1 demonstrates that HMM-VB outperforms clearly the other methods in terms of matching the true clusters, especially for the rare clusters. K-means, hierarchical clustering, and Mclust tend to yield similar-sized clusters. All of them split the largest true cluster E_1^* into 3 smaller ones. Except for HMM-VB, all the other four methods fail to correctly identify all three smallest clusters, E_5^*, E_8^* and E_{12}^*. Specifically, according to the four methods, E_5^* and E_8^* are in the same cluster. The CPU time per model fitting (based on the best model specification) on an iMac with Intel Core i7 3.0GHz/8GB memory is recorded, given in the last row of Table 1. The unit of time is second. Under the same specification of

the number of clusters, K-means is faster than hierarchical clustering. Mclust is performed on 15 mixture components, while both HMM-VB and modal GMM are fitted using 70 mixture components. The fact that HMM-VB is much faster than modal GMM shows the computational advantage to regularize a general GMM by a variable block structure.

In addition, we use this simulation data to test the search algorithm for the variable block structure, which is described in Section 3.4. We run the algorithm with 6 different initial random permutations. The algorithm successfully selects the correct variable blocks according to the true distribution. Furthermore, to empirically demonstrate the efficiency of BIC for model selection, we also incorporate the comparison with (log) marginal likelihood approach in Table 2. Both approaches select the same model under the larger sample size.

Random permutation	Log marginal likelihood	BIC

Table 2: Comparison of BIC and log marginal likelihood for model selection using 6 initial random permutations under two different sample sizes. We mark the model selected by BIC with * and the model selected by log marginal likelihood with †. We use parentheses to indicate a particular variable block, and $*$ to separate the different variable blocks.

5.1.2 No Information on Variable Blocks

We now study the clustering performance of HMM-VB when there are no clear-cut variable block structures. A sample of size $10,000$ with $d = 5$ dimensions is drawn from a $10-$component GMM. We ensure that all the 10 components correspond one-to-one with 10 distinct clusters by setting mean vectors far apart. Hence, each cluster can be described by a single Gaussian component. The detailed description of the data generation mechanism is in Appendix E. Figure 3 shows the scatter plots of the generated data. Colors indicate the cluster membership. Several clusters overlap tremendously within two-dimensional space. As in the previous experiment (Section 5.1.1), we run MBW on the true model density, which identifies in total 10 clusters with cluster memberships matching precisely the true latent component identities.

Table 3: Comparison of clustering performance among three HMM-VB models, K-means, hierarchical clustering (HC), Mclust, and modal GMM for simulation data in Section 5.1.2. The first two HMM-VB models give the same results for major clusters.

To demonstrate the robustness of HMM-VB under different variable block structures, we fit the data using different model specifications. We let model $\mathcal{M}_1$ be a HMM-VB with 5 variable blocks each containing one variable and ordered by the given indices of the

variables. The number of components for each block chosen by BIC is $M_t = 7$, $t = 1, ..., 5$. Model $\mathcal{M}_2$ is defined similarly as $\mathcal{M}_1$, but we reverse the ordering of the variables such that $x = (x_5, x_4, ..., x_1)$. Lastly, we let $\mathcal{M}_3$ be a HMM-VB with 5 variable blocks ordered by a random permutation $x = (x_1, x_3, x_4, x_2, x_5)$. Table 3 shows the clustering results for the three HMM-VB models and the other four baseline methods. The format of the results in this table is the same as that for Table 1 in the previous section. Again we pre-set the number of clusters for K-means, hierarchical clustering, and modal GMM as the true value. The model specification for Mclust is similar to the previous experiment, but we allow `Mclust` to search for up to 12 Gaussian components. For clarity of presentation, clusters that share fewer than 5 points with any true cluster are not reported in Table 3. As expected $\mathcal{M}_1$ and $\mathcal{M}_2$ yield very similar results. As discussed at the end of Section 4.1, when the ordering of the variable blocks is reversed, the GMM casted from the HMM-VB is essentially the same. Small differences may arise due to some random factors caused by initialization. We simply report results from one of the two models. Table 3 suggests that HMM-VB is quite robust to the ordering of the variables. Both K-means and hierarchical clustering fail to extract the cluster structures. As expected, both Mclust and modal GMM can accurately recover all the clusters because the data is generated according to the generic GMM model.

The search scheme for selecting the optimal variable block structure determines that only one variable block is needed (that is, the usual GMM). This is consistent with the true model. However, Table 3 shows that although the HMM-VB with five blocks is not the right model, it can still perform reasonably well for clustering. This finding suggests that HMM-VB can be a new strategy to regularize a GMM, the complexity of which is normally only controlled by the number of components or constraints on the covariance matrices.

5.1.3 Large Data Size

Since HMM-VB is motivated by single-cell data analysis, where the sample size can be up to several millions, we now study the performance of HMM-VB for large data sets with moderately high dimensions. We let dimension $d = 40$, and sample size n ranges from $100,000$, $1,000,000$ and $5,000,000$. The first 10 dimensions are generated from a 3-component GMM. The remaining 30 dimensions are generated from a 5-component GMM, where the mixture component proportions vary according to which normal component the first 10 dimensions are generated from. In addition, the covariance matrices of the last 30 dimensions are block diagonal, containing two blocks of sizes 10×10 and 20×20. Furthermore, by specifically designing the mean vectors and the transition probability matrix from the first 10 dimensions to the rest, the data generated contain 5 distinct normal components which correspond to 5 distinct clusters. The detailed description for the data generation is in Appendix E. The relative proportions for the 5 clusters are about 0.005, 0.045, 0.07, 0.18, and 0.7.

In this particular study, Mclust encounters some numerical errors when performing model selection. Because K-means and hierarchical clustering perform poorly in the previous two studies, we hereby focus on the comparison between HMM-VB and modal GMM. To fit HMM-VB, we divide the 40 dimensions into 3 blocks: $x_i^{(1)} = (x_{i,1}, ..., x_{i,10})$, $x_i^{(2)} = (x_{i,11}, ..., x_{i,20})$, $x_i^{(3)} = (x_{i,21}, ..., x_{i,40})$. According to the model specification, we let $M_1 = 3$, $M_2 = 5$, and $M_3 = 5$. To fit modal GMM, we let the total number of mixture components to be $3\times5 = 15$.

True cluster	HMM-VB	Modal GMM
	$n = 100,000$	
$1:510$	$510(510)$	$4,940(510)$

Table 4: Comparison of clustering performance between HMM-VB and modal GMM for simulation study in Section 5.1.3.

Table 4 shows the clustering results for the two models for simulated data of three different sample sizes. HMM-VB correctly identifies all the clusters for the three data sets. However, modal GMM cannot separate the two smallest clusters. In addition, HMM-VB requires much shorter computation time than modal GMM, even though the equivalent GMM of the HMM-VB has $3 \times 5 \times 5 = 75$ components. The difference in computation time is even more dramatic when the sample size is large. In order to detect more accurately the rare clusters by modal GMM, we could increase the number of mixture components. However, the increase may have to be large causing much slower computation.

5.1.4 Clustering Variation Study

To investigate the variation of clustering results for the above three simulations, we in addition randomly generate 100 replicates from the two variable blocks model in Section 5.1.1, 100 replicates from the 10-component GMMs with randomly generated covariance matrices described in Section 5.1.2, and only 10 replicates for the model in Section 5.1.3 due to the extensive computational time caused by large data size. We use the adjusted Rand index (ARI) (Rand, 1971) to assess the similarity between the clustering result by each method and the true cluster assignments. Summaries based on the ARI for the first two simulation studies are shown in Figure 4, and that for the last simulation is provided in Table 5.

For the simulation in Section 5.1.1, the variables have a two block structure. The average ARI achieved by HMM-VB is substantially better than the other methods, and the variation of the HMM-VB results is much smaller than those by Mclust or modal GMM. For the simulation in Section 5.1.2, Model 1 is used for HMM-VB. The variable structure assumed

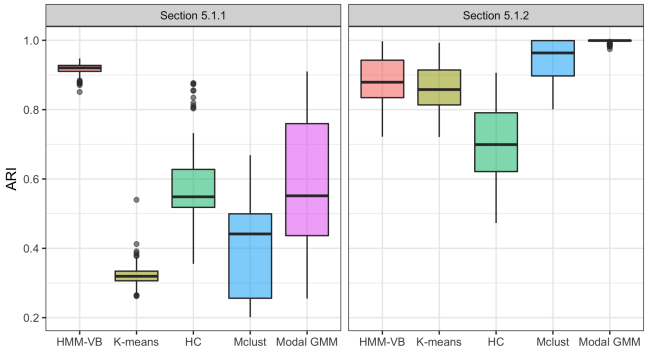

Figure 4: Boxplots of ARI based on 100 replicates generated by simulations in Section 5.1.1 and 5.1.2.

by HMM-VB is not right, while Mclust and modal GMM are based on the correct model. Nevertheless, the boxed range of ARIs by HMM-VB overlaps with that by Mclust although the average by HMM-VB is lower. The best result is obtained by modal GMM. For the third simulation in Section 5.1.3, although both HMM-VB and modal GMM yield high ARIs, the average number of clusters obtained by HMM-VB is always the same or nearly the same as the true value, while that by modal GMM is consistently lower by one. Finally, we note that ARI measures overall similarity between clustering results. Thus small clusters matter less than large clusters for ARI. If finding rare clusters is important, we should not rely only on ARI to evaluate the methods. Results shown in Table 1, 3, and 4 can be more pertinent.

Sample size	mean ARI	median ARI	sd ARI	$\bar{C}$
		HMM-VB		
$100,000$	1	1	0	5
$1,000,000$	1	1	0	5
$5,000,000$	0.9999	1	2.88×10^{-4}	4.9
		Modal GMM		
$100,000$	0.9991	0.9991	5.74×10^{-5}	4
$1,000,000$	0.9992	0.9991	2.88×10^{-4}	4.1
$5,000,000$	0.9513	0.9991	0.15	4.1

5.2 Study of CyTOF Data

As a motivating example, current high-throughput flow cytometry experiments routinely measure $10 \sim 20$ parameters (cell markers/variables) on a large number of single cells. The current mass cytometry (CyTOF) can measure up to 50 parameters at a single cell level. A key first step to analyze this wealth of data is to partition the data (cells) from a blood or tissue sample into clusters based on the measured cell markers. The identified clusters are usually referred to as (cell) subsets.

Many studies adopt clustering based on mixture models to identify cell subsets objectively and automatically for single-cell data analysis (e.g., Boedigheimer and Ferbas (2008); Lo et al. (2008); Chan et al. (2008); Pyne et al. (2009); Aghaeepour et al. (2013); Lin et al. (2016)). One challenge encountered is that cell subsets of interest are typically of low frequencies (e.g., $\sim 0.01\%$ of total cells), while it is important to detect cell heterogeneity, especially very low frequency cell subsets for subsequent analysis, e.g., to understand the association between cellular heterogeneity and disease progression (Darrah et al., 2007; Lin et al., 2015a; Seshadri et al., 2015; Corey et al., 2015).

One important structure of the CyTOF data is a natural chain-like dependence among groups of variables (e.g., Roederer et al. (2004); Perfetto et al. (2004)). Biologists utilize such inherent property of the data to manually identify cell subsets by sequentially visualizing data on the groups of variables, known as manual gating, which has been extensively used in real data analysis. Specifically, the manual gating is a manual sequential process that visually demarcates cells in bounded regions (called gates) on histogram or 2-D scatter plot projections. Interestingly, the modal clustering technique has been applied to assist manual gating for cytometric data by Ray and Pyne (2012). Figure 5 provides a simplified illustration of the manual gating analysis on one flow cytometry data. Red lines are the gates, and cells within the region defined by the gates are identified as a specific cell subset. For example, to discriminate CD4+ T cells, which is one major cell subset, a sequence of subsetting procedures is performed. Two physical markers, Forward (FSC-A) and side (SSC-A) light scatter, are first used to distinguish lymphocytes from all the live cells. Lymphocytes can then be further partitioned based on 3 fluorescence parameters: CD3, CD4, and CD8 cell-surface markers. CD4+ T cells are the subclass of lymphocytes having high values of CD3 and CD4 but low value of CD8. Within CD4+ T-cell populations, additional functional markers such as intracellular makers (IL2 and IFNg) can further distinguish many functionally different CD4+ T-cell subsets. The sequence of groups of markers to use is called *gating hierarchy*, which is determined by expert knowledge. The shape and location of the gates are manually drawn. The gates are typically used to dichotomize the continuous marker expressions into binary value: positive and negative.

In manual gating analysis, the variables are grouped and ordered based on expert knowledge. By using the well-established gating hierarchy that projects cells on lower dimensions, each subplot provides a finer resolution of the cellular heterogeneity. In the sequential visualization process, any move one step further means a new group of variables are examined. Despite its wide usage, the manual gating analysis is highly subjective, time consuming, and hard to reproduce.

In this section, we study the performance of HMM-VB on a data set obtained from CyTOF experiment (Becher et al., 2014). The particular data set that we analyze here is

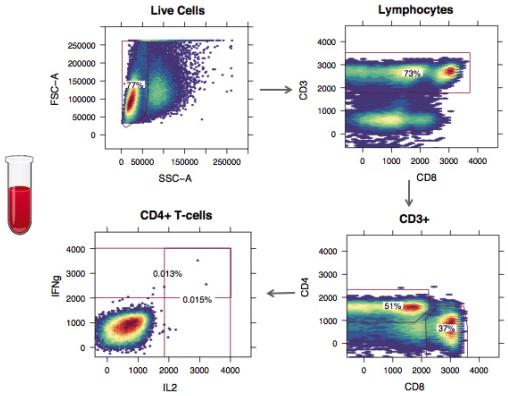

Figure 5: A simplified example of cell subsets identification by manual gating analysis. The flow cytometry measurements on single cells from a blood sample are shown using 4 heat maps of 2-D scatter plots projected on different dimensions (markers). The red lines on each subplots are called gates. Cells within the red lines are the subset of interest, which is subsetted and projected on the next subplot in the sequence. The percentages are the frequencies of the identified cell subsets relative to the total number of cells.

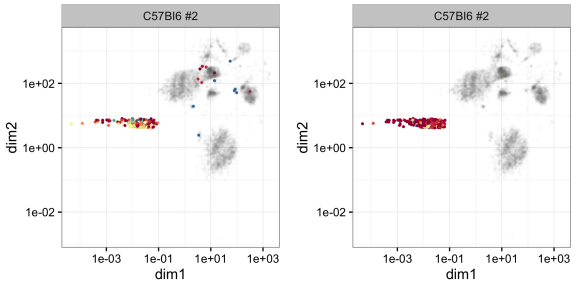
from mouse lung sample obtained from three C57BI6 wild-type mice and three Csf2rb$^{-/-}$ mice, which in total contains $46,204$ single cells with 39 measured cell markers. According to the gating hierarchy provided in Becher et al. (2014), it defines roughly 11 variable blocks, with maximum block size 8 and minimum block size 1. Becher et al. (2014) performed automated clustering on a projected (latent) $2-$dimensional space by first using nonlinear dimension reduction technique on the original $39-$dimensional space. However, it has been studied, e.g. Lin et al. (2015b), that dimension reduction generates a "cluttered" display, which can prevent density estimation from accurately representing low probability regions.

We first standardized the data to compensate for the nearly singular covariance matrix when a single Gaussian is fit despite the moderate dimension. This factor prevents the direct use of GMM. We note that HMM-VB encounters no difficulty in fitting the original data because of the smaller dimensions of the individual variable blocks. In order to compare modal GMM and HMM-VB, we work on the standardized data through the rest of the section.

We first fit the data using HMM-VB. There are 11 variable blocks. For the ith variable blocks with dimension lower than 4, we set the corresponding number of mixture components $M_i = 5$. For the jth variable blocks with dimension between 5 and 7, we set the number of components $M_j = 10$. For the other variable blocks, we set the number of components to 15. After modal clustering, this model results in 194 clusters of size greater than 5. The average

CPU time per model fitting is 11.4 min. We then fit the data using GMM with $M = 500$. On the same iMac, the model fitting takes 284.2 min, 25 times longer than does HMM-VB. Modal clustering results in 232 clusters of size greater than 5.

We compare the performance of the two models for clustering a relatively low probability region, which is shown in Figure 6. Specifically, Figure 6 compares the finer cellular compositions of one well separated region, which is visualized on two latent dimensions obtained from a dimension reduction technique applied to the original 39 dimensions, as provided by the result of Becher et al. (2014). HMM-VB (right subplot) uses 18 clusters to define this particular region. GMM (left subplot) uses 40 clusters to define the same region. However, some of the clusters include cells that are visually far away from the particular region. This result indicates that GMM has difficulty in estimating the structure of this moderately high-dimensional data.



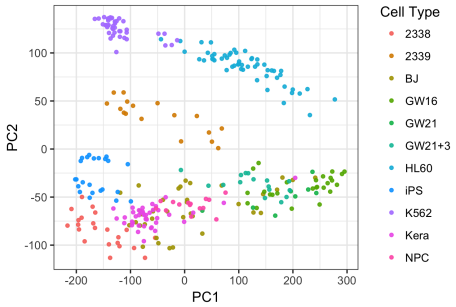


Figure 6: Left: GMM clustering analysis for a particular data region of one selected mouse. Right: The corresponding HMM-VB clustering analysis. The data is shown in grey. Clustering results are in different colors with one color defines one cluster.

5.3 Examples of Very High Dimensional Data

We apply HMM-VB to two data sets with dimension $d \gg n$.

5.3.1 Single-Cell Genomics Data

Current single-cell genomics technologies can routinely generate transcriptomics data at the single-cell level. Similar to the cytometry data, a key first analysis step is to identify cellular heterogeneity among single cells. The challenge is to cluster high dimensional data with substantially more variables (genes) than objects (cells). Existing clustering methods fall roughly into two categories. The first category is based largely on pairwise similarity measures among single cells (e.g., Guo et al. (2015); Wang et al. (2017)). The second category applies clustering, e.g., K-means and mixture models, in a reduced dimension space (typically 2 or 3 dimensions) obtained by principal component analysis or other nonlinear dimension reduction techniques (e.g., Satija et al. (2015); Žurauskienė and Yau (2016); Kiselev et al.

Cell type: size	HMM-VB
2338: 22	22(22)
2339: 17	17(17)
HL60: 54	54(54)
iPS: 23	23(23)
K562: 42	42(42)
NPC: 15	15(15)
BJ: 37	29(29); 9(8)
GW16: 26	28(15); 22(11)
GW21: 8	28(5); 22(3)
GW21+3: 16	28(8); 22(8)
Kera: 40	39(39); 9(1)

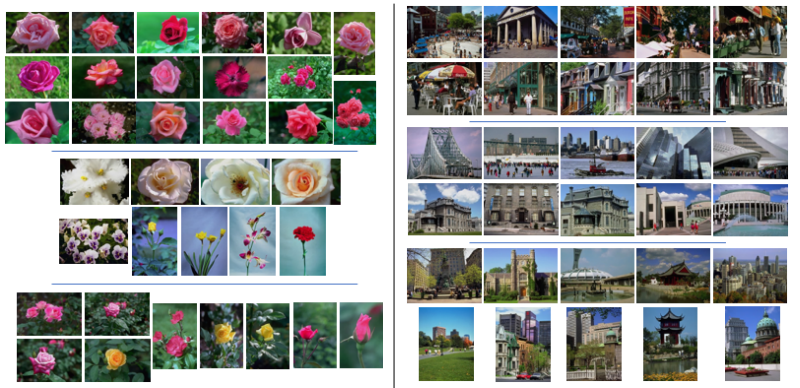
Figure 7: (Left): Visualization of the single cell RNA-seq data based on the first two principal components. Colors indicate the 11 cell types. (Right): Clustering performance for HMM-VB compared with the 11 cell types.

(2017)). Here, we study the performance of HMM-VB on a single-cell RNA-seq data set for 300 cells whose transcriptional measurements were taken across 8,686 genes. The data set is obtained from the Github repository: `https://github.com/JustinaZ/pcaReduce` provided by Žurauskienė and Yau (2016). The data were derived from 11 cell types: K562 – myeloid (chronic leukemia); HL60 – myeloid (acute leukemia); CRL-2339 – lymphoblastoid; iPS – pluripotent; CRL-2338 – epithelial; BJ – fibroblast (from human foreskin); Kera – foreskin keratinocyte; NPC – neural progenitor cells; GW(16, 21, 21+3) – fetal cortex at gestational week (16,21, 21+3 weeks). Figure 7 (Left) shows the data projected on the first two principal components for visualization. It is clear that the 11 cell types in the two-dimensional principal component space cannot be separated into distinct groups. Žurauskienė and Yau (2016) perform clustering analysis in the subspace spanned by the first 30 principal components, and demonstrate the superiority of pcaReduce in terms of clustering accuracy over some competing methods. However, pcaReduce can only correctly identify 4 cell types which are HL60, CRL-2339, CRL-2338, and NPC.

We first identified the top 500 highly variable genes based on their sample variances after applying log transformation. We then fit this reduced data of size 300×500 using HMM-VB. The genes are divided into 5 variable blocks of equal dimension, and each block is set to have 40 mixture components. We also tried other model specifications, and they yielded similar clustering results. HMM-VB identifies 12 cell clusters. More importantly, HMM-VB not only correctly identifies the 4 cell types that were also discovered by pcaReduce, it also finds correctly 2 other cell types: iPS and K562. Moreover, pcaReduce groups the three cell types GW(16, 21, 21+3) into one cluster. HMM-VB partitions these three cell types into two clusters, which could be visually supported by Figure 7 (Left). Figure 7 (Right) provides the details of the clustering performance.

Because the dimension is higher than the data size for this data set, we constrained the covariance matrix for each variable block to be diagonal. This constraint can be offset by having more components for a good fit of data. We found that when the dimension

of the variable block is at similar order of the data size, without any constraint, the estimated covariance matrix is sometimes singular or ill-conditioned even if a single Gaussian distribution is assumed. We also found that the number of modes in a HMM-VB can become quite large if the number of variable blocks is large, while the number of modes is much more stable with the increase of components in each variable block. In summary, as practical guidance on the usage of HMM-VB for very high dimensional data ($d \gg n$), we recommend the use of diagonal covariance and the avoidance of too many variable blocks.



5.3.2 Image Data Analysis

We take a collection of general-purpose photograph images and represent each image by a high dimensional vector. First, the Red, Blue, and Green values of each pixel in an image are converted to the LUV color space. Second, each image is divided into 50×50 blocks and the average LUV values of all the pixels in each block are used to characterize this block. The whole image is represented by a stacked vector of the LUV values of the 2500 blocks. Thus the dimension of the data is $d = 7500$. We put the LUV values of every image block into one variable block. There are thus 2500 variable blocks each of dimension 3. These variable blocks are ordered according to a zig-zag row by row scan, that is, to scan from left to right in the first row, then right to left in the second, so on so forth. Clearly, because each variable block corresponds to a particular location in the image plane, the clustering result based on HMM-VB will be sensitive to the position of objects in an image. For many applications in multimedia retrieval or computer vision, such sensitivity is undesirable. However, our purpose here is not to promote our experiment as a standard for clustering images, but to show the viability of our method when $d \gg n$. We acknowledge that for any particular application, it may be necessary to perform certain pre-processing, such as extracting sub-images based on segmentation, etc. An in-depth evaluation from an image analysis perspective is beyond the scope of this paper.

We estimated the HMM-VB on the aforementioned variable block structure, assuming 5 mixture components for each block. Since the dimension of the variable blocks is small, we did not constrain the covariance matrices to be diagonal in this analysis. We estimated a model for a set of 200 photos of flowers, a set of 200 photos of city scenes, and a set of 2400 photos of various themes. On a Mac with Intel Core i5 3.5GHz/16GB Memory, the time for training is respectively 263, 326, 2118 seconds for the three data sets, and the time for solving the modes for all the images in a data set is respectively 118, 141, 1930 seconds. We found that due to the very high dimension, if we apply the same stringent criterion of identical modes, then nearly every image becomes a single cluster. We obtain larger clusters when the criterion is relaxed. We show in Figure 8 example clusters generated.

6. Discussion

We have developed a novel mixture model, namely, HMM-VB, with the goal of automated clustering of large-scale and high-dimensional data that contain rare clusters. One key feature of HMM-VB is its ability to leverage sequential dependence among groups of variables for more effective clustering, especially in identifying rare clusters that are almost undetectable by existing mixture modeling approaches. Technically, our clustering method integrates two new algorithms, one for estimating HMM-VB and the other for performing modal

(a) Flower (b) City scenes

Figure 8: Example images in the clusters generated for two data sets. The clusters are separated by the horizontal bars.

clustering, both necessary for making the new model a practical tool in large-scale data analysis. Because the number of mixture components grows exponentially with the number of variable groups, existing EM and MEM algorithms for estimation and mode identification have intractable exponential complexity. We have derived and implemented algorithms with linear complexity in the number of variable blocks for both tasks.

We have so far declared clusters based on association with identical modes. Due to the huge number of mixture components in the GMM casted from HMM-VB, many tiny clusters can be generated. The total number of points in those clusters can be a small fraction of the entire data. In this situation, more sophisticated methods that measure the separability of these tiny clusters and other larger ones can be used for clustering (e.g., Lee and Li (2012)). As another direction of future work, we can test the capability of the variable block search algorithm to reveal hidden dependence structure among the variables or to help validate existing gating hierarchy.

We would like to acknowledge support for this work from the National Science Foundation under grant ECCS-1462230 and DMS-1521092. We also thank the reviewers and the AE wholeheartedly for many detailed and constructive suggestions.

Appendix A

We present here the conventional HMM and the Baum-Welch (BW) algorithm for estimation. Consider sequential data $\mathbf{x} = \{x_1, x_2, ..., x_t, ..., x_T\}$, with $x_t \in \mathcal{R}^d$. Same as in the mixture model, assume there is an underlying state s_t associated with every x_t, for $t = 1, ..., T$. The underlying state is the counterpart of the mixture component identity in GMM. The state $s_t \in \mathcal{S} = \{1, 2, ..., M\}$, where M is the number of states. Let the set of all possible state sequences be $\bar{\mathcal{S}}$, that is, the set of T-tuples on $\mathcal{S}$. $|\bar{\mathcal{S}}| = M^T$. Denote $\mathbf{s} = \{s_1, ..., s_T\} \in \bar{\mathcal{S}}$. The basic assumptions of a HMM are:

1. The underlying states $\{s_1, s_2, ..., s_T\}$ follow a Markov chain. The Markov chain is usually time invariant with transition probability matrix $A = (a_{k,l})$, where $a_{k,l} = P(s_{t+1} = l \mid s_t = k)$, $k, l \in \mathcal{S}$. Denote the initial probabilities of states by $\pi_k = P(s_1 = k)$, $k \in \mathcal{S}$.

2. Given the hidden state s_t, the observation x_t is conditionally independent from $s_{t'}$ and $x_{t'}$ for any $t' \neq t$, and the distribution of x_t given s_t depends on s_t, but not on t. Denote the conditional density of $P(x_t|s_t = k)$ by $\varphi_k(x_t)$. In particular, for Gaussian HMM, $\varphi_k(x_t) = \phi(x_t|\mu_k, \Sigma_k)$.

In summary,

$$P(\mathbf{x}, \mathbf{s}) = P(\mathbf{s})P(\mathbf{x} \mid \mathbf{s}) = \pi_{s_1}\varphi_{s_1}(x_1)a_{s_1,s_2}\varphi_{s_2}(x_2)\cdots a_{s_{T-1},s_T}\varphi_{s_T}(x_T),$$
$$P(\mathbf{x}) = \sum_{\mathbf{s}\in\bar{\mathcal{S}}} P(\mathbf{s})P(\mathbf{x} \mid \mathbf{s}) = \sum_{\mathbf{s}\in\bar{\mathcal{S}}} \pi_{s_1}\varphi_{s_1}(x_1)a_{s_1,s_2}\varphi_{s_2}(x_2)\cdots a_{s_{T-1},s_T}\varphi_{s_T}(x_T).$$

The parameters to be estimated in a HMM are the transition probabilities: $a_{k,l}$, $k, l = 1, ..., M$, the initial probabilities: π_k, $k = 1, ..., M$, and μ_k, Σ_k for each state $k = 1, ..., M$.

Under a set of parameters, let $L_k(t)$ be the conditional probability of being in state k at position t given the entire observed sequence $\mathbf{x} = \{x_1, x_2, ..., x_T\}$. Let $I(\cdot)$ be the indicator function that equals 1 when the argument is true and 0 otherwise. Then

$$L_k(t) = P(s_t = k|\mathbf{x}) = \sum_{\mathbf{s}} P(\mathbf{s} \mid \mathbf{x})I(s_t = k), \quad k \in \mathcal{S}. \tag{8}$$

Let $H_{k,l}(t)$ be the conditional probability of being in state k at position t and being in state l at position $t+1$, i.e., seeing a transition from k to l at t, given the entire observed sequence $\mathbf{x}$. Then

$$\begin{aligned} H_{k,l}(t) &= P(s_t = k, s_{t+1} = l|\mathbf{x}) \\ &= \sum_{\mathbf{s}} P(\mathbf{s} \mid \mathbf{x})I(s_t = k)I(s_{t+1} = l), \quad k, l \in \mathcal{S}. \end{aligned} \tag{9}$$

Note that $L_k(t) = \sum_{l=1}^M H_{k,l}(t)$, $\sum_{k=1}^M L_k(t) = 1$. Since $\mathbf{s} \in \bar{\mathcal{S}}$ and the $|\bar{\mathcal{S}}| = M^T$, it is infeasible to compute $L_k(t)$ and $H_{k,l}(t)$ by the above equations directly. As part of the BW algorithm, the *forward-backward* algorithm is used to compute $L_k(t)$ and $H_{k,l}(t)$ efficiently. The amount of computation needed is at the order of M^2T; and the memory required is at the order of MT.

Define the forward probability $\alpha_k(t)$ as the joint probability of observing the first t vectors x_τ, $\tau = 1, ..., t$, and being in state k at time t:

$$\alpha_k(t) = P(x_1, x_2, ..., x_t, s_t = k).$$

This probability can be evaluated by the following recursive formula:

$$\begin{aligned} \alpha_k(1) &= \pi_k\varphi_k(x_1), \quad 1 \le k \le M, \\ \alpha_k(t) &= \varphi_k(x_t)\sum_{l=1}^M \alpha_l(t-1)a_{l,k}, \quad 1 < t \le T,\ 1 \le k \le M. \end{aligned}$$

Define the backward probability $\beta_k(t)$ as the conditional probability of observing the vectors after time t, x_τ, $\tau = t+1, ..., T$, given the state at time t is k.

$$\begin{aligned} \beta_k(t) &= P(x_{t+1}, ..., x_T \mid s_t = k), \quad 1 \le t \le T-1, \\ \beta_k(T) &= 1, \quad \text{for all } k. \end{aligned}$$

As with the forward probability, the backward probability can be evaluated using the following recursion:

$$\begin{aligned} \beta_k(T) &= 1, \\ \beta_k(t) &= \sum_{l=1}^M a_{k,l}\varphi_l(x_{t+1})\beta_l(t+1), \quad 1 \le t < T. \end{aligned}$$

The probabilities $L_k(t)$ and $H_{k,l}(t)$ are solved by

$$L_k(t) = P(s_t = k \mid \mathbf{x}) = \frac{P(\mathbf{x}, s_t = k)}{P(\mathbf{x})} = \frac{1}{P(\mathbf{x})}\alpha_k(t)\beta_k(t),$$

$$\begin{aligned} H_{k,l}(t) &= P(s_t = k, s_{t+1} = l \mid \mathbf{x}) = \frac{P(\mathbf{x}, s_t = k, s_{t+1} = l)}{P(\mathbf{x})} \\ &= \frac{1}{P(\mathbf{x})}\alpha_k(t)a_{k,l}\varphi_l(x_{t+1})\beta_l(t+1), \end{aligned}$$

where $P(\mathbf{x}) = \sum_{k=1}^M \alpha_k(t)\beta_k(t)$.

For notational brevity, we assume all the sequences are of length T. The extension to sequences of different lengths is trivial. Denote the ith sequence by $\mathbf{x}_i = \{x_{i,1}, x_{i,2}, ..., x_{i,T}\}$, $i = 1, ..., n$. In each iteration, we compute the forward and backward probabilities for each sequence separately as previously described. We also compute $L_k(t)$ and $H_{k,l}(t)$ separately for each sequence. As a general pattern of notations, we put a superscript (i) to indicate the quantities for the ith sequence.

1. Compute the forward and backward probabilities $\alpha_k^{(i)}(t)$, $\beta_k^{(i)}(t)$, $k = 1, ..., M$, $t = 1, ..., T$, $i = 1, ..., n$, under the current set of parameters.

$$\begin{aligned}
\alpha_k^{(i)}(1) &= \pi_k \varphi_k(x_{i,1}), \quad 1 \le k \le M,\ 1 \le i \le n, \\
\alpha_k^{(i)}(t) &= \varphi_k(x_{i,t}) \sum_{l=1}^{M} \alpha_l^{(i)}(t-1) a_{l,k}, \quad 1 < t \le T,\ 1 \le k \le M,\ 1 \le i \le n, \\
\beta_k^{(i)}(T) &= 1, \quad 1 \le k \le M,\ 1 \le i \le n, \\
\beta_k^{(i)}(t) &= \sum_{l=1}^{M} a_{k,l} \varphi_l(x_{i,t+1}) \beta_l^{(i)}(t+1), \quad 1 \le t < T,\ 1 \le k \le M,\ 1 \le i \le n.
\end{aligned}$$

2. Compute $L_k^{(i)}(t)$, $H_{k,l}^{(i)}(t)$ using $\alpha_k^{(i)}(t)$, $\beta_k^{(i)}(t)$. Let $P(\mathbf{x}_i) = \sum_{k=1}^{M} \alpha_k^{(i)}(1) \beta_k^{(i)}(1)$.

$$\begin{aligned}
L_k^{(i)}(t) &= \frac{1}{P(\mathbf{x}_i)} \alpha_k^{(i)}(t) \beta_k^{(i)}(t), \\
H_{k,l}^{(i)}(t) &= \frac{1}{P(\mathbf{x}_i)} \alpha_k^{(i)}(t) a_{k,l} \varphi_l(x_{i,t+1}) \beta_l^{(i)}(t+1).
\end{aligned}$$

3. Update the parameters using $L_k^{(i)}(t)$, $H_{k,l}^{(i)}(t)$.

$$\begin{aligned}
\mu_k &= \frac{\sum_{i=1}^{n} \sum_{t=1}^{T} L_k^{(i)}(t) x_{i,t}}{\sum_{i=1}^{n} \sum_{t=1}^{T} L_k^{(i)}(t)}, \\
\Sigma_k &= \frac{\sum_{i=1}^{n} \sum_{t=1}^{T} L_k^{(i)}(t) (x_{i,t} - \mu_k)(x_{i,t} - \mu_k)'}{\sum_{i=1}^{n} \sum_{t=1}^{T} L_k^{(i)}(t)}, \\
a_{k,l} &= \frac{\sum_{i=1}^{n} \sum_{t=1}^{T-1} H_{k,l}^{(i)}(t)}{\sum_{i=1}^{n} \sum_{t=1}^{T-1} L_k^{(i)}(t)}.
\end{aligned}$$

Appendix B

We prove the results in Section 4.1.

The proof for Theorem 2

Proof Because $\mathcal{M}$ and $\mathcal{M}'$ define the same density function, their marginal densities on any block $X^{(t)}$ are also identical. Since $\Theta^{(t)}$ is non-redundant for any t, by Lemma 1, we have $\mathcal{M}'_{X^{(t)}} = \mathcal{O}_t(\mathcal{M}_{X^{(t)}})$, where $\mathcal{O}_t$ is the permutation on the mixture components of $X^{(t)}$, for $t = 1, ..., T$. The permutation $\mathcal{O}_t$ is unique because $\Theta^{(t)}$ is distinct.

Again by Lemma 1, if we remove all the components in $\mathcal{M}$ and $\mathcal{M}'$ with zero priors, that is, $P(s_1 = i_1, s_2 = i_2, ..., s_t = i_T) = 0$ and $P(s'_1 = i'_1, s'_2 = i'_2, ..., s'_T = i'_T) = 0$, the two models have the same number of components, and the Gaussian component parameters as well as the positive priors in $\mathcal{M}$ and $\mathcal{M}'$ are identical up to permutation. Let the permutation

that matches the two models be $\mathcal{O}^*$. Note that $\mathcal{O}^*$ is only defined on T-tuples $(i_1, ..., i_T)$ such that $P(s_1 = i_1, s_2 = i_2, ..., s_t = i_T) > 0$.

Let $\mathcal{O}_{1:T} = \mathcal{O}_1 \times \mathcal{O}_2 \cdots \mathcal{O}_T$. It is obvious that $\Theta' = \mathcal{O}_{1:T}(\Theta)$. Consider a T-tuple with $P(s_1 = i_1, ..., s_T = i_T) > 0$. Let $(i_1^*, ..., i_T^*) = \mathcal{O}^*(i_1, ..., i_T)$. By Lemma 1,

$$\mu_{i_t}^{(t)} = \mu'^{(t)}_{i_t^*}, \quad \Sigma_{i_t}^{(t)} = \Sigma'^{(t)}_{i_t^*},$$

$$\mu_{i_t}^{(t)} = \mu'^{(t)}_{\mathcal{O}_t(i_t)}, \quad \Sigma_{i_t}^{(t)} = \Sigma'^{(t)}_{\mathcal{O}_t(i_t)}.$$

Because $\Theta'^{(t)}$ is distinct, $i_t^* = \mathcal{O}_t(i_t)$, for $t = 1, ..., T$. Thus we have shown that if $P(s_1 = i_1, ..., s_T = i_T) > 0$, $\mathcal{O}^*(i_1, ..., i_T) = \mathcal{O}_{1:T}(i_1, ..., i_T)$. Because $\mathcal{M}$ and $\mathcal{M}'$ have the same number of components with positive priors, if $P(i_1, ..., i_T) = 0$, we can extend the definition of $\mathcal{O}^*$ to these T-tuples by simply setting it to $\mathcal{O}_{1:T}$. Thus we have shown $\mathcal{M}' = \mathcal{O}_{1:T}(\mathcal{M})$. ■

The proof for Lemma 3

Proof Because $\Theta^{(t)}$ is non-redundant for $t = 1, ..., T$, and $\pi_{i_1} = P(s_1 = i_1)$, we have $\pi_{i_1} > 0$, $\forall i_1 \in \{1, ..., M_1\}$. We also have $P(s_t = i_t) > 0$, $\forall i_t \in \{1, ..., M_t\}$, $t = 2, ..., T$. Since $P(s_t = i_t) = \sum_{i_{t-1}=1}^{M_{t-1}} P(s_{t-1} = i_{t-1}) a_{i_{t-1}, i_t}^{(t-1)}$ and $P(s_t = i_t) > 0$, there exist at least one i_{t-1} such that $a_{i_{t-1}, i_t}^{(t-1)} > 0$.

The reverse can be proved by induction. Because $\pi_{i_1} = P(s_1 = i_1)$ and $\pi_{i_1} > 0$, we have $P(s_1 = i_1) > 0$, $\forall i_1 \in \{1, ..., M_1\}$. Assume $P(s_{t-1} = i_{t-1}) > 0$, $\forall i_{t-1} \in \{1, ..., M_{t-1}\}$, then $P(s_t = i_t) = \sum_{i_{t-1}=1}^{M_{t-1}} P(s_{t-1} = i_{t-1}) a_{i_{t-1}, i_t}^{(t-1)} > 0$ because at least for one i_{t-1}, the summand $P(s_{t-1} = i_{t-1}) a_{i_{t-1}, i_t}^{(t-1)} > 0$. ■

The proof for Corollary 4

Proof Because HMM-VB on partition $\mathcal{P}$ is a lattice GMM on the same partition, by Theorem 2, there exists a unique permutation $\mathcal{O}_t$ for each variable block $X^{(t)}$, $t = 1, ..., T$ such that $\mathbb{M}' = \mathcal{O}_{1:T}(\mathbb{M})$ and $\Theta' = \mathcal{O}_{1:T}(\Theta)$.

We only need to show that under permutation $\mathcal{O}_{1:T}$, π_{i_1}, $a_{i_{t-1}, i_t}^{(t-1)}$, $i_1 = 1, ..., M_1$, $i_t = 1, ..., M_t$, $t = 2, ..., T$ are also identical. By Theorem 2, $\Pi(s_1, ..., s_T)$ and $\Pi'(s'_1, ..., s'_T)$ are identical up to permutation $\mathcal{O}_{1:T}$. The same is true for any marginal $\Pi(s_t)$ or $\Pi(s_{t-1}, s_t)$. That is

$$P(s_t = i_t) = P(s'_t = \mathcal{O}_t(i_t)), \ \ \forall t = 1, ..., T, \ \forall i_t = 1, ..., M_t.$$

Since π_{i_1}, $i_1 = 1, ..., M_1$, is the marginal $\Pi(s_1)$, it is identical to π'_{i_1} up to permutation $\mathcal{O}_1$.

Under permutation $\mathcal{O}_{t-1:t}$, we have

$$P(s'_{t-1} = \mathcal{O}_{t-1}(i_{t-1}), s'_t = \mathcal{O}_t(i_t)) = P(s_{t-1} = i_{t-1}, s_t = i_t).$$

Also,

$$P(s'_{t-1} = \mathcal{O}_{t-1}(i_{t-1}), s'_t = \mathcal{O}_t(i_t)) = P(s'_{t-1} = \mathcal{O}_{t-1}(i_{t-1})) a'^{(t-1)}_{\mathcal{O}_{t-1}(i_{t-1}), \mathcal{O}_t(i_t)},$$

$$P(s_{t-1}=i_{t-1}, s_t=i_t) = P(s_{t-1}=i_{t-1}) a^{(t-1)}_{i_{t-1},i_t}.$$

Because Θ and Θ' are non-redundant, $P(s_{t-1}=i_{t-1})>0$, $\forall i_{t-1}$, and similarly $P(s'_{t-1}=i'_{t-1})>0$, $\forall i'_{t-1}$, we thus have

$$a'^{(t-1)}_{\mathcal{O}_{t-1}(i_{t-1}),\mathcal{O}_t(i_t)} = a^{(t-1)}(i_{t-1}, i_t),$$
$$\forall t = 2, ..., T,\ \forall i_{t-1} = 1, ..., M_{t-1},\ \forall i_t = 1, ..., M_t.$$

■

The proof for Theorem 5

Proof If all the variables are put in one block, we can remove any component with zero prior. Hence, the partition containing only one block is always a tight partition. Thus a tight partition always exists. Because there are only finitely many partitions, the maximum partition must exist. We have proved the existence of a maximum partition for any GMM.

We now prove the uniqueness. Suppose $\mathcal{P}_1$ and $\mathcal{P}_2$ are both maximum partitions and $\mathcal{P}_1 \neq \mathcal{P}_2$. Let $\mathcal{P}_i = \{X^{(i,1)}, X^{(i,2)}, ..., X^{(i,T_i)}\}$, $i = 1, 2$. Let the kth Gaussian component parameter for block $X^{(i,j)}$ in partition $\mathcal{P}_i$ be $\theta_k^{(i,j)}$. For any sub-vector of $X^{(i,j)}$ that contains some of the variables in $X^{(i,j)}$, which for instance is denoted by $X^{(i,j,l)}$, we denote the projection of $\theta_k^{(i,j)}$ on the sub-vector by $\theta_k^{(i,j)}(X^{(i,j,l)})$. Specifically, the mean vector projected on $X^{(i,j,l)}$ is a sub-vector of the mean vector $\mu_k^{(i,j)}$ keeping the corresponding dimensions in $X^{(i,j,l)}$, and the covariance matrix projected on $X^{(i,j,l)}$ is a sub-matrix of the covariance $\Sigma_k^{(i,j)}$ keeping the entries for the covariances between the dimensions in $X^{(i,j,l)}$.

By definition of maximum partition, $\mathcal{P}_1 \not\succ \mathcal{P}_2$ and vice versa $\mathcal{P}_1 \not\prec \mathcal{P}_2$. Therefore there exists a $X^{(1,j)}$ such that the variables in this block do not belong to a single block in $\mathcal{P}_2$. Without loss of generality and for brevity of notation, assume $X^{(1,1)}$ is such a block and its variables fall into K blocks in $\mathcal{P}_2$. We divide block $X^{(1,1)}$ into K sub-blocks such that each sub-block belongs to a distinct block in $\mathcal{P}_2$. Denote the K sub-blocks by $X^{(1,1,k)}$. $X^{(1,1)} = \{X^{(1,1,1)}, X^{(1,1,2)}, ..., X^{(1,1,K)}\}$. Again without loss of generality assume sub-block $X^{(1,1,k)} \subset X^{(2,k)}$, $k = 1, ..., K$.

Suppose the number of components for each block in $\mathcal{P}_1$ is M_1, ..., M_{T_1}, and the number of components for each block in $\mathcal{P}_2$ is M'_1, ..., M'_{T_2}. Without loss of generality, we can assume the lattice Θ and Θ' corresponding to $\mathcal{P}_1$ and $\mathcal{P}_2$ are non-redundant. The fact all the component parameters in Θ (or Θ') exist is guaranteed already by $\mathcal{P}_1$ (or $\mathcal{P}_2$) being a tight partition. If any $\Theta^{(t)}$ is not distinct (containing identical components), we can always combine those components without affecting the partition $\mathcal{P}_1$. Therefore we can assume Θ and Θ' are non-redundant without the loss of generality.

Let the underlying component identity be s_j, $j = 1, ..., T_1$ for $\mathcal{P}_1$ and s'_j, $j = 1, ..., T_2$ for $\mathcal{P}_2$. Because the GMM is a lattice-GMM on both $\mathcal{P}_1$ and $\mathcal{P}_2$, the marginal density of variable block $X^{(1,1)}$ according to partition $\mathcal{P}_1$ and $\mathcal{P}_2$ respectively is given by

$$f_{X^{(1,1)}}(x^{(1,1)}) = \sum_{i_1=1}^{M_1} P(s_1 = i_1) \phi(x^{(1,1)} \mid \theta_{i_1}^{(1,1)}), \tag{10}$$

$$f_{X^{(1,1)}}(x^{(1,1)}) = \sum_{i'_1=1}^{M'_1} \cdots \sum_{i'_K=1}^{M'_K} P(s'_1 = i'_1, ..., s'_K = i'_K) \prod_{j=1}^{K} \phi(x^{(1,1,j)} \mid \theta_{i'_j}^{(2,j)}(X^{(1,1,j)})). \tag{11}$$

Because both $\mathcal{P}_1$ and $\mathcal{P}_2$ are tight partitions, the priors in Eqs. (10) and (11) are all positive. The components in mixture (10) are distinct by the non-redundancy of Θ, while the components in (11) may not because $X^{(1,1,j)}$'s are sub-vectors of the blocks in $\mathcal{P}_2$. However, if they are not distinct, we can combine components without losing the positive priors on the components. To be strict, suppose we combined components and mixture model (11) becomes the following model containing distinct components:

$$f_{X^{(1,1)}}(x^{(1,1)}) = \sum_{i''_1=1}^{M''_1} \cdots \sum_{i''_K=1}^{M''_K} P(s''_1 = i''_1, ..., s''_K = i''_K) \prod_{j=1}^{K} \phi(x^{(1,1,j)} \mid \theta_{i''_j}^{(2,j)}(X^{(1,1,j)})). \tag{12}$$

By the identifiability of GMM (Lemma 1), the number of terms in Eq. (12), $M''_1 \times M''_2 \cdots \times M''_K = M_1$ and for each i_1, there is a unique K-tuple $(i''_1, i''_2, ..., i''_K)$ such that

$$\phi(x^{(1,1)} \mid \theta_{i_1}^{(1,1)}) = \prod_{j=1}^{K} \phi(x^{(1,1,j)} \mid \theta_{i''_j}^{(2,j)}(X^{(1,1,j)})). \tag{13}$$

The density of the full-dimensional X according to $\mathcal{P}_1$ is

$$f_{X^{(1,1)}}(x^{(1,1)}) = \sum_{i_1=1}^{M_1} \cdots \sum_{i_T=1}^{M_T} \pi(i_1, i_2, ..., i_T) \prod_{j=1}^{T} \phi(x^{(1,j)} \mid \theta_{i_j}^{(1,j)}).$$

Because the map from i_1 to $(i''_1, i''_2, ..., i''_K)$ is bijective, we can define a set of prior

$$\tilde{\pi}(i''_1, i''_2, ..., i''_K, i_2, i_3, ..., i_T) = \pi(i_1, i_2, ..., i_T).$$

By Eq. (13), we can write

$$\begin{aligned} f_X(x) \quad = \quad & \sum_{i''_1=1}^{M''_1} \cdots \sum_{i''_K=1}^{M''_K} \sum_{i_2=1}^{M_2} \cdots \sum_{i_T=1}^{M_T} \tilde{\pi}(i''_1, ..., i''_K, i_2, ..., i_T) \cdot \\ & \prod_{l=1}^{K} \phi(x^{(1,1,l)} \mid \theta_{i''_l}^{(2,l)}(X^{(1,1,l)})) \prod_{j=2}^{T} \phi(x^{(1,j)} \mid \theta_{i_j}^{(1,j)}). \end{aligned} \tag{14}$$

Eq. (14) shows that the GMM is a lattice-GMM on the partition

$$\mathcal{P}_3 = \{X^{(1,1,1)}, X^{(1,1,2)}, \cdots, X^{(1,1,K)}, X^{(1,2)}, ..., X^{(1,T)}\},$$

and $\mathcal{P}_3$ is a tight partition. Clearly, $\mathcal{P}_3 \succ \mathcal{P}_1$ and $\mathcal{P}_3 \neq \mathcal{P}_1$. This contradicts the assumption that $\mathcal{P}_1$ is a maximum partition. We have thus proved the maximum partition is unique.

■

Appendix C

In this section, we prove Theorem 6.

Proof We follow the idea of the proof of Theorem 2 in Maugis et al. (2009). According to the definition, $\hat{\mathbf{C}} = \text{argmin}_{\mathbf{C}\in\mathcal{C}} BIC(\mathbf{C})$, where $\mathcal{C}$ is the set of all possible partitions under $T = T^0$,

$$BIC(\mathbf{C}) = -2\sum_{i=1}^{n} \log(f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C})})) + \lambda(\mathbf{C})\log(n),$$

where $\lambda(\mathbf{C})$ is the number of model parameters for variable blocks $\mathbf{C}$. Thus

$$\begin{aligned} P(\hat{\mathbf{C}} = \mathbf{C}^0) &= P(BIC(\mathbf{C}^0) \leq BIC(\mathbf{C}), \forall \mathbf{C} \in \mathcal{C}) \\ &= P(BIC(\mathbf{C}) - BIC(\mathbf{C}^0) \geq 0, \forall \mathbf{C} \in \mathcal{C}). \end{aligned}$$

Denote by $\nu(\mathbf{C}) = \lambda(\mathbf{C}) - \lambda(\mathbf{C}^0)$ and $\Delta BIC(\mathbf{C}) = BIC(\mathbf{C}) - BIC(\mathbf{C}^0)$, then

$$\Delta BIC(\mathbf{C}) = 2n\{\frac{1}{n}\sum_{i=1}^{n} \log[\frac{f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C}^0)})}{g(\mathbf{x}_i)}] - \frac{1}{n}\sum_{i=1}^{n}[\frac{f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C})})}{g(\mathbf{x}_i)}]\} + \nu(\mathbf{C})\log(n). \tag{15}$$

All the possible partition $\mathcal{C}$ can be decomposed as follows

$$\mathcal{C} = \mathbf{C}^0 \cup \{\mathbf{C} \in \mathcal{C}; D_{KL}(g||f(.|\gamma^*_{(\mathbf{C})})) \neq 0\}.$$

Let $\mathcal{C}_1 = \{\mathbf{C} \in \mathcal{C}; D_{KL}(g||f(.|\gamma^*_{\mathbf{C}})) \neq 0\}$. We only need to prove that

$$\forall \mathbf{C} \in \mathcal{C}_1,\ P(\Delta BIC(\mathbf{C}) < 0) \xrightarrow[n\to\infty]{} 0.$$

Let $\mathcal{Q}_n(\mathbf{C}) = \frac{1}{n}\sum_{i=1}^{n} \log[\frac{f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C})})}{g(\mathbf{x}_i)}]$, and $\mathcal{Q}(\mathbf{C}) = -D_{KL}(g||f(.|\gamma^*_{(\mathbf{C})}))$,
Following Eq. (15), we then have

$$\begin{aligned} &P(\Delta BIC(\mathbf{C}) < 0) = P(2n[\mathcal{Q}_n(\mathbf{C}^0) - \mathcal{Q}_n(\mathbf{C})] + \nu(\mathbf{C})\log(n) < 0) \\ =&P(\mathcal{Q}_n(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}^0) + \mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) + \mathcal{Q}(\mathbf{C}) - \mathcal{Q}_n(\mathbf{C}) + \frac{\nu(\mathbf{C})\log(n)}{2n} < 0). \end{aligned}$$

Thus, for all $\epsilon > 0$, and according to the Lemma 8 below,

$$\begin{aligned} P(\Delta BIC(\mathbf{C}) < 0) \leq& P(\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}_n(\mathbf{C}^0) > \epsilon) + P(\mathcal{Q}_n(\mathbf{C}) - \mathcal{Q}(\mathbf{C}) > \epsilon) + \\ & P(\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) + \frac{\nu(\mathbf{C})\log(n)}{2n} < 2\epsilon). \end{aligned}$$

From Proposition 1 below, $\forall \mathbf{C}, \mathcal{Q}_n(\mathcal{C}) \xrightarrow[n\to\infty]{P} \mathcal{Q}(\mathcal{C})$. Thus,

$$\forall \epsilon > 0, P(\mathcal{Q}_n(\mathbf{C}) - \mathcal{Q}(\mathbf{C}) > \epsilon) \leq P(|\mathcal{Q}_n(\mathbf{C}) - \mathcal{Q}(\mathbf{C})| > \epsilon) \xrightarrow[n\to\infty]{} 0.$$

Then,

$$P(\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) + \frac{\nu(\mathbf{C})\log(n)}{2n} < 2\epsilon) \leq P(\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) - 2\epsilon < |\frac{\nu(\mathbf{C})\log(n)}{2n}|).$$

We know that $\frac{\nu(\mathbf{C})\log(n)}{2n} \xrightarrow[n\to\infty]{} 0$ and $\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) > 0$ because $\mathbf{C} \in \mathcal{C}_1$. Taking $\epsilon = \frac{\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C})}{4} > 0$, we get

$$P(\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C}) + \frac{\nu(\mathbf{C})\log(n)}{2n} < 2\epsilon) \leq P(\frac{\mathcal{Q}(\mathbf{C}^0) - \mathcal{Q}(\mathbf{C})}{2} < |\frac{\nu(\mathbf{C})\log(n)}{2n}|) \xrightarrow[n\to\infty]{} 0.$$

Finally, $P(\Delta BIC(\mathbf{C}) < 0) \xrightarrow[n\to\infty]{} 0$. ■

Lemma 8 *Let A and B be two real random variables,*

$$\forall \epsilon \in \mathcal{R}, P(A + B \leq 0) \leq P(A \leq \epsilon) + P(-B > \epsilon).$$

Proposition 1 *Under Assumptions* **A1** *and* **A2**, $\forall \mathbf{C} \in \mathcal{C}$,

$$\frac{1}{n}\sum_{i=1}^{n} \log\{\frac{g(\mathbf{x}_i)}{f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C})})}\} \xrightarrow[n\to\infty]{P} D_{KL}(g||f(.|\gamma^*_{(\mathbf{C})})).$$

Proof By the law of large numbers, if $E[|\log(g(X))|] < \infty$,

$$\frac{1}{n}\sum_{i=1}^{n} \log[g(\mathbf{x}_i)] \xrightarrow[n\to\infty]{P} E_X[\log(g(X))]. \tag{16}$$

If we can show that for the family

$$\mathcal{G}_{(\mathbf{C})} := \{\log[f(.|\gamma)]; \gamma \in \Gamma'_{(\mathbf{C})}\},$$

the following holds

$$\frac{1}{n}\sum_{i=1}^{n} \log[f(\mathbf{x}_i|\hat{\gamma}_{(\mathbf{C})})] \xrightarrow[n\to\infty]{P} E_X[\log f(X|\gamma^*{}_{(\mathbf{C})})], \tag{17}$$

then Proposition 1 is proved by combining Eqs. (16) and (17).

Now we only need to prove that $E_X[\log f(X)] < \infty$. First, by the Assumption **A1**, $\Gamma'_{(\mathbf{C})}$ is a compact metric space. And for all $\mathbf{x} \in \mathcal{R}^p$, $\gamma_{(\mathbf{C})} \in \Gamma'_{(\mathbf{C})} \to \log[f(\mathbf{x}|\gamma_{(\mathbf{C})})]$ is continuous. We just need to verify that there is an envelope function G of $\mathcal{G}_{(\mathbf{C})}$ being g-integrable.

Denote by $\mathcal{M} = [M_2^0] \times [M_3^0] \times \cdots \times [M_T^0] = \{1, 2, ..., M_2^0\} \times \{1, 2, ..., M_3^0\} \times \cdots \times \{1, 2, ..., M_T^0\}$. We first write out $\log[f(\mathbf{x}|\gamma_{(\mathbf{C})})]$ explicitly:

$$\begin{aligned}
&\log[f(\mathbf{x}|\gamma_{(\mathbf{C})})] = \log\Big[\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\Pi_{j=1}^T N(x^{(C_j)}|\mu_{k_j}^{(j)},\Sigma_{k_j}^{(j)})\Big]\\
&=\log\Big[\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\\
&\quad\Pi_{j=1}^T(2\pi)^{-|C_j|/2}|\Sigma_{k_j}^{(j)}|^{-1/2}\exp\{-\frac{(x^{(C_j)}-\mu_{k_j}^{(j)})'{\Sigma_{k_j}^{(j)}}^{-1}(x^{(C_j)}-\mu_{k_j}^{(j)})}{2}\}\\
&\le\ \log\Big[\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}(2\pi a)^{-\frac{d}{2}}\Big]\\
&\le\ -\frac{d}{2}\log[2\pi a],
\end{aligned}$$

where $x^{(C_j)}$ being the C_j-th variable block. The inequality is obtained according to Lemma 9 and $(x^{(C_j)}-\mu_{k_j}^{(j)})'{\Sigma_{k_j}^{(j)}}^{-1}(x^{(C_j)}-\mu_{k_j}^{(j)}) \le 0$, for $j = 1, 2, ..., T$, hence is exponential function bounded by 1.

Now we need to obtain a lower bound, and we use the concavity of the logarithm function:

$$\begin{aligned}
&\log[f(\mathbf{x}|\gamma_{(\mathbf{C})})] \ge \sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\\
&\qquad\Pi_{j=1}^T(2\pi)^{-|C_j|/2}|\Sigma_{k_j}^{(j)}|^{-1/2}\exp\{-\frac{(x^{(C_j)}-\mu_{k_j}^{(j)})'{\Sigma_{k_j}^{(j)}}^{-1}(x^{(C_j)}-\mu_{k_j}^{(j)})}{2}\}\\
&=-\frac{d}{2}\log(2\pi)-\frac{1}{2}\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\Big\{\sum_{j=1}^T\log[|\Sigma_{k_j}^{(j)}|]\\
&\quad+\sum_{j=1}^T(x^{(C_j)}-\mu_{k_j}^{(j)})'{\Sigma_{k_j}^{(j)}}^{-1}(x^{(C_j)}-\mu_{k_j}^{(j)})\Big\}.
\end{aligned}$$

According to Lemma 9 and $\forall k_j$, $\mu_{k_j}^{(j)} \in \mathcal{B}(\eta, |C_j|)$

$$\begin{aligned}
(x^{(C_j)}-\mu_{k_j}^{(j)})'{\Sigma_{k_j}^{(j)}}^{-1}(x^{(C_j)}-\mu_{k_j}^{(j)}) &\le \frac{||x^{(C_j)}-\mu_{k_j}^{(j)}||^2}{a}\\
&\le \frac{2(||x^{(C_j)}||^2+||\mu_{k_j}^{(j)}||^2)}{a}\\
&\le \frac{2(||x^{(C_j)}||^2+\eta^2)}{a}.
\end{aligned}$$

Hence,

$$\begin{aligned}
\log[f(\mathbf{x}|\gamma_{(\mathbf{C})})] &\ge -\frac{d}{2}\log(2\pi)-\frac{1}{2}\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\\
&\quad\Big\{\log(b^d)+\sum_{j=1}^T\frac{2}{a}(||x^{(C_j)}||^2+\eta^2)\Big\}\\
&=-\frac{d}{2}\log(2\pi b)-\frac{||\mathbf{x}||^2+2\eta}{a}.
\end{aligned}$$

Hence, each function of the family $\mathcal{G}_{(\mathbf{C})}$ is bounded by

$$-\frac{d}{2}\log(2\pi b)-\frac{||\mathbf{x}||^2+2\eta}{a} \le \log[f(\mathbf{x}|\gamma_{(\mathbf{C})})] \le \frac{d}{2}\log[2\pi a].$$

Therefore, for all $\gamma_{(\mathbf{C})} \in \Gamma'_{(\mathbf{C})}$ and all $\mathbf{x} \in \mathcal{R}^p$,

$$|\log[f(\mathbf{x}|\gamma_{(\mathbf{C})})]| \le Z_1(a,b,\eta)+Z_2(\eta,a)||\mathbf{x}||^2$$

defining the envelope function G, where $Z_1(a,b,\eta)$ and $Z_2(\eta,a)$ are two positive constants.

In order to verify that G is g-integrable, we need to show that $\int||\mathbf{x}||^2 g(\mathbf{x})d\mathbf{x} < \infty$.

$$\begin{aligned}
&\int||\mathbf{x}||^2 g(\mathbf{x})d\mathbf{x} = \int||\mathbf{x}||^2 f(\mathbf{x}|\gamma^*_{(\mathbf{C}^0)})d\mathbf{x}\\
&=\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}\int||\mathbf{x}||^2\phi(\mathbf{x}|\mu_{(k_1,k_2,...,k_T)},\Sigma_{(k_1,k_2,...,k_T)})d\mathbf{x}\\
&\le\sum_{k_1=1}^{M_1^0}\pi_{k_1}\sum_{(k_2,k_3,...,k_T)\in\mathcal{M}} a_{k_1,k_2}a_{k_2,k_3}\cdots a_{k_{T-1},k_T}(2\sum_{j=1}^T||\mu_{k_j}^{(j)}||^2+2\sum_{j=1}^T tr(\Sigma_{k_j}^{(j)})),
\end{aligned}$$

where $\mu_{(k_1,k_2,...,k_T)} = (\mu_{k_1}^{(1)}, \mu_{k_2}^{(2)}, ..., \mu_{k_T}^{(T)})$ and $\Sigma_{(k_1,k_2,...,k_T)}$ is block diagonal with the t-th diagonal block being $\Sigma_{k_t}^{(t)}$, for $t = 1, 2, ..., T$. Because $\int||\mathbf{x}||^2\phi(\mathbf{x}|0,\Sigma)d\mathbf{x} = tr(\Sigma)$. Then using the triangle inequality, we get $\int||\mathbf{x}||^2\phi(\mathbf{x}|\mu,\Sigma)d\mathbf{x} \le 2(||\mu||^2+tr(\Sigma))$. Further, from Lemma 9,

$$\int||\mathbf{x}||^2 g(\mathbf{x})d\mathbf{x} \le 4\eta^2+2bp.$$

Hence, G is g-integrable. Since $\log(g) \in \mathcal{G}_{(\mathbf{C}^0)}$, it implies that $E[|\log g(X)|] \le E[G(X)] < \infty$. We then prove the theorem. ■

Lemma 9 *Let $\Sigma \in \mathcal{D}_d$, where $\mathcal{D}_d$ is defined in* **A**1. *Then*

1. $a^d \le |\Sigma| \le b^d$ *and* $tr(\Sigma) \le bd$
2. $\forall \mathbf{x} \in \mathcal{R}^d$, $\mathbf{x}'\mathbf{x}/b \le \mathbf{x}'\Sigma^{-1}\mathbf{x} \le \mathbf{x}'\mathbf{x}/a$

Proof See for instance Maugis et al. (2007). ■

Appendix D

We prove Theorem 7 in Section 4.3. A configuration of a set of states is a particular tuple of values for these states. Use notation $\Psi(\cdot)$ for the set of all possible configurations of any group of states.

Proof For a HMM-VB, the configuration of the whole state sequence $\mathbf{s} = \{s_1, s_2, ..., s_T\}$ is treated as the index for one mixture component in the mapped GMM. The set of all possible configurations is $\Psi(\{s_1, ..., s_T\})$. Let $\hat{\mathcal{S}} = \Psi(\{s_1, ..., s_T\})$ and $\mathcal{S}_t = \Psi(s_t)$. Each component is a Gaussian distribution with mean $\mu_{\mathbf{s}} = (\mu_{s_1}^{(1)}, \mu_{s_2}^{(2)}, ..., \mu_{s_T}^{(T)})$ (column-wise stack of vectors) and a covariance matrix, denoted by $\Sigma_{\mathbf{s}}$, that is block diagonal. The tth diagonal block in $\Sigma_{\mathbf{s}}$ is $\Sigma_{s_t}^{(t)}$ with dimension $d_t \times d_t$

$$\Sigma_{\mathbf{s}} = \begin{pmatrix} \Sigma_{s_1}^{(1)} & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \Sigma_{s_2}^{(2)} & \mathbf{0} & \cdots & \mathbf{0} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots & \Sigma_{s_T}^{(T)} \end{pmatrix}.$$

If we apply MEM directly to HMM-VB and keep in mind that $\mathbf{s}$ is the index for the mixture component, we need to compute the posterior $P(\mathbf{s} \mid \mathbf{x})$ in the E-step and

$$\left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x})\Sigma_{\mathbf{s}}^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x})\Sigma_{\mathbf{s}}^{-1}\mu_{\mathbf{s}}\right)$$

in the M-step. The computational hurdle is that the number of possible sequences $\mathbf{s}$, that is, $|\hat{\mathcal{S}}|$, grows exponentially with T (assuming similar $|\mathcal{S}_t|$).

Because $\Sigma_{\mathbf{s}}$ is block diagonal, we have

$$\begin{aligned} &\left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x})\Sigma_{\mathbf{s}}^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x})\Sigma_{\mathbf{s}}^{-1}\mu_{\mathbf{s}}\right) \\ &= \begin{pmatrix} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_1}^{(1)}\right)^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_1}^{(1)}\right)^{-1} \mu_{s_1}^{(1)}\right) \\ \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_2}^{(2)}\right)^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_2}^{(2)}\right)^{-1} \mu_{s_2}^{(2)}\right) \\ \vdots \\ \vdots \\ \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_T}^{(T)}\right)^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_T}^{(T)}\right)^{-1} \mu_{s_T}^{(T)}\right) \end{pmatrix}. \end{aligned}$$

Hence the tth variable block of $\mathbf{x}$ is given by

$$x^{(t)} = \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_t}^{(t)}\right)^{-1}\right)^{-1} \left(\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_t}^{(t)}\right)^{-1} \mu_{s_t}^{(t)}\right), \quad t = 1, 2, ..., T.$$

Let $I(\cdot)$ be the indicator function that equals 1 when the argument is true. Note that

$$\begin{aligned} \sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_t}^{(t)}\right)^{-1} &= \sum_{k\in\mathcal{S}_t} \left[\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) I(s_t = k)\right] \cdot \left(\Sigma_k^{(t)}\right)^{-1} \\ &= \sum_{k\in\mathcal{S}_t} L_k(\mathbf{x}, t) \cdot \left(\Sigma_k^{(t)}\right)^{-1} \end{aligned}$$

according to the definition of $L_k(\mathbf{x}, t)$ in Eq. (4). By the same technique, we can show that

$$\sum_{\mathbf{s}\in\hat{\mathcal{S}}} P(\mathbf{s} \mid \mathbf{x}) \left(\Sigma_{s_t}^{(t)}\right)^{-1} \mu_{s_t}^{(t)} = \sum_{k\in\mathcal{S}_t} L_k(\mathbf{x}, t) \cdot \left(\Sigma_k^{(t)}\right)^{-1} \mu_k^{(t)}.$$

■

It is interesting to note that Theorem 7 extends easily to a model more general than HMM-VB. For HMM-VB, s_1, ..., s_T follow a finite state Markov chain. *Bayesian network (BN)* is a generalization of Markov chain on a *directed acyclic graph (DAG)*, which is defined by all the conditional distributions of every state given any configuration of its parent states. If there is no parent, the marginal distribution of a state is specified. See Jensen (1996) for an introduction to BN. If we assume that the latent states s_1, ..., s_T are governed by a BN, and the observed $X^{(t)}$ conditioned on s_t follows a parametric distribution and is conditionally independent of any other $X^{(t')}$ and $s_{t'}$, then we obtain a special lattice MM more broadly defined than HMM-VB. We call this model *Mixture with Latent Bayesian Network* (*MLBN*). Define the following probability for MLBN:

$$L_k(\mathbf{x}, t) = P(s_t = k \mid \mathbf{x}), \quad k \in \mathcal{S}_t,\ t = 1, ..., T. \tag{18}$$

Clearly, the above definition is the same as Eq. (4) in the special case of HMM-VB. The MBW algorithm in Section 3.2 for HMM-VB applies to MLBN in general. We only need to use the definition in Eq. (18) for $L_k(\mathbf{x}^{[r]}, t)$. Theorem 7 can be proved for MLBN in the same way.

Appendix E

In this section, we provide the details for the data generation schemes of the simulation studies. We follow the notations in Eq. (3).

Simulation study in Section 5.1.1

It is a two-block design. The first variable block has 5 variables and is generated from a normal mixture of 7 components. We set $\pi = (0.51, 0.09, 0.20, 0.07, 0.10, 0.01, 0.02)$,

$$\mu^{(1)} = \begin{pmatrix} \mu_1^{(1)} \\ \mu_2^{(1)} \\ \vdots \\ \mu_7^{(1)} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 4.5 & 0 & 0 \\ 4.5 & -2 & 0 & 0 & 0 \\ 0 & 0 & 4 & -1 & 4 \\ 0 & 3 & 0 & 5 & 0 \\ 0 & 7 & 7 & 0 & 0 \\ 0 & 7.7 & 8 & 0 & 0 \end{pmatrix},$$

$\Sigma_{1:5}^{(1)} = 1.5I_5$, $\Sigma_6^{(1)} = I_5$, $\Sigma_7^{(1)} = 0.5I_5$.

The second variable block has 3 variables, and is generated from a mixture of 10 Gaussian components. We set the transition probability matrix as

$$a^{(1)} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.22 & 0.5 & 0.28 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.19 & 0 & 0 & 0 & 0 & 0.46 & 0.35 \\ 0 & 0 & 0 & 0.50 & 0.2 & 0.3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.2 & 0.11 & 0.31 & 0.38 & 0 & 0 \\ 0 & 0 & 0.14 & 0.66 & 0 & 0.20 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.15 & 0 & 0 & 0.2 & 0 & 0 & 0 & 0.65 \end{pmatrix},$$

$$\mu^{(2)} = \begin{pmatrix} \mu_1^{(2)} \\ \mu_2^{(2)} \\ \vdots \\ \mu_{10}^{(2)} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ -4 & -4 & -4 \\ 6.5 & 6.5 & 6.5 \\ -1 & 5 & 0 \\ -1.5 & 0 & 5 \\ 6 & 7 & 6.5 \\ -4.0 & 2 & 4.5 \\ 5 & -5 & -5 \\ -4 & 0 & 0 \\ 5 & -4.5 & -6 \end{pmatrix},$$

$\Sigma_{1,4,5}^{(2)} = 2I_3$, $\Sigma_2^{(2)} = \begin{pmatrix} 2.0 & 0.2 & 0.2 \\ 0.2 & 2.0 & 0.2 \\ 0.2 & 0.2 & 2.0 \end{pmatrix}$, $\Sigma_3^{(2)} = \begin{pmatrix} 2.0 & 0.9 & 0.9 \\ 0.9 & 2.0 & 0.9 \\ 0.9 & 0.9 & 1.5 \end{pmatrix}$, $\Sigma_6^{(2)} = \begin{pmatrix} 2.0 & 0.9 & 0.9 \\ 0.9 & 1.5 & 0.9 \\ 0.9 & 0.9 & 2.0 \end{pmatrix}$,

$\Sigma_7^{(2)} = \begin{pmatrix} 2.0 & -0.6 & -0.6 \\ -0.6 & 2.0 & 0.6 \\ -0.6 & 0.6 & 2.0 \end{pmatrix}$, $\Sigma_8^{(2)} = \begin{pmatrix} 2.0 & -0.6 & -0.6 \\ -0.6 & 5/3 & 0.6 \\ -0.6 & 0.6 & 5/3 \end{pmatrix}$, $\Sigma_{9,10}^{(2)} = \begin{pmatrix} 5/3 & -0.6 & -0.6 \\ -0.6 & 5/3 & 0.6 \\ -0.6 & 0.6 & 5/3 \end{pmatrix}$.

Simulation study in Section 5.1.2

The data is generated from a GMM with 10 components. Hence all the variables form one single variable block. We set

$$\pi = (0.01, 0.02, 0.23, 0.1, 0.15, 0.098, 0.098, 0.098, 0.098, 0.098),$$

$$\mu = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_{10} \end{pmatrix} = \begin{pmatrix} 5 & 5 & 5 & 5 & 5 \\ -5 & -5 & -5 & -5 & -5 \\ 5 & 5 & 0 & 5 & 0 \\ 5 & 0 & 0 & 5 & 5 \\ 0 & 0 & 5 & 5 & 5 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -5 & -5 & -5 \\ -5 & -5 & 0 & 0 & -5 \\ -5 & -5 & -5 & 0 & 0 \\ -5 & 0 & 0 & 0 & -5 \end{pmatrix}.$$

All the variance matrices are independently generated from an inverse Wishart distribution with 10 degrees of freedom and diagonal scale matrix $7I_5$.

Simulation study in Section 5.1.3

The first 10 dimensions of the data are generated from a 3-component GMM. We set $\pi = (0.05, 0.25, 0.70)$,

$$\mu^{(1)} = \begin{pmatrix} \mu_1^{(1)} \\ \mu_2^{(1)} \\ \mu_3^{(1)} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 5 & 5 & 5 & 5 & 5 & 5 & 5 & 5 & 5 & 5 \\ -5 & -5 & -5 & -5 & -5 & -5 & -5 & -5 & -5 & -5 \end{pmatrix},$$

and $\Sigma_{1:3}^{(1)}$ are independently generated from an inverse Wishart distribution with 15 degrees of freedom and diagonal scale matrix $7I_{10}$.

The rest 30 dimensions are conditionally generated from a 5-component GMM. We set the transition probability matrix as

$$a^{(1)} = \begin{pmatrix} 0.1 & 0.9 & 0 & 0 & 0 \\ 0 & 0 & 0.28 & 0.72 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix},$$

$$\mu^{(2)} = \begin{pmatrix} \mu_1^{(2)} \\ \mu_2^{(2)} \\ \cdots \\ \mu_5^{(2)} \end{pmatrix} = \begin{pmatrix} \vec{0}_{30} \\ \vec{5}_{30} \\ -\vec{5}_{30} \\ -\vec{5}_{15}, \vec{5}_{15} \\ \vec{5}_{15}, -\vec{5}_{15} \end{pmatrix},$$

where $\vec{v}_l$ denotes a vector of the form $(v, v, ..., v)$ with l elements of the same value v. $\Sigma_{1:5}^{(2)}$ are block diagonals, which have the form of

$$\Sigma_k^{(2)} = \begin{pmatrix} \mathbf{A}_k^{(2)} & 0 \\ 0 & \mathbf{B}_k^{(2)} \end{pmatrix},$$

where $k = 1, ..., 5$, $\mathbf{A}_k^{(2)}$ is of size 10×10, which is independently generated from an inverse Wishart distribution with 15 degrees of freedom and diagonal scale matrix $7\mathbf{I}_{10}$. $\mathbf{B}_k^{(2)}$ is of size 20×20, and is independently generated from an inverse Wishart distribution with 25 degrees of freedom and diagonal scale matrix $7\mathbf{I}_{10}$.

Abstract

One of the most challenging problems in kernel online learning is to bound the model size and to promote model sparsity. Sparse models not only improve computation and memory usage, but also enhance the generalization capacity – a principle that concurs with the law of parsimony. However, inappropriate sparsity modeling may also significantly degrade the performance. In this paper, we propose Approximation Vector Machine (AVM), a model that can simultaneously encourage sparsity and safeguard its risk in compromising the performance. In an online setting context, when an incoming instance arrives, we approximate this instance by one of its neighbors whose distance to it is less than a predefined threshold. Our key intuition is that since the newly seen instance is expressed by its nearby neighbor the optimal performance can be analytically formulated and maintained. We develop theoretical foundations to support this intuition and further establish an analysis for the common loss functions including Hinge, smooth Hinge, and Logistic (i.e., for the classification task) and ℓ_1, ℓ_2, and ε-insensitive (i.e., for the regression task) to characterize the gap between the approximation and optimal solutions. This gap crucially depends on two key factors including the frequency of approximation (i.e., how frequent the approximation operation takes place) and the predefined threshold. We conducted extensive experiments for classification and regression tasks in batch and online modes using several benchmark datasets. The quantitative results show that our proposed AVM obtained comparable predictive performances with current state-of-the-art methods while simultaneously achieving significant computational speed-up due to the ability of the proposed AVM in maintaining the model size.

Keywords: kernel, online learning, large-scale machine learning, sparsity, big data, core set, stochastic gradient descent, convergence analysis

1. Introduction

In modern machine learning systems, data usually arrive continuously in stream. To enable efficient computation and to effectively handle memory resource, the system should be able to adapt according to incoming data. Online learning represents a family of efficient and scalable learning algorithms for building a predictive model incrementally from a sequence of data examples (Rosenblatt, 1958; Zinkevich, 2003). In contrast to the conventional learning algorithms (Joachims, 1999; Chang and Lin, 2011), which usually require a costly procedure to retrain the entire dataset when a new instance arrives, online learning aims to utilize the new incoming instances to improve the model given the knowledge of the correct answers to previous processed data (and possibly additional available information), making them suitable for large-scale online applications wherein data usually arrive sequentially and evolve rapidly.

The seminal line of work in online learning, referred to as *linear online learning* (Rosenblatt, 1958; Crammer et al., 2006; Dredze et al., 2008), aims at learning a linear predictor in the input space. The crucial limitation of this approach lies in its over-simplified linear modeling choice and consequently may fail to capture non-linearity commonly seen in many real-world applications. This motivated the works in *kernel-based online learning* (Freund and Schapire, 1999; Kivinen et al., 2004) in which a linear model in the feature space corresponding with a nonlinear model in the input space, hence allows one to cope with a variety of data distributions.

One common issue with *kernel-based online learning approach*, also known as the *curse of kernelization*, is that the model size (i.e., the number of vectors with non-zero coefficients) may grow linearly with the data size accumulated over time, hence causing computational problem and potential memory overflow (Steinwart, 2003; Wang et al., 2012). Therefore in practice, one might prefer kernel-based online learning methods with guaranty on a limited and bounded model size. In addition, enhancing model sparsity is also of great interest to practitioners since this allows the generalization capacity to be improved; and in many cases leading to a faster computation. However, encouraging sparsity needs to be done with care since an inappropriate sparsity-encouraging mechanism may compromise the performance. To address the curse of kernelization, budgeted approaches (Crammer et al., 2004; Dekel et al., 2005; Cavallanti et al., 2007; Wang and Vucetic, 2010; Wang et al., 2012; Le et al., 2016a,c) limits the model size to a predefined budget B. Specifically, when the current model size exceeds this budget, a budget maintenance strategy (e.g., removal, projection, or merging) is triggered to recover the model size back to the budget B. In these approaches, determining a suitable value for the predefined budget in a principled way is important, but challenging, since setting a small budget makes the learning faster but may suffer from underfitting, whereas a large budget makes the model fit better to data but may dramatically slow down the training process. An alternative way to address the curse of kernelization is to use random features (Rahimi and Recht, 2007) to approximate a kernel function (Ming et al., 2014; Lu et al., 2015; Le et al., 2016b). For example, Lu et al. (2015) proposed to transform data from the input space to the random-feature space, and then performed SGD in the feature space. However, in order for this approach to achieve good kernel approximation, excessive number of random features is required which could lead to a serious computational issue. To reduce the impact number of random features, Le et al. (2016b) proposed to distribute the model in dual space including the original feature space and the random feature space that approximates the first space.

1. In fact, we used a subset of the dataset a9a which has 123 features. We then project all data points onto 3D using t-SNE. We note that the t-SNE does not do clustering, it only reduces the dimensionality into 3D for visualization while trying to preserve the local properties of the data.

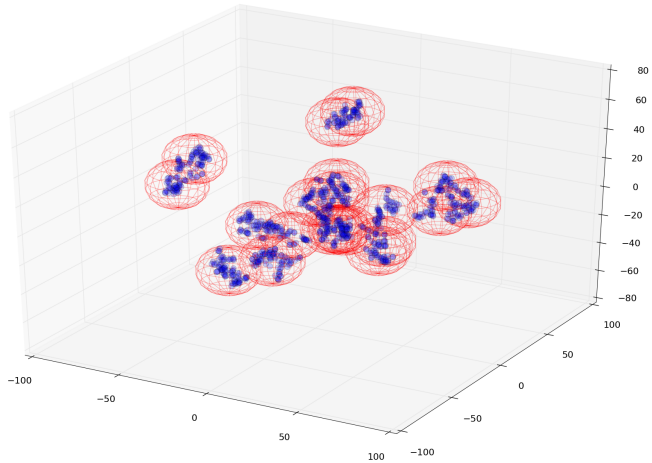

Figure 1: An illustration of the hypersphere coverage for $1,000$ data samples which locate in 3D space. We cover this dataset using hyperspheres with the diameter $\delta = 7.0$, resulting in 20 hypersphere cells as shown in the figure (cf. Sections (6.3,9)). All data samples in a same cell are approximated by a core point in this cell. The model size is therefore significantly reduced from 1,000 to 20.[1]

In this paper, we propose *Approximation Vector Machine* (AVM) to simultaneously encourage model sparsity[2] while preserving the model performance. Our model size is theoretically proven to be bounded regardless of the data distribution and data arrival order. To promote sparsity, we introduce the notion of δ-*coverage* which partitions the data space into overlapped cells whose diameters are defined by δ (cf. Figure 1). This coverage can be constructed in advance or on the fly. Our experiment on the real datasets shows that the coverage can impressively boost sparsity; for example with dataset *KDDCup99* of $4,408,589$ instances, our model size is 115 with $\delta = 3$ (i.e., only 115 cells are required); with dataset *airlines* of $5,336,471$ instances, our model size is 388 with $\delta = 1$.

In an online setting context, when an incoming instance arrives, it can be approximated with the corresponding core point in the cell that contains it. Our intuitive reason is that when an instance is approximated by an its nearby core point, the performance would be largely preserved. We further developed rigorous theory to support this intuitive reason. In particular, our convergence analysis (covers six popular loss functions, namely Hinge, smooth Hinge, and Logistic for classification task and ℓ_2, ℓ_1, and ε-insensitive for regression task) explicitly characterizes the gap between the approximate and optimal solutions. The analysis shows that this gap crucially depends on two key factors including the cell diameter

2. Model sparsity can be computed as the ratio of the model size and the number of vectors received so far.

δ and the approximation process. In addition, the cell parameter δ can be used to efficiently control the trade-off between sparsity level and the model performance. We conducted extensive experiments to validate the proposed method on a variety of learning tasks, including classification in batch mode, classification and regression in online mode on several benchmark large-scale datasets. The experimental results demonstrate that our proposed method maintains a comparable predictive performance while simultaneously achieving an order of magnitude speed-up in computation comparing with the baselines due to its capacity in maintaining model size. We would like to emphasize at the outset that unlike budgeted algorithms (e.g., (Crammer et al., 2004; Dekel et al., 2005; Cavallanti et al., 2007; Wang and Vucetic, 2010; Wang et al., 2012; Le et al., 2016a,c, 2017)), our proposed method is nonparametric in the sense that the number of core sets grow with data on demand, hence care should be exercised in practical implementation.

The rest of this paper is organized as follows. In Section 2, we review works mostly related to ours. In Section 3, we present the primal and dual forms of Support Vector Machine (SVM) as they are important background for our work. Section 4 formulates the proposed problem. In Section 5, we discuss the standard SGD for kernel online learning with an emphasis on the *curse of kernelization*. Section 6 presents our proposed AVM with full technical details. Section 7 devotes to study the suitability of loss functions followed by Section 8 where we extend the framework to multi-class setting. Finally, in Section 9, we conduct extensive experiments on several benchmark datasets and then discuss experimental results as well as their implications. In addition, all supporting proof is provided in the appendix sections.

2. Related Work

One common goal of online kernel learning is to bound the model size and to encourage sparsity. Generally, research in this direction can be broadly reviewed into the following themes.

Budgeted Online Learning. This approach limits the model size to a predefined budget B. When the model size exceeds the budget, a budget maintenance strategy is triggered to decrement the model size by one. Three popular budget maintenance strategies are *removal*, *projection*, and *merging*. In the removal strategy, the most redundant support vector is simply eliminated. In the projection strategy, the information of the most redundant support vector is conserved through its projection onto the linear span of the remaining support vectors. The merging strategy first selects two vectors, and then merges them into one before discarding them. Forgetron (Dekel et al., 2005) is the first budgeted online learning method that employs the removal strategy for the budget maintenance. At each iteration, if the classifier makes a mistake, it conducts a three-step update: (i) running the standard Perceptron (Rosenblatt, 1958) update; (ii) shrinking the coefficients of support vectors with a scaling factor; and (iii) removing the support vector with the smallest coefficient. Randomized Budget Perceptron (RBP) (Cavallanti et al., 2007) randomly removes a support vector when the model size overflows the budget. Budget Perceptron (Crammer et al., 2004) and Budgeted Passive Aggressive (BPA-S)(Wang and Vucetic, 2010) attempt to discard the most redundant support vector (SV). Orabona et al. (2009) used the projection to automatically discover the model size. The new vector is added to the support set if its

projection onto the linear span of others in the feature space exceeds a predefined threshold, or otherwise its information is kept through the projection. Other works involving the projection strategy include Budgeted Passive Aggressive Nearest Neighbor (BPA-NN) (Wang and Vucetic, 2010; Wang et al., 2012). The merging strategy was used in some works (Wang and Vucetic, 2009; Wang et al., 2012).

Random Features. The idea of random features was proposed in (Rahimi and Recht, 2007). Its aim is to approximate a shift-invariant kernel using the harmonic functions. In the context of online kernel learning, the problem of model size vanishes since we can store the model directly in the random features. However, the arising question is to determine the appropriate number of random features D to sufficiently approximate the real kernel while keeping this dimension as small as possible for an efficient computation. Ming et al. (2014) investigated the number of random features in the online kernel learning context. Recently, Lu et al. (2015) proposed to run stochastic gradient descent (SGD) in the random feature space rather than that in the real feature space. The theory accompanied with this work shows that with a high confidence level, SGD in the random feature space can sufficiently approximate that in the real kernel space. Nonetheless, in order to achieve good kernel approximation in this approach, excessive number of random features is required, possibly leading to a serious computational issue. To reduce the impact of the number of random features to learning performance, Le et al. (2016b) proposed to store core vectors in the original feature space, whilst storing remaining vectors in the random feature space that sufficiently approximates the first space.

Core Set. This approach utilizes a core set to represent the model. This core set can be constructed on the fly or in advance. Notable works consist of the Core Vector Machine (CVM) (Tsang et al., 2005) and its simplified version, the Ball Vector Machine (BVM) (Tsang et al., 2007). The CVM was based on the achievement in computational geometry (Badoiu and Clarkson, 2002) to reformulate a variation of ℓ_2-SVM as a problem of finding minimal enclosing ball (MEB) and the core set includes the points lying furthest away the current centre of the current MEB. Our work can be categorized into this line of thinking. However, our work is completely different to (Tsang et al., 2005, 2007) in the mechanism to determine the core set and update the model. In addition, the works of (Tsang et al., 2005, 2007) are not applicable for the online learning.

3. Primal and Dual Forms of Support Vector Machine

Support Vector Machine (SVM) Cortes and Vapnik (1995) represents one of the state-of-the-art methods for classification. Given a training set $\mathcal{D} = \{(x_1, y_1), \ldots, (x_N, y_N)\}$, the data instances are mapped to a feature space using the transformation $\Phi(.)$, and then SVM aims to learn an optimal hyperplane in the feature space such that the margin, the distance from the closest data instance to the hyperplane, is maximized. The optimization problem

of SVM can be formulated as follows

$$\begin{aligned} &\min_{\mathbf{w},b} \left(\frac{\lambda}{2} \|\mathbf{w}\|^2 + \frac{1}{N} \sum_{i=1}^{N} \xi_i \right) \\ &\text{s.t.} : y_i \left(\mathbf{w}^\mathsf{T} \Phi(x_i) + b \right) \geq 1 - \xi_i,\ i = 1, ..., N \\ &\xi_i \geq 0,\ i = 1, ..., N \end{aligned} \tag{1}$$

where $\lambda > 0$ is the regularization parameter, $\Phi(.)$ is the transformation from the input space to the feature space, and $\boldsymbol{\xi} = [\xi_i]_{i=1}^N$ is the vector of slack variables.

Using Karush-Kuhn-Tucker theorem, the above optimization problem is transformed to the *dual form* as follows

$$\begin{aligned} &\min_{\boldsymbol{\alpha}} \left(\frac{1}{2} \boldsymbol{\alpha}^\mathsf{T} Q \boldsymbol{\alpha} - \boldsymbol{e}^\mathsf{T} \boldsymbol{\alpha} \right) \\ &\text{s.t.} : \boldsymbol{y}^\mathsf{T} \boldsymbol{\alpha} = 0 \\ &0 \leq \alpha_i \leq \frac{1}{\lambda N},\ i = 1, ..., N \end{aligned}$$

where $Q = [y_i y_j K(x_i, x_j)]_{i,j=1}^N$ is the Gram matrix, $K(x, x') = \Phi(x)^\mathsf{T} \Phi(x')$ is a kernel function, $\boldsymbol{e} = [1]_{N \times 1}$ is the vector of all 1, and $\boldsymbol{y} = [y_i]_{i=1,..,N}^\mathsf{T}$.

The dual optimization problem can be solved using the solvers (Joachims, 1999; Chang and Lin, 2011). However, the computational complexity of the solvers is over-quadratic (Shalev-Shwartz and Srebro, 2008) and the dual form does not appeal to the online learning setting. To scale up SVM and make it appealing to the online learning, we rewrite the constrained optimization problem in Eq. (1) in the *primal form* as follows

$$\min_{\mathbf{w}} \left(\frac{\lambda}{2} \|\mathbf{w}\|^2 + \frac{1}{N} \sum_{i=1}^{N} l(\mathbf{w}; x_i, y_i) \right) \tag{2}$$

where $l(\mathbf{w}; x, y) = \max\left(0, 1 - y \mathbf{w}^\mathsf{T} \Phi(x)\right)^3$ is Hinge loss.

In our current interest, the advantages of formulating the optimization problem of SVM in the primal form as in Eq. (2) are at least two-fold. First, it encourages the application of SGD-based method to propose a solution for the online learning context. Second, it allows us to extend Hinge loss to any appropriate loss functions (cf. Section 7) to enrich a wider class of problems that can be addressed.

3. We can eliminate the bias b by simply adjusting the kernel.

4. Problem Setting

We consider two following optimization problems for batch and online settings respectively in Eqs. (3) and (4)

$$\min_{\mathbf{w}} f(\mathbf{w}) \triangleq \frac{\lambda}{2}\|\mathbf{w}\|^2 + \mathbb{E}_{(x,y)\sim\mathbb{P}_N}\left[l(\mathbf{w};x,y)\right] \triangleq \frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{N}\sum_{i=1}^{N} l(\mathbf{w};x_i,y_i) \quad (3)$$

$$\min_{\mathbf{w}} f(\mathbf{w}) \triangleq \frac{\lambda}{2}\|\mathbf{w}\|^2 + \mathbb{E}_{(x,y)\sim\mathbb{P}_{\mathcal{X},\mathcal{Y}}}\left[l(\mathbf{w};x,y)\right] \quad (4)$$

where $l(\mathbf{w};x,y)$ is a *convex* loss function, $\mathbb{P}_{\mathcal{X},\mathcal{Y}}$ is the joint distribution of (x,y) over $\mathcal{X}\times\mathcal{Y}$ with the data domain $\mathcal{X}$ and the label domain $\mathcal{Y}$, and $\mathbb{P}_N$ specifies the empirical distribution over the training set $\mathcal{D} = \{(x_1,y_1),\ldots,(x_N,y_N)\}$. Furthermore, we assume that the convex loss function $l(\mathbf{w};x,y)$ satisfies the following property: there exists two positive numbers A and B such that $\left\|l'(\mathbf{w};x,y)\right\| \leq A\|\mathbf{w}\|^{1/2} + B, \forall \mathbf{w},x,y$. As demonstrated in Section 7, this condition is valid for all common loss functions. Hereafter, for given any function $g(\mathbf{w})$, we use the notation $g'(\mathbf{w}_0)$ to denote the gradient (or any sub-gradient) of $g(.)$ w.r.t $\mathbf{w}$ evaluated at $\mathbf{w}_0$.

It is clear that given a fixed $\mathbf{w}$, there exists a random variable g such that $\mathbb{E}[g \mid \mathbf{w}] = f'(\mathbf{w})$. In fact, we can specify $g = \lambda\mathbf{w} + l'(\mathbf{w};x_t,y_t)$ where $(x_t,y_t) \sim \mathbb{P}_{\mathcal{X},\mathcal{Y}}$ or $\mathbb{P}_N$. We assume that a *positive semi-definite* (p.s.d.) and *isotropic* (iso.) kernel Rasmussen and Williams (2005) is used, i.e., $K\left(x,x'\right) = k\left(\left\|x-x'\right\|^2\right)$, where $k: \mathcal{X}\to\mathbb{R}$ is an appropriate function. Let $\Phi(.)$ be the feature map corresponding the kernel (i.e., $K\left(x,x'\right) = \Phi(x)^{\mathsf{T}}\Phi\left(x'\right)$). To simplify the convergence analysis, without loss of generality we further assume that $\|\Phi(x)\|^2 = K(x,x) = 1, \forall x\in\mathcal{X}$. Finally, we denote the optimal solution of optimization problem in Eq. (3) or (4) by $\mathbf{w}^*$, that is, $\mathbf{w}^* = \text{argmin}_{\mathbf{w}} f(\mathbf{w})$.

5. Stochastic Gradient Descent Method

We introduce the standard kernel stochastic gradient descent (SGD) in Algorithm 1 wherein the standard learning rate $\eta_t = \frac{1}{\lambda t}$ is used (Shalev-Shwartz et al., 2007, 2011). Let α_t be a scalar such that $l'(\mathbf{w}_t;x_t,y_t) = \alpha_t\Phi(x_t)$ (we note that this scalar exists for all common loss functions as presented in Section 7). It is apparent that at the iteration t the model $\mathbf{w}_t$ has the form of $\mathbf{w}_t = \sum_{i=1}^{t}\alpha_i^{(t)}\Phi(x_i)$. The vector x_i $(1\leq i\leq t)$ is said to be a *support vector* if its coefficient $\alpha_i^{(t)}$ is nonzero. The model is represented through the support vectors, and hence we can define the model size to be $\left\|\boldsymbol{\alpha}^{(t)}\right\|_0$ and model sparsity as the ratio between the current model size and t (i.e., $\left\|\boldsymbol{\alpha}^{(t)}\right\|_0/t$). Since it is likely that α_t is nonzero (e.g., with Hinge loss, it happens if x_t lies in the margins of the current hyperplane), the standard kernel SGD algorithm is vulnerable to the curse of kernelization, that is, the model size, is almost linearly grown with the data size accumulated over time Steinwart (2003). Consequently, the computation gradually becomes slower or even infeasible when the data size grows rapidly.

Algorithm 1 Stochastic Gradient Descent algorithm.

Input: λ, p.s.d. kernel $K(.,.) = \Phi(\cdot)^{\mathsf{T}}\Phi(\cdot)$

$\mathbf{w}_1 = \mathbf{0}$
for $t = 1,2,\ldots T$ **do**
  Receive (x_t,y_t) //$(x_t,y_t)\sim\mathbb{P}_{\mathcal{X},\mathcal{Y}}$ *or* $\mathbb{P}_N$
  $\eta_t = \frac{1}{\lambda t}$
  $g_t = \lambda\mathbf{w}_t + l'(\mathbf{w}_t;x_t,y_t) = \lambda\mathbf{w}_t + \alpha_t\Phi(x_t)$
  $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t g_t = \frac{t-1}{t}\mathbf{w}_t - \eta_t\alpha_t\Phi(x_t)$
end for

Output: $\overline{\mathbf{w}}_T = \frac{1}{T}\sum_{t=1}^{T}\mathbf{w}_t$ or $\mathbf{w}_{T+1}$

6. Approximation Vector Machines for Large-scale Online Learning

In this section, we introduce our proposed Approximation Vector Machine (AVM) for online learning. The main idea is that we employ an overlapping partition of sufficiently small cells to cover the data domain, i.e., $\mathcal{X}$ or $\Phi(\mathcal{X})$; when an instance arrives, we approximate this instance by a corresponding core point in the cell that contains this instance. Our intuition behind this approximation procedure is that since the instance is approximated by its neighbor, the performance would not be significantly compromised while gaining significant speedup. We start this section with the definition of δ-coverage, its properties and connection with the feature space. We then present AVM and the convergence analysis.

6.1 δ-coverage over a domain

To facilitate our technical development in sequel, we introduce the notion of δ-coverage in this subsection. We first start with the usual definition of a diameter for a set.

Definition 1. (*diameter*) Given a set A, the diameter of this set is defined as $D(A) = \sup_{x,x'\in A}||x-x'||$. This is the maximal pairwise distance between any two points in A.

Next, given a domain $\mathcal{X}$ (e.g., the data domain, input space) we introduce the concept of δ-coverage for $\mathcal{X}$ using a collection of sets.

Definition 2. (*δ-coverage*) The collection of sets $\mathcal{P} = (P_i)_{i\in I}$ is said to be an δ-coverage of the domain $\mathcal{X}$ iff $\mathcal{X}\subset\cup_{i\in I}P_i$ and $D(P_i)\leq\delta, \forall i\in I$ where I is the index set (not necessarily discrete) and each element $P_i\in\mathcal{P}$ is further referred to as a *cell*. Furthermore if the index set I is finite, the collection $\mathcal{P}$ is called a *finite* δ-coverage.

Definition 3. (*core set, core point*) Given an δ-coverage $\mathcal{P} = (P_i)_{i\in I}$ over a given domain $\mathcal{X}$, for each $i\in I$, we select an arbitrary point c_i from the cell P_i, then the collection of all c_i (s) is called the *core set* $\mathcal{C}$ of the δ-coverage $\mathcal{P}$. Each point $c_i\in\mathcal{C}$ is further referred to as a *core point*.

We show that these definitions can be also extended to the feature space with the mapping Φ and kernel K via the following theorem.

Theorem 4. *Assume that the p.s.d. and isotropic kernel* $K(x,x') = k\left(||x-x'||^2\right)$, *where* $k(.)$ *is a monotonically continuous decreasing function with* $k(0) = 1$, *is examined and* $\Phi(.)$ *is its induced feature map. If* $\mathcal{P} = (P_i)_{i\in I}$ *is an* δ*-coverage of the domain* $\mathcal{X}$ *then* $\Phi(\mathcal{P}) = (\Phi(\mathcal{P}_i))_{i\in I}$ *is* **also** *an* δ_Φ*-coverage of the domain* $\Phi(\mathcal{X})$, *where* $\delta_\Phi = \sqrt{2(1-k(\delta^2))}$ *is a monotonically increasing function and* $\lim_{\delta\to 0}\delta_\Phi = 0$.

In particular, the Gaussian kernel given by $K(x,x') = \exp(-\gamma\left\|x-x'\right\|^2)$ is a p.s.d. and iso. kernel and $\delta_\Phi = \sqrt{2(1-\exp(-\gamma\delta^2))}$. Theorem 4 further reveals that the image of an δ-coverage in the input space is an δ_Φ-coverage in the feature space and when the diameter δ approaches 0, so does the induced diameter δ_Φ. For readability, the proof of this theorem is provided in Appendix 11.

We have further developed methods and algorithms to efficiently construct δ-coverage, however to maintain the readability, we defer this construction to Section 6.3.

6.2 Approximation Vector Machines

We now present our proposed Approximation Vector Machine (AVM) for online learning. In an online setting, instances arise on the fly and we need an efficient approach to incorporate incoming instances into the learner. Different from the existing works (cf. Section 2), our approach is to construct an δ-coverage $\mathcal{P} = (P_i)_{i\in I}$ over the input domain $\mathcal{X}$, and for each incoming instance x we find the cell P_i that contains this instance and approximate this instance by a core point $c_i \in P_i$. The coverage $\mathcal{P}$ and core set $\mathcal{C}$ can either be constructed in advance or on the fly as presented in Section 6.3.

In Algorithm 2, when receiving an incoming instance (x_t, y_t), we compute the scalar α_t such that $\alpha_t\Phi(x_t) = l'(\mathbf{w}_t; x_t, y_t)$ (cf. Section 7) in Step 5. Furthermore at Step 7 we introduce a Bernoulli random variable Z_t to govern the approximation procedure. This random variable could be either statistically independent or dependent with the incoming instances and the current model. In Section 9.2, we report on different settings for Z_t and how they influence the model size and learning performance. Our findings at the outset is that, the naive setting with $\mathbb{P}(Z_t = 1) = 1, \forall t$ (i.e., always performing approximation) returns the sparsest model while obtaining comparable learning performance comparing with the other settings. Moreover, as shown in Steps 9 and 11, we only approximate the incoming data instance by the corresponding core point (i.e., c_{i_t}) if $Z_t = 1$. In addition, if $Z_t = 1$, we find a cell that contains this instance in Step 8. It is worth noting that the δ-coverage and the cells are constructed on the fly along with the data arrival (cf. Algorithms 3 and 4). In other words, the incoming data instance might belong to an existing cell or a new cell that has the incoming instance as its core point is created.

Furthermore to ensure that $\|\mathbf{w}_t\|$ is bounded for all $t \geq 1$ in the case of ℓ_2 loss, if $\lambda \leq 1$ then we project $\mathbf{w}_t - \eta_t h_t$ onto the hypersphere with centre origin and radius $y_{\max}\lambda^{-1/2}$, i.e., $\mathcal{B}\left(\mathbf{0}, y_{\max}\lambda^{-1/2}\right)$. Since it can be shown that with ℓ_2 loss the optimal solution $\mathbf{w}^*$ lies in $\mathcal{B}\left(\mathbf{0}, y_{\max}\lambda^{-1/2}\right)$ (cf. Theorem 23 in Appendix 12), this operation could possibly result in a faster convergence. In addition, by reusing the previous information, this operation can be efficiently implemented. Finally, we note that with ℓ_2 loss and $\lambda > 1$, we do not need to perform a projection to bound $\|\mathbf{w}_t\|$ since according to Theorem 25 in Appendix 12, $\|\mathbf{w}_t\|$ is bounded by $\frac{y_{\max}}{\lambda-1}$. Here it is worth noting that we have defined $y_{\max} = \max_{y\in\mathcal{Y}}|y|$ and this notation is only used in the analysis for the regression task with the ℓ_2 loss.

Algorithm 2 Approximation Vector Machine.

Input: λ, p.s.d. & iso. $K(.,.) = \Phi(\cdot)^\mathsf{T}\Phi(\cdot)$, δ-coverage $\mathcal{P} = (P_i)_{i\in I}$

1: $\mathbf{w}_1 = 0$
2: **for** $t = 1, \ldots, T$ **do**
3: Receive (x_t, y_t) //$(x_t, y_t) \sim \mathbb{P}_{\mathcal{X},\mathcal{Y}}$ *or* $\mathbb{P}_N$
4: $\eta_t = \frac{1}{\lambda t}$
5: $l'(\mathbf{w}_t; x_t, y_t) = \alpha_t\Phi(x_t)$ //cf. Section 7
6: Sample a Bernoulli random variable Z_t
7: **if** $Z_t = 1$ **then**
8: Find $i_t \in I$ such that $x_t \in P_{i_t}$
9: $h_t = \lambda\mathbf{w}_t + \alpha_t\Phi(c_{i_t})$ //*do approximation*
10: **else**
11: $h_t = \lambda\mathbf{w}_t + \alpha_t\Phi(x_t)$
12: **end if**
13: **if** ℓ_2 loss is used **and** $\lambda \leq 1$ **then**
14: $\mathbf{w}_{t+1} = \prod_{\mathcal{B}\left(\mathbf{0}, y_{\max}\lambda^{-1/2}\right)}(\mathbf{w}_t - \eta_t h_t)$
15: **else**
16: $\mathbf{w}_{t+1} = \mathbf{w}_t - \eta_t h_t$
17: **end if**
18: **end for**

Output: $\overline{\mathbf{w}}_T = \frac{\sum_{t=1}^T \mathbf{w}_t}{T}$ or $\mathbf{w}_{T+1}$

In what follows, we present the theoretical results for our proposed AVM including the convergence analysis for a general convex or smooth loss function and the upper bound of the model size under the assumption that the incoming instances are drawn from an arbitrary distribution and arrive in a random order.

6.2.1 Analysis for Generic Convex Loss Function

We start with the theoretical analysis for Algorithm 2. The *decision of approximation* (i.e., the random variable Z_t) could be statistically independent or dependent with the current model parameter $\mathbf{w}_t$ and the incoming instance (x_t, y_t). For example, one can propose an algorithm in which the *decision of approximation* is performed iff the confidence level of the incoming instance w.r.t the current model is greater than 1, i.e., $y_t\mathbf{w}_t^\mathsf{T}\Phi(x_t) \geq 1$. We shall develop our theory to take into account all possible cases.

Theorem 5 below establishes an upper bound on the regret under the possible assumptions of the statistical relationship among the decision of approximation, the data distribution, and the current model. Based on Theorem 5, in Theorem 8 we further establish an inequality for the error incurred by a single-point output with a high confidence level.

Theorem 5. *Consider the running of Algorithm 2 where* (x_t, y_t) *is uniformly sampled from the training set* $\mathcal{D}$ *or the joint distribution* $\mathbb{P}_{\mathcal{X},\mathcal{Y}}$, *the following statements hold*

i) If Z_t and $\mathbf{w}_t$ are independent for all t (i.e., the decision of approximation only depends on the data distribution) then

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T} + \frac{\delta_\Phi M^{1/2} W^{1/2}}{T}\sum_{t=1}^{T}\mathbb{P}\left(Z_t = 1\right)^{1/2}$$

where H, M, W are positive constants.

ii) If Z_t is independent with both (x_t, y_t) and $\mathbf{w}_t$ for all t (i.e., the decision of approximation is independent with the current hyperplane and the data distribution) then

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T} + \frac{\delta_\Phi M^{1/2} W^{1/2}}{T}\sum_{t=1}^{T}\mathbb{P}\left(Z_t = 1\right)$$

iii) In general, we always have

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T} + \delta_\Phi M^{1/2} W^{1/2}$$

Remark 6. Theorem 5 consists of the standard convergence analysis. In particular, if the approximation procedure is never performed, i.e., $\mathbb{P}\left(Z_t = 1\right) = 0$, $\forall t$, we have the regret bound $\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{H(\log(T)+1)}{2\lambda T}$.

Remark 7. Theorem 5 further indicates that there exists an error gap between the optimal and the approximate solutions. When δ decreases to 0, this gap also decreases to 0. Specifically, when $\delta = 0$ (so does δ_Φ), any incoming instance is approximated by itself and consequently, the gap is exactly 0.

Theorem 8. *Let us define the gap by d_T, which is $\frac{\delta_\Phi M^{1/2} W^{1/2}}{T}\sum_{t=1}^{T}\mathbb{P}\left(Z_t = 1\right)^{1/2}$ (if Z_t is independent with $\mathbf{w}_t$), $\frac{\delta_\Phi M^{1/2} W^{1/2}}{T}\sum_{t=1}^{T}\mathbb{P}\left(Z_t = 1\right)$ (if Z_t is independent with (x_t, y_t) and $\mathbf{w}_t$), or $\delta_\Phi M^{1/2} W^{1/2}$. Let r be any number randomly picked from $\{1, 2, \ldots, T\}$. With the probability at least $1-\delta$, the following statement holds*

$$f\left(\mathbf{w}_r\right) - f\left(\mathbf{w}^*\right) \leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T} + d_T + \Delta_T\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$$

where $\Delta_T = \max\limits_{1\leq t\leq T}\left(f\left(\mathbf{w}_t\right) - f\left(\mathbf{w}^*\right)\right)$.

We now present the convergence analysis for the case when we output the α-suffix average result as proposed in Rakhlin et al. (2012). With $0 < \alpha < 1$, let us denote

$$\overline{\mathbf{w}}_T^\alpha = \frac{1}{\alpha T}\sum_{t=(1-\alpha)T+1}^{T}\mathbf{w}_t$$

where we assume that the fractional indices are rounded to their ceiling values.

Theorem 9 establishes an upper bound on the regret for the α-suffix average case, followed by Theorem 10 which establishes an inequality for the error incurred by a α-suffix average output with a high confidence level.

Theorem 9. *Consider the running of Algorithm 2 where (x_t, y_t) is uniformly sampled from the training set $\mathcal{D}$ or the joint distribution $\mathbb{P}_{\mathcal{X},\mathcal{Y}}$, the following statements hold*

i) If Z_t and $\mathbf{w}_t$ are independent for all t (i.e., the decision of approximation only depends on the data distribution) then

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{\lambda\left(1-\alpha\right)}{2\alpha}W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T}\sum_{t=(1-\alpha)T+1}^{T}\mathbb{P}\left(Z_t = 1\right)^{1/2} + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}$$

where H, M, W are positive constants and $W_T^\alpha = \mathbb{E}\left[\left\|\mathbf{w}_{(1-\alpha)T+1} - \mathbf{w}^*\right\|^2\right]$.

ii) If Z_t is independent with both (x_t, y_t) and $\mathbf{w}_t$ for all t (i.e., the decision of approximation is independent with the current hyperplane and the data distribution) then

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{\lambda\left(1-\alpha\right)}{2\alpha}W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T}\sum_{t=(1-\alpha)T+1}^{T}\mathbb{P}\left(Z_t = 1\right) + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}$$

iii) In general, we always have

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{\lambda\left(1-\alpha\right)}{2\alpha}W_T^\alpha + \delta_\Phi M^{1/2} W^{1/2} + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}$$

Theorem 10. *Let us once again define the induced gap by d_T, which is respectively*

$$\frac{\lambda\left(1-\alpha\right)}{2\alpha}W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T}\sum_{t=(1-\alpha)T+1}^{T}\mathbb{P}\left(Z_t = 1\right)^{1/2} \text{ (if } Z_t \text{ is independent with } \mathbf{w}_t\text{)},$$

$$\frac{\lambda\left(1-\alpha\right)}{2\alpha}W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T}\sum_{t=(1-\alpha)T+1}^{T}\mathbb{P}\left(Z_t = 1\right) \text{ (if } Z_t \text{ is independent with } (x_t, y_t) \text{ and } \mathbf{w}_t\text{)},$$

or $\frac{\lambda(1-\alpha)}{2\alpha}W_T^\alpha + \delta_\Phi M^{1/2} W^{1/2}$. Let r be any number randomly picked from $\{(1-\alpha)T+1, 2, \ldots, T\}$. With the probability at least $1-\delta$, the following statement holds

$$f\left(\mathbf{w}_r\right) - f\left(\mathbf{w}^*\right) \leq \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} + d_T + \Delta_T^\alpha\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$$

where $\Delta_T^\alpha = \max\limits_{(1-\alpha)T+1\leq t\leq T}\left(f\left(\mathbf{w}_t\right) - f\left(\mathbf{w}^*\right)\right)$.

Remark 11. Theorems 8 and 10 concern with the theoretical warranty if rendering any single-point output $\mathbf{w}_r$ rather than the average outputs. The upper bound gained in Theorem 10 is tighter than that gained in Theorem 8 in the sense that the quantity $\frac{H\log(1/(1-\alpha))}{2\lambda\alpha T} + \Delta_T^\alpha\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$ decreases faster and may decrease to 0 when $T \to +\infty$ given a confidence level $1-\delta$.

6.2.2 Analysis for Smooth Loss Function

Definition 12. A loss function $l(\mathbf{w}; x, y)$ is said to be μ-strongly smooth w.r.t a norm $\|.\|$ iff for all $\boldsymbol{u}, \boldsymbol{v}$ and (x, y) the following condition satisfies

$$l(\boldsymbol{v}; x, y) \leq l(\boldsymbol{u}; x, y) + l'(\boldsymbol{u}; x, y)^{\mathsf{T}}(\boldsymbol{v} - \boldsymbol{u}) + \frac{\mu}{2}\|\boldsymbol{v} - \boldsymbol{u}\|^2$$

Another equivalent definition of μ-strongly smooth function is

$$\left\| l'(\boldsymbol{u}; x, y) - l'(\boldsymbol{v}; x, y) \right\|_* \leq \mu \|\boldsymbol{v} - \boldsymbol{u}\|$$

where $\|.\|_*$ is used to represent the dual norm of the norm $\|.\|$.
It is well-known that

- ℓ_2 loss is 1-strongly smooth w.r.t $\|.\|_2$.
- Logistic loss is 1-strongly smooth w.r.t $\|.\|_2$.
- τ-smooth Hinge loss (Shalev-Shwartz and Zhang, 2013) is $\frac{1}{\tau}$-strongly smooth w.r.t $\|.\|_2$.

Theorem 13. *Assume that ℓ_2, Logistic, or τ-smooth Hinge loss is used, let us denote $L = \frac{\lambda}{2} + 1$, $\frac{\lambda}{2} + 1$, or $\frac{\lambda}{2} + \tau^{-1}$ respectively. Let us define the gap by d_T as in Theorem 10. Let r be any number randomly picked from $\{(1-\alpha)T + 1, 2, \ldots, T\}$. With the probability at least $(1 - \delta)$, the following statement holds*

$$f(\mathbf{w}_r) - f(\mathbf{w}^*) \leq \frac{H \log(1/(1-\alpha))}{2\lambda\alpha T} + d_T + \frac{L M_T^\alpha}{2}\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$$

where $M_T^\alpha = \max_{(1-\alpha)T+1 \leq t \leq T} \|\mathbf{w}_t - \mathbf{w}^*\|$.

Remark 14. Theorem 13 extends Theorem 10 for the case of smooth loss function. This allows the gap $\frac{H \log(1/(1-\alpha))}{2\lambda\alpha T} + \frac{L M_T^\alpha}{2}\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$ to be quantified more precisely regarding the discrepancy in the model itself rather than that in the objective function. The gap $\frac{H \log(1/(1-\alpha))}{2\lambda\alpha T} + \frac{L M_T^\alpha}{2}\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$ could possibly decrease rapidly when T approaches $+\infty$.

Table 1: Comparison on the regret bounds and the budget sizes of the kernel online algorithms. On the column of budget size, NB stands for *Not Bound* (i.e., the model size is not bounded and learning method is vulnerable to the curse of kernelization), MB stands for *Manual Bound* (i.e., the model size is manually bounded by a predefined budget), and AB is an abbreviation of *Automatic Bound* (i.e., the model size is automatically bounded and this model size is automatically inferred).

To end this section, we present the regret bound and the obtained budget size for our AVM(s) together with those of algorithms listed in Table 1. We note that some early works on online kernel learning mainly focused on the mistake rate and did not present any theoretical results regarding the regret bounds.

6.2.3 Upper Bound of Model Size

In what follows, we present the theoretical results regarding the model size and sparsity level of our proposed AVM. Theorem 15 shows that AVM offers a high level of freedom to control the model size. Especially, if we use the always-on setting (i.e., $\mathbb{P}(Z_t = 1) = 1, \forall t$), the model size is bounded regardless of the data distribution and data arrival order.

Theorem 15. *Let us denote $\mathbb{P}(Z_t = 1) = p_t$, $\mathbb{P}(Z_t = 0) = q_t$, and the number of cells generated after the iteration t by M_t. If we define the model size, i.e., the size of support set, after the iteration t by S_t, the following statement holds*

$$\mathbb{E}[S_T] \leq \sum_{t=1}^{T} q_t + \sum_{t=1}^{T} p_t \mathbb{E}[M_t - M_{t-1}] \leq \sum_{t=1}^{T} q_t + \mathbb{E}[M_T]$$

Specially, if we use some specific settings for p_t, we can bound the model size $\mathbb{E}[S_t]$ accordingly as follows
i) If $p_t = 1, \forall t$ then $\mathbb{E}[S_T] \leq \mathbb{E}[M_T] \leq |\mathcal{P}|$, where $|\mathcal{P}|$ specifies the size of the partition $\mathcal{P}$, i.e., its number of cells.
ii) If $p_t = \max\left(0, 1 - \frac{\beta}{t}\right), \forall t$ then $\mathbb{E}[S_T] \leq \beta(\log(T) + 1) + \mathbb{E}[M_T]$.
iii) If $p_t = \max\left(0, 1 - \frac{\beta}{t^\rho}\right), \forall t$, where $0 < \rho < 1$, then $\mathbb{E}[S_T] \leq \frac{\beta T^{1-\rho}}{1-\rho} + \mathbb{E}[M_T]$.

iv) If $p_t = \max\left(0, 1 - \frac{\beta}{t^\rho}\right), \forall t$, *where* $\rho > 1$, *then* $\mathbb{E}[S_T] \leq \beta\zeta(\rho) + \mathbb{E}[M_T] \leq \beta\zeta(\rho) + |\mathcal{P}|$, *where* $\zeta(.)$ *is* ζ*- Riemann function defined by the integral* $\zeta(s) = \frac{1}{\Gamma(s)} \int_0^{+\infty} \frac{t^{s-1}}{e^s - 1} dt$.

Remark 16. We use two parameters β and ρ to flexibly control the rate of approximation p_t. It is evident that when β increases, the rate of approximation decreases and consequently the model size and accuracy increase. On the other hand, when ρ increases, the rate of approximation increases as well and it follows that the model size and accuracy decreases. We conducted experiment to investigate how the variation of these two parameters influence the model size and accuracy (cf. Section 9.2).

Remark 17. The items i) and iv) in Theorem 15 indicate that if $\mathbb{P}(Z_t = 1) = p_t = \max\left(0, 1 - \frac{\beta}{t^\rho}\right)$, where $\rho > 1$ or $\rho = +\infty$, then the model size is bounded by $\beta\zeta(\rho) + |\mathcal{P}|$ (by convention we define $\zeta(+\infty) = 0$). In fact, the tight upper bound is $\beta\zeta(\rho) + \mathbb{E}[M_T]$, where M_T is the number of unique cells used so far. It is empirically proven that M_T could be very small comparing with T and $|\mathcal{P}|$. In addition, since all support sets of $\mathbf{w}_t$ $(1 \leq t \leq T)$ are all lain in the core set, if we output the average $\overline{\mathbf{w}}_T = \frac{\sum_{t=1}^T \mathbf{w}_t}{T}$ or α-suffix average $\overline{\mathbf{w}}_T^\alpha = \frac{1}{\alpha T} \sum_{t=(1-\alpha)T+1}^T \mathbf{w}_T$, the model size is still bounded.

Remark 18. The items ii) and iii) in Theorem 15 indicate that if $\mathbb{P}(Z_t = 1) = p_t = \max\left(0, 1 - \frac{\beta}{t^\rho}\right)$, where $0 < \rho \leq 1$ then although the model size is not bounded, it would slowly increase comparing with T, i.e., $\log(T)$ or $T^{1-\rho}$ when ρ is around 1.

6.3 Construction of δ-Coverage

In this section, we return to the construction of δ-coverage defined in Section 6.1 and present two methods to construct a finite δ-coverage. The first method employs hypersphere cells (cf. Algorithm 3) whereas the second method utilizes the hyperrectangle cells (cf. Algorithm 4). In these two methods, the cells in coverage are constructed on the fly when the incoming instances arrive. Both are theoretically proven to be a finite coverage.

Algorithm 3 Constructing hypersphere δ-coverage.

$\mathcal{P} = \emptyset$
$n = 0$
for $t = 1, 2, \ldots$ **do**
  Receive (x_t, y_t)
  $i_t = \text{argmin}_{k \leq n} \|x_t - c_k\|$
  if $\|x_t - c_{i_t}\| \geq \delta/2$ **then**
    $n = n + 1$
    $c_n = x_t$
    $i_t = n$
    $\mathcal{P} = \mathcal{P} \cup [\mathcal{B}(c_n, \delta/2)]$
  end if
end for

Algorithm 4 Constructing hyperrectangle δ-coverage.

$\mathcal{P} = \emptyset$
$a = \delta/\sqrt{d}$
$n = 0$
for $t = 1, 2, \ldots$ **do**
  Receive (x_t, y_t)
  $i_t = 0$
  for $i = 1$ to n **do**
    if $\|x_t - c_i\|_\infty < a$ **then**
      $i_t = i$
      break
    end if
  end for
  if $i_t = 0$ **then**
    $n = n + 1$
    $c_n = x_t$
    $i_t = n$
    $\mathcal{P} = \mathcal{P} \cup [\mathcal{R}(c_n, a)]$
  end if
end for

Algorithm 3 employs a collection of open hypersphere cell $\mathcal{B}(c, R)$, which is defined as $\mathcal{B}(c, R) = \{x \in \mathbb{R}^d : \|x - c\| < R\}$, to cover the data domain. Similar to Algorithm 3, Algorithm 4 uses a collection of open hyperrectangle $\mathcal{R}(c, a)$, which is given by $\mathcal{R}(c, a) = \{x \in \mathbb{R}^d : \|x - c\|_\infty < a\}$, to cover the data domain.

Both Algorithms 3 and 4 are constructed in the common spirit: if the incoming instance (x_t, y_t) is outside all current cells, a new cell whose centre or vertex is this instance is generated. It is noteworthy that the variable i_t in these two algorithms specifies the cell that contains the new incoming instance and is the same as itself in Algorithm 2.

Theorem 19 establishes that regardless of the data distribution and data arrival order, Algorithms 3 and 4 always generate a finite δ-coverage which implies a bound on the model size of AVM. It is noteworthy at this point that in some scenarios of data arrival, Algorithms 3 and 4 might not generate a coverage for the entire space $\mathcal{X}$. However, since the generated sequence $\{x_t\}_t$ cannot be outside the set $\cup_i \mathcal{B}(c_i, \delta)$ and $\cup_i \mathcal{R}(c_i, \delta)$, without loss of generality we can restrict $\mathcal{X}$ to $\cup_i \mathcal{B}(c_i, \delta)$ or $\cup_i \mathcal{R}(c_i, \delta)$ by assuming that $\mathcal{X} = \cup_i \mathcal{B}(c_i, \delta)$ or $\mathcal{X} = \cup_i \mathcal{R}(c_i, \delta)$.

Theorem 19. *Let us consider the coverages formed by the running of Algorithms 3 and 4. If the data domain* $\mathcal{X}$ *is compact (i.e., close and bounded) then these coverages are all finite* δ*-coverages whose sizes are all dependent on the data domain* $\mathcal{X}$ *and independent with the sequence of incoming data instances* (x_t, y_t) *received.*

Remark 20. Theorem 19 also reveals that regardless of the data arrival order, the model size of AVM is always bounded (cf. Remark 17). Referring to the work of (Cucker and Smale, 2002), it is known that this model size cannot exceed $\left(\frac{4D(\mathcal{X})}{\delta}\right)^d$. However with

many possible data arrival orders, the number of active cells or the model size of AVM is significantly smaller than the aforementioned theoretical bound.

6.4 Complexity Analysis

We now present the computational complexity of our AVM(s) with the hypersphere δ-coverage at the iteration t. The cost to find the hypersphere cell in Step 5 of Algorithm 2 is $\mathrm{O}\left(d^2 M_t\right)$. The cost to calculate α_t in Step 6 of Algorithm 2 is $\mathrm{O}\left(S_t\right)$ if we consider the kernel operation as a unit operation. If ℓ_2 loss is used and $\lambda \leq 1$, we need to do a projection onto the hypersphere $\mathcal{B}\left(\mathbf{0}, y_{\max}\lambda^{-1/2}\right)$ which requires the evaluation of the length of the vector $\mathbf{w}_t - \eta_t h_t$ (i.e., $\|\mathbf{w}_t - \eta_t h_t\|$) which costs S_t unit operations using incremental implementation. Therefore, the computational operation at the iteration t of AVM(s) is either $\mathrm{O}\left(d^2 M_t + S_t\right) = \mathrm{O}\left(\left(d^2+1\right) S_t\right)$ or $\mathrm{O}\left(d^2 M_t + S_t + S_t\right) = \mathrm{O}\left(\left(d^2+2\right) S_t\right)$ (since $M_t \leq S_t$).

7. Suitability of Loss Functions

We introduce six types of loss functions that can be used in our proposed algorithm, namely Hinge, Logistic, ℓ_2, ℓ_1, $\varepsilon-$insensitive, and τ-smooth Hinge. We verify that these loss functions satisfying the necessary condition, that is, $\left\|l'\left(\mathbf{w}; x, y\right)\right\| \leq A\left\|\mathbf{w}\right\|^{1/2} + B$ for some appropriate positive numbers A, B (this is required for our problem formulation presented in Section 4).

For comprehensibility, without loss of generality, we assume that $\left\|\Phi\left(x\right)\right\| = K\left(x,x\right)^{1/2} = 1$, $\forall x \in \mathcal{X}$. At the outset of this section, it is noteworthy that for classification task (i.e., Hinge, Logistic, and τ-smooth Hinge cases), the label y is either -1 or 1 which instantly implies $|y| = y^2 = 1$.

- **Hinge loss**

$$l\left(\mathbf{w}; x, y\right) = \max\left\{0, 1 - y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right\}$$
$$l'\left(\mathbf{w}; x, y\right) = -\mathbb{I}_{\left\{y\mathbf{w}^{\mathsf{T}}\Phi(x) \leq 1\right\}} y\Phi\left(x\right)$$

  where $\mathbb{I}_S$ is the indicator function which renders 1 if the logical statement S is true and 0 otherwise.

  Therefore, by choosing $A = 0$, $B = 1$ we have

$$\left\|l'\left(\mathbf{w}; x, y\right)\right\| \leq \left\|\Phi\left(x\right)\right\| \leq 1 = A\left\|\mathbf{w}\right\|^{1/2} + B$$

- **ℓ_2 loss**

  In this case, at the outset we cannot verify that $\left\|l'\left(\mathbf{w}; x, y\right)\right\| \leq A\left\|\mathbf{w}\right\|^{1/2} + B$ for all $\mathbf{w}, x, y$. However, to support the proposed theory, we only need to check that $\left\|l'\left(\mathbf{w}_t; x, y\right)\right\| \leq A\left\|\mathbf{w}_t\right\|^{1/2} + B$ for all $t \geq 1$. We derive as follows

$$l\left(\mathbf{w}; x, y\right) = \frac{1}{2}\left(y - \mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right)^2$$
$$l'\left(\mathbf{w}; x, y\right) = \left(\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) - y\right)\Phi\left(x\right)$$

$$\left\|l'\left(\mathbf{w}_t; x, y\right)\right\| = \left|\mathbf{w}_t^{\mathsf{T}}\Phi\left(x\right) + y\right|\left\|\Phi\left(x\right)\right\| \leq \left|\mathbf{w}_t^{\mathsf{T}}\Phi\left(x\right)\right| + y_{\max}$$
$$\leq \left\|\Phi\left(x\right)\right\|\left\|\mathbf{w}_t\right\| + y_{\max} \leq A\left\|\mathbf{w}_t\right\|^{1/2} + B$$

  where $B = y_{\max}$ and $A = \begin{cases} y_{\max}^{1/2}\lambda^{-1/4} & \text{if } \lambda \leq 1 \\ y_{\max}^{1/2}\left(\lambda - 1\right)^{-1/2} & \text{otherwise} \end{cases}$.

  Here we note that we make use of the fact that $\left\|\mathbf{w}_t\right\| \leq y_{\max}\left(\lambda - 1\right)^{-1}$ if $\lambda > 1$ (cf. Theorem 25 in Appendix 12) and $\left\|\mathbf{w}_t\right\| \leq y_{\max}\lambda^{-1/2}$ otherwise (cf. Line 12 in Algorithm 2).

- **ℓ_1 loss**

$$l\left(\mathbf{w}; x, y\right) = \left|y - \mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right|$$
$$l'\left(\mathbf{w}; x, y\right) = \operatorname{sign}\left(\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) - y\right)\Phi\left(x\right)$$

  Therefore, by choosing $A = 0$, $B = 1$ we have

$$\left\|l'\left(\mathbf{w}; x, y\right)\right\| = \left\|\Phi\left(x\right)\right\| \leq 1 = A\left\|\mathbf{w}\right\|^{1/2} + B$$

- **Logistic loss**

$$l\left(\mathbf{w}; x, y\right) = \log\left(1 + \exp\left(-y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right)\right)$$
$$l'\left(\mathbf{w}; x, y\right) = \frac{-y\exp\left(-y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right)\Phi\left(x\right)}{\exp\left(-y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right) + 1}$$

  Therefore, by choosing $A = 0$, $B = 1$ we have

$$\left\|l'\left(\mathbf{w}; x, y\right)\right\| < \left\|\Phi\left(x\right)\right\| \leq 1 = A\left\|\mathbf{w}\right\|^{1/2} + B$$

- **ε-insensitive loss**

$$l\left(\mathbf{w}; x, y\right) = \max\left\{0, \left|y - \mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right| - \varepsilon\right\}$$
$$l'\left(\mathbf{w}; x, y\right) = \mathbb{I}_{\left\{\left|y - \mathbf{w}^{\mathsf{T}}\Phi(x)\right| > \varepsilon\right\}}\operatorname{sign}\left(\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) - y\right)\Phi\left(x\right)$$

  Therefore, by choosing $A = 0$, $B = 1$ we have

$$\left\|l'\left(\mathbf{w}; x, y\right)\right\| \leq \left\|\Phi\left(x\right)\right\| \leq 1 = A\left\|\mathbf{w}\right\|^{1/2} + B$$

- **τ-smooth Hinge loss** Shalev-Shwartz and Zhang (2013)

$$l\left(\mathbf{w}; x, y\right) = \begin{cases} 0 & \text{if } y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) > 1 \\ 1 - y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) - \frac{\tau}{2} & \text{if } y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) < 1 - \tau \\ \frac{1}{2\tau}\left(1 - y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right)\right)^2 & \text{otherwise} \end{cases}$$
$$l'\left(\mathbf{w}; x, y\right) = -\mathbb{I}_{\left\{y\mathbf{w}^{\mathsf{T}}\Phi(x) < 1 - \tau\right\}} y\Phi\left(x\right)$$
$$+ \tau^{-1}\mathbb{I}_{1 - \tau \leq y\mathbf{w}^{\mathsf{T}}\Phi(x) \leq 1}\left(y\mathbf{w}^{\mathsf{T}}\Phi\left(x\right) - 1\right) y\Phi\left(x\right)$$

Therefore, by choosing $A = 0$, $B = 2$, we have

$$\left\| l^{'}\left(\mathbf{w}; x, y\right)\right\| \leq |y| \left\|\Phi\left(x\right)\right\| + \tau^{-1} |y| \left\|\Phi\left(x\right)\right\| \tau \leq 2 = A \left\|\mathbf{w}\right\|^{1/2} + B$$

8. Multiclass Setting

In this section, we show that our proposed framework could also easily extend to the multi-class setting. We base on the work of Crammer and Singer (2002) for multiclass classification to formulate the optimization problem in multi-class setting as

$$\min_{W} \left(f\left(W\right) \triangleq \frac{\lambda}{2} \left\|W\right\|_{2,2}^{2} + \frac{1}{N} \sum_{i=1}^{N} l\left(\mathbf{w}_{y_i}^{\mathsf{T}} \Phi\left(x_i\right) - \mathbf{w}_{z_i}^{\mathsf{T}} \Phi\left(x_i\right)\right)\right)$$

where we have defined

$$z_i = \underset{j \neq y_i}{\operatorname{argmax}}\, \mathbf{w}_j^{\mathsf{T}} \Phi\left(x_i\right),$$

$$W = \left[\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_m\right], \left\|W\right\|_{2,2}^{2} = \sum_{j=1}^{m} \left\|\mathbf{w}_j\right\|^2,$$

$$l\left(a\right) = \begin{cases} \max\left(0, 1 - a\right) & \text{Hinge loss} \\ \log\left(1 + e^{-a}\right) & \text{Logistic loss} \end{cases}$$

For the exact update, at the t-th iteration, we receive the instance (x_t, y_t) and modify W as follows

$$\mathbf{w}_j^{(t+1)} = \begin{cases} \frac{t-1}{t} \mathbf{w}_j^{(t)} - \eta_t l^{'}\left(a\right) \Phi\left(x_t\right) & \text{if } j = y_t \\ \frac{t-1}{t} \mathbf{w}_j^{(t)} + \eta_t l^{'}\left(a\right) \Phi\left(x_t\right) & \text{if } j = z_t \\ \frac{t-1}{t} \mathbf{w}_j^{(t)} & \text{otherwise} \end{cases}$$

where $a = \mathbf{w}_{y_t}^{\mathsf{T}} \Phi\left(x_t\right) - \mathbf{w}_{z_t}^{\mathsf{T}} \Phi\left(x_t\right)$ and $l^{'}(a) = -\mathbb{I}_{\{a<1\}}$ or $-1/\left(1 + e^{a}\right)$.

The algorithm for Approximation Vector Machine with multiclass setting proceeds as in Algorithm 5.

Algorithm 5 Multiclass Approximation Vector Machine.

Input: λ, p.s.d. & iso. kernel $K\left(.,.\right)$, δ-coverage $\mathcal{P} = \left(P_i\right)_{i \in I}$

$W_1 = 0$
for $t = 1, \ldots, T$ **do**
  Receive $\left(x_t, y_t\right)$ //$(x_t, y_t) \sim \mathbb{P}_{\mathcal{X},\mathcal{Y}}$ *or* $\mathbb{P}_N$
  $a = \mathbf{w}_{y_t}^{\mathsf{T}} \Phi\left(x_t\right) - \max_{j \neq y_t} \mathbf{w}_j^{\mathsf{T}} \Phi\left(x_t\right)$
  $W^{(t+1)} = \frac{t-1}{t} W^{(t)}$
  Sample a Bernoulli random variable Z_t
  if $Z_t = 1$ **then**
    Find $i_t \in I$ such that $x_t \in P_{i_t}$
    $\mathbf{w}_{y_t}^{(t+1)} = \mathbf{w}_{y_t}^{(t+1)} - \eta_t l^{'}\left(a\right) \Phi\left(c_{i_t}\right)$ //*do approximation*
    $\mathbf{w}_{z_t}^{(t+1)} = \mathbf{w}_{z_t}^{(t+1)} + \eta_t l^{'}\left(a\right) \Phi\left(c_{i_t}\right)$
  else
    $\mathbf{w}_{y_t}^{(t+1)} = \mathbf{w}_{y_t}^{(t+1)} - \eta_t l^{'}\left(a\right) \Phi\left(x_t\right)$
    $\mathbf{w}_{z_t}^{(t+1)} = \mathbf{w}_{z_t}^{(t+1)} + \eta_t l^{'}\left(a\right) \Phi\left(x_t\right)$
  end if
end for

Output $\overline{W}^{(T)} = \frac{\sum_{t=1}^{T} W^{(t)}}{T}$ or $W^{(t+1)}$

9. Experiments

In this section, we conduct comprehensive experiments to quantitatively evaluate the capacity and scalability of our proposed Approximation Vector Machine (AVM) on classification and regression tasks under three different settings:

- *Batch classification*[4]: the regular binary and multiclass classification tasks that follow a standard validation setup, wherein each dataset is partitioned into training set and testing set. The models are trained on the training part, and then their discriminative capabilities are verified on the testing part using classification accuracy measure. The computational costs are commonly measured based on the training time.

- *Online classification*: the binary and multiclass classification tasks that follow a purely online learning setup, wherein there is no division of training and testing sets as in batch setting. The algorithms sequentially receive and process a single data sample turn-by-turn. When an individual data point comes, the models perform prediction to compute the mistake rate first, then use the feature and label information of such data point to continue their learning procedures. Their predictive performances and computational costs are measured basing on the average of mistake rate and execution time, respectively, accumulated in the learning progress on the entire dataset.

- *Online regression*: the regression task that follows the same setting of online classification, except the predictive performances are measured based on the regression error rate accumulated in the learning progress on the entire dataset.

4. This setting is also known as offline classification.

Our main goal is to examine the scalability, classification and regression capabilities of AVMs by directly comparing with those of several recent state-of-the-art batch and online learning approaches using a number of datasets with a wide range of sizes. Our models are implemented in Python with Numpy package. The source code and experimental scripts are published for reproducibility[5]. In what follows, we present the data statistics, experimental setup, results and our observations.

9.1 Data Statistics and Experimental Setup

We use 11 datasets whose statistics are summarized in Table 2. The datasets are selected in a diverse array of sizes in order to clearly expose the differences among scalable capabilities of the models. Five of which (*year*, *covtype*, *poker, KDDCup99*, *airlines*) are large-scale datasets with hundreds of thousands and millions of data points, whilst the rest are ordinal-size databases. Except the *airlines*, all of the datasets can be downloaded from LIBSVM[6] and UCI[7] websites.

Dataset	#training	#testing	#features	#classes	Source
a9a	32,561	16,281	123	2	UCI
w8a	49,749	14,951	300	2	LIBSVM
cod-rna	59,535	271,617	8	2	LIBSVM
ijcnn1	49,990	91,701	22	2	LIBSVM
covtype	522,911	58,101	54	7	LIBSVM
poker	25,010	1,000,000	10	10	UCI
KDDCup99	4,408,589	489,842	41	23	UCI
airlines	5,336,471	592,942	8	2	ASA
Dataset	**#training**	**#testing**	**#features**	**value**	**Source**
casp	45,730	–	9	[0, 1]	UCI
slice	53,500	–	384	[0, 1]	UCI
year	515,345	–	90	[0, 1]	UCI
airlines	5,929,413	–	8	$\mathbb{R}^+$	ASA

Table 2: Data statistics. #training: number of training samples; #testing: number of testing samples.

The airlines dataset is provided by American Statistical Association (ASA[8]). The dataset contains information of all commercial flights in the US from October 1987 to April 2008. The aim is to predict whether a flight will be delayed or not and how long in minutes the flight will be delayed in terms of departure time. The departure delay time is provided in the flight database. A flight is considered *delayed* if its delay time is above 15 minutes, and *non-delayed* otherwise. The average delay of a flight in 2008 was of 56.3 minutes. Following the procedure of (Hensman et al., 2013), we further process the data in two steps. First, we join the data with the information of individual planes basing on their tail numbers in order to obtain the manufacture year. This additional information is provided as a supplemental data source on ASA website. We then extract 8 features of many available fields: the age of the aircraft (computed based on the manufacture year), journey distance, airtime, scheduled departure time, scheduled arrival time, month, day of week and month. All features are normalized into the range $[0, 1]$.

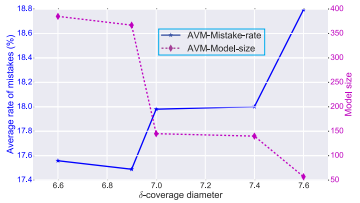
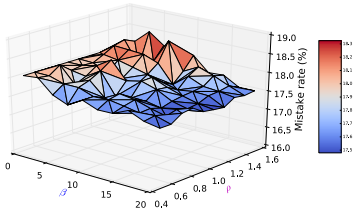
6. https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/.
7. https://archive.ics.uci.edu/ml/datasets.html.
8. The data can be downloaded from http://stat-computing.org/dataexpo/2009/.

In batch classification experiments, we follow the original divisions of training and testing sets in LIBSVM and UCI sites wherever available. For *KDDCup99*, *covtype* and *airlines* datasets, we split the data into 90% for training and 10% for testing. In online classification and regression tasks, we either use the entire datasets or concatenate training and testing parts into one. The online learning algorithms are then trained in a single pass through the data. In both batch and online settings, for each dataset, the models perform 10 runs on different random permutations of the training data samples. Their prediction results and time costs are then reported by taking the average with the standard deviation of the results over these runs.



For comparison, we employ some baseline methods that will be described in the following sections. Their C++ implementations with Matlab interfaces are published as a part of LIBSVM, BudgetedSVM[9] and LSOKL[10] toolboxes. Throughout the experiments, we utilize RBF kernel, i.e., $K\left(x, x'\right) = \exp\left(-\gamma \left\|x - x'\right\|^2\right)$ for all algorithms including ours. We use hypersphere strategy to construct the δ-coverage (cf. Section 6.3), due to its better performance than that of hyperrectangle approach during model evaluation. All experiments are conducted using a Windows machine with 3.46GHz Xeon processor and 96GB RAM.

9.2 Model Evaluation on The Effect of Hyperparameters



In the first experiment, we investigate the effect of hyperparameters, i.e., δ-coverage diameter, sampling parameters β and ρ (cf. Section 6.2.3) on the performance of AVMs. Particularly, we conduct an initial analysis to quantitatively evaluate the sensitivity of these hyperparameters and their impact on the predictive accuracy and model size. This analysis provides a heuristic approach to find the best setting of hyperparameters. Here the AVM with Hinge loss is trained following the online classification scheme using two datasets *a9a* and *cod-rna*.

To find the plausible range of coverage diameter, we use a heuristic approach as follows. First we compute the mean and standard deviation of pairwise Euclidean distances between any two data samples. Treating the mean as the radius, the coverage diameter is then varied around twice of this mean bounded by twice of the standard deviation. Fig. 2a and Fig. 3a report the average mistake rates and model sizes of AVMs with respect to (w.r.t) these values for datasets *a9a* and *cod-rna*, respectively. Here we set $\beta = 0$ and $\rho = 1.0$. There is a consistent pattern in both figures: the classification errors increase for larger δ whilst the model sizes decrease. This represents the trade-off between model performance and model size via the model coverage. To balance the performance and model size, in these cases, we can choose $\delta = 7.0$ for *a9a* data and $\delta = 1.0$ for *cod-rna* data.

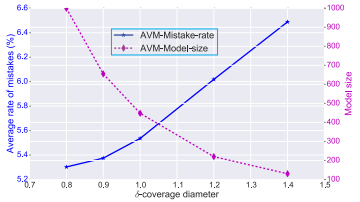
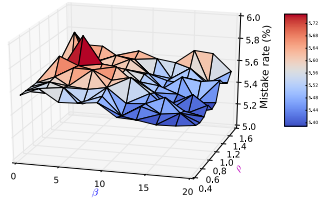
10. http://lsokl.stevenhoi.com/.



(a) The effect of δ-coverage diameter on the mistake rate and model size.



(b) The effect of β and ρ on the classification mistake rate. $\beta = 0$ means always approximating.

Figure 2: Performance evaluation of AVM with Hinge loss trained using *a9a* dataset with different values of hyperparameters.

(a) The effect of δ-coverage diameter on the mistake rate and model size.

(b) The effect of β and ρ on the classification mistake rate. $\beta = 0$ means always approximating.

Figure 3: Performance evaluation of AVM with Hinge loss trained using *cod-rna* dataset with different values of hyperparameters.

Fixing the coverage diameters, we vary β and ρ in 10 values monotonically increasing from 0 to 10 and from 0.5 to 1.5, respectively, to evaluate the classification performance. The smaller β and larger ρ indicate that the machine approximates the new incoming data more frequently, resulting in less powerful prediction capability. This can be observed in Fig. 2b and Fig. 3b, which depict the average mistake rates in 3D as a function of these values for dataset *a9a* and *cod-rna*. Here $\beta = 0$ means that the model always performs approximation without respect to the value of ρ. From these visualizations, we found that the AVM with always-on approximation mode still can achieve fairly comparable classification results. Thus we set $\beta = 0$ for all following experiments.

9.3 Batch Classification

We now examine the performances of AVMs in classification task following batch mode. We use eight datasets: *a9a*, *w8a*, *cod-rna*, *KDDCup99*, *ijcnn1*, *covtype*, *poker* and *airlines*

(delayed and non-delayed labels). We create two versions of our approach: AVM with Hinge loss (AVM-Hinge) and AVM with Logistic loss (AVM-Logit). It is noteworthy that the Hinge loss is not a smooth function with undefined gradient at the point that the classification confidence $yf(x) = 1$. Following the sub-gradient definition, in our experiment, we compute the gradient given the condition that $yf(x) < 1$, and set it to 0 otherwise.

Baselines. For discriminative performance comparison, we recruit the following state-of-the-art baselines to train kernel SVMs for classification in batch mode:

- LIBSVM: one of the most widely-used and state-of-the-art implementations for batch kernel SVM solver (Chang and Lin, 2011). We use the one-vs-all approach as the default setting for the multiclass tasks;
- LLSVM: low-rank linearization SVM algorithm that approximates kernel SVM optimization by a linear SVM using low-rank decomposition of the kernel matrix (Zhang et al., 2012);
- BSGD-M: budgeted stochastic gradient descent algorithm which extends the Pegasos algorithm (Shalev-Shwartz et al., 2011) by introducing a merging strategy for support vector budget maintenance (Wang et al., 2012);
- BSGD-R: budgeted stochastic gradient descent algorithm which extends the Pegasos algorithm (Shalev-Shwartz et al., 2011) by introducing a removal strategy for support vector budget maintenance (Wang et al., 2012);
- FOGD: Fourier online gradient descent algorithm that applies the random Fourier features for approximating kernel functions (Lu et al., 2015);
- NOGD: Nystrom online gradient descent (NOGD) algorithm that applies the Nystrom method to approximate large kernel matrices (Lu et al., 2015).

Hyperparameters setting. There are a number of different hyperparameters for all methods. Each method requires a different set of hyperparameters, e.g., the regularization parameters (C in LIBSVM, λ in Pegasos and AVM), the learning rates (η in FOGD and NOGD), the coverage diameter (δ in AVM) and the RBF kernel width (γ in all methods). Thus, for a fair comparison, these hyperparameters are specified using cross-validation on training subset.

Particularly, we further partition the training set into 80% for learning and 20% for validation. For large-scale databases, we use only 1% of training set, so that the searching can finish within an acceptable time budget. The hyperparameters are varied in certain ranges and selected for the best performance on the validation set. The ranges are given as follows: $C \in \{2^{-5}, 2^{-3}, ..., 2^{15}\}$, $\lambda \in \{2^{-4}/N, 2^{-2}/N, ..., 2^{16}/N\}$, $\gamma \in \{2^{-8}, 2^{-4}, 2^{-2}, 2^{0}, 2^{2}, 2^{4}, 2^{8}\}$, $\eta \in \{16.0, 8.0, 4.0, 2.0, 0.2, 0.02, 0.002, 0.0002\}$ where N is the number of data points. The coverage diameter δ of AVM is selected following the approach described in Section 9.2. For the budget size B in NOGD and Pegasos algorithm, and the feature dimension D in FOGD for each dataset, we use identical values to those used in Section 7.1.1 of Lu et al. (2015).

Results. The classification results, training and testing time costs are reported in Table 3. Overall, the batch algorithms achieve the highest classification accuracies whilst those of online algorithms are lower but fairly competitive. The online learning models, however, are much sparser, resulting in a substantial speed-up, in which the training time costs and model sizes of AVMs are smallest with orders of magnitude lower than those of the standard batch methods. More specifically, the LIBSVM outperforms the other approaches in most of datasets, on which its training phase finishes within the time limit (i.e., two hours), except for the *ijcnn1* data wherein its testing score is less accurate but very close to that of BSGD-M. The LLSVM achieves good results which are slightly lower than those of the state-of-the-art batch kernel algorithm. The method, however, does not support multiclass classification. These two batch algorithms – LIBSVM and LLSVM could not be trained within the allowable amount of time on large-scale datasets (e.g., *airlines*), thus are not scalable.

Furthermore, six online algorithms in general have significant advantages against the batch methods in computational efficiency, especially when running on large-scale datasets. Among these algorithms, the BSGD-M (Pegasos+merging) obtains the highest classification scores, but suffers from a high computational cost. This can be seen in almost all datasets, especially for the airlines dataset on which its learning exceeds the time limit. The slow training of BSGD-M is caused by the merging step with computational complexity $\mathcal{O}\left(B^2\right)$ (B is the budget size). By contrast, the BSGD-R (Pegasos+removal) runs faster than the merging approach, but suffers from very high inaccurate results due to its naive budget maintenance strategy, that simply discards the most redundant support vector which may contain important information.

In terms of predictive performance, our proposed methods outperform the recent advanced online learning algorithms – FOGD and NOGD in most scenarios. The AVM-based models are able to achieve slightly less accurate but fairly comparable results compared with those of the state-of-the-art LIBSVM algorithm. In terms of sparsity and speed, the AVMs are the fastest ones in the training and testing phases in all cases thanks to their remarkable smaller model sizes. The difference between the training speed of our AVMs and that of two approaches varies across datasets. The gap is more significant for datasets with higher dimensional feature spaces. This is expected because the procedure to compute random features for each data point of FOGD involves *sin* and *cos* operators which are costly. These facts indicate that our proposed online kernel learning algorithms are both efficient and effective in solving large-scale kernel classification problems. Thus we believe that the AVM is the fast alternative to the existing SVM solvers for large-scale classification tasks.

Finally, comparing two versions of AVMs, it can be seen that the discriminative performances of AVM with Logistic loss are better than those of AVM with Hinge loss in most of datasets. This is because the Logistic function is smoother than the Hinge function, whilst the Hinge loss encourages sparsity of the model. The AVM-Logit, however, contains additional exponential operators, resulting in worse training time.

Table 3: Classification performance of our AVMs and the baselines in batch mode. The notation $[\delta \mid S \mid B \mid D]$, next to the dataset name, denotes the diameter δ, the model size S of AVM-based models, the budget size B of budgeted algorithms, and the number of random features D of FOGD, respectively. The accuracy is reported in percent (%), the training time and testing time are in second. The best performance is in **bold**. It is noteworthy that the LLSVM does not support multiclass classification and we terminate all runs exceeding the limit of two hours, therefore some results are unavailable.

9.4 Online Classification

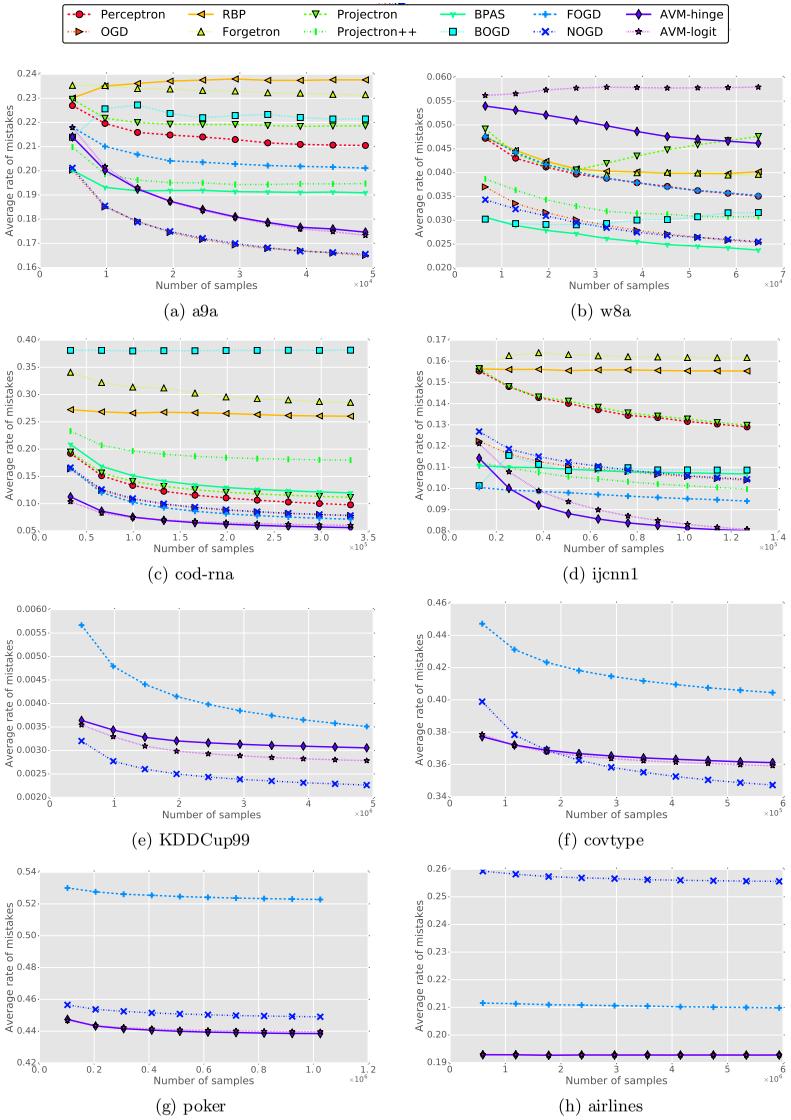
The next experiment investigates the performance of the AVMs in online classification task where individual data point continuously come turn-by-turn in a stream. Here we also use eight datasets and two versions of our approach: AVM with Hinge loss (AVM-Hinge) and AVM with Logistic loss (AVM-Logit) which are used in batch classification setting (cf. Section 9.3).

Baselines. We recruit the two widely-used algorithms – Perceptron and OGD for regular online kernel classification without budget maintenance and 8 state-of-the-art budget online kernel learning methods as follows:

- Perceptron: the kernelized variant without budget of Perceptron algorithm (Freund and Schapire, 1999);
- OGD: the kernelized variant without budget of online gradient descent (Kivinen et al., 2004);
- RBP: a budgeted Perceptron algorithm using random support vector removal strategy (Cavallanti et al., 2007);
- Forgetron: a kernel-based Perceptron maintaining a fixed budget by discarding oldest support vectors (Dekel et al., 2005);
- Projectron: a Projectron algorithm using the projection strategy (Orabona et al., 2009);
- Projectron++: the aggressive version of Projectron algorithm (Orabona et al., 2009);
- BPAS: a budgeted variant of Passive-Aggressive algorithm with simple SV removal strategy (Wang and Vucetic, 2010);
- BOGD: a budgeted variant of online gradient descent algorithm using simple SV removal strategy (Zhao et al., 2012);
- FOGD and NOGD: described in Section 9.3.

Hyperparameters setting. For each method learning on each dataset, we follow the same hyperparameter setting which is optimized in the batch classification task. For time efficiency, we only include the fast algorithms FOGD, NOGD and AVMs for the experiments on large-scale datasets. The other methods would exceed the time limit when running on such data.

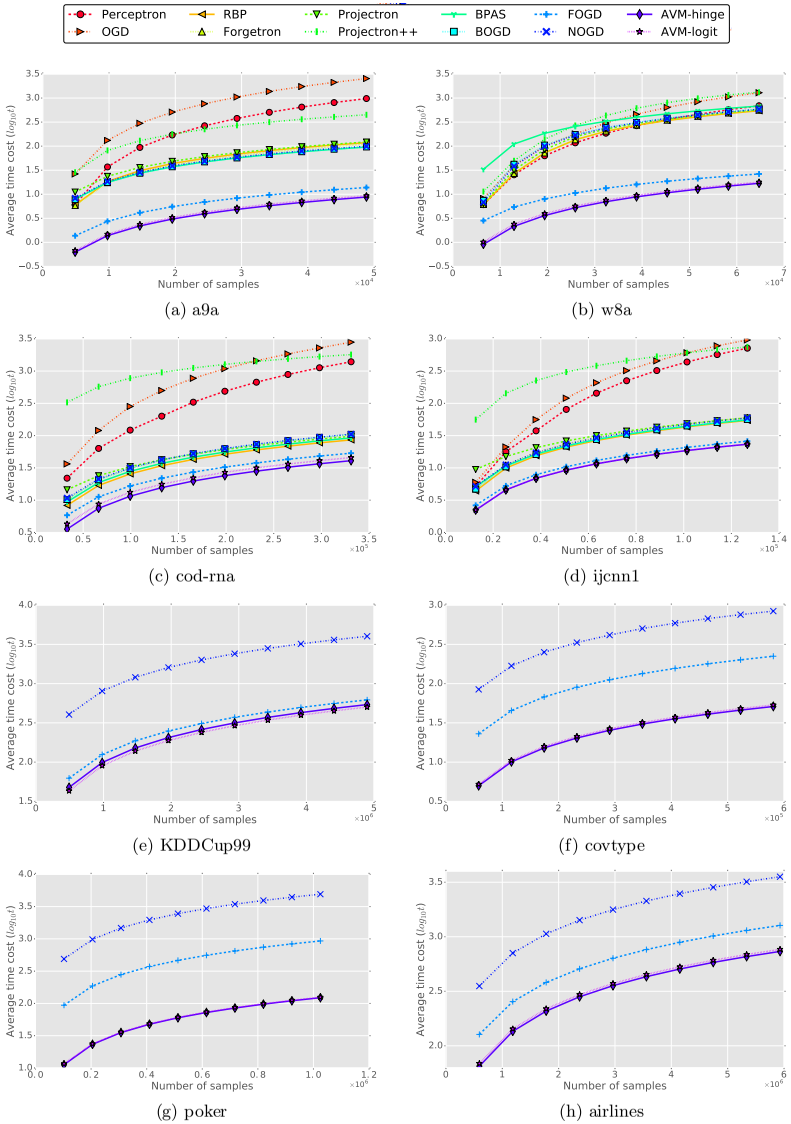
Results. Fig. 4 and Fig. 5 shows the relative performance convergence w.r.t classification error and computation cost of the AVMs in comparison with those of the baselines. Combining these two figures, we compare the average mistake rate and running time in Fig. 6. Table 4 reports the final average results in detailed numbers after the methods see all data samples. It is worthy to note that for the four biggest datasets (*KDDCup99*, *covtype*, *poker*, *airlines*) that consist of millions data points, we exclude the non-budgeted online learning algorithm because of their substantially expensive time costs. From these results, we can draw some observations as follows.



First of all, as can be seen from Fig. 4, there are three groups of algorithms that have different learning progresses in terms of classification mistake rate. The first group includes the BOGD, Projectron and Forgetron that have the error rates fluctuating at the beginning, but then being stable till the end. In the meantime, the rates of the models in the second group, including Perceptron, OGD, RBP, Projectron++ and BPAS, quickly saturate at a plateau after these methods see a few portions, i.e., one-tenth to two-tenth, of the data. By contrast, the last group includes the recent online learning approaches – FOGD, NOGD, and our proposed ones – AVM-Hinge, AVM-Logit, that regularly perform better as more data points come. Exceptionally, for the dataset *w8a*, the classification errors of the methods in the first group keep increasing after seeing four-tenth of the data, whilst those of the last group are unexpectedly worse.

Second, Fig. 6 plots average mistake rate against computational cost, which shows similar patterns as in the our first observation. In addition, it can be seen from Fig. 5 that all algorithms have normal learning pace in which the execution time is accumulated over the learning procedure. Only the Projectron++ is slow at the beginning but then performs faster after receiving more data.

According to final results summarized in Table 4, the budgeted online approaches show efficacies with substantially faster computation than the ones without budgets. This is more obvious for larger datasets wherein the execution time costs of our proposed models are several orders of magnitude lower than those of regular online algorithms. This is because the coverage scheme of AVMs impressively boost their model sparsities, e.g., using $\delta = 3$ resulting in 115 core points for dataset *KDDCup99* consisting of $4,408,589$ instances, and using $\delta = 1$ resulting in 388 core points for dataset *airlines* containing $5,336,471$ data samples.



For classification capability, the non-budgeted methods only surpass the budgeted ones for the smallest dataset, that is, the OGD obtains the best performance for *a9a* data. This again demonstrates the importance of exploring budget online kernel learning algorithms. Between the two non-budgeted algorithms, the OGD achieves considerably better error rates than the Perceptron. The method, however, must perform much more expensive updates, resulting in a significantly larger number of support vectors and significantly higher computational time costs. This represents the trade-off between classification accuracy and computational complexity of the OGD.

Furthermore, comparing the performance of different existing budgeted online kernel learning algorithms, the AVM-Hinge and AVM-Logit outperform others in both discriminative performance and computation efficiency for almost all datasets. In particular, the AVM-based methods achieve the best mistake rates – 5.61 ± 0.17, 8.01 ± 0.18, 43.85 ± 0.09, 19.28 ± 0.00 for the *cod-rna*, *ijcnn1*, *poker* and *airlines* data, that are, respectively, 27.5%, 17.5%, 2.4%, 8.8% lower than the error rates of the second best models – two recent approaches FOGD and NOGD. On the other hand, the computation costs of the AVMs are significantly lower with large margins of hundreds of percents for large-scale databases *covtype*, *poker*, and *airlines* as shown in Table 4.

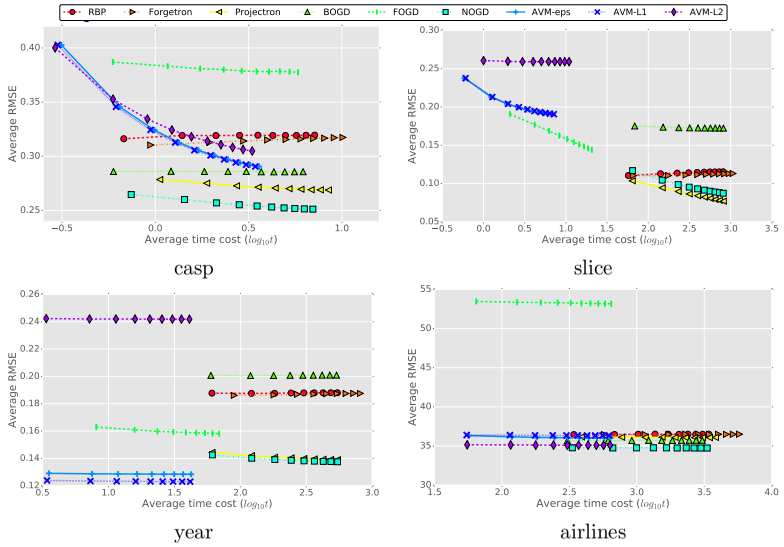

Figure 8: Average RMSE vs. time cost for online regression. The average time (seconds) is shown in the logarithm with base 10. (Best viewed in colors).

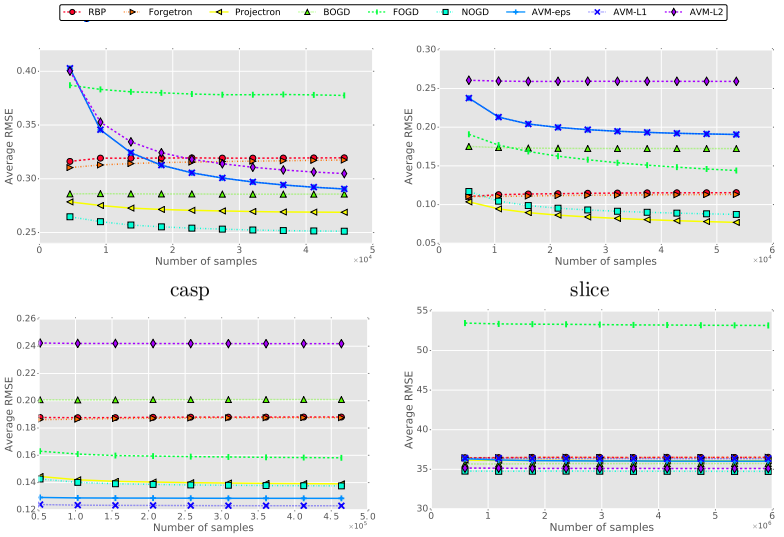
In all experiments, our proposed method produces the model sizes that are much smaller than the budget sizes of baseline methods. Thus we further investigate the performance of the budgeted baselines by varying the budget size B, and compare with our AVM with Hinge loss. Fig. 7 shows our analysis on two datasets *a9a* and *cod-rna*. It can be seen that the larger B helps model obtain better classification results, but hurts their running speed. For both datasets, the budgeted baselines with larger budget sizes still fail to beat the predictive performance of AVM. On the other hand, the baselines with smaller budget sizes run faster than the AVM on *cod-rna* dataset, but slower on *a9a* dataset.

Finally, two versions of AVMs demonstrate similar discriminative performances and computational complexities wherein the AVM-Logit is slightly slower due to the additional exponential operators as also seen in batch classification task. All aforementioned observations validate the effectiveness and efficiency of our proposed technique. Thus, we believe that our approximation machine is a promising technique for building scalable online kernel learning algorithms for large-scale classification tasks.

9.5 Online Regression

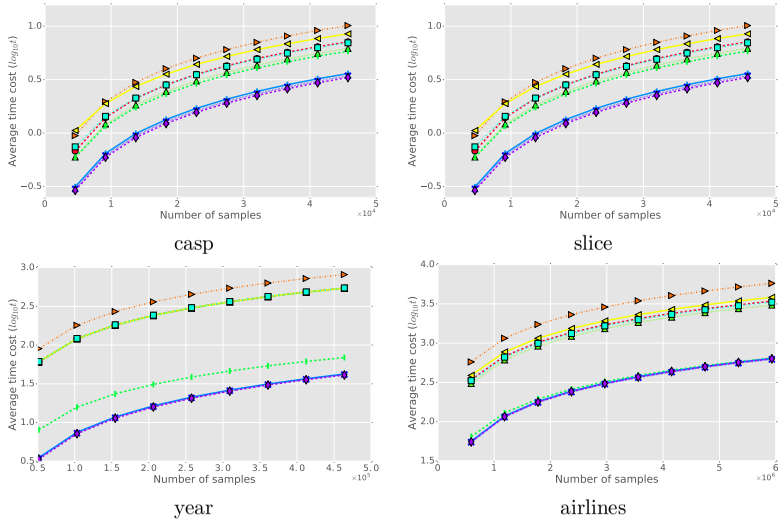
The last experiment addresses the online regression problem to evaluate the capabilities of our approach with three proposed loss functions – ℓ_1,ℓ_2 and ε-insensitive losses as described in Section 7. Incorporating these loss functions creates three versions: AVM-ε, AVM-ℓ_1 and AVM-ℓ_2. We use four datasets: *casp*, *slice*, *year* and *airlines* (delay minutes) with a wide

range of sizes for this task. We recruit six baselines: RBP, Forgetron, Projectron, BOGD, FOGD and NOGD (cf. more detailed description in Section 9.4).



Hyperparameters setting. We adopt the same hyperparameter searching procedure for batch classification task as in Section 9.3. Furthermore, for the budget size B and the feature dimension D in FOGD, we follow the same strategy used in Section 7.1.1 of Lu et al. (2015). More specifically, these hyperparameters are separately set for different datasets as reported in Table 5. They are chosen such that they are roughly proportional to the number of support vectors produced by the batch SVM algorithm in LIBSVM running on a small subset. The aim is to achieve competitive accuracy using a relatively larger budget size for tackling more challenging regression tasks.

Results. Fig. 9a and Fig. 9b shows the relative performance convergence w.r.t regression error (root mean square root - RMSE) and computation cost (seconds) of the AVMs in comparison with those of the baselines. Combining these two figures, we compare the average error and running time in Fig. 8. Table 5 reports the final average results in detailed numbers after the methods traverse all data samples. From these results, we can draw some observations as follows.



First of all, as can be seen from Fig. 9a, there are several different learning behaviors w.r.t regression loss, of the methods training on individual datasets. All algorithms, in general, reach their regression error plateaus very quickly as observed in the datasets *year* and *airlines* where they converge at certain points from the initiation of the learning. On the other hand, for *casp* and *slice* databases, the AVM-based models regularly obtain better performance, that is, their average RMSE scores keep reducing when receiving more data, except in *slice* data, the regression performance of AVM-ℓ_2 are almost unchanged during the learning. Note that, for these two datasets, the learning curve of AVM-ε coincides, thus is overplotted by that of AVM-ℓ_1, resulting in its no-show in the figure. Interestingly, the errors of RBP and Forgetron slightly increase throughout their online learning in these two cases.

Second, Fig. 8 plots average error against computational cost, which shows similar learning behaviors as in the our first observation. The computational cost progresses are simple and more obvious to comprehend than the regression progresses. As illustrated in Fig. 9b, all algorithms have nicely plausible execution time curves in which the time is accumulated over the learning procedure.

According to final results summarized in Table 5, our proposed models enjoy a significant advantage in computational efficacy whilst achieve better (for *year* dataset) or competitive regression results with other methods. The AVM, again, secures the best performance in terms of model sparsity. Among the baselines, the FOGD is the fastest, that is, its time costs can be considered to compare with those of our methods, but its regression performances are worse. The remaining algorithms usually obtain better results, but is traded off by the sacrifice of scalability. This, once again, verifies the effectiveness and efficiency of our proposed techniques. We believe that the AVM is a promising machine to perform online regression task for large-scale datasets.

(a) The average RMSE as a function of the number of samples seen by the models.

(b) The average time costs (seconds in logarithm of 10) as a function of the number of samples seen by the models.

Figure 9: Convergence evaluation of online regresion. (Best viewed in colors).

Finally, comparing the capability of three AVM's variants, all models demonstrate similar computational complexities wherein the AVM-ℓ_2 is slightly faster due to its simpler operator in computing the gradient as derived in Section 7. However, its regression errors are higher than two other methods – AVM-ε and AVM-ℓ_1.

10. Conclusion

In this paper, we have proposed Approximation Vector Machine (AVM) for large-scale online learning. The AVM is theoretically proven to have bounded and sparse model size while not hurting the predictive performance. We have validated our proposed method on several benchmark datasets. The experimental results show that the proposed AVM obtains a comparable predictive performance while simultaneously achieving an impressive model size and a computational speed-up compared with those of the baselines. Our future works are to apply AVM to the context of semi-supervised learning, anomaly detection, and support vector clustering.

11. Proofs Regarding δ-Coverage

Proof of Theorem 4

Assume that $\left\|x - x^{'}\right\| \leq \delta$, then we have

$$\begin{aligned}\left\|\Phi(x) - \Phi\left(x^{'}\right)\right\|^2 &= K(x,x) + K\left(x^{'},x^{'}\right) - 2K\left(x,x^{'}\right) = 2\left(1 - k\left(\left\|x - x^{'}\right\|^2\right)\right) \\ &\leq 2\left(1 - k\left(\delta^2\right)\right) = \delta_\Phi^2\end{aligned}$$

Furthermore, we have

$$\lim_{\delta\to 0}\delta_\Phi = 2^{1/2}\lim_{\delta\to 0}\left(1 - k\left(\delta^2\right)\right)^{1/2} = 2^{1/2}\left(1 - k(0)\right)^{1/2} = 0$$

Finally, since Gaussian kernel is a special radial kernel with $k(t) = \exp(-\gamma t)$, we obtain the final conclusion. ■

Proof of Theorem 19

Since the proof is similar for the hyperrectangle cell case, we present the proof for the hypersphere case. Let us consider the open coverage $\mathcal{U} = \left\{\mathcal{B}\left(z, \frac{\delta}{2}\right)\right\}_{z\in\mathcal{X}}$. From the compactness of the data domain $\mathcal{X}$, it apparent that from $\mathcal{U}$ we must be able to extract a finite subcoverage of size m, that is, $\mathcal{U}_m = \left\{\mathcal{B}\left(z_i, \frac{\delta}{2}\right)\right\}_{i=1}^m \subset \mathcal{U}$. From the construction of the coverage $\mathcal{P}$ in Algorithm 3, we know that

$$\|c_i - c_j\| > \delta/2 \text{ if } i \neq j$$

Hence, each open sphere in the finite coverage $\mathcal{U}_m$ is able to contain at most one core point of $\mathcal{P}$. It means that the cardinality of $\mathcal{P}$ must be less than or equal m, that is, $|\mathcal{P}| \leq m$. ■

Proofs Regarding Convergence Analysis

Given a finite δ-coverage $\mathcal{P} = (P_i)_{i\in I}$ with the core set $\mathcal{C} = (c_i)_{i\in I}$, when receiving an incoming instance (x_t, y_t) we approximate (x_t, y_t) by (c_{i_t}, y_t) with c_{i_t} is a core point whose cell contains x_t, that is, $x_t \in P_{i_t}$. We use a Bernoulli random variable Z_t to control if the approximation is performed or not, that is, $Z_t = 1$ indicates the approximation is performed.

Let us define $g_t = \lambda \mathbf{w}_t + l^{'}(\mathbf{w}_t; x_t, y_t) = \lambda \mathbf{w}_t + \alpha_t \Phi(x_t)$. We have the following

$$h_t = g_t + Z_t \Delta_t$$

where $\Delta_t = \alpha_t (\Phi(c_{i_t}) - \Phi(x_t))$.

The update rule becomes

$$\mathbf{w}_{t+1} = \prod_S (\mathbf{w}_t - \eta_t h_t)$$

where $S = \mathbb{R}^D$ (i.e., the feature space) or $\mathcal{B}\left(\mathbf{0}, y_{\max}\lambda^{-1/2}\right)$.

Lemma 21. *The following statements hold*

i) There exist two positive constants P and M such that $\mathbb{E}\left[\|\mathbf{w}_t\|^2\right] \le P^2$ and $\mathbb{E}\left[\alpha_t^2\right] \le M$ for all t.

ii) $\mathbb{E}\left[\left\|l^{'}(\mathbf{w}_t; x_t, y_t)\right\|^2\right] \le L = \left(A\sqrt{P} + B\right)^2$ for all t.

iii) $\mathbb{E}\left[\|g_t\|^2\right] \le G = \left(\lambda P + A\sqrt{P} + B\right)^2$ for all t.

iv) $\mathbb{E}\left[\|h_t\|^2\right] \le H = \left(\sqrt{G} + \delta_\Phi\left(A\sqrt{P} + B\right)\right)^2$ for all t.

Proof i) We prove by induction that $\mathbb{E}\left[\|\mathbf{w}_t\|^2\right] \le P^2$ where $P = \left(\frac{(\delta_\Phi+1)A + \sqrt{(\delta_\Phi+1)^2A^2 + 4B\lambda(\delta_\Phi+1)}}{2\lambda}\right)^2$ for all t. Assume that the claim is holding for t, using Minkowski inequality, we have

$$\begin{aligned}
\sqrt{\mathbb{E}\left[\|\mathbf{w}_{t+1}\|^2\right]} &\le \sqrt{\mathbb{E}\left[\left\|\prod_S (\mathbf{w}_t - \eta_t h_t)\right\|^2\right]} \le \sqrt{\mathbb{E}\left[\|\mathbf{w}_t - \eta_t h_t\|^2\right]} \\
&\le \frac{t-1}{t}\sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|^2\right]} + \eta_t\sqrt{\mathbb{E}\left[\|l^{'}(\mathbf{w}_t; x_t, y_t)\|^2\right]} + \eta_t\sqrt{\mathbb{E}\left[\|\Delta_t\|^2\right]} \\
&\le \frac{t-1}{t}\sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|^2\right]} + \frac{A\sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|\right]} + B}{\lambda t} + \frac{\delta_\Phi\sqrt{\mathbb{E}\left[\alpha_t^2\right]}}{\lambda t} \\
&\le \frac{(t-1)P}{t} + \frac{A\sqrt{P} + B}{\lambda t} + \frac{\delta_\Phi\sqrt{\mathbb{E}\left[\|l^{'}(\mathbf{w}_t; x_t, y_t)\|^2\right]}}{\lambda t} \\
&\le \frac{(t-1)P}{t} + \frac{(\delta_\Phi+1)\left(A\sqrt{P} + B\right)}{\lambda t} = P
\end{aligned}$$

Note that we have used $\left\|l^{'}(\mathbf{w}_t; x_t, y_t)\right\|^2 = \alpha_t^2 K(x_t, x_t) = \alpha_t^2$, $\mathbb{E}\left[\|\mathbf{w}_t\|\right] \le \sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|^2\right]} \le P$, and $u = P^{1/2} = \frac{(\delta_\Phi+1)A + \sqrt{(\delta_\Phi+1)^2A^2 + 4B\lambda(\delta_\Phi+1)}}{2\lambda}$ is the solution of the quadratic equation

$$u^2 - \frac{(\delta_\Phi+1)Au}{\lambda} - \frac{(\delta_\Phi+1)B}{\lambda} = 0$$

The proof of $\mathbb{E}\left[\alpha_t^2\right] \le M$ is trivial for the case of Hinge, ℓ_1, Logistic, $\varepsilon-$insensitive losses. In these cases, we simply choose $M = \max(y_{\max}, 1)^2$. We only need to consider the ℓ_2-loss case. In particular, we have

$$\begin{aligned}
\alpha_t^2 &= \left(\mathbf{w}_t^\mathsf{T}\Phi(x_t) - y_t\right)^2 \le 2\left(\left(\mathbf{w}_t^\mathsf{T}\Phi(x_t)\right)^2 + y_{\max}^2\right) \\
&\le 2\left(\|\mathbf{w}_t\|^2\|\Phi(x_t)\|^2 + y_{\max}^2\right) \le 2\left(\|\mathbf{w}_t\|^2 + y_{\max}^2\right)
\end{aligned}$$

$$\mathbb{E}\left[\alpha_t^2\right] \le 2\left(P^2 + y_{\max}^2\right) = M$$

ii) We have the following

$$\sqrt{\mathbb{E}\left[\|l^{'}(\mathbf{w}_t; x_t, y_t)\|^2\right]} \le \sqrt{\mathbb{E}\left[\left(A\|\mathbf{w}_t\|^{1/2} + B\right)^2\right]} \le A\sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|\right]} + B \le A\sqrt{P} + B$$

Note that we have used the inequality $\mathbb{E}\left[\|\mathbf{w}_t\|\right] \le \sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|^2\right]} \le P$.

iii) Using Minkowski inequality, we yield

$$\sqrt{\mathbb{E}\left[\|g_t\|^2\right]} \le \lambda\sqrt{\mathbb{E}\left[\|\mathbf{w}_t\|^2\right]} + \sqrt{\mathbb{E}\left[\|l^{'}(\mathbf{w}_t; x_t, y_t)\|^2\right]} \le \lambda P + A\sqrt{P} + B$$

iv) We have the following

$$\begin{aligned}
\sqrt{\mathbb{E}\left[\|h_t\|^2\right]} &\le \sqrt{\mathbb{E}\left[\|g_t\|^2\right]} + \delta_\Phi\sqrt{\mathbb{E}\left[\alpha_t^2\right]} \\
&\le \sqrt{G} + \delta_\Phi\sqrt{\mathbb{E}\left[\|l^{'}(\mathbf{w}_t; x_t, y_t)\|^2\right]} = \sqrt{G} + \delta_\Phi\left(A\sqrt{P} + B\right)
\end{aligned}$$

■

Lemma 22. *There exists a positive constant W such that $\mathbb{E}\left[\|\mathbf{w}_t - \mathbf{w}^*\|^2\right] \le W$ for all t.*

Proof We first remind the definitions of the relevant quantities

$$\begin{aligned}
&g_t = \lambda\mathbf{w}_t + l^{'}(\mathbf{w}_t; x_t, y_t) = \lambda\mathbf{w}_t + \alpha_t\Phi(x_t) \\
&h_t = g_t + Z_t\Delta_t \text{ where } \Delta_t = \alpha_t(\Phi(c_{i_t}) - \Phi(x_t))
\end{aligned}$$

We now prove by induction in t. We derive as follows

$$\begin{aligned}\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2 &= \left\|\prod_S(\mathbf{w}_t-\eta_t h_t)-\mathbf{w}^*\right\|^2 \leq \|\mathbf{w}_t-\eta_t h_t-\mathbf{w}^*\|^2\\ &= \|\mathbf{w}_t-\mathbf{w}^*\|+\eta_t^2\|h_t\|^2-2\eta_t\langle\mathbf{w}_t-\mathbf{w}^*,g_t+Z_t\Delta_t\rangle\end{aligned}$$

where $S=\mathbb{R}^D$ or $\mathcal{B}\left(\mathbf{0},y_{\max}\lambda^{-1/2}\right)$.

Taking conditional expectation w.r.t $\mathbf{w}_t$, we gain

$$\begin{aligned}\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right] \leq& \mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]\\ &+\eta_t^2\mathbb{E}\left[\|h_t\|^2\right]-2\eta_t\left\langle\mathbf{w}_t-\mathbf{w}^*,f'(\mathbf{w}_t)\right\rangle-2\eta_t\langle\mathbf{w}_t-\mathbf{w}^*,Z_t\Delta_t\rangle\\ \leq& \mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]-2\eta_t\lambda\|\mathbf{w}_t-\mathbf{w}^*\|^2+\eta_t^2\mathbb{E}\left[\|h_t\|^2\right]-2\eta_t\langle\mathbf{w}_t-\mathbf{w}^*,Z_t\Delta_t\rangle\end{aligned}$$

Here we note that we have used $\left\langle\mathbf{w}_t-\mathbf{w}^*,f'(\mathbf{w}_t)\right\rangle\geq\lambda\|\mathbf{w}_t-\mathbf{w}^*\|^2$. It comes from the following derivation

$$f(\mathbf{w}^*)-f(\mathbf{w}_t)\geq\left\langle f'(\mathbf{w}_t),\mathbf{w}^*-\mathbf{w}_t\right\rangle+\frac{\lambda}{2}\|\mathbf{w}_t-\mathbf{w}^*\|^2$$

$$\begin{aligned}\left\langle f'(\mathbf{w}_t),\mathbf{w}_t-\mathbf{w}^*\right\rangle &\geq f(\mathbf{w}_t)-f(\mathbf{w}^*)+\frac{\lambda}{2}\|\mathbf{w}_t-\mathbf{w}^*\|^2 \geq \left\langle f'(\mathbf{w}^*),\mathbf{w}_t-\mathbf{w}^*\right\rangle+\lambda\|\mathbf{w}_t-\mathbf{w}^*\|^2\\ &\geq\lambda\|\mathbf{w}_t-\mathbf{w}^*\|^2 \qquad \text{thanks to } \left\langle f'(\mathbf{w}^*),\mathbf{w}_t-\mathbf{w}^*\right\rangle\geq 0\end{aligned}$$

Taking expectation again, we gain

$$\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]\leq\frac{t-2}{t}\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]+\frac{H}{\lambda^2t^2}+\frac{2W^{1/2}M^{1/2}\delta_\Phi}{\lambda t}$$

Choosing $W=\left(\frac{M^{1/2}\delta_\phi+\left(M\delta_\phi^2+2H\right)^{1/2}}{2\lambda}\right)^2$, we gain if $\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]\leq W$ then $\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]\leq W$. The reason is that $W=\left(\frac{M^{1/2}\delta_\phi+\left(M\delta_\phi^2+2H\right)^{1/2}}{2\lambda}\right)^2$ is the solution of the equation

$$W=\frac{t-2}{t}W+\frac{H}{\lambda^2t}+\frac{2W^{1/2}M^{1/2}\delta_\Phi}{\lambda t} \text{ or } 2W-\frac{2W^{1/2}M^{1/2}\delta_\Phi}{\lambda}-\frac{H}{\lambda^2}=0$$

. Hence, if $\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]\leq W$, we arrive at

$$\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]\leq\frac{t-2}{t}W+\frac{H}{\lambda^2t}+\frac{2W^{1/2}M^{1/2}\delta_\Phi}{\lambda t}=W$$

■

We now show the proof of Theorem 5.

Proof of Theorem 5

We first remind the definitions of the relevant quantities

$$\begin{aligned}g_t &= \lambda\mathbf{w}_t+l'(\mathbf{w}_t;x_t,y_t)=\lambda\mathbf{w}_t+\alpha_t\Phi(x_t)\\ h_t &= g_t+Z_t\Delta_t \text{ where } \Delta_t=\alpha_t\left(\Phi(c_{i_t})-\Phi(x_t)\right)\end{aligned}$$

We then derive as follows

$$\begin{aligned}\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2 &= \left\|\prod_S(\mathbf{w}_t-\eta_t h_t)-\mathbf{w}^*\right\|^2 \leq \|\mathbf{w}_t-\eta_t h_t-\mathbf{w}^*\|^2\\ &= \|\mathbf{w}_t-\mathbf{w}^*\|+\eta_t^2\|h_t\|^2-2\eta_t\langle\mathbf{w}_t-\mathbf{w}^*,g_t+Z_t\Delta_t\rangle\end{aligned}$$

where $S=\mathbb{R}^D$ or $\mathcal{B}\left(\mathbf{0},y_{\max}\lambda^{-1/2}\right)$.

$$\langle\mathbf{w}_t-\mathbf{w}^*,g_t\rangle\leq\frac{\|\mathbf{w}_t-\mathbf{w}^*\|^2-\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2}{2\eta_t}+\frac{\eta_t}{2}\|h_t\|^2-\langle\mathbf{w}_t-\mathbf{w}^*,Z_t\Delta_t\rangle$$

Taking conditional expectation w.r.t $\mathbf{w}_t$, we obtain

$$\begin{aligned}\left\langle\mathbf{w}_t-\mathbf{w}^*,f'(\mathbf{w}_t)\right\rangle \leq& \frac{\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]-\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]}{2\eta_t}\\ &+\frac{\eta_t}{2}\mathbb{E}\left[\|h_t\|^2\right]-\langle\mathbf{w}_t-\mathbf{w}^*,\mathbb{E}\left[Z_t\Delta_t\right]\rangle\end{aligned}$$

$$\begin{aligned}f(\mathbf{w}_t)-f(\mathbf{w}^*)+\frac{\lambda}{2}\|\mathbf{w}_t-\mathbf{w}^*\|^2 \leq& \frac{\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]-\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]}{2\eta_t}\\ &+\frac{\eta_t}{2}\mathbb{E}\left[\|h_t\|^2\right]-\langle\mathbf{w}_t-\mathbf{w}^*,\mathbb{E}\left[Z_t\Delta_t\right]\rangle\end{aligned}$$

Taking expectation again, we achieve

$$\begin{aligned}\mathbb{E}\left[f(\mathbf{w}_t)-f(\mathbf{w}^*)\right] \leq& \frac{\lambda}{2}(t-1)\mathbb{E}\left[\|\mathbf{w}_t-\mathbf{w}^*\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\|\mathbf{w}_{t+1}-\mathbf{w}^*\|^2\right]\\ &+\frac{\eta_t}{2}\mathbb{E}\left[\|h_t\|^2\right]-\mathbb{E}\left[\langle\mathbf{w}_t-\mathbf{w}^*,Z_t\Delta_t\rangle\right]\end{aligned}$$

i) If Z_t is independent with $\mathbf{w}_t$, we derive as

$$\begin{aligned}\mathbb{E}\left[f\left(\mathbf{w}_t\right)-f\left(\mathbf{w}^*\right)\right] &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]\\ &+\frac{\eta_t}{2}\mathbb{E}\left[\left\|h_t\right\|^2\right]-\mathbb{E}\left[\left\langle Z_t\left(\mathbf{w}_t-\mathbf{w}^*\right),\Delta_t\right\rangle\right]\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]+\frac{\eta_t}{2}\mathbb{E}\left[\left\|h_t\right\|^2\right]\\ &+\mathbb{E}\left[Z_t^2\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]+\frac{\eta_t}{2}\mathbb{E}\left[\left\|h_t\right\|^2\right]\\ &+\mathbb{E}\left[Z_t^2\right]^{1/2}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]+\frac{\eta_t}{2}H \qquad (5)\\ &+\mathbb{P}\left(Z_t=1\right)^{1/2}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}\end{aligned}$$

Taking sum over $1,2,\ldots,T$ and using the inequalities in Lemmas 21 and 22, we yield

$$\sum_{t=1}^{T}\mathbb{E}\left[f\left(\mathbf{w}_t\right)\right]-Tf\left(\mathbf{w}^*\right)\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}\mathbb{P}\left(Z_t=1\right)^{1/2}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \qquad (6)$$

$$T\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right]\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}\mathbb{P}\left(Z_t=1\right)^{1/2}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}$$

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right]\leq\frac{H\left(\log\left(T\right)+1\right)}{2\lambda T}+\frac{\delta_\Phi M^{1/2}W^{1/2}}{T}\sum_{t=1}^{T}\mathbb{P}\left(Z_t=1\right)^{1/2}$$

ii) If Z_t is independent with $\mathbf{w}_t$ and (x_t,y_t), we derive as

$$\begin{aligned}\mathbb{E}\left[f\left(\mathbf{w}_t\right)-f\left(\mathbf{w}^*\right)\right] &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]\\ &+\frac{\eta_t}{2}H-\mathbb{E}\left[Z_t\left\langle\mathbf{w}_t-\mathbf{w}^*,\Delta_t\right\rangle\right]\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]\\ &+\frac{\eta_t}{2}H-\mathbb{E}\left[Z_t\right]\mathbb{E}\left[\left\langle\mathbf{w}_t-\mathbf{w}^*,\Delta_t\right\rangle\right]\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]+\frac{\eta_t}{2}H \qquad (7)\\ &+\mathbb{P}\left(Z_t=1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}\end{aligned}$$

Taking sum over $1,2,\ldots,T$ and using the inequalities in Lemmas 21 and 22, we yield

$$\sum_{t=1}^{T}\mathbb{E}\left[f\left(\mathbf{w}_t\right)\right]-Tf\left(\mathbf{w}^*\right)\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}P\left(Z_t=1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \qquad (8)$$

$$T\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right]\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}P\left(Z_t=1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}$$

$$\begin{aligned}\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right] &\leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T}+\frac{\delta_\Phi M^{1/2}W^{1/2}}{T}\sum_{t=1}^{T}P\left(Z_t=1\right)\\ &\leq \frac{H\left(\log\left(T\right)+1\right)}{2\lambda T}+\delta_\Phi M^{1/2}W^{1/2}\end{aligned}$$

iii) In general, we derive as

$$\begin{aligned}\mathbb{E}\left[f\left(\mathbf{w}_t\right)-f\left(\mathbf{w}^*\right)\right] &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right]\\ &+\frac{\eta_t}{2}H-\mathbb{E}\left[Z_t\left\langle\mathbf{w}_t-\mathbf{w}^*,\Delta_t\right\rangle\right]\\ &\leq \frac{\lambda}{2}\left(t-1\right)\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]-\frac{\lambda}{2}t\mathbb{E}\left[\left\|\mathbf{w}_{t+1}-\mathbf{w}^*\right\|^2\right] \qquad (9)\\ &+\frac{\eta_t}{2}H+\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}\end{aligned}$$

Taking sum over $1,2,\ldots,T$ and using the inequalities in Lemmas 21 and 22, we yield

$$\sum_{t=1}^{T}\mathbb{E}\left[f\left(\mathbf{w}_t\right)\right]-Tf\left(\mathbf{w}^*\right)\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \qquad (10)$$

$$T\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right]\leq\frac{H}{2\lambda}\sum_{t=1}^{T}\frac{1}{t}+\sum_{t=1}^{T}\mathbb{E}\left[\left\|\mathbf{w}_t-\mathbf{w}^*\right\|^2\right]^{1/2}\mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2}$$

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T\right)-f\left(\mathbf{w}^*\right)\right]\leq\frac{H\left(\log\left(T\right)+1\right)}{2\lambda T}+\delta_\Phi M^{1/2}W^{1/2}$$

■

Proof of Theorem 15

Let us denote the model size, i.e., the number of vectors in support set, after the iteration t by S_t. We also define N_t by the binary random variable which specifies whether the incoming instance (x_t,y_t) locates in a new cell of the coverage, that is, $N_t=1$ indicating the current cell P_{i_t} is a new cell. We assume that Z_t is independent with (x_t,y_t) and so does with N_t. Since a new instance is added to the support set if either a new cell is discovered or the old cell is found but approximation is not performed, we reach the following

$$S_t\leq S_{t-1}+N_t+\left(1-Z_t\right)\left(1-N_t\right)$$

Taking expectation, we obtain

$$\begin{aligned}\mathbb{E}[S_t] &\leq \mathbb{E}[S_{t-1}] + \mathbb{E}[N_t] + (1 - \mathbb{E}[Z_t])(1 - \mathbb{E}[N_t]) \\ &\leq \mathbb{E}[S_{t-1}] + \mathbb{E}[N_t] + (1 - p_t)(1 - \mathbb{E}[N_t]) \\ &\leq \mathbb{E}[S_{t-1}] + \mathbb{E}[N_t] + q_t(1 - \mathbb{E}[N_t])\end{aligned}$$

$$\mathbb{E}[S_t] - \mathbb{E}[S_{t-1}] \leq \mathbb{E}[N_t] + q_t(1 - \mathbb{E}[N_t])$$

Summing over the above when $t = 1, \ldots, T$, we have

$$\begin{aligned}\mathbb{E}[S_T] &\leq \sum_{t=1}^{T} \mathbb{E}[N_t] + \sum_{t=1}^{T} q_t(1 - \mathbb{E}[N_t]) = \sum_{t=1}^{T} q_t + \sum_{t=1}^{T} p_t \mathbb{E}[N_t] \\ &\leq \sum_{t=1}^{T} q_t + \sum_{t=1}^{T} \mathbb{E}[N_t] \leq \sum_{t=1}^{T} q_t + \mathbb{E}[M_T] \qquad (11)\end{aligned}$$

where we have denoted $\mathbb{P}(Z_t = 1) = p_t$, $\mathbb{P}(Z_t = 0) = q_t$, and $M_T = \sum_{t=1}^{T} N_t$ indicates the number of cells discovered so far.

We consider some specific cases and investigate the model size $\mathbb{E}[S_T]$ in these cases.

i) $p_t = \mathbb{P}(Z_t = 1) = 1, \forall t$, that is, we always do approximation. From Eq. (11), we obtain

$$\mathbb{E}[S_T] \leq \mathbb{E}[M_T] \leq |\mathcal{P}|$$

ii) $p_t = \mathbb{P}(Z_t = 1) = \max\left(0, 1 - \frac{\beta}{t}\right), \forall t$. It follows that

$$q_t = 1 - p_t \leq 1 - \left(1 - \frac{\beta}{t}\right) = \frac{\beta}{t}$$

From Eq. (11), we gain

$$\begin{aligned}\mathbb{E}[S_T] &\leq \beta \sum_{t=1}^{T} \frac{1}{t} + \mathbb{E}[M_T] \leq \beta\left(1 + \int_1^T \frac{1}{t} dt\right) + \mathbb{E}[M_T] \\ &\leq \beta(\log T + 1) + \mathbb{E}[M_T]\end{aligned}$$

iii) $p_t = \mathbb{P}(Z_t = 1) = \max\left(0, 1 - \frac{\beta}{t^\rho}\right), \forall t$ where $0 < \rho < 1$. It follows that

$$q_t = 1 - p_t \leq 1 - \left(1 - \frac{\beta}{t^\rho}\right) = \frac{\beta}{t^\rho}$$

From Eq. (11), we gain

$$\mathbb{E}[S_T] \leq \beta \sum_{t=1}^{T} \frac{1}{t^\rho} + \mathbb{E}[M_T] \leq \beta\left(1 + \int_1^T t^{-\rho} dt\right) + \mathbb{E}[M_T] \leq \frac{\beta T^{1-\rho}}{1-\rho} + \mathbb{E}[M_T]$$

iv) $p_t = \mathbb{P}(Z_t = 1) = \max\left(0, 1 - \frac{\beta}{t^\rho}\right), \forall t$ where $\rho > 1$. It follows that

$$q_t = 1 - p_t \leq 1 - \left(1 - \frac{\beta}{t^\rho}\right) = \frac{\beta}{t^\rho}$$

From Eq. (11), we gain

$$\mathbb{E}[S_T] \leq \beta \sum_{t=1}^{T} \frac{1}{t^\rho} + \mathbb{E}[M_T] \leq \beta\zeta(\rho) + \mathbb{E}[M_T] \leq \beta\zeta(\rho) + |\mathcal{P}|$$

where $\zeta(.)$ is ζ- Riemann function defined by the integral $\zeta(s) = \frac{1}{\Gamma(s)} \int_0^{+\infty} \frac{t^{s-1}}{e^s - 1} dt$. ■

We now show the proof of Theorem 8. To realize this proof, we use the famous inequality, namely Hoeffding which for completeness we state below.

Theorem. *(Hoeffding inequality) Let the independent variables $X_1, \ldots, X_n$ where $a_i \leq X_i \leq b_i$ for each $i \in [n]$. Let $S = \sum_{i=1}^{n} X_i$ and $\Delta_i = b_i - a_i$. The following hold*

i) $\mathbb{P}(S - \mathbb{E}[S] > \varepsilon) \leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^{n} \Delta_i^2}\right)$.

ii) $\mathbb{P}(|S - \mathbb{E}[S]| > \varepsilon) \leq 2\exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^{n} \Delta_i^2}\right)$

Proof of Theorem 8

From Eqs. (6, 8, 10), we achieve

$$\frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[f(\mathbf{w}_t)] - f(\mathbf{w}^*) \leq \frac{H(\log(T) + 1)}{2\lambda T} + d_T$$

Let us denote $X = f(\mathbf{w}_r) - f(\mathbf{w}^*)$, where r is uniformly sampled from $\{1, 2, \ldots, T\}$. We have

$$\mathbb{E}_r[X] = \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[f(\mathbf{w}_t)] - f(\mathbf{w}^*) \leq \frac{H(\log(T) + 1)}{2\lambda T} + d_T$$

It follows that

$$\mathbb{E}[X] = \mathbb{E}_{(x_t, y_t)_{t=1}^{T}}[\mathbb{E}_r[X]] \leq \frac{H(\log(T) + 1)}{2\lambda T} + d_T$$

Let us denote $\Delta_T = \max_{1 \leq t \leq T} (f(\mathbf{w}_t) - f(\mathbf{w}^*))$ which implies that $0 < f(\mathbf{w}_r) - f(\mathbf{w}^*) < \Delta_T$. Applying Hoeffding inequality for the random variable X, we gain

$$\mathbb{P}(X - \mathbb{E}[X] > \varepsilon) \leq \exp\left(-\frac{2\varepsilon^2}{\Delta_T^2}\right)$$

$$\mathbb{P}\left(X - \frac{H(\log(T) + 1)}{2\lambda T} - d_T > \varepsilon\right) \leq \exp\left(-\frac{2\varepsilon^2}{\Delta_T^2}\right)$$

$$\mathbb{P}\left(X \leq \frac{H(\log(T) + 1)}{2\lambda T} + d_T + \varepsilon\right) > 1 - \exp\left(-\frac{2\varepsilon^2}{\Delta_T^2}\right)$$

Choosing $\delta = \exp\left(-\frac{2\varepsilon^2}{\Delta_T^2}\right)$ or $\varepsilon = \Delta_T \sqrt{\frac{1}{2} \log \frac{1}{\delta}}$, then with the probability at least $1 - \delta$, we have

$$f(\mathbf{w}_r) - f(\mathbf{w}^*) \leq \frac{H(\log(T) + 1)}{2\lambda T} + d_T + \Delta_T \sqrt{\frac{1}{2} \log \frac{1}{\delta}}$$

■

Proof of Theorem 9

We denote $W_T^\alpha = \mathbb{E}\left[\left\|\mathbf{w}_{(1-\alpha)T+1} - \mathbf{w}^*\right\|^2\right]$. Our proof proceeds as follows.

i) If Z_t is independent with $\mathbf{w}_t$, taking sum in Eq. (5) when $t = (1-\alpha)T+1, \ldots, T$, we gain

$$\begin{aligned}\sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[f\left(\mathbf{w}_t\right)\right] - \alpha T f\left(\mathbf{w}^*\right) \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H}{2\lambda} \sum_{t=(1-\alpha)T+1}^{T} \frac{1}{t} \\ & + \sum_{t=1}^{T} \mathbb{P}\left(Z_t = 1\right)^{1/2} \mathbb{E}\left[\left\|\mathbf{w}_t - \mathbf{w}^*\right\|^2\right]^{1/2} \mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \quad (12) \\ \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda} \\ & + \delta_\Phi M^{1/2} W^{1/2} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{P}\left(Z_t = 1\right)^{1/2}\end{aligned}$$

where we have used the inequality $\sum_{t=(1-\alpha)T+1}^{T} \frac{1}{t} \leq \log\left(1/\left(1-\alpha\right)\right)$.

$$\begin{aligned}\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq & \frac{\lambda\left(1-\alpha\right)}{2\alpha} W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{P}\left(Z_t = 1\right)^{1/2} \\ & + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}\end{aligned}$$

ii) If Z_t is independent with $\mathbf{w}_t$ and (x_t, y_t), taking sum in Eq. (7) when $t = (1-\alpha)T+1, \ldots, T$, we gain

$$\begin{aligned}\sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[f\left(\mathbf{w}_t\right)\right] - \alpha T f\left(\mathbf{w}^*\right) \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H}{2\lambda} \sum_{t=(1-\alpha)T+1}^{T} \frac{1}{t} \\ & + \sum_{t=(1-\alpha)T+1}^{T} \mathbb{P}\left(Z_t = 1\right) \mathbb{E}\left[\left\|\mathbf{w}_t - \mathbf{w}^*\right\|^2\right]^{1/2} \mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \quad (13) \\ \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda} \\ & + \delta_\Phi M^{1/2} W^{1/2} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{P}\left(Z_t = 1\right)\end{aligned}$$

$$\begin{aligned}\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq & \frac{\lambda\left(1-\alpha\right)}{2\alpha} W_T^\alpha + \frac{\delta_\Phi M^{1/2} W^{1/2}}{\alpha T} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{P}\left(Z_t = 1\right) \\ & + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}\end{aligned}$$

iii) In general, taking sum in Eq. (9) when $t = (1-\alpha)T+1, \ldots, T$, we gain

$$\begin{aligned}\sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[f\left(\mathbf{w}_t\right)\right] - \alpha T f\left(\mathbf{w}^*\right) \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H}{2\lambda} \sum_{t=(1-\alpha)T+1}^{T} \frac{1}{t} \\ & + \sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[\left\|\mathbf{w}_t - \mathbf{w}^*\right\|^2\right]^{1/2} \mathbb{E}\left[\left\|\Delta_t\right\|^2\right]^{1/2} \\ \leq & \frac{\lambda\left(1-\alpha\right)T}{2} W_T^\alpha + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda} + \delta_\Phi M^{1/2} W^{1/2} \alpha T \quad (14)\end{aligned}$$

$$\mathbb{E}\left[f\left(\overline{\mathbf{w}}_T^\alpha\right) - f\left(\mathbf{w}^*\right)\right] \leq \frac{\lambda\left(1-\alpha\right)}{2\alpha} W_T^\alpha + \delta_\Phi M^{1/2} W^{1/2} + \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T}$$

■

Proof of Theorem 10

The proof of this theorem is similar to that of Theorem 8 which relies on Hoeffding inequality.

From Eqs. (12, 13, 14), we achieve

$$\frac{1}{\alpha T} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[f\left(\mathbf{w}_t\right)\right] - f\left(\mathbf{w}^*\right) \leq \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} + d_T$$

Let us denote $X = f\left(\mathbf{w}_r\right) - f\left(\mathbf{w}^*\right)$, where r is uniformly sampled from $\{(1-\alpha)T+1, 2, \ldots, T\}$. We have

$$\mathbb{E}_r\left[X\right] = \frac{1}{\alpha T} \sum_{t=(1-\alpha)T+1}^{T} \mathbb{E}\left[f\left(\mathbf{w}_t\right)\right] - f\left(\mathbf{w}^*\right) \leq \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} + d_T$$

It follows that

$$\mathbb{E}\left[X\right] = \mathbb{E}_{(x_t, y_t)_{t=1}^T}\left[\mathbb{E}_r\left[X\right]\right] \leq \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} + d_T$$

Let us denote $\Delta_T^\alpha = \max_{(1-\alpha)T+1 \leq t \leq T} \left(f\left(\mathbf{w}_t\right) - f\left(\mathbf{w}^*\right)\right)$ which implies that $0 < f\left(\mathbf{w}_r\right) - f\left(\mathbf{w}^*\right) < \Delta_T^\alpha$. Applying Hoeffding inequality for the random variable X, we gain

$$\mathbb{P}\left(X - \mathbb{E}\left[X\right] > \varepsilon\right) \leq \exp\left(-\frac{2\varepsilon^2}{\left(\Delta_T^\alpha\right)^2}\right)$$

$$\mathbb{P}\left(X - \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} - d_T > \varepsilon\right) \leq \exp\left(-\frac{2\varepsilon^2}{\left(\Delta_T^\alpha\right)^2}\right)$$

$$\mathbb{P}\left(X \leq \frac{H\log\left(1/\left(1-\alpha\right)\right)}{2\lambda\alpha T} + d_T + \varepsilon\right) > 1 - \exp\left(-\frac{2\varepsilon^2}{\left(\Delta_T^\alpha\right)^2}\right)$$

Choosing $\delta = \exp\left(-\frac{2\varepsilon^2}{(\Delta_T^\alpha)^2}\right)$ or $\varepsilon = \Delta_T^\alpha\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$, then with the probability at least $1-\delta$, we have

$$f(\mathbf{w}_r) - f(\mathbf{w}^*) \leq \frac{H\log(1/(1-\alpha))}{2\lambda\alpha T} + d_T + \Delta_T^\alpha\sqrt{\frac{1}{2}\log\frac{1}{\delta}}$$

■

Proof of Theorem 13

It is apparent that $f(\mathbf{w})$ is L-strongly smooth w.r.t $\|.\|_2$. Therefore, we have

$$f(\mathbf{w}_r) - f(\mathbf{w}^*) \leq f'(\mathbf{w}^*)^\mathsf{T}(\mathbf{w}_r - \mathbf{w}^*) + \frac{L}{2}\|\mathbf{w}_r - \mathbf{w}^*\|^2 \leq \frac{L}{2}\|\mathbf{w}_r - \mathbf{w}^*\|^2$$

It follows that $\Delta_T^\alpha \leq \frac{1}{2}LM_T^\alpha$. Hence we gain the conclusion. ■

12. Proofs of Bound for L2 Loss

We now consider the upper bound of $\|\mathbf{w}^*\|$ in the case that ℓ_2 loss is being used for regression problem. Concretely, we have the following theorem whose proof is similar to that of Theorem 1 in Shalev-Shwartz et al. (2007, 2011).

Theorem 23. *If* $\mathbf{w}^* = argmin_{\mathbf{w}}\left(\frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{N}\sum_{i=1}^N\left(y_i - \mathbf{w}^\mathsf{T}\Phi(x_i)\right)^2\right)$ *then* $\|\mathbf{w}^*\| \leq y_{max}\lambda^{-1/2}$.

Proof Let us consider the equivalent constrains optimization problem

$$\min_{\mathbf{w},\boldsymbol{\xi}}\left(\frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{N}\sum_{i=1}^N\xi_i^2\right)$$
$$\text{s.t.: } \xi_i = y_i - \mathbf{w}^\mathsf{T}\Phi(x_i),\ \forall i$$

The Lagrange function is of the following form

$$\mathcal{L}(\mathbf{w},\boldsymbol{\xi},\boldsymbol{\alpha}) = \frac{\lambda}{2}\left\|\mathbf{w}^2\right\| + \frac{1}{N}\sum_{i=1}^N\xi_i^2 + \sum_{i=1}^N\alpha_i\left(y_i - \mathbf{w}^\mathsf{T}\Phi(x_i) - \xi_i\right)$$

Setting the derivatives to 0, we gain

$$\nabla_{\mathbf{w}}\mathcal{L} = \lambda\mathbf{w} - \sum_{i=1}^N\alpha_i\Phi(x_i) = 0 \rightarrow \mathbf{w} = \lambda^{-1}\sum_{i=1}^N\alpha_i\Phi(x_i)$$

$$\nabla_{\xi_i}\mathcal{L} = \frac{2}{N}\xi_i - \alpha_i = 0 \rightarrow \xi_i = \frac{N\alpha_i}{2}$$

Substituting the above to the Lagrange function, we gain the dual form

$$\begin{aligned}\mathcal{W}(\boldsymbol{\alpha}) &= -\frac{\lambda}{2}\|\mathbf{w}\|^2 + \sum_{i=1}^N y_i\alpha_i - \frac{N}{4}\sum_{i=1}^N\alpha_i^2 \\ &= -\frac{1}{2\lambda}\left\|\sum_{i=1}^N\alpha_i\Phi(x_i)\right\|^2 + \sum_{i=1}^N y_i\alpha_i - \frac{N}{4}\sum_{i=1}^N\alpha_i^2\end{aligned}$$

Let us denote $(\mathbf{w}^*, \boldsymbol{\xi}^*)$ and $\boldsymbol{\alpha}^*$ be the primal and dual solutions, respectively. Since the strong duality holds, we have

$$\frac{\lambda}{2}\|\mathbf{w}^*\|^2 + \frac{1}{N}\sum_{i=1}^N\xi_i^{*2} = -\frac{\lambda}{2}\|\mathbf{w}^*\|^2 + \sum_{i=1}^N y_i\alpha_i^* - \frac{N}{4}\sum_{i=1}^N\alpha_i^{*2}$$

$$\begin{aligned}\lambda\|\mathbf{w}^*\|^2 &= \sum_{i=1}^N y_i\alpha_i^* - \frac{N}{4}\sum_{i=1}^N\alpha_i^{*2} - \frac{1}{N}\sum_{i=1}^N\xi_i^{*2} \\ &\leq \sum_{i=1}^N\left(y_i\alpha_i^* - \frac{N}{4}\alpha_i^{*2}\right) \leq \sum_{i=1}^N\frac{y_i^2}{N} \leq y_{\max}^2\end{aligned}$$

We note that we have used $g(\alpha_i^*) = y_i\alpha_i^* - \frac{N}{4}\alpha_i^{*2} \leq g\left(\frac{2y_i}{N}\right) = \frac{y_i^2}{N}$. Hence, we gain the conclusion. ■

Lemma 24. *Assume that ℓ_2 loss is using, the following statement holds*

$$\|\mathbf{w}_{T+1}\| \leq \lambda^{-1}\left(y_{max} + \frac{1}{T}\sum_{t=1}^{T}\|\mathbf{w}_t\|\right)$$

where $y_{max} = \max_{y\in\mathcal{Y}}|y|$.

Proof We have the following

$$\mathbf{w}_{t+1} = \begin{cases}\prod_S\left(\frac{t-1}{t}\mathbf{w}_t - \eta_t\alpha_t\Phi(x_t)\right) & \text{if } Z_t = 0\\ \prod_S\left(\frac{t-1}{t}\mathbf{w}_t - \eta_t\alpha_t\Phi(c_{i_t})\right) & \text{otherwise}\end{cases}$$

It follows that

$$\|\mathbf{w}_{t+1}\| \leq \frac{t-1}{t}\|\mathbf{w}_t\| + \frac{1}{\lambda t}|\alpha_t| \quad \text{since } \|\Phi(x_t)\| = \|\Phi(c_{i_t})\| = 1$$

It happens that $l'(\mathbf{w}_t; x_t, y_t) = \alpha_t\Phi(x_t)$. Hence, we gain

$$|\alpha_t| = \left|y_t - \mathbf{w}_t^{\mathsf{T}}\Phi(x_t)\right| \leq y_{\max} + \|\mathbf{w}_t\|\,\|\Phi(x_t)\| \leq y_{\max} + \|\mathbf{w}_t\|$$

It implies that

$$t\|\mathbf{w}_{t+1}\| \leq (t-1)\|\mathbf{w}_t\| + \lambda^{-1}(y_{\max} + \|\mathbf{w}_t\|)$$

Taking sum when $t = 1, 2, \ldots, T$, we achieve

$$T\|\mathbf{w}_{T+1}\| \leq \lambda^{-1}\left(Ty_{\max} + \sum_{t=1}^{T}\|\mathbf{w}_t\|\right)$$

$$\|\mathbf{w}_{T+1}\| \leq \lambda^{-1}\left(y_{\max} + \frac{1}{T}\sum_{t=1}^{T}\|\mathbf{w}_t\|\right) \tag{15}$$

■

Theorem 25. *If $\lambda > 1$ then $\|\mathbf{w}_{T+1}\| \leq \frac{y_{max}}{\lambda-1}\left(1 - \frac{1}{\lambda^T}\right) < \frac{y_{max}}{\lambda-1}$ for all T.*

Proof First we consider the sequence $\{s_T\}_T$ which is identified as $s_{T+1} = \lambda^{-1}(y_{\max} + s_T)$ and $s_1 = 0$. It is easy to find the formula of this sequence as

$$s_{T+1} - \frac{y_{\max}}{\lambda-1} = \lambda^{-1}\left(s_T - \frac{y_{\max}}{\lambda-1}\right) = \ldots = \lambda^{-T}\left(s_1 - \frac{y_{\max}}{\lambda-1}\right) = \frac{-\lambda^{-T}y_{\max}}{\lambda-1}$$

$$s_{T+1} = \frac{y_{\max}}{\lambda-1}\left(1 - \frac{1}{\lambda^T}\right)$$

We prove by induction by T that $\|\mathbf{w}_T\| \leq s_T$ for all T. It is obvious that $\|\mathbf{w}_1\| = s_1 = 0$. Assume that $\|\mathbf{w}_t\| \leq s_t$ for $t \leq T$, we verify it for $T+1$. Indeed, we have

$$\begin{aligned}\|\mathbf{w}_{T+1}\| &\leq \lambda^{-1}\left(y_{\max} + \frac{1}{T}\sum_{t=1}^{T}\|\mathbf{w}_t\|\right) \leq \lambda^{-1}\left(y_{\max} + \frac{1}{T}\sum_{t=1}^{T}s_t\right)\\ &\leq \lambda^{-1}(y_{\max} + s_T) = s_{T+1}\end{aligned}$$

■

In addition, from Eq. (15) in case that $\lambda \leq 1$ we cannot bound $\|\mathbf{w}_{T+1}\|$. Concretely, we have the following theorem.

Theorem 26. *If $\{z_T\}_T$ is a sequence such that $z_{T+1} = \lambda^{-1}\left(y_{max} + \frac{1}{T}\sum_{t=1}^{T}z_t\right)$ with $z_1 = 0$ then in case that $\lambda \leq 1$ this sequence is not upper-bounded.*

Proof Let us denote $s_t = y_{\max}^{-1}z_t$. It is obvious that $s_1 = 0$ and $s_{T+1} = \lambda^{-1}\left(1 + \frac{1}{T}\sum_{t=1}^{T}s_t\right)$. We now prove by induction by T that

$$s_T \geq \sum_{t=1}^{T-1}\frac{1}{t} \text{ for all } T \geq 2$$

With $T = 2$, we have $s_2 = \lambda^{-1} \geq 1$. Assume that this holds for all $2 \leq t \leq T$, we verify it for $T+1$.

$$\begin{aligned}s_{T+1} &= \lambda^{-1}\left(1 + \frac{1}{T}\sum_{t=1}^{T}s_t\right) \geq 1 + \frac{1}{T}\sum_{t=1}^{T}s_t\\ &\geq 1 + \frac{1}{T}\sum_{t=1}^{T}\sum_{n=1}^{t-1}\frac{1}{n} \geq 1 + \sum_{t=1}^{T-1}\frac{T-t}{Tt}\\ &\geq 1 + \sum_{t=1}^{T}\left(\frac{1}{t} - \frac{1}{T}\right) = \sum_{t=1}^{T}\frac{1}{t}\end{aligned}$$

The final conclusion is obvious from the fact $\sum_{t=1}^{T}\frac{1}{t} > \log(T+1)$ and hence can exceed any positive number. ■

Abstract

We propose a computationally efficient random walk on a convex body which rapidly mixes with respect to a fixed log-concave distribution and closely tracks a time-varying log-concave distribution. We develop general theoretical guarantees on the required number of steps; this number can be calculated on the fly according to the distance from and the shape of the next distribution. We then illustrate the technique on several examples. Within the context of exponential families, the proposed method produces samples from a posterior distribution which is updated as data arrive in a streaming fashion. The sampling technique can be used to track time-varying truncated distributions, as well as to obtain samples from a changing mixture model, fitted in a streaming fashion to data. In the setting of linear optimization, the proposed method has oracle complexity with best known dependence on the dimension for certain geometries. In the context of online learning and repeated games, the algorithm is an efficient method for implementing no-regret mixture forecasting strategies. Remarkably, in some of these examples, only one step of the random walk is needed to track the next distribution.[1]

1. Introduction

Let $\mathcal{K}$ be a compact convex subset of $\mathbb{R}^d$ with non-empty interior. Let $\mu_0, \ldots, \mu_t, \ldots$ be a sequence of probability measures with support on $\mathcal{K}$. Suppose each probability distribution μ_t has a density

$$\frac{d\mu_t(x)}{dx} = \frac{e^{-s_t(x)}}{Z_t}\ , \qquad Z_t = \int_{x\in\mathcal{K}} e^{-s_t(x)}dx \tag{1}$$

with respect to the Lebesgue measure, where each $s_t(x)$ is a convex function on $\mathcal{K}$. This paper proposes a Markov Chain Monte Carlo method for sequentially sampling from these distributions. The method comes with strong mixing time guarantees, and is shown to be applicable to a variety of problems. Observe that, by definition, the distributions μ_t are *log-concave*, and thus our work falls within the emerging body of literature on sampling from log-concave distributions.

The problem of sampling from distributions arises in many areas of statistics, most notably in Bayesian inference (Robert and Casella, 2004). In particular, Sequential Monte Carlo methods (Doucet et al., 2001) aim to sample from time-varying distributions. The need for such methods arises, for instance, in the case of online arrival of data: it is desirable to be able to update the posterior distribution at a low computational cost. If the distributions are changing "slowly" with time, sequential methods can re-use samples from the previous distribution and perform certain re-weighting to track the next distribution, thus saving computational resources. These ideas are exploited in particle filtering methods (see (Chopin, 2002; Doucet et al., 2001) and references therein). Beyond Bayesian inference, other applications of sampling from distributions include simulated annealing, global optimization, and regret minimization.

The main critique of the MCMC methods is, in many situations, the lack of mixing time analysis. In practice, the number of steps of the chain required to obtain an honest sample from a distribution is mostly calculated based on heuristics. There is a growing body of literature that presents exceptions to these heuristic approaches (Diaconis, 2013). Coupling methods, spectral gap methods, as well as the more recent study of positive Ricci curvature, yield geometric decrease of the distance to the desired stationary distribution – a property known as *geometric ergodicity*. The most well-understood cases in this context are those with a finite or countable state space (see (Meyn and Tweedie, 2009; Diaconis, 2009)). In contrast, we are interested in a random walk on a non-discrete set.

This paper is focused on a particular circle of problems defined via log-concave distributions. These distributions constitute an important subset of the set of unimodal distributions, a fact that has been recognized within Statistics (see e.g. (Walther, 2009)). We are not the first to study mixing times for such distributions: this line of work started with the breakthrough paper of (Dyer et al., 1991), followed by a series of improvements (Frieze et al., 1994; Lovász, 1999; Lovász and Vempala, 2006, 2007). However, the recent advances in (Kannan and Narayanan, 2012) on sampling from convex bodies give an edge to obtaining stronger guarantees. In particular, a variant of the Dikin walk studied in this paper is analyzed in (Narayanan, 2016) for the case of log-linear distributions. Extending the study of this random walk, we show rapid mixing to a log-concave distribution, and further show that we can provably track a *changing* log-concave distribution with a small number (or even only *one step*) of a random walk, provided that the distribution changes slowly enough. *Such a result seems out of reach with other random walk methods due to the lack of scale-free bounds on conductance.*

We assume that we can compute a *self-concordant barrier* (see Section 5 and Appendix 8) for the set $\mathcal{K}$, a requirement that is satisfied in many cases of interest. For instance, the self-concordant barrier can be readily computed in closed form if $\mathcal{K}$ is defined via linear and quadratic constraints. While the availability of the barrier is a stronger assumption than, for instance, access to a separation oracle for $\mathcal{K}$, the barrier gives a better handle on the geometry of the space and yields fast mixing of the Markov chain.

In Section 5, we illustrate the method within several diverse application domains. As one of the examples, we consider the problem of updating the posterior with respect to a conjugate prior in an exponential family, where the parameter is taking values in a space of a

fixed dimensionality given by the sufficient statistics. The constraints then constitute a prior knowledge about the possible location of the parameter. As another example, we consider sampling from a time-varying truncated distribution, as well as the extension to sampling from mixture models fitted to streaming data. We employ the sampling technique to the classical problem of linear optimization via simulated annealing. The final example concerns the problem of regret minimization where the log-concave distribution arises naturally from the exponential weighting scheme.

The paper is organized as follows. In the next section we study the geometry of the set $\mathcal{K}$ induced by a self-concordant barrier and prove a key isoperimetric inequality in the corresponding Riemannian metric. The Markov chain for a given log-concave distribution is defined in Section 3. Conditions on the size of a step are introduced in Section 3.1, and a lower bound on the conductance of the chain is proved in Section 3.2. Section 4 contains main results about tracking time-varying distributions given appropriate measures of change between time steps. Section 5 is devoted to applications. Finally, Sections 6 and 7 contain all the remaining proofs.

2. Geometry Induced by the Self-Concordant Barrier

The Markov chain studied in this paper uses as a proposal a Gaussian distribution with a covariance that approximates well the local geometry of the set $\mathcal{K}$ at the current point. This local geometry plays a crucial role in the theory of interior point methods for optimization, yet for our purposes a handle on the local geometry yields a good lower bound on *conductance* of the Markov chain. Further intriguing similarities between optimization and sampling will be pointed out throughout the paper.

We refer to (Nemirovskii, 2004) for an introduction to the theory of interior point methods, a subject centered around the notion of a self-concordant barrier. Once we have defined a self-concordant barrier for $\mathcal{K}$, the local geometry is defined through the Hessian of the barrier at the current point. For the reader unfamiliar with the literature on self-concordant barriers, it is useful to think of the simple 2-dimensional example of $F(x) = -\log x_1 - \log x_2$ defined on the positive quadrant $\mathcal{K} = [0,\infty)^2$, with $x = (x_1, x_2)$. The Hessian of F at x is $\begin{bmatrix} 1/x_1^2 & 0 \\ 0 & 1/x_2^2 \end{bmatrix}$, and a unit ball centered at x and reshaped according to this matrix is the ellipse that touches the axes, as shown below. That is, the ellipsoid corresponds well to the

local geometry of $\mathcal{K}$ at the point x.

For a function F on the interior $int(\mathcal{K})$ having continuous derivatives of order k, for vectors $h_1, \ldots, h_k \in \mathbb{R}^d$ and $x \in int(\mathcal{K})$, for $k \geq 1$, we recursively define

$$D^k F(x)[h_1, \ldots, h_k] \triangleq \lim_{\epsilon \to 0} \frac{D^{k-1}(x + \epsilon h_k)[h_1, \ldots, h_{k-1}] - D^{k-1}(x)[h_1, \ldots, h_{k-1}]}{\epsilon}$$

where $D^0 F(x) \triangleq F(x)$. Let F be a self-concordant barrier of $\mathcal{K}$ with a parameter ν (see Appendix 8 for the precise definition and Section 5 for examples). The value of the parameter ν depends on the shape of $\mathcal{K}$ and the choice of F. The barrier parameter will enter many of the results in this paper, but it is worth mentioning that there always exists a barrier with $\nu = O(d)$.

The barrier induces a Riemannian metric whose metric tensor is the Hessian of F (Nesterov and Todd, 2008). In other words, the metric tensor on the tangent space at x assigns to a vector v the length

$$\|v\|_x^2 \triangleq D^2 F(x)[v, v],$$

and to a pair of vectors v, w, the inner product

$$\langle v, w \rangle_x \triangleq D^2 F(x)[v, w] \ .$$

The unit ball in $\|\cdot\|_x$ around a point x is called the *Dikin ellipsoid* (Nemirovskii, 2004), and it describes well the local geometry of $\mathcal{K}$ at x in the following sense: (i) the unit Dikin ellipsoid at any point is contained in $\mathcal{K}$, and (ii) the Dikin ellipsoid of radius $r = 2(1 + 3\nu)$ contains $\mathrm{sym}(\mathcal{K}, x) = \{\mathcal{K} - x\} \cap -\{\mathcal{K} - x\}$.

The random walk, introduced in the next section, is *anisotropic*, i.e. the steps change in size and shape from point to point. It is then useful to connect the properties of this random walk directly to the Riemannian distance that is defined in terms of the Hessian of F. More precisely, for $x, y \in \mathcal{K}$, let $\rho(x, y)$ be the Riemannian distance $\rho(x, y) = \inf_\Gamma \int_z \|d\Gamma\|_z$ where the infimum is taken over all rectifiable paths Γ from x to y. Let $\mathcal{M}$ be the metric space whose point set is $\mathcal{K}$ and metric is ρ, and define $\rho(S_1, S_2) = \inf_{x \in S_1, y \in S_2} \rho(x, y)$. The first main ingredient of the analysis is an isoperimetric inequality.

Theorem 1 *Let S_1 and S_2 be measurable subsets of $\mathcal{K}$ and μ a probability measure supported on $\mathcal{K}$ that possesses a density whose logarithm is concave. Then it holds that*

$$\mu((\mathcal{K} \setminus S_1) \setminus S_2) \geq \frac{1}{2(1 + 3\nu)} \rho(S_1, S_2) \mu(S_1) \mu(S_2).$$

The theorem ensures that two subsets well-separated in ρ distance must have a large mass between them. A lower bound on conductance of our Markov chain will follow from this isoperimetric inequality. We remark that convexity of the set $\mathcal{K}$ is crucial for the above property. A classical example of a non-convex shape with a "bottleneck" is a dumbbell. For this body, the above statement clearly fails, and a "local" random walk on such a body gets trapped in either of the two parts for a long time.

2.1 Connections to Interior Point Methods

Interestingly, the idea of tracking a changing distribution with only one step of a random walk parallels the technique of following a central path in the theory of interior point methods for optimization, as discussed in (Narayanan and Rakhlin, 2010). In the analysis of interior point methods, the local (according to the Dikin ellipsoid introduced in the next section) quadratic convergence of the Damped Newton step counters the slowly changing "temperature parameter" of the barrier to ensure sufficiency of one optimization step; in our method, the geometric ergodicity of the scale-free random walk (which is based on the

local shape of the Dikin ellipsoid) balances the additive change in the distribution due to the changing temperature. Once again, the scale-free property of the Dikin walk, introduced below, is crucial for drawing this parallel between one-step interior point methods and our one-step random walk.

We remark that a different parallel between sampling and interior point methods has been recently outlined in (Abernethy and Hazan, 2016). The authors show that the *mean* of the log-concave distribution coincides with the central path when the barrier is chosen to be entropic. Since one still needs to sample from the distribution, this does not imply an "algorithmic equivalence" of the two methods unless one proves a scale-free bound on conductance, as we do in this paper.

3. The Markov Chain

Let $\mathcal{B}$ be the Borel σ-field on $\mathcal{K}$. Given an initial probability measure on $\mathcal{K}$, a Markov chain is specified by a collection of one-step transition probabilities

$$\{\mathsf{P}(x, B), x \in \mathcal{K}, B \in \mathcal{B}\}$$

such that $x \mapsto \mathsf{P}(x, B)$ is a measurable map for any $B \in \mathcal{B}$ and $\mathsf{P}_x(\cdot) \triangleq \mathsf{P}(x, \cdot)$ is a probability measure on $\mathcal{K}$ for any $x \in \mathcal{K}$.

For $x \in int(\mathcal{K})$, let G_x^r denote the unique Gaussian probability density function on $\mathbb{R}^d$ such that

$$G_x^r(y) \propto \exp\left(-\frac{d\|x-y\|_x^2}{r^2} + V(x)\right), \qquad V(x) \triangleq \frac{1}{2}\ln\det D^2F(x)$$

and r is a parameter that is chosen according to a condition specified below. The covariance of this distribution is given by the Hessian of F at point x, and thus the contour lines are scaled Dikin ellipsoids.

The Markov chain considered in this paper is based on the Dikin Walk introduced by Kannan and Narayanan (2012). Adapted to sampling from log-concave distributions in this paper, the Markov chain is parametrized by a convex function s and a step size r. Rather than writing out the unwieldy explicit form of the transition kernel P_x, we can give it implicitly as the following random walk:

With probability 1/2, set $w := x$.

With probability 1/2, sample z from G_x^r and

If $z \notin \mathcal{K}$, let $w := x$.

If $z \in \mathcal{K}$, let $w := \begin{cases} z & \text{with prob.} \quad \min\left(1,\ \frac{G_z^r(x)\exp(s(x))}{G_x^r(z)\exp(s(z))}\right) \\ x & \text{otherwise.} \end{cases}$

The Markov chain is *lazy*, as it stays at the current point with probability at least 1/2. This ensures uniqueness of the stationary distribution (Lovász and Simonovits, 1993). Furthermore, a simple calculation shows that the detailed balance conditions are satisfied with

respect to a stationary distribution μ whose density (with respect to the Lebesgue measure) is proportional to $\exp(-s(x))$. Indeed, to see that $\mu(x)\mathsf{P}_x(dz) = \mu(z)\mathsf{P}_z(dx)$, it suffices to observe that

$$\exp(-s(x))G_x^r(z)\min\left(1,\ \frac{G_z^r(x)\exp(s(x))}{G_x^r(z)\exp(s(z))}\right) = \exp(-s(z))G_z^r(x)\min\left(1,\ \frac{G_x^r(z)\exp(s(z))}{G_z^r(x)\exp(s(x))}\right).$$

Therefore the Markov chain is reversible and has the desired stationary measure μ.

The value of r has a specific meaning: most of the y's sampled from G_x^r are within a thin "Dikin shell" of radius proportional to $(\mathbb{E}\|x-y\|_x^2)^{1/2} = r$ by measure-concentration arguments. We will therefore refer to r as the effective "step size". An important and non-trivial result from the theory of interior point methods is that the unit Dikin ellipsoid is contained in the set $\mathcal{K}$ and gives a good approximation to the local geometry of the set (see Figure 1 below). Thanks to this fact, the sampling procedure has in general better mixing properties than the Ball Walk (Lovász and Simonovits, 1993; Vempala, 2005).

3.1 Step Size Conditions

The analysis of the Markov chain requires the steps r to be not too large to ensure that different enough transition probability functions happen only for far away points. The precise upper bounds on r depend on the convex function $s(x)$ and can be calculated on the fly when we move to the setting of a time-varying function. We give four conditions:

Sufficient Condition 1 (Linear Functions) *If s is linear, we may set $r = 1/d$.*

Sufficient Condition 2 (Lipschitz Functions) *For a function s that is L-Lipschitz with respect to the Euclidean norm, we may set the step size $r = \min\left\{\frac{1}{d}, \frac{1}{L}\right\}$.*

Sufficient Condition 3 (Smooth Functions) *Suppose s has Lipschitz-continuous gradients: there exists $\sigma > 0$ such that $\|\nabla s(x) - \nabla s(y)\| \le \sigma\|x-y\|$. We may then set the step size to be $\min\left\{\frac{1}{d}, \frac{1}{\sqrt{\sigma}}\right\}$.*

These three conditions can be shown to follow from a more general sufficient step size condition that is based on "local" information:

Sufficient Condition 4 (General Condition) *Fix constants $C, C' > 0$. Given the convex function $s(x)$, the step size $r \le \min\left\{\frac{1}{d}, r^*\right\}$ is a valid choice if there exists a linear function $< g, x >$ such that*

$$r^* \le \sup\left\{\ r\ :\ \forall z, w \in \mathcal{K}\ \ \textit{with}\ \ \|z-w\|_z \le C'r, \quad \Big|s(z) - s(w) - \langle g, z-w\rangle\Big| < C\right\}$$

The condition says that for two points, with one being inside the $O(r)$-Dikin ellipsoid around the other point, the function is within a constant of being linear. It follows from the last condition that, for instance, if $s(x) = \langle b, x\rangle + a(x)$ is a sum of a linear and a non-linear Lipschitz part, the step size is only affected by the Lipschitz constant of the non-linear part.

It is simple to verify that the step size in Condition 2 satisfies Condition 4. Indeed, for any w such that $\|z-w\|_z \le C'r$, we have $\|z-w\| \le C''rR$ (where R is the radius of the largest ball contained in $\mathcal{K}$). Take g_z and g_w to be any subgradients of s at z and w, respectively. We then have

$$|s(z) - s(w) - \langle g_w, z-w\rangle| \le \langle g_z - g_w, z-w\rangle \le 2L\|z-w\| \le 2 \ .$$

Notice that for Condition 3, the above calculation becomes

$$\langle g_z - g_w, z-w\rangle \le \sigma\|z-w\|^2 \le 1 \ .$$

In the remainder of this paper, C will denote a universal constant that may change from line to line. The exact value of the final constant in Lemma 4 below can be traced in the proofs; we omit this calculation for the sake of brevity.

3.2 Conductance of the Markov Chain

In order to show rapid mixing of the proposed Markov chain, we prove a lower bound on its *conductance*

$$\Phi \triangleq \inf_{\mu(S_1)\le \frac{1}{2}} \frac{\int_{S_1} \mathsf{P}_x(\mathcal{K}\setminus S_1)d\mu(x)}{\mu(S_1)}, \tag{2}$$

where P_x is the one-step transition function defined earlier. Once such a lower bound is established, the following general result on the reduction of distance between distributions will imply exponentially fast convergence.

Theorem 2 ((Lovász and Simonovits, 1993)) *Let γ_0 be the initial distribution for a lazy reversible ergodic Markov chain whose conductance is Φ and stationary measure is γ. For every bounded f, let $\|f\|_\gamma \triangleq \sqrt{\int_{\mathcal{K}} f(x)^2 d\gamma(x)}$. For any fixed f, let Ef be the map that takes x to $\int_{\mathcal{K}} f(y)d\mathsf{P}_x(y)$. Then if $\int_{\mathcal{K}} f(x)d\gamma(x) = 0$, it holds that*

$$\|E^k f\|_\gamma \le \left(1 - \frac{\Phi^2}{2}\right)^{k/2} \|f\|_\gamma \ .$$

To prove a lower bound on conductance Φ, we first relate the Riemannian metric ρ to the proposed Markov Chain. Intuitively, the following result says that for close-by points, their transition distributions cannot be far apart in the total variation distance d_{TV}.

Lemma 3 *If $x, y \in \mathcal{K}$ and $\rho(x,y) \le \frac{r}{C\sqrt{d}}$ for some constant C, then*

$$d_{TV}(\mathsf{P}_x, \mathsf{P}_y) \le 1 - \frac{1}{C'}$$

for some constant C'.

Lemma 3 together with the isoperimetric inequality of Theorem 1 give a lower bound on conductance of the Markov Chain.

Lemma 4 *Let μ be a log-concave distribution with support on $\mathcal{K}$ whose density with respect to the Lebesgue measure is proportional to $\exp\{-s(x)\}$, and suppose an appropriate step size condition (Section 3.1) for the Markov chain is satisfied. Then there exists a constant $C > 0$ such that the conductance of the above Markov chain is bounded below as*

$$\Phi \ge \frac{r}{C\nu\sqrt{d}} \ .$$

We remark that the step size r enters the lower bound on Φ. While we would like the steps to be large, the conditions outlined earlier dictate a limitation on how large r can be. In particular, we always have $r \le 1/d$. The step size needs to be even smaller for functions s for which a linear approximation is poor.

We also remark that Lemma 4 establishes a *scale-free* bound on the conductance, that is, a bound that does not depend on the measure of the set S_1 in the definition (2). Such a scale-free conductance is needed for the geometric ergodicity of the chain.

4. Tracking the Distributions

Having specified the Markov chain and the step size, we now turn to the problem of tracking a sequence of distributions $\mu_1, \dots, \mu_t, \dots$. For each $t \ge 1$, define a Markov chain with parameters r_t and s_t, and let its transition kernel be denoted by $\mathsf{P}_t(x, B)$ for $x \in \mathcal{K}$ and $B \in \mathcal{B}$. Let Φ_t denote the conductance of this chain. The chain will be run for τ_t steps starting from the end of the chain at time $t-1$. Formally, let the i-th step of the t-th chain be denoted by the random variable $X_{t,i}$. Define $\tau_0 = 0$ and let $\sigma_{0,0}$ be the initial distribution of $X_{0,0}$. Then $X_{t,i}$ has distribution

$$\sigma_{0,0}\mathsf{P}_1^{\tau_1} \cdots \mathsf{P}_{t-1}^{\tau_{t-1}} \mathsf{P}_t^i$$

and we have made the identification $X_{s,\tau_s} = X_{s+1,0}$, gluing the successive chains together. Let the distribution of $X_{t,i}$ be denoted by $\sigma_{t,i}$. By the definition of the chain, $\sigma_{t,i}$ is a distribution with bounded density, supported on $\mathcal{K}$.

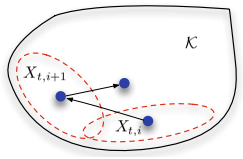

Figure 1: Steps of the Dikin Walk. The next point is sampled from a Gaussian distribution with a shape (contours depicted with dashed lines) corresponding to Dikin ellipsoids. These ellipsoids approximate well the local geometry.

4.1 Measuring the Change

Let $\|\cdot\|_t$ denote the $\mathcal{L}_2$ norm with respect to the measure μ_t, defined as $\|f\|_t = \left(\int_{\mathcal{K}} f^2 d\mu_t\right)^{1/2}$ for a measurable function $f : \mathcal{K} \to \mathbb{R}$. Further, let $\|\cdot\|_{\mathcal{K}}$ denote the supremum norm

$\|f\|_{\mathcal{K}} = \sup_{x\in\mathcal{K}} |f(x)|$ and let

$$\beta_{t+1} = \max\left\{\|d\mu_t/d\mu_{t+1}\|_{\mathcal{K}}, \|d\mu_{t+1}/d\mu_t\|_{\mathcal{K}}\right\} . \tag{3}$$

This ratio provides an upper bound on the point-wise change of the density function. A straightforward way to upper bound β_{t+1} is by writing

$$\sup_{x\in\mathcal{K}} \frac{e^{-s_t(x)}}{e^{-s_{t+1}(x)}} \frac{\int_{\mathcal{K}} e^{-s_{t+1}(x)}dx}{\int_{\mathcal{K}} e^{-s_t(x)}dx} \le \sup_{x\in\mathcal{K}} e^{2|s_t(x)-s_{t+1}(x)|}$$

and, hence,

$$\log\beta_{t+1} \le \ 2\|s_t(x) - s_{t+1}(x)\|_{\mathcal{K}} . \tag{4}$$

Another way to measure the change in successive distributions is with respect to the $\mathcal{L}_2$ norm:

$$\alpha_{t+1} = \|d\mu_t/d\mu_{t+1}\|_{t+1} \ . \tag{5}$$

In contrast to the point-wise change, the ratio α_{t+1} is more difficult to calculate. In this respect, the following result, which follows from the proof of (Lovász and Vempala, 2006; Kalai and Vempala, 2006), will be useful:

Lemma 5 *Let s_t be a convex function and $s_{t+1} = (1-\delta)^{-1} s_t$. Let μ_t and μ_{t+1} be defined as in* (1)*. Then*

$$\alpha_{t+1} \le \left(1 + \frac{\delta^2}{1-2\delta}\right)^{d/2}$$

In particular, if $\delta \le d^{-1/2} \le 1/3$, then $\alpha_{t+1} \le 5$.

We remark that the ratio between μ_t and μ_{t+1} measured in the supremum norm may be exponentially large, while the $\mathcal{L}_2$ change is small. As in (Lovász and Vempala, 2006; Kalai and Vempala, 2006), this fact will be crucial in this paper when we study simulated annealing.

4.2 Tracking the Distributions: Main Results

Denote the error in approximating the stationary distribution at the end of t-th chain by

$$\xi_t \ \triangleq \ \left\|\frac{d\sigma_{t,\tau_t}}{d\mu_t} - 1\right\|_t \tag{6}$$

and let

$$\Delta_t \ \triangleq \ \frac{r_t^2}{C\nu^2 d} .$$

Theorem 6 *The errors ξ_t satisfy the recurrence*

$$\xi_t \le (1-\Delta_t)^{\tau_t}(\beta_t^{3/2}\xi_{t-1} + \sqrt{\beta_t}(\beta_t - 1)) \tag{7}$$

for any $t \ge 1$.

Proof [Proof of Theorem 6] We iteratively apply Theorem 2 with $f = \frac{d\sigma_{t,j}}{d\mu_t} - 1$ and the stationary distribution $\gamma = \mu_t$, and observe that Ef takes $\sigma_{t,j}$ to $\sigma_{t,j+1}$. Then from Lemma 4, for $t \ge 1$ and $i \ge 1$,

$$\left\|\frac{d\sigma_{t,i}}{d\mu_t} - 1\right\|_t \le \left\|\frac{d\sigma_{t,0}}{d\mu_t} - 1\right\|_t \cdot (1-\Delta_t)^i$$

Using the first part of Lemma 11 (see Section 6)

$$\left\|\frac{d\sigma_{t,0}}{d\mu_t} - 1\right\|_t \le \beta_t^{3/2}\left\|\frac{d\sigma_{t,0}}{d\mu_{t-1}} - 1\right\|_{t-1} + \sqrt{\beta_t}(\beta_t - 1),$$

concluding the proof. An alternative recurrence, using the second part of Lemma 11, is

$$\xi_t \le (1-\Delta_t)^{\tau_t}(\sqrt{\beta_t}\xi_{t-1} + \sqrt{\beta_t - 1}),$$

which is better for large β_t but worse for $\beta_t \approx 1$. ■

We would like to adaptively choose τ_t to make the right-hand side (7) small. While the value of the error ξ_{t-1} at the previous round is not available for this purpose, let us maintain an upper bound u_{t-1} on this error. Thus, we may write τ_t as a function $\tau_t(u_{t-1}, s_t, r_t, \beta_t)$. Suppose at round $t = 0$ we ensure that $\xi_0 \le u_0$. Then, recursively, we may compute u_t as the upper bound in (7):

$$u_t \ge (1-\Delta_t)^{\tau_t}(\beta_t^{3/2}u_{t-1} + \sqrt{\beta_t}(\beta_t - 1)) \tag{8}$$

Then, given the initial condition, we have $\xi_t \le u_t$ for all $t \ge 0$.

Let us consider some consequences of Theorem 6. In particular, we are interested in situations when we can track the distributions with only *one step* of the random walk.

Corollary 7 *Let $\tau_t = 1$ for all $t \ge 1$ and suppose $\xi_0 \le u_0 = \sqrt{\beta_0}(\beta_0 - 1)/\Delta_0$ with $\Delta_0 = \frac{1}{Cd^3\nu^2} \le \frac{1}{2}$. Assume that β_t is non-decreasing and Δ_t is non-increasing in t, and suppose*

$$\beta_t^{3/2} \le 1 + \frac{\Delta_t^2}{1-\Delta_t} \tag{9}$$

for all $t \ge 1$. Then we have

$$\xi_t \le u_t = \frac{\sqrt{\beta_t}(\beta_t - 1)}{\Delta_t}$$

for all $t \ge 0$. In particular, (9) *is satisfied whenever $\beta_t - 1 \le 0.4\Delta_t^2$.*

The proof of the above corollary follows from the more general result:

Corollary 8 *Fix a sequence $\epsilon_0, \dots, \epsilon_t, \dots$ of positive target accuracies and assume $\xi_0 \le \epsilon_0$. It is then enough to set*

$$\tau_t = \left\lceil \frac{1}{\Delta_t}\log\left(\beta_t^{3/2}\cdot\frac{\epsilon_{t-1}}{\epsilon_t} + \frac{\sqrt{\beta_t}(\beta_t-1)}{\epsilon_t}\right)\right\rceil \tag{10}$$

in order to ensure $\xi_t \le \epsilon_t$ for each $t \ge 0$.

Proof Immediate by writing

$$u_t = (1-\Delta_t)^{\tau_t}(\beta_t^{3/2}\epsilon_{t-1} + \sqrt{\beta_t}(\beta_t - 1)) \leq \epsilon_t,$$

solving for τ_t, and using the approximation $\log(1/(1-\Delta_t)) \geq \log(1+\Delta_t) \geq \Delta_t$. ■

We now consider the case when one has control on the $\mathcal{L}_2$ norm α_t of the change between successive distributions. First, observe that closeness of the distributions in the norm $\|\cdot\|_t$ implies closeness in total variation distance as

$$\int |d\sigma_{t,i} - d\mu_t| = \int \left|\frac{d\sigma_{t,i}}{d\mu_t} - 1\right| d\mu_t \leq \left\|\frac{d\sigma_{t,i}}{d\mu_t} - 1\right\|_t . \tag{11}$$

Proposition 9 *Fix a sequence $\epsilon_0, \ldots, \epsilon_t, \ldots$ of positive target accuracies and assume $d_{TV}(\sigma_{0,0}, \mu_0) \leq \epsilon_0$. Suppose we set*

$$\tau_t = \left\lceil \frac{1}{\Delta_t} \log\left(\frac{\alpha_t}{\epsilon_t}\right) \right\rceil . \tag{12}$$

Then the total variation distance between σ_{t,τ_t} and μ_t is bounded as

$$d_{TV}(\sigma_{t,\tau_t}, \mu_t) \leq \sum_{s=0}^{t} \epsilon_s \tag{13}$$

for each $t \geq 0$.

Proof For any $t \geq 1$, let us write

$$\sigma_{t,\tau_t} = \mu_t + \gamma_t \tag{14}$$

with a signed measure $\gamma_t = \sigma_{t,\tau_t} - \mu_t$. By way of induction, suppose (13) holds for time t. Consider the operator E_{t+1} corresponding to the random walk of the $t+1$-st chain. The operator acts on a function f by taking f to $\int_{\mathcal{K}} f(y) d\mathsf{P}_{t+1}(x,y)$. Then applying Theorem 2 to the function $d\mu_t/d\mu_{t+1} - 1$, we have

$$\left\| E_{t+1}^{\tau_{t+1}} \left(\frac{d\mu_t}{d\mu_{t+1}} - 1 \right) \right\|_{t+1} \leq \epsilon_{t+1}$$

by the choice of τ_{t+1} and the definition of α_{t+1}. That is, upon the action of $E_{t+1}^{\tau_{t+1}}$, μ_t is mapped to μ_{t+1} within an error of at most ϵ_{t+1} in the $\mathcal{L}_2$ sense (and, hence, in the total variation sense). Since the operator E_{t+1} is non-expanding in the $\mathcal{L}_1$ sense, total variation of γ_t does not increase under the action of $E_{t+1}^{\tau_{t+1}}$. In view of the inductive hypothesis for step t, we conclude $d_{TV}(\sigma_{t+1,\tau_{t+1}}, \mu_{t+1}) \leq \sum_{s=0}^{t} \epsilon_s + \epsilon_{t+1}$, as desired. ■

5. Applications

Before diving into the applications of the random walk, let us give several examples of sets $\mathcal{K}$ for which the self-concordant barrier F and its Hessian can be easily calculated. In the following examples, assume that $\mathcal{K}$ has non-empty interior.

Example 1 *Suppose $\mathcal{K}$ is given by m linear constraints of the form $\langle a_j, x\rangle \leq b_j$, $j = 1, \ldots, m$. Then $F(x) = -\sum_{j=1}^{m} \log(b_j - \langle a_j, x\rangle)$ is a self-concordant barrier with parameter $\nu = m$. The Hessian is easily computable:*

$$D^2F(x) = \sum_{j=1}^{m} \frac{a_j a_j^\mathsf{T}}{(b_j - \langle a_j, x\rangle)^2} .$$

Example 2 *Let $\mathcal{K} = \{x \in \mathbb{R}^d : f_j(x) \leq 0, j = 1, \ldots, m\}$ where each f_j is a convex quadratic form. Then $F(x) = -\sum_{j=1}^{m} \log(-f_j(x))$ is a self-concordant barrier with parameter m. As an example, the function $-\log(R - \|x\|^2)$ is a self-concordant barrier for the unit Euclidean sphere $\{x : \|x\|^2 - 1 \leq 0\}$, with parameter $\nu = 1$, and the Hessian is given by*

$$D^2F(x) = \frac{2}{1-\|x\|^2} I + \frac{4}{(1-\|x\|^2)^2} xx^\mathsf{T} .$$

Importantly, there always exists a self-concordant barrier with $\nu = O(d)$; yet, for some convex sets (such as the sphere) the parameter can even be constant.

Self-concordant barriers can be combined: if F_j is ν_j-self-concordant for $\mathcal{K}_j$, $j = 1, \ldots, m$, then $\sum_j F_j$ is $\sum_j \nu_j$-self-concordant for the intersection $\cap_i \mathcal{K}_i$, given that it has nonempty interior. Thus, closed forms for the Hessian of the barrier, required for defining G_x^r in our Markov chain, can be calculated for many sets $\mathcal{K}$ of interest. We refer to (Nemirovskii, 2004; Nesterov and Nemirovskii, 1994) for further powerful methods for constructing the barriers.

5.1 Sampling from Posterior in Exponential Families

Suppose data $y_1, y_2, \ldots \in \mathcal{Y}$ are distributed i.i.d. according to a member of an exponential family with natural parameter x:

$$p(y|x) = \exp\{\langle x, T(y)\rangle - A(x)\} h(y)$$

where $A(x) = \int h(y) \exp\{\langle x, T(y)\rangle\}$ is a convex function and $T : \mathcal{Y} \mapsto \mathbb{R}^d$ is a sufficient statistic. Suppose $x \in \mathcal{K}$; that is, we have some knowledge about the support of the parameter. We have in mind the situation where data arrive one at a time and we are interested in sampling from the associated posterior distributions. The likelihood function after seeing $y_1, \ldots, y_t$ is

$$\ell(x) \propto \exp\left\{ \left\langle x, \sum_{i=1}^{t} T(y_i) \right\rangle - tA(x) \right\}$$

and, together with a conjugate prior $\pi_{\kappa_1,\kappa_2}(x) \propto \exp\{\langle x, \kappa_1\rangle - \kappa_2 A(x)\}$ for some $(\kappa_1, \kappa_2) \in \mathbb{R}^{d+1}$, we obtain the posterior distribution at time t

$$p_t(x|y) \propto \exp\left\{\left\langle x, \kappa_1 + \sum_{i=1}^{t} T(y_i)\right\rangle - (t+\kappa_2)A(x)\right\} .$$

We apply the sampling technique to this scenario by defining

$$s_0(x) = -\langle x, \kappa_1\rangle + \kappa_2 A(x), \qquad s_t(x) = -\left\langle x, \kappa_1 + \sum_{i=1}^{t} T(y_i)\right\rangle + (t+\kappa_2)A(x) .$$

It remains to calculate the number of steps required to track the distributions as additional data arrive one-by-one. Let L be the Lipschitz constant of $A(x)$ over $\mathcal{K}$ with respect to Euclidean norm, and let us assume L to be finite. Then Condition 4 is satisfied with $r = \min\left\{\frac{1}{(t+\kappa_2)L}, \frac{1}{d}\right\}$. Furthermore, we may set

$$\beta_t = \sup_{x\in\mathcal{K}} \exp\left\{2\left|\langle x, T(y_t)\rangle - A(x)\right|\right\},$$

a quantity that depends on the observed data. Importantly, we do not need to provide an a priori data-independent bound of this type, which might not be finite.

Suppose we would like to maintain a constant level $\epsilon > 0$ of accuracy at each step t. Corollary 8 guarantees this accuracy if each chain is run for

$$\tau_t = \mathcal{O}\left(\nu^2 d \max\{(t+\kappa_2)^2 L^2, d^2\} + \log(1/\epsilon)\right) .$$

One of the features of this bound is a relatively benign dependence on the dimension d, especially if the geometry of the set $\mathcal{K}$ allows the parameter $\nu = \mathcal{O}(1)$, as in the case of a sphere. On the negative side, the number of steps needed after seeing t data points is proportional to t^2. Such an adverse dependence, however, is to be expected as the posterior distribution becomes concentrated very quickly.

We now demonstrate that stronger results can be achieved under additional assumptions via Condition 3. Suppose that A is smooth: there exists $H \succeq 0$ such that

$$A(x) \le A(w) + \langle \nabla A(x), w - x\rangle + (w-x)^{\mathsf{T}} H (w-x)$$

for any $w, x \in \mathcal{K}$. This is a natural assumption, as the second derivative of the log normalization function A corresponds to the variance of the random variable with the given parameter; furthermore, A is differentiable. Let $\lambda_{\max}$ be the largest eigenvalue of H. Then the condition yields $r_t = \frac{C}{\sqrt{(t+\kappa_2)\lambda_{\max}}}$. To obtain ϵ-accuracy, it suffices to set

$$\tau_t = \mathcal{O}\left(\nu^2 d \max\{(t+\kappa_2)\lambda_{\max}, d^2\} + \log(1/\epsilon)\right),$$

which has only linear dependence on the size of the data seen so far.

We remark that each step of the random walk requires evaluation of the log-partition function $A(x)$. If this function is not available in closed form, we may approximate the value $A(x)$ for each query x. In order to do this, we may run an additional sampling procedure with $s'(x) = \langle x, T(y)\rangle$. Alternatively, we may appeal to known methods for this problem, such as Hit-and-Run (Vempala, 2005).

5.2 Examples of Sampling from Drifting Truncated Distributions

In the previous example, we employed the Markov chain to sample a parameter from a log-concave posterior. We now turn to the question of sampling from a log-concave distribution restricted to a convex set. This problem has a long history (see e.g. (Devroye, 1986; Gilks and Wild, 1992)), and it is recognized that sampling from truncated distributions is difficult even for nice forms such as the Normal distribution. One successful approach to this problem is the Gibbs sampling method (Robert, 1995; Damien and Walker, 2001), yet the rate of convergence is not generally available. The MCMC method of this paper yields a provably fast algorithm for such situations. Furthermore, we can track a drifting distribution over $\mathcal{K}$ with a small number of steps.

For illustration purposes, we study a simple example of a truncated Normal distribution; the same techniques, however, apply more generally. To simplify calculations, suppose the distributions μ_t are defined to be $\mathcal{N}(\mathbf{c}_t, \frac{1}{d}I)$ over a convex compact set $\mathcal{K} \subset \mathbb{R}^d$ and suppose the mean $\mathbf{c}_t$ is drifting within a Euclidean ball of radius R. With the definition in (1) we have $s_t(x) = \frac{1}{2}\|x - \mathbf{c}_t\|^2$. Define the drift $\delta_t = \|\mathbf{c}_t - \mathbf{c}_{t-1}\|$. In view of (4),

$$\log \beta_t \le \sup_{x\in\mathcal{K}} \|\mathbf{c}_t - \mathbf{c}_{t-1}\| \cdot \|2x - \mathbf{c}_t - \mathbf{c}_{t-1}\| \le C_{R,\mathcal{K}}\delta_t$$

where $C_{R,\mathcal{K}}$ depends on the radius R and the radius of a smallest Euclidean ball enclosing $\mathcal{K}$. In the same manner, the Lipschitz constant of $s_t(x)$ over $\mathcal{K}$ can be upper bounded by $L_{R,\mathcal{K}}$ that depends solely on the two radii. We may thus set the step size to be $r_t = \min\{\frac{1}{d}, \frac{1}{L_{R,\mathcal{K}}}\}$. If we aim for a fixed target accuracy ϵ for all t, by Corollary 8, it is enough to make

$$\tau_t = \left\lceil \frac{1}{\Delta_t} \log\left(\beta_t^{3/2} + \frac{\sqrt{\beta_t}(\beta_t - 1)}{\epsilon}\right)\right\rceil \tag{15}$$

steps. In the case that the drift δ_t is small enough, only one step is sufficient. To quantify the regime when this happens, observe that $\beta_t \le \exp\{C_{R,\mathcal{K}}\delta\} \le 1 + C\delta_t$, and it is then enough to require

$$\delta_t = \mathcal{O}\left(\Delta_t^2\right) = \mathcal{O}\left(\frac{\min\{1/d^2, 1/L_{R,\mathcal{K}}^2\}}{\nu^2 d}\right)$$

in view of (9). It is quite remarkable that the one-step random walk can track the changing distribution up to the accuracy $\mathcal{O}\left(\delta_t \frac{\nu^2 d}{r_t^2}\right)$, proportional to the size of the drift. Of course, better accuracy can be achieved by performing more steps, as per Corollary 8.

Another related application is to modeling with mixtures of log-concave distributions. Such models have been successful in clustering (McLachlan and Peel, 2000; Walther, 2009), with a mixture of normal distributions being a classical example (Fraley and Raftery, 2002). A mixture of parametric log-concave distributions can be written as $\sum_{i=1}^{k} \alpha_i \pi_i(\theta_i; x)$; here α_i are positive mixing weights summing to one, and π_i are a distributions on $\mathcal{K}$ parametrized by θ_i. A classical method for fitting models to data is the EM algorithm. Given that the parameters $\{\theta_i\}_{i=1}^k$ and the mixing weights $\{\alpha_i\}_{i=1}^k$ have been estimated from data, one may require random samples from this model for integration or other purposes. Given our procedure for sampling from a single log-concave distribution, one may simply pick the mixture according to the weights α_i and then sample from the component. The situation

becomes interesting in the case of online arrival of data, when we need to re-compute the EM solution in light of additional data. By the arguments of (Rakhlin and Caponnetto, 2006; Caponnetto and Rakhlin, 2006), the solution to clustering problems (the analysis was performed for square loss) is *stable* in the following sense: addition of $o(\sqrt{n})$ new data to a sample of size n is unlikely to drastically move the solution (the argument is based on uniqueness of the maximum of an empirical process). This in turn implies that the parameters $\{\theta_i\}$ are unlikely to change by a large amount, and we may thus use the method of sampling from a drifting distribution described earlier. We also remark that the method can be easily parallelized since the Markov chains for the k components do not interact.

5.3 Simulated Annealing for Convex Optimization

Let $f(x)$ be a proper convex 1-Lipschitz function. The aim of convex optimization is to find $\tilde{x}$ with the property $f(\tilde{x}) - \min_{x\in\mathcal{K}} f(x) \leq \epsilon$ for a given target accuracy $\epsilon > 0$. We consider the special case of linear function $f(x) = \langle \ell, x\rangle$, known as Linear Optimization. Complexity of an optimization procedure is often measured in terms of *oracle calls* – queries about the unknown function. A query about the function value is known as the zero-th order information, while a query about a subgradient at a point – as the first order information. In the case that the oracle answer is given without noise, it is known that the complexity scales as $\mathcal{O}\left(\mathrm{poly}(d, \log(1/\epsilon))\right)$. The state-of-the-art result here is the method of (Kalai and Vempala, 2006; Lovász and Vempala, 2006) which attains the $d^{4.5}$ dependence on the dimension.

We now apply our machinery to obtain a $\mathcal{O}\left(\nu^2 d^{3.5}\log(1/\epsilon)\right)$ method. In particular, this yields an improved $d^{3.5}$ dependence on the dimension for the case when $\mathcal{K}$ has a favorable geometry: there exists a self-concordant barrier with a parameter $\nu = \mathcal{O}(1)$.

We use the annealing scheme of (Kalai and Vempala, 2006). To this end, we set $s_t = \left(1 - d^{-1/2}\right)^{-t} f$ and observe that the assumption of Lemma 5 is satisfied with $\delta = d^{-1/2}$. Since functions are linear, we may set the step size $r_t = 1/d$ for all t. Hence, $\alpha_t \leq 5$ whenever $d > 8$ (and a different constant can be obtained for smaller d from the proof). By Proposition 9 with a constant accuracy $\epsilon_t = \epsilon \cdot (\sqrt{d}\log(d/\epsilon))^{-1}$, by making

$$\tau_t = \left\lceil C d^3 \nu^2 \log\left(\frac{5\sqrt{d}\log(d/\epsilon)}{\epsilon}\right)\right\rceil \tag{16}$$

steps for $t = 1, \ldots, k$, we guarantee

$$d_{TV}(\sigma_{k,\tau_k}, \mu_k) \leq k\epsilon(\sqrt{d}\log(d/\epsilon))^{-1} \,. \tag{17}$$

According to (Kalai and Vempala, 2006, Lemma 4.1), if X is chosen from a distribution with density proportional to $\exp\{-T^{-1}\langle \ell, x\rangle\}$, with $\|\ell\| = 1$ and some temperature $T > 0$, then

$$\mathbb{E}(\langle \ell, X\rangle) - \min_{x\in\mathcal{K}} \langle \ell, x\rangle \leq dT.$$

Hence, we take the desired temperature to be $T = \epsilon/d$, and the number of chains that permits the annealing schedule to reach this temperature can be calculated as $k = \sqrt{d}\log(\frac{d}{\epsilon})$. In view of (17), the final output of the procedure is an ϵ-accurate solution to the optimization problem. The complexity of the method is then $\mathcal{O}(d^{3.5}\nu^2\log^2(d/\epsilon))$.

This result can be extended to Lipschitz convex functions beyond linear optimization. However, the step size condition for convex Lipschitz functions requires the steps to be $\mathcal{O}(1/\epsilon)$ towards the end of the annealing schedule. This in turn implies only a suboptimal $\tilde{\mathcal{O}}(\nu^2 d/\epsilon^2)$ complexity. It is an open question of whether Dikin Walk can handle such annealing schedules in a more graceful manner.

5.4 Sequential Prediction

Another application of the proposed sampling technique is to the problem of *sequential prediction* with convex cost functions. Within this setting, the learner (or, the Statistician) is tasked with making a series of predictions while observing a sequence of outcomes on which we place no distributional assumptions. The goal of the learner is to incur cost comparable to that of a fixed strategy chosen in hindsight after observing the data. Initially studied by Hannan (Hannan, 1957), Blackwell (Blackwell, 1956), and Cover (Cover, 1965), the problem of achieving low *regret* for all sequences has received much attention in the last two decades, and we refer the reader to (Cesa-Bianchi and Lugosi, 2006) for a comprehensive treatment. As we show in this section, a strategy that exponentially down-weighs the decisions with large costs is a good regret-minimization strategy, and this exponential form is amenable to the sampling technique of this paper whenever the costs are convex.

More specifically, let $\mathcal{K} \subset \mathbb{R}^d$ be a convex compact set of decisions of the learner. Let $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_T$ be a sequence of unknown cost functions $\boldsymbol{\ell}_t : \mathcal{K} \to \mathbb{R}$. On round t, the learner chooses a distribution (or, a *mixed strategy*) μ_{t-1} supported on $\mathcal{K}$ and "plays" a decision $Y_t \sim \mu_{t-1}$.[2] Nature then reveals the next cost function $\boldsymbol{\ell}_t$. For example, in the well-studied problem of sequential probability assignment, the Statistician predicts the probability $x_t \in [0,1] = \mathcal{K}$ of the next outcome $\{0,1\}$ and incurs the cost $\boldsymbol{\ell}_t(x_t) = |x_t - y_t|$ with respect to the actual outcome y_t. A randomized strategy Y_t then incurs a cost $\boldsymbol{\ell}_t(Y_t)$. The goal of the learner is to minimize *expected regret*

$$\mathrm{Reg}_T(U) \triangleq \mathbb{E}\left[\sum_{t=1}^T \boldsymbol{\ell}_t(Y_t) - \sum_{t=1}^T \boldsymbol{\ell}_t(U)\right]$$

with respect to all randomized strategies defined by $p_U \in \mathcal{P}$, for some collection of distributions $\mathcal{P}$. A procedure that guarantees sublinear growth of regret with respect to any distribution $p_U \in \mathcal{P}$ and for any sequence of cost functions $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_T$ will be called *consistent* with respect to $\mathcal{P}$.

Let $L_t(x) = \sum_{s=1}^t \boldsymbol{\ell}_s(x)$ denote the cumulative cost functions, and let $\eta > 0$ be a parameter called *the learning rate*. Fix $R(x)$ to be some convex function that defines the prior, let

$$s_t(x) = \eta L_t(x) + R(x), \qquad s_0(x) = R(x) \tag{18}$$

and define the probability distributions μ_t as in (1). It turns out that this choice of μ_t is indeed a good regret-minimization strategy, as we show next. The method is similar to the Mixture Forecaster used in the prediction context (Yamanishi, 1998; Vovk, 2001; Azoury and Warmuth, 2001; Kakade and Ng, 2005), and for a discrete set of decisions it is known

2. The index $t-1$ on μ_{t-1} reflects the fact that Y_t is chosen without the knowledge of $\boldsymbol{\ell}_t$.

as the celebrated Exponential Weights Algorithm (Vovk, 1990; Littlestone and Warmuth, 1994).

Let $D(p||q)$ stand for the Kullback-Leibler (KL) divergence between distributions p and q.

Lemma 10 *For each $t \geq 1$, let Y_t be a random variable with distribution μ_{t-1} as defined in (1). The expected regret with respect to U with distribution p_U is*

$$Reg_T(U) = \eta^{-1}\left(D(p_U||\mu_0) - D(p_U||\mu_T)\right) + \eta^{-1}\sum_{t=1}^{T} D(\mu_{t-1}||\mu_t).$$

Specializing to the case $\boldsymbol{\ell}_t : \mathcal{K} \mapsto [0,1]$ for all t,

$$Reg_T(U) \leq \eta^{-1} D(p_U||\mu_0) + T\eta/8.$$

If the KL divergence between the comparator distribution p_U and the prior μ_0 is bounded for all $p_U \in \mathcal{P}$, the second statement of the lemma yields consistency and a $\mathcal{O}(\sqrt{T})$ rate of regret growth. To bound the divergence between a continuous initial μ_0 and a point distribution at some $x^* \in \mathcal{K}$, the analysis can be carried out in two stages: comparison to a "small-covariance" Gaussian centered at x^*, followed by an observation that the loss of the "small-covariance" Gaussian strategy is not very different from the loss of the deterministic strategy x^*. The analysis can be found in (Cesa-Bianchi and Lugosi, 2006, p. 326) and gives a near-optimal $\mathcal{O}(\sqrt{T\log T})$ regret bound.

The easy proof of Lemma 10 appeared in (Narayanan and Rakhlin, 2010) and we include it in Section 6 for completeness. Having exhibited a good prediction strategy, a natural question is whether there exists a computationally efficient algorithm for producing a random draw from a distribution close to the desired mixed strategy μ_{t-1}. To this end, we use the sampling method proposed in this paper.

As a concrete example, consider linear functions $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_T$ and let $R \equiv 0$. For simplicity assume boundedness $\boldsymbol{\ell}_t : \mathcal{K} \mapsto [0,1]$. In this case, we may choose $\eta = \mathcal{O}(1/\sqrt{T})$. Then

$$\beta_t \leq \exp\left\{2\eta\|\boldsymbol{\ell}_t\|_{\mathcal{K}}\right\} \leq 1 + C\eta$$

for large enough T. Further, we set $r_t = 1/d$ according to Condition 1, and the requirement (9) is seen to be satisfied for large enough T. With these choices of the parameters, the sequence of distributions $\mu_1, \ldots, \mu_t$ can be tracked with only one step of a random walk per iteration. The quality of this approximation is $\mathcal{O}\left(\eta d^3\nu^2\right)$ at each step. Therefore, regret of the proposed random walk method is within $\mathcal{O}\left(T\eta d^3\nu^2\right)$ from the ideal procedure of Lemma 10, as can be seen by writing

$$|\mathbb{E}\boldsymbol{\ell}_t(Y_t) - \mathbb{E}\boldsymbol{\ell}_t(X_{t-1,1})| \leq \int_{x\in\mathcal{K}} |\boldsymbol{\ell}_t(x)| \cdot |d\sigma_{t-1,1}(x) - d\mu_{t-1}(x)| \leq C\eta d^3\nu^2 \ .$$

By choosing $\eta = \frac{1}{d^{3/2}\nu\sqrt{T}}$,

$$\mathrm{Reg}_T(U) \leq Cd^{3/2}\nu D(p_U||\mu_0)\sqrt{T}. \tag{19}$$

A similar results holds for nonzero R, under the assumption that the L_2 distance between $d\mu_0(x) \propto \exp\{-R(x)\}dx$ and the uniform distribution on $\mathcal{K}$ is bounded.

We now discuss interesting parallels between the proposed randomized method and the known deterministic optimization-based regret minimization methods. First, the statement of Lemma 10 bears striking similarity to upper bounds on regret in terms of Bregman divergences for the Follow the Regularized Leader and Mirror Descent methods (Rakhlin, 2008; Beck and Teboulle, 2003), (Cesa-Bianchi and Lugosi, 2006, Therem 11.1). Yet, the randomized method operates in the (infinite-dimensional) space of distributions while the deterministic methods work directly with the set $\mathcal{K}$. Second, deterministic methods of online convex optimization face the difficulty of projections back to the set $\mathcal{K}$. This issue does not arise when dealing with distributions, but instead translates into the *difficulty of sampling*. We find these parallels between sampling and optimization intriguing. Third, a single step of the proposed random walk requires sampling from a Gaussian distribution with covariance given by the Hessian of the self-concordant barrier. This step can be implemented efficiently whenever the Hessian can be computed. The computation time exactly matches (Abernethy et al., 2008, Algorithm 2): it is the same as time spent inverting a Hessian matrix, which is $\mathcal{O}(d^3)$ or less. Finally, as already mentioned, the idea of following a time-varying distribution is inspired by the method of following the central path in the theory of interior point methods (Nesterov and Nemirovskii, 1994; Nemirovskii, 2004). Similarly to the fast convergence of the chain under the lower bound on conductance, one has fast quadratic local convergence of interior point methods. One may therefore make parallels between conductance and local curvature. A further investigation of these connections is needed, especially in view of the recent developments on positive Ricci curvature of Markov chains (Ollivier, 2009).

6. Proofs

Lemma 11 *For any t and $i \geq 0$, it holds that*

$$\left\|\frac{d\sigma_{t,i}}{d\mu_t} - 1\right\|_t \leq \beta_t^{3/2}\left\|\frac{d\sigma_{t,i}}{d\mu_{t-1}} - 1\right\|_{t-1} + \sqrt{\beta_t}(\beta_t - 1)$$

and, alternatively,

$$\left\|\frac{d\sigma_{t,i}}{d\mu_t} - 1\right\|_t \leq \beta_t^{1/2}\left\|\frac{d\sigma_{t,i}}{d\mu_{t-1}} - 1\right\|_{t-1} + \sqrt{\beta_t - 1}$$

Proof Let us use the shorthand $d\sigma = d\sigma_{t+1,i}$ and $\beta = \beta_{t+1}$. Using (3), we may write

$$\begin{aligned}\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_{t+1} &\leq \sqrt{\beta}\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_t \\ &\leq \sqrt{\beta}\left(\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_t - \left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t + \left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t\right) \ .\end{aligned}$$

By the triangle inequality,

$$\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_t - \left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t \leq \left\|\frac{d\sigma}{d\mu_{t+1}} - \frac{d\sigma}{d\mu_t}\right\|_t \ .$$

For any function $f : \mathcal{K} \to \mathbb{R}$, let $f^+(x) = \max(0, f(x))$ and $f^-(x) = \min(0, f(x))$. In view of (3),

$$\begin{aligned}\left\|\frac{d\sigma}{d\mu_{t+1}} - \frac{d\sigma}{d\mu_t}\right\|_t^2 &= \left\|\left(\frac{d\sigma}{d\mu_{t+1}} - \frac{d\sigma}{d\mu_t}\right)^+\right\|_t^2 + \left\|\left(\frac{d\sigma}{d\mu_{t+1}} - \frac{d\sigma}{d\mu_t}\right)^-\right\|_t^2 \\ &\le \left\|\frac{d\sigma}{d\mu_t}(\beta-1)\mathbf{1}\left[1 < \frac{d\mu_t}{d\mu_{t+1}}\right]\right\|_t^2 + \left\|\frac{d\sigma}{d\mu_t}\left(1-\frac{1}{\beta}\right)\mathbf{1}\left[1 \ge \frac{d\mu_t}{d\mu_{t+1}}\right]\right\|_t^2 \\ &\le (\beta-1)^2\left\|\frac{d\sigma}{d\mu_t}\right\|_t^2 .\end{aligned}$$

Therefore,

$$\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_t - \left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t \le (\beta-1)\left\|\frac{d\sigma}{d\mu_t}\right\|_t \le (\beta-1)\left(1 + \left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t\right) .$$

The first statement follows by rearranging the terms.

Alternatively, we can obtain an inequality that is slightly weaker for $\beta - 1 \approx 0$ and stronger for large β by simply writing

$$\begin{aligned}\left\|\frac{d\sigma}{d\mu_{t+1}} - 1\right\|_{t+1}^2 &= \int_{\mathcal{K}}\left(\frac{d\sigma}{d\mu_{t+1}} - 1\right)^2 d\mu_{t+1} \\ &= \int_{\mathcal{K}}\frac{d\sigma^2}{d\mu_{t+1}} - 1 = \int_{\mathcal{K}}\frac{d\sigma^2}{d\mu_t^2}\frac{d\mu_t}{d\mu_{t+1}}d\mu_t - 1 .\end{aligned}$$

Using β as an upper bound on the one-sided change $\|d\mu_t/d\mu_{t+1}\|_{\mathcal{K}}$ leads to

$$\beta\int_{\mathcal{K}}\frac{d\sigma^2}{d\mu_t^2}d\mu_t - 1 = \beta\left\|\frac{d\sigma}{d\mu_t} - 1\right\|_t^2 + \beta - 1$$

and subadditivity of the square root function concludes the proof. ■

Proof [**Proof of Theorem 1**]

Given interior points x, y in $int(\mathcal{K})$, suppose p, q are the ends of the chord in $\mathcal{K}$ containing x, y and p, x, y, q lie in that order. Denote the *cross ratio* by

$$\sigma(x, y) = \frac{|x-y||p-q|}{|p-x||q-y|},$$

and for two sets S_1 and S_2 let

$$\sigma(S_1, S_2) \triangleq \inf_{x\in S_1, y\in S_2}\sigma(x, y).$$

A result due to Lovász and Vempala (2007) states the following. If S_1 and S_2 are measurable subsets of $\mathcal{K}$ and μ a probability measure supported on $\mathcal{K}$ that possesses a density whose logarithm is concave, then

$$\mu((\mathcal{K}\setminus S_1)\setminus S_2) \ge \sigma(S_1, S_2)\mu(S_1)\mu(S_2).$$

This is a non-trivial isoperimetric inequality which says that for any partition of the convex set $\mathcal{K}$ into S_1, S_2 and S_3, the "volume" of S_3 is large relative to that of S_1 and S_2 whenever S_1 and S_2 are separated. Given this isoperimetric result, to prove the theorem it only remains to show that the σ-distance can be lower bounded (up to a multiplicative constant) by the Riemannian metric ρ. The proof of this fact goes through the Hilbert (projective) metric, which is defined by

$$d_H(x, y) \triangleq \ln\left(1 + \sigma(x, y)\right).$$

Further, for $x \in \mathcal{K}$ and a vector v, let

$$|v|_x \triangleq \sup_{x\pm\alpha v\in\mathcal{K}}\alpha.$$

The following two relations between the introduced notions hold. The first one (see Nesterov and Nemirovskii (Nesterov and Nemirovskii, 1994, Theorem 2.3.2 (iii))) is

$$|h|_x \le \|h\|_x \le 2(1+3\nu)|h|_x \tag{20}$$

for all $h \in \mathbb{R}^d$ and $x \in int(\mathcal{K})$, where ν is the self-concordance parameter of F. The second relation (see Nesterov and Todd (Nesterov and Todd, 2008, Lemma 3.1)) states that

$$\|x-y\|_x - \|x-y\|_x^2 \le \rho(x, y) \le -\ln(1-\|x-y\|_x). \tag{21}$$

whenever $\|x - y\|_x < 1$.

For any z on the segment $\overline{xy}$ an easy computation shows that $d_H(x, z) + d_H(z, y) = d_H(x, y)$. Therefore it suffices to prove the result infinitesimally. From (21), $\lim_{y\to x}\frac{\rho(x,y)}{\|x-y\|_x} = 1$, and a direct computation shows that

$$\lim_{y\to x}\frac{d_H(x, y)}{|x-y|_x} = \lim_{y\to x}\frac{\sigma(x, y)}{|x-y|_x} \ge 1.$$

Hence, in view of (20), the Hilbert metric and the Riemannian metric satisfy

$$\rho(x, y) \le 2(1+3\nu)d_H(x, y).$$

Using $\ln(1 + x) \le x$ concludes the proof. ■

Proof [**Proof of Lemma 4**] The argument roughly follows the standard path, which is explained, for instance, in (Vempala, 2005). Let S_1 be a measurable subset of $\mathcal{K}$ such that $\mu(S_1) \le \frac{1}{2}$ and $S_2 = \mathcal{K}\setminus S_1$ be its complement. Fix a $C > 1$ and let

$$S_1' = S_1 \cap \{x \big| \mathsf{P}_x(S_2) \le 1/C\} \quad \text{and} \quad S_2' = S_2 \cap \{y \big| \mathsf{P}_y(S_1) \le 1/C\}.$$

That is, points in the set S_1' are unlikely to transition to the set S_2, and S_2' is analogously unlikely to reach S_1 in one step. By the reversibility of the chain, which is easily checked,

$$\int_{S_1}\mathsf{P}_x(S_2)d\mu(x) = \int_{S_2}\mathsf{P}_y(S_1)d\mu(y).$$

For any $x \in S_1'$ and $y \in S_2'$,

$$d_{TV}(\mathsf{P}_x, \mathsf{P}_y) = 1 - \int_{\mathcal{K}} \min\left(\frac{d\mathsf{P}_x}{d\mu}(w), \frac{d\mathsf{P}_y}{d\mu}(w)\right) d\mu(w) \geq 1 - \frac{1}{C}.$$

That is, the transition probabilities for a pair in S_1' and S_2' must be dissimilar. But Lemma 3 implies that if $\rho(x,y) \leq \frac{r}{C\sqrt{d}}$, then $d_{TV}(\mathsf{P}_x, \mathsf{P}_y) \leq 1 - \frac{1}{C}$. Therefore

$$\rho(S_1', S_2') \geq \frac{r}{C\sqrt{d}}.$$

We conclude that the sets S_1' and S_2' must be well-separated. Therefore, the isoperimetric result of Theorem 1 implies that

$$\mu((\mathcal{K} \setminus S_1') \setminus S_2') \geq \frac{\rho(S_1', S_2')}{2(1+3\nu)} \min(\mu(S_1'), \mu(S_2')) \geq \frac{r}{C\nu\sqrt{d}} \min(\mu(S_1'), \mu(S_2')).$$

First suppose $\mu(S_1') \geq (1 - \frac{1}{C})\mu(S_1)$ and $\mu(S_2') \geq (1 - \frac{1}{C})\mu(S_2)$. Then,

$$\begin{aligned}
\int_{S_1} \mathsf{P}_x(S_2) d\mu(x) &= \frac{1}{2}\int_{S_1} \mathsf{P}_x(S_2) d\mu(x) + \frac{1}{2}\int_{S_2} \mathsf{P}_x(S_1) d\mu(x) \\
&\geq \frac{1}{2C}\mu((\mathcal{K} \setminus S_1') \setminus S_2') \\
&\geq \frac{r}{2C^2\nu\sqrt{d}} \min(\mu(S_1'), \mu(S_2')) \\
&\geq \frac{1 - 1/C}{2C^2} \frac{r}{\nu\sqrt{d}} \min(\mu(S_1), \mu(S_2)),
\end{aligned}$$

proving the result. Otherwise, without loss of generality, suppose $\mu(S_1') \leq (1 - \frac{1}{C})\mu(S_1)$. Then

$$\begin{aligned}
\int_{S_1} \mathsf{P}_x(S_2) d\mu(x) &= \frac{1}{2}\int_{S_1} \mathsf{P}_x(S_2) d\mu(x) + \frac{1}{2}\int_{S_2} \mathsf{P}_x(S_1) d\mu(x) \\
&\geq \frac{1}{2}\int_{S_1 \setminus S_1'} \mathsf{P}_x(S_2) d\mu(x) \geq \frac{\mu(S_1)}{2C^2},
\end{aligned}$$

concluding the proof. ■

Proof [**Proof of Lemma 5**] The proof closely follows that in (Kalai and Vempala, 2006). By definition,

$$\|d\mu_t / d\mu_{t+1}\|_{t+1}^2 = \int_{\mathcal{K}} \left(\frac{d\mu_t}{d\mu_{t+1}}\right)^2 d\mu_{t+1} = \int_{\mathcal{K}} \frac{d\mu_t^2}{d\mu_{t+1}} = \int_{\mathcal{K}} \frac{\exp\{-2s_t\}}{Z_t^2} \cdot \frac{Z_{t+1}}{\exp\{-s_{t+1}\}}.$$

Writing out the normalization terms,

$$\|d\mu_t / d\mu_{t+1}\|_{t+1}^2 = \frac{\int_{\mathcal{K}} \exp\{-s_{t+1}\} \int_{\mathcal{K}} \exp\{s_{t+1} - 2s_t\}}{\left(\int_{\mathcal{K}} \exp\{-s_t\}\right)^2} = \frac{Y(1)Y(-1+2(1-\delta))}{Y(1-\delta)Y(1-\delta)}$$

where $Y(a) = \int_{\mathcal{K}} \exp\{-as_{t+1}\}$. As shown in (Kalai and Vempala, 2006, Lemma 3.1), the function $a^d Y(a)$ is log-concave in a, and thus

$$\frac{Y(a)Y(b)}{Y\left(\frac{a+b}{2}\right)^2} \leq \left(\frac{\left(\frac{a+b}{2}\right)^2}{ab}\right)^d.$$

Applying this inequality with $a = 1$ and $b = -1 + 2(1-\delta)$,

$$\|d\mu_t / d\mu_{t+1}\|_{t+1}^2 \leq \left(1 + \frac{\delta^2}{1-2\delta}\right)^d.$$

In particular, if $\delta \leq d^{-1/2} \leq 1/3$ (that is, $d > 8$), we obtain an upper bound of $\exp\left\{\frac{d}{d-2\sqrt{d}}\right\} \leq 21$. ■

Proof [**Proof of Lemma 10**] Observe that $D(\mu_{t-1}||\mu_t)$ can be written as

$$\int_{\mathcal{K}} d\mu_{t-1} \log \frac{q_{t-1}Z_t}{Z_{t-1}q_t} = \log \frac{Z_t}{Z_{t-1}} + \int_{\mathcal{K}} \eta \boldsymbol{\ell}_t(x) d\mu_{t-1}(x) = \log \frac{Z_t}{Z_{t-1}} + \eta \mathbb{E}\boldsymbol{\ell}_t(Y_t). \tag{22}$$

Rearranging, canceling the telescoping terms, and using the fact that $Z_0 = 1$

$$\eta \mathbb{E} \sum_{t=1}^T \boldsymbol{\ell}_t(Y_t) = \sum_{t=1}^T D(\mu_{t-1}||\mu_t) - \log Z_T.$$

Let U be a random variable with a probability distribution p_U. Then

$$-\sum_{t=1}^T \mathbb{E}\boldsymbol{\ell}_t(U) = \eta^{-1} \int_{\mathcal{K}} -\eta L_T(u) dp_U(u) = \eta^{-1} \int_{\mathcal{K}} dp_U(u) \log \frac{q_T(u)}{q_0(u)}$$

Combining,

$$\begin{aligned}
\mathbb{E}\left[\sum_{t=1}^T \boldsymbol{\ell}_t(Y_t) - \sum_{t=1}^T \boldsymbol{\ell}_t(U)\right] &= \eta^{-1} \int_{\mathcal{K}} dp_U(u) \log \frac{q_T(u)/Z_T}{q_0(u)} + \eta^{-1} \sum_{t=1}^T D(\mu_{t-1}||\mu_t) \\
&= \eta^{-1} \left(D(p_U||\mu_0) - D(p_U||\mu_T)\right) + \eta^{-1} \sum_{t=1}^T D(\mu_{t-1}||\mu_t).
\end{aligned}$$

Now, from Eq. (22), the KL divergence can be also written as

$$D(\mu_{t-1}||\mu_t) = \log \frac{\int_{\mathcal{K}} e^{-\eta \boldsymbol{\ell}_t(x)} q_{t-1}(x) dx}{\int_{\mathcal{K}} q_{t-1}(x) dx} + \eta \mathbb{E}\boldsymbol{\ell}_t(Y_t) = \log \mathbb{E} e^{-\eta(\boldsymbol{\ell}_t(Y_t) - \mathbb{E}\boldsymbol{\ell}_t(Y_t))}$$

By representing the divergence in this form, one can obtain upper bounds via known methods, such as *log-Sobolev inequalities* (e.g. (Boucheron et al., 2003)). In the simplest case of bounded loss, it is easy to show that $D(\mu_{t-1}||\mu_t) \leq O(\eta^2)$, and the particular constant $1/8$ can be obtained by, for instance, applying Lemma A.1 in (Cesa-Bianchi and Lugosi, 2006). This proves the second part of the lemma. ■

7. Smooth Variation of the Transition Kernel

In this section, we study the transition $x \to y$. For this purpose, it is enough to assume that x is the origin and that the Dikin ellipsoid at x is a unit Euclidean ball. This can be achieved by an affine transformation, leading to no loss of generality since the resulting statement about measures on $\mathcal{K}$ is invariant with respect to affine transformations. Hence, in what follows, for the particular x we have $<\cdot,\cdot>_x = <\cdot,\cdot>$ and $\|\cdot\|_x = \|\cdot\|$. Since x is the origin, we have $\mathbb{E}\|z\|_x^2 = r^2$ for z sampled from G_x^r. Further, without loss of generality, we may also assume $s(x) = 0$.

Proof [**Proof of Lemma 3**]

In view of the first inequality in Eq. (21),

$$\|x-y\|_x - \|x-y\|_x^2 \le \rho(x,y) \le \frac{r}{C\sqrt{d}}.$$

Without loss of generality, assume $\frac{r}{C\sqrt{d}} \le \frac{1}{8}$. First, we claim that $\|x-y\|_x$ must be small. For the sake of contradiction, suppose $\|x-y\|_x > 1/2$ and consider a point y' with $\|x-y'\|_x = 1/2$ and lying on the geodesic path between x and y with respect to the Riemannian metric. Clearly, $\rho(x,y') \le \frac{r}{C\sqrt{d}} \le \frac{1}{8}$, yet by Eq. (21) we have $\frac{1}{4} \le \rho(x,y')$, contradicting our assumption. Hence, $\|x-y\|_x \le 1/2$, and, therefore, $\|x-y\|_x \le \frac{2r}{C\sqrt{d}}$.

It remains to show that if $x, y \in \mathcal{K}$ and

$$\|x-y\|_x \le \frac{2r}{C\sqrt{d}},$$

then

$$d_{TV}(\mathsf{P}_x, \mathsf{P}_y) = 1 - \frac{1}{C}.$$

By definition, we have that

$$1 - d_{TV}(\mathsf{P}_x, \mathsf{P}_y) = \mathbb{E}_z\left[\min\left\{1, \frac{G_y^r(z)}{G_x^r(z)}, \frac{G_z^r(x)\exp(s(x))}{G_x^r(z)\exp(s(z))}, \frac{G_z^r(y)\exp(s(y))}{G_x^r(z)\exp(s(z))}\right\}\right],$$

where the expectation is taken over a random point z having density G_x^r. Thus, it suffices to prove that for some $C > 1$

$$\mathbb{P}\left[\min\left\{\frac{G_y^r(z)}{G_x^r(z)}, \frac{G_z^r(x)\exp(s(x))}{G_x^r(z)\exp(s(z))}, \frac{G_z^r(y)\exp(s(y))}{G_x^r(z)\exp(s(z))}\right\} > \frac{1}{C}\right] \ge \frac{1}{C}.$$

By our assumption, x is the origin and $D^2F(x) = I$, the latter implying that $V(x) = 0$. Thus,

$$\frac{G_y^r(z)}{G_x^r(z)} = \exp\left\{-\frac{d\|y-z\|_y^2}{r^2} + V(y) + \frac{d\|z\|^2}{r^2}\right\},$$

$$\frac{G_z^r(x)\exp(s(x))}{G_x^r(z)\exp(s(z))} = \exp\left\{-\frac{d\|z\|_z^2}{r^2} + V(z) + \frac{d\|z\|^2}{r^2} + (s(x)-s(z))\right\},$$

and

$$\frac{G_z^r(y)\exp(s(y))}{G_x^r(z)\exp(s(z))} = \exp\left\{-\frac{d\|y-z\|_z^2}{r^2} + V(z) + \frac{d\|z\|^2}{r^2} + (s(y)-s(z))\right\}.$$

Thus, it remains to prove that there exists a constant C such that

$$\mathbb{P}\Big[\max\Big\{d\|y-z\|_y^2 - r^2V(y), \quad d\|z\|_z^2 + r^2(s(z)-s(x)) - r^2V(z), \\ d\|z-y\|_z^2 + r^2(s(z)-s(y)) - r^2V(z)\Big\} < d\|z\|^2 + r^2C\Big] \ge \frac{1}{C}.$$

This fact is shown in technical Lemmas 13 and 14 below. ■

In proving the technical lemmas, we will use the fact that $\|x-y\|_x \le \frac{2r}{C\sqrt{d}}$ as shown above, and that $\|x-z\|_x$ (for z sampled from G_x^r) is likely to be bounded above by a multiple of r by straightforward concentration arguments.

Lemma 12 *There exists a constant $C > 0$ such that*

$$\mathbb{P}\left[\max\left(-V(y), -V(z)\right) < C\right] > 0.9$$

Proof Fix a constant c. First, notice that over a Euclidean ball of radius c/d around the origin, the Hessians $D^2F(u)$ are lower-bounded by a factor of $(1-c/d)^2$ from the Hessian at the origin (the identity) by (24). Hence, the determinant function can decrease from 1 by at most a constant factor. Thus $-V(u) < C'$ for some constant C' for any u with $\|x-u\|_x \le c/d$. Now recall that y is deterministically within the $1/d$ ball, while z is in the ball of radius c/d with high probability. ■

Lemma 13 *Under step size Condition 4, for any*

$$\mathbb{P}\left[\max\left\{s(z)-s(x), s(z)-s(y)\right\} < C\right] > 0.32.$$

Proof Since with large enough probability $\|x-y\|_x < C'r$ and $\|x-z\|_x < C'r$, we also have $\|z-y\|_x < 2C'r$. Then, by (24), the norms at z and x are within a multiplicative constant, and thus the pairs (z,x) and (z,y) are subject to the step size choice specified in the condition. That is, there exists a g such that

$$s(z) - s(x) = s(z) - s(x) - \langle g, z-x\rangle + \langle g, z-x\rangle \le C + \langle g, z-x\rangle$$

and similarly

$$s(z) - s(y) = s(z) - s(y) - \langle g, z-y\rangle + \langle g, z-y\rangle \le C + \langle g, z-y\rangle$$

Then, assuming (without loss of generality) $x = 0$,

$$\mathbb{P}\left[\max\left\{\langle g, z-x\rangle, \langle g, z-y\rangle\right\} < 0\right] = \mathbb{P}\left[\langle g, z\rangle \le \min\left\{0, \langle g, y\rangle\right\}\right].$$

Observe that $\langle g, z\rangle$ is a Gaussian random variable whose standard deviation is larger than $\|g\|\,\|y\|$. Therefore,

$$\mathbb{P}\left[\langle g, z\rangle \le \min\left\{0, \langle g, y\rangle\right\}\right] \ge \operatorname{erfc}\left(1/\sqrt{2}\right) > 0.32,$$

where $\operatorname{erfc}(x) \triangleq \frac{2}{\sqrt{\pi}}\int_x^\infty e^{-t^2}dt$ is the usual complementary error function. ■

The following probabilistic upper bound completes the proof.

Lemma 14 *There exists a constant $C > 0$ such that*

$$\mathbb{P}\left[\max\left\{\|y-z\|_y^2, \|z\|_z^2, \|z-y\|_z^2\right\} - \|z\|^2 < \frac{Cr^2}{d}\right] > 0.9$$

Proof [**Proof of Lemma 14**] Since $\|y\| < \frac{Cr}{\sqrt{d}}$, $\|y\|_y$ and $\|y\|_z$ are less than $\frac{Cr}{\sqrt{d}}$. So it suffices to show that

$$\mathbb{P}\left[\max\left\{\|z\|_y^2 - \|z\|^2, \|z\|_z^2 - \|z\|^2, \langle y,z\rangle_y, \langle y,z\rangle_z\right\} < \frac{Cr^2}{d}\right] > 0.9$$

We proceed to do so by proving probabilistic upper bounds on each of the terms

$$\text{(a) } \|z\|_y^2 - \|z\|^2\,, \qquad \text{(b) } \|z\|_z^2 - \|z\|^2\,, \qquad \text{(c) } \langle y,z\rangle_y\,, \quad \text{and} \quad \text{(d) } \langle y,z\rangle_z$$

separately, and finally applying the union bound. We first prove an upper bound on (a) and (b). Note that $r \le \frac{1}{d}$ and thus $r^3 \le \frac{r^2}{d}$. It suffices to observe that by (24)

$$\|z\|_z^2 - \|z\|^2 \le \left(\left(\frac{1}{1-\|z\|}\right)^2 - 1\right)\|z\|^2 \le 8\|z\|^3,$$

whenever $\|z\| < 1/2$. Similarly, for $\|y\| < 1/2$,

$$\|z\|_y^2 - \|z\|^2 \le \left(\left(\frac{1}{1-\|y\|}\right)^2 - 1\right)\|z\|^2 \le 8\|z\|^3.$$

There exists a constant C such that the quantity $\|z\|^3$ is bounded by Cr^3 with probability at least 0.99.

We now turn to bounding (c) and (d). Let $[0,u]$ denote the line segment between the origin and u. By the mean-value theorem,

$$\langle y,z\rangle_y = \langle y,z\rangle + (\langle y,z\rangle_y - \langle y,z\rangle) \le \langle y,z\rangle + \sup_{y'\in[0,y]} D^3F(y')[y,y,z]$$

$$\langle y,z\rangle_z = \langle y,z\rangle + (\langle y,z\rangle_z - \langle y,z\rangle) \le \langle y,z\rangle + \sup_{z'\in[0,z]} D^3F(z')[y,z,z]$$

Observe that

$$\langle y,z\rangle \le \frac{C\|y\|\|z\|}{\sqrt{d}}$$

with probability at least 0.99 by a measure-concentration argument. Indeed, most of the vectors z are almost perpendicular to the given vector y. Now, using (23),

$$\sup_{y'\in[0,y]} D^3F(y')[y,y,z] \le \sup_{y'\in[0,y]} 2\|y\|_{y'}^2\|z\|_{y'} \le \frac{Cr^2}{d}$$

and

$$\sup_{z'\in[0,z]} D^3F(z')[y,z,z] \le \sup_{z'\in[0,z]} 2\|y\|_{z'}\|z\|_{z'}^2 \le \frac{Cr^3}{\sqrt{d}} \le \frac{Cr^2}{d}$$

with probability at least 0.99. Therefore, there exists a constant $C > 0$ such that

$$\mathbb{P}\left[\langle y,z\rangle_y < \frac{Cr^2}{d}\right] > 0.98$$

and the same statement holds for $\langle y,z\rangle_z$. We also have that

$$\mathbb{P}\left[\frac{\|y\|\|z\|}{\sqrt{d}} + \sup_{z'\in[0,z]} 2\|y\|_{z'}\|z\|_{z'}^2 \le \frac{Cr^2}{d}\right] > 0.99$$

Therefore,

$$\mathbb{P}\left[\langle y,z\rangle_z < \frac{Cr^2}{d}\right] > 0.98.$$

■

8. Self-concordant barriers

Let $\mathcal{K}$ be a convex subset of $\mathbb{R}^d$ that is not contained in any $(d-1)$-dimensional affine subspace and $int(\mathcal{K})$ denote its interior. Following Nesterov and Nemirovskii, we call a real-valued function $F : int(\mathcal{K}) \to \mathbb{R}$, a regular self-concordant barrier if it satisfies the conditions stated below. For convenience, if $x \notin int(\mathcal{K})$, we define $F(x) = \infty$.

1. (Convex, Smooth) F is a convex thrice continuously differentiable function on $int(\mathcal{K})$.
2. (Barrier) For every sequence of points $\{x_i\} \in int(\mathcal{K})$ converging to a point $x \notin int(\mathcal{K})$, $\lim_{i\to\infty} f(x_i) = \infty$.
3. (Differential Inequalities) For all $h \in \mathbb{R}^d$ and all $x \in int(\mathcal{K})$, the following inequalities hold.
   (a) $D^2F(x)[h,h]$ is 2-Lipschitz continuous with respect to the local norm, which is equivalent to
   $$D^3F(x)[h,h,h] \le 2(D^2F(x)[h,h])^{\frac{3}{2}}.$$
   (b) $F(x)$ is ν-Lipschitz continuous with respect to the local norm defined by F,
   $$|DF(x)[h]|^2 \le \nu D^2F(x)[h,h].$$
   We call the smallest positive integer ν for which this holds, *the self-concordance parameter* of the barrier.

The following results can be found, for instance, in (Nesterov and Nemirovskii, 1994; Nemirovskii, 2004; Nemirovski and Todd, 2008). First,

$$|D^3F(x)[h_1,\ldots,h_k]| \le 2\|h_1\|_x\|h_2\|_x\|h_3\|_x\,. \tag{23}$$

Second, if $\delta = \|h\|_x < 1$, then

$$(1-\delta)^2D^2F(x) \preceq D^2F(x+h) \preceq (1-\delta)^{-2}D^2F(x)\,. \tag{24}$$

Abstract

We present an approach based on feed-forward neural networks for learning the distribution over textual documents. This approach is inspired by the Neural Autoregressive Distribution Estimator (NADE) model which has been shown to be a good estimator of the distribution over discrete-valued high-dimensional vectors. In this paper, we present how NADE can successfully be adapted to textual data, retaining the property that sampling or computing the probability of an observation can be done exactly and efficiently. The approach can also be used to learn deep representations of documents that are competitive to those learned by alternative topic modeling approaches. Finally, we describe how the approach can be combined with a regular neural network N-gram model and substantially improve its performance, by making its learned representation sensitive to the larger, document-level context.

Keywords: Neural networks, Deep learning, Topic models, Language models, Autoregressive models

1. Introduction

One of the most common problems in machine learning is to estimate a distribution $p(\mathbf{v})$ of multidimensional data from a set of examples $\{\mathbf{v}^{(t)}\}_{t=1}^{T}$. Indeed, good estimates of $p(\mathbf{v})$ implicitly require modeling the dependencies between the variables in $\mathbf{v}$, which is required to extract meaningful representations of this data or make predictions about this data. We are particularly interested in the case where $\mathbf{v}$ is not a sequence, where the order in the vector is not relevant (random order).

The biggest challenge one faces in distribution estimation is the well-known curse of dimensionality. In fact, this issue is particularly important in distribution estimation, even more so than in other machine learning problems. This is because a good distribution estimator must provide an accurate value of $p(\mathbf{v})$ for any given $\mathbf{v}$ (i.e. not only for likely values of $\mathbf{v}$), while the number of possible values grows exponentially as the number of dimensions of the input vector $\mathbf{v}$ increases.

One example of such a model that has been successful at tackling the curse of dimensionality is the restricted Boltzmann machine (RBM) (Hinton, 2002). The RBM and other models derived from it (e.g. the Replicated Softmax of Salakhutdinov and Hinton (2009)) are frequently trained as models of the probability distribution of high-dimensional observations and then used as feature extractors. Unfortunately, one problem with these models is that for moderately large models, calculating their estimate of $p(\mathbf{v})$ is intractable. Indeed, this calculation requires computing the partition function which normalizes the model distribution. The consequences of this property of the RBM are that approximation must be taken to train it by maximum likelihood, and that its estimation of $p(\mathbf{v})$ cannot be entirely trusted.

In an attempt to tackle these issues of the RBM, the Neural Autoregressive Distribution Estimator (NADE) was introduced by Larochelle and Murray (2011). NADE's parametrization is inspired by the RBM, but uses feed-forward neural networks and the framework of autoregression for modeling the probability distribution of binary variables in high-dimensional vectors. Importantly, computing the probability of an observation under NADE can be done exactly and efficiently.

In this paper, we describe a variety of ways to extend NADE to model data from text documents. Why work with text, where the word order is important, when we said previously that we are interested in the order not being relevant? Because the text is often represented with bag-of-words, and it has no information about the order of the words. The advantage here is that we can model a good part of the text semantically while ignoring its syntax.

We start by describing Document NADE (DocNADE), a single hidden layer feed-forward neural network model for bag-of-words observations, i.e. orderless sets of words. This requires adapting NADE to vector observations $\mathbf{v}$, where each of element v_i represents a word and where the order of the dimensions is random. Each word is represented with a lower-dimensional, real-valued embedding vector, where similar words should have similar embeddings. This is in line with much of the recent work on using feed-forward neural network models to learn word vector embeddings (Bengio et al., 2003; Mnih and Hinton, 2007, 2009; Mikolov, 2013) to counteract the curse of dimensionality. However, in DocNADE, the word representations are trained to reflect the topics (i.e. semantics) of documents only, as opposed to their syntactical properties, due to the orderless nature of bags-of-words.

We then describe how to train a deep version of DocNADE. First described by Zheng et al. (2015) in the context of image modeling, here we empirically evaluate them for text documents and show that they are competitive to existing topic models, both in terms of perplexity and document retrieval performances.

Finally, we present how the topic-level modeling ability of DocNADE can be used to obtain a useful representation of context (semantic information about the past) for language modeling. We empirically demonstrate that by learning a topical representation (representation based on subjects, topics) of previous sentences, we can improve the perplexity performance of an N-gram neural language model.

2. Document NADE (DocNADE)

DocNADE is derived from the Neural Autoregressive Distribution Estimation (NADE). We first describe NADE in this Section.

2.1 Neural Autoregressive Distribution Estimation (NADE)

NADE, introduced by Larochelle and Murray (2011), is a tractable distribution estimator for modeling the distribution over high-dimensional binary vectors. Let us consider a binary vector of D observations, $\mathbf{v} \in \{0,1\}^D$, where the order has no meaning. We use the notation v_i to denote the i-th component of $\mathbf{v}$ and $\mathbf{v}_{<i} \in \{0,1\}^{i-1}$ to contain the first $i-1$ components of $\mathbf{v}$. $\mathbf{v}_{<i}$ is the sub-vector $[v_1, \ldots, v_{i-1}]^\top$:

$$\mathbf{v} = [\underbrace{v_1, \ \ldots, v_{i-1}}_{\mathbf{v}_{<i}}, v_i, \ \ldots, v_D]^T. \tag{1}$$

The NADE model estimates the probability of the vector $\mathbf{v}$ by applying the probability chain rule as follows:

$$p(\mathbf{v}) = \prod_{i=1}^{D} p(v_i|\mathbf{v}_{<i}). \tag{2}$$

The peculiarity of NADE lies in the neural architecture designed to estimate the conditional probabilities involved in Equation 2. To predict the component i, the model first computes its hidden layer of dimension H

$$\mathbf{h}_i(\mathbf{v}_{<i}) = \mathbf{g}\left(\mathbf{c} + \mathbf{W}_{:,<i} \cdot \mathbf{v}_{<i}\right), \tag{3}$$

leading to the following probability model:

$$p(v_i = 1|\mathbf{v}_{<i}) = \mathrm{sigm}\left(b_i + \mathbf{V}_{i,:} \cdot \mathbf{h}_i(\mathbf{v}_{<i})\right). \tag{4}$$

In these two equations, $\mathrm{sigm}(x) = 1/(1+\exp(-x))$ denotes the sigmoid activation function while function $\mathbf{g}(\cdot)$ could be any activation function. Larochelle and Murray (2011) used the sigmoid function for $\mathbf{g}(\cdot)$. $\mathbf{W} \in \mathbb{R}^{H \times D}$ and $\mathbf{V} \in \mathbb{R}^{D \times H}$ are the parameter matrices along with the associated bias terms $\mathbf{b} \in \mathbb{R}^D$ and $\mathbf{c} \in \mathbb{R}^H$. The notation $\mathbf{W}_{:,<i}$ represents a matrix made of the $i-1$ first columns of $\mathbf{W}$. The vector $\mathbf{V}_{i,:}$ is made from the i-th row of $\mathbf{V}$ and is composed of weights associated to a logistic classifier, meaning that each row of $\mathbf{V}$ represent a different logistic classifier.

Instead of a single projection of the input vector (like for a typical autoencoder, the left part of Figure 1), the NADE model relies on a set of separate hidden layers $\mathbf{h}_i(\mathbf{v}_{<i})$ that each represent the previous inputs in a latent space (right part of Figure 1). The connections between the input dimension v_i and each hidden layer $\mathbf{h}_i(\mathbf{v}_{<i})$ are tied as shown with the blue lines in Figure 1, allowing the model to compute all the hidden layers for one input in $O(DH)$. The parameters $\{\mathbf{b}, \mathbf{c}, \mathbf{W}, \mathbf{V}\}$ are learned by minimizing the average negative log-likelihood using stochastic gradient descent.

2.2 From NADE to DocNADE

The Document NADE model (DocNADE) aims at learning meaningful representations of texts from a collection of unlabeled documents. Implemented as a feed-forward architecture, it extends NADE to provide an efficient and meaningful generative model of document bags-of-words. This model embeds, as NADE did, a set of hidden layers. Their role is to capture salient statistical patterns in the

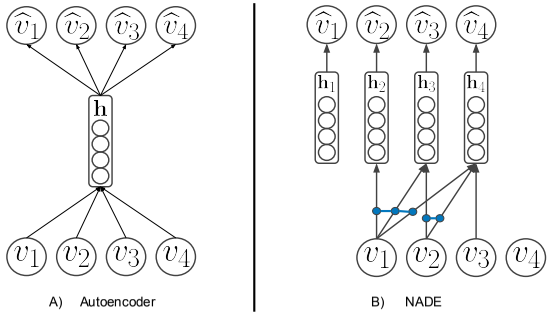

Figure 1: **A)** Typical structure for an autoencoder. **B)** Illustration of NADE. Colored lines identify the connections that share parameters and $\widehat{v}_i$ is a shorthand for the autoregressive conditional $p(v_i|\mathbf{v}_{<i})$. The observations v_i are binary.

co-occurrence of words within documents and can be considered as modeling hidden topics. This is called topic modeling (Steyvers and Griffiths, 2007), where a topic model gives a mathematical representation of a document in the form of a vector (of real values). In our case each element of the vector is a neuron of the hidden layer and can be associated to a hidden subject where its value would represent how much that subject is part of the text. This representation can be seen as a composition of the subjects.

To represent a document for DocNADE, we transform a bag-of-words into a sequence $\mathbf{v}$ of arbitrary size D. Each element of $\mathbf{v}$ corresponds to a multinomial observation (representing a word) over a fixed vocabulary of size V:

$$\mathbf{v} = [v_1, v_2, \ \ldots, v_D], \ \ v_i \in \{1, 2, \ \ldots, V\}. \tag{5}$$

Therefore v_i represents the index in the vocabulary of the i-th word of the document. For now, we assume that an ordering of the words is given, but we will discuss the general case of orderless bags-of-words in the next Section (2.2.1) and show that we can simply use a random order for the words during training.

The DocNADE model uses a word representation matrix $\mathbf{W} \in \mathbb{R}^{H \times V}$, where each column $\mathbf{W}_{:,v_i}$ of the matrix is a vector representing one of the words in the vocabulary (see Figure 2). This matrix makes the connection possible between the index v_i of a word and its embedding.

The main approach taken by DocNADE is similar to NADE, but differs significantly in the design of parameter tying. The probability of a document $\mathbf{v}$ is estimated using the probability chain rule, but the architecture is modified to cope with large vocabularies. Each word observation v_i of the document $\mathbf{v}$ leads to a hidden layer $\mathbf{h}_i$, which represents the past observations $\mathbf{v}_{<i}$ (see figure 3).

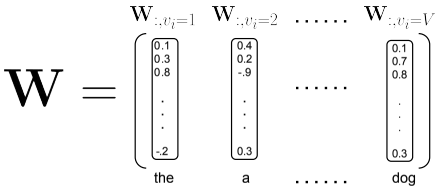

Figure 2: Word representation matrix $\mathbf{W}$, where each column of the matrix is a vector representing a word of the vocabulary.

This hidden layer is computed as follows:

$$\mathbf{h}_i(\mathbf{v}_{<i}) = \mathbf{g}\left(\mathbf{c} + \sum_{k<i} \mathbf{W}_{:,v_k}\right), \tag{6}$$

where each column of the matrix $\mathbf{W}$ acts as a vector of size H that represents a word. The embedding of the i^{th} word in the document is thus the column of index v_i in the matrix $\mathbf{W}$.

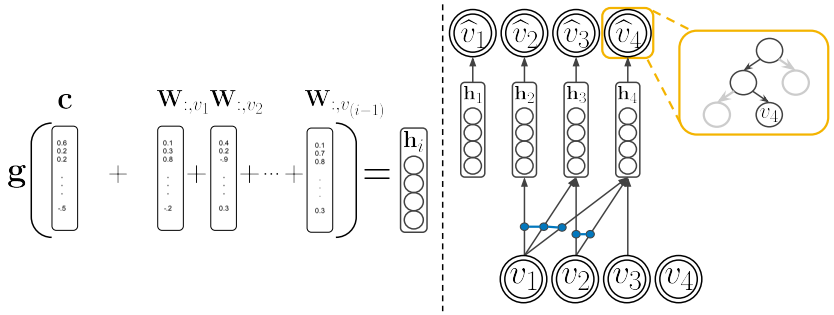

Figure 3: (**Left**) Representation of the computation of a hidden layer $\mathbf{h}_i$, function $\mathbf{g}(\cdot)$ can be any activation function. (**Right**) Illustration of DocNADE. Connections between each multinomial observation v_i and hidden units are also shared, and each conditional $p(v_i|\mathbf{v}_{<i})$ is decomposed into a tree of binary logistic regressions.

Notice that by sharing the word representation matrix across positions in the document, each hidden layer $\mathbf{h}_i(\mathbf{v}_{<i})$ is in fact independent of the order of the words within $\mathbf{v}_{<i}$. We made the hypothesis that even if the word order affect semantics, most of its information depends on the set of words used. DocNADE ignores in which order the previously observed words appeared. The implications of this choice is that the learned hidden representation will not model the syntactic structure of the document and focus entirely on its document-level semantics, i.e. its topics. It also means that the first word at the beginning of the sequence has the same influence as the last one, and

its importance compared to the other words does not deteriorate over time. This phenomenon can be observed in the left part of Figure 3. With this illustration we see that if we swap the first word v_1 with the last one v_{i-1} we would obtain the same hidden representation $\mathbf{h}_i$.

It is also worth noticing that we can compute $\mathbf{h}_{i+1}$ recursively by keeping track of the pre-activation of the previous hidden layer $\mathbf{h}_i$ as follows:

$$\mathbf{h}_{i+1}(\mathbf{v}_{<i+1}) = \mathbf{g}\left(\mathbf{W}_{:,v_i} + \underbrace{\mathbf{c} + \sum_{k<i} \mathbf{W}_{:,v_k}}_{\text{Precomputed for } \mathbf{h}_i(\mathbf{v}_{<i})}\right) \tag{7}$$

The weight sharing between the hidden layers enables us to compute all the hidden layers $\mathbf{h}_i(\mathbf{v}_{<i})$ for a document in $O(DH)$.

To compute the probability of a full document $p(\mathbf{v})$, we need to estimate all conditional probabilities $p(v_i|\mathbf{v}_{<i})$. A straightforward solution would be to compute each $p(v_i|\mathbf{v}_{<i})$ using a softmax layer with a shared weight matrix and bias with each of the hidden layers $\mathbf{h}_i$. However, the computational cost of this approach is prohibitive, as it scales linearly with the vocabulary size.[1] To overcome this issue, we represent a distribution over the vocabulary by a probabilistic binary tree, where the leaves correspond to the words. This approach is widely used in the field of neural probabilistic language models (Morin and Bengio, 2005; Mnih and Hinton, 2009). Each word is represented by a path in the tree, going from the root to the leaf associated to that word. A binary logistic regression unit is associated to each node in the tree and gives the probability of the binary choice, going left or right. A word probability can therefore be estimated by the path's probability in this tree, resulting in a complexity in $O(\log V)$ for a balanced tree. In our experiments, we used a randomly generated full binary tree with V leaves, each assigned to a unique word in the vocabulary.

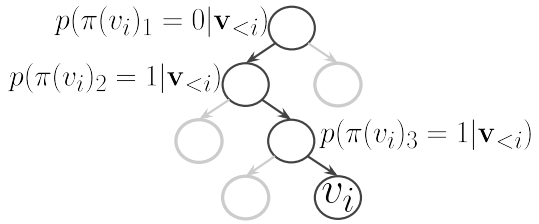

Figure 4: Path of the word v_i in a binary tree. We compute the probability of the left/right choice (0/1) for each node of the path.

More formally, let's denote by $\mathbf{l}(v_i)$ the sequence of nodes composing the path, from the root of the tree to the leaf corresponding to the word v_i. Then, $\boldsymbol{\pi}(v_i)$ is the sequence of left/right decisions of the nodes in $\mathbf{l}(v_i)$. For example, the root of the tree is always the first element $l(v_i)_1$ and the value

1. For most natural language processing tasks, the vocabulary size exceeds $10,000$.

$\pi(v_i)_1$ will be 0 if the word is in the left sub-tree and 1 if it is in the right sub-tree (see figure 4). The matrix $\mathbf{V}$ stores by row the weights associated to each logistic classifier. There is one logistic classifier per node in the tree, but only a fraction of them is used for each word. Let $\mathbf{V}_{l(v_i)_m,:}$ and $b_{l(v_i)_m}$ be the weights and bias of the logistic unit associated with the node $n(v_i)_m$. The probability $p(v_i|\mathbf{v}_{<i})$ given the tree and the hidden layer $\mathbf{h}_i(\mathbf{v}_{<i})$ is computed by the following formulas:

$$p(v_i = w|\mathbf{v}_{<i}) = \prod_{m=1}^{|\boldsymbol{\pi}(v_i)|} p(\pi(v_i)_m = \pi(w)_m|\mathbf{v}_{<i}), \text{ with} \tag{8}$$

$$p(\pi(v_i)_m = 1|\mathbf{v}_{<i}) = \text{sigm}\left(b_{l(v_i)_m} + \mathbf{V}_{l(v_i)_m,:} \cdot \mathbf{h}_i(\mathbf{v}_{<i})\right). \tag{9}$$

This hierarchical architecture allows us to efficiently compute the probability of each word in a document and therefore the probability of the whole document with the probability chain rule (see Equation 2). As in the NADE model, the parameters of the model $\{\mathbf{b}, \mathbf{c}, \mathbf{W}, \mathbf{V}\}$ are learnt by minimizing the negative log-likelihood using stochastic gradient descent.

Since there is $\log(V)$ logistic regression units for a word (one per node), each of them has a time complexity of $O(H)$, the complexity of computing the probability for a document of D words is in $O(\log(V)DH)$.

For using DocNADE to extract features from a complete document, we propose to use

$$\mathbf{h}(\mathbf{v}) = \mathbf{h}_{D+1}(\mathbf{v}_{<D+1}) = \mathbf{g}\left(\mathbf{c} + \sum_{k=1}^{D} \mathbf{W}_{:,v_k}\right) \tag{10}$$

which would be the hidden layer computed to obtain the conditional probability of a hypothetical $(D+1)$-th word appearing in the document. In other words, $\mathbf{h}(\mathbf{v})$ is the representation of all the words in the document. Notice that we do not average the document representation to become invariant to document length. Averaging did not result in any performance improvement in our preliminary experiments. We conjecture that it is because every word count n_i in the data was replaced by $\log(1 + n_i)$, which reduces the variability of the input values and makes the model more invariant to the document length. However, averaging sometimes is useful, such as for the language model approach (see Section 4).

Algorithm 1 gives the pseudo-code for computing the negative log-likelihood cost used during training and the hidden layer used for representing the whole document under DocNADE.

2.2.1 Training from bag-of-words counts

So far, we have assumed that the ordering of the words in the document is known. However, a document often takes the form of word-count vectors in which the original word order, required for specifying the sequence of conditionals $p(v_i|\mathbf{v}_{<i})$, has been lost.

It is however still possible to successfully train a DocNADE despite the absence of this information. The idea is to assume that each observed document $\mathbf{v}$ was generated by initially sampling a *seed* document $\widetilde{\mathbf{v}}$ from DocNADE, whose words were then shuffled using a randomly generated ordering to produce $\mathbf{v}$. With this approach, we can express the probability distribution of $\mathbf{v}$ by computing the marginal over all possible seed document:

$$p(\mathbf{v}) = \sum_{\widetilde{\mathbf{v}} \in \mathcal{V}(\mathbf{v})} p(\mathbf{v}, \widetilde{\mathbf{v}}) = \sum_{\widetilde{\mathbf{v}} \in \mathcal{V}(\mathbf{v})} p(\mathbf{v}|\widetilde{\mathbf{v}}) p(\widetilde{\mathbf{v}}) \tag{11}$$

Algorithm 1 Computing of the cost for training and the hidden layer for representing an entire document (DocNADE model)

Input: Multinomial observation $\mathbf{v}$

$\mathbf{a} \leftarrow \mathbf{c}$
$NLL \leftarrow 0$
For $i = 1$ to D **Do**
  $\mathbf{h}_i \leftarrow \mathbf{g}(\mathbf{a})$

  $p(v_i) \leftarrow 1$
  For $m = 1$ to $|\boldsymbol{\pi}(v_i)|$ **Do**
    $p(\pi(v_i)_m = 1|\mathbf{v}_{<i}) \leftarrow \text{sigm}\left(b_{l(v_i)_m} + \mathbf{V}_{l(v_i)_m,:} \cdot \mathbf{h}_i(\mathbf{v}_{<i})\right)$
    $p(v_i) \leftarrow p(v_i)\left(p(\pi(v_i)_m = 1|\mathbf{v}_{<i})^{\pi(v_i)_m} + (1 - p(\pi(v_i)_m = 1|\mathbf{v}_{<i})^{1-\pi(v_i)_m})\right)$
  End for

  $NLL \leftarrow NLL - \log p(v_i)$
  $\mathbf{a} \leftarrow \mathbf{a} + \mathbf{W}_{:,v_i}$
End for

$\mathbf{h}_{final} \leftarrow \mathbf{g}(\mathbf{a})$

Return NLL, $\mathbf{h}_{final}$

where $p(\widetilde{\mathbf{v}})$ is modeled by DocNADE. $\widetilde{\mathbf{v}}$ is the same as the observed document $\mathbf{v}$ but with a different (random) word sequence order, and $\mathcal{V}(\mathbf{v})$ is the set of all the documents $\widetilde{\mathbf{v}}$ that has the same word count $\mathbf{n}(\mathbf{v}) = \mathbf{n}(\widetilde{\mathbf{v}})$. With the assumption of orderings being uniformly sampled, we can replace $p(\mathbf{v}|\widetilde{\mathbf{v}})$ with $\frac{1}{|\mathcal{V}(\mathbf{v})|}$ giving us:

$$p(\mathbf{v}) = \sum_{\widetilde{\mathbf{v}} \in \mathcal{V}(\mathbf{v})} \frac{1}{|\mathcal{V}(\mathbf{v})|} p(\widetilde{\mathbf{v}}) = \frac{1}{|\mathcal{V}(\mathbf{v})|} \sum_{\widetilde{\mathbf{v}} \in \mathcal{V}(\mathbf{v})} p(\widetilde{\mathbf{v}}). \tag{12}$$

In practice, one approach to training the DocNADE model over $\widetilde{\mathbf{v}}$ is to artificially generate ordered documents by uniformly sampling words, without replacement, from the bags-of-words in the dataset. This would be equivalent to taking each original document and shuffling the order of its words. This approach can be shown to minimize a stochastic upper bound on the true negative log-likelihood of documents. As we will see, experiments show that convincing performance could still be reached.

With this training procedure, DocNADE shows its ability to learn and predict a new word in a document at a random position while preserving the overall semantic properties of the document. The model is therefore learning not to insert intruder words, i.e. words that do not belong with the others. After training, a document's learned representation should contain valuable information to identify intruder words for this document. It is interesting to note that the detection of such intruder words has been used previously as a task in user studies to evaluate the quality of the topics learned by LDA, though at the level of single topics and not whole documents (Chang et al., 2009).

The goal with DocNADE is to have a simple, powerful, fast way to train model that can also be used with data that have lost the information about ordering. We want to learn topic-level semantics, where the order of the words is less important than the existence of words is, instead of learning syntax, where the order of the words is more important. In this context, it makes no sense to apply an RNN-like model on randomly shuffled words, since there's no position varying information to model.

3. Deep Document NADE

The single hidden layer version of DocNADE already achieves very competitive performance for topic modeling (Larochelle and Lauly, 2012). Extending it to a deep architecture with multiple hidden layer could however enable better performance, as suggested by the recent and impressive success of deep neural networks. Unfortunately, deriving a deep version of DocNADE cannot be achieved solely by adding hidden layers to the definition of the conditionals $p(v_i|\mathbf{v}_{<i})$. Indeed, computing $p(\mathbf{v})$ requires computing each $p(v_i|\mathbf{v}_{<i})$ conditional (one for each word), and it is no longer possible to use Equation 7 to compute the sequence of all hidden layers in $O(DH)$ when there are multiple deep hidden layers.

In this Section, we describe an alternative training procedure that enables us the introduction of multiple stacked hidden layers. This procedure was first introduced by Zheng et al. (2015) to model images, which was itself borrowing from the training scheme introduced by Uria et al. (2014).

As mentioned in Section 2.2.1, DocNADE can be trained on random permutations of the words from training documents. As noticed by Uria et al. (2014), the use of many orderings during training can be seen as the instantiation of many different DocNADE models that share a single set of parameters. Thus, training DocNADE with random permutations also amounts to minimizing the negative log-likelihood averaged across all possible orderings, for each training example $\mathbf{v}$.

In the context of deep NADE models, a key observation is that training on all possible orderings implies that for a given context $\mathbf{v}_{<i}$, we encourage the model to be equally good at predicting any of the remaining words appearing next. Thus, we redesign the training algorithm such that, instead of sampling a complete ordering of all words for each update, we instead sample a single context $\mathbf{v}_{<i}$ and perform an update of the conditionals using that context. This is done as follows. For a given document, after generating vector $\mathbf{v}$ by shuffling the words from the document, a split point i is randomly drawn. From this split point we obtain two parts of the document, $\mathbf{v}_{<i}$ and $\mathbf{v}_{\geq i}$:

$$\mathbf{v} = [\underbrace{v_1, \ \ldots, v_{i-1}}_{\mathbf{v}_{<i}}, \underbrace{v_i, \ \ldots, v_D}_{\mathbf{v}_{\geq i}}]^\top. \tag{13}$$

The vector $\mathbf{v}_{<i}$ is considered as the input and the vector $\mathbf{v}_{\geq i}$ contains the targets to be predicted by the model. Since a training update relies on the computation of a single latent representation, that of $\mathbf{v}_{<i}$ for the drawn value of i, deeper hidden layers can be added at a reasonable increase in computation. We call a deep DocNADE trained with this procedure a DeepDocNADE.

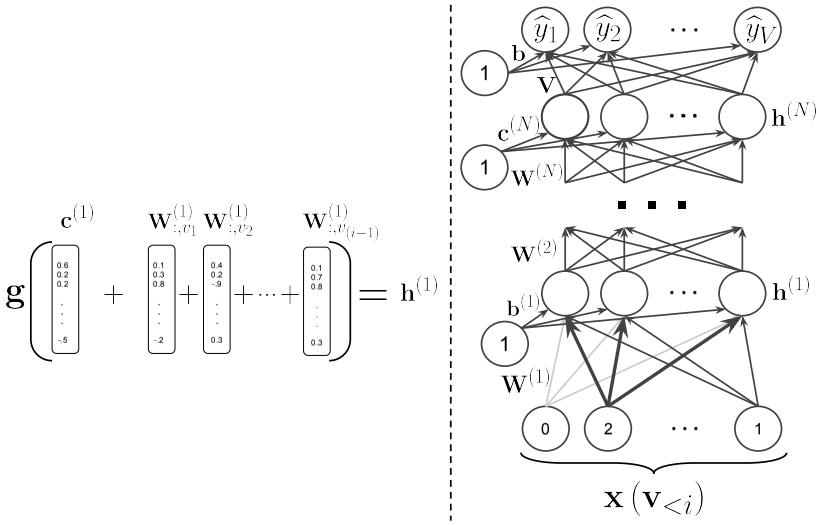

Figure 5: (**Left**) Representation of the computation by summation of the first hidden layer $\mathbf{h}^{(1)}$, which is equivalent to multiplying the bag-of-words $\mathbf{x}\left(\mathbf{v}_{<i}\right)$ with the word representation matrix $\mathbf{W}^{(1)}$. (**Right**) Illustration of DeepDocNADE architecture.

In DeepDocNADE the conditionals $p(v_i|\mathbf{v}_{<i})$ are modeled as follows. The first hidden layer $\mathbf{h}^{(1)}(\mathbf{v}_{<i})$ represents the conditioning context $\mathbf{v}_{<i}$ as in the single hidden layer DocNADE:

$$\mathbf{h}^{(1)}\left(\mathbf{v}_{<i}\right) = \mathbf{g}\left(\mathbf{c}^{(1)} + \sum_{k<i} \mathbf{W}^{(1)}_{:,v_k}\right) = \mathbf{g}\left(\mathbf{c}^{(1)} + \mathbf{W}^{(1)} \cdot \mathbf{x}\left(\mathbf{v}_{<i}\right)\right) \tag{14}$$

where $\mathbf{x}\left(\mathbf{v}_{<i}\right)$ is the histogram vector representation (bag-of-words) of the word sequence $\mathbf{v}_{<i}$, and the exponent is used as an index over the hidden layers and its parameters, with (1) referring to the first layer (see Figure 5). The matrix $\mathbf{W}^{(1)}$ is the word representation matrix of DeepDocNADE. Notice that like DocNADE, the first hidden layer $\mathbf{h}^{(1)}(\mathbf{v}_{<i})$ of DeepDocNADE is independent of the order of the words within $\mathbf{v}_{<i}$. We can now easily add new hidden layers as in a regular deep feed-forward neural network:

$$\mathbf{h}^{(n)}(\mathbf{v}_{<i}) = \mathbf{g}(\mathbf{c}^{(n)} + \mathbf{W}^{(n)} \cdot \mathbf{h}^{(n-1)}(\mathbf{v}_{<i})), \tag{15}$$

for $n = 2, \ldots, N$, where N is the total number of hidden layers. From the last hidden layer $\mathbf{h}^{(N)}$, we compute the conditional $p(v_i = w|\mathbf{v}_{<i})$, for any word w:

$$\widehat{y}_w = p(v_i = w|\mathbf{v}_{<i}) = \text{softmax}(\mathbf{V}_{w,:} \cdot \mathbf{h}^{(N)}(\mathbf{v}_{<i}) + b_w), \tag{16}$$

$$\widehat{\mathbf{y}} = \text{softmax}(\mathbf{V} \cdot \mathbf{h}^{(N)}(\mathbf{v}_{<i}) + \mathbf{b}), \tag{17}$$

where $\mathbf{V} \in \mathbb{R}^{V \times H^{(N)}}$ is the output parameter matrix and $\mathbf{b}$ the bias vector. The notation $\widehat{\mathbf{y}}$ is a vector that represents the probability of all the vocabulary words computed at once. Each element of the vector, $\hat{y}_1$ to $\hat{y}_V$, represents one of the words in the vocabulary. We use $\hat{y}_w$ to make the connection with $v_i = w$ (the index of the word w at time i).

Finally, the loss function used to update the model for the given context $\mathbf{v}_{<i}$ is:

$$L(\mathbf{v}) = \frac{D_\mathbf{v}}{D_\mathbf{v} - i + 1} \sum_{w \in \mathbf{v}_{\geq i}} -\log p(v_i = w | \mathbf{v}_{<i}), \tag{18}$$

where $D_\mathbf{v}$ is the number of words in $\mathbf{v}$, and the summation iterates over all the words w present in $\mathbf{v}_{\geq i}$. Thus, as described earlier, the model predicts each remaining word after the splitting position i as if it was actually at position i. The factor in front of the summation comes from the fact that the complete log-likelihood would contain $D_\mathbf{v}$ log-conditionals and that we are averaging over $D_\mathbf{v} - i + 1$ possible choices for the word at position i. For a more detailed presentation, see Zheng et al. (2015). The average loss function of Equation 18 is optimized with stochastic gradient descent.[2]

Note that to compute the probability $p(v_i = w | \mathbf{v}_{<i})$, a probabilistic tree could again be used. However, since all probabilities needed for an update are based on a single context $\mathbf{v}_{<i}$, a single softmax layer is sufficient to compute all necessary quantities. Therefore the computational burden of a conventional softmax is not as prohibitive as for DocNADE, especially with an efficient implementation on the GPU. For this reason, in our experiments with DeepDocNADE we opted for a regular softmax.

4. DocNADE Language Model

While topic models such as DocNADE can be useful in learning topic representations of documents, they are very poor models of language. In DocNADE, this is due to the fact that, when assigning a probability to the next word in a sentence, it ignores the order in which the previously observed words appeared. Yet, this ordering of words conveys a lot of information regarding a syntactic role of the next word or the finer semantics within the sentence. In fact, most of that information is predictable from the last few words, which is why N-gram language models remain a dominating approach to language modeling.

In this Section, we propose a new model that extends DocNADE to mitigate the influence of both short and long term dependencies in a single model, which we refer to as the DocNADE language model or DocNADE-LM. The solution we propose enhances the bag-of-words representation with the explicit inclusion of n-gram dependencies.

Figure 6 depicts the overall architecture. This model can be seen as an extension of the seminal work on neural language models by Bengio et al. (2003) that includes the representation of a document's larger context. It can also be seen as a neural extension of the cache-based language model introduced in (Kuhn and Mori, 1990), where the n-gram probability is interpolated with the

2. A document is usually represented as bag-of-words. Generating a word vector $\mathbf{v}$ from its bag-of-words, shuffling the word count vector $\mathbf{v}$, splitting it, and then regenerating the histogram $\mathbf{x}\,(\mathbf{v}_{<i})$ and $\mathbf{x}\,(\mathbf{v}_{\geq i})$ is unfortunately fairly inefficient for processing samples in a mini-batch fashion. Hence, in practice, we split the original histogram $\mathbf{x}\,(\mathbf{v})$ directly by uniformly sampling, for each word individually, how many are put on the left of the split (the others are put on the right of the split). This procedure, used also by Zheng et al. (2015), is only an approximation to the correct procedure mentioned in the main text, but results in substantial speedup while also yielding good performance.

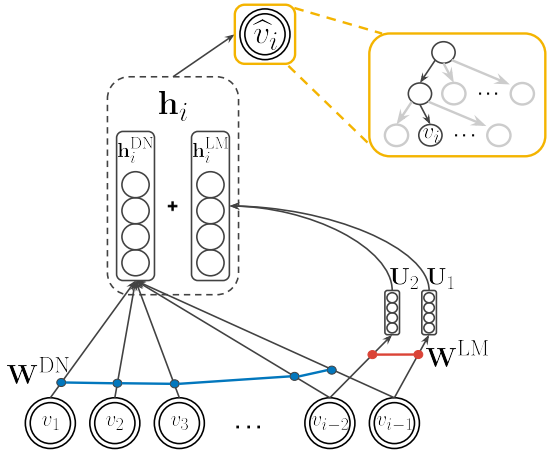

Figure 6: Illustration of the conditional $p(v_i|\mathbf{v}_{<i})$ in a trigram NADE language model. Compared to DocNADE, this model incorporates the architecture of a neural language model, that first maps previous words (2 for a trigram model) to vectors using an embedding matrix $\mathbf{W}^{\mathrm{LM}}$ before connecting them to the hidden layer using regular (untied) parameter matrices ($\mathbf{U_1}$, $\mathbf{U_2}$ for a trigram). In our experiments, each conditional $p(v_i|\mathbf{v}_{<i})$ exploits decomposed into a tree of logistic regressions, the hierarchical softmax.

word distribution observed in a dynamic cache. This cache of a fixed size keeps track of previously observed words to include long term dependencies in the prediction and preserve semantic consistency beyond the scope of the n-gram. The DocNADE language model maintains an unbounded cache and defines a proper, jointly trained solution to mitigate these two kinds (long and short) of dependencies.

As in DocNADE, a document $\mathbf{v}$ is modeled as a sequence of multinomial observations. The sequence size is arbitrary and this time the order is important, each element v_i consists of the i-th word of the sequence and represent an index in a vocabulary of size V. The conditional probability of a word given its history $p(v_i|\mathbf{v}_{<i})$ is now expressed as a smooth function of a hidden layer $\mathbf{h}_i(\mathbf{v}_{<i})$ used to predict word v_i. The peculiarity of the DocNADE language model lies in the definition of this hidden layer, which now includes two terms:

$$\mathbf{h}_i(\mathbf{v}_{<i}) = \mathbf{g}(\mathbf{b} + \mathbf{h}_i^{\mathrm{DN}}(\mathbf{v}_{<i}) + \mathbf{h}_i^{\mathrm{LM}}(\mathbf{v}_{<i})). \tag{19}$$

The first term borrows from the DocNADE model by aggregating embeddings for all the previous words in the history:

$$\mathbf{h}_i^{\mathrm{DN}}(\mathbf{v}_{<i}) = \frac{1}{i-1} \sum_{k<i} \mathbf{W}^{\mathrm{DN}}_{:,v_k}, \tag{20}$$

where $i - 1$ is the number of words used to create $\mathbf{h}_i^{\mathrm{DN}}(\mathbf{v}_{<i})$. We average the hidden representation by the number of words to get good results for the language modeling task, so that the

representation can become invariant to the document's length. The hidden representation $\mathbf{h}_i^{\text{DN}}(\mathbf{v}_{<i})$ models the semantic aspects of the text that have been observed so far. As we explained earlier for DocNADE, the order of the words within $\mathbf{v}_{<i}$ is not modeled. The hidden layer $\mathbf{h}_i^{\text{DN}}(\mathbf{v}_{<i})$ can be seen as a context representation of the past where the influence of a word relative to other words does not diminish over time.

The second contribution derives from a neural n-gram language model as follows:

$$\mathbf{h}_i^{\text{LM}}(\mathbf{v}_{<i}) = \sum_{k=1}^{n-1} \mathbf{U}_k \cdot \mathbf{W}^{\text{LM}}_{:,v_{i-k}} \ . \tag{21}$$

In this formula, the history for the word v_i is restricted to the $n-1$ preceding words, following the common n-gram assumption. The term $\mathbf{h}_i^{\text{LM}}$ hence represents the continuous representation of these $n-1$ words, in which word embeddings are linearly transformed by the ordered matrices $\mathbf{U}_1, \mathbf{U}_2, ..., \mathbf{U}_{n-1}$. Moreover, $\mathbf{b}$ gathers the bias terms for the hidden layer. In this model, two sets of word embeddings are defined, $\mathbf{W}^{\text{DN}}$ and $\mathbf{W}^{\text{LM}}$, which are respectively associated to the DocNADE and neural language model parts. For simplicity, we assume both are of the same size H.

Given hidden layer $\mathbf{h}_i(\mathbf{v}_{<i})$, conditional probabilities $p(v_i|\mathbf{v}_{<i})$ can be estimated, and thus $p(\mathbf{v})$. For the aforementioned reason explained in DocNADE, the output layer is structured as a probabilistic tree for efficient computations. Specifically, we decided to use a variation of the probabilistic binary tree, known as a hierarchical softmax layer. In this case, instead of having binary nodes with multiple levels in the tree, we have only two levels where all words have their leaf at level two and each node is a multiclass (i.e. softmax) logistic regression with roughly $\sqrt{V}$ classes (one for each children). Computing probabilities in such a structured layer can be done using only two matrix multiplications, which can be efficiently computed on the GPU.

With a hidden layer of size H, the complexity of computing the softmax at one node is $O(H\sqrt{V})$. If we have D words in a given document, the complexity of computing all necessary probabilities from the hidden layers is thus $O(DH\sqrt{V})$. It also requires $O(DH)$ computations to compute the hidden representations for the DocNADE part and $O(nH^2)$ for the language model part. The full complexity for computing $p(\mathbf{v})$ and the updates for the parameters is thus $O(DH\sqrt{V}+DH+nH^2)$.

Once again, the loss function of the model is the negative log-likelihood, and we minimize it by using stochastic gradient descent over documents, to learn the values of the parameters $\{\mathbf{b}, \mathbf{c}, \mathbf{V}, \mathbf{W}^{\text{LM}}, \mathbf{W}^{\text{DN}}, \mathbf{U}_1, ..., \mathbf{U}_n\}$.

5. Related Work

As NADE was inspired by the RBM, DocNADE can be seen as related to the Replicated Softmax model (Salakhutdinov and Hinton, 2009), an extension of the RBM to document modeling. Here, we describe in more detail the Replicated Softmax, along with its relationship with DocNADE.

Much like the RBM, the Replicated Softmax models observations using a latent, stochastic binary layer $\mathbf{h}$. Here, the observation is a document $\mathbf{v}$ and interacts with the hidden layer $\mathbf{h}$ through an energy function similar to RBM's:

$$E(\mathbf{v}, \mathbf{h}) = -D\, \mathbf{c}^\top \mathbf{h} + \sum_{i=1}^{D} -\mathbf{h}^\top \mathbf{W}_{:,v_i} - b_{v_i} = -D\, \mathbf{c}^\top \mathbf{h} - \mathbf{h}^\top \mathbf{W}\mathbf{n}(\mathbf{v}) - \mathbf{b}^\top \mathbf{n}(\mathbf{v}), \tag{22}$$

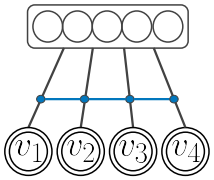

Figure 7: Replicated Softmax model. Each multinomial observation v_i is a word. Connections between each multinomial observation v_i and hidden units are shared.

where $\mathbf{n}(\mathbf{v})$ is a bag-of-words vector of size V (the size of the vocabulary) containing the word count of each word in the vocabulary for document $\mathbf{v}$. $\mathbf{h}$ is a stochastic, binary hidden layer vector, and $\mathbf{W}_{:,v_i}$ is the v_i-th column vector of matrix $\mathbf{W}$. $\mathbf{c}$ and $\mathbf{b}$ are the bias vectors for the visible and the hidden layers. We see here that the larger $\mathbf{v}$ is, the bigger the number of terms in the sum over i is, resulting in a high energy value. For this reason, the hidden bias term $\mathbf{c}^\top \mathbf{h}$ is multiplied by D, to be commensurate with the contribution of the visible layer.. We can see also that connection parameters are shared across different positions i in $\mathbf{v}$, as illustrated in Figure 7.

The conditional probabilities of the hidden and the visible layer factorize as in the RBM, in the following way:

$$p(\mathbf{h}|\mathbf{v}) = \prod_j p(h_j|\mathbf{v}) \ , \quad p(\mathbf{v}|\mathbf{h}) = \prod_{i=1}^{D} p(v_i|\mathbf{h}) \tag{23}$$

where the factors $p(h_j|\mathbf{v})$ and $p(v_i|\mathbf{h})$ are such that

$$p(h_j = 1|\mathbf{v}) = \text{sigm}(Dc_j + \sum_i W_{jv_i}) \tag{24}$$

$$p(v_i = w|\mathbf{h}) = \frac{\exp(b_w + \mathbf{h}^\top \mathbf{W}_{:,w})}{\sum_{w'} \exp(b_{w'} + \mathbf{h}^\top \mathbf{W}_{:,w'})} \tag{25}$$

The normalized exponential part in $p(v_i = w|\mathbf{h})$ is simply the softmax function. To train this model, we minimize the negative log-likelihood (NLL). Its gradient for a document $\mathbf{v}^{(t)}$ with respect to the parameters $\theta = \{\mathbf{W}, \mathbf{c}, \mathbf{b}\}$ is calculated as follows:

$$-\frac{\partial \log p(\mathbf{v}^{(t)})}{\partial \theta} = \mathbf{E}_{\mathbf{h}|\mathbf{v}^{(t)}} \left[\frac{\partial}{\partial \theta} E(\mathbf{v}^{(t)}, \mathbf{h}) \right] - \mathbf{E}_{\mathbf{v},\mathbf{h}} \left[\frac{\partial}{\partial \theta} E(\mathbf{v}, \mathbf{h}) \right]. \tag{26}$$

As with the conventional RBM, the second expectation in Equation 26 is computationally intractable. The gradient of the negative log-likelihood is therefore approximated by replacing the second expectation with an estimated value obtained by contrastive divergence (Hinton, 2002). This approach consists of performing K steps of block Gibbs sampling, starting at $\mathbf{v}^{(t)}$ and using Equations 24 and 25, to obtain a point estimate of the expectation over $\mathbf{v}$. A large values of K must be used to reduce the bias of gradient estimates and obtain good estimates of the distribution. This approximation is used to perform stochastic gradient descent.

During Gibbs sampling, the Replicated Softmax model must compute and sample from $p(v_i = w|\mathbf{h})$, which requires the computation of a large softmax. Most importantly, the computation of the softmax most be repeated K times for each update, which can be prohibitive, especially for large vocabularies. Unlike DocNADE, this softmax cannot simply be replaced by a structured softmax.

DocNADE is closely related to how the Replicated Softmax approximates, through mean-field inference, the conditionals $p(v_i = w|\mathbf{v}_{<i})$. Computing the conditional $p(v_i = w|\mathbf{v}_{<i})$ with the Replicated Softmax is intractable. However, we could use mean-field inference to approximate the full conditional $p(v_i, \mathbf{v}_{>i}, \mathbf{h}|\mathbf{v}_{<i})$ by introducing a factorized approximate distribution:

$$q(v_i, \mathbf{v}_{>i}, \mathbf{h}|\mathbf{v}_{<i}) = \prod_{k \geq i} q(v_k|\mathbf{v}_{<i}) \prod_j q(h_j|\mathbf{v}_{<i}) \,, \tag{27}$$

where $q(v_k = w|\mathbf{v}_{<i}) = \mu_{kw}(i)$ and $q(h_j = 1|\mathbf{v}_{<i}) = \tau_j(i)$. We would find the parameters $\mu_{kw}(i)$ and $\tau_j(i)$ that minimize the KL divergence between $q(v_i, \mathbf{v}_{>i}, \mathbf{h}|\mathbf{v}_{<i})$ and $p(v_i, \mathbf{v}_{>i}, \mathbf{h}|\mathbf{v}_{<i})$ by applying the following message passing equations until convergence:

$$\tau_j(i) \leftarrow \text{sigm}\left(D\, c_j + \sum_{k \geq i} \sum_{w'=1}^{V} W_{jw'} \mu_{kw'}(i) + \sum_{k<i} W_{jv_k} \right), \tag{28}$$

$$\mu_{kw}(i) \leftarrow \frac{\exp(b_w + \sum_j W_{jw} \tau_j(i))}{\sum_{w'} \exp(b_{w'} + \sum_j W_{jw'} \tau_j(i))}. \tag{29}$$

with $k \in \{i, \ldots, D\}$, $j \in \{1, \ldots, H\}$ and $w \in \{1, \ldots, V\}$. The conditional $p(v_i = w|\mathbf{v}_{<i})$ is then estimated with $\mu_{kw}(i)$ for all i. We note that one iteration of mean-field (with $\mu_{kw'}(i)$ initialized to 0) in the Replicated Softmax corresponds to the conditional $p(v_i = w|\mathbf{v}_{<i})$ computed by DocNADE with a single hidden layer and a flat softmax output layer.

In our experiment, we show that DocNADE compares favorably to Replicated Softmax.

5.1 Related work discussion

With DocNADE, the conditional probability of each word in a document is computed given the set of previously observed words. The probability distribution of the whole document is modeled using the probability chain rule. DocNADE automatically learns the underlying word representations and can compute the probability of a document exactly and efficiently. Similarly, the Replicated Softmax (Salakhutdinov and Hinton, 2009) also models the distribution, but because calculating the needed partition function for moderately large models is intractable, an approximation must be made to compute the probability of a document, making the estimate not entirely trustable. There are also other works that can learn good word representations like DocNADE, such as typical autoencoder, word2vec, doc2vec, etc. For example, people could use continuous bag-of-words autoencoder to learn good representations. The popular word2vec approaches, CBOW and Skip-gram (Mikolov et al., 2013), also learn word representations. The CBOW task is to predict a word given a surrounding context of N words where the Skip-gram does the opposite, predicting the N context words surrounding a specific word. To generate a document representation, Doc2vec (Le and Mikolov, 2014) (also called paragraph-vectors) modifies word2vec by adding a document-unique feature vector during training. For inference, a new document is presented, and all the model parameters are fixed to calculate the document vector. The advantage of DocNADE over all these above proposals is that it can model the probability of the documents as well as learn representations of words. Hence, the representations are more suitable for document retrieval tasks.

6. Topic modeling experiments

To compare the topic models, two quantitative measures are used. The first one evaluates the generative ability of different models, by computing the perplexity on held-out texts. The second one compares the quality of document representations for information retrieval.

Two different datasets are used for the experiments in this Section, a small one and a relatively big one, 20 Newsgroups and RCV1-V2 (Reuters Corpus Volume I) respectively. The 20 Newsgroups corpus has 18,786 documents (postings) partitioned into 20 different classes (newsgroups). RCV1-V2 is a much bigger dataset composed of 804,414 documents (newswire stories) manually categorized into 103 classes (topics). The two datasets were preprocessed by stemming the text and removing common stop-words. The 2,000 most frequent words of the 20 Newsgroups training set and the 10,000 most frequent words of the RCV1-V2 training set were used to create the dictionary for each dataset. Also, every word count n_i, used to represent the number of times a word appears in a document, was replaced with $log(1 + n_i)$ rounded to the nearest integer, following Salakhutdinov and Hinton (2009).

For these experiments, all the hidden representations of all the models are composed of 50 dimensional features. Early stopping on the validation set is used for avoiding overfitting and for model selection.

6.1 Generative Model Evaluation

For the generative model evaluation, we follow the experimental setup proposed by Salakhutdinov and Hinton (2009) for 20 Newsgroups and RCV1-V2 datasets. We use the exact same split for the sake of comparison. The setup consists of respectively 11,284 and 402,207 training examples for 20 Newsgroups and RCV1-V2. We randomly extract 1,000 and 10,000 documents from the training sets of 20 Newsgroups and RCV1-V2, respectively, to build a validation set. The average perplexity per word is used for comparison. This perplexity is estimated using the 50 first documents of a separate test set, as follows:

$$\exp\left(-\frac{1}{T} \sum_t \frac{1}{|\mathbf{v}^t|} \log p(\mathbf{v}^t) \right), \tag{30}$$

where T is the total number of examples in the test set and $\mathbf{v}^t$ is the t-th test document.[3]

Table 1 presents the perplexities per word results for 20 Newsgroups and RCV1-V2. We compare 5 different models: the Latent Dirichlet Allocation (LDA) (Blei et al., 2003), the Replicated Softmax, the recently proposed fast Deep AutoRegressive Networks (fDARN) (Mnih and Gregor, 2014), DocNADE and DeepDocNADE (DeepDN in the table). Each model uses 50 latent topics (size of the representation of a document). For the experiments with DeepDocNADE, we provide the performance when using 1, 2, and 3 hidden layers. As shown in Table 1, DeepDocNADE results in the best generative performances. Our best DeepDocNADE models were trained with the Adam optimizer (Kingma and Ba, 2014) and with $\tanh$ activation function. The hyper-parameters of Adam were selected on the validation set.

3. Note that there is a difference between the sizes, for the training sets and test sets of 20 Newsgroups and RCV1-V2 reported in this paper and the one reported in the original data paper of Salakhutdinov and Hinton (2009). The correct values are the ones given in this Section, which was confirmed after personal communication with Salakhutdinov and Hinton (2009).

Dataset	LDA	Replicated Softmax	fDARN	DocNADE	DeepDN (1layer)	DeepDN (2layer)	DeepDN (3layer)
20 News	1091	953	917	896	**835**	877	923
RCV1-v2	1437	988	724	742	579	552	**539**

Table 1: Test perplexity per word for models with a document representation of size 50 (50 topics). The results for LDA and Replicated Softmax were taken from Salakhutdinov and Hinton (2009).

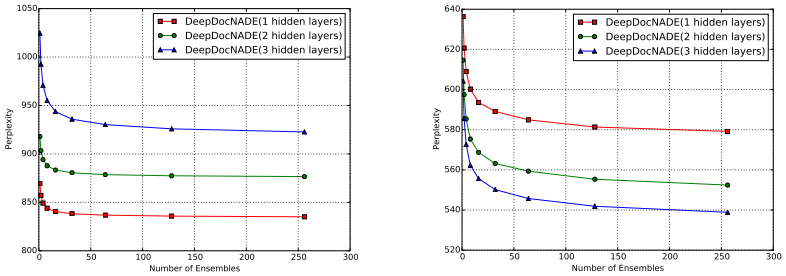

Figure 8: Perplexity obtained with different numbers of word orderings m for 20 Newsgroups on the left and RCV1-V2 on the right.

Furthermore, following Uria et al. (2014), an ensemble approach is used to compute the probability of documents, where each component of the ensembles are the same DeepDocNADE model evaluated on a different word ordering. The perplexity with M ensembles is then

$$\exp\left(-\frac{1}{T}\sum_{t}\frac{1}{|\mathbf{v}^t|}\log\left(\frac{1}{M}\sum_{m}p(\mathbf{v}^{(t,m)})\right)\right), \tag{31}$$

where T is the total number of examples, M is the number of ensembles (word orderings) and $\mathbf{v}^{(t,m)}$ denotes the m-th word ordering for the t-th document. We try $M = \{1, 2, 4, 16, 32, 64, 128, 256\}$, with the results in Table 1 using $M = 256$. For the 20 Newsgroups dataset, adding more hidden layers to DeepDocNADE fails to further improve the performance. We hypothesize that the relatively small size of this dataset makes it hard to successfully train a deep model. However, the opposite is observed on the RCV1-V2 dataset, which is more than an order of magnitude larger than 20 Newsgroups. In this case, DeepDocNADE outperforms fDARN and DocNADE, with a relative perplexity reduction of 20%, 24% and 26% with respectively 1,2 and 3 hidden layers.

To illustrate the impact of M on the performance of DeepDocNADE, Figure 8 shows the perplexity on both datasets using the different values for M that we tried. We can observe that beyond $M = 128$, this hyper-parameter has only a minimal impact on the perplexity.

6.2 Document Retrieval Evaluation

A document retrieval evaluation task was also used to evaluate the quality of the document representation learned by each model. As in the previous Section, the datasets under consideration are 20 Newsgroups and RCV1-V2. The experimental setup is the same for the 20 Newsgroups dataset, while for the RCV1-V2 dataset, we reproduce the same setup as the one used by Srivastava et al. (2013). The training set contains 794,414 examples and 10,000 examples constituted the test set.

For DocNADE and DeepDocNADE, the representation of a document is obtained simply by computing the top-most hidden layer (Equation 10) when feeding all the words of a document as input.

The retrieval task follows the setup by Srivastava et al. (2013). The documents in the training and validation sets are used as the database for retrieval, while the test set is used as the query set. The similarity between a query and all examples in the database is computed using the cosine similarity between their vector representations. For each query, documents in the database are then ranked according to this similarity, and precision/recall (PR) curves are computed, by comparing the label of the query documents with those of the database documents. Since documents often have multiple labels (specifically those in RCV1-V2), the PR curves for each of its labels are computed individually and then averaged for each query. Finally, we report the global average of these (query-averaged) curves to compare models against each other. Training and model selection is otherwise performed as done in the generative modeling evaluation.

As shown in Figure 9, DeepDocNADE always yields very competitive results, on both datasets, and outperforming the other models in most cases. Specifically, for the 20 Newsgroups dataset, DeepDocNADE with 2 and 3 hidden layers always perform better than the other methods. DeepDocNADE with 1 hidden layer also performs better than the other baselines when retrieving the top few documents (e.g. when recall is smaller than 0.2).

6.3 Qualitative Inspection of Learned Representations

In this Section, we want to assess if the DocNADE approach for topic modeling can capture meaningful semantic properties of texts.

First, one way to explore the semantic properties of trained models is through their learned word embeddings. Each of the columns of the matrix W represents a word w where $W_{:,w}$ is the vector representation of w. Table 2 shows the five nearest words for some chosen words according to their embeddings, from a DocNADE model. We observe for each example the semantic consistency of the word representations. Similar results are observed for DeepDocNADE models.

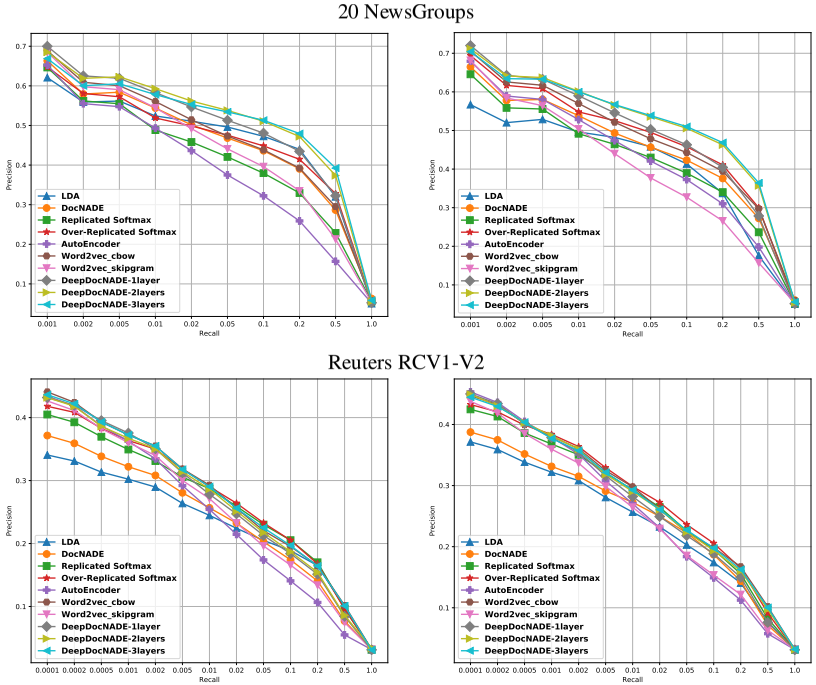

Figure 9: Precision-Recall curves for document retrieval task. On the left are the results using a hidden layer size of 128, while the plots on the right are for a size of 512.

We have also attempted to measure whether the hidden units of the first hidden layer of DocNADE and DeepDocNADE models modeled distinct topics. Understanding the function represented by hidden units in neural networks is not a trivial affair, but we considered the following simple approach. For a given hidden unit, its connections to words are interpreted as the importance of the word for the associated topic. We thus select the words having the strongest positive connections for a hidden unit, i.e. for the i-th hidden unit we chose the words w that have the highest connection values $W_{i,w}$.

With this approach, fifty topics were obtained from a DocNADE model (with the sigmoid activation function) trained on 20 Newsgroups. Four of the fifty topics are shown in Table 3 and can be readily interpreted as topics representing: religion, space, sports and security. Note that those four topics are actual (sub)categories in 20 Newsgroups.

That said, we have had less success understanding the topics extracted when using the $\tanh$ activation function or when using DeepDocNADE. It thus seems that these models learn a latent

Hidden unit topics

representation that does not align its dimensions with concepts that are easily interpretable, even though it is clearly capturing well the statistics of documents.

7. Language Modeling Experiments

In this Section, we test whether our proposed approach to incorporating a DocNADE component to a neural language model can improve the performance of a neural language model. Specifically, we considered treating a text corpus as a sequence of documents. We used the APNews dataset, as provided by Mnih and Hinton (2009). Unfortunately, information about the original segmentation into documents of the corpus was not available in the data as provided by Mnih and Hinton (2009), thus we simulated the presence of documents by grouping one or more adjacent sentences, for training and evaluating DocNADE-LM, making sure the generated documents were non-overlapping. This approach still allows us to test whether DocNADE-LM is able to effectively leverage the larger context of words in making its predictions.

Since language models are generative models, the perplexity measured on some held-out texts is widely used for evaluation. Following Mnih and Hinton (2007) and Mnih and Hinton (2009), we use the APNews dataset containing Associated Press news stories from 1995 and 1996. The dataset is again split into training, validation and test sets with respectively 633,143, 43,702 and 44,601 sentences. The vocabulary is composed of 17,964 words.

For these experiments, all the hidden representations of all the models are composed of 100 dimensional features. Early stopping on the validation set is used for avoiding overfitting and for model selection. The perplexity scores of Table 4 are computed on the test set.

The LM model in Table 4 corresponds to a regular neural (feed-forward) network language model. It is equivalent to using only the language model part of DocNADE-LM. These results are meant to measure whether the DocNADE part of DocNADE-LM indeed improves performances.

We also compare against the log-bilinear language (LBL) model of Mnih and Hinton (2007)). While we used a hierarchical softmax to compute the conditional word probabilities for the LM model (see Section 4), the LBL model uses a full softmax output layer that uses the same word representation matrix at the input and output. This latter model is therefore slower to train. Later, Mnih

Models	Number of grouped sentences	Perplexity
KN6	1	123.5
LBL	1	117.0
HLBL	1	112.1
LSTM	1	116.26
GRU	1	109.42
LM	1	119.78
DocNADE-LM	1	111.93
DocNADE-LM	2	110.9
DocNADE-LM	3	109.8
DocNADE-LM	4	109.78
DocNADE-LM	5	109.22

Table 4: Test perplexity per word for models with 100 topics. The results for HLBL and LBL were taken from Mnih and Hinton (2009).

and Hinton (2009) also proposed an adaptive approach to learning a structured softmax layer, thus we also compare against their best approach. All the aforementioned baselines are 6-gram models, taking in consideration the five previous words to predict the next one. We also compare with a more traditional 6-gram model using Kneser-Ney smoothing, taken from Mnih and Hinton (2007). Finally we compare our results against recurrent language model using ether LSTM from Graves (2013) or GRU from Cho et al. (2014). These models are trained with stochastic gradient descent, using full backpropagation through time. They are considered as states of the art for modeling sequences.

From Table 4, we see that adding context to DocNADE-LM, by increasing the size of the multi-sentence segments, improves the performance of the model (compared to LM) and also surpasses the performance of the most competitive alternatives.

7.1 Qualitative Inspection of Learned Representations

In this Section we explore the semantic properties of texts learned by the DocNADE-LM model. Interestingly, we can examine the two different components (DN and LM) separately. Because the DocNADE part and the language modeling part of the model each have their own word matrix, $\mathbf{W}^{\mathrm{DN}}$ and $\mathbf{W}^{\mathrm{LM}}$ respectively, we can compare their contribution through these learned embeddings. As explained in the previous Section, each of the columns of the matrices represents a word w where $\mathbf{W}^{\mathrm{DN}}_{:,w}$ and $\mathbf{W}^{\mathrm{LM}}_{:,w}$ are two different vector representations of the same word w.

We can see from Tables 5 and 6 that the two parts of the DocNADE-LM model have learned different properties of words. An interesting example is the nearest neighbors of the word *israel*, where the DocNADE focuses on the politico-cultural relation between these words, whereas the language model part has learned the concept of countries in general.

weapons	**medical**	**companies**	**define**	**israel**	**book**	**windows**

8. Conclusion

We have presented models inspired by NADE that can achieve state-of-the-art performances for modeling documents. For topic modeling, DocNADE had competitive results while its deep version, DeepDocNADE, outperformed the current state-of-the-art in generative document modeling, based on a test set perplexity. Good performances were also observed when we used these models as feature extractors to represent documents for the task of information retrieval. As for language modeling, the competitive performances of the DocNADE language model showed that combining contextual information by leveraging the DocNADE architecture can significantly improve the performance of a neural probabilistic N-gram language model.

Abstract

We consider the effect of introducing a curriculum of targets when training Boolean models on supervised Multi Label Classification (MLC) problems. In particular, we consider how to order targets in the absence of prior knowledge, and how such a curriculum may be enforced when using meta-heuristics to train discrete non-linear models.

We show that hierarchical dependencies between targets can be exploited by enforcing an appropriate curriculum using hierarchical loss functions. On several multi-output circuit-inference problems with known target difficulties, Feedforward Boolean Networks (FBNs) trained with such a loss function achieve significantly lower out-of-sample error, up to 10% in some cases. This improvement increases as the loss places more emphasis on target order and is strongly correlated with an easy-to-hard curricula. We also demonstrate the same improvements on three real-world models and two Gene Regulatory Network (GRN) inference problems.

We posit a simple a-priori method for identifying an appropriate target order and estimating the strength of target relationships in Boolean MLCs. These methods use *intrinsic dimension* as a proxy for target difficulty, which is estimated using optimal solutions to a combinatorial optimisation problem known as the Minimum-Feature-Set (minFS) problem. We also demonstrate that the same generalisation gains can be achieved without providing any knowledge of target difficulty.

Keywords: Multi-Label Classification, Target Curriculum, Boolean Networks, k-Feature Set

1. Introduction

When students are first taught the concept of addition, they are not simply handed an eclectic set of many digit number pairs and their summations; rather, we provide them a learning curve of carefully chosen examples which increase in difficulty (i.e. number of digits). From standard classroom practices we can glean two key sources of inspiration regarding effective learning and teaching processes of humans: the curriculum of examples, and the curriculum of targets. This paper examines the latter.

Khan et al. (2011) found that humans naturally follow an easy-to-hard example-based curriculum when teaching a single-target concept to an unknown learner. Methods of scheduling examples this way have been explored in the machine learning community for some time, with positive results for non-convex scenarios (Bengio et al., 2009).

The typical explanation for the success of example curricula in non-convex scenarios is that it imposes a form of transfer learning where the simpler concept is discovered first and subsequently informs the more complex concept (Bengio et al., 2009). This leads neatly into a consideration of the second inspiration from the classroom: target curricula.

We consider the problem of learning discrete models for MLC problems with Boolean inputs, where closed-form solutions and gradient-guided optimisation techniques are unavailable. We use Feedforward Boolean Networks (FBNs)—defined in Section 1.2—as a case study for implementing target-curriculum regularisation with simple modifications to the typical L_1/L_2-Loss. We also introduce methods for estimating target overlap and target difficulty order in Boolean MLCs by finding a lower bound to the intrinsic dimension of the induced function. The intrinsic dimension has been presented as a proxy for the overall complexity of arbitrary data sets (Granata and Carnevale, 2016) suggesting its promise as a metric for ordering targets.

1.1 Contributions

We provide three novel contributions:

- we show that using hierarchical loss functions improves generalisation performance of FBNs trained on several circuit-inference problems possessing a natural target progression,
- we describe a simple method for estimating the complexity and overlap of Boolean targets by lower bounding their intrinsic dimensions using solutions to the minFS problem, and
- we demonstrate the success of the combined method on the same problem instances when knowledge of the target difficulty is withheld.

In the remainder of this section we define FBNs as a learning model, give background on MLC and outline existing work on sample and target curricula. In Section 2 we define hierarchical loss functions as well as the minFS problem and how it can be used to detect target overlap and estimate an appropriate curriculum. Finally, in Section 3 we present results on several problems.

1.2 Boolean Networks

This paper focuses on Boolean MLC problems where the targets possess differing complexities. In this section we provide definitions of the problem domain, its relevance and the representation of interest to this work: the Feedforward Boolean Network.

A Boolean MLC problem is one where inputs and targets take values in $\mathcal{B} \in \{0, 1\}$. An intuitive model for such a problem is a digital circuit, or FBN. A FBN with l inputs and m outputs computes a function of the form $f : \mathcal{B}^l \to \mathcal{B}^m$ by chaining computations from internal nodes (commonly called gates).

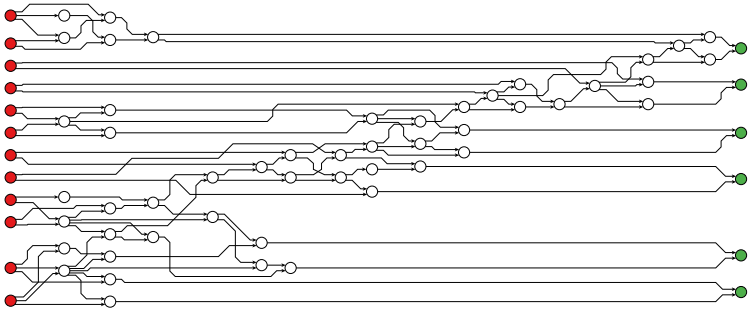

Figure 1: A 56-node FBN resulting from our learning procedure, which correctly implements the 6-bit addition function. Each node takes 2 inputs and computes the NAND function as its output. Inputs (far left) have been coloured red and outputs (far right) green. Note the ripple-carry style flow of information between sub-networks.

Internally, a FBN is a directed acyclic graph (DAG) where each node has an associated value in $\mathcal{B}$. Nodes take the values of their predecessors as input to a Boolean function which they provide as output. Input nodes are those with no predecessors and their value is provided from outside the network. The output of the network is simply the values at a particular subset of externally visible output nodes. A FBN can thus compute a function from many inputs to many outputs by combining simpler functional elements. Figure 1 shows an example FBN which correctly implements a 6-bit adder.

One advantage to working with this representation is that two singleton functionally complete operator sets exist: the negated-and (NAND) and negated-or (NOR) functions. Every Boolean mapping can be computed by some degree-2 DAG consisting purely of NAND nodes. We will use this representation for the remainder of the paper.

FBNs have a number of other advantages as learning models. They are efficient in time and memory to simulate and trivial for direct hardware implementation and logical rule conversion. Logical relationships are simple for humans to extract information from which is important if the goal of the learning procedure is knowledge-generation. While other representations have received significantly more attention, FBNs are trivial to map to existing digital hardware—an open problem for neural nets. They can use packed integer representations and bitwise arithmetic to improve model evaluation speed during training and deployment. Recent literature presents methods for binarising the internal layers of deep neural nets precisely for these reasons (Courbariaux et al., 2016).

As the name suggests, FBNs compute with purely Boolean logic, rather than using weighted sums and continuous activations. This brings challenges, the most prevalent being the lack of gradient-based optimisation procedures or closed form solutions. All optimisation techniques discussed below use general purpose combinatorial meta-heuristics, such as Simulated Annealing (SA). Herein all networks were optimised using local search in the space of graph structures—possible due to the functional completeness of the NAND operator.

1.3 Learning with Boolean Networks

Since the late publication of Turing's first description of a machine which learns by changing the connections of a NAND-gate circuit (Turing, 1948) the majority of the work on learning with a Boolean Network model has been done in the field of physics. Some time later, Patarnello and Carnevali (1987), and subsequently others (Van den Broeck and Kawai, 1990; Goudarzi et al., 2014), demonstrated that FBNs could generalise well on some problems, despite training set sizes significantly smaller than the space of all possible patterns.

Learning FBNs is a *combinatorial* optimisation problem, typically solved using meta-heuristics such as SA or genetic algorithms. Patarnello and Carnevali (1987) optimised networks by SA in the space of feedforward structures. Each move in the search procedure consisted of a random change in a single connection. Moves which also changed the node activation have been considered (Van den Broeck and Kawai, 1990; Goudarzi et al., 2014), however in light of the NAND function's functional completeness, this becomes unnecessary.

To simplify the following loss function definitions we define the $n \times m$ error matrix E, which fully characterises the mistakes made by a candidate network on a set of n example patterns with m targets. E is the element-wise absolute difference between the network output matrix Y' and the target matrix Y, with elements given by

$$E_{i,j} = \left| Y_{i,j} - Y'_{i,j} \right|,$$

where $E_{i,j} \in \mathcal{B}$ is the error for the j^{th} target for the i^{th} example.

Even for problems with multiple outputs, the only loss functions used to date (Patarnello and Carnevali, 1987; Teuscher et al., 2007; Goudarzi et al., 2014) have been analogues of the L_1-loss:[1]

$$L_1 = \frac{1}{m\,|\mathcal{I}|} \sum_{j=1}^{m} \sum_{i \in \mathcal{I}} E_{i,j},$$

where $\mathcal{I}$ is the set of example indices shown to the network. This loss treats all examples and targets equally and is the natural first choice for a guiding function, but for multi-target problems there are other options which we explore in Section 2.1.

So far no work has considered differences between learning single and multiple output FBNs. Results for Multi Task Learning (MTL) suggest that, with multiple related target, some networks may be favoured due to target correlation, increasing generalisation performance. To explore the possibility of further improvements, we use FBNs as a case study in the effects of target curriculum enforcement by hierarchical loss-functions on purely discrete models. In the following section we outline the relevant work on target curricula.

1.4 Example Curricula

The approach we present in this work draws strong inspiration from *example* curricula. In this subsection we give a brief outline of some relevant work to better frame our approach.

Curriculum learning by applying a ranking of *examples* can be split into two main camps: Curriculum Learning (CL) and Self-Paced Learning (SPL) (Kumar et al., 2010). In the former the ranking is determined a priori while in the latter it is learned jointly

1. With purely binary predictors and targets the L_1- and L_2-loss are identical.

with the model. Jiang et al. (2015) demonstrated a combined approach—intuitively called Self-Paced Curriculum Learning—where constraints on the example-ranking are imposed by a fixed curriculum and the ranking is learned jointly with the model but subject to the curriculum constraints. SPL and CL emerge as special cases of their framework. They present positive results in comparison to baseline methods on matrix factorization and multimedia event detection problems.

Spitkovsky et al. (2009) demonstrated the success of a curriculum of samples of *increasing complexity* on the problem of determining grammar from free-form sentences. Their proxy for complexity in this case is the length of the example sentence. They also noted the appearance of a "sweet-spot" in sentence length, the inclusion of samples above which reduced performance. The combination of both their curriculum and complexity limitation improved on the state-of-the-art.

It is important to note that the terms Curriculum Learning (CL) and Self-Paced Learning (SPL) used within this subsection related *example* curricula. It is possible to also consider a learner—in a MLC framework—to be following a curriculum of *targets* (or to be self-paced in the same respect). We primarily cover the former case of a fixed curriculum of targets, and throughout this paper "curriculum" will refer to a curriculum of targets.

1.5 Target Curricula

Learning multiple targets concurrently with a shared representation has been shown, theoretically and experimentally, to improve generalisation results when there are relationships between the targets (Caruana, 1997; Wang et al., 2016). The number of publications discussing multi-label and multi-task learning is growing rapidly and using a *curriculum* of targets, while less general, is also beginning to garner attention.

The importance of sharing knowledge between targets increases when there is a disparity in target complexity. Gülçehre and Bengio (2016) showed a visual task, on which many popular methods—including deep neural nets, SVMs and decision trees—failed. This same task became solvable when a simpler hinting target was provided (in much the same way as introduced by Abu-Mostafa, 1990). However, unless relative target difficulties are known (or suspected), we also face the issue of determining an appropriate order during learning.

Pentina et al. (2015) presented a self-paced method using adaptive linear SVMs. The implementation was model-specific, providing information transfer by using the optimal weight vector for the most recently learned task to regularise the next task's weight vector. They discover the curricula by solving all remaining tasks and selecting the best fitting, resulting in a quadratic increase in training time over solving tasks individually. While this may be acceptable for a linear model, it would be prohibitive for a FBN.

Li et al. (2017) implemented task curricula with linear models by weighting the contribution of each task-example pair to the loss function. They used a regulariser in which task-example pairs with low training error receive larger values for these weights. However, this approach does not appear applicable to inferring highly non-linear discrete models.

Lad et al. (2009) present the only model-agnostic approach to determine an optimal order of tasks that we are aware of. They use conditional entropy to produce a pairwise order matrix and solve the resulting NP-Hard Linear Ordering Problem (see Ceberio et al., 2015, for a definition). Their approach is not applicable to Boolean MLCs since the conditional

entropy difference calculation they use reduces to the difference of the entropies of the individual targets; which, for balanced binary targets, rapidly approaches zero as more training samples are given.

The impact of target order is highlighted by Read et al. (2011). Their approach uses *classifier chains*: independent learners for each binary label, trained in an arbitrary order, with the output of all prior classifiers included as input to each subsequent classifier. The authors note that the ordering of targets has a notable effect on classifier performance; which they address using ensembles of chains, each with a different random order. They note consistent superiority of the ensemble approach over a single random ordering, which suggests non-trivial variability in the impact of different orderings. Due to the large space of permutations, a principled approach to determine appropriate orderings a priori would be of value.

We have not seen work using hierarchical loss-functions (or similar regularisers) to impose a target curriculum, nor have we seen methods for determining a curriculum by use of feature selection methods. The following section describes our approach.

2. Learning Targets in Order

Here we describe three loss functions which we used to enforce a curriculum of targets, as well as a novel method for obtaining said curriculum which reduces the problem to m instances of the Minimum-Feature-Set (minFS) problem.

2.1 Hierarchical Loss Functions

Assume a two-target Boolean MLC for which we have three candidate learners, and assume we know that the first target is "easier" under some definition than the second. The first learner labels target 1 correctly and target 2 incorrectly for all examples. The second learner does the opposite, and the third learner labels 50% of the examples incorrectly for both targets. All three networks will have an equal $L1$-loss.

The rationale behind the loss functions we are about to define is that the first of the above learners should be preferred. By focusing on easier targets earlier in the training process the network is more likely to find substructures useful to later targets. The expectation is faster convergence speed, better generalisation or both.

The L_1-loss is simply the mean of the error matrix. In addition, we consider three loss functions which hierarchically aggregate the error matrix elements in progressively more strict ways:

- a linearly weighted mean: L_w,
- a locally hierarchical mean: L_{lh}, and
- a globally hierarchical mean: L_{gh}.

All definitions below assume the targets are ordered by difficulty, with the simplest target at the lowest index.

The first function, L_w, encourages the target curriculum by weighting the easier targets more highly. The weighting is linear and the resulting summation is normalised to the unit

interval:

$$L_w = \frac{2}{m\,(m-1)\,|\mathcal{I}|} \sum_{i \in \mathcal{I}} \sum_{j=1}^{m} (m-j+1)\, E_{i,j} \ .$$

We named the second function, L_{lh}, the *locally hierarchical* loss, as it enforces a hierarchy of targets on a per-example basis. The learner is rewarded for correctly labelling target j of example i if and only if it has also correctly labelled all prior targets $\{1, 2, ..., j-1\}$ *for that example*. To define this function, for each example i, we define the recurrence:

$$a_{i,1} = E_{i,1}$$
$$a_{i,k+1} = \begin{cases} E_{i,k+1}, & \text{if } a_{i,k} = 0 \\ 1, & \text{if } a_{i,k} = 1 \end{cases} ,$$

from which we can define

$$L_{lh} = \frac{1}{m\,|\mathcal{I}|} \sum_{i \in \mathcal{I}} \sum_{k=1}^{m} a_{i,k} \ .$$

The final loss, L_{gh}, follows the same principle as the former but across all examples. For this reason we named it the *globally hierarchical* loss. In this case the learner is given reward for correctly labelling target j (of any example) if and only if it has also correctly labelled all prior targets $\{1, 2, ..., j-1\}$ for all examples given. This function is effectively a "soft" equivalent to learning the targets rigidly in order. We can define L_{gh} using the mean per-target errors (the row-means of E):

$$\delta_j = \frac{1}{|\mathcal{I}|} \sum_{i \in \mathcal{I}} E_{i,j} \ .$$

These can be used to define another recurrence,

$$b_0 = \delta_0$$
$$b_{k+1} = \begin{cases} \delta_{k+1}, & \text{if } b_k = 0 \\ 1, & \text{if } b_k > 0 \end{cases} ,$$

giving

$$L_{gh} = \frac{1}{m} \sum_{j=1}^{m} b_j \ .$$

Unless the difficulty order is known, or suspected, from domain specific knowledge we also require a method for estimating the target order from the training examples. We describe a method suitable for Boolean or categorical MLCs in the following section.

2.2 Measuring Target Overlap and Difficulty Order

The key requirement for ordering targets is an estimation of their relative difficulty. It is likely most suitable to use domain knowledge where available, however in cases where this is impossible or difficult to obtain we suggest a rule of thumb: order by increasing intrinsic dimension. We present an intuitive approach below using a combinatorial problem which

did not significantly increase the learning time for the instances considered. In Section 3.4 we show that the target order estimated by this method gives generalisation improvements close to those obtained using the known order (Section 3.3).

Our key assumption is that a target can be expected to be simpler than another if its intrinsic dimension (the number of input variables on which it truly depends) is smaller. This assumption is strong but there is also a strong basis for it as a rule-of-thumb in the Boolean domain, as a function's intrinsic dimension places an upper bound on the size of the smallest FBN which implements it. Furthermore, intrinsic dimension is showing promise as a method for estimating the complexity of arbitrary data (Granata and Carnevale, 2016) and as such we expect the validity of this idea may extend beyond the Boolean case.

The likelihood of effective information transfer can also be estimated by measuring the overlap in intrinsic input features. Thus estimating both target overlap, and relative complexity, is reduced to the problem of determining the minimum set of input features on which a valid function can be defined; that is, where no pattern is mapped to multiple target values. This is well known as the Minimum-Feature-Set (minFS) problem.

2.2.1 The Minimum-Feature-Set Problem

The smallest intrinsic dimension of any Boolean function which is in full agreement with given set of examples can be found using the Minimum-Feature-Set (minFS) problem. It asks: what is the smallest subset of given input features, on which a single target can still form a non-contradictory mapping? This problem, and particularly this view of it, is not in any way new to the machine learning community (Davies and Russell, 1994). However, to our knowledge, it has not been used to estimate relative target difficulty before.

This equivalent decision problem is known as the *k-Feature-Set (kFS)* problem. Formally:

k-Feature-Set

Given: A binary $n \times p$ matrix, $\mathcal{M}$, where the rows describe n examples and the columns describe p input features as well as n-element target vector, $\mathcal{T}$, and a positive integer k.

Question: $\exists S \subseteq [1, ..., p], |S| \leq k$, such that, $\forall i, j \in [1, ..., n]$ where $\mathcal{T}_i \neq \mathcal{T}_j$, $\exists l \in S$ such that $\mathcal{M}_{i,l} \neq \mathcal{M}_{j,l}$?

That is: is there a cardinality k subset, S, of the input features, such that no pair of examples which have identical values across all features in S have a different value for the target feature?

The problem is NP-complete (Davies and Russell, 1994) and assumed to not be fixed-parameter tractable, when parametrised by k, under current complexity assumptions (Cotta and Moscato, 2003). Nonetheless the exact solver used herein solved all instances in significantly less time than was required for subsequently optimising the FBN. At least one fast meta-heuristic solver exists for a generalised version of the problem, with reasonable run-times for very large instances (Rocha de Paula et al., 2015), and problem instances can be reformulated as instances of the well known Set Cover Problem, for which there are numerous powerful heuristic solvers.

We implemented instances of the minFS problem below as Mixed-Integer Programs and solved using them using the Python interface to the IBM CPLEX solver. With a solution

procedure in hand we can now define a simple method for estimating the target difficulty order and the level of target overlap.

2.2.2 Target ordering method

Given a procedure for solving the minFS problem our proposed method for ordering the targets reduces to solving m such instances; one for each target. For all instances the input feature matrix $\mathcal{M}$ is identical to the entire input matrix for the original learning problem. Each instance is solved to optimality resulting in a set of features $S_1, ..., S_m$ for each target.

An estimate of the intrinsic dimension for a target i is then simply $|S_i|$. Targets are sorted by this estimate with ties broken randomly, and the resulting total order is used in the loss functions defined in Section 2.1. These losses could be redefined to treat a subset of targets equally to avoid tie-breaking but we did not explore this possibility.

2.2.3 Target overlap score

Estimating target overlap also follows from the minFS solutions. For two targets, y_i and y_j, with solutions, S_i and S_j, the target overlap is estimated by the Szymkiewicz-Simpson overlap coefficient:

$$\sigma(i,j) = \frac{|S_i \cap S_j|}{min(|S_i|, |S_j|)} \ .$$

The overlap coefficient gives a value between 0 and 1 where 0 indicates that there is zero overlap between two sets and 1 indicates that one set is a subset of the other; values in between occur when sets are partially overlapping. This measure was chosen over the more popular Jaccard index as we wish to consider all fully overlapping cases ($A \subseteq B$) equivalent regardless of their relative sizes.

We can then define the *nestedness* score, η, as the mean overlap coefficient between successive targets (when ordered by the method in Section 2.2.2) giving the formula

$$\eta = \frac{1}{m-1} \sum_{i=2}^{m} \sigma(i, i-1) \ ,$$

which takes the value 1 when the minFS solutions for all targets forms a perfectly nested sequence of sets, and the value 0 when the sets have no pairwise overlap. A high value for η is thus a necessary but not sufficient condition for strongly inter-dependent Boolean targets. A value near zero indicates that there is unlikely to be any benefit gained from a target curriculum.

The nestedness score allows us to rule out some Boolean MLC problems for which a target curriculum would be inappropriate, and the proposed target ordering method gives us a curriculum otherwise. We show experimental results in the following section.

3. Experimental Results

It is important to see how the loss functions defined in Section 2.1 affect generalisation performance over a range of training set sizes. When optimising L_1, generalisation performance for all problems considered transitions from essentially random behaviour to near perfect

prediction as training set size increases. With this in mind we generated 1000 samples each for a range of training set sizes chosen to span that transition by a reasonable margin. We report the training set size as the fraction, $s = |\mathcal{I}| / 2^l$, of all possible patterns.

For each sample we trained one network for each loss function until they achieved zero training error. This allows us to report the difference in test error between the network optimised under L_1 and each of the remaining losses, for the same training set. Using the same training set for each loss removes the significant variation in instance difficulty as a confounding factor.

3.1 Data Sets

Here we define the problems considered. We first outline problems for which we already have a difficulty curricula. Then we consider several published models of real-world phenomena and finally we test our overall approach on the problem of discovering regulatory network update rules from discretised time-series data.[2]

3.1.1 Circuit inference test-beds

For the first test-bed we chose five circuit-inference problems: binary addition (add) and subtraction (sub) and cascaded variants of three typical circuit-learning and genetic programming problems: multiplexer (cmux), majority (cmaj) and parity (cpar). These were chosen as they all possess a natural hierarchy of targets.

Binary addition and subtraction are well known multi-output problems. For the three remaining problems, multi-output versions are constructed by cascading single-output subcircuits; each successive output is the result of applying the original function over a larger set of inputs. By this method we construct problems for which we know there is a difficulty order, and what that order is. More detailed definitions of these problems are given in Online Appendix 1.

The cascaded parity and multiplexer possess the strongest dependencies between successive targets, as each subsequent output can be computed directly from the previous output and an additional subset of inputs not already used. The cascaded majority, binary addition and binary subtraction problems have weaker dependencies, requiring extra inputs as well as the previous output and new inputs to compute the next output. This allows us to see the effect of imposing target curricula of problems with varying levels of inter-target dependency.

FBNs are a high variance learner. As such we selected problem sizes so that a meaningful effect size can be seen, but also so that 1000 instances per loss/sample-size combination could be completed in under a week. Table 1 outlines the dimensions selected, as well as the ranges in training sample size.

The hierarchy of targets is known for the above problems since they are constructed from cascading well-known circuits. This ground-truth allows us to further evaluate the methods outlined in Section 2.2 by considering the correlation between this known order and the predicted order.

2. Data and code are available at `github.com/shannonfenn/Multi-Label-Curricula-via-Minimum-Feature-Selection`.

Problem	Inputs	Targets	Training set size	Example pool size
Cascaded Parity	7	7	[8, 112]	128
Cascaded Majority	9	5	[8, 384]	512
Binary Subtraction	10	5	[8, 192]	1,024
Binary Addition	12	6	[8, 208]	4,096
Cascaded Multiplexer	15	7	[8, 180]	32,768
74181 ALU	14	8	[64, 384]	16,384
FA/BRCA pathway	28	28	[8, 96]	1,024
Mammalian cell cycle	10	9	[8, 180]	1,024
Yeast	10	9	8	9
E. Coli	10	8	4	5

Table 1: Instance sizes of the test-bed problems.

3.1.2 Boolean Models of Real Phenomena

In addition to the problems above we also conducted similar experiments using real-world models. This included a commercial integrated circuit: the 74181 4-bit Arithmetic Logic Unit (ALU), and two published biological models.

The 74181 ALU has 14 inputs and 8 outputs. It performs 32 different arithmetic and logical operations on an 8-bit input with carry in, generating a 4-bit output with carry out as well as 2 other carry-related outputs useful for faster calculations when chaining multiple ALUs. The 74181 represents a reverse engineering problem of a realistic size that is less idealised than the above problems, as there is no expected absolute ordering to the targets.

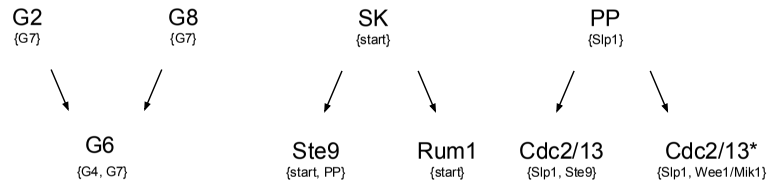
The biological models we considered were Boolean models of the Fanconi Anemia/Breast Cancer (FA/BRCA) pathway and the mammalian cell cycle (Poret and Boissel, 2014). Boolean regulatory network models like these describe the time-evolution of gene activity, levels of regulatory products and protein activity with a single Boolean variable per element. The system dynamics are then defined with Boolean update functions and an update method (synchronous, partly or fully asynchronous). Both models we consider are synchronous as this enables the inference of a single deterministic update equation by treating successive time steps as input-output pairs. More detail on all models in this section are given in Online Appendix 1.

For these three problems we ran experiments just as in Section 3.1, with the exception of the ALU problem for which we only trained 100 networks per training set size due to time constraints. Similarly, due to the large memory requirement of generating all 2^{28} patterns for the FA/BRCA model, we used a reduced example pool of 2^{10} patterns sampled uniformly. The problem dimensions, training set sizes and example pool sizes are given in Table 1. We have no suspected optimal target order for these problems, so the ordering used for all ordered losses was found using the minFS-based intrinsic dimension estimation described in Section 2.2.

3.1.3 Learning Regulatory Networks From Time-Series Data

While conducting the above experiments we observed that the primary performance gain is seen at smaller sample sizes. For this reason we chose a real-world test-bed where a key issue is the extremely limited amount of available data: inferring Boolean GRN update models from time-series gene expression data. Barman and Kwon (2017) provide binarised time-series data for an *E. coli* GRN and a cell-cycle regulatory network of fission yeast: each consisting of 10 nodes and only a handful of examples. One desirable result is a synchronous update model such as in the models described in Section 3.1.2, and one way to achieve this is to treat each sequential pair of states as an input-output pair thus deriving a FBN which predicts the next state from the current state. Again, further detail is given in Online Appendix 1.

Some preprocessing of the data were required. First we removed repeat patterns—these occur due to time disparities which we are not attempting to model. Instead we require pairs of distinct patterns as otherwise the requirements for a valid minFS instance are not met. Secondly we removed constant targets since they represent nodes for which there is no information suggesting a relationship to any other nodes: one such target was removed from the yeast data, and two from the *E. coli* data.



Finally, since we have very small example sets allowing rapid training, we use leave-one-out cross validation for all patterns whose removal does not introduce additional constant targets (the first was the only such pattern in both cases). For each fold we learned 1000 networks for each configuration of interest, to account for the significant variance typical in such heavily under-determined problems.

Our initial tests including all targets of the yeast and *E. coli* data sets as a single problem showed little improvement from the ordered losses. Preliminary feature set analysis suggested that there were distinct, shallow hierarchies among the targets (see Figure 2), rather than the deeper hierarchies seen in prior problems. A lack of improvement is unsurprising in this case since imposing an order upon unrelated targets is not expected to offer any benefit and to potentially detriment the performance.

Due to this we opted to learn networks only for the nodes involved in a hierarchy (2 for yeast and 1 for *E. coli*). For fair comparison we compared with the baseline L_1 network on both target sets: only those in the suspected hierarchy and all targets. Results are only shown for the former however, since the results of learning a single overall network using L_1 were notably worse. Again we used estimated target curricula for all ordered losses (see Section 2.2).

3.2 The Learning Procedure

Here we describe the local search procedure used for training. We learned each function by optimising FBNs comprised of only NAND gates using stochastic local search. As the NAND operator is functionally complete the optimisation process does not need to consider node transfer functions and can instead learn any mapping by modifying just the network structure. We set network size, n_g, for all problems at $21m$ and represented the structure using a $2 \times n_g$ integer matrix, with column i containing the indices of the two sources for the ith node.

(a) E. Coli (b) Yeast

Figure 2: Possible target hierarchies found using minFS in the yeast and *E. coli* data sets. In the *E. coli* data (a) we see the target G6 (with feature set $\{G4, G7\}$) may benefit from being learned after G2 or G8 (both have the feature set $\{G7\}$). In the yeast data (b) we see two potential hierarchies: either of Ste9 or Rum1 (both with feature set $\{start, PP\}$) may benefit from being learned after SK, and either of Cdc2/Cdc13 or Cdc2/Cdc13* (with feature sets $\{Ste9, Slp1\}$ and $\{Slp1, Wee1/Mik1\}$ respectively) may benefit from first learning PP.

We ensure the network remains feedforward by imposing a topological ordering of nodes; each node may only accept input from nodes before it in the ordering. Since any DAG has at least one topological ordering, no structure is excluded by this constraint.

Training involved performing stochastic local search in the space of valid feed-forward structure, using the Late-Acceptance Hill Climbing (LAHC) meta-heuristic (Burke and Bykov, 2008) with random restarts. This method assumes a black-box view of the learner and is similar in implementation to SA while being less sensitive to scaling in the guiding function and requiring only a single meta-parameter in place of a cooling schedule. While the particulars of the optimiser are not of relevance to this work, a brief description is given below and the pseudo-code is given in Online Appendix 1.

LAHC works similarly to typical stochastic hill climbing: a modification is made to the current solution and accepted based on some criterion. This modification involves a random change to the source of one connection in the DAG. A modification is accepted if the resulting network has equal or lower loss than the solution obtained L iterations beforehand.

The single meta-parameter, L, is the length of a history of costs which provides a dynamic error bound. In preliminary tests, the out-of-sample error was consistent over a wide range in L and so we selected the value which provided the best average convergence speed when using the $L1$-loss. The resulting value was 250 for all problems, except parity, for which it was 1000.

For MLCs with discrete inputs there are only finitely many possible patterns. Since our test-bed problems are fully defined, we construct each test set from all possible patterns except those used in that particular training set. In doing so the true out-of-sample error for each sample is known.

3.3 Results for Hierarchical Loss Functions

In this section we present results showing that the losses defined in Section 2.1 improve the out-of-sample error achieved on all test-bed problems mentioned in Section 3.1.

Learning FBNs with structure-based local search displays high variance. As such, each point shown in Figures 3, 4, and 5 represents the mean performance over 1000 different training sets of that size. We have also displayed 95% confidence intervals as transparent bands in Figure 4. For Figure 3 this interval was too small for bars or bands to be visible.

The overall test accuracy as it varies with sample size for the 7-bit cascaded parity problem is shown in the top of Figure 3. A phase transition between poor and near perfect generalisation is expected (Patarnello and Carnevali, 1987). What we see in Figure 3 is a leftward shift in this transition as we impose an increasingly strict order to the targets. Less examples are required to achieve the same generalisation if a difficulty-based target curriculum is imposed.

Even for a single problem instance the improvement is not expected to be consistent across all targets. In fact our earlier reasoning suggests the improvement should increase for successive targets. In the bottom of Figure 3 we have also shown the test accuracy improvement given by each loss, for each target of 7-bit cascaded parity. The first two targets are not shown; as expected there is little improvement for them. Beyond this, we see that the improvement increases with each successive target until the last (the same trend appears in all five problems). This peaks at the second-last target with an increase from 58% test accuracy using L_1, to 84% test accuracy using L_{gh}.

Generalisation improvements can be most readily observed when looking at the test accuracy differences between L_1 and each of L_w, L_{lh} and L_{gh} as they vary with s. Figure 4 shows the mean of these differences with respect to s along with transparent bands indicating the 95% confidence interval of the mean. We can see that the improvement differs significantly between targets but is consistently positive and statistically significant across a range of training set sizes for all five problem instances.

More importantly, the loss which most strictly enforces the learning order: L_{gh}, also confers the largest improvement, and vice versa for the loss which least strictly enforces it: L_w. This phenomena is consistent across all five problems and confirms the central idea presented in this paper.

In terms of overall generalisation accuracy we can see that training to a curriculum of targets offers a significant advantage in Boolean MLCs with target hierarchies. Furthermore we can see that a curriculum can be enforced in a combinatorial black-box optimiser using only slight modifications to the typical guiding function.

3.4 Evaluating the Discovered Curricula

Here we evaluate the effectiveness of the proposed methods for estimating target overlap and difficulty order described in Section 2 on the same test-bed problems. We also observe how the improvement conferred by hierarchical loss functions varies when random orderings are used.

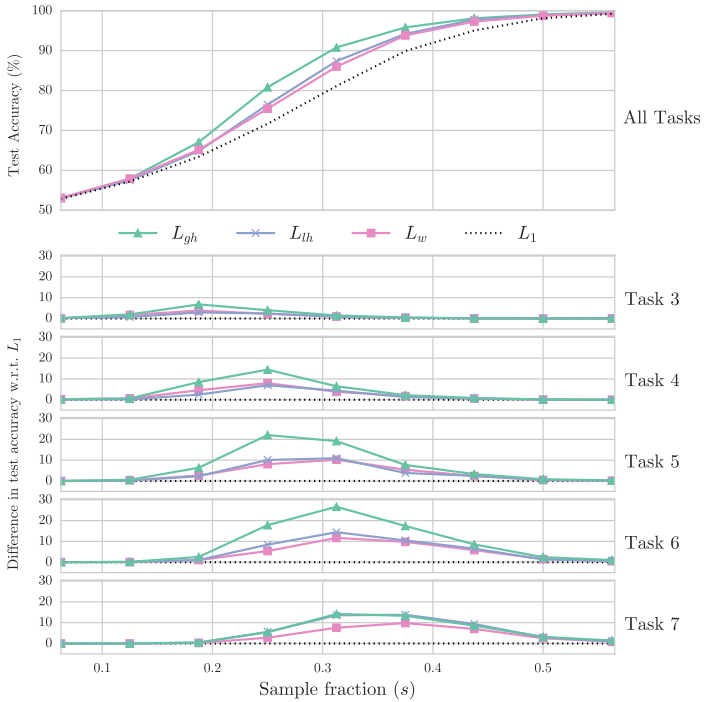


Figure 3: Generalisation performance of each loss function on the 7-bit cascaded parity problem. The top plot shows the mean test accuracy averaged across all targets for each loss while the remaining plots show the mean difference in test accuracy, on each target, between L_1 (dotted baseline) and each of L_w, L_{lh} and L_{gh}. The first two targets are not shown as they show only a negligible improvement. Confidence intervals (95%) are also not shown as they were too narrow to be visible, the widest being less than 2%. A leftward shift in the transition (top) from poor to near-perfect performance can be seen. This becomes more pronounced as the loss more strictly enforces the learning order ($L_w \to L_{lh} \to L_{gh}$) with L_{gh} achieving a 16% reduction in the number of training examples needed to achieve above 90% mean test accuracy. The differences in test accuracy for individual targets (bottom) shows an increase in improvement with target difficulty, as expected; reaching a large peak improvement—from 58% to 84% test accuracy—for the sixth target. On this particular problem the difference between L_{lh} and L_w is not statistically significant. For all loss functions the out-of-sample accuracy is significantly better than obtained with L_1 (dotted line).

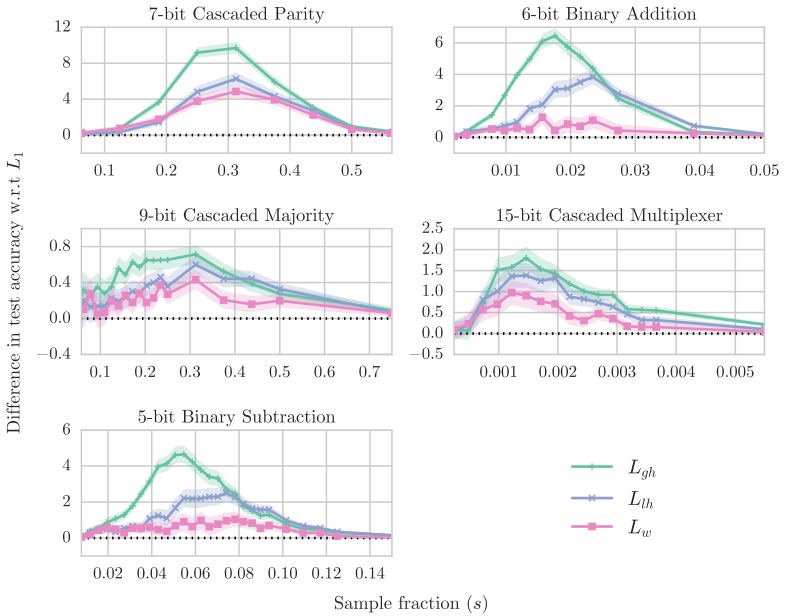

Figure 4: Mean difference in test accuracy between L_1 (dotted baseline) and each of L_w, L_{lh} and L_{gh} on each training sample and problem instance. The 95% confidence interval of the mean is shown with transparent bands. On all problems we can see a statistically significant net increase in test accuracy—though the magnitude varies widely between problems. We can also see that this improvement increases as the loss more strictly enforces the ordering ($L_w \to L_{lh} \to L_{gh}$).

3.4.1 Effectiveness of order estimation

We know the difficulty curricula for the problems in Section 3.1.1. Thus we can quantify the effectiveness of the proposed target ordering method on these, by using the rank correlation between the known and estimated orderings. Since these are permutations there are no ties to consider and we can use the simplest version of Kendall's τ:

$$\tau = \frac{P - Q}{P + Q} ,$$

where P is the number of target pairs which are placed in the same relative order under both orderings, and Q the number which are not. Being a correlation, τ takes values in $[-1, 1]$, with 1 indicating the two orderings are identical, 0 indicating they are uncorrelated and -1 that they are inverses.

We used the same experimental configuration as before but for each training instance we randomly shuffled the targets, to reduce the effect of any deterministic biases. Then we estimated an ordering using the minFS-based method and computed the rank correlation between this ordering and the order used in Section 3.3, as well as the nestedness score, η, defined in Section 2.2.3. Finally we learned one network for each instance using L_{gh} with the estimated target order. Only L_{gh} was considered since it produced the largest improvement with the known order (see Figure 4). These results are shown in Figure 5.

For each problem, Figure 5 shows the nestedness score and the rank correlation between the known and automatically discovered target orders; as well as the generalisation improvement imparted by L_{gh} when given each ordering.

We see that not all problems are easily detected as possessing overlapping hierarchical targets. On parity and majority the mean nestedness score and τ quickly reach 1.0 indicating that the proposed method is successful at automatically determining that there is an overlap, and the correct order of targets. For addition and subtraction the results are weaker but still promising however for the multiplexer there is only a weak correlation between the expected and known target orders and a low nestedness score. It is interesting that, even with a weakly correlated target order, some improvement is still gained from enforcing that order.

Except for CMUX—for which there is still an overall improvement—the third row in Figure 5 shows a high agreement between test accuracies gains using given and automatically detected target orderings. With zero prior knowledge of the respective target difficulties, the minFS-based method combined only with a slight change in the loss function, yields significant improvements in generalisation. This is promising given we are considering a learner which was already leveraging the expected benefits associated with a shared internal representation.

3.4.2 How performance correlates with target order

The next experiment we describe had two principal aims: to examine the relationship between the performance of hierarchical loss functions and the given curriculum, and to determine if the difficulty based curriculum that we have assumed as ground truth is actually optimal.

To do this we used a slightly smaller single problem—5-bit addition—and trained networks using L_{gh} with randomly generated target permutations and L_1. This gives us another

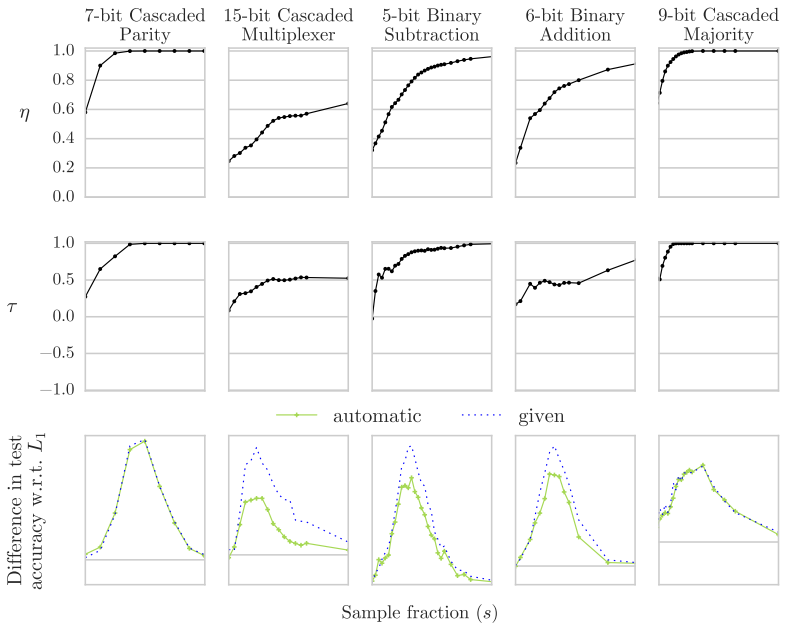

Figure 5: Mean increase in test accuracy—over networks trained using L_1—for networks trained using L_{gh} with the known target order (given) and the automatically detected target order (automatic). For all problems except CMUX both τ and η reach values above 0.5 before the respective peaks in test error difference. For these same problems the detected target order provides the nearly the same benefit as the known target order, which is no surprise given the strong correlation between the known and estimated orderings. The problem with the largest deviation, CMUX, is also the one for which τ and η are weakest. Note: the x-axes are only shared within columns, and the y-axis for the third row is not shared, since some problems have a much larger improvement than others.

important baseline—random target orderings—and also allows us to see how the performance of L_{gh} varies with τ, and if the least-to-most-significant curriculum we propose is outperformed by some other ordering.

We did not draw permutations uniformly since the rank correlation, τ, is heavily skewed over the space of permutations; the values ± 1 are only represented by 2, in combinatorially many, possibilities. However for a n-target permutation there are only $\lceil n \times (n-1)/2 \rceil$ unique values of τ, so selecting permutations uniformly distributed over τ is trivial. As such we trained 5 networks for each of 50 permutations (selected with replacement) for every value of τ over the range of sample sizes. The baseline L_1 does not vary with order so we again learned 1000 networks per sample size.

Figure 6 shows the resulting difference in test accuracy. Each line shows the mean improvement (over networks trained using L_1) as it varies with sample size for networks trained with L_{gh} for all permutations with that correlation value. One clear observation is that permutations which positively correlate (blue) with the easy-to-hard ordering give improvement while permutations which negatively correlate (red) actually detriment performance. The second key observation is that this varies with the strength of the correlation; and, most importantly, the largest improvement is given by the exact easy-to-hard curriculum ($\tau = +1$).

These results confirm our intuition that an easy-to-hard ordering is optimal—at least for this method of enforcing a target curriculum. They also agree with the results seen in Section 3.4.1 which showed that some improvement was seen for the CMUX problem even with a weak mean order correlation, but also that weaker correlation in the discovered curriculum reduced the improvement given by L_{gh}.

3.5 Real-World Problems

Here we present results for the experiments described in Sections 3.1.2 and 3.1.3. We lack an expected target order so the results for all ordered losses are with automatically detected curriculum (Section 2.2).

For the ALU, mammalian cell-cycle, and FA/BRCA pathway models we have the same regime as for the prior test-beds, so we have presented the results in the same manner. Figure 7 shows the mean difference in test accuracy between each hierarchical loss function and the baseline L_1 as sample size is varied. We also see that with the mammalian cell-cycle model there is much less differentiation between the hierarchical losses, in fact L_w appears to have given the most benefit. Overall, in all three cases imposing the target order improved test accuracy and the proposed method clearly discovered a beneficial curriculum.

For the time-series data sets the leave-one-out testing regime did not involve varying the sample size so we have instead presented the results in Tables 2 and 3. Again we see that imposing a target curriculum improved the generalisation performance of some targets later in the suspected order even for shallow hierarchies and with extremely limited sample sizes. In Table 3 we see an improvement in the target G6 and in Table 2 we see improvement for both subsequent targets—Cdc2/Cdc13 and Cdc2/Cdc13*—in one of the two estimated hierarchies (see Figure 2).

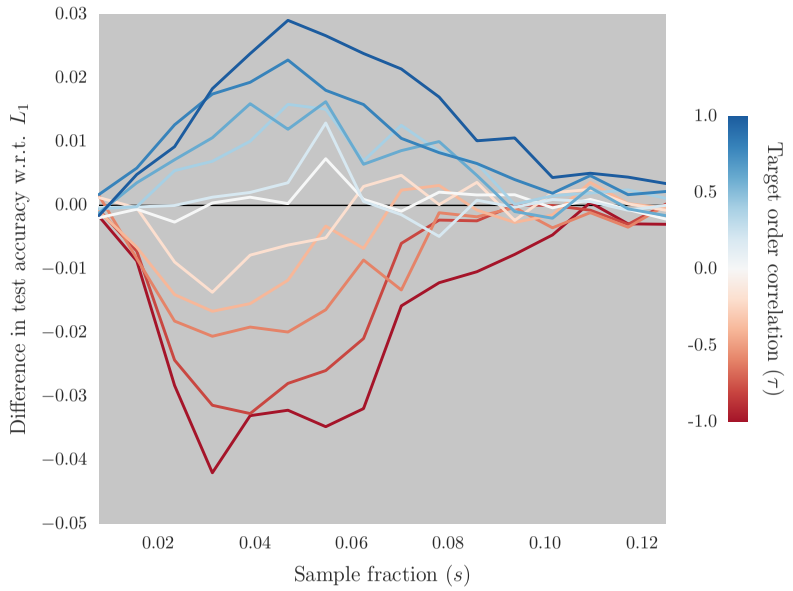

Figure 6: Mean difference in test accuracy between L_{gh} and L_1 over various training set sizes for the 5-bit addition problem for randomised target orderings. Each line represents the mean change in test accuracy for each possible level of correlation between the randomly given order and the known order. For an n-element permutation there are $\lceil n \times (n-1)/2 \rceil$ possible values of τ, hence 11 lines. The central permutations offer little benefit, and since the random permutations are skewed heavily toward $\tau = 0$ we can infer that a randomly generated ordering would offer no improvement on average. We see very clearly that that direct opposite ($\tau = -1$) of the suggested curricula impeded the learning performance by as much as the correct order improved it and that the exact easy-to-hard ordering ($\tau = 1$) conferred the largest benefit.

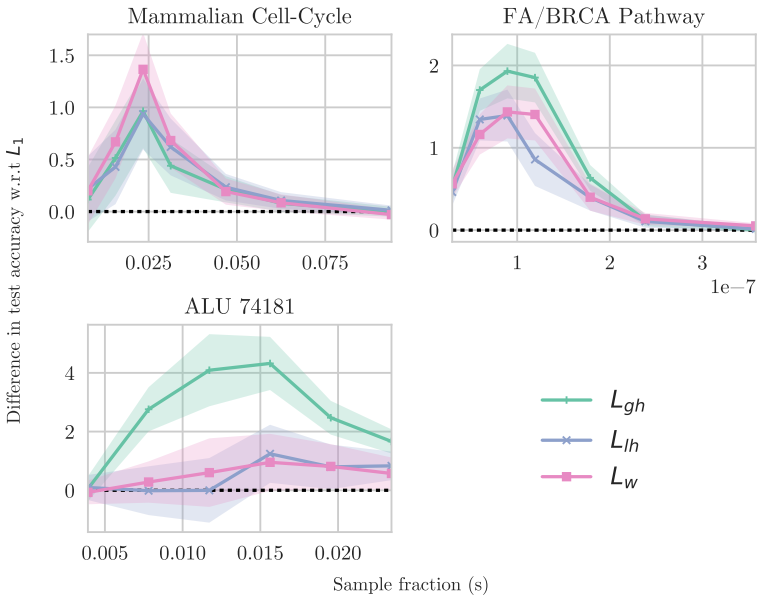

Figure 7: Mean difference in test accuracy between L_1 (dotted baseline) and each of L_w, L_{lh} and L_{gh} on each training sample for the 74181, mammalian cell-cycle and FA/BRCA pathway models. The 95% confidence interval of the mean is shown with transparent bands. On all problems we see the same net increase in test accuracy—again varying widely between problems. We see again that, except in the case of the mammalian cell-cycle model for which the losses are not clearly distinguishable, this improvement increases as the loss more strictly enforces the ordering ($L_w \to L_{lh} \to L_{gh}$).

	SK	Ste9	Rum1	PP	Cdc2/Cdc13	Cdc2/Cdc13*
L_w	0.4	0.5	0.4	1.6	1.2	0.6
L_{lh}	0.6	0.5	0.4	0.8	1.0	0.1
L_{gh}	0.9	0.5	0.3	0.5	1.3	1.4

Table 2: Results for the yeast data set. See Figure 2 for the estimated hierarchies. The SK→ {Ste9, Rum1} hierarchy has given little improvement, however we see more promise in the PP→ {Cdc2/Cdc13, Cdc2/Cdc13*} hierarchy, particularly for L_{gh}.

	G2	G8	G6
L_w	0.1	0.2	0.8
L_{lh}	0.7	-0.9	1.3
L_{gh}	0.1	0.1	1.4

Table 3: Results for the *E. coli* data set. See Figure 2 for the estimated hierarchies. The {G2, G8}→G6 hierarchy has given some improvement, however for L_{lh} we see a drop in performance on one of the base targets in the hierarchy. For L_{gh} the results are still overall positive.

4. Discussion and Future Work

We have shown that loss functions that impose a target order improve the overall generalisation performance of FBNs using a series of hierarchical multi-target circuit-inference problems. We also showed this improvement increases as the target order is more strictly enforced. Note that the losses considered do not alter the set of global optima. This approach does not restrict the space of networks but instead modifies their probability of discovery in a natural way using concepts inspired by human teaching and learning practices.

The set of circuit-inference problems described in Section 3.1.1 all possess a common element: intermediate values which are useful for computing the $m+1^{th}$ output are computed for the m^{th} output. A human designer with access to a complete m-bit circuit would have a much easier time building an $(m+1)$-bit circuit. It is natural to assume that this ease should extend—in terms of convergence speed, generalisation or both—to a optimiser which builds such circuits in the correct order. We observed the latter but not the former.

We observed that performance improvements primarily occur around the existent generalisation phase transition. This is intuitive: there are fundamental limits with respect to training-set size that cannot be alleviated, and there are also sizes for which there is enough information present that teaching a target order confers no advantage. What we have shown is that—in the interim region between too little and plenty of training information—teaching targets in order of difficulty can make better use of what data is present. This improvement is expected in light of the positive effects of hierarchical cost functions on optimiser performance (Moscato, 1993).

The improvement on the final target from L_{gh} actually decreases (bottom of Figure 3). Initially, this appears as a cause for concern as it seems to indicate a point of diminishing returns. However this happened consistently only on the final target for all problems. Were

there a per-problem tipping point we would expect to see it before the last target, or not at all, on some problems. This is also the same for varying sizes of binary addition (see Online Appendix 2).

A more likely explanation is the gate budget coupled with a lack of constraints on which gates each target can source from. The loss function for which we see the issue occurring, L_{gh} essentially forces optimisation of each target in succession. As the process continues, it becomes increasingly more likely that any given target will have a majority of its computational nodes closer to the end of the ordering of gates. Subsequent sub-networks will thus require later and later nodes to be available in order to correctly discover the hierarchical structure of the problem which becomes an issue toward the end when the gate budget is exhausted. This could be alleviated by reserving nodes for each target.

We have also suggested an intuitive approach to determining the target overlap for Boolean MLCs, and to automatically determine an appropriate target order. For the problems considered, the bulk of the generalisation improvement conferred by the curriculum remained, even when no information on the true target order was provided to the learner.

We further examined the same loss functions in conjunction with the target curricula estimation method on three models of real world phenomena as well as on two regulatory network time-series data sets. On all three models we observed test accuracy increases similar to that seen on the circuit-inference problems. In the case of the yeast and *E. coli* data set we discovered possible target hierarchies which were shallow and as such we expected less improvement (Figure 3 shows that generalisation gains are focused primarily on later targets). Nonetheless the results are still in line with what we have observed for the previous problems. This is promising as we have not explicitly accounted for noise in either the curricula detection method or design of the loss functions.

Finally we examine the importance of the curricula itself in Section 3.4.2. We see that the easy-to-hard curricula gave the strongest improvement, that curricula which were anti-correlated with the easy-to-hard permutation actually decreased test accuracy, and that the curricula which were uncorrelated (i.e. essentially random) gave no improvement over learning with no curriculum. The fact that the peak in the distribution of permutations over τ occurs at zero means that randomly generated curricula will most commonly give no benefit and thus highlights the importance of principled methods for determining target curricula.

Not discussed here is the effect that the use of these guiding functions has on the average convergence time. We observed a variable effect on training speed and, for some problems, there is a cost in convergence speed when using target curricula. More information on training time is available in Online Appendix 2.

Another possible impact on training speed is the requirement for the target ordering method to solve an NP-hard optimisation problem. However, for all problems considered, the target order detection process had almost no impact on overall training time. For significantly larger problem instances, however, heuristic solvers would likely be required.

Noise has not been considered as a factor in this work. It is uncertain whether the minFS based methods for estimating target overlap and target schedules—or FBNs themselves—are robust to incorrect target labels. Future work should address this shortfall, perhaps by allowing the per-target error constraints in L_{gh} to be non-zero. The drop in performance on

the final target should also be addressed; possibly by using stratified networks, or annealed depth constraints, to prevent later gates being consumed by earlier targets.

While our results are only for the case of Boolean MLCs learned with FBNs, we expect they may extend to other non-convex learners, such as deep neural nets, for problems with categorical or Boolean domains, provided differentiable analogues to L_{lh} and L_{gh} are found. Future work could also examine target feature selection methods for real valued domains, as well as heuristic Boolean feature selection methods, to determine if the approach presented here is more generally applicable. A recent discussion of the use of intrinsic dimension as a proxy for the overall complexity of arbitrary data sets (Granata and Carnevale, 2016) is promising.

Abstract

In modern large-scale machine learning applications, the training data are often partitioned and stored on multiple machines. It is customary to employ the "data parallelism" approach, where the aggregated training loss is minimized without moving data across machines. In this paper, we introduce a novel distributed dual formulation for regularized loss minimization problems that can directly handle data parallelism in the distributed setting. This formulation allows us to systematically derive dual coordinate optimization procedures, which we refer to as *Distributed Alternating Dual Maximization* (DADM). The framework extends earlier studies described in (Boyd et al., 2011; Ma et al., 2017; Jaggi et al., 2014; Yang, 2013) and has rigorous theoretical analyses. Moreover, with the help of the new formulation, we develop the accelerated version of DADM (Acc-DADM) by generalizing the acceleration technique from (Shalev-Shwartz and Zhang, 2014) to the distributed setting. We also provide theoretical results for the proposed accelerated version, and the new result improves previous ones (Yang, 2013; Ma et al., 2017) whose iteration complexities grow linearly on the condition number. Our empirical studies validate our theory and show that our accelerated approach significantly improves the previous state-of-the-art distributed dual coordinate optimization algorithms.

1. Introduction

In large-scale machine learning applications for big data analysis, it becomes a common practice to partition the training data and store them on multiple machines connected via a commodity network. A typical setting of distributed machine learning is to allow these machines to train in parallel, with each machine processing its local data with no data communication. This paradigm is often referred to as *data parallelism*. To reduce the overall training time, it is often necessary to increase the number of machines and to minimize the communication overhead. A significant challenge is to reduce the training time as much as possible when we increase the number of machines. A practical solution requires two research directions: one is to improve the underlying system design making it suitable for machine learning algorithms (Dean and Ghemawat, 2008; Zaharia et al., 2012; Dean et al., 2012; Li et al., 2014); the other is to adapt traditional single-machine optimization methods to handle data parallelism (Boyd et al., 2011; Yang, 2013; Mahajan et al., 2013; Shamir et al., 2014; Jaggi et al., 2014; Mahajan et al., 2017; Ma et al., 2017; Takáč et al., 2015; Zhang and Lin, 2015). This paper focuses on the latter.

For big data machine learning on a single machine, there are two types of algorithms: batch algorithms such as gradient descent or L-BFGS (Liu and Nocedal, 1989), and stochastic optimization algorithms such as stochastic gradient descent and their modern variance reduced versions (Defazio et al., 2014; Johnson and Zhang, 2013). It is known that batch algorithms are relatively easy to parallelize. However, on a single machine, they converge more slowly than the modern stochastic optimization algorithms due to their high per-iteration computation costs. Specifically, it has been shown that the modern stochastic optimization algorithms converge faster than the traditional batch algorithms for convex regularized loss minimization problems. The faster convergence can be guaranteed in theory and observed in practice.

The fast convergence of modern stochastic optimization methods has led to studies to extend these methods to the distributed computing setting. Specifically, this paper considers the generalization of Stochastic Dual Coordinate Ascent (SDCA) method (Hsieh et al., 2008; Shalev-Shwartz and Zhang, 2013) and its proximal variant (Shalev-Shwartz and Zhang, 2014) to handle distributed training using data parallelism. Although this problem has been considered previously (Yang, 2013; Jaggi et al., 2014; Ma et al., 2017), these earlier approaches work with the dual formulation that is the same as the traditional single-machine dual formulation, where dual variables are coupled, and hence run into difficulties when they try to motivate and analyze the derived methods under the distributed environment.

One contribution of this work is to introduce a new dual formulation specifically for distributed regularized loss minimization problems when data are distributed to multiple machines. In our new formulation, we decouple the local dual variables through introducing another dual variable β. This unique dual formulation allows us to naturally extend the proximal SDCA algorithm (ProxSDCA) of (Shalev-Shwartz and Zhang, 2014) to the setting of multi-machine distributed optimization that can benefit from data parallelism. Moreover, the analysis of the original ProxSDCA can be easily adapted to the new formu-

lation, leading to new theoretical results. This new dual formulation can also be combined with the acceleration technique of (Shalev-Shwartz and Zhang, 2014) to further improve convergence.

In the proposed formulation, each iteration of the distributed dual coordinate ascent optimization is naturally decomposed into a local step and a global step. In the local step, we allow the use of any local procedure to optimize a local dual objective function using local parameters and local data on each machine. This flexibility is similar to those of (Ma et al., 2017; Jaggi et al., 2014). For example, we may apply ProxSDCA as the local procedure. In the local step, a computer node can perform the optimization independently without communicating with each other. While in the global step, nodes communicate with each other to synchronize the local parameters and jointly update the global primal solution. Only this global step requires communication among nodes.

We summarize our main contributions as follows:

New distributed dual formulation This new formulation naturally leads to a two-step local-global dual alternating optimization procedure for distributed machine learning. We thus call the resulting procedure *Distributed Alternating Dual Maximization* (DADM). Note that DADM directly generalizes ProxSDCA, which can handle complex regularizations such as L_2-L_1 regularization.

New convergence analysis The new formulation allows us to directly generalize the analysis of ProxSDCA in (Shalev-Shwartz and Zhang, 2014) to the distributed setting. This analysis is in contrast to that of CoCoA$^+$ in (Ma et al., 2017), which employs a different way based on the Θ-approximate solution assumption of the local solver. Our analysis can lead to simplified results in the commonly used mini-batch setup.

Acceleration with theoretical guarantees Based on the new distributed dual formulation, we can naturally derive a distributed version of the accelerated proximal SDCA method (AccProxSDCA) of (Shalev-Shwartz and Zhang, 2014), which has been shown to be effective on a single machine. We call the resulting procedure *Accelerated Distributed Alternating Dual Maximization* (Acc-DADM). The main idea is to modify the original formulation using a sequence of approximations that have stronger regularizations. Moreover, we directly adapt theoretical analyses of AccProxSDCA to the distributed setting and provide guarantees for Acc-DADM. Our theorems guarantee that we can always obtain a computation speedup compared with the single-machine AccProxSDCA. These guarantees improve the theoretical results of DADM and previous methods (Yang, 2013; Ma et al., 2017) whose iteration complexities grow linearly on the condition number. Latter methods possibly fail to provide computation time improvement over the single-machine ProxSDCA when the condition number is large.

Extensive empirical studies We perform extensive experiments to compare the convergence and the scalability of the accelerated approach with that of previous state-of-the-art distributed dual coordinate ascent methods. Our empirical studies show that Acc-DADM can achieve faster convergence and better scalability than the previous state-of-the-art, in particular when the condition number is large. This phenomenon is consistent with our theory.

We organize the rest of the paper as follows. Section 2 discusses related works. Section 3 provides preliminary definitions. Section 4 to 6 present the distributed primal formulation, the distributed dual formulation and our DADM method respectively. Section 7 then provides theorems for DADM. Section 8 introduces the accelerated version and provides corresponding theoretical guarantees. Section 9 includes all proofs of this paper. Section 10 provides extensive empirical studies of our novel method. Finally, Section 11 concludes the whole paper.

2. Related Work

Several generalizations of SDCA to the distributed settings have been proposed in the literature, including DisDCA (Yang, 2013), CoCoA (Jaggi et al., 2014), and CoCoA$^+$ (Ma et al., 2017).

DisDCA was the first attempt to study distributed SDCA, and it provided a basic theoretical analysis and a practical variant that behaves well empirically. Nevertheless, their theoretical result only applies to a few specially chosen mini-batch local dual updates that differ from the practical method used in their experiments. In particular, they did not show that optimizing each local dual problem leads to convergence. This limitation makes the methods they analyzed inflexible.

CoCoA was proposed to fix the above gap between theory and practice, and it was claimed to be a framework for distributed dual coordinate ascent in that it allows any local dual solver to be used for the local dual problem, rather than the impractical choices of DisDCA. However, the actual performance of CoCoA is inferior to the practical variant proposed in DisDCA with an aggressive local update. We note that the practical variant of DisDCA did not have a solid theoretical guarantee at that time.

CoCoA$^+$ fixed this situation and may be regarded as a generalization of CoCoA. The most effective choice of the aggregation parameter leads to a version which is similar to DisDCA, but allows exact optimization of each dual problem in their theory. According to studies in (Ma et al., 2017), the resulting CoCoA$^+$ algorithm performs significantly better than the original CoCoA both theoretically and empirically. The original CoCoA$^+$ (Ma et al., 2015) can only handle problems with the L_2 regularizer, and it was generalized to general strongly convex regularizers in the long version (Ma et al., 2017). Besides, (Smith et al., 2016) extended the framework to solve the primal problem of regularized loss minimization and cover general non-strongly convex regularizers such as L_1 regularizer, and (Hsieh et al., 2015) studied parallel SDCA with asynchronous updates.

Although CoCoA$^+$ has the advantage of allowing arbitrary local solvers and flexible approximate solutions of local dual problems, its theoretical analyses do not capture the contribution of the number of machines and the mini-batch size to the iteration complexity explicitly. Moreover, the iteration complexities of both CoCoA$^+$ and DisDCA grow linearly with the condition number. Thus they probably cannot provide computation time improvement over the single-machine SDCA when the condition number is large. This paper will remedy these unsatisfied aspects by providing a different analysis based on a new distributed dual formulation. Using this formulation, we can analyze procedures that can take an arbitrary local dual solver, which is like CoCoA$^+$; moreover, we allow the dual updates to be a mini-batch, which is like DisDCA. Besides, this formulation also allows

us to naturally generalize AccProxSDCA and relevant theoretical results to the distributed setting. Our empirical results also validate the superiority of the accelerated approach.

While we focus on extending SDCA in this paper, we note that there are other approaches for parallel optimization. For example, there are direct attempts to parallelize stochastic gradient descent (Niu et al., 2011; Zinkevich et al., 2010). Some of these procedures only consider multi-core shared memory situation, which is very different from the distributed computing environment investigated in this paper. In the setting of distributed computing, data are partitioned into multiple machines, and one often needs to study communication-efficient algorithms. In such cases, one extreme is to allow exact optimization of subproblems on each local machine as considered in (Shamir et al., 2014; Zhang and Lin, 2015). Although this approach minimizes communication, the computation cost for each local solver can dominate the overall training. Therefore in practice, it is necessary to do a trade-off by using the mini-batch update approach (Takáč et al., 2013, 2015). However, it is difficult for traditional mini-batch methods to design reasonable aggregation strategies to achieve fast convergence. (Takáč et al., 2015) studied how the step size can be reduced when the mini-batch size grows in the distributed setting. (Lee and Roth, 2015) derived an analytical solution of the optimal step size for dual linear support vector machine problems. Besides, (Mahajan et al., 2013) presented a general framework for distributed optimization based on local functional approximation, which include several first-order and second-order methods as special cases. (Mahajan et al., 2017) considered each machine to handle a block of coordinates and proposed distributed block coordinate descent methods for solving ℓ_1 regularized loss minimization problems.

Different from those methods, *Distributed Alternating Dual Maximization* (DADM) proposed in this work handles the trade-off between computation and communication by developing bounds for mini-batch dual updates, which is similar to (Yang, 2013). Moreover, DADM allows other better local solvers to achieve faster convergence in practice.

3. Preliminaries

In this section, we introduce some notations used later. All functions that we consider in this paper are proper convex functions over a Euclidean space.

Given a function $f : \mathbb{R}^d \to \mathbb{R}$, we denote its **conjugate function** as

$$f^*(b) = \sup_a [b^\top a - f(a)].$$

A function $f : \mathbb{R}^d \to \mathbb{R}$ is L**-Lipschitz** with respect to $\|\cdot\|_2$ if for all $a, b \in \mathbb{R}^d$, we have

$$|f(a) - f(b)| \leq L\|a - b\|_2.$$

A function $f : \mathbb{R}^d \to \mathbb{R}$ is $(1/\gamma)$**-smooth** with respect to $\|\cdot\|_2$ if it is differentiable and its gradient is $(1/\gamma)$-Lipschitz with respect to $\|\cdot\|_2$. An equivalent definition is that for all $a, b \in \mathbb{R}^d$, we have

$$f(b) \leq f(a) + \nabla f(a)^\top (b - a) + \frac{1}{2\gamma}\|b - a\|_2^2.$$

A function $f : \mathbb{R}^d \to \mathbb{R}$ is λ**-strongly convex** with respect to $\|\cdot\|_2$ if for any $a, b \in \mathbb{R}^d$, we have

$$f(b) \geq f(a) + \nabla f(a)^\top (b - a) + \frac{\lambda}{2}\|b - a\|_2^2,$$

where $\nabla f(a)$ is any subgradient of $f(a)$.

It is well known that a function f is γ-strongly convex with respect to $\|\cdot\|_2$ if and only if its conjugate function f^* is $(1/\gamma)$-smooth with respect to $\|\cdot\|_2$.

4. Distributed Primal Formulation

In this paper, we consider the following generic regularized loss minimization problem:

$$\min_{w \in \mathbb{R}^d} \left[P(w) := \sum_{i=1}^n \phi_i(X_i^\top w) + \lambda n g(w) + h(w) \right], \tag{1}$$

which is often encountered in practical machine learning problems. Here we assume each $X_i \in \mathbb{R}^{d \times q}$ is a $d \times q$ matrix, $w \in \mathbb{R}^d$ is the model parameter vector, $\phi_i(u)$ is a convex loss function defined on $\mathbb{R}^q$, which is associated with the i-th data point, $\lambda > 0$ is the regularization parameter, $g(w)$ is a strongly convex regularizer and $h(w)$ is another convex regularizer. A special case is to simply set $h(w) = 0$. Here we allow the more general formulation, which can be used to derive different distributed dual forms that may be useful for special purposes.

The above optimization formulation can be specialized to a variety of machine learning problems. As an example, we may consider the L_2-L_1 regularized least squares problem, where $\phi_i(x_i^\top w) = (w^\top x_i - y_i)^2$ for vector input data $x_i \in \mathbb{R}^d$ and real valued output $y_i \in \mathbb{R}$, $g(w) = \|w\|_2^2 + a\|w\|_1$, and $h(w) = b\|w\|_1$ for some $a, b \geq 0$.

If we set $h(w) = 0$, then it is well-known (see, for example, (Shalev-Shwartz and Zhang, 2014)) that the primal problem (1) has an equivalent single-machine dual form of

$$\max_{\alpha \in \mathbb{R}^n} \left[D(\alpha) := -\sum_{i=1}^n \phi_i^*(-\alpha_i) - \lambda n g^*\left(\frac{\sum_{i=1}^n X_i \alpha_i}{\lambda n} \right) \right], \tag{2}$$

where $\alpha = [\alpha_1, \cdots, \alpha_n], \alpha_i \in \mathbb{R}^q$ $(i = 1, ..., n)$ are dual variables, ϕ_i^* is the convex conjugate function of ϕ_i, and similarly, g^* is the convex conjugate function of g.

The stochastic dual coordinate ascent method, referred to as SDCA in (Shalev-Shwartz and Zhang, 2014), maximizes the dual formulation (2) by optimizing one randomly chosen dual variable at each iteration. Throughout the algorithm, the following primal-dual relationship is maintained:

$$w(\alpha) = \nabla g^*\left(\frac{\sum_{i=1}^n X_i \alpha_i}{\lambda n} \right), \tag{3}$$

for some subgradient $\nabla g^*(v)$.

It is known that $w(\alpha^*) = w^*$, where w^* and α^* are optimal solutions of the primal problem and the dual problem respectively. It was shown in (Shalev-Shwartz and Zhang, 2014) that the duality gap defined as $P(w(\alpha)) - D(\alpha)$, which is an upper-bound of the primal sub-optimality $P(w(\alpha)) - P(w^*)$, converges to zero. Moreover, a convergence rate can be established. In particular, for smooth loss functions, the convergence rate is linear.

We note that SDCA is suitable for optimization on a single machine because it works with a dual formulation that is suitable for a single machine. In the following, we will

generalize the single-machine dual formulation (2) to the distributed setting, and study the corresponding distributed version of SDCA.

In the distributed setting, we assume that the training data are partitioned and distributed to m machines. In other words, the index set $S = \{1, ..., n\}$ of the training data is divided into m non-overlapping partitions, where each machine $\ell \in \{1, ..., m\}$ contains its own partition $S_\ell \subseteq S$. We assume that $\cup_\ell S_\ell = S$, and we use $n_\ell := |S_\ell|$ to denote the size of the training data on machine ℓ.

Next, we can rewrite the primal problem (1) as the following constrained minimization problem that is suitable for the multi-machine distributed setting:

$$\begin{aligned} &\min_{w;\{w_\ell\}_{\ell=1}^m} \sum_{\ell=1}^m P_\ell(w_\ell) + h(w) \\ &\quad s.t. \quad w_\ell = w, \quad \text{for all } \ell \in \{1, ..., m\}, \\ &\text{where} \quad P_\ell(w_\ell) := \sum_{i \in S_\ell} \phi_i(X_i^\top w_\ell) + \lambda n_\ell g(w_\ell), \end{aligned} \tag{4}$$

where w_ℓ represents the local primal variable on each machine ℓ, P_ℓ is the corresponding local primal problem and the constraints $w_\ell = w$ are imposed to synchronize the local primal variables. Obviously this multi-machine distributed primal formulation (4) is equivalent to the original primal problem (1).

We note that the idea of objective splitting in (4) is similar to the global variable consensus formulation described in (Boyd et al., 2011). Instead of using the commonly used ADMM (Alternating Direction Method of Multipliers) method that is not a generalization of (2), in this paper we derive a distributed dual formulation based on (4) that directly generalizes (2). We further propose a framework called Distributed Alternating Dual Maximization (DADM) to solve the distributed dual formulation. One advantage of DADM over ADMM is that DADM does not need to solve the subproblems in high accuracy, and thus it can naturally enjoy the trade-off between computation and communication, which is similar to related methods such as DisDCA, CoCoA and CoCoA$^+$.

5. Distributed Dual Formulation

The optimization problem (4) can be further rewritten as:

$$\begin{aligned} &\min_{w;\{w_\ell\};\{u_i\}} \sum_{\ell=1}^m \left[\sum_{i \in S_\ell} \phi_i(u_i) + \lambda n_\ell g(w_\ell) \right] + h(w) \\ &\quad s.t \quad u_i = X_i^\top w_\ell, \text{ for all } i \in S_\ell \\ &\qquad w_\ell = w, \text{ for all } \ell \in \{1, ..., m\}. \end{aligned} \tag{5}$$

Here we introduce n dual variables $\alpha := \{\alpha_i\}_{i=1}^n$, where each α_i is the Lagrange multiplier for the constraint $u_i - X_i^\top w_\ell = 0$, and m dual variables $\beta := \{\beta_\ell\}_{\ell=1}^m$, where each β_ℓ is the Lagrange multiplier for the constraint $w_\ell - w = 0$. We can now introduce the primal-dual objective function with Lagrange multipliers as follows:

$$\begin{aligned} &J(w; \{w_\ell\}; \{u_i\}; \{\alpha_i\}; \{\beta_\ell\}) \\ :=&\sum_{\ell=1}^m \left[\sum_{i \in S_\ell} \left(\phi_i(u_i) + \alpha_i^\top (u_i - X_i^\top w_\ell) \right) + \lambda n_\ell g(w_\ell) + \beta_\ell^\top (w_\ell - w) \right] + h(w). \end{aligned}$$

Proposition 1 *Define the dual objective as*

$$D(\alpha, \beta) := \sum_{\ell=1}^m \left[\sum_{i \in S_\ell} -\phi_i^*(-\alpha_i) - \lambda n_\ell g^* \left(\frac{\sum_{i \in S_\ell} X_i \alpha_i - \beta_\ell}{\lambda n_\ell} \right) \right] - h^* \left(\sum_\ell \beta_\ell \right).$$

Then we have

$$D(\alpha, \beta) = \min_{w;\{w_\ell\};\{u_i\}} J(w; \{w_\ell\}; \{u_i\}; \{\alpha_i\}; \{\beta_\ell\}),$$

where the minimizers are achieved when the following equations are satisfied

$$\begin{aligned} \nabla \phi_i(u_i) + \alpha_i &= 0, \\ -\left(\sum_{i \in S_\ell} X_i \alpha_i - \beta_\ell \right) + \lambda n_\ell \nabla g(w_\ell) &= 0, \\ -\sum_\ell \beta_\ell + \nabla h(w) &= 0, \end{aligned} \tag{6}$$

for some subgradients $\nabla \phi_i(u_i)$, $\nabla g(w_\ell)$, and $\nabla h(w)$.

When $\beta = \{\beta_\ell\}$ are fixed, we may define the local single-machine dual formulation on each machine ℓ with respect to $\alpha_{(\ell)}$ as

$$\tilde{D}_\ell(\alpha_{(\ell)} | \beta_\ell) := \sum_{i \in S_\ell} -\phi_i^*(-\alpha_i) - \lambda n_\ell g^* \left(\frac{\sum_{i \in S_\ell} X_i \alpha_i - \beta_\ell}{\lambda n_\ell} \right), \tag{7}$$

where $\alpha_{(\ell)}$ represents local dual variables $\{\alpha_i; i \in S_\ell\}$ on machine ℓ, $\beta_\ell \in \mathbb{R}^d$ serves as a carrier for synchronization of machine ℓ. Based on Proposition 1, we obtain the following multi-machine distributed dual formulation for the corresponding primal problem (4):

$$D(\alpha, \beta) = \sum_{\ell=1}^m \tilde{D}_\ell(\alpha_{(\ell)} | \beta_\ell) - h^* \left(\sum_{\ell=1}^m \beta_\ell \right). \tag{8}$$

Moreover, we have the non-negative duality gap, and zero duality gap can be achieved when w is the minimizer of $P(w)$ and (α, β) maximizes the dual $D(\alpha, \beta)$.

Proposition 2 *Given any (w, α, β), the following duality gap is non-negative:*

$$P(w) - D(\alpha, \beta) \geq 0.$$

Moreover, zero duality gap can be achieved at (w^*, α^*, β^*), where w^* is the minimizer of $P(w)$ and (α^*, β^*) is a maximizer of $D(\alpha, \beta)$.

We note that the parameters $\{\beta_\ell\}_{\ell=1}^m$ pass the global information across multiple machines. When β_ℓ is fixed, $\tilde{D}_\ell(\alpha_{(\ell)}|\beta_\ell)$ with respect to $\alpha_{(\ell)}$ corresponds to the dual of the adjusted local primal problem:

$$\tilde{P}_\ell(w_\ell|\beta_\ell) := \sum_{i\in S_\ell} \phi_i(X_i^\top w_\ell) + \lambda n_\ell \tilde{g}_\ell(w_\ell), \tag{9}$$

where the original regularizer $\lambda n_\ell g(w_\ell)$ in $P_\ell(w_\ell)$ is replaced by the adjusted regularizer

$$\lambda n_\ell \tilde{g}_\ell(w_\ell) := \lambda n_\ell g(w_\ell) + \beta_\ell^\top w_\ell.$$

Similar to the single-machine primal-dual relationship of (3), we have the following local primal-dual relationship on each machine as:

$$w_\ell(\alpha_{(\ell)}, \beta_\ell) = \nabla g^*\left(\tilde{v}_\ell\right) = \nabla \tilde{g}_\ell^*\left(v_\ell\right), \tag{10}$$

where

$$v_\ell = \frac{\sum_{i\in S_\ell} X_i\alpha_i}{\lambda n_\ell}, \qquad \tilde{v}_\ell = v_\ell - \frac{\beta_\ell}{\lambda n_\ell}.$$

Moreover, we can define the global primal-dual relationship as

$$w(\alpha, \beta) = \nabla g^*\left(\tilde{v}\right) = \nabla \tilde{g}^*\left(v\right), \tag{11}$$

where

$$v = \frac{\sum_{i=1}^n X_i\alpha_i}{\lambda n}, \qquad \tilde{v} = v - \frac{\sum_\ell \beta_\ell}{\lambda n}.$$

We can also establish the relationship of global-local duality in Proposition 3.

Proposition 3 *Given (w, α, β) and $\{w_\ell\}$ such that $w_1 = \cdots = w_m = w$, we have the following decomposition of global duality gap as the sum of local duality gaps:*

$$P(w) - D(\alpha, \beta) \geq \sum_{\ell=1}^m \left[\tilde{P}_\ell(w_\ell|\beta_\ell) - \tilde{D}_\ell(\alpha_{(\ell)}|\beta_\ell)\right],$$

and the equality holds when $\nabla h(w) = \sum_\ell \beta_\ell$ for some subgradient $\nabla h(w)$.

Although we allow arbitrary $h(w)$, the case of $h(w) = 0$ is of special interests. This corresponds to the conjugate function

$$h^*(\beta) = \begin{cases} +\infty & \text{if } \beta \neq 0 \\ 0 & \text{if } \beta = 0 \end{cases}.$$

That is, the term $h^*\left(\sum_{\ell=1}^m \beta_\ell\right)$ is equivalent to imposing the constraint $\sum_{\ell=1}^m \beta_\ell = 0$.

Algorithm 1 Local Dual Update

Retrieve local parameters $(\alpha_\ell^{(t-1)}, \tilde{v}_\ell^{(t-1)})$
Randomly pick a mini-batch $Q_\ell \subset S_\ell$
Approximately maximize (12) w.r.t $\Delta\alpha_{Q_\ell}$
Update $\alpha_i^{(t)}$ as $\alpha_i^{(t)} = \alpha_i^{(t-1)} + \Delta\alpha_i$ for all $i \in Q_\ell$
return $\Delta v_\ell^{(t)} = \frac{1}{\lambda n_\ell}\sum_{i\in Q_\ell} X_i\Delta\alpha_i$

6. Distributed Alternating Dual Maximization

Minimizing the primal formulation (4) is equivalent to maximizing the dual formulation (8), and the latter can be achieved by repeatedly using the following alternating optimization strategy, which we refer to as **D**istributed **A**lternating **D**ual **M**aximization (**DADM**):

- **Local step**: fix β_ℓ and let each machine approximately optimize $\tilde{D}_\ell(\alpha_{(\ell)}|\beta_\ell)$ w.r.t $\alpha_{(\ell)}$ in parallel.
- **Global step**: maximize the global dual objective w.r.t β_ℓ, and set the global primal parameter w accordingly.

The above steps are applied in iterations $t = 1, 2, \ldots, T$. At the beginning of each iteration t, we assume that the local primal and dual variables on each local machine are $(\alpha_{(\ell)}^{(t-1)}, \beta_\ell^{(t-1)}, v_\ell^{(t-1)})$, then we seek to update $\alpha_{(\ell)}^{(t-1)}$ to $\alpha_{(\ell)}^{(t)}$ and $v_\ell^{(t-1)}$ to $v_\ell^{(t)}$ in the local step, and seek to update $\beta_\ell^{(t-1)}$ to $\beta_\ell^{(t)}$ in the global step.

We note that the local step can be executed in parallel w.r.t dual variables $\{\alpha_{(\ell)}\}_{\ell=1}^m$. In practice, it is often useful to optimize (7) approximately by using a randomly selected mini-batch $Q_\ell \subset S_\ell$ of size $|Q_\ell| = M_\ell$. That is, we want to find $\Delta\alpha_i^{(t)}$ with $i \in Q_\ell$ to approximately maximize the local dual objective as follows:

$$\tilde{D}_{Q_\ell}^{(t)}(\Delta\alpha_{Q_\ell}) := -\sum_{i\in Q_\ell} \phi_i^*(-\alpha_i^{(t-1)} - \Delta\alpha_i) - \lambda n_\ell g^*\left(\tilde{v}_\ell^{(t-1)} + \frac{\sum_{i\in Q_\ell} X_i\Delta\alpha_i}{\lambda n_\ell}\right). \tag{12}$$

This step is described in Algorithm 1. We can use any solver for this approximate optimization, and in our experiments, we choose ProxSDCA.

The global step is to synchronize all local solutions, which requires communication among the machines. This is achieved by optimizing the following dual objective with respect to all $\beta = \{\beta_\ell\}$:

$$\beta^{(t)} \in \arg\max_\beta D(\alpha^{(t)}, \beta). \tag{13}$$

Proposition 4 *Given v, let $w(v)$ be the unique solution of the following optimization problem*

$$w(v) = \arg\min_w \left[-\lambda n w^\top v + \lambda n g(w) + h(w)\right] \tag{14}$$

that satisfies

$$\lambda n \nabla g(w) + \nabla h(w) = \lambda n v$$

for some subgradients $\nabla g(w)$ *and* $\nabla h(w) = \rho$ *at* $w = w(v)$*. Then* $\bar{\beta}(v) = \rho$ *is a solution of*

$$\max_b \left[-\lambda n g^* \left(v - \frac{b}{\lambda n} \right) - h^*(b) \right],$$

and

$$w(v) = \nabla g^* \left(v - \frac{\bar{\beta}(v)}{\lambda n} \right).$$

Proposition 5 *Given* α*, a solution of*

$$\max_\beta D(\alpha, \beta)$$

can be obtained by setting

$$\beta_\ell = \lambda n_\ell \left(v_\ell(\alpha_{(\ell)}) - v(\alpha) + \frac{\bar{\beta}(v(\alpha))}{\lambda n} \right)$$

where $\bar{\beta}(v(\alpha))$ *is defined in Proposition 4,*

$$v(\alpha) = \frac{\sum_{i=1}^n X_i \alpha_i}{\lambda n}, \qquad v_\ell(\alpha_{(\ell)}) = \frac{\sum_{i \in S_\ell} X_i \alpha_i}{\lambda n_\ell}.$$

Moreover, if we let

$$w = w(\alpha, \beta) = w(v(\alpha)) = \nabla g^* \left(v(\alpha) - \frac{\bar{\beta}(v(\alpha))}{\lambda n} \right),$$

where $w(v)$ *is defined in Proposition 4, and*

$$w_\ell = w_\ell(\alpha_{(\ell)}, \beta_\ell) = \nabla g^* \left(v_\ell(\alpha_{(\ell)}) - \frac{\beta_\ell}{\lambda n_\ell} \right),$$

then $w = w_\ell$ *for all* ℓ*, and*

$$P(w) - D(\alpha, \beta) = \sum_{\ell=1}^m [\tilde{P}_\ell(w_\ell | \beta_\ell) - \tilde{D}_\ell(\alpha_{(\ell)} | \beta_\ell)].$$

According to Proposition 5, the solution of (13) is given by

$$\beta_\ell^{(t)} = \lambda n_\ell \left(v_\ell^{(t)} - v^{(t)} + \frac{\rho^{(t)}}{\lambda n} \right),$$

where

$$v^{(t)} = \sum_{\ell=1}^m \frac{n_\ell}{n} v_\ell^{(t)} = v^{(t-1)} + \sum_{\ell=1}^m \frac{n_\ell}{n} \Delta v_\ell^{(t)},$$

Algorithm 2 Distributed Alternating Dual Maximization (DADM)

Input: Objective $P(w)$, target duality gap ϵ, warm start variables $w^{\text{init}}, \alpha^{\text{init}}, \beta^{\text{init}}, v^{\text{init}}$, (if not specified, set $w^{\text{init}} = 0, \alpha^{\text{init}} = 0, \beta^{\text{init}} = 0, v^{\text{init}} = 0$), .
Initialize: let $w^{(0)} = w^{\text{init}}$, $\alpha^{(0)} = \alpha^{\text{init}}$, $\beta^{(0)} = \beta^{\text{init}}$, $v^{(0)} = v^{\text{init}}$.
for $t = 1, 2, \ldots$ **do**
  (**Local step**)
  for all machines $\ell = 1, 2, ..., m$ **in parallel do**
    call an arbitrary local procedure, such as Algorithm 1
  end for
  (**Global step**)
  Aggregate $v^{(t)} = v^{(t-1)} + \sum_{\ell=1}^m \frac{n_\ell}{n} \Delta v_\ell^{(t)}$
  Compute $\tilde{v}^{(t)}$ according to (15)
  Let $\Delta \tilde{v}^{(t)} = \tilde{v}^{(t)} - \tilde{v}^{(t-1)}$
  for all machines $\ell = 1, 2, ..., m$ **in parallel do**
    update local parameter $\tilde{v}_\ell^{(t)} = \tilde{v}_\ell^{(t-1)} + \Delta \tilde{v}^{(t)}$
  end for
  Stopping condition: Stop if $P(w^{(t)}) - D(\alpha^{(t)}, \beta^{(t)}) \le \epsilon$.
end for
return $w^{(t)} = \nabla g^*(\tilde{v}^{(t)})$, $\alpha^{(t)}$, $\beta^{(t)}$, $v^{(t)}$, and the duality gap $P(w^{(t)}) - D(\alpha^{(t)}, \beta^{(t)})$.

and $\rho^{(t)} = \nabla h(w^{(t)})$ is a subgradient of h at the solution $w^{(t)}$ of

$$w^{(t)} = \arg\min_w \left[-\lambda n w^\top v^{(t)} + \lambda n g(w) + h(w) \right],$$

that can achieve the first order optimality condition

$$-\lambda n v^{(t)} + \lambda n \nabla g(w^{(t)}) + \rho^{(t)} = 0$$

for some subgradient $\nabla g(w^{(t)})$.

The definition of $\tilde{v}$ implies that after each global update, we have

$$\tilde{v}_\ell^{(t)} = \tilde{v}^{(t)} = v^{(t)} - \frac{\rho^{(t)}}{\lambda n} = \nabla g(w^{(t)}), \quad \text{for all } \ell = 1, \ldots, m. \tag{15}$$

Since the objective (12) for the local step on each machine only depends on the mini-batch Q_ℓ (sampled from S_ℓ) and the vector $\tilde{v}_\ell^{(t)}$, which needs to be synchronized at each global step, we know from (15) that at each time t, we can pass the same vector $\tilde{v}^{(t)}$ as $\tilde{v}_\ell^{(t)}$ to all nodes. In practice, it may be beneficial to pass $\Delta \tilde{v}^{(t)}$ instead, especially when $\Delta \tilde{v}^{(t)}$ is sparse but $\tilde{v}^{(t)}$ is dense. Put things together, the local-global DADM iterations can be summarized in Algorithm 2.

If we consider the special case of $h(w) = 0$, the solution of (15) is simply $\tilde{v}_\ell^{(t)} = \tilde{v}^{(t)} = v^{(t)}$, and the global step in Algorithm 2 can be simplified as first aggregating updates by

$$\Delta \tilde{v}^{(t)} = \Delta v^{(t)} = \sum_{\ell=1}^m \frac{n_\ell}{n} \Delta v_\ell^{(t)},$$

and then updating local parameters in parallel. Further, if $h(w) = 0$ and the data partition is balanced, that is n_ℓ are identical for all $\ell = 1, \ldots, m$, it can be verified that the DADM procedure (ignoring the mini-batch variation) is equivalent to CoCoA$^+$. Therefore the framework presented here may be regarded as an alternative interpretation.

Moreover, when the added regularization in (1) is complex and might involves more than one non-smooth term, considering the splitting of $g(w)$ and $h(w)$ can bring computational advantages. For example, to promote both sparsity and group sparsity in the predictor we often use the sparse group lasso regularization (Friedman et al., 2010), where a combination of L_1 norm and mixed L_2/L_1 norm (group sparse norm) is introduced: $\lambda_1 \sum_{\mathcal{G}} \|w_{\mathcal{G}}\|_2 + \lambda_2 \|w\|_1 + \lambda_3/2 \|w\|_2^2$, where we add a slight L_2 regularization to make it strongly convex, as did in (Shalev-Shwartz and Zhang, 2014). The proximal mapping with respect to the sparse group lasso regularization function does not have closed form solution, thus often relies on iterative minimization steps, but there are closed form proximal mapping with respect to either L_2-L_1 norm or the group norm. Thus if we simply set $h(w) = 0$ and $\lambda g(w) = \lambda_1 \sum_{\mathcal{G}} \|w_{\mathcal{G}}\|_2 + \lambda_2 \|w\|_1 + \lambda_3/2 \|w\|_2^2$, then both the local optimization update (12) and global synchronization step (14) will not have closed form solution. However, if we assign the group norm on $h(w)$ such that $h(w) = \lambda_1 \sum_{\mathcal{G}} \|w_{\mathcal{G}}\|_2$, and hence $\lambda g(w) = \lambda_2 \|w\|_1 + \lambda_3/2 \|w\|_2^2$, the local updates steps (12) will enjoy closed form update, which makes the implementation much easier and we only need to use iterative minimization on the (rare) global synchronization step (14).

7. Convergence Analysis

Let w^* be the optimal solution for the primal problem $P(w)$ and (α^*, β^*) be the optimal solution for the dual problem $D(\alpha, \beta)$ respectively. For the primal solution $w^{(t)}$ and the dual solution $(\alpha^{(t)}, \beta^{(t)})$ at iteration t, we define the **primal sub-optimality** as

$$\epsilon_P^{(t)} := P(w^{(t)}) - P(w^*),$$

and the **dual sub-optimality** as

$$\epsilon_D^{(t)} := D(\alpha^*, \beta^*) - D(\alpha^{(t)}, \beta^{(t)}).$$

Due to the close relationship of the distributed dual formulation and the single-machine dual formulation, an analysis of DADM can be obtained by directly generalizing that of SDCA. We consider two kinds of loss functions, smooth loss functions that imply fast linear convergence and general L-Lipschitz loss functions. For the following two theorems we always assume that g is 1-strongly convex w.r.t $\|\cdot\|_2$, $\|X_i\|_2^2 \leq R$ for all i, $M_\ell = |Q_\ell|$ is fixed on each machine, and our local procedure optimizes $\tilde{D}_{Q_\ell}^{(t)}$ sufficiently well on each machine such that $\tilde{D}_{Q_\ell}^{(t)}(\Delta\alpha_{Q_\ell}) \geq \tilde{D}_{Q_\ell}^{(t)}(\Delta\tilde{\alpha}_{Q_\ell})$, where $\Delta\tilde{\alpha}_{Q_\ell}$ is given by a special choice in each theorem.

Theorem 6 *Assume that each ϕ_i is $(1/\gamma)$-smooth w.r.t $\|\cdot\|_2$ and $\Delta\tilde{\alpha}_{Q_\ell}$ is given by*

$$\Delta\tilde{\alpha}_i := s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)}), \quad \text{for all } i \in Q_\ell,$$

where $u_i^{(t-1)} := -\nabla\phi_i(X_i^\top w_\ell^{(t-1)})$ and $s_\ell := \frac{\gamma\lambda n_\ell}{\gamma\lambda n_\ell + M_\ell R} \in [0, 1]$. To reach an expected duality gap of $\mathbb{E}[P(w^{(T)}) - D(\alpha^{(T)}, \beta^{(T)})] \leq \epsilon$, every T satisfying the following condition is sufficient,

$$T \geq \left(\frac{R}{\gamma\lambda} + \max_\ell \frac{n_\ell}{M_\ell}\right) \log\left(\left(\frac{R}{\gamma\lambda} + \max_\ell \frac{n_\ell}{M_\ell}\right) \cdot \frac{\epsilon_D^{(0)}}{\epsilon}\right). \tag{16}$$

Theorem 7 *Assume that each ϕ_i is L-Lipschitz w.r.t $\|\cdot\|_2$, and $\Delta\tilde{\alpha}_{Q_\ell}$ is given by*

$$\Delta\tilde{\alpha}_i := \frac{q n_\ell}{M_\ell}(u_i^{(t-1)} - \alpha_i^{(t-1)}), \quad \text{for all } i \in Q_\ell,$$

where $-u_i^{(t-1)} := \nabla\phi_i(X_i^\top w_\ell^{(t-1)})$ and $q \in [0, \min_\ell(M_\ell/n_\ell)]$. To reach an expected normalized duality gap of $\mathbb{E}\left[\frac{P(\overline{w}) - D(\overline{\alpha}, \overline{\beta})}{n}\right] \leq \epsilon$, every T satisfying the following condition is sufficient,

$$T \geq T_0 + \tilde{n} + \frac{G}{\lambda\epsilon} \geq \max\left\{0, \lceil \tilde{n} \log(2\lambda\tilde{n}\frac{\epsilon_D^{(0)}}{nG})\rceil\right\} + \tilde{n} + \frac{5G}{\lambda\epsilon}, \tag{17}$$

where $T_0 \geq \max\{t_0, \frac{4G}{\lambda\epsilon} - 2\tilde{n} + t_0\}$, $t_0 = \max\{0, \lceil \tilde{n} \log(2\lambda\tilde{n}\frac{\epsilon_D^{(0)}}{nG})\rceil\}$, $\tilde{n} = \max_\ell(n_\ell/M_\ell)$, $G = 4RL^2$, and $\overline{w}, \overline{\alpha}, \overline{\beta}$ represent either the average vector or a randomly chosen vector of $w^{(t-1)}, \alpha^{(t-1)}, \beta^{(t-1)}$ over $t \in \{T_0+1, ..., T\}$ respectively, such as $\overline{\alpha} = \frac{1}{T-T_0}\sum_{t=T_0+1}^T \alpha^{(t-1)}$, $\overline{\beta} = \frac{1}{T-T_0}\sum_{t=T_0+1}^T \beta^{(t-1)}$, $\overline{w} = \frac{1}{T-T_0}\sum_{t=T_0+1}^T w^{(t-1)}$.

Remark 8 *Both Theorem 6 and Theorem 7 incorporate two key components: the term $\max_\ell \frac{n_\ell}{M_\ell}$ and the condition number term $\frac{1}{\lambda\gamma}$ or $\frac{L^2}{\lambda}$. When the term $\max_\ell \frac{n_\ell}{M_\ell}$ dominates the iteration complexity, we can speed up convergence and reduce the number of communications by increasing the number of machines m or the local mini-batch size M_ℓ. However, in some circumstances when the condition number is large, it will become the leading factor, and increasing m or M_ℓ will not contribute to the computation speedup. To tackle this problem, we develop the accelerated version of DADM in Section 8.*

Remark 9 *Our method is closely related to previous distributed extensions of SDCA. Theorems 6, 7 that provide theoretical guarantees for more general local updates achieve the same iteration complexity with the ones in DisDCA that only allows some special choices of local mini-batch updates. Compared with theoretical results of CoCoA$^+$ that are based on the Θ-approximate solution of the local dual subproblem, although the derived bounds are within the same scale, $\tilde{\mathcal{O}}(1/\epsilon)$ for Lipschitz losses and $\tilde{\mathcal{O}}(\log(1/\epsilon))$ for smooth losses, our bounds are different and complementary. The analysis of CoCoA$^+$ can provide better insights for more accurate solutions of the local sub-problems. While our analysis is based on the mini-batch setup, it can capture the contributions of the mini-batch size and the number of machines more explicitly.*

Remark 10 *Since the bounds are derived with a special choice of $\Delta\tilde{\alpha}_{Q_\ell}$, the actual performance of the algorithm can be significantly better than what is indicated by the bounds when the local duals are better optimized. For example, we can choose ProxSDCA in (Shalev-Shwartz and Zhang, 2014) as the local procedure and adopt the sequential update strategy as the local solver of CoCoA$^+$ does. This is also the one used in our experiments.*

Algorithm 3 Accelerated Distributed Alternating Dual Maximization (Acc-DADM).

Parameters κ, $\eta = \sqrt{\lambda/(\lambda+2\kappa)}$, $\nu = (1-\eta)/(1+\eta)$.
Initialize $v^{(0)} = y^{(0)} = w^{(0)} = 0$, $\alpha^{(0)} = 0$, $\xi_0 = (1+\eta^{-2})(P(0) - D(0,0))$.
for $t = 1, 2, \ldots, T_{\text{outer}}$ **do**

1. **Construct new objective**:
$$P_t(w) = \sum_{i=1}^{n} \phi_i(X_i^\top w) + \lambda n g(w) + h(w) + \frac{\kappa n}{2}\left\|w - y^{(t-1)}\right\|_2^2.$$

2. **Call DADM solver**:
$$(w^{(t)}, \alpha^{(t)}, \beta^{(t)}, v^{(t)}, \epsilon_t) = \text{DADM}(P_t, (\eta\xi_{t-1})/(2+2\eta^{-2}), w^{(t-1)}, \alpha^{(t-1)}, \beta^{(t-1)}, v^{(t-1)}).$$

3. **Update**:
$$y^{(t)} = w^{(t)} + \nu(w^{(t)} - w^{(t-1)}).$$

4. **Update**:
$$\xi_t = (1 - \eta/2)\xi_{t-1}.$$

end for
Return $w^{(T_{\text{outer}})}$.

8. Acceleration

Theorems 6, 7 all imply that when the condition number $\frac{1}{\gamma\lambda}$ or $\frac{L^2}{\lambda}$ is relatively small, DADM converges fast. However, the convergence may be slow when the condition number is large and dominates the iteration complexity. In fact, we observe empirically that the basic DADM method converges slowly when the regularization parameter λ is small. This phenomenon is also consistent with that of SDCA for the single-machine case. In this section, we introduce the Accelerated Distributed Alternating Dual Maximization (Acc-DADM) method that can alleviate the problem.

The procedure is motivated by (Shalev-Shwartz and Zhang, 2014), which employs an inner-outer iteration: at every iteration t, we solve a slightly modified objective, which adds a regularization term centered around the vector

$$y^{(t-1)} = w^{(t-1)} + \nu\left(w^{(t-1)} - w^{(t-2)}\right), \tag{18}$$

where $\nu \in [0, 1]$ is called the momentum parameter.

The accelerated DADM procedure (described in Algorithm 3) can be similarly viewed as an inner-outer algorithm, where DADM serves as the inner iteration. In the outer iteration, we adjust the regularization vector $y^{(t-1)}$. That is, at each outer iteration t, we define a modified local primal objective on each machine ℓ, which has the same form as the original local primal objective (9), except that $\tilde{g}_\ell(w_\ell)$ is modified to $\tilde{g}_{\ell_t}(w_\ell)$ that is defined by

$$\begin{aligned}\lambda n_\ell \tilde{g}_{\ell_t}(w_\ell) =& \lambda n_\ell g_t(w_\ell) + \beta_\ell^\top w_\ell,\\ \lambda g_t(w_\ell) =& \lambda g(w_\ell) + \frac{\kappa}{2}\|w_\ell - y^{(t-1)}\|_2^2.\end{aligned}$$

It follows that we will need to solve a modified dual at each local step with $g^*(\cdot)$ replaced by $g_t^*(\cdot)$ in the local dual problem (12). Therefore, compared to the basic DADM procedure, nothing changes other than $g^*(\cdot)$ being replaced by $g_t^*(\cdot)$ at each iteration. Specifically, when the number of machines m equals 1, this algorithm reduces to AccProxSDCA described in (Shalev-Shwartz and Zhang, 2014). Thus Acc-DADM can be naturally regarded as the distributed generalization of the single-machine AccProxSDCA. Moreover, Acc-DADM also allows arbitrary local procedures as DADM does.

Our empirical studies show that Acc-DADM significantly outperforms DADM in many cases. There are probably two reasons. One reason is the use of a modified regularizer $g_t(w)$ that is more strongly convex than the original regularizer $g(w)$ when κ is much larger than λ. The other reason is closely related to the distributed setting considered in this paper. Observe that in the modified local primal objective

$$\tilde{P}_{\ell_t}(w_\ell|\beta_\ell) := \tilde{P}_\ell(w_\ell|\beta_\ell) + \frac{\kappa n_\ell}{2}\|w_\ell - y^{(t-1)}\|_2^2,$$

the first term corresponds to the original local primal objective and the second term is an extra regularization due to acceleration that constrains w_ℓ to be close to $y^{(t-1)}$. The effect is that different local problems become more similar to each other, which stabilize the overall system.

8.1 Theoretical Results of Acc-DADM for Smooth Losses

The following theorem establishes the computation efficiency guarantees for Acc-DADM.

Theorem 11 *Assume that each ϕ_i is $(1/\gamma)$-smooth, and g is 1-strongly convex w.r.t $\|\cdot\|_2$, $\|X_i\|_2^2 \le R$ for all i, $M_\ell = |Q_\ell|$ is fixed on each machine. To obtain expected ϵ primal sub-optimality:*

$$\mathbb{E}[P(w^{(t)})] - P(w^*) \le \epsilon,$$

it is sufficient to have the following number of stages in Algorithm 3

$$T_{\text{outer}} \ge 1 + \frac{2}{\eta}\log\left(\frac{\xi_0}{\epsilon}\right) = 1 + \sqrt{\frac{4(\lambda+2\kappa)}{\lambda}}\left(\log\left(\frac{2\lambda+2\kappa}{\lambda}\right) + \log\left(\frac{P(0)-D(0,0)}{\epsilon}\right)\right),$$

and the number of inner iterations in DADM at each stage:

$$T_{\text{inner}} \ge \left(\frac{R}{\gamma(\lambda+\kappa)} + \max_\ell \frac{n_\ell}{M_\ell}\right)\left(\log\left(\frac{R}{\gamma(\lambda+\kappa)} + \max_\ell \frac{n_\ell}{M_\ell}\right) + 7 + \frac{5}{2}\log\left(\frac{\lambda+2\kappa}{\lambda}\right)\right).$$

In particular, suppose we assume $n_1 = n_2 = \ldots = n_m$, and $M_1 = M_2 = \ldots = M_m = b$, then the total vector computations for each machine are bounded by

$$\tilde{\mathcal{O}}(T_{\text{outer}} T_{\text{inner}} b) = \tilde{\mathcal{O}}\left(\left(1 + \sqrt{\frac{\kappa+\lambda}{\lambda}}\right)\left(\frac{R}{\gamma(\lambda+\kappa)} + \frac{n}{mb}\right)b\right).$$

Remark 12 *When $\kappa = 0$, then the guarantees reduce to DADM. However, DADM only enjoys linear speedup over ProxSDCA when the number of machines satisfies $m \le (n\gamma\lambda)/R$,*

and being able to obtain sub-linear speedup when $\frac{R}{\lambda\gamma} = \mathcal{O}(n)$*. Besides enjoying the properties described above as DADM, if we choose* κ *in Algorithm 3 as* $\kappa = \frac{mR}{\gamma n} - \lambda$*, and* $b = 1$*, then the total vector computations for each machine are bounded by*

$$\tilde{\mathcal{O}}\left(\sqrt{\frac{Rm}{\gamma n\lambda}}\left(\frac{n}{m}\right)\right) = \tilde{\mathcal{O}}\left(\sqrt{\frac{Rn}{\gamma\lambda m}}\right),$$

which means Acc-DADM can be much faster than DADM when the condition number is large and always obtain a reduction of computations over the single-machine AccProxSDCA by a factor of $\tilde{\mathcal{O}}(\sqrt{1/m})$*.*

8.2 Acceleration for Non-smooth, Lipschitz Losses

Theorem 11 establishes the rate of convergence for smooth loss functions, but the acceleration framework can also be used on non-smooth, Lipschitz loss functions. The main idea is to use the Nesterov's smoothing technique (Nesterov, 2005) to construct a smooth approximation of the non-smooth function $\phi_i(\cdot)$, by adding a strongly-convex regularization term on the conjugate of $\phi_i(\cdot)$:

$$\tilde{\phi}_i^*(-\alpha_i) := \phi_i^*(-\alpha_i) + \frac{\gamma}{2}\|\alpha_i\|_2^2,$$

by the property of conjugate functions (e.g. Lemma 2 in (Shalev-Shwartz and Zhang, 2014)), we know $\tilde{\phi}_i(\cdot)$, as the conjugate function of $\tilde{\phi}_i^*(\cdot)$ is $(1/\gamma)$-smooth, and

$$0 \le \tilde{\phi}_i(u_i) - \phi_i(u_i) \le \frac{\gamma L^2}{2}.$$

Then instead of the original function with non-smooth losses, we minimize the smoothed objective:

$$\min_{w\in\mathbb{R}^d}\left[\hat{P}(w) := \sum_{i=1}^n \tilde{\phi}_i(X_i^\top w) + \lambda n g(w) + h(w)\right]. \tag{19}$$

The following corollary establishes the computation efficiency guarantees for Acc-DADM on non-smooth, Lipschitz loss functions.

Corollary 13 *Assume that each* ϕ_i *is L-Lipschitz, and* g *is 1-strongly convex w.r.t* $\|\cdot\|_2$*,* $\|X_i\|_2^2 \le R$ *for all* i*,* $M_\ell = |Q_\ell|$ *is fixed on each machine. To obtain expected* ϵ *normalized primal sub-optimality:*

$$\mathbb{E}\left[\frac{P(w^{(t)})}{n}\right] - \frac{P(w^*)}{n} \le \epsilon,$$

it is sufficient to run Algorithm 3 on the smoothed objective (19)*, with*

$$\gamma = \frac{\epsilon}{L^2},$$

and the following number of stages,

$$T_{\text{outer}} \ge 1 + \frac{2}{\eta}\log\left(\frac{2\xi_0}{\epsilon}\right) = 1 + \sqrt{\frac{4(\lambda+2\kappa)}{\lambda}}\left(\log\left(\frac{2\lambda+2\kappa}{\lambda}\right) + \log\left(\frac{2(P(0)-D(0,0))}{\epsilon}\right)\right),$$

and the number of inner iterations in DADM at each stage:

$$T_{\text{inner}} \ge \left(\frac{L^2R}{\epsilon(\lambda+\kappa)} + \max_\ell \frac{n_\ell}{M_\ell}\right)\left(\log\left(\frac{L^2R}{\epsilon(\lambda+\kappa)} + \max_\ell \frac{n_\ell}{M_\ell}\right) + 7 + \frac{5}{2}\log\left(\frac{\lambda+2\kappa}{\lambda}\right)\right).$$

In particular, suppose we assume $n_1 = n_2 = \ldots = n_m$*, and* $M_1 = M_2 = \ldots = M_m = b$*, then the total vector computations for each machine are bounded by*

$$\tilde{\mathcal{O}}(T_{\text{outer}}T_{\text{inner}}b) = \tilde{\mathcal{O}}\left(\left(1 + \sqrt{\frac{\kappa+\lambda}{\lambda}}\right)\left(\frac{L^2R}{\epsilon(\lambda+\kappa)} + \frac{n}{mb}\right)b\right).$$

Remark 14 *When* $\kappa = 0$*, then the guarantees reduce to DADM for Lipschitz losses. Moreover, when* $L^2Rm \ge n\epsilon\lambda$*, if we choose* κ *in Algorithm 3 as* $\kappa = \frac{mL^2R}{n\epsilon} - \lambda$*, and* $b = 1$*, then the total vector computations for each machine are bounded by*

$$\tilde{\mathcal{O}}\left(\sqrt{\frac{L^2Rm}{n\epsilon\lambda}}\left(\frac{n}{m}\right)\right) = \tilde{\mathcal{O}}\left(L\sqrt{\frac{Rn}{\epsilon\lambda m}}\right),$$

which means Acc-DADM can be much faster than DADM when ϵ *is small and always obtain a reduction of computations over the single-machine AccProxSDCA by a factor of* $\tilde{\mathcal{O}}(\sqrt{1/m})$*.*

9. Proofs

In this section, we first present proofs about several previous propositions to establish our framework solidly. Then based on our new distributed dual formulation, we directly generalize the analysis of SDCA and adapt it to DADM in the commonly used mini-batch setup. Finally, we describe the proof for the theoretical guarantees of Acc-DADM.

9.1 Proof of Proposition 1

Proof Given any set of parameters $(w; \{w_\ell\}; \{u_i\}; \{\alpha_i\}; \{\beta_\ell\})$, we have

$$\begin{aligned}&\min_{w;\{w_\ell\};\{u_i\}} J(w; \{w_\ell\}; \{u_i\}; \{\alpha_i\}; \{\beta_\ell\}) \\ &= \underbrace{\min_{w;\{w_\ell\}} \sum_{\ell=1}^m \left[\sum_{i\in S_\ell} \min_{u_i}\left(\phi_i(u_i) + \alpha_i^\top(u_i - X_i^\top w_\ell)\right) + \lambda n_\ell g(w_\ell) + \beta_\ell^\top(w_\ell - w)\right]}_{A} + h(w),\end{aligned}$$

where the minimum is achieved at $\{u_i\}$ such that $\nabla\phi_i(u_i)+\alpha_i=0$. By eliminating u_i we obtain

$$\begin{aligned}A=&\min_{w;\{w_\ell\}}\sum_{\ell=1}^m\left[\sum_{i\in S_\ell}\left(-\phi_i^*(-\alpha_i)-\alpha_i^\top X_i^\top w_\ell\right)+\lambda n_\ell g(w_\ell)+\beta_\ell^\top(w_\ell-w)\right]+h(w)\\ =&\underbrace{\min_w\sum_{\ell=1}^m\min_{w_\ell}\left[\sum_{i\in S_\ell}-\phi_i^*(-\alpha_i)-\left(\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell\right)^\top w_\ell+\lambda n_\ell g(w_\ell)-\beta_\ell^\top w\right]+h(w)}_{B},\end{aligned}$$

where minimum is achieved at $\{w_\ell\}$ such that $-\left(\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell\right)+\lambda n_\ell\nabla g(w_\ell)=0$. By eliminating w_ℓ we obtain

$$\begin{aligned}B=&\min_w\sum_{\ell=1}^m\left[\sum_{i\in S_\ell}-\phi_i^*(-\alpha_i)-\lambda n_\ell g^*\left(\frac{\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell}{\lambda n_\ell}\right)-\beta_\ell^\top w\right]+h(w)\\ =&\underbrace{\sum_{\ell=1}^m\left[\sum_{i\in S_\ell}-\phi_i^*(-\alpha_i)-\lambda n_\ell g^*\left(\frac{\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell}{\lambda n_\ell}\right)\right]-h^*\left(\sum_\ell\beta_\ell\right)}_{D(\alpha,\beta)},\end{aligned}$$

where the minimizer is achieved at w such that $-\sum_\ell\beta_\ell+\nabla h(w)=0$. This completes the proof. ■

9.2 Proof of Proposition 2

Proof Given any w, if we take $u_i=X_i^\top w_\ell$ and $w_\ell=w$ for all i and ℓ, then $P(w)=J(w;\{w_\ell\};\{u_i\};\{\alpha_i\};\{\beta_\ell\})$ for arbitrary $(\{\alpha_i\};\{\beta_\ell\})$. It follows from Proposition 1 that

$$P(w)=J(w;\{w_\ell\};\{u_i\};\{\alpha_i\};\{\beta_\ell\})\geq D(\alpha,\beta).$$

w^* is the minimizer of $P(w)$. When $w=w^*$, we may set $u_i=u_i^*=X_i^\top w^*$ and $w_\ell=w_\ell^*=w^*$. From the first order optimality condition, we can obtain

$$\sum_i X_i\nabla\phi_i(u_i^*)+\sum_\ell\lambda n_\ell\nabla g(w_\ell^*)+\nabla h(w^*)=0.$$

If we take $\alpha_i^*=-\nabla\phi_i(u_i^*)$ and $\beta_\ell^*=\sum_{i\in S_\ell}X_i\alpha_i^*-\lambda n_\ell\nabla g(w_\ell^*)$ for some subgradients, then it is not difficult to check that all equations in (6) are satisfied. It follows that we can achieve equality in Proposition 1 as

$$P(w^*)=J(w^*;\{w_\ell^*\};\{u_i^*\};\{\alpha_i^*\};\{\beta_\ell^*\})=D(\alpha^*,\beta^*).$$

This means that zero duality gap can be achieved with w^*. It is easy to verify that (α^*,β^*) maximizes $D(\alpha,\beta)$, since for any (α,β), we have

$$\begin{aligned}D(\alpha,\beta)&\leq J(w^*;\{w_\ell^*\};\{u_i^*\};\{\alpha_i\};\{\beta_\ell\})\\&=P(w^*)\\&=D(\alpha^*,\beta^*).\end{aligned}$$

■

9.3 Proof of Proposition 3

Proof We have the decompositions

$$D(\alpha,\beta)=\sum_{\ell=1}^m\tilde{D}_\ell(\alpha_{(\ell)}|\beta_\ell)-h^*\left(\sum_\ell\beta_\ell\right),$$

and

$$P(w)=\sum_{\ell=1}^m\tilde{P}_\ell(w_\ell|\beta_\ell)-\left(\sum_\ell\beta_\ell\right)^\top w+h(w).$$

It follows that the duality gap

$$P(w)-D(\alpha,\beta)=\sum_{\ell=1}^m[\tilde{P}_\ell(w_\ell|\beta_\ell)-\tilde{D}_\ell(\alpha_{(\ell)}|\beta_\ell)]+h^*\left(\sum_\ell\beta_\ell\right)+h(w)-\left(\sum_\ell\beta_\ell\right)^\top w.$$

Note that the definition of convex conjugate function implies that

$$h^*\left(\sum_\ell\beta_\ell\right)+h(w)-\left(\sum_\ell\beta_\ell\right)^\top w\geq 0,$$

and the equality holds when $\nabla h(w)=\sum_\ell\beta_\ell$. This implies the desired result. ■

9.4 Proof of Proposition 4

Proof It is easy to check by using the duality that for any b and w:

$$\begin{aligned}&-\lambda n g^*\left(v-\frac{b}{\lambda n}\right)-h^*(b)\\ \leq&\left[-\lambda n w^\top\left(v-\frac{b}{\lambda n}\right)+\lambda n g(w)\right]+\left[-b^\top w+h(w)\right]\\ =&-\lambda n w^\top v+\lambda n g(w)+h(w),\end{aligned}$$

and the equality holds if $b=\nabla h(w)$ and $v-\frac{b}{\lambda n}=\nabla g(w)$ for some subgradients. Based on the assumptions, the equality can be achieved at $b=\bar{\beta}(v)=\nabla h(w(v))$ and $w=w(v)$. This proves the desired result by noticing that $v-\frac{b}{\lambda n}=\nabla g(w)$ implies that $w=\nabla g^*(v-b/(\lambda n))$. ■

9.5 Proof of Proposition 5

Proof Since α is fixed, we know that the problem $\max_\beta D(\alpha,\beta)$ is equivalent to

$$\max_\beta \left[\sum_{\ell=1}^m -\lambda n_\ell g^*\left(v_\ell(\alpha_{(\ell)}) - \frac{\beta_\ell}{\lambda n_\ell}\right) - h^*\left(\sum_\ell \beta_\ell\right)\right].$$

Now by using Jensen's inequality, we obtain for any (β'_ℓ):

$$\begin{aligned}
&\sum_{\ell=1}^m -\lambda n_\ell g^*\left(v_\ell(\alpha_{(\ell)}) - \frac{\beta'_\ell}{\lambda n_\ell}\right) - h^*\left(\sum_\ell \beta'_\ell\right)\\
\leq& -\lambda n g^*\left(\sum_{\ell=1}^m \frac{n_\ell}{n}\frac{\sum_{i\in S_\ell} X_i\alpha_i - \beta'_\ell}{\lambda n_\ell}\right) - h^*\left(\sum_\ell \beta'_\ell\right)\\
=& -\lambda n g^*\left(v(\alpha) - \frac{\sum_\ell \beta'_\ell}{\lambda n}\right) - h^*\left(\sum_\ell \beta'_\ell\right)\\
\leq& -\lambda n g^*\left(v(\alpha) - \frac{\bar\beta(v(\alpha))}{\lambda n}\right) - h^*\left(\bar\beta(v(\alpha))\right).
\end{aligned} \tag{20}$$

In the above derivation, the last inequality has used Proposition 4. Here the equalities can be achieved when

$$v_\ell(\alpha_{(\ell)}) - \frac{\beta'_\ell}{\lambda n_\ell} = v(\alpha) - \frac{\bar\beta(v(\alpha))}{\lambda n}$$

for all ℓ, which can be obtained with the choice of $\{\beta'_\ell\} = \{\beta_\ell\}$ given in the statement of the proposition. ■

9.6 Proof of Theorem 6

The following result is the mini-batch version of a related result in the analysis of ProxSDCA, which we apply to any local machine ℓ. The proof is included for completeness.

Lemma 15 *Assume that ϕ_i^* is γ-strongly convex w.r.t $\|\cdot\|_2$ (where γ can be zero) and g^* is 1-smooth w.r.t $\|\cdot\|_2$. Every local step, we randomly pick a mini-batch $Q_\ell \subset S_\ell$, whose size is $M_\ell := |Q_\ell|$, and optimize w.r.t dual variables $\alpha_i, i \in Q_\ell$. Then, using the simplified notation*

$$P_\ell(w_\ell^{(t-1)}) = \tilde P_\ell(w_\ell^{(t-1)}|\beta_\ell^{(t-1)}), \qquad D_\ell(\alpha_{(\ell)}^{(t-1)}) = \tilde D_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)}),$$

we have

$$\mathbb{E}\left[D_\ell(\alpha_{(\ell)}^{(t)}) - D_\ell(\alpha_{(\ell)}^{(t-1)})\right] \geq \frac{s_\ell M_\ell}{n_\ell}\mathbb{E}\left[P_\ell(w_\ell^{(t-1)}) - D_\ell(\alpha_{(\ell)}^{(t-1)})\right] - \frac{s_\ell^2 M_\ell^2}{2\lambda n_\ell^2} G_\ell^{(t)}$$

where

$$\begin{aligned}
G_\ell^{(t)} &:= \sum_{i\in S_\ell}\left[\|X_i\|_2^2 - \frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}\right]\mathbb{E}\left[\|u_i^{(t-1)} - \alpha_i^{(t-1)}\|_2^2\right]\\
\Delta\tilde\alpha_i &:= \alpha_i^{(t)} - \alpha_i^{(t-1)} = s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)}), \quad \textit{for all } i \in Q_\ell,
\end{aligned}$$

and $-u_i^{(t-1)} = \nabla\phi_i(X_i^\top w_\ell^{(t-1)})$, $s_\ell \in [0,1]$.

Proof Since only the elements in Q_ℓ are updated, the improvement in the dual objective can be written as

$$\begin{aligned}
&D_\ell(\alpha_{(\ell)}^{(t)}) - D_\ell(\alpha_{(\ell)}^{(t-1)})\\
=&\left(\sum_{i\in Q_\ell} -\phi_i^*(-\alpha_i^{(t)}) - \lambda n_\ell g^*\left(v_\ell^{(t-1)} + (\lambda n_\ell)^{-1}\sum_{i\in Q_\ell} X_i\Delta\tilde\alpha_i\right)\right)\\
&-\left(\sum_{i\in Q_\ell} -\phi_i^*(-\alpha_i^{(t-1)}) - \lambda n_\ell g^*\left(v_\ell^{(t-1)}\right)\right)\\
\geq&\underbrace{\left(\sum_{i\in Q_\ell} -\phi_i^*(-\alpha_i^{(t-1)} - \Delta\tilde\alpha_i) - \nabla g^*(v_\ell^{(t-1)})^\top\left(\sum_{i\in Q_\ell} X_i\Delta\tilde\alpha_i\right) - \frac{1}{2\lambda n_\ell}\|\sum_{i\in Q_\ell} X_i\Delta\tilde\alpha_i\|_2^2\right)}_{A}\\
&-\underbrace{\left(\sum_{i\in Q_\ell} -\phi_i^*(-\alpha_i^{(t-1)})\right)}_{B},
\end{aligned}$$

where we have used the fact the g^* is 1-smooth in the derivation of the inequality.

By the definition of the update in the algorithm, and the definition of $\Delta\tilde\alpha_i = s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)}), s_\ell \in [0,1]$, we have

$$\begin{aligned}
A \geq& \sum_{i\in Q_\ell} -\phi_i^*(-(\alpha_i^{(t-1)} + s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)}))\\
&-\nabla g^*(v^{(t-1)})^\top\left(\sum_{i\in Q_\ell} X_i s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)})\right)\\
&-\frac{1}{2\lambda n_\ell}\|\sum_{i\in Q_\ell} X_i s_\ell(u_i^{(t-1)} - \alpha_i^{(t-1)})\|_2^2
\end{aligned} \tag{21}$$

From now on, we omit the superscript $(t-1)$. Since ϕ_i^* is γ-strongly convex w.r.t $\|\cdot\|_2$, we have

$$\begin{aligned}
\phi_i^*(-(\alpha_i + s_\ell(u_i - \alpha_i))) &= \phi^*(s_\ell(-u_i) + (1-s_\ell)(-\alpha_i))\\
&\leq s_\ell\phi^*(-u_i) + (1-s_\ell)\phi_i^*(-\alpha_i) - \frac{\gamma}{2}s_\ell(1-s_\ell)\|u_i - \alpha_i\|_2^2
\end{aligned} \tag{22}$$

Bringing Eq. (22) into Eq. (21), we get

$$\begin{aligned}
A \geq & \sum_{i\in Q_\ell}\left(-s_\ell\phi_i^*(-u_i)-(1-s_\ell)\phi_i^*(-\alpha_i)+\frac{\gamma}{2}s_\ell(1-s_\ell)\|u_i-\alpha_i\|_2^2\right)\\
& -w_\ell^\top\left(\sum_{i\in Q_\ell}s_\ell X_i(u_i-\alpha_i)\right)-\frac{1}{2\lambda n_\ell}\|\sum_{i\in Q_\ell}s_\ell X_i(u_i-\alpha_i)\|_2^2\\
\geq & \underbrace{\left(\sum_{i\in Q_\ell}-\phi_i^*(-\alpha_i)\right)}_{B}+\sum_{i\in Q_\ell}\left(s_\ell\left(w_\ell^\top X_i(-u_i)-\phi_i^*(-u_i)\right)+s_\ell\phi_i^*(-\alpha_i)+s_\ell w_\ell^\top X_i\alpha_i\right)\\
& +\sum_{i\in Q_\ell}\frac{\gamma}{2}s_\ell(1-s_\ell)\|u_i-\alpha_i\|_2^2-\sum_{i\in Q_\ell}\frac{M_\ell\|X_i(u_i-\alpha_i)\|_2^2}{2\lambda n_\ell}s_\ell^2,
\end{aligned}$$

where we get the second inequality according to the fact that $\|\sum_{i\in Q_\ell}a_i\|_2^2\leq\sum_{i\in Q_\ell}M_\ell\|a_i\|_2^2$.

Since we choose $-u_i=\nabla\phi_i(X_i^\top w_\ell)$, for some subgradients $\nabla\phi_i(X_i^\top w_\ell)$, which yields $w_\ell^\top X_i(-u_i)-\phi_i^*(-u_i)=\phi_i(X_i^\top w_\ell)$, then we obtain

$$\begin{aligned}
A-B\geq & \sum_{i\in Q_\ell}s_\ell\left[\phi_i(X_i^\top w_\ell)+\phi_i^*(-\alpha_i)+w_\ell^\top X_i\alpha_i\right]\\
& +\sum_{i\in Q_\ell}s_\ell\|u_i-\alpha_i\|_2^2\left[\frac{\gamma(1-s_\ell)}{2}-\frac{s_\ell M_\ell\|X_i\|_2^2}{2\lambda n_\ell}\right].\\
= & \sum_{i\in Q_\ell}s_\ell\left[\phi_i(X_i^\top w_\ell)+\phi_i^*(-\alpha_i)+w_\ell^\top X_i\alpha_i\right]\\
& +\frac{M_\ell}{2\lambda n_\ell}\sum_{i\in Q_\ell}s_\ell^2\|u_i-\alpha_i\|_2^2\left[\frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}-\|X_i\|_2^2\right].
\end{aligned}\tag{23}$$

Recall that with $w_\ell=\nabla g^*(\tilde{v}_\ell)$, we have $g(w)+g^*(\tilde{v})=w^\top\tilde{v}$. Then we derive the local duality gap as

$$\begin{aligned}
& P_\ell(w_\ell)-D_\ell(\alpha_{(\ell)})\\
= & \sum_{i\in S_\ell}\phi_i(X_i^\top w_\ell)+\lambda n_\ell g(w_\ell)+\beta_\ell^\top w_\ell-\left(\sum_{i\in S_\ell}-\phi_i^*(-\alpha_i)-\lambda n_\ell g^*\left(\frac{\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell}{\lambda n_\ell}\right)\right)\\
= & \sum_{i\in S_\ell}\left(\phi_i(X_i^\top w_\ell)+\phi_i^*(-\alpha_i)+w_\ell^\top X_i\alpha_i\right)
\end{aligned}$$

Then, taking the expectation of Eq. (23) w.r.t the random choice of mini-batch set Q_ℓ at round t, we obtain

$$\begin{aligned}
E_t[A_\ell-B_\ell]\geq & \frac{M_\ell}{n_\ell}\sum_{i\in S_\ell}s_\ell\left[\phi_i(X_i^\top w_\ell)+\phi_i^*(-\alpha_i)+w_\ell^\top X_i\alpha_i\right]\\
& +\frac{M_\ell^2}{2\lambda n_\ell^2}\sum_{i\in S_\ell}s_\ell^2\|u_i-\alpha_i\|_2^2\left[\frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}-\|X_i\|_2^2\right]\\
= & \frac{s_\ell M_\ell}{n_\ell}\sum_{i\in S_\ell}\left[\phi_i(X_i^\top w_\ell)+\phi_i^*(-\alpha_i)+w_\ell^\top X_i\alpha_i\right]\\
& -\frac{M_\ell^2}{2\lambda n_\ell^2}\sum_{i\in S_\ell}s_\ell^2\|u_i-\alpha_i\|_2^2\left[\|X_i\|_2^2-\frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}\right].
\end{aligned}$$

Take expectation of both sides w.r.t the randomness in previous iterations, we have

$$\mathbb{E}[A_\ell-B_\ell]\geq\frac{s_\ell M_\ell}{n_\ell}\mathbb{E}\left[P_\ell(w_\ell)-D_\ell(\alpha_{(\ell)})\right]-\frac{s_\ell^2M_\ell^2}{2\lambda n_\ell^2}G_\ell^{(t)},$$

where

$$G_\ell^{(t)}:=\sum_{i\in S_\ell}\left[\|X_i\|_2^2-\frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}\right]\mathbb{E}\left[\|u_i-\alpha_i\|_2^2\right].$$

■

Proof of Theorem 6.

Proof We will apply Lemma 15 with

$$s_\ell=\frac{1}{1+\frac{RM_\ell}{\gamma\lambda n_\ell}}=\frac{\gamma\lambda n_\ell}{\gamma\lambda n_\ell+M_\ell R}\in[0,1], i\in S_\ell.$$

Recall that $\|X_i\|_2^2\leq R$ for all $i\in S_\ell$, then we have

$$\|X_i\|_2^2-\frac{\gamma\lambda n_\ell(1-s_\ell)}{M_\ell s_\ell}\leq 0,\ \text{for all } i\in S_\ell,$$

which implies that $G_\ell^{(t)}\leq 0$ for all ℓ. It follows that for all ℓ after the local update step we have:

$$\begin{aligned}
& \mathbb{E}\left[\tilde{D}_\ell(\alpha_{(\ell)}^{(t)}|\beta_\ell^{(t-1)})-\tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\right]\\
\geq & \frac{s_\ell M_\ell}{n_\ell}\mathbb{E}\left[\tilde{P}_\ell(w_\ell^{(t-1)}|\beta_\ell^{(t-1)})-\tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\right].
\end{aligned}\tag{24}$$

Now we note that after the global step at iteration $t-1$, the choices of $w^{(t-1)}$ and $\beta^{(t-1)}$ in DADM is according to the choice of Proposition 4 and Proposition 5. It follows from

Proposition 5 that the following relationship between the global and local duality gap at the beginning of the t-th iteration is satisfied:

$$P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)}) = \sum_{\ell} \left[\tilde{P}_\ell(w_\ell^{(t-1)}|\beta_\ell^{(t-1)}) - \tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)}) \right].$$

Using this decomposition and summing over ℓ in (24), we obtain

$$\mathbb{E}\left[D(\alpha^{(t)}, \beta^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})\right] \geq q\mathbb{E}\left[P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})\right],$$

where

$$q = \min_\ell \frac{s_\ell M_\ell}{n_\ell} = \min_\ell \frac{\gamma\lambda M_\ell}{\gamma\lambda n_\ell + M_\ell R}.$$

Since $D(\alpha^{(t)}, \beta^{(t)}) \geq D(\alpha^{(t)}, \beta^{(t-1)})$, we obtain

$$\mathbb{E}\left[D(\alpha^{(t)}, \beta^{(t)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})\right] \geq q\mathbb{E}\left[P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})\right].$$

Let (α^*, β^*) be the optimal solution of the dual problem, we have defined the dual suboptimality as $\epsilon_D^{(t)} := D(\alpha^*, \beta^*) - D(\alpha^{(t)}, \beta^{(t)})$. Let $\epsilon_G^{(t-1)} = P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})$, and we know that $\epsilon_D^{(t-1)} \leq \epsilon_G^{(t-1)}$. It follows that

$$\mathbb{E}[\epsilon_D^{(t-1)}] \geq \mathbb{E}[\epsilon_D^{(t-1)} - \epsilon_D^{(t)}] \geq q\mathbb{E}[\epsilon_G^{(t-1)}] \geq q\mathbb{E}[\epsilon_D^{(t-1)}].$$

Therefore we have

$$q\mathbb{E}[\epsilon_G^{(t)}] \leq \mathbb{E}[\epsilon_D^{(t)}] \leq (1-q)\mathbb{E}[\epsilon_D^{(t-1)}] \leq (1-q)^t \epsilon_D^{(0)} \leq e^{-qt}\epsilon_D^{(0)}.$$

To obtain an expected duality gap of $E[\epsilon_G^{(T)}] \leq \epsilon$, every T, which satisfies

$$T \geq \frac{1}{q}\log\left(\frac{1}{q}\frac{\epsilon_D^{(0)}}{\epsilon}\right),$$

is sufficient. This proves the desired bound. ■

9.7 Proof of Theorem 7

Now, we consider L-Lipschitz loss functions and use the following basic lemma for L-Lipschitz losses taken from (Shalev-Shwartz and Zhang, 2013, 2014).

Lemma 16 *Let $\phi : \mathbb{R}^q \to \mathbb{R}$ be an L-Lipschitz function w.r.t $\|\cdot\|_2$, then we have $\phi^*(\alpha) = \infty$, for any $\alpha \in \mathbb{R}^q$ s.t. $\|\alpha\|_2 > L$.*

Proof of Theorem 7.
Proof Applying Lemma 15 with $\gamma = 0$, then we have

$$G_\ell^{(t)} = \sum_{i \in S_\ell} \|X_i\|_2^2 \ \mathbb{E}\left[\|u_i^{(t-1)} - \alpha_i^{(t-1)}\|_2^2\right].$$

According to Lemma 16, we know that $\|u_i^{(t-1)}\|_2 \leq L$ and $\|\alpha_i^{(t-1)}\|_2 \leq L$, thus we have

$$\|u_i^{(t-1)} - \alpha_i^{(t-1)}\|_2^2 \leq 2\left(\|u_i^{(t-1)}\|_2^2 + \|\alpha_i^{(t-1)}\|_2^2\right) \leq 4L^2.$$

Recall that $\|X_i\|_2^2 \leq R$, then we have $G_\ell^{(t)} \leq G_\ell$, where $G_\ell = 4n_\ell RL^2$. Combining this into Lemma 15, we have

$$\begin{aligned}
&\mathbb{E}\left[\tilde{D}_\ell(\alpha_{(\ell)}^{(t)}|\beta_\ell^{(t-1)}) - \tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\right] \\
\geq &\frac{s_\ell M_\ell}{n_\ell}\mathbb{E}\left[\tilde{P}_\ell(w_\ell^{(t-1)}|\beta_\ell^{(t-1)}) - \tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\right] - \frac{s_\ell^2 M_\ell^2}{2\lambda n_\ell^2}G_\ell. \qquad (25)
\end{aligned}$$

Now we also note that after the global step at iteration $t-1$, the choices of $w^{(t-1)}$ and $\beta^{(t-1)}$ in DADM is according to the choice of Proposition 4 and Proposition 5. It follows from Proposition 5 that the following relationship of global and local duality gap at the beginning of the t-th iteration is satisfied:

$$P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)}) = \sum_{\ell} \left[\tilde{P}_\ell(w_\ell^{(t-1)}|\beta_\ell^{(t-1)}) - \tilde{D}_\ell(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)}) \right].$$

Summing the inequality (25) over ℓ, combining with the above decomposition and bringing $D(\alpha^{(t)}, \beta^{(t)}) \geq D(\alpha^{(t)}, \beta^{(t-1)})$ into it, we get

$$\mathbb{E}[D(\alpha^{(t)}, \beta^{(t)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})] \geq q\mathbb{E}[P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)})] - \sum_{\ell=1}^{m} \frac{q^2}{2\lambda}G_\ell, \quad (26)$$

where $q \in [0, \min_\ell \frac{M_\ell}{n_\ell}]$, $q = \frac{s_\ell M_\ell}{n_\ell}$ and $s_\ell \in [0,1]$ is chosen so that all $\frac{s_\ell M_\ell}{n_\ell}(\ell = 1, ..., m)$ are equal.

Let (α^*, β^*) be the optimal solution for the dual problem $D(\alpha, \beta)$, and we have defined the dual suboptimality as $\epsilon_D^{(t)} := D(\alpha^*, \beta^*) - D(\alpha^{(t)}, \beta^{(t)})$. Note that the duality gap is an upper bound of the dual suboptimality, $P(w^{(t-1)}) - D(\alpha^{(t-1)}, \beta^{(t-1)}) \geq \epsilon_D^{(t-1)}$. Then (26) implies that

$$\mathbb{E}\left[\frac{\epsilon_D^{(t)}}{n}\right] \leq (1-q)\mathbb{E}\left[\frac{\epsilon_D^{(t-1)}}{n}\right] + q^2\frac{G}{2\lambda}, \text{ where } G = \frac{1}{n}\sum_{\ell=1}^{m} G_\ell = 4RL^2$$

Starting from this recursion, we can now apply the same analysis for L-Lipschitz loss functions of the single-machine SDCA in (Shalev-Shwartz and Zhang, 2013) to obtain the following desired inequality:

$$\mathbb{E}\left[\frac{\epsilon_D^{(t)}}{n}\right] \leq \frac{2G}{\lambda(2\tilde{n} + t - t_0)}, \qquad (27)$$

for all $t \geq t_0 = \max(0, \lceil \tilde{n}\log(\frac{2\lambda\epsilon_D^{(0)}\tilde{n}}{nG})\rceil)$, where $\tilde{n} = \max_\ell(n_\ell/M_\ell)$. Further applying the same strategies in (Shalev-Shwartz and Zhang, 2013) based on (27) proves the desired bound. ■

9.8 Proof of Theorem 11

Our proof strategy follows (Shalev-Shwartz and Zhang, 2014) and (Frostig et al., 2015), which both used acceleration techniques of (Nesterov, 2004) on top of approximate proximal point steps, the main differences compared with (Shalev-Shwartz and Zhang, 2014) and (Frostig et al., 2015) are here we warm start with two groups dual variables (α and β) where (Shalev-Shwartz and Zhang, 2014) warm start only with α as it consider the single machine setting, and (Frostig et al., 2015) warm start from primal variables w.

Proof The proof consists of the following steps:

- In Lemma 17 we show that one can construct a quadratic lower bound of the original objective $P(w)$ from an approximate minimizer of the proximal objective $P_t(w)$.
- Using the quadratic lower bound we construct an estimation sequence, based on which in Lemma 18 we prove the accelerated convergence rate for the outer loops.
- We show in Lemma 19 that by warm start the iterates from the last stage, the dual sub-optimality for the next stage is small.

Based on Lemma 19, we know the contraction factor between the initial dual sub-optimality and the target primal-dual gap at stage t can be upper bounded by

$$\begin{aligned}\frac{D_t(\alpha_{\text{opt}}^{(t)},\beta_{\text{opt}}^{(t)})-D_t(\alpha^{(t-1)},\beta^{(t-1)})}{(\eta\xi_{t-1})/(2+2\eta^{-2})}\leq&\frac{\epsilon_{t-1}}{(\eta\xi_{t-1})/(2+2\eta^{-2})}+\frac{36\kappa\xi_{t-3}}{\lambda(\eta\xi_{t-1})/(2+2\eta^{-2})}\\ \leq&\frac{1}{1-\eta/2}+\frac{36(2+2\eta^{-2})}{\eta(1-\eta/2)^2}\cdot\frac{\kappa}{\lambda}\\ \leq&2+\frac{36}{\eta^5(1-\eta^2)}\end{aligned}$$

where the last step we used the fact that $\eta^{-4}=(\eta^{-2}-1)(\eta^{-2}+1)+1>(\eta^{-2}-1)(\eta^{-2}+1)=\frac{2\kappa(\eta^{-2}+1)}{\lambda}$. Thus using the results from plain DADM (Theorem 6), we know the number of inner iterations in each stage is upper bounded by

$$\begin{aligned}&\chi\left(\log(\chi)+\log\left(\frac{D_t(\alpha_{\text{opt}}^{(t)},\beta_{\text{opt}}^{(t)})-D_t(\alpha^{(t-1)},\beta^{(t-1)})}{(\eta\xi_{t-1})/(2+2\eta^{-2})}\right)\right)\\ \leq&\chi\left(\log(\chi)+7+\frac{5}{2}\log\left(\frac{\lambda+2\kappa}{\lambda}\right)\right),\end{aligned}$$

where $\chi=\frac{R}{\gamma(\lambda+\kappa)}+\max_\ell\frac{n_\ell}{M_\ell}$. ■

9.9 Proof of Corollary 13

By the property of $\tilde{\phi}_i(u_i)$, for every w we have

$$0\leq\frac{\hat{P}(w)}{n}-\frac{P(w)}{n}\leq\frac{\gamma L^2}{2},$$

thus if we found a predictor $w^{(t)}$ that is $\frac{\epsilon}{2}$-suboptimal with respect to $\frac{\hat{P}(w)}{n}$:

$$\frac{\hat{P}(w^{(t)})}{n}-\min_w\frac{\hat{P}(w)}{n}\leq\frac{\epsilon}{2},$$

and we choose $\gamma=\epsilon/L^2$, we know it must be ϵ-suboptimal with respect to $\frac{P(w)}{n}$, because

$$\begin{aligned}\frac{P(w^{(t)})}{n}-\frac{P(w^*)}{n}\leq&\frac{\hat{P}(w^{(t)})}{n}-\frac{\hat{P}(w^*)}{n}+\frac{\gamma L^2}{2}\\ \leq&\frac{\hat{P}(w^{(t)})}{n}-\min_w\frac{\hat{P}(w)}{n}+\frac{\epsilon}{2}\leq\epsilon.\end{aligned}$$

The rest of the proof just follows the smooth case as proved in Theorem 11.

Dual subproblems in Acc-DADM Define: $\tilde{\lambda}=\lambda+\kappa$, $f(w)=\frac{\lambda}{\tilde{\lambda}}g(w)+\frac{\kappa}{2\tilde{\lambda}}\|w\|_2^2$. Let

$$\begin{aligned}P_t(w)=&\sum_{i=1}^n\phi_i(X_i^\top w)+\lambda ng(w)+h(w)+\frac{\kappa n}{2}\left\|w-y^{(t-1)}\right\|_2^2\\ =&\sum_{i=1}^n\phi_i(X_i^\top w)+\tilde{\lambda}n\left(f(w)-\frac{\kappa}{\tilde{\lambda}}w^\top y^{(t-1)}\right)+h(w)+\frac{\kappa n_\ell}{2}\left\|y^{(t-1)}\right\|_2^2\end{aligned}$$

be the global primal problem to solve, and

$$P_{\ell_t}(w_\ell)=\sum_{i\in S_\ell}\phi_i(X_i^\top w_\ell)+\lambda n_\ell g(w_\ell)+\frac{\kappa n_\ell}{2}\left\|w_\ell-y^{(t-1)}\right\|_2^2$$

be the separated local problem. Given each dual variable β_ℓ, we also define the adjusted local primal problem as:

$$\tilde{P}_{\ell_t}(w_\ell|\beta_\ell)=\sum_{i\in S_\ell}\phi_i(X_i^\top w_\ell)+\lambda n_\ell g(w_\ell)+\beta_\ell^\top w_\ell+\frac{\kappa n_\ell}{2}\left\|w_\ell-y^{(t-1)}\right\|_2^2,$$

it is not hard to see the adjusted local dual problem is

$$\tilde{D}_{\ell_t}(\alpha_{(\ell)}|\beta_\ell)=\sum_{i\in S_\ell}-\phi_i^*(-\alpha_i)-\tilde{\lambda}n_\ell f^*\left(\frac{\sum_{i\in S_\ell}X_i\alpha_i-\beta_\ell+\kappa n_\ell y^{(t-1)}}{\tilde{\lambda}n_\ell}\right)+\frac{\kappa n_\ell}{2}\left\|y^{(t-1)}\right\|_2^2,$$

and the global dual objective can be written as

$$D_t(\alpha,\beta)=\sum_{\ell=1}^m\tilde{D}_{\ell_t}(\alpha_{(\ell)}|\beta_\ell)-h^*\left(\sum_{\ell=1}^m\beta_\ell\right).$$

Quadratic lower bound for $P(w)$ based on approximate proximal point algorithm Since $P_t(w)=P(w)+\frac{\kappa n}{2}\left\|w-y^{(t-1)}\right\|_2^2$, and let $w_{\text{opt}}^{(t)}=\arg\min_w P_t(w)$. The following lemma shows we can construct a lower bound of $P(w)$ from an approximate minimizer of $P_t(w)$.

Lemma 17 *Let w^+ be an ϵ-approximated minimizer of $P_t(w)$, i.e.*

$$P_t(w^+) \leq P_t(w_{\text{opt}}^{(t)}) + \epsilon.$$

We can construct the following quadratic lower bound for $P(w)$, as $\forall w$

$$P(w) \geq P(w^+) + Q(w; w^+, y^{(t-1)}, \epsilon), \tag{28}$$

where

$$\begin{aligned} Q(w; w^+, y^{(t-1)}, \epsilon) =& \frac{\lambda n}{4} \left\| w - \left(y^{(t-1)} - \left(1 + \frac{2\kappa}{\lambda}\right)(y^{(t-1)} - w^+) \right) \right\|_2^2 \\ & - \frac{\kappa^2 n}{\lambda} \left\| w^+ - y^{(t-1)} \right\|_2^2 - \left(\frac{2\kappa + 2\lambda}{\lambda} \right) \epsilon. \end{aligned}$$

Proof Since $w_{\text{opt}}^{(t)}$ is the minimizer of a $(\kappa+\lambda)n$-strongly convex objective $P_t(w)$, we know $\forall w$,

$$\begin{aligned} P_t(w) \geq & P_t(w_{\text{opt}}^{(t)}) + \frac{(\kappa+\lambda)n}{2} \left\| w - w_{\text{opt}}^{(t)} \right\|_2^2 \\ \geq & P_t(w^+) + \frac{(\kappa+\lambda)n}{2} \left\| w - w_{\text{opt}}^{(t)} \right\|_2^2 - \epsilon, \end{aligned}$$

which is equivalent to

$$P(w) \geq P(w^+) + \frac{(\kappa+\lambda)n}{2} \left\| w - w_{\text{opt}}^{(t)} \right\|_2^2 - \epsilon + \frac{\kappa n}{2} \left(\left\| w^+ - y^{(t-1)} \right\|_2^2 - \left\| w - y^{(t-1)} \right\|_2^2 \right).$$

Since

$$\begin{aligned} \frac{\kappa+\lambda/2}{2} \left\| w - w^+ \right\|_2^2 =& \frac{\kappa+\lambda/2}{2} \left\| w - w_{\text{opt}}^{(t)} + w_{\text{opt}}^{(t)} - w^+ \right\|_2^2 \\ =& \frac{\kappa+\lambda/2}{2} \left(\left\| w - w_{\text{opt}}^{(t)} \right\|_2^2 + \left\| w_{\text{opt}}^{(t)} - w^+ \right\|_2^2 \right) \\ & + (\kappa+\lambda/2) \langle w - w_{\text{opt}}^{(t)}, w_{\text{opt}}^{(t)} - w^+ \rangle \\ \leq & \frac{\kappa+\lambda/2}{2} \left(\left\| w - w_{\text{opt}}^{(t)} \right\|_2^2 + \left\| w_{\text{opt}}^{(t)} - w^+ \right\|_2^2 \right) + \frac{\lambda/2}{2} \left\| w_{\text{opt}}^{(t)} - w \right\|_2^2 \\ & + \frac{(\kappa+\lambda/2)^2}{\lambda} \left\| w^+ - w_{\text{opt}}^{(t)} \right\|_2^2, \end{aligned}$$

re-organizing terms we get

$$\frac{\kappa+\lambda}{2} \left\| w_{\text{opt}}^{(t)} - w \right\|_2^2 \geq \frac{\kappa+\lambda/2}{2} \left\| w - w^+ \right\|_2^2 - \frac{(\kappa+\lambda)(\kappa+\lambda/2)}{\lambda} \left\| w^+ - w_{\text{opt}}^{(t)} \right\|_2^2$$

So

$$\begin{aligned} P(w) \geq & P(w^+) + \frac{(\kappa+\lambda/2)n}{2} \left\| w - w^+ \right\|_2^2 - \frac{(\kappa+\lambda)(\kappa+\lambda/2)n}{\lambda} \left\| w^+ - w_{\text{opt}}^{(t)} \right\|_2^2 - \epsilon \\ & + \frac{\kappa n}{2} \left(\left\| w^+ - y^{(t-1)} \right\|_2^2 - \left\| w - y^{(t-1)} \right\|_2^2 \right) \end{aligned}$$

Also noted that $\frac{(\kappa+\lambda)n}{2} \left\| w^+ - w_{\text{opt}}^{(t)} \right\|_2^2 \leq \epsilon$, we get

$$\begin{aligned} P(w) \geq & P(w^+) + \frac{(\kappa+\lambda/2)n}{2} \left\| w - w^+ \right\|_2^2 - \left(\frac{2\kappa+2\lambda}{\lambda} \right) \epsilon \\ & + \frac{\kappa n}{2} \left(\left\| w^+ - y^{(t-1)} \right\|_2^2 - \left\| w - y^{(t-1)} \right\|_2^2 \right) \end{aligned}$$

Decompose $\left\| w - w^+ \right\|_2^2$ we get

$$\left\| w - w^+ \right\|_2^2 = \left\| w - y^{(t-1)} \right\|^2 + \left\| y^{(t-1)} - w^+ \right\|_2^2 + 2\langle w - y^{(t-1)}, y^{(t-1)} - w^+ \rangle.$$

So

$$\begin{aligned} P(w) \geq & P(w^+) + \frac{(\lambda/2)n}{2} \left\| w - y^{(t-1)} \right\|_2^2 - \left(\frac{2\kappa+2\lambda}{\lambda} \right) \epsilon \\ & + \frac{(2\kappa+\lambda/2)n}{2} \left\| y^{(t-1)} - w^+ \right\|_2^2 + (\kappa+\lambda/2)n \langle w - y^{(t-1)}, y^{(t-1)} - w^+ \rangle \end{aligned}$$

Noticed that the right hand side of above inequality is a quadratic function with respect to w, and the minimum is achieved when

$$w = y^{(t-1)} - \left(1 + \frac{2\kappa}{\lambda}\right)(y^{(t-1)} - w^+),$$

with minimum value

$$-\frac{\kappa^2 n}{\lambda} \left\| w^+ - y^{(t-1)} \right\|_2^2 - \left(\frac{2\kappa+2\lambda}{\lambda} \right) \epsilon,$$

with above we finished the proof of Lemma 17. ■

Convergence proof Define the following sequence of quadratic functions

$$\psi_0(w) = P(0) + \frac{\lambda n}{4} \left\| w \right\|_2^2 - \left(\frac{2\kappa+2\lambda}{\lambda} \right)(P(0) - D(0,0)),$$

and for $t \geq 1$,

$$\psi_t(w) = (1-\eta)\psi_{t-1}(w) + \eta(P(w^{(t)}) + Q(w; w^{(t)}, y^{(t-1)}, \epsilon_t)),$$

where $\eta = \sqrt{\frac{\lambda}{\lambda+2\kappa}}$, We first calculate the explicit form of the quadratic function $\psi_t(w)$ and its minimizer $v^{(t)} = \arg\min_w \psi_t(w)$. Clearly $v^{(0)} = 0$, and noticed that $\psi_t(w)$ is always a $\frac{\lambda n}{2}$-strongly convex function, we know $\psi_t(w)$ is in the following form:

$$\psi_t(w) = \psi_t(v^{(t)}) + \frac{\lambda n}{4} \left\| w - v^{(t)} \right\|_2^2.$$

Based on the definition of $\psi_{t+1}(w)$, and $v^{(t+1)}$ is minimizing $\psi_{t+1}(w)$, based on first-order optimality condition, we know

$$\frac{(1-\eta)\lambda n}{2}(v^{(t+1)}-v^{(t)})+\frac{\eta\lambda n}{2}\left(v^{(t+1)}-\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{(t+1)})\right)\right)=0,$$

rearranging we get

$$v^{(t+1)}=(1-\eta)v^{(t)}+\eta\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{(t+1)})\right).$$

The following lemma proves the convergence rate of $w^{(t)}$ to its minimizer.

Lemma 18 *Let*

$$\epsilon_t\leq\frac{\eta}{2(1+\eta^{-2})}\xi_t,$$

and

$$\xi_t=(1-\eta/2)^t\xi_0,$$

we will have the following convergence guarantee:

$$P(w^{(t)})-P(w^*)\leq\xi_t.$$

Proof It is sufficient to prove

$$P(w^{(t)})-\min_w\psi_t(w)\leq\xi_t, \tag{29}$$

then we get

$$P(w^{(t)})-P(w^*)\leq P(w^{(t)})-\psi_t(w^*)\leq P(w^{(t)})-\min_w\psi_t(w)\leq\xi_t.$$

We prove equation (29) by induction. When $t=0$, we have

$$P(w^{(0)})-\phi_0(v^{(0)})=\left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_0=\xi_0,$$

which verified (29) is true for $t=0$. Suppose the claim holds for some $t\geq1$, for the stage $t+1$, we have

$$\begin{aligned}
\psi_{t+1}(v^{(t+1)})=&(1-\eta)\left(\psi_t(v^{(t)})+\frac{\lambda n}{4}\left\|v^{(t+1)}-v^{(t)}\right\|_2^2\right)\\
&+\eta(P(w^{(t+1)})+Q(v^{(t+1)};w^{(t+1)},y^{(t)},\epsilon_t))\\
=&(1-\eta)\psi_t(v^{(t)})+\frac{(1-\eta)\eta^2\lambda n}{4}\left\|v^{(t)}-\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{t+1})\right)\right\|_2^2\\
&+\eta P(w^{(t+1)})+\frac{\eta(1-\eta)^2\lambda n}{4}\left\|v^{(t)}-\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{(t+1)})\right)\right\|_2^2\\
&-\frac{\eta\kappa^2 n}{\lambda}\left\|y^{(t)}-w^{(t+1)}\right\|_2^2-\eta\left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t\\
=&(1-\eta)\psi_t(v^{(t)})+\eta P(w^{(t+1)})-\frac{\eta\kappa^2 n}{\lambda}\left\|y^{(t)}-w^{(t+1)}\right\|_2^2-\eta\left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t\\
&+\frac{\eta(1-\eta)\lambda n}{4}\left\|v^{(t)}-\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{(t+1)})\right)\right\|_2^2.
\end{aligned}$$

Since

$$\begin{aligned}
&-\frac{\eta\kappa^2 n}{\lambda}\left\|y^{(t)}-w^{(t+1)}\right\|_2^2+\frac{\eta(1-\eta)\lambda n}{4}\left\|v^{(t)}-\left(y^{(t)}-\left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)}-w^{(t+1)})\right)\right\|_2^2\\
\geq&\left(-\frac{\eta\kappa^2 n}{\lambda}+\frac{\eta(1-\eta)\lambda n}{4}\left(1+\frac{2\kappa}{\lambda}\right)^2\right)\left\|y^{(t)}-w^{(t+1)}\right\|_2^2\\
&+\eta(1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle v^{(t)}-y^{(t)},y^{(t)}-w^{(t+1)}\rangle\\
\geq&\left(-\frac{\eta\kappa^2 n}{\lambda}+\frac{\eta(1-\eta)\kappa^2 n}{\lambda}\right)\left\|y^{(t)}-w^{(t+1)}\right\|_2^2\\
&+\eta(1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle v^{(t)}-y^{(t)},y^{(t)}-w^{(t+1)}\rangle\\
=&-\frac{\eta^2\kappa^2 n}{\lambda}\left\|y^{(t)}-w^{(t+1)}\right\|_2^2+\eta(1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle v^{(t)}-y^{(t)},y^{(t)}-w^{(t+1)}\rangle
\end{aligned}$$

Thus

$$\begin{aligned}
\psi_{t+1}(v^{(t+1)})\geq&(1-\eta)\psi_t(v^{(t)})+\eta P(w^{(t+1)})-\eta\left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t\\
&-\frac{\eta^2\kappa^2 n}{\lambda}\left\|y^{(t)}-w^{(t+1)}\right\|_2^2+\eta(1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle v^{(t)}-y^{(t)},y^{(t)}-w^{(t+1)}\rangle
\end{aligned}$$

Also using (28) with $w = w^{(t)}$, we have

$$\begin{aligned}
P(w^{(t)}) \geq & P(w^{(t+1)}) + \frac{\lambda n}{4}\left\|w^{(t)} - \left(y^{(t)} - \left(1+\frac{2\kappa}{\lambda}\right)(y^{(t)} - w^{(t+1)})\right)\right\|_2^2 \\
& - \frac{\kappa^2 n}{\lambda}\left\|w^{(t+1)} - y^{(t)}\right\|_2^2 - \left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t \\
\geq & P(w^{(t+1)}) + n\left(\kappa+\frac{\lambda}{2}\right)\langle w^{(t)} - y^{(t)}, y^{(t)} - w^{(t+1)}\rangle - \left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t \\
& + \left(\frac{\lambda n}{4}\left(1+\frac{2\kappa}{\lambda}\right)^2 - \frac{\kappa^2 n}{\lambda}\right)\left\|w^{(t+1)} - y^{(t)}\right\|_2^2 \\
\geq & P(w^{(t+1)}) + n\left(\kappa+\frac{\lambda}{2}\right)\langle w^{(t)} - y^{(t)}, y^{(t)} - w^{(t+1)}\rangle - \left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t \\
& + \kappa n\left\|w^{(t+1)} - y^{(t)}\right\|_2^2.
\end{aligned}$$

we get

$$\begin{aligned}
P(w^{(t+1)}) - \psi_{t+1}(v^{(t+1)}) \leq & (1-\eta)(P(w^{(t)}) - \psi_t(v^{(t)})) + \left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t \\
& + \left(\frac{\eta^2\kappa^2 n}{\lambda} - (1-\eta)\kappa n\right)\left\|y^{(t)} - w^{(t+1)}\right\|_2^2 \\
& + (1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle y^{(t)} - w^{(t)}, y^{(t)} - w^{(t+1)}\rangle. \\
& + \eta(1-\eta)n\left(\kappa+\frac{\lambda}{2}\right)\langle y^{(t)} - v^{(t)}, y^{(t)} - w^{(t+1)}\rangle
\end{aligned}$$

Since

$$\begin{aligned}
(1-\eta)(P(w^{(t)}) - \psi_t(v^{(t)})) + \left(\frac{2\kappa+2\lambda}{\lambda}\right)\epsilon_t \leq & (1-\eta)\xi_t + \left(\frac{2\kappa+2\lambda}{\lambda}\right)\cdot\frac{\eta}{2(1+\eta^{-2})}\xi_t \\
= & \left(1-\eta+\frac{\eta}{2}\right)\xi_t = \xi_{t+1},
\end{aligned}$$

and

$$\frac{\eta^2\kappa^2 n}{\lambda} - (1-\eta)\kappa n = \kappa n\left(\frac{\kappa}{\lambda+2\kappa} + \sqrt{\frac{\lambda}{\lambda+2\kappa}} - 1\right) \leq 0,$$

If we set $y^{(t)} = (\eta v^{(t)} + w^{(t)})/(1+\eta)$, which is equivalent to the update rule as $y^{(t)} = w^{(t)} + \nu(w^{(t)} - w^{(t-1)})$, because in that way we have

$$\begin{aligned}
\eta v^{(t)} = & \eta((1-\eta)v^{(t-1)}) + \eta^2\left(y^{(t-1)} - \left(1+\frac{2\kappa}{\lambda}\right)(y^{(t-1)} - w^{(t)})\right) \\
= & w^{(t)} + (1-\eta)(\eta v^{(t-1)} - (1+\eta)y^{(t-1)}) \\
= & w^{(t)} - (1-\eta)w^{(t-1)},
\end{aligned}$$

thus

$$\begin{aligned}
y^{(t)} = & \frac{\eta v^{(t)} + w^{(t)}}{1+\eta} \\
= & \frac{2w^{(t)} - (1-\eta)w^{(t-1)}}{1+\eta} \\
= & w^{(t)} + \nu(w^{(t)} - w^{(t-1)}).
\end{aligned}$$

So

$$y^{(t)} - w^{(t)} + \eta(y^{(t)} - v^{(t)}) = 0,$$

combining above we obtain

$$P(w^{(t+1)}) - \psi_{t+1}(v^{(t+1)}) \leq \xi_{t+1},$$

which concludes the proof. ■

Initial dual sub-optimality in each acceleration stage In the lemma below we upper bound the quantity

$$D_t(\alpha_{\text{opt}}^{(t)}, \beta_{\text{opt}}^{(t)}) - D_t(\alpha^{(t-1)}, \beta^{(t-1)}),$$

where $\alpha_{\text{opt}}^{(t)}, \beta_{\text{opt}}^{(t)} = \arg\max_{\alpha,\beta} D_t(\alpha, \beta)$.

Lemma 19 *We have the following upper bound on the initial dual sub-optimality at stage t:*

$$D_t(\alpha_{\text{opt}}^{(t)}, \beta_{\text{opt}}^{(t)}) - D_t(\alpha^{(t-1)}, \beta^{(t-1)}) \leq \epsilon_{t-1} + \frac{36\kappa}{\lambda}\xi_{t-3}.$$

Proof On one hand, since $f(\cdot)$ is 1-strongly convex, we know $f^*(\cdot)$ is 1-smooth. Thus

$$\begin{aligned}
& \tilde{\lambda} n_\ell f^*\left(\frac{\sum_{i\in S_\ell} X_i\alpha_i^{(t-1)} - \beta_\ell^{(t-1)} + \kappa n_\ell y^{(t-1)}}{\tilde{\lambda} n_\ell}\right) \\
\leq & \tilde{\lambda} n_\ell f^*\left(\frac{\sum_{i\in S_\ell} X_i\alpha_i^{(t-1)} - \beta_\ell^{(t-1)} + \kappa n_\ell y^{(t-2)}}{\tilde{\lambda} n_\ell}\right) \\
& + \kappa n_\ell \nabla f^*\left(\frac{\sum_{i\in S_\ell} X_i\alpha_i^{(t-1)} - \beta_\ell^{(t-1)} + \kappa n_\ell y^{(t-2)}}{\tilde{\lambda} n_\ell}\right)^\top (y^{(t-1)} - y^{(t-2)}) \\
& + \frac{\kappa^2 n_\ell^2}{2\tilde{\lambda} n_\ell}\left\|y^{(t-1)} - y^{(t-2)}\right\|_2^2,
\end{aligned}$$

noted that

$$\nabla f^*\left(\frac{\sum_{i\in S_\ell} X_i\alpha_i^{(t-1)} - \beta_\ell^{(t-1)} + \kappa n_\ell y^{(t-2)}}{\tilde{\lambda} n_\ell}\right) = w^{(t-1)},$$

we see

$$\begin{aligned}&-\tilde{D}_{\ell_t}(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})+\tilde{D}_{\ell_{t-1}}(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\\ \leq&\kappa n_\ell {w_\ell^{(t-1)}}^\top(y^{(t-1)}-y^{(t-2)})+\frac{\kappa^2 n_\ell^2}{2\tilde{\lambda}n_\ell}\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2\\ &+\frac{\kappa n_\ell}{2}\left\|y^{(t-2)}\right\|_2^2-\frac{\kappa n_\ell}{2}\left\|y^{(t-1)}\right\|_2^2.\end{aligned}$$

On the other hand, since

$$\begin{aligned}&\tilde{P}_{\ell_t}(w_\ell^{(t-1)}|\beta_\ell^{(t-1)})-\tilde{P}_{\ell_{t-1}}(w_\ell^{(t-1)}|\beta_\ell^{(t-1)})\\ =&\kappa n_\ell {w_\ell^{(t-1)}}^\top(y^{(t-2)}-y^{(t-1)})-\frac{\kappa n_\ell}{2}\left\|y^{(t-2)}\right\|_2^2+\frac{\kappa n_\ell}{2}\left\|y^{(t-1)}\right\|_2^2.\end{aligned}$$

Combining above we know

$$\begin{aligned}&\tilde{P}_{\ell_t}(w_\ell^{(t-1)}|\beta_\ell^{(t-1)})-\tilde{D}_{\ell_t}(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})\\ \leq&\tilde{P}_{\ell_{t-1}}(w_\ell^{(t-1)}|\beta_\ell^{(t-1)})-\tilde{D}_{\ell_{t-1}}(\alpha_{(\ell)}^{(t-1)}|\beta_\ell^{(t-1)})+\frac{\kappa^2 n_\ell^2}{2\tilde{\lambda}n_\ell}\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2,\end{aligned}$$

Since $\kappa\leq\tilde{\lambda}$, summing over above inequality we know

$$P_t(w_\ell^{(t-1)})-D_t(\alpha^{(t-1)},\beta^{(t-1)})\leq\epsilon_{t-1}+\frac{\kappa n}{2}\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2,$$

also noted that $P_t(w_\ell^{(t-1)})\geq D_t(\alpha_{\text{opt}}^{(t)},\beta_{\text{opt}}^{(t)})$, we get

$$D_t(\alpha_{\text{opt}}^{(t)},\beta_{\text{opt}}^{(t)})-D_t(\alpha^{(t-1)},\beta^{(t-1)})\leq\epsilon_{t-1}+\frac{\kappa n}{2}\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2.$$

For the term $\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2$, based on the definition of $y^{(t-1)}$ and the fact $\eta\leq 1$, we know

$$\begin{aligned}\left\|y^{(t-1)}-y^{(t-2)}\right\|_2\leq&\left\|w^{(t-1)}-w^{(t-2)}-\eta(w^{(t-1)}-w^{(t-2)}-(w^{(t-2)}-w^{(t-3)}))\right\|_2\\ \leq&3\max_{i=\{1,2\}}\left\|w^{(t-i)}-w^{(t-i-1)}\right\|_2.\end{aligned}$$

Then we upper bound $\left\|w^{(t-i)}-w^{(t-i-1)}\right\|_2$ using objective sub-optimality, using triangle inequality and the fact that $P(w^*)$ is λn-strongly convex, we have

$$\begin{aligned}\left\|w^{(t-i)}-w^{(t-i-1)}\right\|_2\leq&\left\|w^{(t-i)}-w^*\right\|_2+\left\|w^{(t-i-1)}-w^*\right\|_2\\ \leq&\sqrt{\frac{2(P(w^{(t-i)})-P(w^*))}{\lambda n}}+\sqrt{\frac{2(P(w^{(t-i-1)})-P(w^*))}{\lambda n}}\\ \leq&2\sqrt{2\frac{\xi_{t-i-1}}{\lambda n}}.\end{aligned}$$

We know

$$\left\|y^{(t-1)}-y^{(t-2)}\right\|_2^2\leq 9\max_{i=\{1,2\}}\left\|w^{(t-i)}-w^{(t-i-1)}\right\|_2^2\leq\frac{72\xi_{t-3}}{\lambda n}.$$

Combining above we get

$$D_t(\alpha_{\text{opt}}^{(t)},\beta_{\text{opt}}^{(t)})-D_t(\alpha^{(t-1)},\beta^{(t-1)})\leq\epsilon_{t-1}+\frac{36\kappa}{\lambda}\xi_{t-3}.$$

■

10. Experiments

In this section, we apply algorithms to solve L_2-L_1 regularized loss minimization problems. We compare **Acc-DADM** to **CoCoA**$^+$ and **OWL-QN** (Andrew and Gao, 2007), as they have already been shown to be superior to other related algorithms in (Yang, 2013; Jaggi et al., 2014; Ma et al., 2017; Andrew and Gao, 2007). For **Acc-DADM** and **CoCoA**$^+$, we apply ProxSDCA of (Shalev-Shwartz and Zhang, 2014) as the local procedure and perform aggressively sequential updates, as the practical variant of DisDCA did in (Yang, 2013) and CoCoA$^+$ did in (Ma et al., 2015). For details about the updates of the local procedure (ProxSDCA), please refer to the application section of (Shalev-Shwartz and Zhang, 2014). For fair comparisons, we use same balanced data partitions and random seeds.

We implement all algorithms using OpenMPI (Graham et al., 2006) and run them on a small cluster inside a private OpenStack cloud service. To simplify the programming efforts, we use one processor to simulate one machine. We test algorithms on four real datasets with different properties (see Table 1). These datasets are publicly available from LIBSVM dataset collections[1].

Table 1: Datasets

Dataset	**Size** (n)	**Features** (d)	**Sparsity**
covtype	581,012	54	22.12%
rcv1	677,399	47,236	0.16%
HIGGS	11,000,000	28	92.11%
kdd2010	19,264,097	29,890,095	$9.8e^{-7}$

Different loss functions The optimization problem we consider to solve is

$$\min_w\frac{1}{n}\sum_{i=1}^n\phi_i(x_i^\top w)+\frac{\lambda}{2}\|w\|_2^2+\mu\|w\|_1,$$

where $x_i\in\mathbb{R}^d$ is a feature vector, $y_i\in\{-1,1\}$ is a binary class label and $\phi_i:\mathbb{R}\to\mathbb{R}$ is the associated loss function. We consider two models: Support Vector Machine (SVM)

1. https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets

and Logistic Regression (LR). For SVM, we follow (Shalev-Shwartz and Zhang, 2014) and employ the smooth hinge loss $\tilde{\phi}_i$ (1-smooth) that is:

$$\tilde{\phi}_i(a) = \begin{cases} 0 & a \geq 1 \\ 1 - y_i a - 1/2 & a \leq 0 \\ \frac{1}{2}(1 - y_i a)^2 & o.w. \end{cases} \tag{30}$$

For LR, we employ the logistic loss ($\frac{1}{4}$-smooth) $\phi_i(a) = \log(1 + \exp(-y_i a))$. To apply Acc-DADM, we choose $\lambda g(w) = \frac{\lambda}{2}\|w\|_2^2 + \mu\|w\|_1$ and $h(w) = 0$. Please refer to (Shalev-Shwartz and Zhang, 2014) for detailed derivations of specific loss functions. For datasets with a medium sample size, such as *covtype* and *rcv1*, we employ 8 machines ($m = 8$). For relatively large datasets, such as *HIGGS* and *kdd2010*, we employ 20 machines ($m = 20$). In experiments, we set $\mu = 1e^{-5}$ and vary λ in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ on different datasets to see the convergence behaviours.

Mini-batch size Adjusting the mini-batch size M_ℓ corresponds to trading between computation and communication. We use $sp := \frac{M_\ell}{n_\ell}$ to denote the sampling percentage of the local procedure. In experiments, we test three sp values, 0.05 (red), 0.20 (green) and 0.80 (blue). For each case, we run algorithms for 100 passes over the data. As sp increases, the total number of communications needed to run 100 passes through the data decreases.

Acceleration parameters For all experiments, we set $\kappa = \frac{mR}{\gamma n} - \lambda$ as our theory suggests. As for ν, our theory suggests $\nu = \frac{1-\eta}{1+\eta}$ where $\eta = \sqrt{\frac{\lambda}{\lambda+2\kappa}}$. While in practice we find that $\nu = 0$ also works well and the algorithm can converge more smoothly. In Figure 1, we plot the empirical convergence results for the theory suggested ν and the choice $\nu = 0$. We observe that Acc-DADM with the theory suggested ν does enjoy the acceleration effect, though often converges with rippling behavior. Such a rippling behavior is normal for the accelerated methods, for example, as studied in (Odonoghue and Candès, 2015). Moreover, we observe simply setting $\nu = 0$ also works well in practice and produces more smooth convergence behavior. Thus we use $\nu = 0$ in later experiments for better visualization.

Figures 2, 3, 4 and 5 show detailed comparison experiments of CoCoA$^+$ and Acc-DADM. Figures 2, 3 show **the normalized duality gap versus the number of communications** and **the normalized duality gap versus time (s)** experiments for SVM respectively. Figures 4, 5 show similar plots for LR. From Figures 2, 4, we can see that larger M_ℓ corresponds to more local computations and enjoys less communications accordingly. Looking at Figures 3, 5 about the normalized duality gap versus time (s), we can see the practical effect of adjusting M_ℓ. Moreover, Figures 6, 7 show the total comparisons of OWL-QN, CoCoA$^+$ and Acc-DADM by solving LR problems. For OWL-QN, we follow the standard implementation of (Andrew and Gao, 2007) and set the memory parameter as 10. For CoCoA$^+$ and Acc-DADM, we set $sp = 1.0$ and it implies that each communication round corresponds to one pass over the data.

Our empirical studies show that Acc-DADM always yields the best results. When λ is relatively large, CoCoA$^+$ sometimes also converges as fast as Acc-DADM. However, CoCoA$^+$ slows down rapidly as λ becomes small, while Acc-DADM still enjoys fast convergence. These observations are consistent with our theory.

Scalability Scalability is an important metric for distributed algorithms. We study the scalability by observing the number of communications or the running time (s) needed to reach a certain accuracy ($1e^{-3}$ duality gap) versus the number of machines when the mini-batch size is fixed. For balanced partitions, the mini-batch size of each machine is $\frac{n}{m}sp$. To fix the mini-batch size, we need to adjust sp accordingly when m varies. In experiments, we vary sp in the range $\{0.04, 0.08, 0.16, 0.32\}$ when m grows exponentially from 4 to 32 or from 5 to 40. For each case, we run algorithms for at most 100 passes over the data. It implies that if the algorithm does not reach enough accuracy within 100 passes over the data, we record the number of communications or the running time as the final value after 100 passes.

Figures 8, 9 show scalability results when solving SVM problems. Figures 10, 11 show similar results of LR. From Figures 8, 10, where the y-axis represents the number of communications, we can see the effect of increasing machines only from the algorithm aspect regardless of different communication overheads when employing various distributed computing frameworks (Dean and Ghemawat, 2008; Zaharia et al., 2012; Li et al., 2014). Besides, we show the actual running time versus the number of machines in Figures 9, 11 with the communication time colored green. Empirical results show that Acc-DADM usually enjoys good scalability. Especially when λ is relatively small, such as $1e^{-7}$, CoCoA$^+$ may not reach enough accuracy even after 100 passes over the data, while Acc-DADM works significantly better. These observations are consistent with our theory.

Non-smooth Losses Our acceleration technique also works for non-smooth losses (see Section 8.2). Figures 12, 13 show experimental results when employing the hinge loss $\phi_i(a) = \max\{0, 1 - a\}$. In practice, we just set $\kappa = \frac{mL^2R}{n} - \lambda$ and run Algorithm 3 directly without applying the smoothing technique described in Section 8.2. We can observe that Acc-DADM also enjoys the acceleration effect as in the smooth case and converges significantly faster than CoCoA$^+$ when λ is small.

11. Conclusions

In this paper, we have introduced a novel distributed dual formulation for regularized loss minimization problems. Based on this new formulation, we studied a distributed generalization of the single-machine ProxSDCA, which we refer to as DADM. We have shown that the analysis of ProxSDCA can be easily generalized to establish the convergence of DADM. Moreover, we have adapted AccProxSDCA to the distributed setting by using this new dual formulation and provided corresponding theoretical guarantees. We performed numerous experiments on real datasets to validate our theory and show that our new approach improves the previous state-of-the-art in distributed dual optimization.

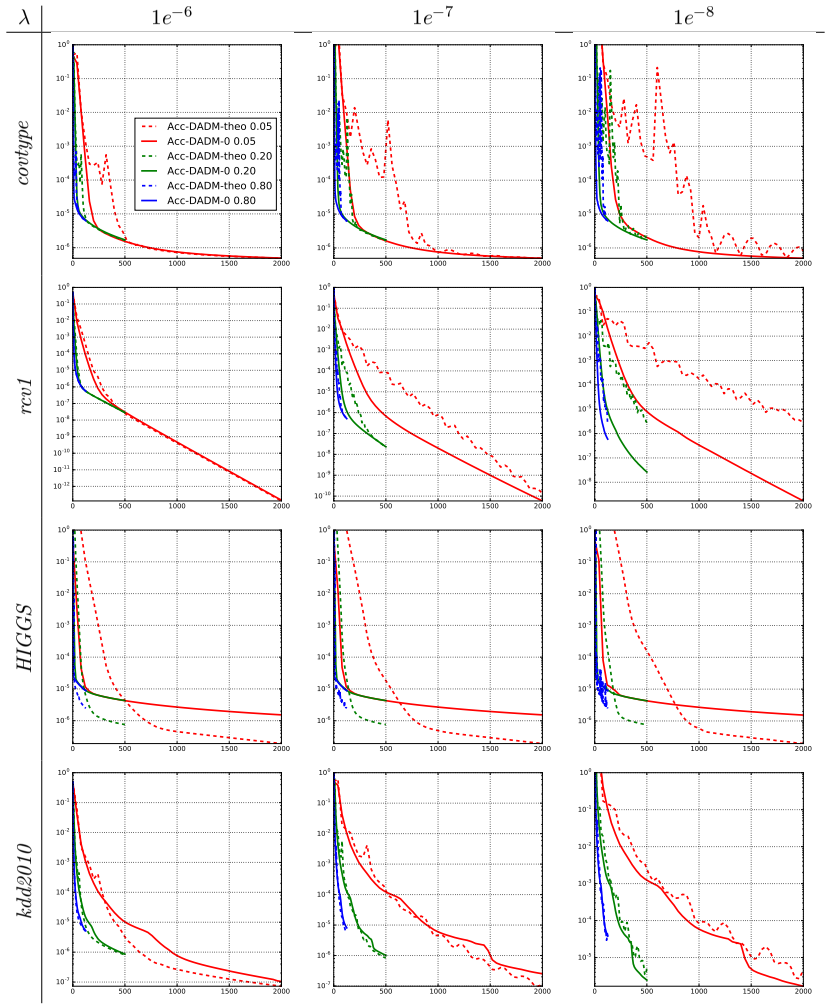

Figure 1: **The normalized duality gap versus the number of communications** of **SVM** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and sp varing in the range $\{0.05, 0.20, 0.80\}$ on four datasets. Acc-DADM-theo represents the theory suggested ν, Acc-DADM-0 represents the empirical choice $\nu = 0$. We run methods in each case for 100 passes over the data.

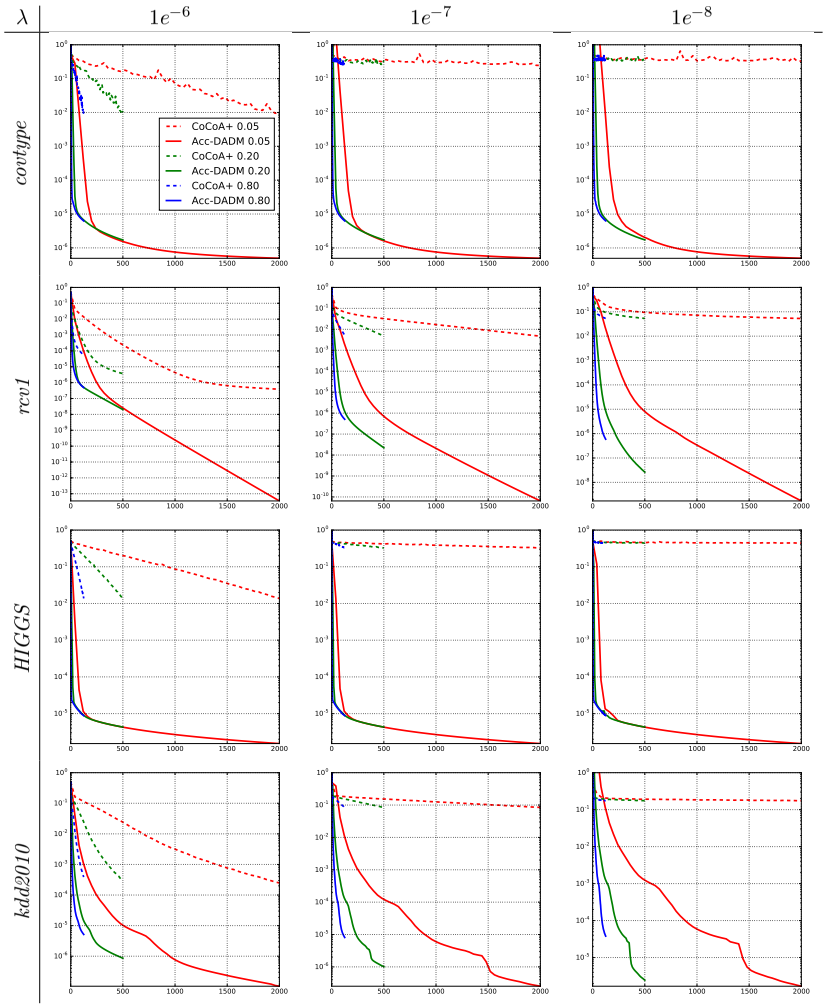

Figure 2: **The normalized duality gap versus the number of communications** of **SVM** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and sp varing in the range $\{0.05, 0.20, 0.80\}$ on four datasets. We run methods in each case for 100 passes over the data.

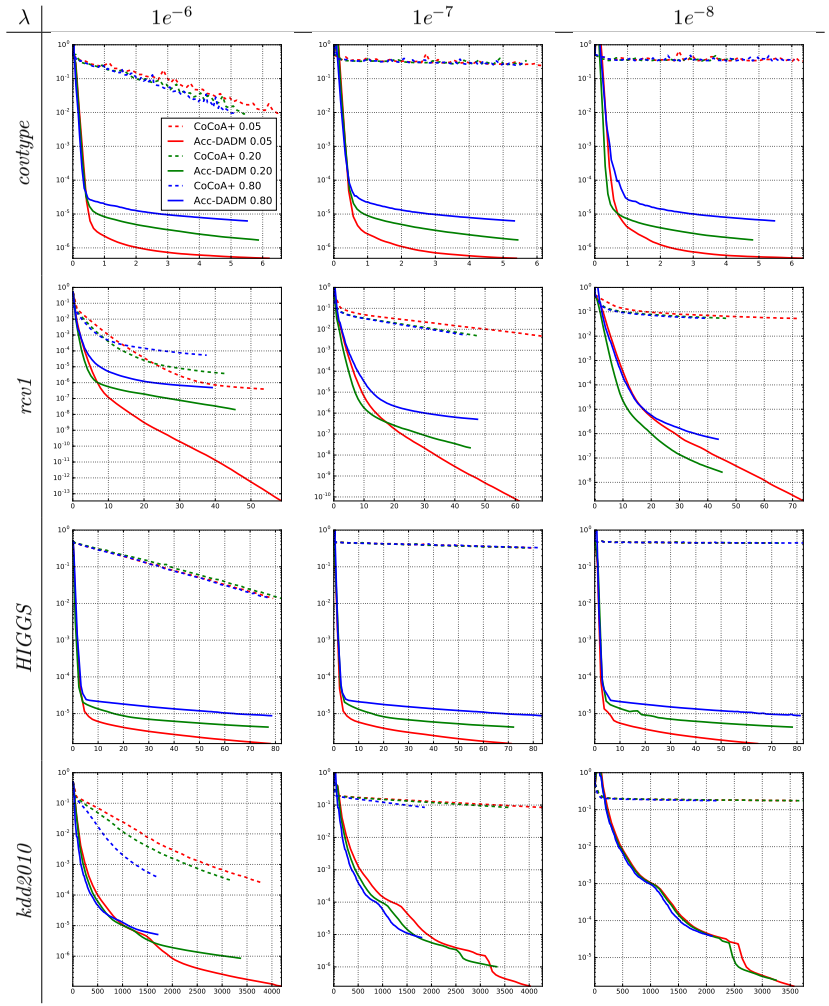

Figure 3: **The normalized duality gap versus time (s)** of **SVM** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and sp varing in the range $\{0.05, 0.20, 0.80\}$ on four datasets. We run methods in each case for 100 passes over the data.

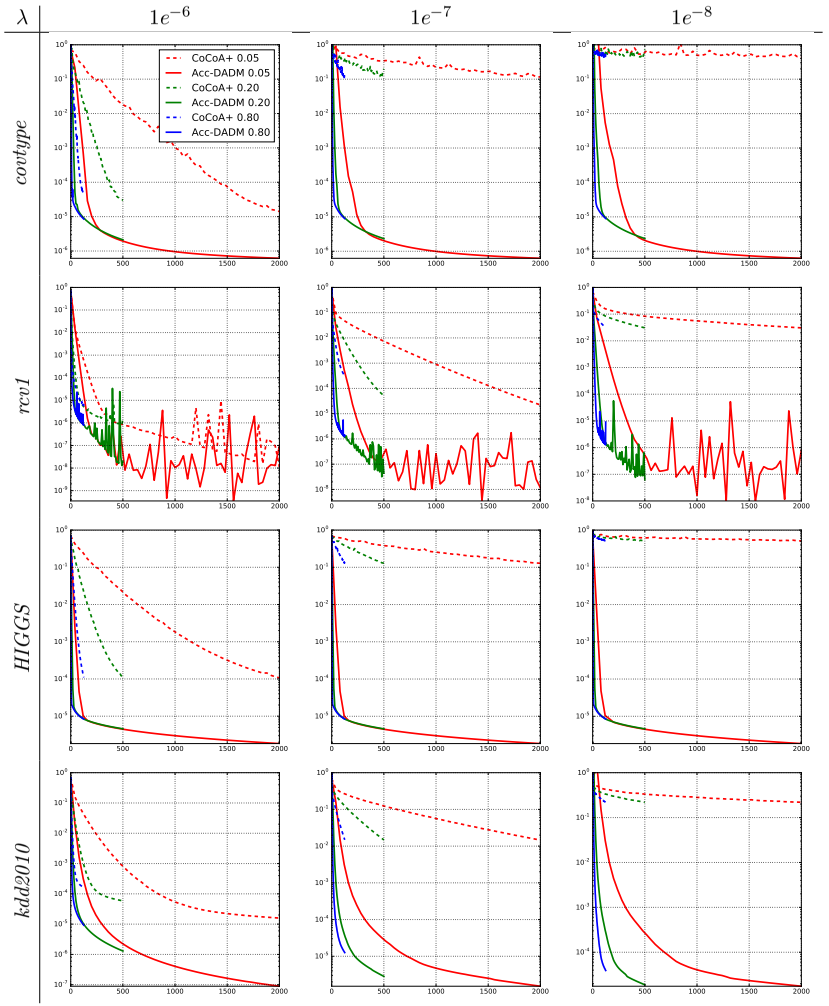

Figure 4: **The normalized duality gap versus the number of communications** of **LR** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and sp varing in the range $\{0.05, 0.20, 0.80\}$ on four datasets. We run methods in each case for 100 passes over the data.

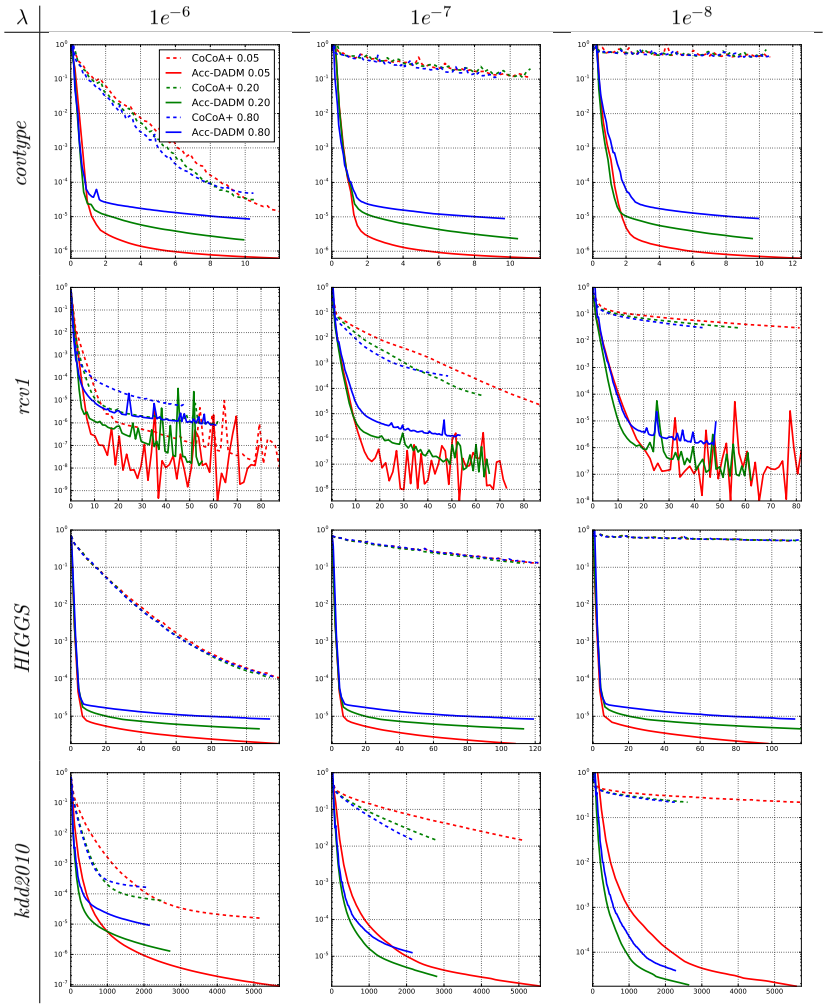

Figure 5: **The normalized duality gap versus time(s)** of LR experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and sp varing in the range $\{0.05, 0.20, 0.80\}$ on four datasets. We run methods in each case for 100 passes over the data.

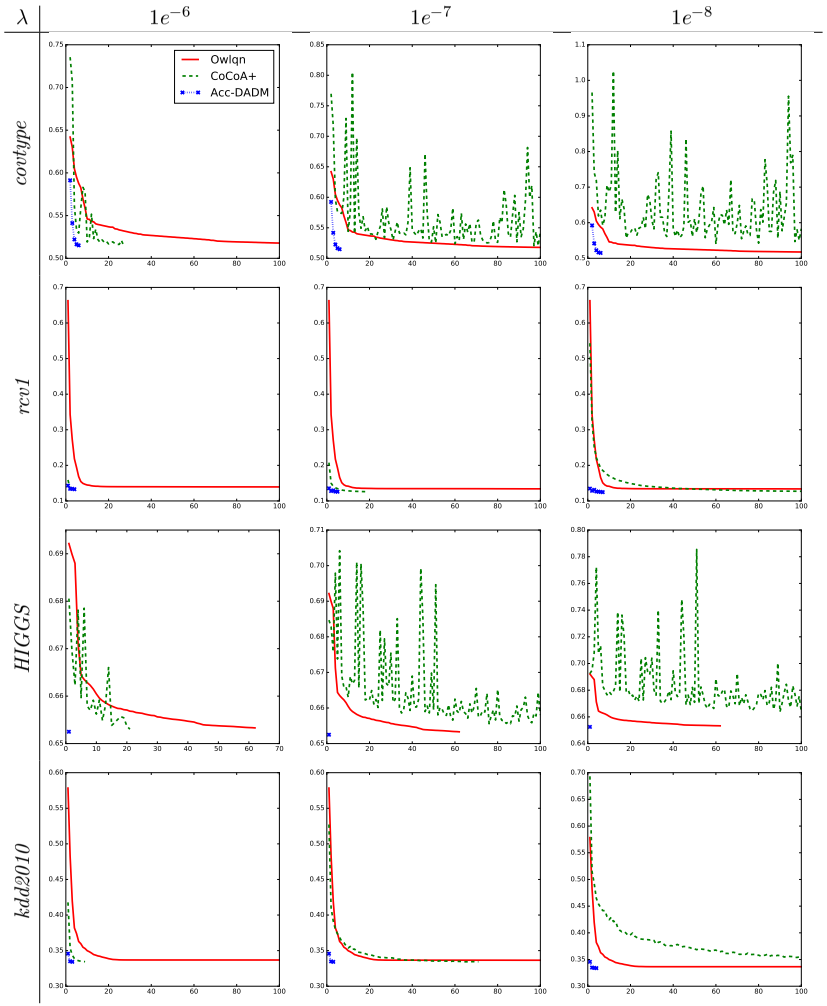

Figure 6: **The normalized primal objective versus the number of passes over the data** of **LR** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and $sp = 1.0$ on four datasets. We terminate methods either if the stopping condition is met ($1e^{-3}$ duality gap) or after 100 passes over the data.

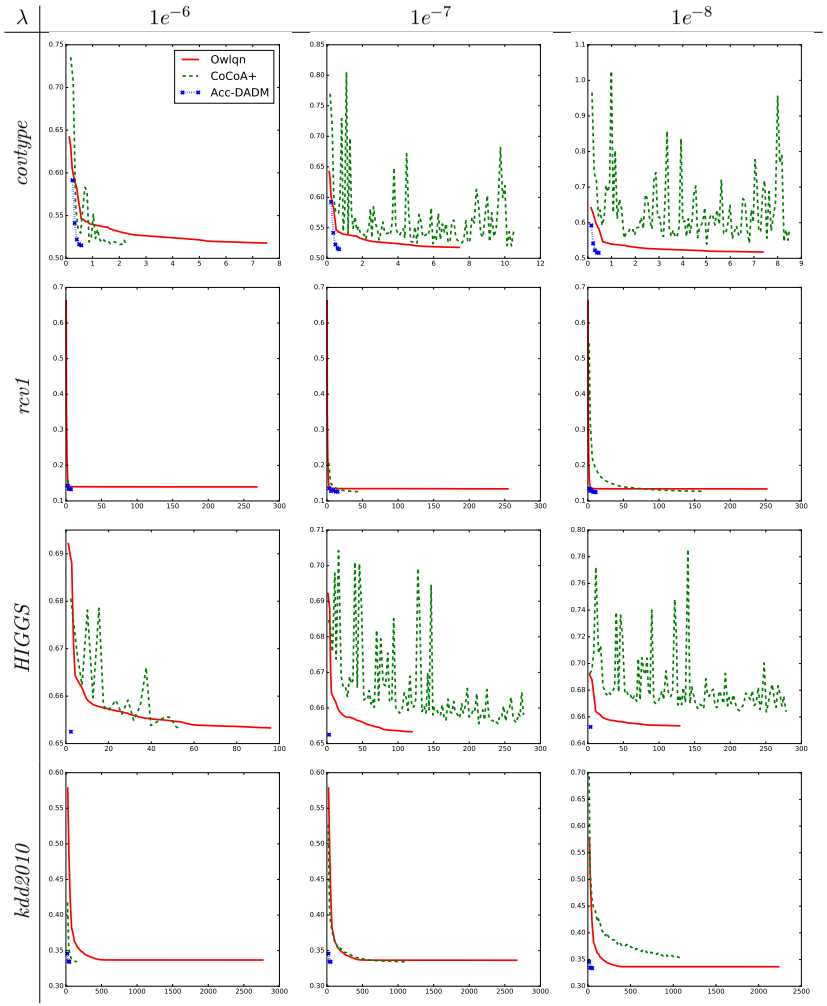

Figure 7: **The normalized primal objective versus time (s)** of **LR** experiments with $\mu = 1e^{-5}$, λ varing in the range $\{1e^{-6}, 1e^{-7}, 1e^{-8}\}$ and $sp = 1.0$ on four datasets. We terminate methods either if the stopping condition is met ($1e^{-3}$ duality gap) or after 100 passes over the data.

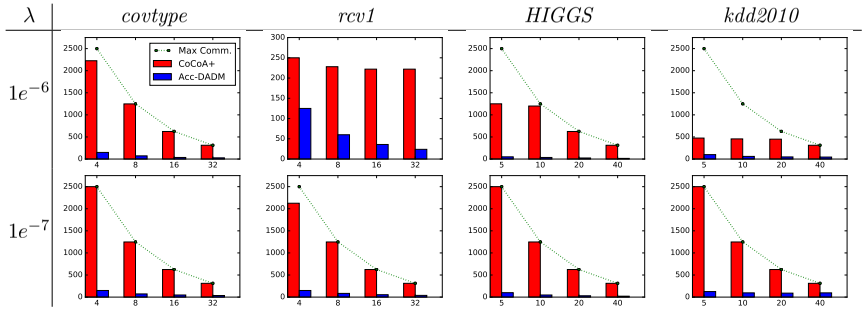

Figure 8: **The number of communications to reach $1e^{-3}$ duality gap versus the number of machines** of **SVM** experiments on four datasets. We fix the mini-batch size by varying sp as 0.04, 0.08, 0.16, 0.32 when m grows exponentially from 4 to 32 or from 10 to 80. For each case, we run algorithms for at most 100 passes over the data. *Max Comm.* represents the total number of communications needed to go through 100 passes over the data.

Abstract

First-order stochastic methods are the state-of-the-art in large-scale machine learning optimization owing to efficient per-iteration complexity. Second-order methods, while able to provide faster convergence, have been much less explored due to the high cost of computing the second-order information. In this paper we develop second-order stochastic methods for optimization problems in machine learning that match the per-iteration cost of gradient based methods, and in certain settings improve upon the overall running time over popular first-order methods. Furthermore, our algorithm has the desirable property of being implementable in time linear in the sparsity of the input data.

Keywords: second-order optimization, convex optimization, regression

1. Introduction

In recent literature stochastic first-order optimization has taken the stage as the primary workhorse for training learning models, due in large part to its affordable computational costs which are linear (in the data representation) per iteration. The main research effort devoted to improving the convergence rates of first-order methods have introduced elegant ideas and algorithms in recent years, including adaptive regularization (Duchi et al., 2011), variance reduction (Johnson and Zhang, 2013; Defazio et al., 2014), dual coordinate ascent (Shalev-Shwartz and Zhang, 2013), and many more.

In contrast, second-order methods have typically been much less explored in large scale machine learning (ML) applications due to their prohibitive computational cost per iteration which requires computation of the Hessian in addition to a matrix inversion. These operations are infeasible for large scale problems in high dimensions.

In this paper we propose a family of novel second-order algorithms, LiSSA (Linear time Stochastic Second-Order Algorithm) for convex optimization that attain fast convergence rates while also allowing for an implementation with linear time per-iteration cost, matching the running time of the best known gradient-based methods. Moreover, in the setting where the number of training examples m is much larger than the underlying dimension d, we show that our algorithm has provably faster running time than the best known gradient-based methods.

Formally, the main optimization problem we are concerned with is the empirical risk minimization (ERM) problem:

$$\min_{\mathbf{x}\in\mathbb{R}^d} f(\mathbf{x}) = \min_{\mathbf{x}\in\mathbb{R}^d} \left\{ \frac{1}{m}\sum_{k=1}^{m} f_k(\mathbf{x}) + R(\mathbf{x}) \right\}$$

where each $f_k(\mathbf{x})$ is a convex function and $R(\mathbf{x})$ is a convex regularizer. The above optimization problem is the standard objective minimized in most supervised learning settings. Examples include logistic regression, SVMs, etc. A common aspect of many applications of ERM in machine learning is that the loss function $f_i(\mathbf{x})$ is of the form $l(\mathbf{x}^\top \mathbf{v}_i, y_i)$ where $(\mathbf{v}_i, y_i)$ is the i^{th} training example-label pair. We call such functions generalized linear models (GLM) and will restrict our attention to this case. We will assume that the regularizer is an ℓ_2 regularizer,[1] typically $\|\mathbf{x}\|^2$.

Our focus is second-order optimization methods (Newton's method), where in each iteration, the underlying principle is to move to the minimizer of the second-order Taylor approximation at any point. Throughout the paper, we will let $\nabla^{-2} f(\mathbf{x}) \triangleq \left[\nabla^2 f(\mathbf{x})\right]^{-1}$. The update of Newton's method at a point $\mathbf{x}_t$ is then given by

$$\mathbf{x}_{t+1} = \mathbf{x}_t - \nabla^{-2} f(\mathbf{x}_t) \nabla f(\mathbf{x}_t). \tag{1}$$

Certain desirable properties of Newton's method include the fact that its updates are independent of the choice of coordinate system and that the Hessian provides the necessary regularization based on the curvature at the present point. Indeed, Newton's method can be shown to eventually achieve quadratic convergence (Nesterov, 2013). Although Newton's method comes with good theoretical guarantees, the complexity per step grows roughly as $\Omega(md^2 + d^\omega)$ (the former term for computing the Hessian and the latter for inversion, where $\omega \approx 2.37$ is the matrix multiplication constant), making it prohibitive in practice. Our main contribution is a suite of algorithms, each of which performs an approximate Newton update based on stochastic Hessian information and is implementable in linear $O(d)$ time. These algorithms match and improve over the performance of first-order methods in theory and give promising results as an optimization method on real world data sets. In the following we give a summary of our results. We propose two algorithms, LiSSA and LiSSA-Sample.

LiSSA: Algorithm 1 is a practical stochastic second-order algorithm based on a novel estimator of the Hessian inverse, leading to an efficient approximate Newton step (Equation 1). The estimator is based on the well known Taylor approximation of the inverse (Fact 2) and is described formally in Section 3.1. We prove the following informal theorem about LiSSA.

1. It can be seen that some of these assumptions can be relaxed in our analyses, but since these choices are standard in ML, we make these assumptions to simplify the discourse.

Theorem 1 (Informal) *LiSSA returns a point* $\mathbf{x}_t$ *such that* $f(\mathbf{x}_t) \leq \min_{\mathbf{x}^*} f(\mathbf{x}^*) + \varepsilon$ *in total time*

$$\tilde{O}\left((m + S_1\kappa)\, d \log\left(\frac{1}{\varepsilon}\right)\right)$$

where κ *is the underlying condition number of the problem and* S_1 *is a bound on the variance of the estimator.*

The precise version of the above theorem appears as Theorem 7. In theory, the best bound we can show for S_1 is $O(\kappa^2)$; however, in our experiments we observe that setting S_1 to be a small constant (often 1) is sufficient. We conjecture that S_1 can be improved to $O(1)$ and leave this for future work. If indeed S_1 can be improved to $O(1)$ (as is indicated by our experiments), LiSSA enjoys a convergence rate comparable to first-order methods. We provide a detailed comparison of our results with existing first-order and second-order methods in Section 1.2. Moreover, in Section 7 we present experiments on real world data sets that demonstrate that LiSSA as an optimization method performs well as compared to popular first-order methods. We also show that LiSSA runs in time proportional to input sparsity, making it an attractive method for high-dimensional sparse data.

LiSSA-Sample: This variant brings together efficient first-order algorithms with matrix sampling techniques (Li et al., 2013; Cohen et al., 2015) to achieve better runtime guarantees than the state-of-the-art in convex optimization for machine learning in the regime when $m > d$. Specifically, we prove the following theorem:

Theorem 2 (Informal) *LiSSA-Sample returns a point* $\mathbf{x}_t$ *such that* $f(\mathbf{x}_t) \leq \min_{\mathbf{x}^*} f(\mathbf{x}^*) + \varepsilon$ *in total time*

$$\tilde{O}\left(m + \sqrt{\kappa d}\right) d \log^2\left(\frac{1}{\varepsilon}\right) \log\log\left(\frac{1}{\varepsilon}\right).$$

The above result improves upon the best known running time for first-order methods achieved by acceleration when we are in the setting where $\kappa > m >> d$. We discuss the implication of our bounds and further work in Section 1.3.

In all of our results stated above κ corresponds to the condition number of the underlying problem. In particular we assume some strong convexity for the underlying problem. This is a standard assumption which is usually enforced by the addition of the ℓ_2 regularizer. In stating our results formally we stress on the nuances between different notions of the condition number (ref. Section 2.1), and we state our results precisely with respect to these notions. In general, all of our generalization/relaxations of the condition number are smaller than $\frac{1}{\lambda}$ where λ is the regularization parameter, and this is usually taken to be the condition number of the problem. The condition of strong convexity has been relaxed in literature by introducing proximal methods. It is an interesting direction to adapt our results in those setting which we leave for future work.

We also remark that all of our results focus on the very high accuracy regime. In general the benefits of linear convergence and second-order methods can be seen to be effective only when considerably small error is required. This is also the case for recent advances in fast first-order methods where their improvement over stochastic gradient descent becomes apparent only in the high accuracy regime. Our experiments also demonstrate that second-order methods can improve upon fast first-order methods in the regime of very high accuracy.

While it is possible that this regime is less interesting for generalization, in this paper we focus on the optimization problem itself.

We further consider the special case when the function f is self-concordant. Self-concordant functions are a sub-class of convex functions which have been extensively studied in convex optimization literature in the context of interior point methods (Nemirovski, 2004). For self-concordant functions we propose an algorithm (Algorithm 5) which achieves linear convergence with running time guarantees independent of the condition number. We prove the formal running time guarantee as Theorem 25.

We believe our main contribution to be a demonstration of the fact that second-order methods are comparable to, or even better than, first-order methods in the large data regime, in both theory and practice.

1.1 Overview of Techniques

LiSSA: The key idea underlying LiSSA is the use of the Taylor expansion to construct a natural estimator of the Hessian inverse. Indeed, as can be seen from the description of the estimator in Section 3.1, the estimator we construct becomes unbiased in the limit as we include additional terms in the series. We note that this is not the case with estimators that were considered in previous works such as that of Erdogdu and Montanari (2015), and so we therefore consider our estimator to be more natural. In the implementation of the algorithm we achieve the optimal bias/variance trade-off by truncating the series appropriately.

An important observation underlying our linear time $O(d)$ step is that for GLM functions, $\nabla^2 f_i(\mathbf{x})$ has the form $\alpha \mathbf{v}_i \mathbf{v}_i^\top$ where α is a scalar dependent on $\mathbf{v}_i^\top \mathbf{x}$. A single step of LiSSA requires us to efficiently compute $\nabla^2 f_i(\mathbf{x})\mathbf{b}$ for a given vector $\mathbf{b}$. In this case it can be seen that the matrix-vector product reduces to a vector-vector product, giving us an $O(d)$ time update.

LiSSA-Sample: LiSSA-Sample is based on Algorithm 2, which represents a general family of algorithms that couples the quadratic minimization view of Newton's method with any efficient first-order method. In essence, Newton's method allows us to reduce (up to $\log\log$ factors) the optimization of a general convex function to solving intermediate quadratic or ridge regression problems. Such a reduction is useful in two ways.

First, as we demonstrate through our algorithm LiSSA-Sample, the quadratic nature of ridge regression problems allows us to leverage powerful sampling techniques, leading to an improvement over the running time of the best known accelerated first-order method. On a high level this improvement comes from the fact that when solving a system of m linear equations in d dimensions, a constant number of passes through the data is enough to reduce the system to $O(d\log(d))$ equations. We carefully couple this principle and the computation required with accelerated first-order methods to achieve the running times for LiSSA-Sample. The result for the quadratic sub-problem (ridge regression) is stated in Theorem 15, and the result for convex optimization is stated in Theorem 16.

The second advantage of the reduction to quadratic sub-problems comes from the observation that the intermediate quadratic sub-problems can potentially be better conditioned than the function itself, allowing us a better choice of the step size in practice. We define these local notions of condition number formally in Section 2.1 and summarize the typical benefits for such algorithms in Theorem 13. In theory this is not a significant improve-

ment; however, in practice we believe that this could be significant and lead to runtime improvements.[2]

To achieve the bound for LiSSA-Sample we extend the definition and procedure for sampling via leverage scores described by Cohen et al. (2015) to the case when the matrix is given as a sum of PSD matrices and not just rank one matrices. We reformulate and reprove the theorems proved by Cohen et al. (2015) in this context, which may be of independent interest.

1.2 Comparison with Related Work

In this section we aim to provide a short summary of the key ideas and results underlying optimization methods for large scale machine learning. We divide the summary into three high level principles: first-order gradient-based methods, second-order Hessian-based methods, and quasi-Newton methods. For the sake of brevity we will restrict our summary to results in the case when the objective is strongly convex, which as justified above is usually ensured by the addition of an appropriate regularizer. In such settings the main focus is often to obtain algorithms which have provably linear convergence and fast implementations.

First-Order Methods: First-order methods have dominated the space of optimization algorithms for machine learning owing largely to the fact that they can be implemented in time proportional to the underlying dimension (or sparsity). Gradient descent is known to converge linearly to the optimum with a rate of convergence that is dependent upon the condition number of the objective. In the large data regime, stochastic first-order methods, introduced and analyzed first by Robbins and Monro (1951), have proven especially successful. Stochastic gradient descent (SGD), however, converges sub-linearly even in the strongly convex setting. A significant advancement in terms of the running time of first-order methods was achieved recently by a clever merging of stochastic gradient descent with its full version to provide *variance reduction*. The representative algorithms in this space are SAGA (Roux et al., 2012; Defazio et al., 2014) and SVRG (Johnson and Zhang, 2013; Zhang et al., 2013). The key technical achievement of the above algorithms is to relax the running time dependence on m (the number of training examples) and κ (the condition number) from a product to a sum. Another algorithm which achieves similar running time guarantees is based on dual coordinate ascent, known as SDCA (Shalev-Shwartz and Zhang, 2013).

Further improvements over SAGA, SVRG and SDCA have been obtained by applying the classical idea of *acceleration* emerging from the seminal work of Nesterov (1983). The progression of work here includes an accelerated version of SDCA (Shalev-Shwartz and Zhang, 2016); APCG (Lin et al., 2014); Catalyst (Lin et al., 2015), which provides a generic framework to accelerate first order algorithms; and Katyusha (Allen-Zhu, 2016), which introduces the concept of negative momentum to extend acceleration for variance reduced algorithms beyond the strongly convex setting. The key technical achievement of accelerated methods in general is to reduce the dependence on condition number from linear to a square root. We summarize these results in Table 1.

2. While this is a difficult property to verify experimentally, we conjecture that this is a possible explanation for why LiSSA performs better than first-order methods on certain data sets and ranges of parameters.

LiSSA places itself naturally into the space of fast first-order methods by having a running time dependence that is comparable to SAGA/SVRG (ref. Table 1). In LiSSA-Sample we leverage the quadratic structure of the sub-problem for which efficient sampling techniques have been developed in the literature and use accelerated first-order methods to improve the running time in the case when the underlying dimension is much smaller than the number of training examples. Indeed, to the best of our knowledge LiSSA-Sample is the theoretically fastest known algorithm under the condition $m >> d$. Such an improvement seems out of hand for the present first-order methods as it seems to strongly leverage the quadratic nature of the sub-problem to reduce its size. We summarize these results in Table 1.

Algorithm	Runtime	Reference
SVRG, SAGA, SDCA	$(md + O(\hat{\kappa}d)) \log\left(\frac{1}{\varepsilon}\right)$	Johnson and Zhang (2013) Zhang et al. (2013) Roux et al. (2012) Shalev-Shwartz and Zhang (2013)

Table 1: Run time comparisons. Refer to Section 2.1 for definitions of the various notions of condition number.

Second-Order Methods: Second-order methods such as Newton's method have classically been used in optimization in many different settings including development of interior point methods (Nemirovski, 2004) for general convex programming. The key advantage of Newton's method is that it achieves a linear-quadratic convergence rate. However, naive implementations of Newton's method have two significant issues, namely that the standard analysis requires the full Hessian calculation which costs $O(md^2)$, an expense not suitable for machine learning applications, and the matrix inversion typically requires $O(d^3)$ time. These issues were addressed recently by the algorithm NewSamp (Erdogdu and Montanari, 2015) which tackles the first issue by subsampling and the second issue by low-rank projections. We improve upon the work of Erdogdu and Montanari (2015) by defining a more *natural* estimator for the Hessian inverse and by demonstrating that the estimator can be computed in time proportional to $O(d)$. We also point the reader to the works of Martens (2010); Byrd et al. (2011) which incorporate the idea of taking samples of the Hessian; however, these works do not provide precise running time guarantees on their proposed algorithm based on problem specific parameters. Second-order methods have also enjoyed success in the distributed setting (Shamir et al., 2014).

Quasi-Newton Methods: The expensive computation of the Newton step has also been tackled via estimation of the curvature from the change in gradients. These algorithms are generally known as quasi-Newton methods stemming from the seminal BFGS algo-

rithm (Broyden, 1970; Fletcher, 1970; Goldfarb, 1970; Shanno, 1970). The book of Nocedal and Wright (2006) is an excellent reference for the algorithm and its limited memory variant (L-BFGS). The more recent work in this area has focused on stochastic quasi-Newton methods which were proposed and analyzed in various settings by Schraudolph et al. (2007); Mokhtari and Ribeiro (2014); Byrd et al. (2016). These works typically achieve sub-linear convergence to the optimum. A significant advancement in this line of work was provided by Moritz et al. (2016) who propose an algorithm based on L-BFGS by incorporating ideas from variance reduction to achieve linear convergence to the optimum in the strongly convex setting. Although the algorithm achieves linear convergence, the running time of the algorithm depends poorly on the condition number (as acknowledged by the authors). Indeed, in applications that interest us, the condition number is not necessarily a constant as is typically assumed to be the case for the theoretical results in Moritz et al. (2016).

Our key observation of linear time Hessian-vector product computations for machine learning applications provides evidence that in such instances, obtaining true Hessian information is efficient enough to alleviate the need for quasi-Newton information via gradients.

1.3 Discussion and Subsequent Work

In this section we provide a brief survey of certain technical aspects of our bounds which have since been improved by subsequent work.

An immediate improvement in terms of $S_2 \sim \kappa$ (in fact suggested in the original manuscript) was achieved by Bollapragada et al. (2016) via conjugate gradient on a sub-sampled Hessian which reduces this to $\sqrt{\kappa}$. A similar improvement can also be achieved in theory through the extensions of LiSSA proposed in the paper. As we show in Section 7, the worse dependence on condition number has an effect on the running time when κ is quite large.[3] Accelerated first-order methods, such as APCG (Lin et al., 2014), outperform LiSSA in this regime. To the best of our knowledge second-order stochastic methods have so far not exhibited an improvement in that regime experimentally. We believe a more practical version of LiSSA-Sample could lead to improvements in this regime, leaving this as future work.

To the best of our knowledge the factor of $S_1 = \kappa^2$ that appears to reduce the variance of our estimator has yet not been improved despite it being $O(1)$ in our experiments. This is an interesting question to which partial answers have been provided in the analysis of Ye et al. (2017).

Significant progress has been made in the space of inexact Newton methods based on matrix sketching techniques. We refer the reader to the works of Pilanci and Wainwright (2015); Xu et al. (2016); Cohen (2016); Luo et al. (2016); Ye et al. (2017) and the references therein.

We would also like to comment on the presence of a warm start parameter $\frac{1}{\kappa M}$ in our proofs of Theorems 7 and 15. In our experiments the warm start we required would be quite small (often a few steps of gradient descent would be sufficient) to make LiSSA converge. The warm start does not affect the asymptotic results proven in Theorems 7 and 15 because getting to such a warm start is independent of ε. However, improving this warm start, especially in the context of Theorem 15, is left as interesting future work.

3. Equivalently, λ is small.

On the complexity side, Arjevani and Shamir (2016) proved lower bounds on the best running times achievable by second-order methods. In particular, they show that to get the faster rates achieved by LiSSA-Sample, it is necessary to use a non-uniform sampling based method as employed by LiSSA-Sample. We would like to remark that in theory, up to logarithmic factors, the running time of LiSSA-Sample is still the best achieved so far in the setting $m >> d$. Some of the techniques and motivations from this work were also generalized by the authors to provide faster rates for a large family of non-convex optimization problems (Agarwal et al., 2017).

1.4 Organization of the Paper

The paper is organized as follows: we first present the necessary definitions, notations and conventions adopted throughout the paper in Section 2. We then describe our estimator for LiSSA, as well as state and prove the convergence guarantee for LiSSA in Section 3. After presenting a generic procedure to couple first-order methods with Newton's method in 4, we present LiSSA-Sample and the associated fast quadratic solver in Section 5. We then present our results regarding self-concordant functions in Section 6. Finally, we present an experimental evaluation of LiSSA in Section 7.

2. Preliminaries

We adopt the convention of denoting vectors and scalars in lowercase, matrices in uppercase, and vectors in boldface. We will use $\|\cdot\|$ without a subscript to denote the ℓ_2 norm for vectors and the spectral norm for matrices. Throughout the paper we denote $\mathbf{x}^* \triangleq \operatorname{argmin}_{\mathbf{x}\in\mathcal{K}} f(\mathbf{x})$. A convex function f is defined to be α-strongly convex and β-smooth if, for all $\mathbf{x}, \mathbf{y}$,

$$\nabla f(\mathbf{x})^\top(\mathbf{y}-\mathbf{x}) + \frac{\beta}{2}\|\mathbf{y}-\mathbf{x}\|^2 \geq f(\mathbf{y}) - f(\mathbf{x}) \geq \nabla f(\mathbf{x})^\top(\mathbf{y}-\mathbf{x}) + \frac{\alpha}{2}\|\mathbf{y}-\mathbf{x}\|^2.$$

The following is a well known fact about the inverse of a matrix A s.t. $\|A\| \leq 1$ and $A \succ 0$:

$$A^{-1} = \sum_{i=0}^{\infty}(I-A)^i. \tag{2}$$

2.1 Definition of Condition Numbers

We now define several measures for the condition number of a function f. The differences between these notions are subtle and we use them to precisely characterize the running time for our algorithms.[4]

For an α-strongly convex and β-smooth function f, the condition number of the function is defined as $\kappa(f) \triangleq \frac{\beta}{\alpha}$, or κ when the function is clear from the context. Note that by definition this corresponds to the following notion:

$$\kappa \triangleq \frac{\max_{\mathbf{x}} \lambda_{\max}(\nabla^2 f(\mathbf{x}))}{\min_{\mathbf{x}} \lambda_{\min}(\nabla^2 f(\mathbf{x}))} \ .$$

4. During initial reading we suggest the reader to skip the subtlety with these notions with the knowledge that they are all smaller than the pessimistic bound one can achieve by considering a value proportional to $O(\lambda^{-1})$, where λ is the coefficient of the ℓ_2 regularizer.

We define a slightly relaxed notion of condition number where the *max* moves out of the fraction above. We refer to this notion as a *local* condition number κ_l as compared to the *global* condition number κ defined above:

$$\kappa_l \triangleq \max_{\mathbf{x}} \frac{\lambda_{\max}(\nabla^2 f(\mathbf{x}))}{\lambda_{\min}(\nabla^2 f(\mathbf{x}))} \ .$$

It follows that $\kappa_l \leq \kappa$. The above notions are defined for any general function f, but in the case of functions of the form $f(\mathbf{x}) = \frac{1}{m}\sum_{k=1}^{m} f_k(\mathbf{x})$, a further distinction is made with respect to the component functions. We refer to such definitions of the condition number by $\hat{\kappa}$. In such cases one typically assumes the each component is bounded by $\beta_{max}(\mathbf{x}) \triangleq \max_k \lambda_{\max}(\nabla^2 f_k(\mathbf{x}))$. The running times of algorithms like SVRG depend on the following notion of condition number:

$$\hat{\kappa} = \frac{\max_{\mathbf{x}} \beta_{\max}(\mathbf{x})}{\min_{\mathbf{x}} \lambda_{\min}(\nabla^2 f(\mathbf{x}))} \ .$$

Similarly, we define a notion of local condition number for $\hat{\kappa}$, namely

$$\hat{\kappa}_l \triangleq \max_{\mathbf{x}} \frac{\beta_{\max}(\mathbf{x})}{\lambda_{\min}(\nabla^2 f(\mathbf{x}))},$$

and it again follows that $\hat{\kappa}_l \leq \hat{\kappa}$.

For our (admittedly pessimistic) bounds on the variance we also need a per-component strong convexity bound $\alpha_{\min}(\mathbf{x}) \triangleq \min_k \lambda_{\min}(\nabla^2 f_k(\mathbf{x}))$. We can now define

$$\hat{\kappa}_l^{\max} \triangleq \max_{\mathbf{x}} \frac{\beta_{\max}(\mathbf{x})}{\alpha_{\min}(\mathbf{x})} \ .$$

Assumptions: In light of the previous definitions, we make the following assumptions about the given function $f(\mathbf{x}) = \frac{1}{m}\sum_{k=1}^{m} f_k(\mathbf{x})$ to make the analysis easier. We first assume that the regularization term has been divided equally and included in $f_k(\mathbf{x})$. We further assume that each $\nabla^2 f_k(\mathbf{x}) \preceq I$.[5] We also assume that f is α-strongly convex and β-smooth, $\hat{\kappa}_l$ is the associated local condition number and $\nabla^2 f$ has a Lipschitz constant bounded by M.

We now collect key concepts and pre-existing results that we use for our analysis in the rest of the paper.

Matrix Concentration: The following lemma is a standard concentration of measure result for sums of independent matrices.[6] An excellent reference for this material is by Tropp (2012).

5. The scaling is without loss of generality, even when looking at additive errors, as this gets picked up in the log-term due to the linear convergence.
6. The theorem in the reference states the inequality for the more nuanced bounded variance case. We only state the simpler bounded spectral norm case which suffices for our purposes.

Theorem 3 (Matrix Bernstein, Tropp, 2012) *Consider a finite sequence $\{X_k\}$ of independent, random, Hermitian matrices with dimension d. Assume that*

$$\mathbf{E}[X_k] = 0 \text{ and } \|X_k\| \leq R.$$

Define $Y = \sum_k X_k$. Then we have for all $t \geq 0$,

$$\mathbf{Pr}\left(\|Y\| \geq t\right) \leq d \exp\left(\frac{-t^2}{4R^2}\right).$$

Accelerated SVRG: The following theorem was proved by Lin et al. (2015).

Theorem 4 *Given a function $f(\mathbf{x}) = \frac{1}{m}\sum_{k=1}^{m} f_k(\mathbf{x})$ with condition number κ, the accelerated version of SVRG via Catalyst (Lin et al., 2015) finds an ε-approximate minimum with probability $1-\delta$ in time*

$$\tilde{O}(md + \min(\sqrt{\kappa m}, \kappa)d) \log\left(\frac{1}{\varepsilon}\right).$$

Sherman-Morrison Formula: The following is a well-known expression for writing the inverse of rank one perturbations of matrices:

$$\left(A + \mathbf{v}\mathbf{v}^T\right)^{-1} = A^{-1} - \frac{A^{-1}\mathbf{v}\mathbf{v}^T A^{-1}}{1 + \mathbf{v}^T A^{-1}\mathbf{v}} \ .$$

3. LiSSA: Linear (time) Stochastic Second-Order Algorithm

In this section, we provide an overview of LiSSA (Algorithm 1) along with its main convergence results.

3.1 Estimators for the Hessian Inverse

Based on a recursive reformulation of the Taylor expansion (Equation 2), we may describe an unbiased estimator of the Hessian. For a matrix A, define A_j^{-1} as the first j terms in the Taylor expansion, i.e.,

$$A_j^{-1} \triangleq \sum_{i=0}^{j} (I - A)^i, \text{ or equivalently } A_j^{-1} \triangleq I + (I - A)A_{j-1}^{-1} \ .$$

Note that $\lim_{j\to\infty} A_j^{-1} \to A^{-1}$. Using the above recursive formulation, we now describe an unbiased estimator of $\nabla^{-2} f$ by first deriving an unbiased estimator $\tilde{\nabla}^{-2} f_j$ for $\nabla^{-2} f_j$.

Definition 5 (Estimator) *Given j independent and unbiased samples $\{X_1 \dots X_j\}$ of the Hessian $\nabla^2 f$, define $\{\tilde{\nabla}^{-2} f_0, \dots, \tilde{\nabla}^{-2} f_j\}$ recursively as follows:*

$$\tilde{\nabla}^{-2} f_0 = I \text{ and } \tilde{\nabla}^{-2} f_t = I + (I - X_t)\tilde{\nabla}^{-2} f_{t-1} \text{ for } t = 1, \dots, j.$$

It can be readily seen that $\mathbf{E}[\tilde{\nabla}^{-2} f_j] = \nabla^{-2} f_j$, and so $\mathbf{E}[\tilde{\nabla}^{-2} f_j] \to \nabla^{-2} f$ as $j \to \infty$, providing us with an unbiased estimator in the limit.

Algorithm 1 LiSSA: Linear (time) Stochastic Second-Order Algorithm

Input: T, $f(\mathbf{x}) = \frac{1}{m}\sum_{k=1}^{m} f_k(\mathbf{x})$, S_1, S_2, T_1
$\mathbf{x}_1 = FO(f(\mathbf{x}), T_1)$
for $t = 1$ to T **do**
  for $i = 1$ to S_1 **do**
    $X_{[i,0]} = \nabla f(\mathbf{x}_t)$
    for $j = 1$ to S_2 **do**
      Sample $\tilde{\nabla}^2 f_{[i,j]}(\mathbf{x}_t)$ uniformly from $\{\nabla^2 f_k(\mathbf{x}_t) \mid k \in [m]\}$
      $X_{[i,j]} = \nabla f(\mathbf{x}_t) + (I - \tilde{\nabla}^2 f_{[i,j]}(\mathbf{x}_t))X_{[i,j-1]}$
    end for
  end for
  $X_t = 1/S_1 \left(\sum_{i=1}^{S_1} X_{[i,S_2]}\right)$
  $\mathbf{x}_{t+1} = \mathbf{x}_t - X_t$
end for
return $\mathbf{x}_{T+1}$

Remark 6 *One can also define and analyze a simpler (non-recursive) estimator based on directly sampling terms from the series in Equation* (2)*. Theoretically, one can get similar guarantees for the estimator; however, empirically our proposed estimator exhibited better performance.*

3.2 Algorithm

Our algorithm runs in two phases: in the first phase it runs any efficient first-order method FO for T_1 steps to shrink the function value to the regime where we can then show linear convergence for our algorithm. It then takes approximate Newton steps based on the estimator from Definition 5 in place of the true Hessian inverse. We use two parameters, S_1 and S_2, to define the Newton step. S_1 represents the number of unbiased estimators of the Hessian inverse we average to get better concentration for our estimator, while S_2 represents the depth to which we capture the Taylor expansion. In the algorithm, we compute the average Newton step directly, which can be computed in linear time as observed earlier, instead of estimating the Hessian inverse.

3.3 Main Theorem

In this section we present our main theorem which analyzes the convergence properties of LiSSA. Define $FO(M, \hat{\kappa}_l)$ to be the total time required by a first-order algorithm to achieve accuracy $\frac{1}{4\hat{\kappa}_l M}$.

Theorem 7 *Consider Algorithm 1, and set the parameters as follows:* $T_1 = FO(M, \hat{\kappa}_l)$, $S_1 = O((\hat{\kappa}_l^{\max})^2 \ln(\frac{d}{\delta}))$, $S_2 \geq 2\hat{\kappa}_l \ln(4\hat{\kappa}_l)$*. The following guarantee holds for every* $t \geq T_1$ *with probability* $1 - \delta$*,*

$$\|\mathbf{x}_{t+1} - \mathbf{x}^*\| \leq \frac{\|\mathbf{x}_t - \mathbf{x}^*\|}{2}.$$

Moreover, we have that each step of the algorithm takes at most $\tilde{O}(md + (\hat{\kappa}_l^{\max})^2 \hat{\kappa}_l d^2)$ *time. Additionally if* f *is GLM, then each step of the algorithm can be run in time* $\tilde{O}(md + (\hat{\kappa}_l^{\max})^2 \hat{\kappa}_l d)$*.*

As an immediate corollary, we obtain the following:

Corollary 8 *For a GLM function* $f(\mathbf{x})$*, Algorithm 1 returns a point* $\mathbf{x}_t$ *such that with probability at least* $1 - \delta$*,*

$$f(\mathbf{x}_t) \leq \min_{\mathbf{x}^*} f(\mathbf{x}^*) + \varepsilon$$

in total time $\tilde{O}(m + (\hat{\kappa}_l^{\max})^2 \hat{\kappa}_l) d \ln\left(\frac{1}{\varepsilon}\right)$ *for* $\varepsilon \to 0$*.*

In the above theorems $\tilde{O}$ hides log factors of $\kappa, d, \frac{1}{\delta}$. We note that our bound $(\hat{\kappa}_l^{\max})^2$ on the variance is possibly pessimistic and can likely be improved to a more average quantity. However, since in our experiments setting the parameter $S_1 \sim O(1)$ suffices, we have not tried to optimize it further.

We now prove our main theorem about the convergence of LiSSA (Theorem 7).

Proof [Proof of Theorem 7]

Note that since we use a first-order algorithm to get a solution of accuracy at least $\frac{1}{4\hat{\kappa}_l M}$, we have that

$$\|\mathbf{x}_1 - \mathbf{x}^*\| \leq \frac{1}{4\hat{\kappa}_l M}. \tag{3}$$

As can be seen from Definition 5, a single step of our algorithm is equivalent to $\mathbf{x}_{t+1} = \mathbf{x}_t - \tilde{\nabla}^{-2} f(\mathbf{x}_t) \nabla f(\mathbf{x}_t)$, where $\tilde{\nabla}^{-2} f(\mathbf{x}_t)$ is the average of S_1 independent estimators $\tilde{\nabla}^{-2} f(\mathbf{x}_t)_{S_2}$. We now make use of the following lemma.

Lemma 9 *Let* $\mathbf{x}_{t+1} = \mathbf{x}_t - \tilde{\nabla}^{-2} f(\mathbf{x}_t) \nabla f(\mathbf{x}_t)$*, as per a single iteration of Algorithm 1, and suppose* S_1, S_2 *are as defined in Algorithm 1. Then if we choose* $S_2 \geq 2\hat{\kappa}_l \ln(2\hat{\kappa}_l)$ *we have the following guarantee on the convergence rate for every step with probability* $1 - \delta$*:*

$$\|\mathbf{x}_{t+1} - \mathbf{x}^*\| \leq \gamma \|\mathbf{x}_t - \mathbf{x}^*\| + M \|\nabla^{-2} f(\mathbf{x}_t)\| \|\mathbf{x}_t - \mathbf{x}^*\|^2$$

where $\gamma = 16\hat{\kappa}_l^{\max} \sqrt{\frac{\ln(d\delta^{-1})}{S_1}} + \frac{1}{16}$.

Substituting the values of S_1 and S_2, combining Equation (3) and Lemma 9, and noting that $\|\nabla^{-2} f(\mathbf{x}_t)\| \leq \hat{\kappa}_l$, we have that at the start of the Newton phase the following inequality holds:

$$\|\mathbf{x}_{t+1} - \mathbf{x}^*\| \leq \frac{\|\mathbf{x}_t - \mathbf{x}^*\|}{4} + M\hat{\kappa}_l^{\max} \|\mathbf{x}_t - \mathbf{x}^*\|^2 \leq \frac{\|\mathbf{x}_t - \mathbf{x}^*\|}{2} \ .$$

It can be shown via induction that the above property holds for all $t \geq T_1$, which concludes the proof. ■

We now provide a proof of Lemma 9.

Proof [Proof of Lemma 9] Define $\chi(\mathbf{x}_t) = \int_0^1 \nabla^2 f(\mathbf{x}^* + \tau(\mathbf{x}_t - \mathbf{x}^*))d\tau$. Note that $\nabla f(\mathbf{x}_t) = \chi(\mathbf{x}_t)(\mathbf{x}_t - \mathbf{x}^*)$. Following an analysis similar to that of Nesterov (2013), we have that

$$\begin{aligned}\|\mathbf{x}_{t+1} - \mathbf{x}^*\| &= \|\mathbf{x}_t - \mathbf{x}^* - \tilde{\nabla}^{-2} f(\mathbf{x}_t)\nabla f(\mathbf{x}_t)\| \\ &= \|\mathbf{x}_t - \mathbf{x}^* - \tilde{\nabla}^{-2} f(\mathbf{x}_t)\chi(\mathbf{x}_t)(\mathbf{x}_t - \mathbf{x}^*)\| \\ &\leq \|I - \tilde{\nabla}^{-2} f(\mathbf{x}_t)\chi(\mathbf{x}_t)\|\|\mathbf{x}_t - \mathbf{x}^*\|.\end{aligned}$$

Following from the previous equations, we have that

$$\frac{\|\mathbf{x}_{t+1} - \mathbf{x}^*\|}{\|\mathbf{x}_t - \mathbf{x}^*\|} \leq \|I - \tilde{\nabla}^{-2} f(\mathbf{x}_t)\chi(\mathbf{x}_t)\| = \| \underbrace{I - \nabla^{-2} f(\mathbf{x}_t)\chi(\mathbf{x}_t)}_{a} - \underbrace{\left(\tilde{\nabla}^{-2} f(\mathbf{x}_t) - \nabla^{-2} f(\mathbf{x}_t)\right)\chi(\mathbf{x}_t)}_{b} \|.$$

We now analyze the above two terms a and b separately:

$$\begin{aligned}\|a\| &= \|I - \nabla^{-2} f(\mathbf{x}_t)\chi(\mathbf{x}_t)\| \\ &\leq \|\nabla^{-2} f(\mathbf{x}_t) \int_0^1 \left(\nabla^2 f(\mathbf{x}_t) - \nabla^2 f(\mathbf{x}^* + \tau(\mathbf{x}_t - \mathbf{x}^*))d\tau\right) \| \\ &\leq M\|\nabla^{-2} f(\mathbf{x}_t)\|\|\mathbf{x}_t - \mathbf{x}^*\|.\end{aligned}$$

The second inequality follows from the Lipschitz bound on the Hessian. The second term can be bounded as follows:

$$\|b\| \leq \left(\| \left(\tilde{\nabla}^{-2} f(\mathbf{x}_t) - \nabla^{-2} f(\mathbf{x}_t)\right) \|\|\chi(\mathbf{x}_t)\|\right) \leq \gamma.$$

The previous claim follows from Lemma 10 which shows a concentration bound on the sampled estimator and by noting that due to our assumption on the function, we have that for all $\mathbf{x}$, $\|\nabla^2 f(\mathbf{x})\| \leq 1$, and hence $\|\chi(\mathbf{x})\| \leq 1$.

Putting the above two bounds together and using the triangle inequality, we have that

$$\frac{\|\mathbf{x}_{t+1} - \mathbf{x}^*\|}{\|\mathbf{x}_t - \mathbf{x}^*\|} \leq M\|\nabla^{-2} f(\mathbf{x}_t)\|\|\mathbf{x}_t - \mathbf{x}^*\| + \gamma$$

which concludes the proof. ■

Lemma 10 *Let $\tilde{\nabla}^{-2} f(\mathbf{x}_t)$ be the average of S_1 independent samples of $\tilde{\nabla}^{-2} f(\mathbf{x}_t)_{S_2}$, as defined in Definition 5 and used in the per-step update of Algorithm 1, and let $\nabla^2 f(\mathbf{x}_t)$ be the true Hessian. If we set $S_2 \geq 2\hat{\kappa}_l \ln(\hat{\kappa}_l S_1)$, then we have that*

$$\mathbf{Pr}\left(\|\tilde{\nabla}^{-2} f(\mathbf{x}_t) - \nabla^{-2} f(\mathbf{x}_t)\| > 16\hat{\kappa}_l^{\max}\sqrt{\frac{\ln(\frac{d}{\delta})}{S_1}} + 1/16\right) \leq \delta.$$

Proof [Proof of Lemma 10] First note the following statement which is a straightforward implication of our construction of the estimator:

$$\mathbf{E}[\tilde{\nabla}^{-2} f(\mathbf{x}_t)] = \mathbf{E}[\tilde{\nabla}^{-2} f(\mathbf{x}_t)_{S_2}] = \sum_{i=0}^{S_2} (I - \nabla^2 f(\mathbf{x}_t))^i.$$

We also know from Equation (2) that for matrices X such that $\|X\| \leq 1$ and $X \succ 0$,

$$X^{-1} = \sum_{i=0}^{\infty} (I - X)^i.$$

Since we have scaled the function such that $\|\nabla^2 f_k\| \leq 1$, it follows that

$$\nabla^{-2} f(\mathbf{x}_t) = \mathbf{E}\left[\tilde{\nabla}^{-2} f(\mathbf{x}_t)_{S_2}\right] + \sum_{i=S_2+1}^{\infty} (I - \nabla^2 f(\mathbf{x}_t))^i. \tag{4}$$

Also note that since $\nabla^2 f(\mathbf{x}_t) \succeq \frac{I}{\hat{\kappa}_l}$, it follows that $\|I - \nabla^2 f(\mathbf{x}_t)\| \leq 1 - \frac{1}{\hat{\kappa}_l}$. Observing the second term in the above equation,

$$\begin{aligned}\|\sum_{i=S_2}^{\infty} (I - \nabla^2 f(\mathbf{x}_t))^i\| &\leq \|(I - \nabla^2 f(\mathbf{x}_t))\|^{S_2} \left(\sum_{i=0}^{\infty} \|I - \nabla^2 f(\mathbf{x}_t)\|^i\right) \\ &\leq (1 - \frac{1}{\hat{\kappa}_l})^{S_2} \left(\sum_{i=0}^{\infty} (1 - \frac{1}{\hat{\kappa}_l})^i\right) \\ &\leq (1 - \frac{1}{\hat{\kappa}_l})^{S_2} \hat{\kappa}_l \\ &\leq \exp\left(-\frac{S_2}{\hat{\kappa}_l}\right) \hat{\kappa}_l.\end{aligned}$$

Since we have chosen $S_2 \geq 2\hat{\kappa}_l \ln(4\hat{\kappa}_l)$, we get that the above term is bounded by $\frac{1}{16}$. We will now show, using the matrix Bernstein inequality (Theorem 3), that the estimate $\tilde{\nabla}^{-2} f$ is concentrated around its expectation. To apply the inequality we first need to bound the spectral norm of each random variable. To that end we note that $\tilde{\nabla}^{-2} f_{S_2}$ has maximum spectral norm bounded by

$$\|\tilde{\nabla}^{-2} f_{S_2}\| \leq \sum_{i=0}^{S_2} (1 - 1/\hat{\kappa}_l^{\max})^i \leq \hat{\kappa}_l^{\max}.$$

We can now apply Theorem 3, which gives the following:

$$\mathbf{Pr}\left(\|\tilde{\nabla}^{-2} f - \mathbf{E}[\tilde{\nabla}^{-2} f]\| > \varepsilon\right) \leq 2d \exp\left(\frac{-\varepsilon^2 S_1}{64(\hat{\kappa}_l^{\max})^2}\right).$$

Setting $\varepsilon = 16\hat{\kappa}_l^{\max}\sqrt{\frac{ln(\frac{d}{\delta})}{S_1}}$ gives us that the probability above is bounded by δ. Now putting together the bounds and Equation (4) we get the required result. ■

3.4 Leveraging Sparsity

A key property of real-world data sets is that although the input is a high dimensional vector, the number of non-zero entries is typically very low. The following theorem shows

that LiSSA can be implemented in a way to leverage the underlying sparsity of the data. Our key observation is that for GLM functions, the rank one Hessian-vector product can be performed in $O(s)$ time where s is the sparsity of the input $\mathbf{x}_k$.

Theorem 11 *For GLM functions Algorithm 1 returns a point $\mathbf{x}_t$ such that with probability at least $1-\delta$*

$$f(\mathbf{x}_t) \leq \min_{\mathbf{x}^*} f(\mathbf{x}^*) + \varepsilon$$

in total time $\tilde{O}(ms + (\hat{\kappa}_l^{\max})^2 \hat{\kappa}_l s) \ln\left(\frac{1}{\varepsilon}\right)$ for $\varepsilon \to 0$.

We will prove the following theorem, from which Theorem 11 will immediately follow.

Theorem 12 *Consider Algorithm 1, let f be of the form described above, and let s be such that the number of non zero entries in $\mathbf{x}_i$ is bounded by s. Then each step of the algorithm can be implemented in time $O(ms + (\kappa_l^{\max})^2 \kappa_l s)$.*

Proof [Proof of Theorem 12] Proof by induction. Let $c_0 = 1$, $d_0 = 1$, $\mathbf{v}_0 = \mathbf{0}$, and consider the update rules $c_{j+1} = 1 + (1-\lambda)c_j$, $d_{j+1} = (1-\lambda)d_j$, and $\mathbf{v}_{j+1} = \mathbf{v}_j - \frac{1}{(1-\lambda)d_j}\tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x})(c_j \nabla f(\mathbf{x}) + d_j \mathbf{v}_j)$, where λ is the regularization parameter. For the base case, note that $X_{[i,0]} = c_0 \nabla f(\mathbf{x}) + d_0 \mathbf{v}_0 = \nabla f(\mathbf{x})$, as is the case in Algorithm 1. Furthermore, suppose $X_{[i,j]} = c_j \nabla f(\mathbf{x}) + d_j \mathbf{v}_j$. Then we see that

$$\begin{aligned}
X_{[i,j+1]} &= \nabla f(\mathbf{x}) + (I - \lambda I - \tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x})) X_{[i,j]} \\
&= \nabla f(\mathbf{x}) + ((1-\lambda)I - \tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x}))(c_j \nabla f(\mathbf{x}) + d_j \mathbf{v}_j) \\
&= (1 + (1-\lambda)c_j)\nabla f(\mathbf{x}) + (1-\lambda)(d_j \mathbf{v}_j) - \tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x})(c_j \nabla f(\mathbf{x}) + d_j \mathbf{v}_j) \\
&= c_{j+1} \nabla f(\mathbf{x}) + d_{j+1} \mathbf{v}_{j+1}.
\end{aligned}$$

Note that updating c_{j+1} and d_{j+1} takes constant time, and $\tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x})(c_j \nabla f(\mathbf{x}))$ and $\tilde{\nabla}^2 f_{[i,j+1]}(\mathbf{x})\mathbf{v}_j$ can each be calculated in $O(s)$ time. It can also be seen that each product gives an s-sparse vector, so computing $\mathbf{v}_{j+1}$ takes time $O(s)$. Since $\nabla f(\mathbf{x})$ can be calculated in $O(ms)$ time, and since $\mathbf{v}_0$ is 0-sparse which implies the number of non-zero entries of $\mathbf{v}_j$ is at most js, it follows that the total time to calculate X_t is $O(ms + (\kappa_l^{\max})^2 \kappa_l s)$. ■

4. LiSSA: Extensions

In this section we first describe a family of algorithms which generically couple first-order methods as sub-routines with second-order methods. In particular, we formally describe the algorithm LiSSA-Quad (Algorithm 2) and provide its runtime guarantee (Theorem 13). The key idea underlying this algorithm is that Newton's method essentially reduces a convex optimization problem to solving intermediate quadratic sub-problems given by the second-order Taylor approximation at a point, i.e., the sub-problem Q_t given by

$$Q_t(\mathbf{y}) = f(\mathbf{x}_{t-1}) + \nabla f(\mathbf{x}_{t-1})^T \mathbf{y} + \frac{\mathbf{y}^T \nabla^2 f(\mathbf{x}_{t-1}) \mathbf{y}}{2}$$

Algorithm 2 LiSSA-Quad

Input: T, $f(\mathbf{x}) = \sum_{k=1}^{m} f_k(\mathbf{x})$, ALG, ALG_{params}, T_1, ε
$\mathbf{x}_0 = \text{ALG}\ (f(\mathbf{x}), T_1)$
for $t = 1$ to T **do**
  $Q_t(\mathbf{y}) = \nabla f(\mathbf{x}_{t-1})^T \mathbf{y} + \frac{\mathbf{y}^T \nabla^2 f(\mathbf{x}_{t-1}) \mathbf{y}}{2}$
  $\mathbf{x}_t = A(Q_t, \varepsilon^2, A_{params})$
end for
return $\mathbf{x}_T$

where $\mathbf{y} \triangleq \mathbf{x} - \mathbf{x}_{t-1}$. The above ideas provide an alternative implementation of our estimator for $\nabla^{-2} f(\mathbf{x})$ used in LiSSA. Consider running gradient descent on the above quadratic Q_t, and let $\mathbf{y}_t^i$ be the i^{th} step in this process. By definition we have that

$$\mathbf{y}_t^{i+1} = \mathbf{y}_t^i - \nabla Q_t(\mathbf{y}_t^i) = (I - \nabla^2 f(\mathbf{x}_{t-1}))\mathbf{y}_t^i - \nabla f(\mathbf{x}_{t-1}).$$

It can be seen that the above expression corresponds exactly to the steps taken in LiSSA (Algorithm 2, line 8), the difference being that we use a sample of the Hessian instead of the true Hessian. Therefore LiSSA can also be interpreted as doing a partial stochastic gradient descent on the quadratic Q_t. It is partial because we have a precise estimate of gradient of the function f and a stochastic estimate for the Hessian. We note that this is essential for the linear convergence guarantees we show for LiSSA.

The above interpretation indicates the possibility of using any first-order linearly convergent scheme for approximating the minimizer of the quadratic Q_t. In particular, consider any algorithm ALG that, given a convex quadratic function Q_t and an error value ε, produces a point $\mathbf{y}$ such that

$$\|\mathbf{y} - \mathbf{y}_t^*\| \leq \varepsilon \tag{5}$$

with probability at least $1 - \delta_{ALG}$, where $\mathbf{y}_t^* = \operatorname{argmin} Q_t$. Let the total time taken by the algorithm ALG to produce the point be $T_{ALG}(\varepsilon, \delta_{ALG})$. For our applications we require ALG to be linearly convergent, i.e. T_{ALG} is proportional to $\log(\frac{1}{\varepsilon})$ with probability at least $1 - \delta_{ALG}$.

Given such an algorithm ALG, LiSSA-Quad, as described in Algorithm 2, generically implements the above idea, modifying LiSSA by replacing the inner loop with the given algorithm ALG. The following is a meta-theorem about the convergence properties of LiSSA-Quad.

Theorem 13 *Given the function $f(\mathbf{x}) = \sum f_i(\mathbf{x})$ which is α-strongly convex, let $\mathbf{x}^*$ be the minimizer of the function and $\{\mathbf{x}_t\}$ be defined as in Algorithm 2. Suppose the algorithm ALG satisfies condition (5) with probability $1 - \delta_{ALG}$ under the appropriate setting of parameters ALG_{params}. Set the parameters in the algorithm as follows: $T_1 = T_{ALG}(1/4\alpha M)$, $T = \log\log(1/\varepsilon)$, $\delta_{ALG} = \delta/T$, where ε is the final error guarantee one wishes to achieve. Then we have that after T steps, with probability at least $1 - \delta$,*

$$\min_{t=\{1\ldots T\}} \|\mathbf{x}_t - \mathbf{x}^*\| \leq \varepsilon.$$

In particular, LiSSA-Quad(ALG) produces a point $\mathbf{x}$ *such that*

$$\|\mathbf{x} - \mathbf{x}^*\| \leq \varepsilon$$

in total time $O(T_{ALG}(\varepsilon, \delta_{ALG}) \log\log(1/\varepsilon))$ *with probability at least* $1 - \delta$ *for* $\varepsilon \to 0$.

Note that for GLM functions, the $\nabla Q_t(\mathbf{y})$ at any point can be computed in time linear in d. In particular, a full gradient of Q_t can be computed in time $O(md)$ and a stochastic gradient (corresponding to a stochastic estimate of the Hessian) in time $O(d)$. Therefore, a natural choice for the algorithm *ALG* in the above are first-order algorithms which are linearly convergent, for example SVRG, SDCA, and Acc-SDCA. Choosing a first-order algorithm FO gives us a family of algorithms LiSSA-Quad(FO), each with running time comparable to the running time of the underlying FO, up to logarithmic factors. The following corollary summarizes the typical running time guarantees for LiSSA-Quad(FO) when FO is Acc-SVRG.

Corollary 14 *Given a GLM function* $f(\mathbf{x})$*, if ALG is replaced by Acc-SVRG (Lin et al., 2015), then under a suitable setting of parameters, LiSSA-Quad produces a point* $\mathbf{x}$ *such that*

$$f(\mathbf{x}) - f(\mathbf{x}^*) \leq \varepsilon$$

with probability at least $1 - \delta$*, in total time* $\tilde{O}(m + \min\left\{\sqrt{\hat{\kappa}_l m}, \hat{\kappa}_l\right\}) d \log(1/\varepsilon) \log\log(1/\varepsilon)$.

Here the $\tilde{O}$ above hides logarithmic factors in κ, d, δ, but not in ε. Note that the above running times depend upon the condition number $\hat{\kappa}_l$ which as described in Section 2 can potentially provide better dependence compared to its global counterpart. In practice this difference could lead to faster running time for LiSSA-Quad as compared to the underlying first-order algorithm FO. We now provide a proof for Theorem 13.

Proof [Proof of Theorem 13] We run the algorithm A to achieve accuracy ε^2 on each of the intermediate quadratic functions Q_t, and we set $\delta_A = \delta/T$ which implies via a union bound that for all $t \leq T$,

$$\|\mathbf{x}_{t+1} - \mathbf{x}_t^*\| \leq \varepsilon^2 \tag{6}$$

with probability at least $1 - \delta$.

Assume that for all $t < T$, $\|\mathbf{x}_t - \mathbf{x}^*\| \geq \varepsilon$ (otherwise the theorem is trivially true). Using the analysis of Newton's method as before, we get that for all $t \leq T$,

$$\begin{aligned}
\|\mathbf{x}_{t+1} - \mathbf{x}^*\| &\leq \|\mathbf{x}_t^* - \mathbf{x}^*\| + \|\mathbf{x}_{t+1} - \mathbf{x}_t^*\| \\
&\leq \|\mathbf{x}_t - \nabla^{-2} f(\mathbf{x}_t) \nabla f(\mathbf{x}_t) - \mathbf{x}^*\| + \|\mathbf{x}_{t+1} - \mathbf{x}_t^*\| \\
&\leq \frac{M}{4\alpha} \|\mathbf{x}_t - \mathbf{x}^*\|^2 + \varepsilon^2 \\
&\leq \left(\frac{M}{4\alpha} + 1\right) \|\mathbf{x}_t - \mathbf{x}^*\|^2
\end{aligned}$$

where the second inequality follows from the analysis in the proof of Theorem 7 and Equation (6). We know that $\|\mathbf{x}_0 - \mathbf{x}_t\| \leq \sqrt{\frac{\alpha}{M}}$ from the initial run of the first-order algorithm *FO*. Applying the above inductively and using the value of T prescribed by the theorem statement, we get that $\|\mathbf{x}_T - \mathbf{x}^*\| \leq \varepsilon$. ■

5. Runtime Improvement through Fast Quadratic Solvers

The previous section establishes the reduction from general convex optimization to quadratic functions. In this section we show how we can leverage the fact that for quadratic functions the running time for accelerated first-order methods can be improved in the regime when $\kappa > m >> d$. In particular, we show the following theorem.

Theorem 15 *Given a vector* $\mathbf{b} \in \mathbb{R}^d$ *and a matrix* $A = \sum A_i$ *where each* A_i *is of the form* $A_i = \mathbf{v}_i \mathbf{v}_i^T + \lambda I$ *for some* $\mathbf{v}_i \in \mathbb{R}^d, \|\mathbf{v}_i\| \leq 1$ *and* $\lambda \geq 0$ *a fixed parameter, Algorithm 4 computes a vector* $\tilde{\mathbf{v}}$ *such that* $\|A^{-1}\mathbf{b} - \tilde{\mathbf{v}}\| \leq \varepsilon$ *with probability at least* $1 - \delta$ *in total time*

$$\tilde{O}\left(md \log\left(\frac{1}{\varepsilon}\right) + \left(d + \sqrt{\kappa_{sample}(A) d}\right) d \log^2\left(\frac{1}{\varepsilon}\right)\right).$$

$\tilde{O}()$ *contains factors logarithmic in* $m, d, \kappa_{sample}(A), \|b\|, \delta$.

$\kappa_{sample}(A)$ is the condition number of an $O(d \log(d))$ sized sample of A and is formally defined in Equation (11). We can now use Algorithm 4 to compute an approximate Newton step by setting $A = \nabla^2 f(x)$ and $\mathbf{b} = \nabla f(x)$. We therefore propose LiSSA-Sample to be a variant of LiSSA-Quad where Algorithm 4 is used as the subroutine ALG and any first-order algorithm can be used in the initial phase. The following theorem bounding the running time of LiSSA-Sample follows immediately from Theorem 13 and Theorem 15.

Theorem 16 *Given a GLM function* $f(\mathbf{x}) = \sum_i f_i(\mathbf{x})$*, let* $\mathbf{x}^* = \operatorname{argmin} f(\mathbf{x})$*. LiSSA-Sample produces a point* $\mathbf{x}$ *such that*

$$\|\mathbf{x} - \mathbf{x}^*\| \leq \varepsilon$$

with probability at least $1 - \delta$ *in total time*

$$\tilde{O}\left(\left(md \log\left(\frac{1}{\varepsilon}\right) + \left(d + \sqrt{\kappa_{sample}(f) d}\right) d \log^2\left(\frac{1}{\varepsilon}\right)\right) \log\log\left(\frac{1}{\varepsilon}\right)\right).$$

$\tilde{O}()$ *contains factors logarithmic in* $m, d, \kappa_{sample}(f), G, \delta$.

5.1 Fast Quadratic Solver - Outline

In this section we provide a short overview of Algorithm 4. To simplify the discussion, lets consider the case when we have to compute $A^{-1}\mathbf{b}$ for a $d \times d$ matrix A given as $A = \sum_{i=1}^m \mathbf{v}_i \mathbf{v}_i^T = VV^T$ where the i^{th} column of V is $\mathbf{v}_i$. The computation can be recast as minimization of a convex quadratic function $Q(\mathbf{y}) = \frac{\mathbf{y}^T A \mathbf{y}}{2} + \mathbf{b}^T y$ and can be solved up to accuracy ε in total time $\left(m + \sqrt{\kappa(A) m}\right) d \log(1/\varepsilon)$ as can be seen from Theorem 4 Algorithm 4 improves upon the running time bound in the case when $m > d$. In the following we provide a high level outline of the procedure which is formally described as Algorithm 4.

- Given A we will compute a low complexity constant spectral approximation B of A. Specifically $B = \sum_{i=1}^{O(d\log(d))} \mathbf{u}_i\mathbf{u}_i^T$ and $B \preceq A \preceq 2B$. This is achieved by techniques developed in matrix sampling/sketching literature, especially those of Cohen et al. (2015). The procedure requires solving a constant number of $O(d\log(d))$ sized linear systems, which we do via Accelerated SVRG.
- We use B as a preconditioner and compute $BA^{-1}\mathbf{b}$ by minimizing the quadratic $\frac{\mathbf{y}^T AB^{-1}\mathbf{y}}{2} + \mathbf{b}^T\mathbf{y}$. Note that this quadratic is well conditioned and can be minimized using gradient descent. In order to compute the gradient of the quadratic which is given by $AB^{-1}\mathbf{y}$, we again use Accelerated SVRG to solve a linear system in B.
- Finally, we compute $A^{-1}\mathbf{b} = B^{-1}BA^{-1}\mathbf{b}$ using Accelerated SVRG to solve a linear system in B.

In the rest of the section we formally describe the procedure outlined and provide the necessary definitions. One key nuance we must take into account is the fact that based on our assumption we have included the regularization term into the component functions. Due to this, the Hessian does not necessarily look like a sum of rank one matrices. Of course, one can decompose the identity matrix that appears due to the regularizer as a sum of rank one matrices. However, note that the procedure above requires that each of the sub-samples must have good condition number too in order to solve linear systems on them with Accelerated SVRG. Therefore, the sub-samples generated must look like sub-samples formed from the Hessians of component functions. For this purpose we extend the procedure and the definition for leverage scores described by Cohen et al. (2015) to the case when the matrix is given as a sum of PSD matrices and not just rank one matrices. We reformulate and reprove the basic theorems proved by Cohen et al. (2015) in this context. To maintain computational efficiency of the procedure, we then make use of the fact that each of the PSD matrices actually is a rank one matrix plus the Identity matrix. We now provide the necessary preliminaries for the description of the algorithm and its analysis.

5.2 Preliminaries for Fast Quadratic Solver

For all the definitions and preliminaries below assume we are given a $d \times d$ PSD matrix $A \triangleq \sum_{i=1}^m A_i$ where A_i are also PSD matrices. Let $A \cdot B \triangleq Tr(B^T A)$ be the standard matrix dot product. Given two matrices A and B we say B is a λ-spectral approximation of A if $\frac{1}{\lambda}A \preceq B \preceq A$.

Definition 17 (Generalized Matrix Leverage Scores) *Define*

$$\tau_i(A) \triangleq A^+ \cdot A_i \tag{7}$$

$$\tau_i^B(A) \triangleq B^+ \cdot A_i. \tag{8}$$

Then we have the following facts:

Fact 18

$$\sum_{i=1}^n \tau_i(A) = Tr\left(\sum A^+ A_i\right) = Tr(A^+A) = rank(A) \leq d. \tag{9}$$

Fact 19 *If B is a λ-spectral approximation of A, then $\tau_i(A) \leq \tau_i^B(A) \leq \lambda\tau_i(A)$.*

Given A of the form $A = \sum A_i$, we define a sample of A of size r as the following. Consider a subset of indices of size r, $I = \{i_1 \dots i_r\} \subseteq [m]$. For every such sample I and given a weight vector $\mathbf{w} \in \mathbb{R}^r$, we can associate the following matrix:

$$Sample(\mathbf{w}, I) \triangleq \sum_{j\in I} w_j A_j. \tag{10}$$

When the sample is unweighted, i.e., $\mathbf{w} = \mathbf{1}$, we will simply denote the above as $Sample(I)$. We can now define $\kappa_{sample}(A, r)$ to be

$$\kappa_{sample}(A, r) \triangleq \max_{I:|I|\geq r} \kappa(Sample(r, I)). \tag{11}$$

This is the worst-case condition number of an unweighted sub-sample of size r of the matrix A. For our results we will be concerned with a $\Omega(d\log(d))$ sized sub-sample, i.e., the quantity $\kappa_{sample}(A, O(d\log(d)))$. We remind the reader that by definition κ_{sample} for Hessians of the functions we are concerned with is always larger than $1/\lambda$, where λ is the coefficient of the ℓ_2 regularizer.

The following lemma is a generalization of the leverage score sampling lemma (Lemma 4, Cohen et al. 2015). The proof is very similar to the original proof by Cohen et al. (2015) and is included in the Appendix for completeness.

Lemma 20 (Spectral Approximation via Leverage Score Sampling) *Given an error parameter $0 < \varepsilon < 1$, let $\mathbf{u}$ be a vector of leverage score overestimates, i.e., $\tau_i(A) \leq \mathbf{u}_i$, for all $i \in [m]$. Let α be a sampling rate parameter and let c be a fixed positive constant. For each matrix A_i, we define a sampling probability $p_i(\alpha) = \min\{1, \alpha\mathbf{u}_i c\log d\}$. Let I be a random sample of indices drawn from $[m]$ by sampling each index with probability $p_i(\alpha)$. Define the weight vector $\mathbf{w}(\alpha)$ to be the vector such that $\mathbf{w}(\alpha)_i = \frac{1}{p_i(\alpha)}$. By definition of weighted samples we have that*

$$Sample(\mathbf{w}(\alpha), I) = \sum_{i=1}^m \frac{1}{p_i(\alpha)} A_i \mathbf{1}_{x_i\sim p_i(\alpha)}(x_i = 1)$$

where x_i is a Bernoulli random variable with probability $p_i(\alpha)$.

If we set $\alpha = \varepsilon^{-2}$, $S = Sample(\mathbf{w}(\alpha), I)$ is formed by at most $\sum_i \min\{1, \alpha\mathbf{u}_i c\log(d)\} \leq \alpha c\log(d)\|\mathbf{u}\|_1$ entries in the above sum, and $\frac{1}{1+\varepsilon}S$ is a $\frac{1+\varepsilon}{1-\varepsilon}$ spectral approximation for A with probability at least $1 - d^{-c/3}$.

The following theorem is an analogue of the key theorem regarding uniform sampling (Theorem 1, Cohen et al. 2015). The proof is identical to the original proof and is also included in the appendix for completeness.

Theorem 21 (Uniform Sampling) *Given any $A = \sum_{i=1}^m A_i$ as defined above, let $S = \sum_{j=1}^r X_j$ be formed by uniformly sampling r matrices $X_1 \dots X_r \sim \{A_i\}$ without repetition. Define*

$$\tilde{\tau}_i^S(A) = \begin{cases} \tau_i^S(A) & \text{if } \exists\, j \;\; s.t. \;\; X_j = A_i \\ \tau_i^{S+A_i}(A) & \text{otherwise} \end{cases}.$$

Then $\tilde{\tau}_i^S(A) \geq \tau_i(A)$ *for all* i*, and*

$$\mathbb{E}\left[\sum_{i=1}^{n} \tilde{\tau}_i^S(A)\right] \leq \frac{md}{r}.$$

Unlike the case of rank one matrices as was done by Cohen et al. (2015), it is not immediately clear how to efficiently compute $\tilde{\tau}_i$ as we cannot directly apply the Sherman-Morrison formula. In our case though, since we have that each $A_i = \mathbf{v}_i\mathbf{v}_i^T + \lambda I$ we define slightly different estimates which are efficiently computable and prove that they work as well.

Theorem 22 *Suppose we are given any* $A = \sum_{i=1}^m A_i$ *where each* A_i *is of the form* $A_i = \mathbf{v}_i\mathbf{v}_i^T + \lambda I$*. Let* $S = \sum_{j=1}^m X_j$ *be formed by uniformly sampling* r *matrices* $X_1 \ldots X_r \sim \{A_i\}$ *without repetition. Define*

$$\hat{\tau}_i^S(A) = \begin{cases} \mathbf{v}_i^T S^+ \mathbf{v}_i^T + \frac{d}{r} & \text{if } \exists\, j \;\; s.t.\; X_j = A_i \\ \frac{1}{1+\frac{1}{\mathbf{v}_i^T(S+\lambda I)^+\mathbf{v}_i^T}} + \frac{d}{r} & \text{otherwise} \end{cases}.$$

Then $\hat{\tau}_i^S(A) \geq \tau_i(A)$ *for all* i*, and*

$$\mathbb{E}\left[\sum_{i=1}^{n} \hat{\tau}_i^S(A)\right] \leq O\left(\frac{md}{r}\right).$$

Proof [Proof of Theorem 22] We will prove that

$$\frac{d}{m} \geq \hat{\tau}_i^S(A) - \tilde{\tau}_i^S(A) \geq 0. \tag{12}$$

Consider the case when $\exists\, j \;\; s.t.\; X_j = A_i$. By definition of $\tilde{\tau}_i^S(A)$,

$$\begin{aligned}\tilde{\tau}_i^S(A) = \tau_i^S(A) = S^+ \cdot A_i = S^+ \cdot (\mathbf{v}_i\mathbf{v}_i^T + \lambda I) = \mathbf{v}_i^T S^+ \mathbf{v}_i + \lambda S^+ \cdot \lambda I \\ \leq \mathbf{v}_i^T S^+ \mathbf{v}_i^T + (r\lambda I)^+ \cdot I = \mathbf{v}_i^T S^+ \mathbf{v}_i^T + \frac{d}{r} = \hat{\tau}_i^S(A).\end{aligned}$$

The above follows by noting that $S \succeq r\lambda I$. It also follows from the definition that $\hat{\tau}^S(A)_i - \tilde{\tau}^S(A)_i \leq \frac{d}{r}$.

In the other case a similar inequality can be shown by noting via the Sherman-Morrison formula that

$$\mathbf{v}_i^T(S+\lambda I+\mathbf{v}_i\mathbf{v}_i^T)^+\mathbf{v}_i = \mathbf{v}_i^T\left((S+\lambda I)^+ - \frac{(S+\lambda I)^+\mathbf{v}_i\mathbf{v}_i^T(S+\lambda I)^+}{1+\mathbf{v}_i^T(S+\lambda I)^+\mathbf{v}_i}\right)\mathbf{v}_i = \frac{1}{1+\frac{1}{\mathbf{v}_i^T(S+\lambda I)^+\mathbf{v}_i^T}}.$$

This proves Equation (12). A direct application of Theorem 21 now finishes the proof. ■

Algorithm 3 REPEATED HALVING

Input: $A = \sum_{i=1}^m (\mathbf{v}_i\mathbf{v}_i^T + \lambda I)$
Output: B **an** $O(d\log(d))$ **size weighted sample of** A **and** $B \preceq A \preceq 2B$
Take a uniformly random unweighted sample of size $\frac{m}{2}$ of A to form A'
if A' has size $> O(d\log(d))$ **then**
  Recursively compute an 2-spectral approximation $\tilde{A}'$ of A'
end if
Compute estimates γ_i of generalized leverage scores $\{\hat{\tau}_i^{A'}(A)\}$ s.t. the following are satisfied

$$\gamma_i \geq \hat{\tau}_i^{A'}(A)$$
$$\sum \gamma_i \leq \sum 16\hat{\tau}_i^{A'}(A) + 1$$

Use these estimates to sample matrices from A to form B

5.3 Algorithms

In the following we formally state the two sub-procedures: Algorithm 4, which solves the required system, and Algorithm 3, which is the sampling routine for reducing the size of the system.

We prove the following theorem regarding the above algorithm REPEATED HALVING (Algorithm 3).

Theorem 23 *REPEATED HALVING (Algorithm 3) produces an* $\tilde{O}(d)$ *sized sample* B *such that* $\frac{B}{2} \preceq A \preceq 2B$ *and can be implemented in total time*

$$\tilde{O}\left(md + d^2 + \sqrt{\kappa_{sample}(O(d\log(d)))d}\right).$$

The $\tilde{O}$ in the above contains factors logarithmic in $m, d, \|A\|_F$. Note that the Frobenius norm of A is bounded by $d\|A\|$ which is bounded in our case by d.

Algorithm 4 Fast Quadratic Solver (FQS)

Input: $A = \sum_{i=1}^m (\mathbf{v}_i\mathbf{v}_i^T + \lambda I)$**,** $\mathbf{b}$**,** ε
Output : $\tilde{\mathbf{v}}$ **s.t.** $\|A^{-1}\mathbf{b} - \tilde{\mathbf{v}}\| \leq \varepsilon$
Compute B s.t. $2B \succeq A \succeq B$ using REPEATED HALVING(Algorithm 3)
$Q(\mathbf{y}) = \frac{\mathbf{y}^T AB^{-1}\mathbf{y}}{2} + \mathbf{b}^T\mathbf{y}$
Compute $\hat{\mathbf{y}}$ such that $\|\hat{\mathbf{y}} - \operatorname{argmin} Q(\mathbf{y})\| \leq \frac{\varepsilon}{4\|B^{-1}\|}$
Output $\tilde{\mathbf{v}}$ such that $\|B^{-1}\hat{\mathbf{y}} - \tilde{\mathbf{v}}\| \leq \varepsilon/2$

We first provide the proof of Theorem 15 using Theorem 23 and then provide the proof for Theorem 23. For the purpose of clarity of discourse we hide the terms that appear due to the probabilistic part of the lemmas. We can take a union bound to bound the total probability of failure, and those terms show up in the log factor.

Proof [Proof of Theorem 15] We will first prove correctness which follows from noting that $\operatorname{argmin}_{\mathbf{y}} Q(\mathbf{y}) = BA^{-1}b$. Therefore we have that

$$\varepsilon/2 \geq \|B^{-1}(\hat{\mathbf{y}} - \operatorname*{argmin}_{\mathbf{y}} Q(\mathbf{y}))\| = \|B^{-1}\hat{\mathbf{y}} - A^{-1}b\|.$$

A simple application of the triangle inequality proves that $\|A^{-1}b - \tilde{\mathbf{v}}\| \leq \varepsilon$.

Running Time Analysis: We now prove that the algorithm can be implemented efficiently. We first note the following two simple facts: since B is a 2-approximation of A, $\kappa(B) \leq 2\kappa(A)$; furthermore, the quadratic $Q(\mathbf{y})$ is 1-strongly convex and 2-smooth. Next, we consider the running time of implementing step 5. For this purpose we will perform gradient descent over the quadratic $Q(\mathbf{y})$. Note that the gradient of $Q(\mathbf{y})$ is given by

$$\nabla Q(\mathbf{y}) = AB^{-1}\mathbf{y} - \mathbf{b}.$$

Let $\mathbf{y}_0 = 0$, $\tilde{\varepsilon} = \left(\frac{\varepsilon}{4\|B^{-1}\|}\right)^2$ and G_Q be a bound on the gradient of the quadratic Q($\mathbf{y}$). Let $\mathbf{v}_t$ and $\mathbf{y}_{t+1}$ be such that

$$\|B^{-1}\mathbf{y}_{t-1} - \mathbf{v}_t\| \leq \frac{\tilde{\varepsilon}}{100\|A\|G_Q}$$

$$\mathbf{y}_{t+1} = \mathbf{y}_t - \eta\left(A\mathbf{v}_t - \mathbf{b}\right).$$

Define $h_t = Q(\mathbf{y}_t) - \min_{\mathbf{y}} Q(\mathbf{y})$. Using the standard analysis of gradient descent, we show that the following holds true for $t > 0$:

$$h_t \leq \max\{\tilde{\varepsilon}, (0.9)^t h_0\}.$$

This follows directly from the gradient descent analysis which we outline below. To make the analysis easier, we define a *true* gradient descent series:

$$\mathbf{z}_{t+1} = \mathbf{y}_t - \eta\nabla Q(\mathbf{y}_t).$$

Note that

$$\|\mathbf{z}_{t+1} - \mathbf{y}_{t+1}\| = \|A\left(\mathbf{v}_t - B^{-1}\mathbf{y}_t\right)\| \leq \frac{\tilde{\varepsilon}}{10G_Q}.$$

We now have that

$$\begin{aligned}
h_{t+1} - h_t &= Q(\mathbf{y}_{t+1}) - Q(\mathbf{y}_t) \\
&\leq \langle\nabla Q(\mathbf{y}_t), \mathbf{y}_{t+1} - \mathbf{y}_t\rangle + \frac{\beta}{2}\|\mathbf{y}_{t+1} - \mathbf{y}_t\|^2 \\
&= \langle\nabla Q(\mathbf{y}_t), \mathbf{z}_{t+1} - y_t\rangle + \langle\nabla Q(\mathbf{y}_t), \mathbf{y}_{t+1} - \mathbf{z}_{t+1}\rangle + \frac{\beta}{2}\|\mathbf{z}_{t+1} - \mathbf{y}_t + \mathbf{y}_{t+1} - \mathbf{z}_{t+1}\|^2 \\
&\leq -\eta\|\nabla Q(\mathbf{y}_t)\|^2 + \langle\nabla Q(\mathbf{y}_t), \mathbf{y}_{t+1} - \mathbf{z}_{t+1}\rangle + \beta\eta^2\|\nabla Q(\mathbf{y}_t)\|^2 + \beta\|\mathbf{y}_{t+1} - \mathbf{z}_{t+1}\|^2 \\
&\leq \frac{1}{\beta}\|\nabla Q(\mathbf{y}_t)\|^2 + \frac{2}{10\beta}\left((\|\nabla Q(\mathbf{y}_t)\| + 1)\tilde{\varepsilon}\right) \\
&\leq -\frac{\alpha}{\beta}h_t + \frac{\tilde{\varepsilon}}{50\beta}
\end{aligned}$$

where $\beta \geq 1$ and $\alpha \leq 2$ are the strong convexity and smoothness parameters of $Q(\mathbf{y})$. Therefore, we have that

$$h_{t+1} \leq 0.75h_t + 0.08\tilde{\varepsilon}.$$

Using the inductive assumption that $\|h_t\| \leq \max\{\tilde{\varepsilon}, (0.9)^t h_0\}$, it follows easily that

$$h_{t+1} \leq \max\{\tilde{\varepsilon}, (0.9)^{t+1} h_0\}.$$

Using the above inequality, it follows that for $t \geq O(\log(\frac{1}{\tilde{\varepsilon}}))$, we have that h_t is less than or equal to $\tilde{\varepsilon}$. By the 1-strong convexity of $Q(\mathbf{y})$, we have that if $h_t \leq \tilde{\varepsilon}$, then

$$\|\mathbf{y}_t - \operatorname*{argmin}_{\mathbf{y}} Q(\mathbf{y})\| \leq \sqrt{\tilde{\varepsilon}} \leq \frac{\varepsilon}{4\|B\|^{-1}}.$$

The running time of the above sub-procedure is bounded by the time to multiply a vector with A, which takes $O(md)$ time, and the time required to compute $\mathbf{v}_t$, which involves solving a linear system in B at each step. Finally, in step 6 we once again compute the solution of a linear system in B. Combining these we get that the total running time is

$$\tilde{O}(md + LIN(B, \hat{\varepsilon}))\log\left(\frac{1}{\tilde{\varepsilon}}\right)$$

where $\hat{\varepsilon} = \frac{\varepsilon}{400\|A\|\|B\|^{-1}G_Q} = \Omega\left(\frac{\varepsilon}{\kappa(A)G_Q}\right)$. Now we can bound $LIN(B, \varepsilon)$ by $\tilde{O}(d^2 + d\sqrt{\kappa(A)d})\log(1/\varepsilon)$ by using Acc-SVRG to solve the linear system and by noting that B is an $O(d\log(d))$ sized 2-approximation sample of A. The bound G_Q can be taken as a bound on the gradient of the quadratic at the start of the procedure, as the norm of gradient only shrinks along the gradient descent path. It is therefore enough to take $G_Q \leq \|b\|$, which finishes the proof. ■

Proof [Proof of Theorem 23]

The correctness of the algorithm is immediate from Theorems 22 and 20. The key challenge in the proof lies in proving that there is an efficient way to implement the algorithm, which we describe next.

Runtime Analysis: To analyze the running time of the algorithm we consider the running time of the computation required in step 7 of the algorithm. We will show that there exists an efficient algorithm to compute numbers γ_i such that

$$\gamma_i \geq \hat{\tau}_i^{A'}(A)$$

$$\sum\gamma_i \leq \sum 16\hat{\tau}_i^{A'}(A) + 8k\varepsilon\|A\|_F^2.$$

First note that by recursion, $\tilde{A}'$ is a 2-spectral approximation of A', and so we have that

$$\hat{\tau}_i^{A'}(A) \leq \hat{\tau}_i^{\tilde{A}'}(A) \leq 2\hat{\tau}_i^{A'}(A).$$

We also know that A' is an $O(d\log(d))$ sized weighted sub-sample of A', and so it is of the form

$$\tilde{A}' = \sum_{i=1}^{O(d\log(d))} \mathbf{v}_i\mathbf{v}_i^T + \lambda I = \sum_{i=1}^{O(d\log(d))} b_i b_i^T$$

where such a decomposition can be achieved easily via decomposing the identity into canonical vectors. Therefore, any such $\tilde{A}'$ can be written as BB^T, where the columns of B are b_i.

To compute $\hat{\tau}_i^{\tilde{A}'}(A)$, we need to compute the value of $\mathbf{v}_i^T(\tilde{A}')^+\mathbf{v}_i = \|B^T(\tilde{A}')^+\mathbf{v}_i\|_2^2$. Indeed, computing this directly for all vectors v_i may be inefficient, but one can compute a constant approximation using the following procedure outlined by Cohen et al. (2015).

To compute a constant approximation, we randomly sample a Gaussian matrix G consisting of k rows and compute instead the norms $\gamma'(i) = \|GB^T(\tilde{A}')^+\mathbf{v}_i\|_2^2$. By the Johnson-Lindenstrauss lemma, setting $k = O(\log(md))$, we have that with high probability,

$$1/2\|B^T(\tilde{A}')^+\mathbf{v}_i\|_2^2 \leq \gamma'(i) \leq 2\|B^T(\tilde{A}')^+\mathbf{v}_i\|_2^2.$$

Consider the following procedure for the computation of $\gamma'(i)$:

1. Compute the matrix $G' = GB^T$ first which takes $\tilde{O}(kd^2)$ time.
2. For each row G'_i of G' compute a vector G''_i such that $\|G''_i - G'_i\tilde{A}'^+\|^2 \leq \varepsilon$. This takes a total time of $kLIN(\tilde{A}', \varepsilon)$.
3. For each v_i compute $\gamma''_i \triangleq \sum_{j=1}^k < G''_j, \mathbf{v}_i >^2$. This takes a total time of $O(kmd)$.

Here, $LIN(S, \varepsilon)$ is the running time of solving a linear system in S with error ε. Therefore, substituting $k = O(\log(md))$, the total running time of the above algorithm is

$$O(md + d^2 + LIN(\tilde{A}', \varepsilon)).$$

It is now easy from the definitions of γ''_i and γ'_i to see that

$$\gamma''_i \in \left[\gamma'_i - k\varepsilon\|\mathbf{v}_i\|^2, \gamma'_i + k\varepsilon\|\mathbf{v}_i\|^2\right].$$

Setting $\gamma_i = 4(\gamma''_i + k\varepsilon\|\mathbf{v}_i\|^2)$, it follows from the definitions that

$$\gamma_i \geq \hat{\tau}_i^{A'}(A)$$

$$\sum \gamma_i \leq \sum 16\hat{\tau}_i^{A'}(A) + 8k\varepsilon\|A\|_F^2.$$

Now setting $\varepsilon = \frac{1}{8k\|V\|_F^2}$ satisfies the required inequality for γ_i. This implies that when sampling from γ_i, we will have a 2-approximation, and the number of matrices will be bounded by $O(d\log(d))$.

To solve the linear systems required above we use Accelerated SVRG (Theorem 4) which ensures that the running time of $LIN(S, \varepsilon) \leq \tilde{O}(d^2 + d\sqrt{\kappa(S)d})\log(\frac{1}{\varepsilon})$. This follows by noting that in our case S is a sum of $O(d\log(d))$ matrices. To bound the condition number of S, note that it is a 2-approximation of some unweighted sample of the matrix A of size greater than $O(d\log(d))$. Therefore, we have that $\kappa(S) \leq \kappa_{sample}(A)$.

Putting the above arguments together we get that the total running time of the procedure is bounded by

$$\tilde{O}(md + (d^2 + d\sqrt{\kappa_{sample(A)}d})),$$

which proves the theorem. ■

6. Condition Number Independent Algorithms

In this section we state our main result regarding self-concordant functions and provide the proof. The following is the definition of a self-concordant function:

Definition 24 (Self-Concordant Functions) *Let $\mathcal{K} \subseteq \mathbb{R}^n$ be a non-empty open convex set, and let $f : \mathcal{K} \mapsto \mathbb{R}$ be a C^3 convex function. Then, f is said to be self-concordant if*

$$|\nabla^3 f(\mathbf{x})[\mathbf{h}, \mathbf{h}, \mathbf{h}]| \leq 2(\mathbf{h}^\top \nabla^2 f(\mathbf{x})\mathbf{h})^{3/2},$$

where we have

$$\nabla^k f(\mathbf{x})[\mathbf{h}_1, \ldots, \mathbf{h}_k] \triangleq \frac{\partial^k}{\partial t_1 \ldots \partial t_k}|_{t_1=\cdots=t_k} f(\mathbf{x} + t_1\mathbf{h}_1 + \cdots + t_k\mathbf{h}_k).$$

Our main theorem regarding self-concordant functions is as follows:

Theorem 25 *Let $0 < r < 1$, let $\gamma \geq 1$, and let ν be a constant depending on γ, r. Set $\eta = 10(1-r)^2$, $S_1 = c_r = \frac{50}{(1-r)^4}$, where c_r is a constant depending on r, and $T = \frac{f(\mathbf{x}_1) - f(\mathbf{x}^*)}{\nu}$. Then, after $t > T$ steps, the following linear convergence guarantee holds between two full gradient steps for Algorithm 5:*

$$\mathbf{E}\left[f(w_s) - f(w^*)\right] \leq \frac{1}{2}\mathbf{E}\left[f(w_{s-1}) - f(w^*)\right].$$

Moreover, the time complexity of each full gradient step is $O(md + c_r d^2)$, where c_r is a constant depending on r (independent of the condition number).

To describe the algorithm we first present the requisite definitions regarding self-concordant functions.

6.1 Self-Concordant Functions Preliminaries

An excellent reference for this material is the lecture notes on this subject by Nemirovski (2004).

A key object in the analysis of self-concordant functions is the notion of a Dikin ellipsoid, which is the unit ball around a point $\mathbf{x}$ in the norm given by the Hessian $\|\cdot\|_{\nabla^2 f(\mathbf{x})}$ at the point. We will refer to this norm as the *local norm* around a point and denote it as $\|\cdot\|_{\mathbf{x}}$. Formally, we have:

Definition 26 (Dikin ellipsoid) *The Dikin ellipsoid of radius r centered at a point $\mathbf{x}$ is defined as*

$$W_r(\mathbf{x}) \triangleq \{\mathbf{y} \mid \|\mathbf{y} - \mathbf{x}\|_{\nabla^2 f(\mathbf{x})} \leq r\}.$$

One of the key properties of self-concordant functions is that inside the Dikin ellipsoid, the function is well conditioned with respect to the local norm at the center, and furthermore, the function is smooth. The following lemmas makes these notions formal, and the proofs of these lemmas can be found in the lecture notes of Nemirovski (2004).

Lemma 27 (Nemirovski 2004) *For all* $\mathbf{h}$ *such that* $\|\mathbf{h}\|_{\mathbf{x}} < 1$ *we have that*

$$(1 - \|\mathbf{h}\|_{\mathbf{x}})^2 \nabla^2 f(\mathbf{x}) \preceq \nabla^2 f(\mathbf{x} + \mathbf{h}) \preceq \frac{1}{(1 - \|\mathbf{h}\|_{\mathbf{x}})^2} \nabla^2 f(\mathbf{x}).$$

Lemma 28 (Nemirovski 2004) *For all* $\mathbf{h}$ *such that* $\|\mathbf{h}\|_{\mathbf{x}} < 1$ *we have that*

$$f(\mathbf{x} + \mathbf{h}) \leq f(\mathbf{x}) + \langle \nabla f(\mathbf{x}), \mathbf{h} \rangle + \rho\left(\|\mathbf{h}\|_{\mathbf{x}}\right)$$

where $\rho(x) \triangleq -\ln(1 - x) - x$.

Another key quantity which is used both as a potential function as well as a dampening for the step size in the analysis of Newton's method in general is the Newton decrement which is defined as $\lambda(\mathbf{x}) \triangleq \|\nabla f(\mathbf{x})\|_{\mathbf{x}}^* = \sqrt{\nabla f(\mathbf{x})^\top \nabla^{-2} f(\mathbf{x}) \nabla f(\mathbf{x})}$. The following lemma quantifies how $\lambda(\mathbf{x})$ behaves as a potential by showing that once it drops below 1, it ensures that the minimum of the function lies in the current Dikin ellipsoid. This is the property which we use crucially in our analysis.

Lemma 29 (Nemirovski 2004) *If* $\lambda(\mathbf{x}) < 1$ *then*

$$\|\mathbf{x} - \mathbf{x}^*\|_{\mathbf{x}} \leq \frac{\lambda(\mathbf{x})}{1 - \lambda(\mathbf{x})}.$$

6.2 Condition Number Independent Algorithms

In this section we describe an efficient linearly convergent method (Algorithm 5) for optimization of self-concordant functions for which the running time is independent of the condition number. We have not tried to optimize the complexity of the algorithms in terms of d as our main focus is to make it condition number independent.

The key idea here is the ellipsoidal view of Newton's method, whereby we show that after making a constant number of full Newton steps, one can identify an ellipsoid and a norm such that the function is well conditioned with respect to the norm in the ellipsoid. This is depicted in Figure 1.

At this point one can run any desired first-order algorithm. In particular, we choose SVRG and prove its fast convergence. Algorithm 6 (described in the appendix) states the modified SVRG routine for general norms used in Algorithm 5.

We now state and prove the following theorem regarding the convergence of Algorithm 5.

Proof It follows from Lemma 31 that at $t = \frac{f(\mathbf{x}_1) - f(\mathbf{x}^*)}{\nu}$, the minimizer is contained in the Dikin ellipsoid of radius r, where ν is a constant depending on γ, r. This fact, coupled with Lemma 30, shows that the function satisfies the following property with respect to $W_{\mathbf{x}_t}$:

$$\forall \mathbf{x} \in W_{\mathbf{x}_t} \;\; (1 - r)^2 \nabla^2 f(\mathbf{x}_T) \preceq \nabla^2 f(\mathbf{x}) \preceq (1 - r)^{-2} \nabla^2 f(\mathbf{x}_T).$$

Using the above fact along with Lemma 32, and substituting for the parameters, concludes the proof. ■

We describe the Algorithm N-SVRG (Algorithm 6 in the appendix). Since the algorithm and the following lemmas are minor variations of their original versions, we include the proofs of the following lemmas in the appendix for completeness.

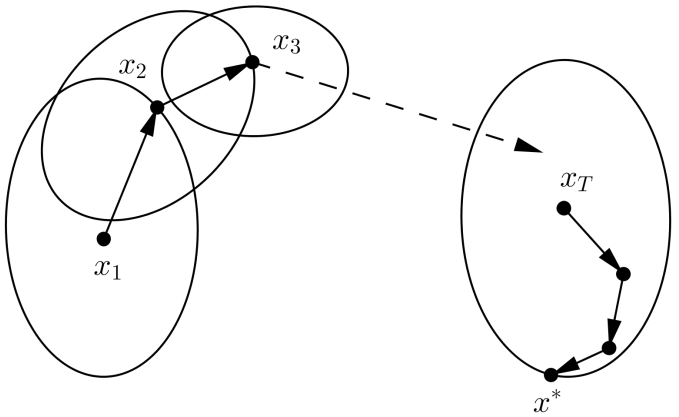

Figure 1: Visualization of the steps taken in Algorithm 5.

Lemma 30 *Let* f *be a self-concordant function over* $\mathcal{K}$*, let* $0 < r < 1$*, and consider* $\mathbf{x} \in \mathcal{K}$*. Let* $W_r(\mathbf{x})$ *be the Dikin ellipsoid of radius* r*, and let* $\alpha = (1 - r)^2$ *and* $\beta = (1 - r)^{-2}$*. Then, for all* $\mathbf{h}$ *s.t.* $\mathbf{x} + \mathbf{h} \in W_r(\mathbf{x})$*,*

$$\alpha \nabla^2 f(\mathbf{x}) \preceq \nabla^2 f(\mathbf{x} + \mathbf{h}) \preceq \beta \nabla^2 f(\mathbf{x}).$$

Lemma 31 *Let* f *be a self-concordant function over* $\mathcal{K}$*, let* $0 < r < 1$*, let* $\gamma \geq 1$*, and consider following the damped Newton step as described in Algorithm 5 with initial point* $\mathbf{x}_1$*. Then, the number of steps* t *of the algorithm before the minimizer of* f *is contained in the Dikin ellipsoid of radius* r *of the current iterate, i.e.* $\mathbf{x}^* \in W_r(\mathbf{x}_t)$*, is at most* $t = \frac{f(\mathbf{x}_1) - f(\mathbf{x}^*)}{\nu}$*, where* ν *is a constant depending on* γ, r*.*

Algorithm 5 ellipsoidCover

Input : Self-concordant $f(\mathbf{x}) = \sum_{i=1}^{m} f_i(\mathbf{x})$, T, $r \in \{0, 1\}$, initial point $\mathbf{x}_1 \in \mathcal{K}$, $\gamma > 1$, S_1, η, T

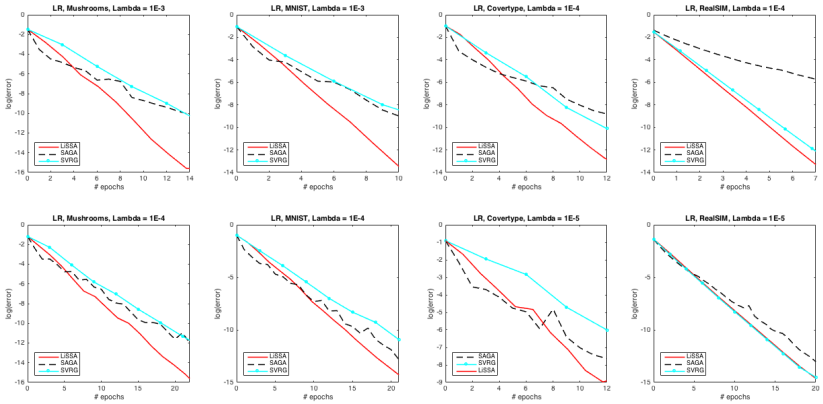

Figure 2: Performance of LiSSA as compared to a variety of related optimization methods for different data sets and choices of regularization parameter λ. $S_1 = 1$, $S_2 \sim \kappa \ln(\kappa)$.

Lemma 32 *Let f be a convex function. Suppose there exists a convex set $\mathcal{K}$ and a positive semidefinite matrix A such that for all $\mathbf{x} \in \mathcal{K}$, $\alpha A \preceq \nabla^2 f(\mathbf{x}) \preceq \beta A$. Then the following holds between two full gradient steps of Algorithm 6:*

$$\mathbf{E}\left[f(\mathbf{x}_s) - f(\mathbf{x}^*)\right] \leq \left(\frac{1}{\alpha\eta(1-2\eta\beta)n} + \frac{2\eta\beta}{(1-2\eta\beta)}\right)\mathbf{E}\left[f(\mathbf{x}_{s-1}) - f(\mathbf{x}^*)\right].$$

7. Experiments

In this section we present experimental evaluation for our theoretical results.[7] We perform the experiments for a classification task over two labels using the logistic regression (LR) objective function with the ℓ_2 regularizer. For all of the classification tasks we choose two values of λ:$\frac{1}{m}$ and $\frac{10}{m}$, where m is the number of training examples. We perform the above classification tasks over four data sets: MNIST, CoverType, Mushrooms, and RealSIM. Figure 2 displays the log-error achieved by LiSSA as compared to two standard first-order algorithms, SVRG and SAGA (Johnson and Zhang, 2013; Defazio et al., 2014), in terms of the number of passes over the data. Figure 3 presents the performance of LiSSA as compared to NewSamp (Erdogdu and Montanari, 2015) and standard Newton's method with respect to both time and iterations.

7. Our code for LiSSA can be found here: `https://github.com/brianbullins/lissa_code`.

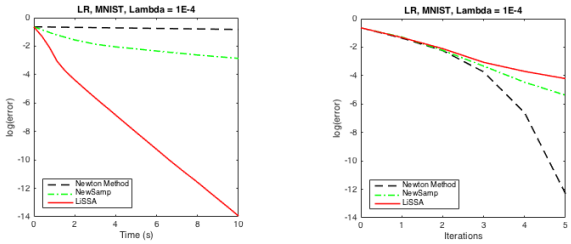

Figure 3: Convergence of LiSSA over time/iterations for logistic regression with MNIST, as compared to NewSamp and Newton's method.

7.1 Experiment Details

In this section we describe our experiments and choice of parameters in detail. Table 2 provides details regarding the data sets chosen for the experiments. To make sure our functions are scaled such that the norm of the Hessian is bounded, we scale the above data set points to unit norm.

Table 2: A description of data sets used in the experiments.

Data set	m	d	Reference
MNIST4-9	11791	784	LeCun and Cortes (1998)
Mushrooms	8124	112	Lichman (2013)
CoverType	100000	54	Blackard and Dean (1999)
RealSIM	72309	20958	McCallum (1997)

7.2 Comparison with Standard Algorithms

In Figures 2 and 4 we present comparisons between the efficiency of our algorithm with different standard and popular algorithms. In both cases we plot $\log(CurrentValue - OptimumValue)$. We obtained the optimum value for each case by running our algorithm for a long enough time until it converged to the point of machine precision.

Epoch Comparison: In Figure 2, we compare LiSSA with SVRG and SAGA in terms of the accuracy achieved versus the number of passes over the data. To compute the number of passes in SVRG and SAGA, we make sure that the inner stochastic gradient iteration in both the algorithms counts as exactly one pass. This is done because although it accesses gradients at two different points, one of them can be stored from before in both cases. The outer full gradient in SVRG counts as one complete pass over the data. We set the number of inner iterations of SVRG to $2m$ for the case when $\lambda = 1/m$, and we parameter tune the number of inner iterations when $\lambda = 10/m$. The stepsizes for all of the algorithms are parameter tuned by an exhaustive search over the parameters.

Time Comparison: For the comparison with respect to time (Figure 4), we consider the following algorithms: AdaGrad (Duchi et al., 2011), BFGS (Broyden, 1970; Fletcher, 1970;

Goldfarb, 1970; Shanno, 1970), gradient descent, SGD, SVRG (Johnson and Zhang, 2013) and SAGA (Defazio et al., 2014). The $\log(Error)$ is plotted as a function of the time elapsed from the start of the run for each algorithm. We next describe our choice of parameters for the algorithms. For AdaGrad we used the faster diagonal scaling version proposed by Duchi et al. (2011). We implemented the basic version of BFGS with backtracking line search. In each experiment for gradient descent, we find a reasonable step size using parameter tuning. For stochastic gradient descent, we use the variable step size $\eta_t = \gamma/\sqrt{t}$ which is usually the prescribed step size, and we hand tune the parameter γ. The parameters for SVRG and SAGA were chosen in the same way as before.

Choice of Parameters for LiSSA: To pick the parameters for our algorithm, we observe that it exhibits smooth behavior even in the case of $S_1 = 1$, so this is used for the experiments. However, we observe that increasing S_2 has a positive effect on the convergence of the algorithm up to a certain point, as a higher S_2 leads to a larger per-iteration cost. This behavior is consistent with the theoretical analysis. We summarize the comparison between the per-iteration convergence and the value of S_2 in Figure 5. As the theory predicts S_2 to be of the order $\kappa \ln(\kappa)$, for our experiments we determine an estimate for κ and set S_2 to around $\kappa \ln(\kappa)$. This value is typically equal to m in our experiments. We observe that setting S_2 in this way resulted in the experimental results displayed in Figure 2.

Comparison with Second-Order Methods: Here we present details about the comparison between LiSSA, NewSamp (Erdogdu and Montanari, 2015), and standard Newton's method, as displayed in Figure 3. We perform this experiment on the MNIST data set and show the convergence properties of all three algorithms over time as well as over iterations. We could not replicate the results of NewSamp on all of our data sets as it sometimes seems to diverge in our experiments. For logistic regression on the MNIST data set, we could get it to converge by setting the value of S_1 to be slightly higher. We observe as is predicted by the theory that when compared in terms of the number of iterations, NewSamp and LiSSA perform similarly, while Newton's method performs the best as it attains a quadratic convergence rate. This can be seen in Figure 3. However, when we consider the performance in terms of time for these algorithms, we see that LiSSA has a significant advantage.

Comparison with Accelerated First-Order Methods: Here we present experimental results comparing LiSSA with a popular accelerated first-order method, APCG (Lin et al., 2014), as seen in Figure 6. We ran the experiment on the RealSIM data set with three settings of $\lambda = 10^{-5},\ 10^{-6},\ 10^{-7}$, to account for the high condition number setting. We observe a trend that can be expected from the runtime guarantees of the algorithms. When λ is not too low, LiSSA performs better than APCG, but as λ gets very low we see that APCG performs significantly better than LiSSA. This is not surprising when considering that the running time of APCG grows proportional to $\sqrt{\kappa m}$, whereas for LiSSA the running time can at best be proportional to κ. We note that for accelerated first-order methods to be useful, one needs the condition number to be quite large which is not often the case for applications. Nevertheless, we believe that an algorithm with running time guarantees similar to LiSSA-Sample can get significant gains in these settings, and we leave this exploration as future work.

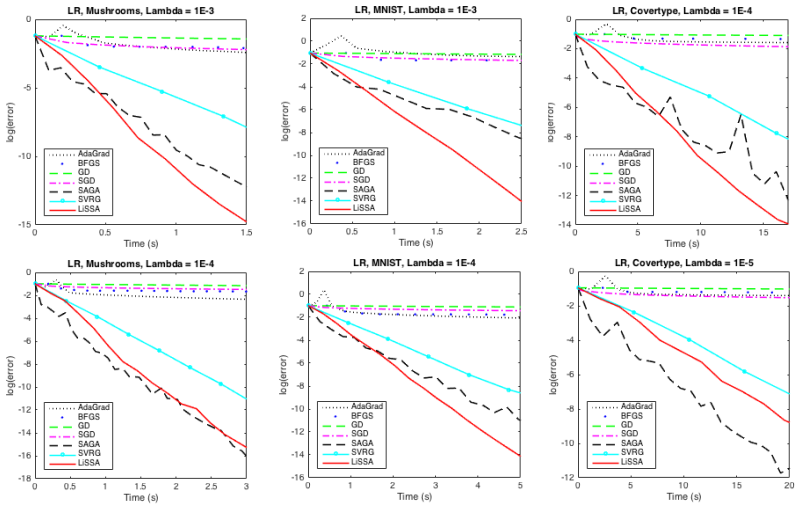

Figure 4: Performance of LiSSA as compared to a variety of related optimization methods for different data sets and choices of regularization parameter λ. $S_1 = 1$, $S_2 \sim \kappa \ln(\kappa)$.

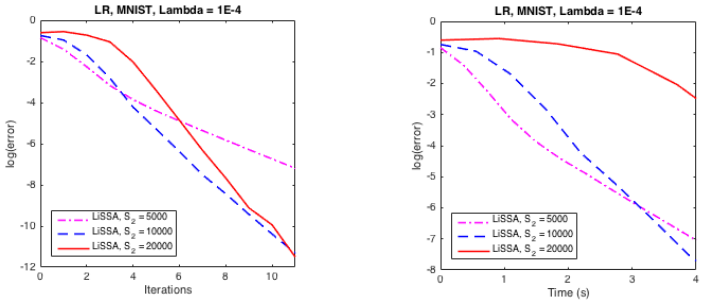

Figure 5: Differing convergence rates for LiSSA based on different choices of the S_2 parameter.

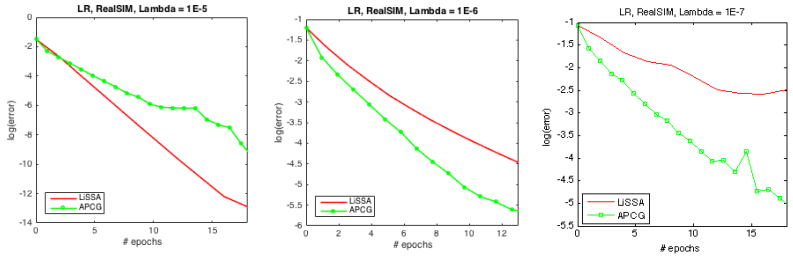

Figure 6: Comparison with accelerated first-order methods in ill-conditioned settings.

Acknowledgments

The authors would like to thank Zeyuan Allen-Zhu, Dan Garber, Haipeng Luo and David McAllester for several illuminating discussions and suggestions. We would especially like to thank Aaron Sidford and Yin Tat Lee for discussions regarding the matrix sampling approach.

Appendix A. Remaining Proofs

Here we provide proofs for the remaining lemmas.

A.1 Proof of Lemma 20

Proof The proof is almost identical to the proof of Lemma 4 by Cohen et al. (2015). As in there we will use the following lemma on matrix concentration, which appears as Lemma 11 in the work of Cohen et al. (2015).

Lemma 33 (Cohen et al. 2015) *Let $Y_1 \dots Y_k$ be independent random positive semidefinite matrices of size $d \times d$. Let $Y = \sum Y_i$ and let $Z = E[Y]$. If $Y_i \preceq R \cdot Z$, then*

$$P\left[\sum Y_i \preceq (1-\varepsilon)Z\right] \leq de^{\frac{\varepsilon^2}{2R}}$$

$$P\left[\sum Y_i \succeq (1+\varepsilon)Z\right] \leq de^{\frac{\varepsilon^2}{3R}}.$$

For every matrix A_i choose $Y_i = \frac{A_i}{p_i}$ with probability p_i and 0 otherwise. Therefore we need to bound $\sum Y_i$. Note that $E[Y_i] = A$. We will now show that

$$\forall i \;\; Y_i \preceq \frac{1}{c \log d \varepsilon^{-2}} A$$

which will finish the proof by a direct application of Lemma 33. First we will show that

$$\frac{A_i}{\tau_i(A)} \preceq A.$$

We need to show that $\forall \mathbf{x}\ \mathbf{x}^T A_i \mathbf{x} \leq \tau_i(A) \mathbf{x}^T A \mathbf{x}$. By noting that the A_i are PSD we have that if $\mathbf{x}^T A \mathbf{x} = 0$ then $\forall i, \mathbf{x}^T A_i \mathbf{x} = 0$. We can now consider $\mathbf{x} = A^{+/2}\mathbf{y}$. Therefore, we need to show that

$$\mathbf{y} A^{+/2} A_i A^{+/2} \mathbf{y} \leq \tau_i(A) \|y\|^2.$$

This is true because the maximum eigenvalue of $A^{+/2} A_i A^{+/2}$ is bounded by its $Trace(A^{+/2} A_i A^{+/2})$ (due to positive semidefiniteness), which is equal to $\tau_i(A)$ by definition. Therefore when $p_i < 1$, i.e., $\alpha c \mathbf{u}_i \log(d) < 1$, the facts $\tau_i(A) \leq \mathbf{u}_i$ immediately provide

$$Y_i \preceq \frac{1}{c \log d \varepsilon^{-2}} A.$$

When $p_i = 1$ the above does not hold, but we can essentially replace $Y_i = A_i$ with $c \log d \varepsilon^{-2}$ variables each equal to $\frac{A_i}{c \log d \varepsilon^{-2}}$, each being sampled with probability 1. This does not change $E[\sum Y_i]$ but proves concentration. Now a direct application of Lemma 33 finishes the proof. Also note that a standard Chernoff bound proves the required bound on the sample size. ■

A.2 Proof of Lemma 21

Proof The proof is almost identical to the proof of Theorem 1 by Cohen et al. (2015). We include the proof here for completeness. Define S_i to be S if $\exists j$ such that $X_j = A_i$, and $S + A_i$ otherwise. Now since $S^i \preceq A$, we have that $\tilde{\tau}_i^S(A) \geq \tau_i(A)$. To bound the expected sum we break it down into two parts:

$$\sum_i \tilde{\tau}_i^S(A) = \sum_{i \in S} \tilde{\tau}_i^S(A) + \sum_{i \notin S} \tilde{\tau}_i^S(A).$$

The first part is a sum of the leverage scores of S, and so it is bounded by d. To bound the second term, consider a random process that first selects S, then selects a random $i \notin S$ and returns $\tilde{\tau}_i^S(A)$. There are always exactly $m - r$ such i, so the value returned by this random process is, in expectation, exactly equal to $\frac{1}{m-r} E[\sum_{i \notin S} \tilde{\tau}_i^S(A)]$. This random process is also equivalent to randomly selecting a set S of size $r + 1$, then randomly choosing an $i \in S'$ and returning its leverage score. In expectation it is therefore equal to the average leverage score in S. S' has size $r + 1$, and its leverage scores sum to its rank, so we can bound its average leverage score by $\frac{d}{r+1}$. Overall, we have that

$$E[\sum_i \tilde{\tau}_i^S(A)] = d + \frac{d(m-r)}{r+1} \leq O\left(\frac{md}{r}\right).$$

■

A.3 Proof of Ellipsoidal Cover Lemma

Proof [Proof of Lemma 31] Let $\lambda(\mathbf{x})$ be the Newton decrement at $\mathbf{x}$. By Lemma 29, we know that if $\lambda(\mathbf{x}) \leq \frac{r}{1+r} < 1$, then

$$||\mathbf{x} - \mathbf{x}^*||_{\mathbf{x}} \leq \frac{\lambda(\mathbf{x})}{1 - \lambda(\mathbf{x})} = r.$$

Consider a single iteration of the algorithm at time t. If $\lambda(\mathbf{x}_t) \leq \frac{r}{1+r}$, then we may conclude that $\mathbf{x}^* \in W_r(\mathbf{x}_t)$. Therefore, it is only when $\lambda(\mathbf{x}_t) > \frac{r}{1+r}$ that $\mathbf{x}^*$ may not be contained within $W_r(\mathbf{x}_t)$. Since our update is of the form

$$\mathbf{x}_{t+1} = \mathbf{x}_t - \frac{1}{\gamma(1 + \lambda(\mathbf{x}_t))} \nabla^{-2} f(\mathbf{x}_t) \nabla f(\mathbf{x}_t),$$

we have the following:

$$\begin{aligned}
f(\mathbf{x}_{t+1}) &\leq f(\mathbf{x}_t) - \frac{1}{\gamma(1 + \lambda(\mathbf{x}_t))} \nabla f(\mathbf{x}_t)^\top ([\nabla^2 f(\mathbf{x}_t)]^{-1} \nabla f(\mathbf{x}_t)) + \rho\left(\frac{\lambda(\mathbf{x}_t)}{\gamma(1 + \lambda(\mathbf{x}_t))}\right) \\
&= f(\mathbf{x}_t) - \frac{(\lambda(\mathbf{x}_t))^2}{\gamma(1 + \lambda(\mathbf{x}_t))} + \rho\left(\frac{\lambda(\mathbf{x}_t)}{\gamma(1 + \lambda(\mathbf{x}_t))}\right) \\
&= f(\mathbf{x}_t) - \frac{(\lambda(\mathbf{x}_t))^2}{\gamma(1 + \lambda(\mathbf{x}_t))} - \ln\left(1 - \frac{\lambda(\mathbf{x}_t)}{\gamma(1 + \lambda(\mathbf{x}_t))}\right) - \frac{\lambda(\mathbf{x}_t)}{\gamma(1 + \lambda(\mathbf{x}_t))} \\
&= f(\mathbf{x}_t) - \frac{\lambda(\mathbf{x}_t)}{\gamma} + \ln\left(1 + \frac{\lambda(\mathbf{x}_t)}{\gamma + (\gamma - 1)\lambda(\mathbf{x}_t)}\right)
\end{aligned}$$

where the first inequality follows from Lemma 28. It now follows that

$$\begin{aligned}
f(\mathbf{x}_t) - f(\mathbf{x}_{t+1}) &\geq \frac{\lambda(\mathbf{x}_t)}{\gamma} - \ln\left(1 + \frac{\lambda(\mathbf{x}_t)}{\gamma + (\gamma - 1)\lambda(\mathbf{x}_t)}\right) \\
&\geq \frac{\lambda(\mathbf{x}_t)}{\gamma} - \frac{\lambda(\mathbf{x}_t)}{\gamma + (\gamma - 1)\lambda(\mathbf{x}_t)} \\
&= \lambda(\mathbf{x}_t)\left(\frac{1}{\gamma} - \frac{1}{\gamma + (\gamma - 1)\lambda(\mathbf{x}_t)}\right) \\
&> \frac{r}{1+r}\left(\frac{1}{\gamma} - \frac{1}{\gamma + \frac{(\gamma-1)r}{1+r}}\right) \\
&> 0
\end{aligned}$$

where the second inequality comes from the fact that, for all $x \in \mathbb{R}$, $\ln(1 + x) \leq 1 + x$. Let $\nu = \frac{r}{1+r}\left(\frac{1}{\gamma} - \frac{1}{\gamma + \frac{(\gamma-1)r}{1+r}}\right)$. Then we see that after

$$\frac{f(\mathbf{x}_1) - f(\mathbf{x}^*)}{\nu}$$

steps, we can guarantee that we have arrived at $\mathbf{x}_t$ such that $\mathbf{x}^* \in W_r(\mathbf{x}_t)$. ■

A.4 Proof of SVRG Lemma

Proof [Proof of Lemma 32] The proof follows the original proof of SVRG (Johnson and Zhang, 2013) with a few modifications to take the general norm into account. For any i, consider

$$g_i(\mathbf{x}) = f_i(\mathbf{x}) - f_i(\mathbf{x}^*) - \langle \nabla f_i(\mathbf{x}^*), \mathbf{x} - \mathbf{x}^* \rangle.$$

We know that $g_i(\mathbf{x}^*) = \min_{\mathbf{x}} g_i(\mathbf{x})$ since $\nabla g_i(\mathbf{x}^*) = 0$. Therefore,

$$\begin{aligned} 0 = g_i(\mathbf{x}^*) &\leq \min_{\eta} \left(g_i(\mathbf{x} - \eta A^{-1} \nabla g_i(\mathbf{x}^*)) \right) \\ &\leq \min_{\eta} \left(g_i(\mathbf{x}) - \eta \|g_i(\mathbf{x})\|^2_{A^{-1}} + 0.5\beta\eta^2 \|g_i(\mathbf{x})\|^2_{A^{-1}} \right) \\ &= g_i(\mathbf{x}) - \frac{1}{2\beta} \|g_i(\mathbf{x})\|^2_{A^{-1}} \ . \end{aligned}$$

The second inequality follows from smoothness of g_i, where we note that g_i is as smooth as f_i. Summing the above inequality over i and setting $\mathbf{x}^*$ to be the minimum of f so that $\nabla f(\mathbf{x}^*) = 0$, we get

$$\frac{\sum_{i=1}^m \|\nabla f_i(\mathbf{x}) - \nabla f_i(\mathbf{x}^*)\|^2_{A^{-1}}}{2m\beta} \leq f(\mathbf{x}) - f(\mathbf{x}^*).$$

Define $v_t = \nabla f_{i_t}(\mathbf{x}_{t-1}) - \nabla f_{i_t}(\tilde{\mathbf{x}}) + \tilde{\mu}$. Conditioned on $\mathbf{x}_{t-1}$, we can take the expectation with respect to i_t and obtain

$$\begin{aligned} \mathbf{E}\left[\|v_t\|^2_{A^{-1}}\right] &\leq 2\mathbf{E}\left[\|\nabla f_{i_t}(\mathbf{x}_{t-1}) - \nabla f_{i_t}(\mathbf{x}^*)\|^2_{A^{-1}}\right] + 2\mathbf{E}\left[\|\nabla f_{i_t}(\tilde{\mathbf{x}}) - \nabla f_{i_t}(\mathbf{x}^*) - \nabla f(\tilde{\mathbf{x}})\|^2_{A^{-1}}\right] \\ &\leq 2\mathbf{E}\left[\|\nabla f_{i_t}(\mathbf{x}_{t-1}) - \nabla f_{i_t}(\mathbf{x}^*)\|^2_{A^{-1}}\right] + 2\mathbf{E}\left[\|\nabla f_{i_t}(\tilde{\mathbf{x}}) - \nabla f_{i_t}(\mathbf{x}^*)\|^2_{A^{-1}}\right] \\ &\leq 4\beta \left(f(\mathbf{x}_{t-1}) - f(\mathbf{x}^*) + f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*) \right). \end{aligned}$$

The above inequalities follow by noting the following three facts:

- $\|a+b\|^2_{A^{-1}} \leq 2\|a\|^2_{A^{-1}} + 2\|b\|^2_{A^{-1}}$.
- $\tilde{\mu} = \nabla f(\tilde{\mathbf{x}})$.
- $\mathbf{E}\left[\|X - \mathbf{E}X\|^2_{A^{-1}}\right] \leq \mathbf{E}\|X\|^2_{A^{-1}}$.

Now note that conditioned on $\mathbf{x}_{t-1}$, we have that $\mathbf{E}v_t = \nabla f(\mathbf{x}_{t-1})$, and so

$$\begin{aligned} \mathbf{E}\|\mathbf{x}_t - \mathbf{x}^*\|^2_A &\leq \|\mathbf{x}_{t-1} - \eta A^{-1} v_t - \mathbf{x}^*\|^2_A \\ &= \|\mathbf{x}_{t-1} - \mathbf{x}^*\|^2_A - 2\eta\langle \mathbf{x}_{t-1} - \mathbf{x}^*, AA^{-1}\mathbf{E}v_t\rangle + \eta^2 \mathbf{E}\|v_t\|^2_{A^{-1}} \\ &\leq \|\mathbf{x}_{t-1} - \mathbf{x}^*\|^2_A - 2\eta\langle \mathbf{x}_{t-1} - \mathbf{x}^*, \nabla f(\mathbf{x}_{t-1})\rangle + 4\beta\eta^2 \left(f(\mathbf{x}_{t-1}) - f(\mathbf{x}^*) + f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*) \right) \\ &\leq \|\mathbf{x}_{t-1} - \mathbf{x}^*\|^2_A - 2\eta \left(f(\mathbf{x}_{t-1}) - f(\mathbf{x}^*) \right) + 4\beta\eta^2 \left(f(\mathbf{x}_{t-1}) - f(\mathbf{x}^*) + f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*) \right) \\ &= \|\mathbf{x}_{t-1} - \mathbf{x}^*\|^2_A - 2\eta(1 - 2\eta\beta) \left(f(\mathbf{x}_{t-1}) - f(\mathbf{x}^*) \right) + 4\beta\eta^2 \left(f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*) \right). \end{aligned}$$

The first inequality uses the Pythagorean inequality for norms, the second inequality uses the derived inequality for $\mathbf{E}\|v_t\|^2_{A^{-1}}$, and the third inequality uses the convexity of $f(\mathbf{x})$. Consider a fixed stage s, so that $\tilde{\mathbf{x}} = \tilde{\mathbf{x}}_{s-1}$ and $\tilde{\mathbf{x}}_s$ are selected after all of the updates have been completed. By summing the previous inequality over t and taking an expectation over the history, we get

$$\begin{aligned} \mathbf{E}\|\mathbf{x}_n - \mathbf{x}^*\|^2_A + 2\eta(1 - 2\eta\beta)n\mathbf{E}\left[f(\mathbf{x}_s) - f(\mathbf{x}^*)\right] &\leq \mathbf{E}\|\mathbf{x}_0 - \mathbf{x}^*\|^2_A + 4\beta n\eta^2 \mathbf{E}\left[f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*)\right] \\ &= \|\tilde{\mathbf{x}} - \mathbf{x}^*\|^2_A + 4\beta n\eta^2 \mathbf{E}\left[f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*)\right] \\ &\leq 2\frac{\mathbf{E}\left[f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*)\right]}{\alpha} + 4\beta n\eta^2 \mathbf{E}\left[f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*)\right] \\ &= 2\left(\frac{1}{\alpha} + 2\beta n\eta^2\right) \mathbf{E}\left[f(\tilde{\mathbf{x}}) - f(\mathbf{x}^*)\right]. \end{aligned}$$

The second inequality uses the strong convexity property. Therefore, we have that

$$\mathbf{E}\left[f(\mathbf{x}_s) - f(\mathbf{x}^*)\right] \leq \left(\frac{1}{\alpha\eta(1 - 2\eta\beta)n} + \frac{2\eta\beta}{(1 - 2\eta\beta)}\right) \mathbf{E}\left[f(\mathbf{x}_{s-1}) - f(\mathbf{x}^*)\right].$$

Abstract

Dynamical systems comprising of multiple components that can be partitioned into distinct *blocks* originate in many scientific areas. A pertinent example is the interactions between financial assets and selected macroeconomic indicators, which has been studied at *aggregate level*—e.g. a stock index and an employment index—extensively in the macroeconomics literature. A key shortcoming of this approach is that it ignores potential influences from other related components (e.g. Gross Domestic Product) that may impact the system's dynamics and structure and thus produces incorrect results. To mitigate this issue, we consider a multi-block linear dynamical system with Granger-causal ordering between blocks, wherein the blocks' temporal dynamics are described by vector autoregressive processes and are influenced by blocks higher in the system hierarchy. We derive the maximum likelihood estimator for the posited model for Gaussian data in the high-dimensional setting based on appropriate regularization schemes for the parameters of the block components. To optimize the underlying non-convex likelihood function, we develop an iterative algorithm with convergence guarantees. We establish theoretical properties of the maximum likelihood estimates, leveraging the decomposability of the regularizers and a careful analysis of the iterates. Finally, we develop testing procedures for the null hypothesis of whether a block "Granger-causes" another block of variables. The performance of the model and the testing procedures are evaluated on synthetic data, and illustrated on a data set involving log-returns of the US S&P100 component stocks and key macroeconomic variables for the 2001–16 period.

Keywords: Vector-autoregression; Stability; Block-coordinate descent; Consistency; Global testing

1. Introduction.

The study of linear dynamical systems has a long history in control theory (Kumar and Varaiya, 1986) and economics (Hansen and Sargent, 2013) due to their analytical tractability and ease to estimate their parameters. Such systems in their so-called *reduced form* give rise to Vector Autoregressive (VAR) models (Lütkepohl, 2005) that have been widely used in macroeconomic modeling for policy analysis (Sims, 1980, 1992), in financial econometrics (Gourieroux and Jasiak, 2001), and more recently in functional genomics (Shojaie et al., 2012), financial systemic risk analysis (Billio et al., 2012) and neuroscience (Seth, 2013).

In many applications, the components of the system under consideration can be naturally partitioned into *interacting blocks*. For example, Cushman and Zha (1997) studied the impact of monetary policy in a small open economy, where the economy under consideration is modeled as one block, while variables in other (foreign) economies as the other. Both blocks have their own autoregressive structure, and the inter-dependence between blocks is unidirectional: the foreign block *influences* the small open economy, but *not* the other way around, thus effectively introducing a *linear ordering* amongst blocks. Another example comes from the connection between the stock market and employment macroeconomic variables (Fitoussi et al., 2000; Phelps, 1999; Farmer, 2015) that focuses on the impact through a wealth effect mechanism of the former on the latter. Once again, the underlying hypothesis of interest is that the stock market influences employment, but not the other way around. In another application domain, molecular biologists conduct time course experiments on cell lines or animal models and collect data across multiple molecular compartments (transcripotmics, proteomics, metabolomics, lipidomics) in order to delineate mechanisms for disease onset and progression or to study basic biological processes. In this case, the interactions amongst the blocks (molecular compartments) are clearly delineated (transciptomic compartment influencing the proteomic and metabolomic ones), thus leading again to a linear ordering of the blocks.

The proposed model also encompasses the popular in marketing, regional science and growth theory VAR-X model, provided that the temporal evolution of the *exogenous* block of variables "X" exhibits autoregressive dynamics. For example, Nijs et al. (2001) examine the sensitivity of over 500 product prices to various marketing promotion strategies (the exogenous block), while Pauwels and Weiss (2008) examine changes in subscription rates, search engine referrals and marketing efforts of customers when switched from a free account to a fee-based structure, the latter together with customer characteristics representing the exogenous block. Pesaran et al. (2004) examine regional inter-dependencies, building a model where country specific macroeconomic indicators evolve according to a VAR model and they are influenced exogenously by key macroeconomic variables from neighboring countries/regions. Finally, Abeysinghe (2001) studies the impact of the price of oil on Gross Domestic Product growth rates for a number of countries, while controlling for other exogenous variables such as the country's consumption and investment expenditures along with its trade balance.

The proposed model gives rise to a network structure that in its most general form corresponds to a multi-partite graph, depicted in Figure 1 for 3 blocks, that exhibits a *directed acyclic structure* between the constituent blocks, and can also exhibit additional dependence between the nodes in each block. Selected properties of such multi-block structures, known as *chain graphs*, have been studied in the literature. Specifically, their maximum likelihood estimation for *independent and identically distributed* Gaussian data under a high-dimensional *sparse* regime is thoroughly investigated in Lin et al. (2016), where a provably convergent estimation procedure is introduced and its theoretical properties are established.

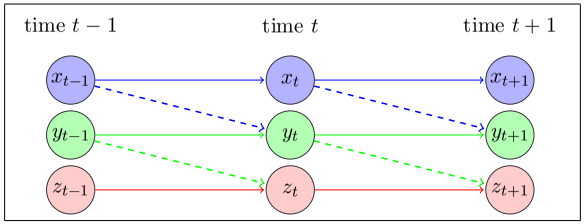

Figure 1: Diagram for a dynamic system with three groups of variables

Given the wide range of applications of multi-block VAR models, which in addition encompass the widely used VAR-X model, the key contributions of the current paper are fourfold: (i) formulating the model as a recursive dynamical system and examining its stability properties; (ii) developing a provably convergent algorithm for obtaining the regularized maximum likelihood estimates (MLE) of the model parameters under high-dimensional scaling; (iii) establishing theoretical properties of the ML estimates; and (iv) devising a testing procedure for the parameters that connect the constituent blocks of the model: if the null hypothesis is not rejected, then one is dealing with a set of independently evolving VAR models, otherwise with the posited multi-block VAR model. Finally, the model, estimation and testing procedures are illustrated on an important problem in macroeconomics, as gleaned by the background of the problem and discussion of the results provided in Section 6.

For the multi-block VAR model, we assume that the time series within each block are generated by a Gaussian VAR process. Further, the transition matrices within and across blocks can be either *sparse* or *low rank*. The posited regularized Gaussian likelihood function is not *jointly convex* in all the model parameters, which poses a number of technical challenges that are compounded by the presence of temporal dependence. These are successfully addressed and resolved in Section 3, where we provide a numerically convergent algorithm and establish the theoretical properties of the resulting ML estimates, that constitutes a key contribution in the study of multi-block VAR models.

The remainder of this paper is organized as follows. In Section 2, we introduce the model setup and the corresponding estimation procedure. In Section 3, we provide consistency properties of the obtained ML estimates under a high-dimensional scaling. In Section 4, we introduce the proposed testing framework, both for low-rank and sparse interaction matrices between the blocks. Section 5 contains selected numerical results that assess the performance of the estimation and testing procedures. Finally, an application to financial and macroeconomic data that was previously discussed as motivation for the model under consideration is presented in Section 6.

Notation. Throughout this paper, we use $|||A|||_1$ and $|||A|||_\infty$ respectively to denote the matrix induced 1-norm and infinity norm of $A \in \mathbb{R}^{m\times n}$, that is, $|||A|||_1 = \max_{1\le j\le n}\sum_{i=1}^m |a_{ij}|$, $|||A|||_\infty = \max_{1\le i\le m}\sum_{j=1}^n |a_{ij}|$, and use $\|A\|_1$ and $\|A\|_\infty$ respectively to denote the element-wise 1-norm and infinity norm: $\|A\|_1 = \sum_{i,j}|a_{ij}|$, $\|A\|_\infty = \max_{i,j}|a_{ij}|$. Moreover, we use $|||A|||_*$, $|||A|||_F$ and $|||A|||_{op}$ to denote the nuclear, Frobenius and operator norms of A, respectively. For two matrices A and B of commensurate dimensions, denote their inner product by $\langle\!\langle A, B\rangle\!\rangle = \mathrm{trace}(A'B)$. Finally, we write $A \gtrsim B$ if there exists some absolute constant c that is independent of the model parameters such that $A \ge cB$.

2. Problem Formulation.

To convey the main ideas and the key technical contributions, we consider a recursive linear dynamical system comprising of two blocks of variables, whose structure is given by:

$$\begin{aligned} X_t &= AX_{t-1} + U_t, \\ Z_t &= BX_{t-1} + CZ_{t-1} + V_t, \end{aligned} \tag{1}$$

where $X_t \in \mathbb{R}^{p_1}, Z_t \in \mathbb{R}^{p_2}$ are the variables in groups 1 and 2, respectively. The temporal intra-block dependence is captured by transition matrices A and C, while the inter-block dependence by B. Noise processes $\{U_t\}$ and $\{V_t\}$, respectively, capture additional contemporaneous intra-block dependence of X_t and Z_t, after conditioning on their respective past values. Further, we assume that U_t and V_t follow mean zero Gaussian distributions with covariance matrices given by Σ_u and Σ_v, i.e.,

$$U_t \sim \mathcal{N}(0, \Sigma_u), \quad \text{and} \quad V_t \sim \mathcal{N}(0, \Sigma_v).$$

With the above model setup, the parameters of interest are transition matrices $A \in \mathbb{R}^{p_1\times p_1}$, $B \in \mathbb{R}^{p_2\times p_1}$ and $C \in \mathbb{R}^{p_2\times p_2}$, as well as the covariances Σ_u, Σ_v. In high-dimensional settings, different combinations of structural assumptions can be imposed on these transition matrices to enable their estimation from limited time series data. In particular, the intra-block transition matrices A and C are sparse, while the inter-block matrix B can be either sparse or low rank. Note that the block of X_t variables acts as an *exogenous* effect to the evolution of the Z_t block (e.g., Cushman and Zha, 1997; Nicolson et al., 2016). Further, we assume $\Omega_u := \Sigma_u^{-1}$ and $\Omega_v := \Sigma_v^{-1}$ are sparse.

Remark 1 *For ease of exposition, we posit a* VAR(1) *modeling structure. Extensions to general multi-block structures akin to the one depicted in Figure 1 and* VAR(d) *specifications are rather straightforward and briefly discussed in Section 7.*

The triangular (recursive) structure of the system enables a certain degree of separability between X_t and Z_t. In the posited model, X_t is a stand-alone VAR(1) process, and the time series in block Z_t is "Granger-caused" by that in block X_t, but not vice versa. The second equation in (1), as mentioned in the introductory section, also corresponds to the so-called "VAR-X" model in the econometrics literature (e.g., Sims, 1980; Bianchi et al., 2010), that extends the standard VAR model to include influences from lagged values of *exogenous* variables. Consider the joint process $W_t = (X_t', Z_t')'$, it corresponds to a VAR(1) model whose transition matrix G has a block triangular form:

$$W_t = GW_{t-1} + \varepsilon_t, \qquad \text{where} \quad G := \begin{bmatrix} A & O \\ B & C \end{bmatrix}, \quad \varepsilon_t = \begin{bmatrix} U_t \\ V_t \end{bmatrix}. \tag{2}$$

The model in (2) can also be viewed from a Structural Equations Modeling viewpoint involving time series data, and also has a Moving Average representation corresponding to a

structural VAR representation with Granger causal ordering (Lütkepohl, 2005). As mentioned in the introductory section, the focus of this paper is model parameter estimation under high-dimensional scaling, rather than their cause and effect relationship. For a comprehensive discourse of causality issues for VAR models, we refer the readers to Granger (1969); Lütkepohl (2005), and references therein.

Next, we introduce the notion of stability and spectrum with respect to the system.

System Stability. To ensure that the joint process $\{W_t\}$ is stable (Lütkepohl, 2005), we require the spectral radius, denoted by $\rho(\cdot)$, of the transition matrix G to be smaller than 1, which is guaranteed by requiring that $\rho(A) < 1$ and $\rho(C) < 1$, since

$$|\lambda \mathrm{I}_{p_1 \times p_2} - G| = \begin{vmatrix} \lambda \mathrm{I}_{p_1} - A & O \\ -B & \lambda \mathrm{I}_{p_2} - C \end{vmatrix} = |\lambda \mathrm{I}_{p_1} - A||\lambda \mathrm{I}_{p_2} - C|,$$

implying that the set of eigenvalues of G is the union of the sets of eigenvalues of A and C, hence

$$\rho(A) < 1 \ , \rho(C) < 1, \qquad \Rightarrow \qquad \rho(G) = \max\{\rho(A), \rho(C)\} < 1.$$

The latter relation implies that the stability of such a recursive system imposes spectrum constraints only on the diagonal blocks that govern the intra-block evolution, whereas the off-diagonal block that governs the inter-block interaction is left unrestricted.

Spectrum of the joint process. Throughout, we assume that the spectral density of $\{W_t\}$ exists, which then possesses a special structure as a result of the block triangular transition matrix G. Formally, we define the spectral density of $\{W_t\}$ as

$$f_W(\theta) = \frac{1}{2\pi} \sum_{h=-\infty}^{\infty} \Gamma_W(h) e^{-ih\theta}, \qquad \theta \in [-\pi, \pi],$$

where $\Gamma_W(h) := \mathbb{E} W_t W_{t+h}'$. For two (generic) processes $\{X_t\}$ and $\{Z_t\}$, define their cross-covariance as $\Gamma_{X,Z}(h) = \mathbb{E} X_t Z_{t+h}'$ and $\Gamma_{Z,X}(h) = \mathbb{E} Z_t X_{t+h}'$. In general, $\Gamma_{X,Z}(h) \neq \Gamma_{Z,X}(h)$. The cross-spectra are defined as:

$$f_{X,Z}(\theta) := \frac{1}{2\pi} \sum_{h=-\infty}^{\infty} \Gamma_{X,Z}(h) e^{-ih\theta}, \quad \text{and} \quad f_{Z,X}(\theta) := \frac{1}{2\pi} \sum_{h=-\infty}^{\infty} \Gamma_{Z,X}(h) e^{-ih\theta}, \quad \theta \in [-\pi, \pi].$$

For the model given in (2), by writing out the dynamics of Z_t, the cross-spectra between X_t and Z_t are given by

$$f_{X,Z}(\theta)(\mathrm{I}_{p_2} - C' e^{-i\theta}) = f_X(\theta) B' e^{-i\theta}, \qquad \text{and} \qquad (\mathrm{I}_{p_2} - C e^{i\theta}) f_{Z,X}(\theta) = B e^{i\theta} f_X(\theta). \quad (3)$$

Similarly, we have

$$(\mathrm{I}_{p_2} - C e^{i\theta}) f_Z(\theta) = B e^{i\theta} f_{X,Z}(\theta) + f_{V,Z}(\theta). \quad (4)$$

Combining (3) and (4), the spectrum of the joint process W_t is given by

$$f_W(\theta) = \big[H_1(e^{i\theta})\big]^{-1} \Big(\big[H_2(e^{i\theta})\big] \big[\mathbf{1}_{2\times 2} \otimes f_X(\theta)\big] \big[H_2(e^{-i\theta})\big]^\top + \begin{bmatrix} O & O \\ O & \Sigma_v \end{bmatrix} \Big) \big[H_1(e^{-i\theta})\big]^{-\top}, \quad (5)$$

where $\mathbf{1}_{2\times 2}$ is a 2×2 matrix with all entries being 1, and

$$H_1(x) := \begin{bmatrix} \mathrm{I}_{p_1} & O \\ O & \mathrm{I}_{p_2} - Cx \end{bmatrix} \in \mathbb{R}^{(p_1+p_2)\times(p_1+p_2)}, \quad H_2(x) := \begin{bmatrix} \mathrm{I}_{p_1} & O \\ O & Bx \end{bmatrix} \in \mathbb{R}^{(p_1+p_2)\times(2p_1)}.$$

Equation (5) implies that the spectrum of the joint process $\{W_t\}$ can be decomposed into the sum of two parts: the first, is a function of $f_X(\theta)$, while the second part involves the idiosyncratic error process $\{V_t\}$, which only affects the right-bottom block of the spectrum. Note that since $\{W_t\}$ is a VAR(1) process, its matrix-valued characteristic polynomial is given by

$$\mathcal{G}(\theta) := \mathrm{I}_{(p_1+p_2)} - G\theta,$$

and its spectral density also takes the following form (c.f. Hannan, 1970):

$$f_W(\theta) = \frac{1}{2\pi} \big[\mathcal{G}^{-1}(e^{i\theta})\big] \Sigma_\varepsilon \big[\mathcal{G}^{-1}(e^{i\theta})\big]^*,$$

where

$$\mathcal{G}(x) = \begin{bmatrix} \mathrm{I}_{p_1} - Ax & O \\ -Bx & \mathrm{I}_{p_2} - Cx \end{bmatrix}, \qquad \Sigma_\varepsilon = \begin{bmatrix} \Sigma_u & O \\ O & \Sigma_v \end{bmatrix},$$

and $\mathcal{G}^*$ is the conjugate transpose. One can easily reach the same conclusion as in (5) by multiplying each term, followed by some algebraic manipulations.

2.1 Estimation.

Next, we outline the algorithm for obtaining the ML estimates of the transition matrices A, B and C and inverse covariance matrices Σ_u^{-1} and Σ_v^{-1} from time series data. We allow for a potential high-dimensional setting, where the ambient dimensions p_1 and p_2 of the model exceed the total number of observations T.

Given centered times series data $\{x_0, \cdots, x_T\}$ and $\{z_0, \cdots, z_T\}$, we use $\mathcal{X}^T$ and $\mathcal{Z}^T$ respectively, to denote the "response" matrix from time 1 to T, that is:

$$\mathcal{X}^T = \begin{bmatrix} x_1 & x_2 & \dots & x_T \end{bmatrix}' \quad \text{and} \quad \mathcal{Z}^T = \begin{bmatrix} z_1 & z_2 & \dots & z_T \end{bmatrix}',$$

and use $\mathcal{X}$ and $\mathcal{Z}$ without the superscript to denote the "design" matrix from time 0 to $T-1$:

$$\mathcal{X} = \begin{bmatrix} x_0 & x_1 & \dots & x_{T-1} \end{bmatrix}' \quad \text{and} \quad \mathcal{Z} = \begin{bmatrix} z_0 & z_1 & \dots & z_{T-1} \end{bmatrix}'.$$

We use $\mathcal{U}$ and $\mathcal{V}$ to denote the error matrices. To obtain estimates for the parameters of interest, we formulate optimization problems using a penalized log-likelihood function, with regularization terms corresponding to the imposed structural assumptions on the model parameters–sparsity and/or low-rankness. To solve the optimization problems, we employ block-coordinate descent algorithms, akin to those described in Lin et al. (2016), to obtain the solution.

As previously mentioned, $\{X_t\}$ is not "Granger-caused" by Z_t and hence it is a stand-alone VAR(1) process; this enables us to separately estimate the parameters governing the X_t process (A and Σ_u^{-1}) from those of the Z_t process (B, C, and Σ_v^{-1}).

Estimation of A and Σ_u^{-1}. Conditional on the initial observation x_0, the likelihood of $\{x_t\}_{t=1}^T$ is given by:

$$\begin{aligned} L(x_T, x_{T-1}, \cdots, x_1 | x_0) &= L(x_T | x_{T-1}, \cdots, x_0) L(x_{T-1} | x_{T-2}, \cdots, x_0) \cdots L(x_1 | x_0) \\ &= L(x_T | x_{T-1}) L(x_{T-1} | x_{T-2}) \cdots L(x_1 | x_0), \end{aligned}$$

where the second equality follows from the Markov property of the process. The log-likelihood function is given by:

$$\ell(A, \Sigma_u^{-1}) = \frac{T}{2} \log\det(\Sigma_u^{-1}) - \frac{1}{2} \sum_{t=1}^{T} (x_t - A x_{t-1})' \Sigma_u^{-1} (x_t - A x_{t-1}) + \text{constant}.$$

Letting $\Omega_u := \Sigma_u^{-1}$, then the penalized maximum likelihood estimator can be written as

$$(\widehat{A}, \widehat{\Omega}_u) = \underset{\substack{A \in \mathbb{R}^{p_1 \times p_2} \\ \Omega_u \in \mathbb{S}^{++}_{p_1 \times p_1}}}{\arg\min} \Big\{ \mathrm{tr}\big[\Omega_u (\mathcal{X}^T - \mathcal{X} A')'(\mathcal{X}^T - \mathcal{X} A')/T\big] - \log\det\Omega_u + \lambda_A \|A\|_1 + \rho_u \|\Omega_u\|_{1,\text{off}} \Big\}. \quad (6)$$

Algorithm 1 describes the key steps for obtaining $\widehat{A}$ and $\widehat{\Omega}_u$.

Algorithm 1: Computational procedure for estimating A and Σ_u^{-1}.

Input: Time series data $\{x_t\}_{t=1}^T$, tuning parameter λ_A and ρ_u.

1 **Initialization:** Initialize with $\widehat{\Omega}_u^{(0)} = \mathrm{I}_{p_1}$, then
$$\widehat{A}^{(0)} = \arg\min_A \big\{ \tfrac{1}{T} \big\| \mathcal{X}^T - \mathcal{X} A' \big\|_F^2 + \lambda_A \|A\|_1 \big\};$$

2 **Iterate until convergence:**

– Update $\widehat{\Omega}_u^{(k)}$ by graphical Lasso (Friedman et al., 2008) on the residuals with the plug-in estimate $\widehat{A}^{(k)}$;

– Update $\widehat{A}^{(k)}$ with the plug-in $\widehat{\Omega}_u^{(k-1)}$ and cyclically update each row with a Lasso penalty, which solves

$$\min_A \big\{ \tfrac{1}{T} \mathrm{tr}\big[\widehat{\Omega}_u^{(k-1)} (\mathcal{X}^T - \mathcal{X} A)'(\mathcal{X}^T - \mathcal{X} A)/T\big] + \lambda_A \|A\|_1 \big\}. \quad (7)$$

Output: Estimated sparse transition matrix $\widehat{A}$ and sparse $\widehat{\Omega}_u$.

Estimation of B, C and Σ_v^{-1}. Similarly, to obtain estimates of B, C and $\Omega_v := \Sigma_v^{-1}$, we formulate the optimization problem as follows:

$$\begin{aligned} (\widehat{B}, \widehat{C}, \widehat{\Omega}_v) = \underset{\substack{B \in \mathbb{R}^{p_2 \times p_1}, C \in \mathbb{R}^{p_2 \times p_2} \\ \Omega_v \in \mathbb{S}^{++}_{p_2 \times p_2}}}{\arg\min} \Big\{ & \mathrm{tr}\big[\Omega_v (\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C')'(\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C')/T\big] - \log\det\Omega_v \\ & + \lambda_B \mathcal{R}(B) + \lambda_C \|C\|_1 + \rho_v \|\Omega_v\|_{1,\text{off}} \Big\}, \end{aligned} \quad (8)$$

where the regularizer $\mathcal{R}(B) = \|B\|_1$ if B is assumed to be sparse, and $\mathcal{R}(B) = \|B\|_*$ if B is assumed to be low rank. Algorithm 2 outlines the procedure for obtaining estimates $\widehat{B}$, $\widehat{C}$

Algorithm 2: Computational procedure for estimating B, C and Σ_v^{-1}.

Input: Time series data $\{x_t\}_{t=1}^T$ and $\{z_t\}_{t=1}^T$, tuning parameters λ_B, λ_C, ρ_v.

1 **Initialization:** Initialize with $\widehat{\Omega}_v^{(0)} = \mathrm{I}_{p_2}$, then
$$(\widehat{B}^{(0)}, \widehat{C}^{(0)}) = \underset{(B,C)}{\arg\min} \big\{ \tfrac{1}{T} \big\| \mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C' \big\|_F^2 + \lambda_B \mathcal{R}(B) + \lambda_C \|C\|_1 \big\}.$$

2 **Iterate until convergence:**

– Update $\widehat{\Omega}_v^{(k)}$ by graphical Lasso on the residuals with the plug-in estimates $\widehat{B}^{(k)}$ and $\widehat{C}^{(k)}$;

– For fixed $\widehat{\Omega}_v^{(k)}$, $(\widehat{B}^{(k+1)}, \widehat{C}^{(k+1)})$ solves
$$\min_{B,C} \big\{ \tfrac{1}{T} \mathrm{tr}\big[\widehat{\Omega}_v^{(k)} (\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C')'(\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C')\big] + \lambda_B \mathcal{R}(B) + \lambda_C \|C\|_1 \big\}.$$

· Fix $\widehat{C}^{[s]}$, update $\widehat{B}^{[s+1]}$ by Lasso or singular value thresholding, which solves
$$\min_B \big\{ \tfrac{1}{T} \mathrm{tr}\big[\widehat{\Omega}_v^{(k)} (\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} \widehat{C}^{[s]'})'(\mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} \widehat{C}^{[s]'})\big] + \lambda_B \mathcal{R}(B) \big\};$$

· Fix $\widehat{B}^{[s]}$, update $\widehat{C}^{[s]}$ by Lasso, which solves
$$\min_C \big\{ \tfrac{1}{T} \mathrm{tr}\big[\widehat{\Omega}_v^{(k)} (\mathcal{Z}^T - \mathcal{X} \widehat{B}^{[s]'} - \mathcal{Z} C')'(\mathcal{Z}^T - \mathcal{X} \widehat{B}^{[s]'} - \mathcal{Z} C')\big] + \lambda_C \|C\|_1 \big\}.$$

Output: Estimated transition matrices $\widehat{B}$, $\widehat{C}$ and sparse $\widehat{\Omega}_v$.

and $\widehat{\Omega}_v$. Note that $\widehat{B}^{(k)}$ and $\widehat{C}^{(k)}$ need to be treated as a "joint block" in the outer update and convergence of the "joint block" is required before moving on to updating Ω_v.

Note that the objective function in (6) is not *jointly convex* in both parameters, but *biconvex*. Similarly in (8), the objective function is biconvex in $[(B, C), \Omega_v]$. Consequently, convergence to a stationary point is guaranteed, as long as estimates from all iterations lie within a ball around the true value of the parameters, with the radius of the ball upper bounded by a universal constant that only depends on model dimensions and sample size (Lin et al., 2016, Theorem 4.1). This condition is satisfied upon the establishment of consistency properties of the estimates.

To establish consistency properties of the estimates requires the existence of good initial values for the model parameters (A, Ω_u), and (B, C, Ω_v), respectively, in the sense that they are sufficiently close to the true parameters. For the (A, Ω_u) parameters, the results in Basu and Michailidis (2015) guarantee that for random realizations of $\{X_t, E_t\}$, with sufficiently large sample size, the errors of $\widehat{A}^{(0)}$ and $\widehat{\Omega}_u^{(0)}$ are bounded with high probability, which provides us with good initialization values. Yet, additional handling of the bounds is required to ensure that estimates from subsequent iterations are also uniformly close to the true value (see Section 3.2 Theorem 5). A similar property for $(\widehat{B}^{(0)}, \widehat{C}^{(0)}, \widehat{\Omega}_v^{(0)})$ and subsequent iterations is established in Section 3.2 Theorem 6 (see also Theorem 15 in Appendix A).

3. Theoretical Properties.

In this section, we investigate the theoretical properties of the penalized maximum likelihood estimation procedure proposed in Section 2, with an emphasis on the error bounds for the obtained

estimates. We focus on the model specification in which the inter-block transition matrix B is *low rank*, which is of interest in many applied settings. Specifically, we consider the consistency properties of $\widehat{A}$ and $(\widehat{B}, \widehat{C})$ that are solutions to the following two optimization problems:

$$(\widehat{A}, \widehat{\Omega}_u) = \underset{A,\Omega_u}{\arg\min} \Big\{ \mathrm{tr}\left[\Omega_u(\mathcal{X}^T - \mathcal{X}A')'(\mathcal{X}^T - \mathcal{X}A')/T\right] - \log\det\Omega_u + \lambda_A\|A\|_1 + \rho_u\|\Omega_u\|_{1,\mathrm{off}} \Big\}, \quad (9)$$

and

$$(\widehat{B}, \widehat{C}, \widehat{\Omega}_v) = \underset{B,C,\Omega_v}{\arg\min} \Big\{ \mathrm{tr}\left[\Omega_v(\mathcal{Z}^T - \mathcal{X}B' - \mathcal{Z}C')'(\mathcal{Z}^T - \mathcal{X}B' - \mathcal{Z}C')/T\right] - \log\det\Omega_v + \lambda_B|||B|||_* + \lambda_C\|C\|_1 + \rho_v\|\Omega_v\|_{1,\mathrm{off}} \Big\}. \quad (10)$$

The case of a sparse B can be handled similarly to that of A and/or C with minor modifications (details shown in Supplementary Material **??**).

3.1 A road map for establishing the consistency results.

Next, we outline the main steps followed in establishing the theoretical properties for the model parameters. Throughout, we denote with a superscript "$\star$" the true value of the corresponding parameters.

The following key concepts, widely used in high-dimensional regularized estimation problems, are needed in subsequent developments.

Definition 2 (Restricted Strong Convexity (RSC)) *For some generic operator $\mathfrak{X} : \mathbb{R}^{m_1\times m_2} \mapsto \mathbb{R}^{T\times m_1}$, it satisfies the RSC condition with respect to norm Φ with curvature $\alpha_{RSC} > 0$ and tolerance $\tau > 0$ if*

$$\frac{1}{2T}|||\mathfrak{X}(\Delta)|||_F^2 \geq \alpha_{RSC}|||\Delta|||_F^2 - \tau\Phi^2(\Delta), \qquad \textit{for some } \Delta \in \mathbb{R}^{m_1\times m_2}.$$

Note that the choice of the norm Φ is context specific. For example, in sparse regression problems, $\Phi(\Delta) = \|\Delta\|_1$ corresponds to the element-wise ℓ_1 norm of the matrix (or the usual vector ℓ_1 norm for the vectorized version). The RSC condition becomes equivalent to the *restricted eigenvalue (RE) condition* (see Loh and Wainwright, 2012; Basu and Michailidis, 2015, and references therein). This is the case for the problem of estimating transition matrix A. For estimating B and C, define $\mathcal{Q}$ to be the weighted regularizer $\mathcal{Q}(B, C) := |||B|||_* + \frac{\lambda_C}{\lambda_B}\|C\|_1$, and the associated norm Φ in this setting is defined as

$$\Phi(\Delta) := \inf_{B_{\mathrm{aug}}+C_{\mathrm{aug}}=\Delta} \mathcal{Q}(B, C).$$

Definition 3 (Diagonal dominance) *A matrix $\Omega \in \mathbb{R}^{p\times p}$ is strictly diagonally dominant if*

$$|\Omega_{ii}| > \sum_{j\neq i}|\Omega_{ij}|, \quad \forall \;\; i = 1, \cdots, p.$$

Definition 4 (Incoherence condition (Ravikumar et al., 2011)) *A matrix $\Omega \in \mathbb{R}^{p\times p}$ satisfies the incoherence condition if:*

$$\max_{e\in(S_\Omega)^c} \|H_{eS_\Omega}(H_{S_\Omega S_\Omega})^{-1}\|_1 \leq 1 - \xi, \quad \textit{for some } \xi \in (0, 1),$$

where $H_{S_\Omega S_\Omega}$ denotes the Hessian of the log-determinant barrier $\log\det\Omega$ restricted to the true edge set of Ω denoted by S_Ω, and H_{eS} is similarly defined.

The above two conditions are associated with the inverse covariance matrices Ω_u and Ω_v. Specifically, the diagonal dominance condition is required for $\Omega_u^\star$ and $\Omega_v^\star$ as we build the consistency properties for $\widehat{A}$ and $(\widehat{B}, \widehat{C})$ with the penalized maximum likelihood formulation. The incoherence condition is primarily required for establishing the consistency of $\widehat{\Omega}_u$ and $\widehat{\Omega}_v$.

We additionally introduce the upper and lower extremes of the spectrum, defined as

$$\mathcal{M}(f_X) := \operatorname*{esssup}_{\theta\in[-\pi,\pi]} \Lambda_{\max}(f_X(\theta)) \qquad \text{and} \qquad \mathfrak{m}(f_X) := \operatorname*{essinf}_{\theta\in[-\pi,\pi]} \Lambda_{\min}(f_X(\theta)).$$

Analogously, the upper extreme for the cross-spectrum is given by:

$$\mathcal{M}(f_{X,Z}) := \operatorname*{esssup}_{\theta\in[-\pi,\pi]} \sqrt{\Lambda_{\max}(f^*_{X,Z}(\theta)f_{X,Z}(\theta))},$$

with $f^*_{X,Z}(\theta)$ being the conjugate transpose of $f_{X,Z}(\theta)$. With this definition,

$$\mathcal{M}(f_{X,Z}) = \mathcal{M}(f_{Z,X}).$$

Next, consider the solution to (9) that is obtained by the alternate update between A and Ω_u. If Ω_u is held fixed, then A solves (11), and we denote the solution by $\bar{A}$ and its corresponding vectorized version as $\bar{\beta}_A := \mathrm{vec}(\bar{A})$:

$$\bar{\beta}_A := \underset{\beta\in\mathbb{R}^{p_1^2}}{\arg\min} \big\{ -2\beta'\gamma_X + \beta'\Gamma_X\beta + \lambda_A\|\beta\|_1 \big\}, \quad (11)$$

where

$$\Gamma_X = \Omega_u \otimes \tfrac{\mathcal{X}'\mathcal{X}}{T}, \qquad \gamma_X = \tfrac{1}{T}\left(\Omega_u \otimes \mathcal{X}'\right)\mathrm{vec}(\mathcal{X}^T). \quad (12)$$

Using a similar notation, if A is held fixed, then Ω_u solves (13) with the solution being $\bar{\Omega}_u$:

$$\bar{\Omega}_u := \underset{\Theta\in\mathbb{S}^{++}_{p_1\times p_1}}{\arg\min} \big\{ \log\det\Omega_u - \mathrm{trace}\,(S_u\Omega_u) + \rho_u\|\Omega_u\|_{1,\mathrm{off}} \big\}, \quad (13)$$

where

$$S_u = \tfrac{1}{T}(\mathcal{X}^T - \mathcal{X}A')'(\mathcal{X}^T - \mathcal{X}A'). \quad (14)$$

For *fixed* realizations of $\mathcal{X}$ and $\mathcal{U}$, by Basu and Michailidis (2015), the error bound of $\bar{\beta}_A$ relies on (1) Γ_X satisfying the RSC condition defined above; and (2) the tuning parameter λ_A is chosen in accordance with a deviation bound condition associated with $\|\mathcal{X}'\mathcal{U}\Omega_u/T\|_\infty$. By Ravikumar et al. (2011), the error bound of $\bar{\Omega}_u$ relies on how well S_u concentrates around $\Sigma_u^\star$, that is, $\|S_u - \Sigma_u^\star\|_\infty$. Specifically, for (12) and (14), with $\Omega_u^\star$ and $A^\star$ plugged in respectively, for *random* realizations of $\mathcal{X}$ and $\mathcal{U}$, these conditions hold with high probability. In the actual implementation of the algorithm, however, quantities in (12) and (14) are substituted by estimates so that at iteration k, $\widehat{\beta}_A^{(k)}$ and $\widehat{\Omega}_u^{(k)}$ solve

$$\widehat{\beta}_A^{(k)} := \underset{\beta\in\mathbb{R}^{p_1^2}}{\arg\min} \big\{ -2\beta'\widehat{\gamma}_X^{(k)} + \beta'\widehat{\Gamma}_X^{(k)}\beta + \lambda_A\|\beta\|_1 \big\},$$

$$\widehat{\Omega}_u^{(k)} := \underset{\Omega_u\in\mathbb{S}^{++}_{p_1\times p_1}}{\arg\min} \big\{ \log\det\Omega_u - \mathrm{trace}\big(\widehat{S}_u^{(k)}\Omega_u\big) + \rho_u\|\Omega_u\|_{1,\mathrm{off}} \big\},$$

where

$$\widehat{\Gamma}_X^{(k)} = \widehat{\Omega}_u^{(k-1)} \otimes \tfrac{\mathcal{X}'\mathcal{X}}{T}, \quad \widehat{\gamma}_X^{(k)} = \tfrac{1}{T}\big(\widehat{\Omega}_u^{(k-1)} \otimes \mathcal{X}\big), \quad \widehat{S}_u^{(k)} = \tfrac{1}{T}\big[\mathcal{X}^T - \mathcal{X}(\widehat{A}^{(k)})'\big]'\big[\mathcal{X}^T - \mathcal{X}(\widehat{A}^{(k)})'\big].$$

As a consequence, to establish the finite-sample bounds of $\widehat{A}$ and $\widehat{\Omega}_u$ given in (9), we need $\widehat{\Gamma}_X^{(k)}$ to satisfy the RSC condition, a bound on $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(k-1)}\|_\infty$ and a bound on $\|\widehat{S}_u^{(k)} - \Sigma_u^\star\|_\infty$ for all k. Toward this end, we prove that for random realizations of $\mathcal{X}$ and $\mathcal{U}$, with high probability, the RSC condition for $\widehat{\Gamma}_X^{(k)}$ and the universal bounds for $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(k-1)}\|_\infty$ and $\|\widehat{S}_u^{(k)} - \Sigma_u^\star\|_\infty$ hold for *all iterations* k, albeit the quantities of interest rely on estimates from the previous or current iterations. Consistency results of $\widehat{A}$ and $\widehat{\Omega}_u$ then readily follow.

Next, consider the solution to (10) that alternately updates (B, C) and Ω_v. As the regularization term involves both the nuclear norm penalty and the ℓ_1 norm penalty, additional handling of the norms is required which leverages the idea of decomposable regularizers (Agarwal et al., 2012). Specifically, if Ω_v and (B, C) are respectively held fixed, then

$$(\bar{B}, \bar{C}) := \arg\min_{B,C} \Big\{ \tfrac{1}{T}\mathrm{tr}\big[\Omega_v(\mathcal{Z}^T - \mathcal{X}B' - \mathcal{Z}C')'(\mathcal{Z}^T - \mathcal{X}B' - \mathcal{Z}C')\big] + \lambda_B|||B|||_* + \lambda_C\|C\|_1 \Big\},$$
$$\bar{\Omega}_v := \arg\min_{\Omega_v} \big\{ \log\det\Omega_v - \mathrm{trace}\big(S_v\Omega_v\big) + \rho_v\|\Omega_v\|_{1,\mathrm{off}} \big\},$$

where $S_v = \frac{1}{T}(Z^T - \mathcal{X}B' - \mathcal{Z}C')'(Z^T - \mathcal{X}B' - \mathcal{Z}C')$. If we let $\mathcal{W} := [\mathcal{X}, \mathcal{Z}] \in \mathbb{R}^{T\times(p_1+p_2)}$, and define the operator $\mathfrak{W}_{\Omega_v} : \mathbb{R}^{p_2\times(p_1+p_2)} \mapsto \mathbb{R}^{T\times p_2}$ induced jointly by $\mathcal{W}$ and Ω_v as

$$\mathfrak{W}_{\Omega_v}(\Delta) := \mathcal{W}\Delta'\Omega_v^{1/2} \quad \text{for } \Delta \in \mathbb{R}^{p_2\times(p_1+p_2)}, \tag{15}$$

then $\bar{B}_{\mathrm{aug}} := [\bar{B}, O_{p_2\times p_1}]$ and $\bar{C}_{\mathrm{aug}} := [O_{p_2\times p_1}, \bar{C}]$ are equivalently given by

$$(\bar{B}_{\mathrm{aug}}, \bar{C}_{\mathrm{aug}}) = \arg\min_{B,C} \Big\{ \tfrac{1}{T}\Big|\Big|\Big|\mathcal{Z}^T\Omega_v^{1/2} - \mathfrak{W}_{\Omega_v}(B_{\mathrm{aug}} + C_{\mathrm{aug}})\Big|\Big|\Big|_F^2 + \lambda_B|||B|||_* + \lambda_C\|C\|_1 \Big\}, \tag{16}$$

where $B_{\mathrm{aug}} := [B, O_{p_2\times p_2}], C_{\mathrm{aug}} := [O_{p_2\times p_1}, C] \in \mathbb{R}^{p_2\times(p_1+p_2)}$. Then, for fixed realizations of $\mathcal{Z}$, $\mathcal{X}$ and $\mathcal{V}$, with an extension of Agarwal et al. (2012) the error bound of $(\bar{B}_{\mathrm{aug}}, \bar{C}_{\mathrm{aug}})$ relies on (1) the operator $\mathfrak{W}_{\Omega_v}$ satisfying the RSC condition; and (2) tuning parameters λ_B and λ_C are respectively chosen in accordance with the deviation bound conditions associated with

$$|||\mathcal{W}'\mathcal{V}\Omega_v/T|||_{op} \qquad \text{and} \qquad |||\mathcal{W}'\mathcal{V}\Omega_v/T|||_\infty. \tag{17}$$

The error bound of $\bar{\Omega}_v$ again relies on $\|S_v - \Sigma_v^\star\|_\infty$. In an analogous way, for the actual alternate update,

$$(\widehat{B}_{\mathrm{aug}}^{(k)}, \widehat{C}_{\mathrm{aug}}^{(k)}) = \arg\min_{B,C} \Big\{ \tfrac{1}{T}\Big|\Big|\Big|\mathcal{Z}^T\big[\widehat{\Omega}_v^{(k-1)}\big]^{1/2} - \mathfrak{W}_{\widehat{\Omega}_v^{(k-1)}}(B_{\mathrm{aug}} + C_{\mathrm{aug}})\Big|\Big|\Big|_F^2 + \lambda_B|||B|||_* + \lambda_C\|C\|_1 \Big\},$$
$$\widehat{\Omega}_v^{(k)} := \arg\min_{\Omega_v} \big\{ \log\det\Omega_v - \mathrm{trace}\big(\widehat{S}_v^{(k)}\Omega_v\big) + \rho_v\|\Omega_v\|_{1,\mathrm{off}} \big\},$$

and the error bound of $(\widehat{B}, \widehat{C}, \widehat{\Omega}_v)$ defined in (10) depends on the properties of $\mathfrak{W}_{\widehat{\Omega}_v^{(k)}}$, $|||\mathcal{W}'\mathcal{V}\Omega_v^{(k)}/T|||_{op}$ and $|||\mathcal{W}'\mathcal{V}\Omega_v^{(k)}/T|||_\infty$ for all k. Specifically, when Ω_v and (B, C) (in (15) and (17), resp.) are substituted by estimated quantities, we prove that the RSC condition and bounds hold with high probability for random realizations of $\mathcal{Z}$, $\mathcal{X}$ and $\mathcal{V}$, for *all iterations* k, which then establishes the consistency properties of $(\widehat{B}, \widehat{C})$ and $\widehat{\Omega}_v$.

3.2 Consistency results for the Maximum Likelihood estimators.

Theorems 5 and 6 below give the error bounds for the estimators in (9) and (10) obtained through Algorithms 1 and 2, using random realizations coming from the stable VAR system defined in (1). As previously mentioned, to establish error bounds for both the transition matrices and the inverse covariance matrix obtained from alternating updates, we need to take into account that the quantities associated with the RSC condition and the deviation bound condition are based on *estimated quantities* obtained from the previous iteration. On the other hand, the sources of randomness contained in the observed data are fixed, hence errors from observed data stop accumulating once all sources of randomness are considered after a few iterations, which govern both the leading term of the error bounds and the probability for the bounds to hold.

Specifically, using the same notation as defined in Section 3.1, we obtain the error bounds of the estimated transition matrices and inverse covariance matrices iteratively, building upon that for all iterations k:

(1) $\widehat{\Gamma}_X^{(k)}$ or the operator $\mathfrak{W}_{\widehat{\Omega}_v^{(k)}}$ satisfies the RSC condition;
(2) deviation bounds hold for $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(k)}/T\|_\infty$, $\|\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T\|_\infty$, and $|||\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T|||_{\mathrm{op}}$;
(3) a good concentration given by $\|\widehat{S}_u^{(k)} - \Sigma_u^\star\|_\infty$ and $\|\widehat{S}_v^{(k)} - \Sigma_v^\star\|_\infty$.

We keep track of how the bounds change in each iteration until convergence, by properly controlling the norms and track the rate of the error bound that depends on p_1, p_2 and T, and reach the conclusion that the error bounds *hold uniformly for all iterations*, for the estimates of both the transition matrices A, B and C and the inverse covariance matrices Ω_u and Ω_v.

Theorem 5 *Consider the stable Gaussian VAR process defined in (1) in which $A^\star$ is assumed to be $s_A^\star$-sparse. Further, assume the following:*

C.1 The incoherence condition holds for $\Omega_u^\star$.

C.2 $\Omega_u^\star$ is diagonally dominant.

C.3 The maximum node degree of $\Omega_u^\star$ satisfies $d^{\max}_{\Omega_u^\star} = o(p_1)$.

Then, for random realizations of $\{X_t\}$ and $\{U_t\}$, and the sequence $\{\widehat{A}^{(k)}, \widehat{\Omega}_u^{(k)}\}_k$ returned by Algorithm 1 outlined in Section 2.1, there exist constants $c_1, c_2, \tilde{c}_1, \tilde{c}_2 > 0, \tau > 0$ such that for sample size $T \gtrsim \max\{(d^{\max}_{\Omega_u^\star})^2, s_A^\star\}\log p_1$, with probability at least

$$1 - c_1\exp(-c_2 T) - \tilde{c}_1\exp(-\tilde{c}_2\log p_1) - \exp(-\tau\log p_1),$$

the following hold for all $k \geq 1$ for some $C_0, C_0' > 0$ that are functions of the upper and lower extremes $\mathcal{M}(f_X), \mathfrak{m}(f_X)$ of the spectrum $f_X(\theta)$ and do not depend on p_1, T or k:

(i) $\widehat{\Gamma}_X^{(k)}$ satisfies the RSC condition;

(ii) $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(k)}/T\|_\infty \leq C_0\sqrt{\frac{\log p_1}{T}}$;

(iii) $\|\widehat{S}_u^{(k)} - \Sigma_u^\star\|_\infty \le C_0' \sqrt{\frac{\log p_1}{T}}$.

As a consequence, the following bounds hold uniformly for all iterations $k \ge 1$*:*

$$\left\|\left|\widehat{A}^{(k)} - A^\star\right|\right\|_F = O\Big(\sqrt{\tfrac{s_A^\star \log p_1}{T}}\Big), \qquad \left\|\left|\widehat{\Omega}_u^{(k)} - \Omega_u^\star\right|\right\|_F = O\Big(\sqrt{\tfrac{(s_{\Omega_u}^\star + p_1)\log p_1}{T}}\Big).$$

It should be noted that the above result establishes the *consistency for the ML estimates* of the model presented in Basu and Michailidis (2015).

Theorem 6 *Consider the stable Gaussian VAR system defined in (1) in which* $B^\star$ *is assumed to be low rank with rank* $r_B^\star$ *and* $C^\star$ *is assumed to be* $s_C^\star$*-sparse. Further, assume the following*

C.1 The incoherence condition holds for $\Omega_v^\star$.

C.2 $\Omega_v^\star$ *is diagonally dominant.*

C.3 The maximum node degree of $\Omega_v^\star$ *satisfies* $d^{\max}_{\Omega_v^\star} = o(p_2)$.

Then, for random realizations of $\{X_t\}$, $\{Z_t\}$ *and* $\{V_t\}$*, and the sequence* $\{(\widehat{B}^{(k)}, \widehat{C}^{(k)}), \widehat{\Omega}_v^{(k)}\}_k$ *returned by Algorithm 2 outlined in Section 2.1, there exist constants* $\{c_i, \tilde{c}_i\}, i = (0, 1, 2)$ *and* $\tau > 0$ *such that for sample size* $T \gtrsim (d^{\max}_{\Omega_v^\star})^2(p_1 + 2p_2)$*, with probability at least*

$$1 - c_0 \exp\{-\tilde{c}_0(p_1+p_2)\} - c_1 \exp\{-\tilde{c}_1(p_1+2p_2)\} - c_2 \exp\{-\tilde{c}_2 \log[p_2(p_1+p_2)]\} - \exp\{-\tau \log p_2\},$$

the following hold for all $k \ge 1$ *for* $C_0, C_0', C_0'' > 0$ *that are functions of the upper and lower extremes* $\mathcal{M}(f_W), \mathfrak{m}(f_W)$ *of the spectrum* $f_W(\theta)$ *and of the upper extreme* $\mathcal{M}(f_{W,V})$ *of the cross-spectrum* $f_{W,V}(\theta)$ *and do not depend on* p_1, p_2 *or* T*:*

(i) $\widehat{\Gamma}_W^{(k)}$ *satisfies the RSC condition;*

(ii) $\|\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T\|_\infty \le C_0 \sqrt{\frac{(p_1+p_2)+p_2}{T}}$ *and* $\|\!|\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T|\!\|_{op} \le C_0' \sqrt{\frac{(p_1+p_2)+p_2}{T}}$;

(iii) $\|\widehat{S}_v^{(k)} - \Sigma_v^\star\|_\infty \le C_0'' \sqrt{\frac{(p_1+p_2)+p_2}{T}}$.

As a consequence, the following bounds hold uniformly for all iterations $k \ge 1$*:*

$$\left\|\left|\widehat{B}^{(k)} - B^\star\right|\right\|_F^2 + \left\|\left|\widehat{C}^{(k)} - C^\star\right|\right\|_F^2 = O\Big(\tfrac{\max\{r_B^\star, s_C^\star\}(p_1+2p_2)}{T}\Big), \quad \left\|\left|\widehat{\Omega}_v^{(k)} - \Omega_v^\star\right|\right\|_F = O\Big(\sqrt{\tfrac{(s_{\Omega_v}^\star + p_2)(p_1+2p_2)}{T}}\Big).$$

Remark 7 *It is worth pointing out that the initializers* $\widehat{A}^{(0)}$ *and* $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$ *are slightly different from those obtained in successive iterations, as they come from the penalized least square formulation where the inverse covariance matrices are temporarily assumed diagonal. Consistency results for these initializers under deterministic realizations are established in Theorems 14 and 15 (see Appendix A), and the corresponding conditions are later verified for random realizations in Lemmas 16 to 19 (see Appendix B). These theorems and lemmas serve as the stepping stone toward the proofs of Theorems 5 and 6.*

Further, the constants C_0, C_0', C_0'' *reflect both the temporal dependence among* X_t *and* Z_t *blocks, as well as the cross-sectional dependence within and across the two blocks.*

3.3 The effect of temporal and cross-dependence on the established bounds.

We conclude this section with a discussion on the error bounds of the estimators that provides additional insight into the impact of temporal and cross dependence within and between the blocks; specifically, how the exact bounds depend on the underlying processes through their spectra when explicitly taking into consideration the triangular structure of the joint transition matrix.

First, we introduce additional notations needed in subsequent technical developments. The definition of the spectral densities and the cross-spectrum are the same as previously defined in Section 2 and their upper and lower extremes are defined in Section 3.1. For $\{X_t\}$ defined in (1), let $\mathcal{A}(\theta) = \mathrm{I}_{p_1} - A\theta$ denote the characteristic matrix-valued polynomial of $\{X_t\}$ and $\mathcal{A}^*(\theta)$ denote its conjugate. We further define its upper and lower extremes by:

$$\mu_{\max}(\mathcal{A}) = \max_{|\theta|=1} \Lambda_{\max}\left(\mathcal{A}^*(\theta)\mathcal{A}(\theta)\right), \quad \mu_{\min}(\mathcal{A}) = \min_{|\theta|=1} \Lambda_{\min}\left(\mathcal{A}^*(\theta)\mathcal{A}(\theta)\right).$$

The same set of quantities for the joint process $\{W_t = (X_t', Z_t')'\}$ are analogously defined, that is,

$$\mathcal{G}(\theta) = \mathrm{I}_{p_1+p_2} - G\theta, \quad \mu_{\max}(\mathcal{G}) = \max_{|\theta|=1} \Lambda_{\max}\left(\mathcal{G}^*(\theta)\mathcal{G}(\theta)\right), \quad \mu_{\min}(\mathcal{G}) = \min_{|\theta|=1} \Lambda_{\min}\left(\mathcal{G}^*(\theta)\mathcal{G}(\theta)\right).$$

Using the result in Theorem 6 as an example, we show how the error bound depends on the underlying processes $\{(X_t', Z_t')'\}$. Specifically, we note that the bounds for $(\widehat{B}^{(k)}, \widehat{C}^{(k)})$ can be equivalently written as

$$\|\widehat{B}^{(k)} - B^\star\|_F^2 + \|\widehat{C}^{(k)} - C^\star\|_F^2 \le \bar{C}\Big(\tfrac{\max\{r_B^\star, s_C^\star\}(p_1+2p_2)}{T}\Big),$$

which holds for all k and some constant $\bar{C}$ that does not depend on p_1, p_2 or T. Specifically, by Theorem 15, Lemmas 18 and 19,

$$C_0 \propto \left[\mathcal{M}(f_W) + \tfrac{1}{2\pi}\Lambda_{\max}(\Sigma_v) + \mathcal{M}(f_{W,V})\right] / \mathfrak{m}(f_W).$$

This indicates that the exact error bound depends on $\mathfrak{m}(f_W), \mathcal{M}(f_W)$ and $\mathcal{M}(f_{W,V})$. Next, we provide bounds on these quantities. The joint process W_t as we have noted in (2), is a VAR(1) process with characteristic polynomial $\mathcal{G}(\theta)$ and spectral density $f_W(\theta)$. The bounds for $\mathfrak{m}(f_W)$ and $\mathcal{M}(f_W)$ are given by Basu and Michailidis (2015, Proposition 2.1), that is,

$$\mathfrak{m}(f_W) \ge \frac{\min\{\Lambda_{\min}(\Sigma_u), \Lambda_{\min}(\Sigma_v)\}}{(2\pi)\mu_{\max}(\mathcal{G})} \quad \text{and} \quad \mathcal{M}(f_W) \le \frac{\max\{\Lambda_{\max}(\Sigma_u), \Lambda_{\max}(\Sigma_v)\}}{(2\pi)\mu_{\min}(\mathcal{G})}. \quad (18)$$

Consider the bound for $\mathcal{M}(f_{W,V})$. First, we note that $\{V_t\}$ is a sub-process of the joint error process $\{\varepsilon_t\}$, where $\varepsilon_t = (U_t', V_t')'$. Then, by Lemma 24,

$$\mathcal{M}(f_{W,V}) \le \mathcal{M}(f_{W,\varepsilon}) \le \mathcal{M}(f_W)\mu_{\max}(\mathcal{G}),$$

where the second inequality follows from Basu and Michailidis (2015, Proof of Proposition 2.4).

What are left to be bounded are $\mu_{\min}(\mathcal{G})$ and $\mu_{\max}(\mathcal{G})$. By Proposition 2.2 in Basu and Michailidis (2015), these two quantities are bounded by:

$$\mu_{\max}(\mathcal{G}) \leq \left[1 + \frac{|||G|||_\infty + |||G|||_1}{2}\right]^2 \tag{19}$$

and

$$\mu_{\min}(\mathcal{G}) \geq (1 - \rho(G))^2 \cdot |||P|||_{op}^{-2} \cdot |||P^{-1}|||_{op}^{-2},$$

where $G = P\Lambda_G P^{-1}$ with Λ_G being a diagonal matrix consisting of the eigenvalues of G. Since $|||P^{-1}|||_{op} \geq |||P|||_{op}^{-1}$, it follows that

$$|||P|||_{op}^{-2} \cdot |||P^{-1}|||_{op}^{-2} \geq |||P^{-1}|||_{op}^{2} \cdot |||P^{-1}|||_{op}^{-2} = 1,$$

and therefore

$$\mu_{\min}(\mathcal{G}) \geq (1 - \max\{\rho(A), \rho(C)\})^2 . \tag{20}$$

Remark 8 The impact of the system's lower-triangular structure on the established bounds. *Consider the bounds in (19) and (20). An upper bound of $\mu_{\max}(\mathcal{G})$ depends on $|||G|||_\infty$ and $|||G|||_1$, whereas a lower bound of $\mu_{\min}(\mathcal{G})$ involves only the spectral radius of G. Combined with (18), this suggests that the lower extreme of the spectral density is associated with the average of the maximum weighted in-degree and out-degree of the system, whereas the upper extreme is associated with the stability condition: the* less the system is intra- and inter-connected, *the* tighter the bound *for the lower extreme will be; similarly, the* more stable *(exhibits smaller temporal dependence) the system is, the* tighter the bound *for the upper extreme will be. Finally, we note that an upper bound for $(|||G|||_\infty + |||G|||_1)$ is given by*

$$\max\{|||A|||_\infty + |||B|||_\infty, |||C|||_\infty\} + \max\{|||A|||_1, |||B|||_1 + |||C|||_1\}.$$

The presence of $|||B|||_\infty$ and $|||B|||_1$ depicts the role of the inter-connectedness between $\{X_t\}$ and $\{Z_t\}$ on the lower extreme of the spectrum, which is associated with the overall curvature of the joint process.

The impact of the system's lower-triangular structure on the system capacity. *With G being a lower-triangular matrix, we only require $\rho(A) < 1$ and $\rho(C) < 1$ to ensure the stability of the system. This enables the system to have "larger capacity" (can accommodate more cross-dependence within each block), since the two sparse components A and C can exhibit larger average weighted in- and out-degrees compared with a system where G does not possess such triangular structure. In the case where G is a complete matrix, one deals with a $(p_1 + p_2)$-dimensional VAR system and $\rho(G) < 1$ is required to ensure its stability. As a consequence, the average weighted in- and out-degree requirements for each time series become more restrictive.*

4. Testing Group Granger-Causality.

In this section, we develop a procedure for testing the hypothesis $H_0 : B = 0$. Note that without the presence of B, the blocks X_t and Z_t in the model become *decoupled* and can be treated as two separate VAR models, whereas with a nonzero B, the group of variables in

Z_t is collectively "Granger-caused" by those in X_t. Moreover, since we are testing whether or not the entire block of B is zero, we do not need to rely on the exact distribution of its individual entries, but rather on the properly measured correlation between the responses and the covariates. To facilitate presentation of the testing procedure, we illustrate the proposed framework via a simpler model setting with $Y_t = \Pi X_t + \epsilon_t$ and testing whether $\Pi = 0$; subsequently, we translate the results to the actual setting of interest, namely, whether or not $B = 0$ in the model $Z_t = BX_{t-1} + CZ_{t-1} + V_t$.

The testing procedure focuses on the following sequence of tests for the rank of B:

$$H_0 : \text{rank}(B) \leq r, \qquad \text{for an arbitrary} \quad r < \min(p_1, p_2). \tag{21}$$

Note that the hypothesis of interest, $B = 0$ corresponds to the special case with $r = 0$. To test for it, we develop a procedure associated with *canonical correlations*, which leverages ideas present in the literature (see Anderson, 2002).

As mentioned above, we consider a simpler setting similar to that in Anderson (2002), given by

$$Y_t = \Pi X_t + \epsilon_t,$$

where $Y_t \in \mathbb{R}^{p_2}$, $X \in \mathbb{R}^{p_1}$ and ϵ_t is independent of X_t. At the population level, let

$$\mathbb{E}Y_t Y_t' = \Sigma_Y, \qquad \mathbb{E}X_t X_t' = \Sigma_X, \qquad \mathbb{E}Y_t X_t' = \Sigma_{YX} = \Sigma_{XY}'.$$

The population canonical correlations between Y_t and X_t are the roots of

$$\begin{vmatrix} -\rho\Sigma_Y & \Sigma_{YX} \\ \Sigma_{XY} & -\rho\Sigma_X \end{vmatrix} = 0,$$

i.e., the nonnegative solutions to

$$|\Sigma_{YX}\Sigma_X^{-1}\Sigma_{XY} - \rho^2\Sigma_Y| = 0, \tag{22}$$

with ρ being the unknown. By the results in Anderson (2002), the number of positive solutions to (22) is equal to the rank of Π, and indicates the "degree of dependency" between processes Y_t and X_t. This suggests that if $\text{rank}(\Pi) \leq r < p$, we would expect $\sum_{k=r+1}^{p} \lambda_k$ to be small, where the λ's solve the eigen-equation

$$|S_{YX}S_X^{-1}S_{XY} - \lambda S_Y| = 0, \qquad \text{with} \quad \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_p,$$

and S_X, S_{XY} and S_Y are the sample counterparts corresponding to Σ_X, Σ_{XY} and Σ_Y, respectively.

With this background, we switch to our model setting given by

$$Z_t = BX_{t-1} + CZ_{t-1} + V_t, \tag{23}$$

where V_t is assumed to be independent of X_{t-1} and Z_{t-1}, B encodes the canonical correlation between Z_t and X_{t-1}, conditional on Z_{t-1}. We use the same notation as in Section 3; that

is, let $\Gamma_X(h) = \mathbb{E}X_tX_{t+h}'$, $\Gamma_Z(h) = \mathbb{E}Z_tZ_{t+h}'$, and $\Gamma_{X,Z}(h) = \mathbb{E}X_tZ_{t+h}'$, with (h) omitted whenever $h = 0$. At the population level, under the Gaussian assumption,

$$\begin{bmatrix} Z_t \\ X_{t-1} \\ Z_{t-1} \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \Gamma_Z & \Gamma_{X,Z}'(1) & \Gamma_Z(1) \\ \Gamma_{X,Z}(1) & \Gamma_X & \Gamma_{X,Z} \\ \Gamma_Z'(1) & \Gamma_{X,Z}' & \Gamma_Z \end{bmatrix} \right),$$

which suggests that conditionally,

$$Z_t \big| Z_{t-1} \sim \mathcal{N}\left(\Gamma_Z(1)\Gamma_Z^{-1}Z_{t-1}, \Sigma_{00}\right) \qquad \text{and} \qquad X_{t-1}\big|Z_{t-1} \sim \mathcal{N}\left(\Gamma_{X,Z}\Gamma_Z^{-1}Z_{t-1}, \Sigma_{11}\right),$$

where

$$\Sigma_{00} := \Gamma_Z - \Gamma_Z(1)\Gamma_Z^{-1}\Gamma_Z'(1) \qquad \text{and} \qquad \Sigma_{11} := \Gamma_X - \Gamma_{X,Z}\Gamma_Z^{-1}\Gamma_{X,Z}'. \tag{24}$$

Then, we have that jointly

$$\begin{bmatrix} Z_t \\ X_{t-1} \end{bmatrix} \Big| Z_{t-1} \sim \mathcal{N}\left(\begin{bmatrix} \Gamma_Z(1) \\ \Gamma_{X,Z} \end{bmatrix} \Gamma_Z^{-1}Z_{t-1}, \begin{bmatrix} \Gamma_Z & \Gamma_{XZ}'(1) \\ \Gamma_{XZ}(1) & \Gamma_Z \end{bmatrix} - \begin{bmatrix} \Gamma_Z(1) \\ \Gamma_{XZ} \end{bmatrix} \Gamma_Z^{-1} \begin{bmatrix} \Gamma_Z'(1) & \Gamma_{ZX} \end{bmatrix} \right),$$

so the partial covariance matrix between Z_t and X_{t-1} conditional on Z_{t-1} is given by

$$\Sigma_{10} = \Sigma_{01}' := \Gamma_{X,Z}(1) - \Gamma_Z(1)\Gamma_Z^{-1}\Gamma_{X,Z}. \tag{25}$$

The population canonical correlations between Z_t and X_{t-1} conditional on Z_{t-1} are the non-negative roots of

$$\left|\Sigma_{01}\Sigma_{11}^{-1}\Sigma_{10} - \rho^2\Sigma_{00}\right| = 0,$$

and the number of positive solutions corresponds to the rank of B; see Anderson (1951) for a discussion in which the author is interested in estimating and testing linear restrictions on regression coefficients. Therefore, to test $\text{rank}(B) \leq r$, it is appropriate to examine the behavior of $\Psi_r := \sum_{k=r+1}^{\min(p_1,p_2)} \phi_k$, where ϕ's are ordered non-increasing solutions to

$$|S_{01}S_{11}^{-1}S_{10} - \phi S_{00}| = 0, \tag{26}$$

and S_{01}, S_{11} and S_{00} are the empirical surrogates for the population quantities Σ_{01}, Σ_{11} and Σ_{00}. For subsequent developments, we make the very mild assumption that $p_1 < T$ and $p_2 < T$ so that $\mathcal{Z}'\mathcal{Z}$ is invertible.

Proposition 9 gives the tail behavior of the eigenvalues and Corollary 11 gives the testing procedure for block "Granger-causality" as a direct consequence.

Proposition 9 *Consider the model setup given in (23), where $B \in \mathbb{R}^{p_2 \times p_1}$. Further, assume all positive eigenvalues μ of the following eigen-equation are of algebraic multiplicity one:*

$$\left|\Sigma_{01}\Sigma_{11}^{-1}\Sigma_{10} - \mu\Sigma_{00}\right| = 0, \tag{27}$$

where Σ_{00}, Σ_{11} and Σ_{01} are given in (24) and (25). The test statistic for testing

$$H_0 : \text{rank}(B) \leq r, \qquad \textit{for an arbitrary} \quad r < \min(p_1, p_2),$$

is given by

$$\Psi_r := \sum_{k=r+1}^{\min(p_1,p_2)} \phi_k,$$

where ϕ_k's are ordered decreasing solutions to the eigen-equation $|S_{01}S_{11}^{-1}S_{10} - \phi S_{00}| = 0$ where

$$S_{11} = \tfrac{1}{T}\mathcal{X}'(I - P_z)\mathcal{X}, \quad S_{00} = \tfrac{1}{T}\left(\mathcal{Z}^T\right)'(I - P_z)\left(\mathcal{Z}^T\right), \quad S_{10} = S_{01}' = \tfrac{1}{T}\mathcal{X}'(I - P_z)\left(\mathcal{Z}^T\right),$$

and $P_z = \mathcal{Z}(\mathcal{Z}'\mathcal{Z})^{-1}\mathcal{Z}'$. Moreover, the limiting behavior of Ψ_r is given by

$$T\Psi_r \sim \chi^2_{(p_1-r)(p_2-r)}.$$

Remark 10 *We provide a short comment on the assumption that the positive solutions to (27) have algebraic multiplicity one in Proposition 9. This assumption is imposed on the eigen-equation associated with population quantities, to exclude the case where a positive root has algebraic multiplicity greater than one and its geometric multiplicity does not match the algebraic one, and hence we would fail to obtain r mutually independent canonical variates and the rank-r structure becomes degenerate. With the imposed assumption which is common in the canonical correlation analysis literature (e.g. Anderson, 2002), such a scenario is automatically excluded. Specifically, this condition is not stringent, as for ϕ's that are solutions to the eigen-equation associated with sample quantities, the distinctiveness amongst roots is satisfied with probability 1 (see Hsu, 1941b, Proof of Lemma 3).*

Corollary 11 (Testing group Granger-causality) *Under the model setup in (23), the test statistic for testing $B = 0$ is given by*

$$\Psi_0 := \sum_{k=1}^{\min(p_1,p_2)} \phi_k,$$

with ϕ_k being the ordered decreasing solutions of

$$\left|S_{01}\left[\text{diag}(S_{11})\right]^{-1}S_{10} - \phi S_{00}\right| = 0.$$

Asymptotically, $T\Psi_0 \sim \chi^2_{p_1p_2}$. To conduct a level α test, we reject the null hypothesis $H_0 : B = 0$ if

$$\Psi_0 > \frac{1}{T}\chi^2_{p_1p_2}(\alpha),$$

where $\chi^2_d(\alpha)$ is the upper α quantile of the χ^2 distribution with d degrees of freedom.

Remark 12 *Corollary 11 is a special case of Proposition 9 with the null hypothesis being $H_0 : r = 0$, which corresponds to the Granger-causality test. Under this particular setting, we are able to take the inverse with respect to $diag(S_{11})$, yet maintain the same asymptotic distribution due to the fact that $S_{01} = S_{10} = 0$ under the null hypothesis $B = 0$. This enables us to perform the test even with $p_1 > T$.*

The above testing procedure takes advantage of the fact that when $B = 0$, the canonical correlations among the partial regression residuals after removing the effect of Z_{t-1} are very close to zero. However, the test may not be as powerful under a sparse alternative, i.e., $H_A : B$ is sparse. In Supplementary Material **??**, we present a testing procedure that specifically takes into consideration the fact that the alternative hypothesis is sparse, and the corresponding performance evaluation is shown in Section 5.2 under this setting.

5. Performance Evaluation.

Next, we present the results of numerical studies to evaluate the performance of the developed ML estimates (Section 2.1) of the model parameters, as well as that of the testing procedure (Section 4).

5.1 Simulation results for the estimation procedure.

A number of factors may potentially influence the performance of the estimation procedure; in particular, the model dimension p_1 and p_2, the sample size T, the rank of $B^\star$ and the sparsity level of $A^\star$ and $C^\star$, as well as the spectral radius of $A^\star$ and $C^\star$. Hence, we consider several settings where these parameters vary.

For all settings, the data $\{x_t\}_1^T$ and $\{z_t\}_1^T$ are generated according to the model

$$x_t = A^\star x_{t-1} + u_t,$$
$$z_t = B^\star x_{t-1} + C^\star z_{t-1} + v_t.$$

For the sparse components, each entry in $A^\star$ and $C^\star$ is nonzero with probability $2/p_1$ and $1/p_2$ respectively, and the nonzero entries are generated from $\mathsf{Unif}([-2.5,-1.5]\cup[1.5,2.5])$, then scaled down so that the spectral radii $\rho(A)$ and $\rho(C)$ satisfy the stability condition. For the low rank component, each entry in $B^\star$ is generated from $\mathsf{Unif}(-10,10)$, followed by singular value thresholding, so that $\mathrm{rank}(B^\star)$ conforms with the model setup. For the contemporaneous dependence encoded by $\Omega_u^\star$ and $\Omega_v^\star$, both matrices are generated according to an Erdös-Rényi random graph, with sparsity being 0.05 and condition number being 3.

Table 1 depicts the values of model parameters under different model settings. Specifically, we consider three major settings in which the size of the system, the rank of the cross-dependence component, and the stability of the system vary. The sample size is fixed at $T = 200$ unless otherwise specified. Additional settings examined (not reported due to space considerations) are consistent with the main conclusions presented next.

We use sensitivity (SEN), specificity (SPC) and relative error in Frobenius norm (Error) as criteria to evaluate the performance of the estimates of transition matrices A, B and C. Tuning parameters are chosen based on BIC. Since the exact contemporaneous dependence is not of primary concern, we omit the numerical results for $\widehat{\Omega}_u$ and $\widehat{\Omega}_v$.

$$\mathrm{SEN} = \frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FN}}, \quad \mathrm{SPE} = \frac{\mathrm{TN}}{\mathrm{FP}+\mathrm{TN}}, \quad \mathrm{Error} = \frac{|||\mathrm{Est.} - \mathrm{Truth}|||_F}{|||\mathrm{Truth}|||_F}.$$

Table 2 illustrates the performance for each of the parameters under different simulation settings considered. The results are based on an average of 100 replications and their

Table 1: Model parameters under different model settings

standard deviations are given in parentheses. Overall, the results are highly satisfactory and all the parameters are estimated with a high degree of accuracy. Further, all estimates were obtained in less than 20 iterations, thus indicating that the estimation procedure is numerically stable. As expected, when the the spectral radii of A and C increase thus leading to less stable $\{X_t\}$ and $\{Z_t\}$ processes, a larger sample size is required for the estimation procedure to match the performance of the setting with same parameters but smaller $\rho(A)$ and $\rho(C)$. This is illustrated in row C.3' of Table 2, where the sample size is increased to $T = 500$, which outperforms the results in row C.3 in which $T = 200$ and broadly matches that of row A.1.

Since in some application settings the data may deviate from the posited Gaussian assumption, we further investigate the robustness of the algorithm in the presence of heavier than Gaussian distributions in the Supplementary Material **??**. Further, a brief comparison of the ML estimates with their two-step (non-iterative) counterparts is given in the Supplementary Material **??** , that illustrates the numerical benefits of the proposed procedure.

Lastly, we examine the performance with respect to one-step-ahead forecasting. Recall that VAR models are widely used for forecasting purposes in many application areas

(Lütkepohl, 2005). The performance metric is given by the relative error as measured by the ℓ_2 norm of the out-of-sample points x_{T+1} and z_{T+1}, where the predicted values are given by $\widehat{x}_{T+1} = \widehat{A}x_T$ and $\widehat{z}_{T+1} = \widehat{B}x_T + \widehat{C}z_T$, respectively. It is worth noting that both $\{X_t\}$ and $\{Z_t\}$ are mean-zero processes. However, since the transition matrix of $\{X_t\}$ is subject to the spectral radius constraints to ensure the stability of the corresponding process, the magnitude of the realized value $\{x_t\}$ is small; whereas for $\{Z_t\}$, since no constraints are imposed on the B coefficient matrix that encodes the inter-dependence, z_t's has the capacity of having relative large values in magnitude. Consequently, the relative error of $\widehat{x}_{T+1}$ is significantly larger than that of $\widehat{z}_{T+1}$, partially due to the small total magnitude of the denominator.

The results show that an increase in the spectral radius (keeping the other structural parameters fixed) leads to a decrease of the relative error, since future observations become more strongly correlated over time. On the other hand, an increase in dimension leads to a deterioration in forecasting, since the available sample size impacts the quality of the parameter estimates. Finally, an increase in the rank of the B matrix is beneficial for forecasting, since it plays a stronger role in the system's temporal evolution.

Table 3: One-step-ahead relative forecasting error.

		$\frac{\|\widehat{x}_{T+1}-x_{T+1}\|_2}{\|x_{T+1}\|_2}$	$\frac{\|\widehat{z}_{T+1}-z_{T+1}\|_2}{\|z_{T+1}\|_2}$

5.2 Simulation results for the block Granger-causality test.

Next, we illustrate the empirical performance of the testing procedure introduced in Section 4, together with the one specifically tailored to a sparse alternative (described in detail in the Supplementary Material **??**) with the null hypothesis being $B^\star = 0$ and the alternative being $B^\star \neq 0$, either low rank or sparse. Specifically, when the alternative hypothesis is true and has a low-rank structure, we use the general testing procedure proposed in Section 4, whereas when the alternative is true and sparse, we use the testing procedure presented in Supplementary Material **??**. We focus on evaluating the type I error (empirical false rejection rate) when $B^\star = 0$, as well as the power of the test when $B^\star$ has nonzero entries.

For both testing procedures, the transition matrix $A^\star$ is generated with each entry being nonzero with probability $2/p_1$, and the nonzeros are generated from $\mathsf{Unif}([-2.5,-1.5]\cup[1.5,2.5])$, then further scaled down so that $\rho(A^\star) = 0.5$. For transition matrix $C^\star$, each entry is nonzero with probability $1/p_2$, and the nonzeros are generated from $\mathsf{Unif}([-2.5,-1.5]\cup[1.5,2.5])$,

then further scaled down so that $\rho(C^\star) = 0.5$ or 0.8, depending on the simulation setting. Finally, we only consider the case where v_t and u_t have diagonal covariance matrices.

We use sub-sampling as in Politis et al. (1999) with the number of subsamples set to 3,000; an alternative would have been a block bootstrap procedure (e.g., Hall, 1985). Note that the length of the subsamples varies across simulation settings in order to gain insight on how sample size impacts the type I error or the power of the test.

Low-rank testing. To evaluate the type I error control and the power of the test, we primarily consider the case where $\mathrm{rank}(B^\star) = 0$, with the data alternatively generated based on $\mathrm{rank}(B^\star) = 1$. We test the hypothesis $H_0 : \mathrm{rank}(B) = 0$ and tabulate the empirical proportion of falsely rejecting H_0 when $\mathrm{rank}(B^*) = 0$ (type I error) and the probability that we reject H_0 when $\mathrm{rank}(B^*) = 1$ (power). In addition, we also show how the testing procedure performs when the underlying $B^\star$ has rank $r \geq 0$. In particular, when $\mathrm{rank}(B^\star) = r^\star$, the type I error of the test corresponds to the empirical proportion of rejections of the null hypothesis $H_0 : r \leq r^\star$, while the power of the test to the empirical proportion of rejections of the null hypothesis set to $H_0 : r \leq (r^\star - 1)$. The latter resembles the sequential test in Johansen (1988).

Empirically, we expect that when $B^\star = 0$, the value of the proposed test statistic mostly falls below the cut-off value (upper α quantile), while when $\mathrm{rank}(B^\star) = 1$, the value of the proposed test statistic mostly falls beyond the critical value $\chi^2(\alpha)_{p_1p_2}/T$ with T being the sample size, hence leading to a detection. Table 4 gives the type I error of the test when setting $\alpha = 0.1, 0.05, 0.1$, and the power of the test using the upper 0.01 quantile of the reference distribution as the cut-off, for different combinations of model dimensions (p_1, p_2) and sample size.

Based on the results shown in Table 4, it can be concluded that the proposed low-rank testing procedure accurately detects the presence of "Granger causality" across the two blocks, when the data have been generated based on a truly multi-layer VAR system. Further, when $B^\star = 0$, the type I error is close to the nominal α level for sufficiently large sample sizes, but deteriorates for increased model dimensions. In particular, relatively large values of p_2 and larger spectral radius $\rho(C^\star)$ negatively impact the empirical false rejection proportion, which deviates from the desired control level of the type I error. In the case where $\mathrm{rank}(B^\star) = r > 0$, the testing procedure provides satisfactory type I error control for larger sample sizes and excellent power.

Sparse testing. Since the rejection rule of the HC-statistic is based on empirical process theory (Shorack and Wellner, 2009) and its dependence on α is not explicit, we focus on illustrating how the empirical proportion of false rejections (type I error) varies with the sample size T, the model dimensions (p_1, p_2) and the spectral radius of $C^\star$. To show the power of the test, each entry in $B^\star$ is nonzero with probability $q \in (0,1)$ such that $q(p_1p_2) = (p_1p_2)^\theta$ with $\theta = 0.6$, to ensure the overall sparsity of $B^\star$ satisfies the sparsity requirement posited in Proposition **??**. The magnitude is set such that the signal-to-noise ratio is 1.2. Note that the actual number of parameters is p_1p_2, while the total number of subsamples used is 3000 with the length of subsamples varying according to different simulation settings to demonstrate the dependence of type I error and power on sample sizes.

Table 4: Empirical type I error and power for low-rank testing

			type I error ($B^\star = 0$)			power (rank($B^\star$) = 1)

	$(50, 20)$	0.393	0.131	0.108	0.074	1	1	1	1
	$(20, 50)$	0.996	0.351	0.153	0.093	1	1	1	1
	$(100, 50)$	1.000	0.963	0.270	0.115	1	1	1	1
$\rho(C^\star) = 0.8$	$(50, 20)$	0.402	0.158	0.112	0.075	0.829	0.996	1	1
	$(20, 50)$	0.999	0.430	0.166	0.111	1	1	1	1

Based on the results shown in Table 5, when $B^\star = 0$, the proposed testing procedure can effectively detect the absence of block "Granger causality", provided that the sample size is moderately large compared to the total number of parameters being tested. However, if the model dimension is large, whereas the sample size is small, the test procedure becomes problematic and fails to provide legitimate type I error control as desired. When $B^\star$ is

nonzero, empirically the test is always able detect its presence, as long as the effective signal-to-noise ratio is beyond the detection threshold.

6. Real Data Analysis Illustration.

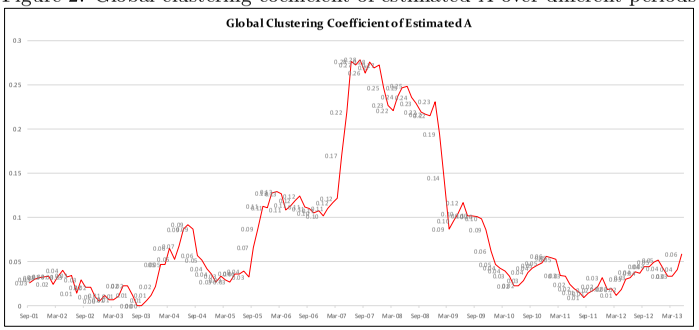
We employ the developed framework and associated testing procedures to address one of the motivating applications. Specifically, we analyze the temporal dynamics of the log-returns of stocks with large market capitalization and key macroeconomic variables, as well as their cross-dependence. Specifically, using the notation in (1), we assume that the X_t block consists of the stock log-returns, while the macroeconomic variables form the Z_t block. With this specification, we assume that the macroeconomic variables are "Granger-caused" by the stock market, but not vice versa. Note that our framework allows us to pose and test a more general question than previous work in the economics literature considered. For example, Farmer (2015) building on previous work by Fitoussi et al. (2000); Phelps (1999) tests only the relationship between the employment index and the composite stock index, using a bivariate VAR model. On the other hand, our framework enables us to consider the components of the S&P 100 index and the "medium" list of macroeconomic variables considered in the work of Stock and Watson (2005).

Next, we provide a brief description of the data used. The stock data consist of monthly observations of 71 stocks corresponding to a stable set of historical components comprising the S&P 100 index for the 2001-2016 period. The macroeconomic variables are chosen from the "medium" list in Stock and Watson (2005). The complete lists of stocks and macroeconomic variables, together with the preprocessing to ensure stationarity used in this study are given in Supplementary Material **??**.

We start the analysis by using the VAR model for the stock log-returns to study their evolution over the 2001-2016 period. Analogously to the strategy employed by Billio et al. (2012), we consider 36-month-long rolling-windows for fitting the model $X_t = AX_{t-1} + U_t$, for a total of 143 estimates of the transition matrix A. VAR models involving more than 1 lag were also fitted to the data, but did not indicate temporal dependence beyond lag 1. To obtain the final estimates across all 143 subsamples, we employ *stability selection* (Meinshausen and Bühlmann, 2010), with the threshold set at 0.6 for including an edge in A.[1] Figure 2 depicts the global clustering coefficient (Luce and Perry, 1949) of the skeleton of the estimated A over all 143 rolling windows, with the time stamps on the horizontal axis specifying the starting time of the corresponding window. The results clearly indicate strong connectivity in lead-lag stock relationships during the financial crisis period March 2007-June 2009. Next, we present the analysis based on the VAR-X component of our model, given by $Z_t = BX_{t-1} + CZ_{t-1} + V_t$ with the stock log-returns corresponding to the X_t block and the (stationary) macroeconomic variables to the Z_t block. As before, we fit the data within each rolling window, with the tuning parameters based on a search over a 10×10 lattice (with $(\lambda_B, \lambda_C) \in [0.5, 4] \times [0.2, 2]$, equal-spaced) using the BIC. It should be noted that for the majority of the rolling windows, the rank of B is 1 (data not shown). The sparsity level of the estimated C over the 143 rolling windows is depicted in Figure 3. The connectivity patterns in C show more complex and nuanced patterns than

1. The threshold is set at a relatively low level to compensate for the relative small rolling window size.

Figure 2: Global clustering coefficient of estimated A over different periods



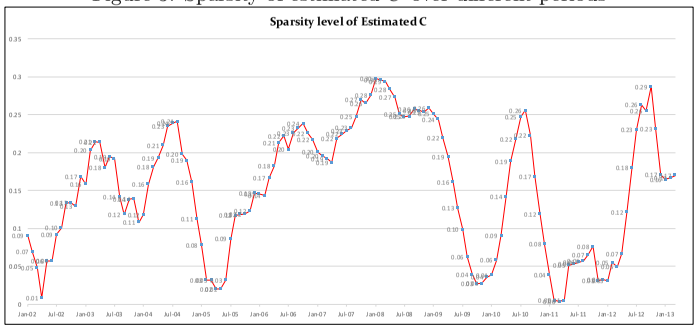


Figure 3: Sparsity of estimated C over different periods

for stocks. A more detailed analysis of the various peaks identified through our model is given in Supplementary Material **??**.

Based on the previous findings, we partition the time frame spanning 2001-2016 into the following periods: pre- (2001/07–2007/03), during- (2007/01–2009/12) and post-crisis (2010/01-2016/06) one. We estimate the model parameters using the data within the entire sub-period(s).

The estimation procedure of the transition matrix A for different periods is identical to that described above using subsamples over rolling-windows. For the pre- and post- crisis periods, since we have 76 and 77 samples respectively, the stability selection threshold is set at 0.75, whereas for the during-crisis period, at 0.6 to compensate for the small sample size (36). Table 6 shows the average R-square for all 71 stocks, as well as its standard deviation, which is calculated based on in-sample fit; i.e.,the proportion of variation explained by using the VAR(1) model to fit the data. The overall sparsity level and the spectral radius of the estimated transition matrices A are also presented. The results are consistent with the previous finding of increased connectivity during the crisis. Further, for all periods the estimate of the spectral radius is fairly large, indicating strong temporal dependence of the log-returns.

Table 6: Summary for estimated A within different periods.

	2001/07–2007/03	2007/01–2009/12	2010/01–2016/06
Averaged R sq	0.31	0.72	0.28
Sd of R sq	0.103	0.105	0.094
Sparsity level of $\widehat{A}$	0.17	0.23	0.19
Spectral radius of $\widehat{A}$	0.67	0.90	0.75

Next, we focus on the key motivation for developing the proposed modeling framework, namely the inter-dependence of stocks and macroeconomic variables over the specified three sub-periods. The p-value for testing the hypothesis of lack of block "Granger causality" $H_0 : B = 0$, together with the spectral radius and the sparsity level for the estimated C transition matrices are listed in Table 7. Specifically, for all three periods, the rank of estimated B is 1, indicating that the stock market as captured by its leading stocks, "Granger-causes" the temporal evolution of the macroeconomic variables. The fact that the rank of B is 1, indicates that the inter-block influence can be captured as a single portfolio acting in unison. To investigate the relative importance of each sector in the portfolio, we group the stocks by sectors. The proportion of each sector (up to normalization) is obtained by summing up the loadings (first right singular vector of the estimated B) of the stocks within this sector, weighted by their market capitalization (results shown in Supplementary Material **??**).

Next, we discuss some key relationships emerging from the model. We start with total employment (ETTL), whose dynamics are only influenced by its own past values as seen by the lack of an incoming arrow in Figure **??**. Further, an examination of the left singular vector (see Table 8) of B strongly indicates the impact of the stock market on total employment. This finding is consistent with the analysis in Farmer (2015), which argues that the crash of the stock market provides a plausible explanation for the great recession. However,

the analysis in Farmer (2015) is based on bivariate VAR models involving only employment and the stock index. Therefore, there is a possibility that the stock market is reacting to some other information captured by other macroeconomic variables, such as GDP, capital spending, inflation, interest rates, etc. However, our high-dimensional VAR model simultaneously analyzes a key set of macroeconomic variables and also accounts for the influence of the largest stocks in the market. Hence, it automatically overcomes the criticism leveraged by Sims (1992) about misinterpretations of findings from small scale VAR models due to the omission of important variables, and further echoed in the discussion in Bernanke et al. (2005). Other interesting findings are presented in Supplementary Material **??**.

Table 7: Summary for estimated B and C within different periods.

	2001/07–2007/03	2007/01–2009/12	2010/01–2016/16

Remark 13 *We also applied our multi-block model with the first block X_t corresponding to the macro-economic variables and the second block Z_t the stocks variables (results not shown). The key question is whether there is also "Granger causality" from the broader economy to the stock market. The results are inconclusive due to sample size issues that do not allow us to properly test for the key hypothesis whether $B = 0$ or not. Specifically, the length of the sub-periods is short compared to the dimensionality required for the test procedure. A similar issue arises, which is related to the detection boundary for the sparse testing procedure during the crisis period. Further, for a sparse B, an examination of its entries shows that Employment Total did not impact the stock market, which is in line with the conclusion reached at the aggregate level by Farmer (2015). On the other hand, GDP negatively impacts stock log-returns, which may act as a leading indicator for suppressed investment and business growth and hence future stock returns.*

7. Discussion.

We briefly discuss generalizations of the model to the case of more than two blocks, as mentioned in the introductory section. For the sake of concreteness, consider a triangular recursive linear dynamical system given by:

$$\begin{aligned} X_t^{(1)} &= A_{11}X_{t-1}^{(1)} + \epsilon_t^{(1)}, \\ X_t^{(2)} &= A_{12}X_{t-1}^{(1)} + A_{22}X_{t-1}^{(2)} + \epsilon_t^{(2)}, \\ X_t^{(3)} &= A_{13}X_{t-1}^{(1)} + A_{23}X_{t-1}^{(2)} + A_{33}X_{t-1}^{(3)} + \epsilon_t^{(3)}, \\ &\vdots \end{aligned} \tag{28}$$

where $X^{(j)} \in \mathbb{R}^{p_j}$ denotes the variables in group j, A_{ij} $(i < j)$ encodes the dependency of $X^{(j)}$ on the past values of variables in group i, and A_{jj} encodes the dependency on its own past values. Further, $\{\epsilon_t^{(j)}\}$ is the innovation process that is neither temporally, nor cross-sectionally correlated, i.e.,

$$\mathrm{Cov}(\epsilon_t^{(j)}, \epsilon_s^{(j)}) = 0 \ (s \neq t), \quad \mathrm{Cov}(\epsilon_t^{(i)}, \epsilon_s^{(j)}) = 0 \ (i \neq j, \ \forall \ (s,t)), \quad \mathrm{Cov}(\epsilon_t^{(j)}, \epsilon_t^{(j)}) = \big(\Omega^{(j)}\big)^{-1},$$

with $\Omega^{(j)}$ capturing the conditional contemporaneous dependency of variables within group j. The model in (28) can also be viewed from a multi-layered time-varying network perspective: nodes in each layer are "Granger-caused" by nodes from its previous layers, and are also dependent on its own past values. As previously mentioned, in various real applications, it is of interest to obtain estimates of the transition matrices, and/or test if "Granger-causality" is present between interacting blocks; i.e., to test $A_{ij} = 0$ for some $i \neq j$.

The triangular structure of the system decouples the estimation of the transition matrices from each equation, and hence a straightforward extension of the estimation procedure presented in Section 2.1 becomes applicable. Specifically, to obtain estimates of the transition matrices A_{ij}'s for fixed j and $1 \leq i \leq j$, and the inverse covariance $\Omega^{(j)}$, the optimization problem is formulated as follows:

$$\begin{aligned} (\{\widehat{A}_{ij}\}_{i\leq j}, \widehat{\Omega}^{(j)}) = \underset{A_{ij},\Omega^{(j)}}{\arg\min} \Big\{ &- \log\det\Omega^{(j)} + \frac{1}{T}\sum_{t=1}^{T} \big(x_t^{(j)} - \sum_{i=1}^{j} A_{ij}x_{t-1}^{(i)}\big)'\Omega^{(j)}\big(x_t^{(j)} - \sum_{1\leq i\leq j} A_{ij}x_{t-1}^{(i)}\big) \\ &+ \sum_{i=1}^{j} \mathcal{R}(A_{ij}) + \rho^{(j)}\|\Omega^{(j)}\|_{1,\mathrm{off}}\Big\}, \end{aligned} \tag{29}$$

where the exact expression for the $\mathcal{R}(A_{ij})$ adapts to the structural assumption imposed on the corresponding transition matrix (sparse/low-rank). Solving (29) again requires an iterative algorithm involving the alternate update between transition matrices and the inverse

covariance matrices. Further, for updating the values of the transition matrices, a cyclic block-coordinate updating procedure is used.

Consistency results can be established analogously to those provided in Section 3, under the posited conditions of restricted strong convexity (RSC) and a deviation bound. With a larger number of interacting blocks of variables, lower bounds for the lower extremes of the spectra involve all corresponding transition matrices. The error rates that can be obtained are as follows: (i) if equation k only involves sparse transition matrices, then the finite-sample bounds of the transition matrices in this layer in Frobenius norm are of the order $O\big(\sqrt{\frac{\log p_k + \log \sum_{i \le k} p_k}{T}}\big)$, while (ii) if some of the transition matrices are assumed low rank, then the corresponding finite sample bounds are of the order $O\big(\sqrt{\frac{p_k + \sum_{i<k} p_k}{T}}\big)$.

Another generalization that can be handled algorithmically with the same estimation procedure discussed above is the presence of d-lags in the specification of the linear dynamical system. Based on the consistency results developed in this work, together with the theoretical findings for VAR(d) models presented in Basu and Michailidis (2015), we expect all the established theoretical properties of the transition matrices estimates to go through under appropriate RSC and deviation bound conditions.

Appendix A. Additional Theorems and Proofs for Theorems.

In this section, we introduce two additional theorems that respectively establish the consistency properties for the initializers $\widehat{A}^{(0)}$ and $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$, for *fixed* realizations of the processes $\{X_t\}$ and $\{Z_t\}$. Specifically, $\widehat{A}^{(0)}$ and $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$ are solutions to the following optimization problems:

$$\widehat{A}^{(0)} := \arg\min_{A} \big\{ \tfrac{1}{T} \big\| \mathcal{X}^T - \mathcal{X} A' \big\|_F + \lambda_A \|A\|_1 \big\}, \tag{30}$$

$$(\widehat{B}^{(0)}, \widehat{C}^{(0)}) := \arg\min_{B,C} \big\{ \tfrac{1}{T} \big\| \mathcal{Z}^T - \mathcal{X} B' - \mathcal{Z} C' \big\|_F + \lambda_B \|B\|_* + \lambda_C \|C\|_1 \big\}. \tag{31}$$

Note that they also correspond to estimators of the setting where there is no contemporaneous dependence among the idiosyncratic error processes. If we additionally introduce operators $\mathfrak{X}_0$ and $\mathfrak{W}_0$ defined as

$$\begin{aligned} \mathfrak{X}_0 : &\quad \mathfrak{X}_0(\Delta) = \mathcal{X}'\Delta, \quad \text{for } \Delta \in \mathbb{R}^{p_1 \times p_1}, \\ \mathfrak{W}_0 : &\quad \mathfrak{W}_0(\Delta) = \mathcal{W}'\Delta, \quad \text{for } \Delta \in \mathbb{R}^{p_2 \times (p_1+p_2)} \quad \text{where } \mathcal{W} := [\mathcal{X}, \mathcal{Z}], \end{aligned}$$

then (30) and (31) can be equivalently written as

$$\widehat{A}^{(0)} := \arg\min_{A} \big\{ \tfrac{1}{T} \big\| \mathcal{X}^T - \mathfrak{X}_0(A) \big\|_F + \lambda_A \|A\|_1 \big\},$$

$$(\widehat{B}^{(0)}, \widehat{C}^{(0)}) := \arg\min_{B,C} \big\{ \tfrac{1}{T} \big\| \mathcal{Z}^T - \mathfrak{W}_0(B_{\text{aug}}, C_{\text{aug}}) \big\|_F + \lambda_B \|B\|_* + \lambda_C \|C\|_1 \big\},$$

where $B_{\text{aug}} := [B, O_{p_2 \times p_2}], C_{\text{aug}} := [O_{p_2 \times p_1}, C]$.

Theorem 14 (Error bounds for $\widehat{A}^{(0)}$) *Suppose the operator $\mathfrak{X}_0$ satisfies the RSC condition with norm $\Phi(\Delta) = \|\Delta\|_1$, curvature $\alpha_{RSC} > 0$ and tolerance $\tau > 0$, so that*

$$s_A^\star \tau \le \alpha_{RSC}/32.$$

Then, with regularization parameter λ_A satisfying $\lambda_A \ge 4\|\mathcal{X}'\mathcal{U}/T\|_\infty$, the solution to (30) satisfies the following bounds:

$$\|\widehat{A}^{(0)} - A^\star\|_F \le 12\sqrt{s_A^\star}\lambda_A/\alpha_{RSC} \qquad \text{and} \qquad \|\widehat{A} - A^\star\|_1 \le 48 s_A^\star \lambda_A/\alpha_{RSC}.$$

Theorem 15 (Error bound for $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$) *Let $\mathcal{J}_{C^\star}$ be the support set of $C^\star$ and $s_C^\star$ denote its cardinality. Let $r_B^\star$ be the rank of $B^\star$. Assume that $\mathfrak{W}_0$ satisfies the RSC condition with norm*

$$\Phi(\Delta) := \inf_{B_{aug} + C_{aug} = \Delta} \mathcal{Q}(B, C), \qquad \text{where} \quad \mathcal{Q}(B, C) := \|B\|_* + \tfrac{\lambda_C}{\lambda_B}\|C\|_1,$$

curvature α_{RSC} and tolerance τ such that

$$128\tau r_B^\star < \alpha_{RSC}/4 \qquad \text{and} \qquad 64\tau s_C^\star (\lambda_C/\lambda_B)^2 < \alpha_{RSC}/4.$$

Then, with regularization parameters λ_B and λ_C satisfying

$$\lambda_B \ge 4\big\|\mathcal{W}'\mathcal{V}/T\big\|_{op} \quad \text{and} \quad \lambda_C \ge 4\big\|\mathcal{W}'\mathcal{V}/T\big\|_\infty,$$

the solution to (31) satisfies the following bounds:

$$\|\widehat{B}^{(0)} - B^\star\|_F^2 + \|\widehat{C}^{(0)} - C^\star\|_F^2 \le 4\left(2 r_B^\star \lambda_B^2 + s_C^\star \lambda_C^2\right)/\alpha_{RSC}^2.$$

In the rest of this subsection, we first prove Theorem 14 and 15, then prove Theorem 5 and 6, whose statements are given in Section 3.2.

Proof [**Proof of Theorem 14**]

For the ease of notation, in this proof, we use $\widehat{A}$ to refer to $\widehat{A}^{(0)}$ whenever there is no ambiguity. Let $\beta_A^\star = \text{vec}(A^\star)$ and denote the residual matrix and its vectorized version by $\Delta_A = \widehat{A} - A^\star$ and $\Delta_{\beta_A} = \widehat{\beta}_A - \beta_A^\star$, respectively. By the optimality of $\widehat{A}$ and the feasibility of $A^\star$, the following *basic inequality* holds:

$$\tfrac{1}{T}\|\mathfrak{X}_0(\Delta_A)\|_F^2 \le \tfrac{2}{T}\langle\!\langle \Delta_A, \mathcal{X}'\mathcal{U}\rangle\!\rangle + \lambda_A\left\{\|A^\star\|_1 - \|A^\star + \Delta_A\|_1\right\},$$

which is equivalent to:

$$\Delta_{\beta_A}'\widehat{\Gamma}_X^{(0)}\Delta_{\beta_A} \le \tfrac{2}{T}\langle\Delta_{\beta_A}, \text{vec}(\mathcal{X}'\mathcal{U})\rangle + \lambda_A\left\{\|\beta_A^\star\|_1 - \|\beta_A^\star + \Delta_{\beta_A}\|_1\right\}, \tag{32}$$

where $\widehat{\Gamma}_X^{(0)} = \mathrm{I}_{p_1} \otimes \frac{\mathcal{X}'\mathcal{X}}{T}$. By Hölder's inequality and the triangle inequality, an upper bound for the right-hand-side of (32) is given by

$$\tfrac{2}{T}\|\Delta_{\beta_A}\|_1\left\|\mathcal{X}'\mathcal{U}\right\|_\infty + \lambda_A\|\Delta_{\beta_A}\|_1. \tag{33}$$

Now with the specified choice of λ_A, by Lemma **??**, $\|\Delta_{\beta_A|\mathcal{J}_{A^\star}}\|_1 \le 3\|\Delta_{\beta_A|\mathcal{J}_{A^\star}^c}\|_1$ i.e., $\Delta_{\beta_A} \in \mathcal{C}(\mathcal{J}_{A^\star}, 3)$, hence $\|\Delta_{\beta_A}\|_1 \le 4\|\Delta_{\beta_A|\mathcal{J}_{A^\star}}\|_1 \le 4\sqrt{s_A^\star}\|\Delta_{\beta_A}\|$. By choosing $\lambda_A \ge 4\|\mathcal{X}'\mathcal{U}/T\|_\infty$, (33) is further upper bounded by

$$\frac{3}{2}\lambda_A\|\Delta_{\beta_A}\|_1 \le 6\sqrt{s_A^\star}\lambda_A\|\Delta_{\beta_A}\|. \tag{34}$$

Combined with the RSC condition and the upper bound given in (34), we have

$$\frac{\alpha_{\text{RSC}}}{2}\|\Delta_{\beta_A}\|^2 - \frac{\tau}{2}\|\Delta_{\beta_A}\|_1^2 \le \frac{1}{2}\Delta_{\beta_A}'\widehat{\Gamma}_X^{(0)}\Delta_{\beta_A} \le 3\sqrt{s_A^\star}\lambda_A\|\Delta_{\beta_A}\|,$$
$$\frac{\alpha_{\text{RSC}}}{4}\|\Delta_{\beta_A}\|^2 \le \left(\frac{\alpha_{\text{RSC}}}{2} - \frac{16 s_A^\star\tau}{4}\right)\|\Delta_{\beta_A}\|^2 \le 3\sqrt{s_A^\star}\lambda_A\|\Delta_{\beta_A}\|,$$

which implies

$$\|\Delta_{\beta_A}\| \le 12\sqrt{s_A^\star}\lambda_A/\alpha_{\text{RSC}} \qquad \text{and} \qquad \|\Delta_{\beta_A}\|_1 \le 48 s_A^\star\lambda_A/\alpha_{\text{RSC}}.$$

It is easy to see that these bounds also hold for $\|\Delta_A\|_F$ and $\|\Delta_A\|_1$, respectively. ■

Next, to prove Theorem 15, we introduce the following two sets of subspaces $\{\mathcal{S}_\Theta, \mathcal{S}_\Theta^\perp\}$ and $\{\mathcal{R}_\Theta, \mathcal{R}_\Theta^c\}$ associated with some generic matrix $\Theta \in \mathbb{R}^{m_1\times m_2}$, in which the nuclear norm and the ℓ_1-norm are decomposable, respectively (see Negahban et al., 2012). Specifically, let the singular value decomposition of Θ be $\Theta = U\Sigma V'$ with U and V being orthogonal matrices. Let $r = \text{rank}(\Theta)$, and we use U^r and V^r to denote the first r columns of U and V associated with the r singular values of Θ. Further, define

$$\begin{aligned}\mathcal{S}_\Theta &:= \left\{\Delta \in \mathbb{R}^{m_1\times m_2} | \text{row}(\Delta) \subseteq V^r \quad \text{and} \quad \text{col}(\Delta) \subseteq U^r\right\},\\ \mathcal{S}_\Theta^\perp &:= \left\{\Delta \in \mathbb{R}^{m_1\times m_2} | \text{row}(\Delta) \perp V^r \quad \text{and} \quad \text{col}(\Delta) \perp U^r\right\}.\end{aligned} \tag{35}$$

Then, for an arbitrary (generic) matrix $M \in \mathbb{R}^{m_1\times m_2}$, its restriction on the subspace $\mathcal{S}(\Theta)$ and $\mathcal{S}^\perp(\Theta)$, denoted by $M_{\mathcal{S}(\Theta)}$ and $M_{\mathcal{S}^\perp(\Theta)}$ respectively, are given by:

$$M_{\mathcal{S}_\Theta} = U\begin{bmatrix}\widetilde{M}_{11} & \widetilde{M}_{12}\\ \widetilde{M}_{21} & O\end{bmatrix}V' \qquad \text{and} \qquad M_{\mathcal{S}_\Theta^\perp} = U\begin{bmatrix}O & O\\ O & \widetilde{M}_{22}\end{bmatrix}V',$$

where $\Theta = U\Sigma V'$ and $\widetilde{M}$ is defined and partitioned as

$$\widetilde{M} = U'MV = \begin{bmatrix}\widetilde{M}_{11} & \widetilde{M}_{12}\\ \widetilde{M}_{21} & \widetilde{M}_{22}\end{bmatrix}, \quad \text{where } \widetilde{M}_{11} \in \mathbb{R}^{r\times r}.$$

Note that by Lemma **??**, $M_{\mathcal{S}_\Theta} + M_{\mathcal{S}_\Theta^\perp} = M$. Moreover, when Θ is restricted to the subspace induced by itself $\Theta_{\mathcal{S}_\Theta}$ (and we write $\Theta_{\mathcal{S}}$ for short for this specific case), the following decomposition for the nuclear norm holds:

$$\|\Theta\|_* = \|\Theta_{\mathcal{S}} + \Theta_{\mathcal{S}^\perp}\|_* = \|\Theta_{\mathcal{S}}\|_* + \|\Theta_{\mathcal{S}^\perp}\|_*.$$

Let $\mathcal{J}(\Theta)$ be the set of indexes in which Θ is nonzero. Analogously, we define

$$\begin{aligned}\mathcal{R}_\Theta &:= \left\{\Delta \in \mathbb{R}^{m_1\times m_2} | \Delta_{ij} = 0 \ \text{ for } \ (i,j) \notin \mathcal{J}(\Theta)\right\},\\ \mathcal{R}_\Theta^c &:= \left\{\Delta \in \mathbb{R}^{m_1\times m_2} | \Delta_{ij} = 0 \ \text{ for } \ (i,j) \in \mathcal{J}(\Theta)\right\}.\end{aligned} \tag{36}$$

Then, for an arbitrary matrix M, $M_{\mathcal{J}_\Theta} \in \mathcal{R}_\Theta$ is obtained by setting the entries of M whose indexes are not in $\mathcal{J}(\Theta)$ to 0, and $M_{\mathcal{J}_\Theta^c} \in \mathcal{R}_\Theta^c$ is obtained by setting the entries of M whose indexes are in $\mathcal{J}(\Theta)$ to 0. Then, the following decomposition holds:

$$\left\|M_{\mathcal{J}_\Theta} + M_{\mathcal{J}_\Theta^c}\right\|_1 = \|M_{\mathcal{J}_\Theta}\|_1 + \left\|M_{\mathcal{J}_\Theta^c}\right\|_1.$$

Proof [**Proof of Theorem 15**] Again for the ease of notation, in this proof, we drop the superscript and use $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$ to denote $(\widehat{B}, \widehat{C})$ whenever there is no ambiguity. Define $\mathcal{Q}$ to be the weighted regularizer:

$$\mathcal{Q}(B, C) = \|B\|_* + \tfrac{\lambda_C}{\lambda_B}\|C\|_1.$$

Note that $(B^\star, C^\star)$ is always feasible, and by the optimality of $(\widehat{B}, \widehat{C})$, the following inequality holds:

$$\frac{1}{T}\|\mathcal{Z}^T - \mathfrak{W}_0(\widehat{B}_{\text{aug}} + \widehat{C}_{\text{aug}})\|_F^2 + \lambda_B\|\widehat{B}\|_* + \lambda_C\|\widehat{C}\|_1 \le \frac{1}{T}\|\mathcal{Z}^T - \mathfrak{W}_0(B^\star + C^\star)\|_F^2 + \lambda_B\|B^\star\|_* + \lambda_C\|C^\star\|_1,$$

By defining $\Delta_{\text{aug}}^B = \widehat{B}_{\text{aug}} - B_{\text{aug}}^\star = [\Delta^B, O]$, $\Delta_{\text{aug}}^C = \widehat{C}_{\text{aug}} - C_{\text{aug}}^\star = [O, \Delta^C]$, we obtain the following *basic inequality*:

$$\tfrac{1}{T}\left\|\mathfrak{W}_0(\Delta_{\text{aug}}^B + \Delta_{\text{aug}}^C)\right\|_F^2 \le \tfrac{2}{T}\langle\!\langle \Delta_{\text{aug}}^B + \Delta_{\text{aug}}^C, \mathcal{W}'\mathcal{V}\rangle\!\rangle + \lambda_B\mathcal{Q}(B^\star, C^\star) - \lambda_B\mathcal{Q}(\widehat{B}, \widehat{C}). \tag{37}$$

By Hölder's inequality and Lemma 21, we have

$$\begin{aligned}\tfrac{1}{T}\left\|\mathfrak{W}_0(\Delta_{\text{aug}}^B + \Delta_{\text{aug}}^C)\right\|_F^2 \le{}& \tfrac{2}{T}\left(\left\|\Delta_{\mathcal{S}_{B^\star}}^B\right\|_* + \|\Delta_{\mathcal{S}_{B^\star}^\perp}^B\|_*\right)\|\mathcal{W}'\mathcal{V}\|_{op} + \tfrac{2}{T}\left(\|\Delta_{\mathcal{J}_{C^\star}^c}^C\|_1 + \|\Delta_{\mathcal{J}_{C^\star}^c}^C\|_1\right)\|\mathcal{W}'\mathcal{V}\|_\infty\\ &+ \lambda_B\mathcal{Q}(\Delta_{\mathcal{S}_{B^\star}}^B, \Delta_{\mathcal{J}_{C^\star}}^C) - \lambda_B\mathcal{Q}(\Delta_{\mathcal{S}_{B^\star}^\perp}^B, \Delta_{\mathcal{J}_{C^\star}^c}^C).\end{aligned} \tag{38}$$

With the specified choice of λ_B and λ_C, after some algebra, (38) is further bounded by

$$\frac{3\lambda_B}{2}\mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) - \frac{\lambda_B}{2}\mathcal{Q}(\Delta^B_{\mathcal{S}^\perp_{B^\star}}, \Delta^C_{\mathcal{J}^c_{C^\star}}).$$

By Lemma 22, and using this upper bound, we obtain

$$\frac{\alpha_{\text{RSC}}}{2}(|||\Delta^B|||_F^2 + |||\Delta^C|||_F^2) - \frac{\lambda_B}{2}\mathcal{Q}(\Delta^B, \Delta^C) \le \frac{3\lambda_B}{2}\mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) - \frac{\lambda_B}{2}\mathcal{Q}(\Delta^B_{\mathcal{S}^\perp_{B^\star}}, \Delta^C_{\mathcal{J}^c_{C^\star}}).$$

By the triangle inequality, $\mathcal{Q}(\Delta^B, \Delta^C) \le \mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) + \mathcal{Q}(\Delta^B_{\mathcal{S}^\perp_{B^\star}}, \Delta^C_{\mathcal{J}^c_{C^\star}})$, rearranging gives

$$\frac{\alpha_{\text{RSC}}}{2}(|||\Delta^B|||_F^2 + |||\Delta^C|||_F^2) \le 2\lambda_B\mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}). \tag{39}$$

By Lemma **??**, with $N = B^\star$, $M_1 = \Delta^B_{\mathcal{S}_{B^\star}}$, $M_2 = \Delta^B_{\mathcal{S}^\perp_{B^\star}}$, we get

$$\text{rank}(\Delta^B_{\mathcal{S}_{B^\star}}) \le 2r^\star_B \qquad \text{and} \qquad \langle\!\langle \Delta^B_{\mathcal{S}_{B^\star}}, \Delta^B_{\mathcal{S}^\perp_{B^\star}} \rangle\!\rangle = 0,$$

which implies $|||\Delta^B_{\mathcal{S}_{B^\star}}|||_* \le (\sqrt{2r^\star_B})|||\Delta^B_{\mathcal{S}_{B^\star}}|||_F \le (\sqrt{2r^\star_B})|||\Delta^B|||_F$. Since $\Delta^C_{\mathcal{J}_{C^\star}}$ has at most $s^\star_C$ nonzero entries, it follows that $\|\Delta^C_{\mathcal{J}_{C^\star}}\|_1 \le \sqrt{s^\star_C}|||\Delta^C_{\mathcal{J}_{C^\star}}|||_F \le \sqrt{s^\star_C}|||\Delta^C|||_F$. Therefore,

$$\mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) = \lambda_B|||\Delta^B_{\mathcal{S}_{B^\star}}|||_* + \lambda_C\|\Delta^C_{\mathcal{J}_{C^\star}}\|_1 \le \lambda_B(\sqrt{2r^\star_B})|||\Delta^B|||_F + \lambda_C(\sqrt{s^\star_C})|||\Delta^C|||_F$$

With an application of the Cauchy-Schwartz inequality, (39) yields:

$$\frac{\alpha_{\text{RSC}}}{2}(|||\Delta^B|||_F^2 + |||\Delta^C|||_F^2) \le \sqrt{2r^\star_B\lambda_B^2 + s^\star_C\lambda_C^2} * \sqrt{|||\Delta^B|||_F^2 + |||\Delta^C|||_F^2}$$

and we obtain the following bound:

$$|||\Delta^B|||_F^2 + |||\Delta^C|||_F^2 \le 4\left(2r^\star_B\lambda_B^2 + s^\star_C\lambda_C^2\right)/\alpha^2_{\text{RSC}}.$$

■

Proof [**Proof of Theorem 5**] At iteration 0, $\widehat{A}^{(0)}$ solves the following optimization problem:

$$\widehat{A}^{(0)} = \underset{A\in\mathbb{R}^{p_1\times p_1}}{\arg\min}\left\{\tfrac{1}{T}|||\mathcal{X}^T - \mathcal{X}A'|||_F^2 + \lambda_A|||A|||_*\right\}.$$

By Theorem 14, its error bound is given by

$$\|\widehat{A}^{(0)} - A^\star\|_1 \le 48s^\star_A\lambda_A/\alpha_{\text{RSC}},$$

provided that $\widehat{\Gamma}^{(0)}_X = \mathrm{I}_{p_1}\otimes\mathcal{X}'\mathcal{X}/T$ satisfies the RSC condition, and the regularization parameter λ_A satisfies $\lambda_A \ge 4\|\mathcal{X}'\mathcal{U}/T\|_\infty$. For random realizations $\mathcal{X}$ and $\mathcal{U}$, by Lemma 16 and Lemma 17, there exist constants c_i and c_i' such that for sample size $T \gtrsim s^\star_A\log p_1$, with probability at least $1 - c_1\exp(-c_2T\min\{1,\omega^{-2}\})$, where $\omega = c_3\mu_{\max}(\mathcal{A})/\mu_{\min}(\mathcal{A})$

$$(\mathbf{E_1}) \qquad \widehat{\Gamma}^{(0)}_X \text{ satisfies RSC condition with } \alpha_{\text{RSC}} = \Lambda_{\min}(\Sigma^\star_u)/(2\mu_{\max}(\mathcal{A}))\ ,$$

and with probability at least $1 - c_1'\exp(-c_2'\log p_1)$,

$$(\mathbf{E_2}) \qquad \|\mathcal{X}'\mathcal{U}/T\|_\infty \le C_0\sqrt{\frac{\log p_1}{T}}, \qquad \text{for some constant } C_0.$$

Hence with probability at least $1 - c_1\exp(-c_2T) - c_1'\exp(-c_2'\log p_1)$,

$$\|\widehat{A}^{(0)} - A^\star\|_1 = O\Big(s^\star_A\sqrt{\tfrac{\log p_1}{T}}\Big).$$

Moving onto $\widehat{\Omega}^{(0)}_u$, which is given by

$$\widehat{\Omega}^{(0)}_u = \underset{\Omega_u\in\mathbb{S}^{p_1\times p_1}_{++}}{\arg\min}\left\{\log\det\Omega_u - \text{trace}\big(\widehat{S}^{(0)}_u\Omega_u\big) + \rho_u\|\Omega_u\|_{1,\text{off}}\right\},$$

where $\widehat{S}^{(0)}_u = \frac{1}{T}(\mathcal{X}^T - \mathcal{X}\widehat{A}^{(0)\prime})'(\mathcal{X}^T - \mathcal{X}\widehat{A}^{(0)\prime})$. By Theorem 1 in Ravikumar et al. (2011), the error bound for $\widehat{\Omega}^{(0)}_u$ relies on how well $\widehat{S}^{(0)}_u$ concentrates around $\Sigma^\star_u$, more specifically, $\|\widehat{S}^{(0)}_u - \Sigma^\star_u\|_\infty$. Note that

$$\|\widehat{S}^{(0)}_u - \Sigma^\star_u\|_\infty \le \|S_u - \Sigma^\star_u\|_\infty + \|\widehat{S}^{(0)}_u - S_u\|_\infty,$$

where $S_u = \mathcal{U}'\mathcal{U}/T$ is the sample covariance based on true errors. For the first term, by Ravikumar et al. (2011), there exists constant $\tau_0 > 2$ such that with probability at least $1 - 1/p_1^{\tau_0-2} = 1 - \exp(-\tau\log p_1)$ $(\tau > 0)$, the following bound holds:

$$(\mathbf{E_3}) \qquad \|S_u - \Sigma^\star_u\|_\infty \le C_1\sqrt{\frac{\log p_1}{T}}, \qquad \text{for some constant } C_1.$$

For the second term,

$$\widehat{S}^{(0)}_u - S_u = \tfrac{2}{T}\mathcal{U}'\mathcal{X}(A^\star - \widehat{A}^{(0)})' + (A^\star - \widehat{A}^{(0)})\left(\tfrac{\mathcal{X}'\mathcal{X}}{T}\right)(A^\star - \widehat{A}^{(0)})' := I_1 + I_2,$$

For I_1, based on the analysis of $\|A^\star - \widehat{A}^{(0)}\|_1$ and $\|\mathcal{X}'\mathcal{U}/T\|_\infty$,

$$\|I_1\|_\infty \le 2|||A^\star - \widehat{A}^{(0)}|||_\infty\|\tfrac{1}{T}\mathcal{X}'\mathcal{U}\|_\infty \le 2\|A^\star - \widehat{A}^{(0)}\|_1\|\tfrac{1}{T}\mathcal{X}'\mathcal{U}\|_\infty = O\Big(\tfrac{s^\star_A\log p_1}{T}\Big)$$

For I_2,

$$\begin{aligned}\|(A^\star - \widehat{A}^{(0)})\left(\tfrac{\mathcal{X}'\mathcal{X}}{T}\right)(A^\star - \widehat{A}^{(0)})'\|_\infty &\le |||A^\star - \widehat{A}^{(0)}|||_\infty|||A^\star - \widehat{A}^{(0)}|||_1\|\tfrac{\mathcal{X}'\mathcal{X}}{T}\|_\infty \\ &\le \|A^\star - \widehat{A}^{(0)}\|_1^2\|\tfrac{\mathcal{X}'\mathcal{X}}{T}\|_\infty,\end{aligned}$$

where by Proposition 2.4 in Basu and Michailidis (2015) and then taking a union bound, with probability at least $1 - c_1''\exp(-c_2''\log p_1)$ $(c_1'', c_2'' > 0)$,

$$(\mathbf{E_4}) \qquad \|\tfrac{\mathcal{X}'\mathcal{X}}{T}\|_\infty \le C_2\sqrt{\frac{\log p_1}{T}} + \Lambda_{\max}(\Gamma_X), \qquad \text{for some constant } C_2.$$

Hence,

$$\|I_2\|_\infty = O\Big((s_A^\star)^2\big(\tfrac{\log p_1}{T}\big)^{3/2}\Big) + O\Big((s_A^\star)^2\tfrac{\log p_1}{T}\Big)$$

Combining all terms, and since we assume that $T^{-1}\log p_1$ is small, $O(\sqrt{T^{-1}\log p_1})$ becomes the leading term, and the following bound holds with probability at least $1-c_1\exp(-c_2T)-c_1'\exp(-c_2'\log p_1)-c_1''\exp(-c_2''\log p_1)-\exp(-\tau\log p_1)$:

$$\|\widehat{S}_u^{(0)} - \Sigma_u^\star\|_\infty = O\Big(\sqrt{\tfrac{\log p_1}{T}}\Big).$$

Consequently,

$$\|\widehat{\Omega}_u^{(0)} - \Omega_u^\star\|_\infty = O\Big(\sqrt{\tfrac{\log p_1}{T}}\Big).$$

At iteration 1, the vectorized $\widehat{A}^{(1)}$ solves

$$\widehat{\beta}_A^{(1)} = \underset{\beta\in\mathbb{R}^{p_1^2}}{\arg\min}\big\{-2\beta'\widehat{\gamma}_X^{(1)} + \beta'\widehat{\Gamma}_X^{(1)}\beta + \lambda_A\|\beta\|_1\big\},$$

where

$$\widehat{\gamma}_X^{(1)} = \tfrac{1}{T}(\widehat{\Omega}_u^{(0)}\otimes\mathcal{X}')\mathrm{vec}(\mathcal{X}^T), \qquad \widehat{\Gamma}_X^{(1)} = \widehat{\Omega}_u^{(0)}\otimes\tfrac{\mathcal{X}'\mathcal{X}}{T}.$$

The error bound for $\widehat{\beta}_A^{(1)}$ relies on (1) $\widehat{\Gamma}_X^{(1)}$ satisfying the RSC condition, which holds for sample size $T \gtrsim (d_{\Omega_u^\star}^{\max})^2\log p_1$ upon $\|\widehat{\Omega}_u^{(0)} - \Omega_u^\star\|_\infty = O(\sqrt{T^{-1}\log p_1})$; and (2) a bound for $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(0)}/T\|_\infty$. For $\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(0)}/T\|_\infty$,

$$\tfrac{1}{T}\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(0)} = \tfrac{1}{T}\mathcal{X}'\mathcal{U}\Omega_u^\star + \tfrac{1}{T}\mathcal{X}'\mathcal{U}(\widehat{\Omega}_u^{(0)} - \Omega_u^\star) := I_3 + I_4.$$

For I_3, by Lemma 3 in Lin et al. (2016) and with the aid of Proposition 2.4 in Basu and Michailidis (2015), again with probability at least $1-c_1'''\exp(-c_2'''\log p_1)$ we get

$$(\mathbf{E_5}) \qquad \big\|\tfrac{1}{T}\mathcal{X}'\mathcal{U}\Omega_u^\star\big\|_\infty \le C_3\sqrt{\frac{\log p_1}{T}}, \qquad \text{for some constant } C_3.$$

For I_4, by Corollary 3 in Ravikumar et al. (2011), we get

$$\Big\|\tfrac{1}{T}\mathcal{X}'\mathcal{U}(\widehat{\Omega}_u^{(0)} - \Omega_u^\star)\Big\|_\infty \le d_{\Omega_u^\star}^{\max}\|\tfrac{1}{T}\mathcal{X}'\mathcal{U}\|_\infty\|\widehat{\Omega}_u^{(0)} - \Omega_u^\star\|_\infty = O\Big(\tfrac{\log p_1}{T}\Big).$$

Combining all terms and taking the leading one, once again we have

$$\|\widehat{A}^{(1)} - A^\star\|_1 = O\Big(s_A^\star\sqrt{\tfrac{\log p_1}{T}}\Big),$$

which holds with probability at least $1-c_1\exp(-c_2T)-\tilde{c}_1\exp(-\tilde{c}_2\log p_1)-\exp(-\tau\log p_1)$, by letting $\tilde{c}_1 = \max\{c_1', c_1'', c_1'''\}$ and $\tilde{c}_1 = \min\{c_2', c_2'', c_2'''\}$. It should be noted that up to this step, all sources of randomness from the random realizations have been captured by events from $\mathbf{E_1}$ to $\mathbf{E_5}$; thus, for $\widehat{\Omega}_u^{(1)}$ and iterations thereafter, the probability for which the bounds hold will no longer change, and the same holds for the error bounds for $\widehat{A}^{(k)}$ and $\widehat{\Omega}_u^{(k)}$ in

terms of the relative order with respect to the dimension p_1 and sample size T. Therefore, we conclude that with high probability, for all iterations k,

$$\|\mathcal{X}'\mathcal{U}\widehat{\Omega}_u^{(k)}/T\|_\infty = O\Big(\sqrt{\tfrac{\log p_1}{T}}\Big), \qquad \|\widehat{S}_u^{(k)} - \Sigma_u^\star\|_\infty = O\Big(\sqrt{\tfrac{\log p_1}{T}}\Big).$$

With the aid of Theorem 14, it then follows that

$$\|\widehat{A}^{(k)} - A^\star\|_F = O\Big(\sqrt{\tfrac{s_A^\star\log p_1}{T}}\Big), \qquad \|\widehat{\Omega}_u^{(k)} - \Omega_u^\star\|_F = O\Big(\sqrt{\tfrac{(s_{\Omega_u^\star}+p_1)\log p_1}{T}}\Big).$$

■

Proof [**Proof of Theorem 6**] At iteration 0, $(\widehat{B}^{(0)}, \widehat{C}^{(0)})$ solves the following optimization:

$$(\widehat{B}^{(0)}, \widehat{C}^{(0)}) = \underset{(B,C)}{\arg\min}\Big\{\tfrac{1}{T}\|\mathcal{Z}^T - \mathcal{X}B' - \mathcal{Z}C'\|_F^2 + \lambda_B\|B\|_* + \lambda_C\|C\|_1\Big\}.$$

Let $W_t = (X_t', Z_t')' \in \mathbb{R}^{p_1+p_2}$ be the joint process and $\mathcal{W}$ be the realizations, with operators $\mathfrak{W}_0$ identically defined to that in Theorem 15 . By Theorem 15,

$$\|\widehat{B}^{(0)} - B^\star\|_F^2 + \|\widehat{C}^{(0)} - C^\star\|_F^2 \le 4(2r_B^\star\lambda_B^2 + s_C^\star\lambda_C^2)/\alpha_{\mathrm{RSC}}^2,$$

provided that $\mathfrak{W}$ satisfies the RSC condition and λ_B, λ_C respectively satisfy

$$\lambda_B \ge 4\big\|\mathcal{W}'\mathcal{V}/T\big\|_{op} \quad \text{and} \quad \lambda_C \ge 4\big\|\mathcal{W}'\mathcal{V}/T\big\|_\infty.$$

In particular, by Lemma 18 for random realizations of $\mathcal{X}$, $\mathcal{Z}$ and $\mathcal{V}$, for sample size $T \gtrsim c_0(p_1+2p_2)$, with probability at least $1-c_1\exp\{-c_2(p_1+p_2)\}$,

$$(\mathbf{E_1'}) \qquad \mathfrak{W}_0 \text{ satisfies the RSC condition.}$$

By Lemma 19, for sample size $T \gtrsim (p_1+2p_2)$ and some constant $C_1, C_2 > 0$,

$$(\mathbf{E_2'}) \qquad \big\|\mathcal{W}'\mathcal{V}/T\big\|_{op} \le C_1\sqrt{\frac{p_1+2p_2}{T}} \quad \text{and} \quad \big\|\mathcal{W}'\mathcal{V}/T\big\|_\infty \le C_2\sqrt{\frac{\log(p_1+p_2)+\log p_2}{T}},$$

with probability at least $1-c_1'\exp\{-c_2'(p_1+2p_2)\}$ and $1-c_1''\exp\{-c_2''\log[p_2(p_1+p_2)]\}$, respectively. Hence, with probability at least

$$1-c_1\exp\{-c_2(p_1+p_2)\}-c_1'\exp\{-c_2'(p_1+2p_2)\}-c_1''\exp\{-c_2''\log[p_2(p_1+p_2)]\},$$

the following bound holds for the initializers as long as sample size $T \gtrsim (p_1+2p_2)$:

$$\|\widehat{B}^{(0)} - B^\star\|_F^2 + \|\widehat{C}^{(0)} - C^\star\|_F^2 = O\Big(\tfrac{p_1+2p_2}{T}\Big) + O\Big(\tfrac{\log(p_1+p_2)+\log p_2}{T}\Big). \tag{40}$$

Considering the estimation of $\widehat{\Omega}_v^{(0)}$, it solves a graphical Lasso problem:

$$\widehat{\Omega}_v^{(0)} = \underset{\Omega_v\in\mathbb{S}_{++}^{p_2\times p_2}}{\arg\min}\Big\{\log\det\Omega_v - \mathrm{trace}\big(\widehat{S}_u^{(0)}\Omega_v\big) + \rho_v\|\Omega_v\|_{1,\mathrm{off}}\Big\},$$

where $\widehat{S}_v^{(0)} = \frac{1}{T}(\mathcal{Z}^T - \mathcal{X}\widehat{B}^{(0)\prime} - \mathcal{Z}\widehat{C}^{(0)\prime})'(\mathcal{Z}^T - \mathcal{X}\widehat{B}^{(0)\prime} - \mathcal{Z}\widehat{C}^{(0)\prime})$. Similar to the proof of Theorem 5, the error bound for $\widehat{\Omega}_v^{(0)}$ depends on $\|\widehat{S}_v^{(0)} - \Sigma_v^\star\|_\infty$, which can be decomposed as

$$\|\widehat{S}_v^{(0)} - \Sigma_v^\star\|_\infty \leq \|S_v - \Sigma_v^\star\|_\infty + \|\widehat{S}_v^{(0)} - S_v\|_\infty,$$

where $S_v = \mathcal{V}'\mathcal{V}/T$ is the sample covariance based on the true errors. For the first term, by Lemma 1 in Ravikumar et al. (2011), there exists constant $\tau_0 > 2$ such that with probability at least $1 - 1/p_2^{\tau_0 - 2} = 1 - \exp(-\tau \log p_2)$ $(\tau > 0)$, the following bound holds:

$$(\mathbf{E}_\mathbf{3}') \qquad \|S_v - \Sigma_v^\star\|_\infty \leq C_3\sqrt{\frac{\log p_1}{T}}, \qquad \text{for some constant } C_3.$$

For the second term, let $\Pi = [B, C] \in \mathbb{R}^{p_2 \times (p_1+p_2)}$, then

$$\widehat{S}_v^{(0)} - S_v = \frac{2}{T}\mathcal{V}'\mathcal{W}(\Pi^\star - \widehat{\Pi}^{(0)})' + (\Pi^\star - \widehat{\Pi}^{(0)})\left(\frac{\mathcal{W}'\mathcal{W}}{T}\right)(\Pi^\star - \widehat{\Pi}^{(0)})' := I_1 + I_2,$$

For I_1, we have

$$\|\tfrac{2}{T}\mathcal{V}'\mathcal{W}(\Pi^\star - \widehat{\Pi}^{(0)})'\|_\infty \leq \|\tfrac{2}{T}\mathcal{V}'\mathcal{W}(\Pi^\star - \widehat{\Pi}^{(0)})'\|_F \leq 2\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\|_{op}\|\Pi^\star - \widehat{\Pi}^{(0)}\|_F.$$

Consider the leading term of $\|\Pi^\star - \widehat{\Pi}^{(0)}\|_F$ as in (40), whose rate is $O(\sqrt{T^{-1}(p_1+2p_2)})$. We therefore obtain

$$\|I_1\|_\infty \leq \|I_1\|_F = O\Big(\tfrac{p_1+2p_2}{T}\Big).$$

Similarly for I_2,

$$\|I_2\|_\infty \leq \|I_2\|_F \leq \|\Pi^\star - \widehat{\Pi}^{(0)}\|_F^2\|\tfrac{\mathcal{W}'\mathcal{W}}{T}\|_{op},$$

where with a similar derivation to that in Lemma 23, for sample size $T \gtrsim (p_1+p_2)$, with probability at least $1 - c_1'''\exp\{-c_2'''(p_1+p_2)\}$, we get

$$(\mathbf{E}_\mathbf{4}') \qquad \|\tfrac{\mathcal{W}'\mathcal{W}}{T}\|_{op} \leq C_4\sqrt{\frac{p_1+2p_2}{T}} + \Lambda_{\max}(\Gamma_X), \qquad \text{for some constant } C_4.$$

Hence,

$$\|I_2\|_\infty \leq \|I_2\|_F \leq = O\Big((\frac{p_1+2p_2}{T})^{3/2}\Big).$$

Combining all terms and then taking the leading one, with probability at least

$$1 - c_1\exp\{-c_2(p_1+p_2)\} - c_1'\exp\{-c_2'(p_1+2p_2)\} - c_1''\exp\{-c_2''\log[p_2(p_1+p_2)]\}$$
$$-c_1'''\exp\{-c_2'''(p_1+p_2)\} - \exp(-\tau\log p_2),$$

we obtain

$$\|\widehat{S}_v^{(0)} - \Sigma_v^\star\|_\infty = O\Big(\sqrt{\tfrac{p_1+2p_2}{T}}\Big).$$

Note that here with the required sample size, $(p_1+2p_2)/T$ is a small quantity, and therefore

$$O\Big((\tfrac{p_1+2p_2}{T})^{3/2}\Big) \leq O\Big(\tfrac{p_1+2p_2}{T}\Big) \leq O\Big(\sqrt{\tfrac{p_1+2p_2}{T}}\Big).$$

At iteration 1, the bound of $\|\widehat{B}^{(1)} - B^\star\|_F^2 + \|\widehat{C}^{(1)} - C^\star\|_F^2$ relies on the following two quantities:

$$\Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(0)}\Big\|_{op} \qquad \text{and} \qquad \Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(0)}\Big\|_\infty.$$

Using a similar derivation to that in the proof of Theorem 5,

$$\Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(0)}\Big\|_\infty \leq \Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}(\widehat{\Omega}_v^{(0)} - \Omega_v^\star)\Big\|_\infty + \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\Omega_v^\star\|_\infty, \tag{41}$$

where by viewing $\mathcal{V}\Omega_v^\star$ as some random realization coming from a certain sub-Gaussian process, with probability at least $1 - \bar{c}_1''\exp\{-\bar{c}_2''\log[p_2(p_1+p_2)]\}$, we get

$$(\mathbf{E}_\mathbf{5}') \qquad \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\Omega_v^\star\|_\infty \leq C_5\sqrt{\frac{\log(p_1+p_2) + \log p_2}{T}}, \qquad \text{for some constant } C_5,$$

and

$$\Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}(\widehat{\Omega}_v^{(0)} - \Omega_v^\star)\Big\|_\infty \leq d_{\max}^{\Omega_v^\star}\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\|_\infty\|\widehat{\Omega}_v^{(0)} - \Omega_v^\star\|_\infty$$
$$= O\Big(\sqrt{\tfrac{\log(p_1+p_2)+\log p_2}{T}}\Big)\cdot O\Big(\sqrt{\tfrac{p_1+2p_2}{T}}\Big).$$

For $\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(0)}\|_{op}$, similarly we have

$$\Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(0)}\Big\|_{op} \leq \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}(\widehat{\Omega}_v^{(0)} - \Omega_v^\star)\|_{\text{op}} + \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\Omega_v^\star\|_{\text{op}}, \tag{42}$$

where with probability at least $1 - \bar{c}_1'\exp\{-\bar{c}_2'(p_1+p_2)\}$,

$$(\mathbf{E}_\mathbf{6}') \qquad \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\Omega_v^\star\|_{op} \leq C_6\sqrt{\frac{p_1+2p_2}{T}} \qquad \text{for some constant } C_6,$$

and

$$\Big\|\tfrac{1}{T}\mathcal{W}'\mathcal{V}(\widehat{\Omega}_v^{(0)} - \Omega_v^\star)\Big\|_{op} \leq \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\|_{\text{op}}\|\widehat{\Omega}_v^{(0)} - \Omega_v^\star\|_{\text{op}}$$
$$\leq \|\tfrac{1}{T}\mathcal{W}'\mathcal{V}\|_{op}\Big[d_{\max}^{\Omega_v^\star}\|\widehat{\Omega}_v^{(0)} - \Omega_v^\star\|_\infty\Big] = O\Big(\tfrac{p_1+2p_2}{T}\Big),$$

where the second inequality follows from Corollary 3 of Ravikumar et al. (2011). Combining all terms from (41) and (42), the leading term gives the following bound:

$$\|\widehat{B}^{(1)} - B^\star\|_F^2 + \|\widehat{C}^{(1)} - C^\star\|_F^2 \leq C_7\Big(\frac{p_1+2p_2}{T}\Big) \qquad \text{for some constant } C_7,$$

and this error rate coincides with that in the bound of $\|\widehat{B}^{(0)} - B^\star\|_F^2 + \|\widehat{C}^{(0)} - C^\star\|_F^2$. This implies that for $\widehat{\Omega}_v^{(1)}$ and iterations thereafter, the error rate remains unchanged. Moreover, all sources of randomness have been captured up to this step in events $\mathbf{E}_\mathbf{1}'$ to $\mathbf{E}_\mathbf{6}'$, and therefore the probability for the bounds to hold no longer changes. Consequently, the following bounds hold for all iterations k:

$$\|\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T\|_\infty = \|\mathcal{W}'\mathcal{V}\widehat{\Omega}_v^{(k)}/T\|_{\text{op}} = O\Big(\sqrt{\tfrac{p_1+2p_2}{T}}\Big)$$

and

$$\|\widehat{S}_v^{(k)} - \Sigma_v^\star\|_\infty = O\Big(\sqrt{\tfrac{p_1+2p_2}{T}}\Big),$$

with probability at least

$$1-c_0\exp\{-\tilde{c}_0(p_1+p_2)\}-c_1\exp\{-\tilde{c}_1(p_1+2p_2)\}-c_2\exp\{-\tilde{c}_2\log[p_2(p_1+p_2)]\}-\exp\{-\tau\log p_2\}.$$

for some new positive constants $c_i, \tilde{c}_i$ $(i=0,1,2)$ and τ.[2] The above bounds directly imply the bound in the statement in Theorem 6, with the aid of Theorem 15. ■

Appendix B. Key Lemmas and Their Proofs.

In this section, we verify the conditions that are required for establishing the consistency results in Theorem 14 and 15, under random realizations of $\mathcal{X}$, $\mathcal{Z}$, $\mathcal{U}$ and $\mathcal{V}$.

The following two lemmas verify the conditions for establishing the consistency properties for $\widehat{A}^{(0)}$. Specifically, Lemma 16 establishes that with high probability, $\mathfrak{X}_0$ satisfies the RSC condition. Further, Lemma 17 gives a high probability upper bound for $\|\mathcal{X}'\mathcal{U}/T\|_\infty$ for random $\mathcal{X}$ and $\mathcal{U}$.

Lemma 16 (Verification of the RSC condition) *For the* VAR(1) *model* $\{X_t\}$ *posited in* (1)*, there exist* $c_i > 0$ $(i=1,2,3)$ *such that for sample size* $T \gtrsim \max\{\omega^2,1\}s_A^\star \log p_1$*, with probability at least*

$$1-c_1\exp\left[-c_2 T\min\{1,\omega^{-2}\}\right], \qquad \omega = c_3\frac{\Lambda_{\max}(\Sigma_u)\mu_{\max}(\mathcal{A})}{\Lambda_{\min}(\Sigma_u)\mu_{\min}(\mathcal{A})},$$

the following inequality holds

$$\frac{1}{2T}|||\mathfrak{X}_0(\Delta)|||_F^2 \geq \alpha_{RSC}|||\Delta|||_F^2 - \tau\|\Delta\|_1^2, \qquad \text{for } \Delta\in\mathbb{R}^{p_1\times p_1},$$

where $\alpha_{RSC} = \frac{\Lambda_{\min}(\Sigma_u)}{\mu_{\max}(\mathcal{A})}$, $\tau = 4\alpha_{RSC}\max\{\omega^2,1\}\log p_1/T$.

Proof [**Proof of Lemma 16**] For the specific VAR(1) process $\{X_t\}$ given in (1), using Proposition 4.2 in Basu and Michailidis (2015) with $d=1$ directly gives the result. Specifically, we note that by letting $\theta = \mathrm{vec}(\Delta)$,

$$\tfrac{1}{T}|||\mathfrak{X}_0(\Delta)|||_F^2 = \theta'\widehat{\Gamma}_X^{(0)}\theta,$$

where $\widehat{\Gamma}_X^{(0)} = \mathrm{I}_{p_1}\otimes(\mathcal{X}'\mathcal{X}/T)$, and $\|\theta\|_2^2 = |||\Delta|||_F^2$, $\|\theta\|_1 = \|\Delta\|_1$. ■

Lemma 17 (Verification of the deviation bound) *For the model in* (1)*, there exist constants* $c_i > 0$, $i=0,1,2$ *such that for* $T \gtrsim 2\log p_1$*, with probability at least* $1 - c_1\exp(-2c_2\log p_1)$*, the following bound holds:*

$$\|\mathcal{X}'\mathcal{U}/T\|_\infty \leq c_0\Lambda_{\max}(\Sigma_u)\left[1+\frac{1}{\mu_{\min}(\mathcal{A})}+\frac{\mu_{\max}(\mathcal{A})}{\mu_{\min}(\mathcal{A})}\right]\sqrt{\frac{2\log p_1}{T}}. \tag{43}$$

2. Here we slightly abuse the notations and redefine $c_0 := \max\{c_1, c_1''\}$, $c_1 := \max\{c_1', \tilde{c}_1'\}$, $\tilde{c}_1 := \min\{c_2', \tilde{c}_2'\}$, $c_2 = \max\{c_1'', \tilde{c}_1''\}$, $\tilde{c}_2 := \min\{c_2'', \tilde{c}_2''\}$.

Proof [**Proof of Lemma 17**] First, we note that,

$$\|\mathcal{X}'\mathcal{U}/T\|_\infty = \max_{\substack{1\leq i\leq p_1\\ 1\leq j\leq p_1}}\left|e_i'\left(\mathcal{X}'\mathcal{U}/T\right)e_j\right|.$$

Applying Proposition 2.4(b) in Basu and Michailidis (2015) for an arbitrary pair of (i,j) gives:

$$\mathbb{P}\left(\left|e_i'\left(\mathcal{X}'\mathcal{U}/T\right)e_j\right| > \eta\left[\Lambda_{\max}(\Sigma_u)\left(1+\frac{1}{\mu_{\min}(\mathcal{A})}+\frac{\mu_{\max}(\mathcal{A})}{\mu_{\min}(\mathcal{A})}\right)\right]\right) \leq 6\exp[-cT\min\{\eta,\eta^2\}].$$

Setting $\eta = c_0\sqrt{2\log p_1/T}$ and taking a union bound over all $1\leq i\leq p_1, 1\leq j\leq p_1$, we get that for some $c_1, c_2 > 0$, with probability at least $1-c_1\exp[-2c_2\log p_1]$,

$$\max_{\substack{1\leq i\leq p_1\\ 1\leq j\leq p_1}}\left|e_i'\left(\mathcal{X}'\mathcal{U}/T\right)e_j\right| \leq c_0\Lambda_{\max}(\Sigma_u)\left[1+\frac{1}{\mu_{\min}(\mathcal{A})}+\frac{\mu_{\max}(\mathcal{A})}{\mu_{\min}(\mathcal{A})}\right]\sqrt{\frac{2\log p_1}{T}}.$$

■

In the next two lemmas, Lemma 18 gives an RSC curvature that holds with high probability for $\mathfrak{W}$ induced by a random $\mathcal{W}$, and Lemma 19 gives a high probability upper bound for $|||W'\mathcal{V}/T|||_{\mathrm{op}}$ and $\|W'\mathcal{V}/T\|_\infty$.

Lemma 18 (Verification of the RSC condition) *Consider the covariance stationary process* $W_t = (X_t', Z_t')' \in \mathbb{R}^{p_1+p_2}$ *whose spectral density exists. Suppose* $\mathfrak{m}(f_W) > 0$*. There exist constants* $c_i > 0, i=1,2,3$ *such that with probability at least* $1-2c_1\exp(-c_2(p_1+p_2))$*, the RSC condition for* $\mathfrak{W}$ *induced by a random* $\mathcal{W}$ *holds for* α_{RSC} *and tolerance 0, where*

$$\alpha_{RSC} = \pi\mathfrak{m}(f_W)/4,$$

whenever $T \gtrsim c_3(p_1+p_2)$*.*

Proof [**Proof of Lemma 18**] First ,we note that the following inequality holds, for any $\mathcal{W}$:

$$\frac{1}{2T}|||\mathfrak{W}_0(\Delta)|||_F^2 = \frac{1}{2T}|||\mathcal{W}'\Delta|||_F^2 = \frac{1}{2T}\sum_{j=1}^{p_2}\left\|[\mathcal{W}'\Delta]_j\right\|_2^2 \geq \frac{1}{2}\Lambda_{\min}\left(\widehat{\Gamma}_W^{(0)}\right)|||\Delta|||_F^2. \tag{44}$$

where $\widehat{\Gamma}_W^{(0)} = \mathcal{W}'\mathcal{W}/T$. Applying Lemma 4 in Negahban and Wainwright (2011) on $\mathcal{W}$ together with Proposition 2.3 in Basu and Michailidis (2015), the following bound holds with probability at least $1-2c_1\exp[-c_2(p_1+p_2)]$, as long as $T\gtrsim c_3(p_1+p_2)$:

$$\Lambda_{\min}\left(\widehat{\Gamma}_W^{(0)}\right) \geq \frac{\Lambda_{\min}(\Gamma_W(0))}{4} \geq \frac{\pi}{2}\mathfrak{m}(f_W),$$

where $\Gamma_W(0) = \mathbb{E}W_tW_t'$. Combining with (44), the RSC condition holds with $\kappa(\mathfrak{W}) = \pi\mathfrak{m}(f_W)/4$. ■

Lemma 19 (Verification of the deviation bound) *There exist constants $c_i > 0$ and $c_i' > 0, i = 1, 2, 3$ such that the following statements hold:*

(a) With probability at least $1 - c_1 \exp[-c_2(p_1 + 2p_2)]$, as long as $T \gtrsim c_3(p_1 + 2p_2)$,

$$\left\|\left|\mathcal{W}'\mathcal{V}/T\right|\right\|_{op} \leq c_0 \left[\mathcal{M}(f_W) + \tfrac{1}{2\pi}\Lambda_{\max}(\Sigma_v) + \mathcal{M}(f_{W,V})\right] \sqrt{\frac{p_1 + 2p_2}{T}}. \tag{45}$$

(b) With probability at least $1 - c_1' \exp(-c_2' \log(p_1+p_2) - c_2' \log p_2)$, as long as $T \gtrsim c_3' \log[(p_1 + p_2)p_2]$,

$$\left\|\mathcal{W}'\mathcal{V}/T\right\|_{\infty} \leq c_0' \left[\mathcal{M}(f_W) + \tfrac{1}{2\pi}\Lambda_{\max}(\Sigma_v) + \mathcal{M}(f_{W,V})\right] \sqrt{\frac{\log(p_1 + p_2) + \log p_2}{T}}. \tag{46}$$

Proof [**Proof of Lemma 19**] (a) is a direct application of Lemma 23 on processes $\{W_t\} \in \mathbb{R}^{(p_1+p_2)}$ and $\{V_t\} \in \mathbb{R}^{p_2}$, and (b) is a direct application of Lemma 17. ■

Appendix C. Auxiliary Lemmas and Their Proofs.

Lemma 20 *Consider two centered stationary Gaussian processes $\{X_t\}$ and $\{Z_t\}$. Further, assume that the spectral density of the joint process $\{(X_t', Z_t')'\}$ exists. Denote their cross-covariance by $\Gamma_{X,Z}(\ell) := \mathrm{Cov}(X_t, Z_{t+\ell})$, and their cross-spectral density is defined as*

$$f_{X,Z}(\theta) := \frac{1}{2\pi} \sum_{\ell=-\infty}^{\infty} \Gamma_{X,Z}(\ell) e^{-i\ell\theta}, \qquad \theta \in [-\pi, \pi],$$

whose upper extreme is given by:

$$\mathcal{M}(f_{X,Z}) = \mathrm{esssup}_{\theta\in[-\pi,\pi]} \sqrt{\Lambda_{\max}\left(f_{X,Z}^*(\theta) f_{X,Z}(\theta)\right)}.$$

Let $\mathcal{X}$ and $\mathcal{Z}$ be data matrices with sample size n. Then, there exists a constant $c > 0$, such that for any $u, v \in \mathbb{R}^p$ with $\|u\| \leq 1$, $\|v\| \leq 1$, we have

$$\mathbb{P}\left[\left|u'\left(\frac{\mathcal{X}'Z}{T} - \mathrm{Cov}(X_t, Z_t)\right)v\right| > 2\pi\left(\mathcal{M}(f_X) + \mathcal{M}(f_Z) + \mathcal{M}(f_{X,Z})\right)\eta\right] \leq 6\exp\left(-cT\min\{\eta, \eta^2\}\right).$$

Proof Let $\xi_t = \langle u, X_t\rangle$, $\eta_t = \langle v, Z_t\rangle$. Let $f_X(\theta), f_Z(\theta)$ denote the spectral density of $\{X_t\}$ and $\{Z_t\}$, respectively. Then, the spectral density of $\{\xi_t\}$ and $\{\eta_t\}$, respectively, is $f_\xi(\theta) = u' f_X(\theta) u$, $f_\eta(\theta) = v' f_Z(\theta) v$. Also, we note that $\mathcal{M}(f_\xi) \leq \mathcal{M}(f_X)$, $\mathcal{M}(f_\eta) \leq \mathcal{M}(f_Z)$. Then,

$$\begin{aligned}\frac{2}{T}\left[\sum_{t=0}^{T} \xi_t\eta_t - \mathrm{Cov}(\xi_t, \eta_t)\right] &= \left[\frac{1}{T}\sum_{t=0}^{T}(\xi_t + \eta_t)^2 - \mathrm{Var}(\xi_t + \eta_t)\right] \\ &\quad - \left[\frac{1}{T}\sum_{t=0}^{T}(\xi_t)^2 - \mathrm{Var}(\xi_t)\right] - \left[\frac{1}{T}\sum_{t=0}^{T}(\eta_t)^2 - \mathrm{Var}(\eta_t)\right].\end{aligned} \tag{47}$$

By Proposition 2.7 in Basu and Michailidis (2015),

$$\mathbb{P}\left(\left|\frac{1}{T}\sum_{t=0}^{T}(\xi_t)^2 - \mathrm{Var}(\xi_t)\right| > 2\pi\mathcal{M}(f_X)\eta\right) \geq 2\exp\left[-cn\min(\eta, \eta^2)\right],$$

and

$$\mathbb{P}\left(\left|\frac{1}{T}\sum_{t=0}^{T}(\eta_t)^2 - \mathrm{Var}(\eta_t)\right| > 2\pi\mathcal{M}(f_Z)\eta\right) \geq 2\exp\left[-cn\min(\eta, \eta^2)\right].$$

What remains to be considered is the first term in (47), whose spectral density is given by

$$f_{\xi+\eta}(\theta) = u' f_X(\theta) u + v' f_Z(\theta) z + u' f_{X,Z}(\theta) v + v' f_{X,Z}^*(\theta) u,$$

and its upper extreme satisfies

$$\mathcal{M}(f_{\xi+\eta}) \leq \mathcal{M}(f_X) + \mathcal{M}(f_Z) + 2\mathcal{M}(f_{X,Z}).$$

Hence, we get:

$$\mathbb{P}\left(\left|\frac{1}{T}\sum_{t=0}^{T}(\xi_t + \eta_t)^2 - \mathrm{Var}(\xi_t + \eta_t)\right| > 2\pi[\mathcal{M}(f_X) + \mathcal{M}(f_Z) + 2\mathcal{M}(f_{X,Z})]\eta\right) \geq 2\exp[-cn\min(\eta, \eta^2)].$$

Combining all three terms yields the desired result. ■

Lemma 21 *Define the error matrix by $\Delta^B = \widehat{B} - B^\star$ and $\Delta^C = \widehat{C} - C^\star$, and let the weighted regularizer $\mathcal{Q}$ be defined as*

$$\mathcal{Q}(B, C) = \left\|\left|B\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\|C\|_1.$$

With the subspaces defined in (35) and (36), the following inequality holds:

$$\mathcal{Q}(B^\star, C^\star) - \mathcal{Q}(\widehat{B}, \widehat{C}) \leq \mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) - \mathcal{Q}(\Delta^B_{\mathcal{S}^\perp_{B^\star}}, \Delta^C_{\mathcal{J}^c_{C^\star}}).$$

Proof First, from definitions (35) and (36), we know that $B^\star_{\mathcal{S}^\perp} = 0$ and $C^\star_{\mathcal{J}^c_{C^\star}} = 0$. Using the definition of $\mathcal{Q}$, we obtain

$$\mathcal{Q}(B^\star, C^\star) = \left\|\left|B^\star_{\mathcal{S}} + B^\star_{\mathcal{S}^\perp}\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\left\|C^\star_{\mathcal{J}_{C^\star}} + C^\star_{\mathcal{J}^c_{C^\star}}\right\|_1 = \left\|\left|B^\star_{\mathcal{S}}\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\left\|C^\star_{\mathcal{J}_{C^\star}}\right\|_1,$$

and

$$\begin{aligned}\mathcal{Q}(\widehat{B}, \widehat{C}) &= \mathcal{Q}(B^\star + \Delta^B, C^\star + \Delta^C) \\ &= \left\|\left|B^\star_{\mathcal{S}} + \Delta^B_{\mathcal{S}^\perp_{B^\star}} + \Delta^B_{\mathcal{S}_{B^\star}} + B^\star_{\mathcal{S}^\perp}\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\left\|C^\star_{\mathcal{J}_{C^\star}} + \Delta^C_{\mathcal{J}_{C^\star}} + C^\star_{\mathcal{J}^c_{C^\star}} + \Delta^C_{\mathcal{J}^c_{C^\star}}\right\|_1 \\ &\geq \left\|\left|B^\star_{\mathcal{S}} + \Delta^B_{\mathcal{S}^\perp_{B^\star}}\right|\right\|_* - \left\|\left|\Delta^B_{\mathcal{S}_{B^\star}}\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\left(\left\|C^\star_{\mathcal{J}_{C^\star}} + \Delta^C_{\mathcal{J}_{C^\star}}\right\|_1 + \left\|\Delta^C_{\mathcal{J}^c_{C^\star}}\right\|_1\right) \\ &\geq \left\|\left|B^\star_{\mathcal{S}}\right|\right\|_* + \left\|\left|\Delta^B_{\mathcal{S}^\perp_{B^\star}}\right|\right\|_* - \left\|\left|\Delta^B_{\mathcal{S}_{B^\star}}\right|\right\|_* + \frac{\lambda_C}{\lambda_B}\left(\left\|C^\star_{\mathcal{J}_{C^\star}}\right\|_1 + \|\Delta^C_{\mathcal{J}_{C^\star}}\|_1 - \left\|\Delta^C_{\mathcal{J}^c_{C^\star}}\right\|_1\right).\end{aligned}$$

The decomposition of the first term comes from the construction of $\Delta^B_{\mathcal{S}^\perp_{B^\star}}$. It then follows that

$$\begin{aligned}\mathcal{Q}(B^\star, C^\star) - \mathcal{Q}(\widehat{B}, \widehat{C}) &\le \frac{\lambda_C}{\lambda_B}\left\|C^\star_{\mathcal{J}^\star_C}\right\|_1 + |||\Delta^B_{\mathcal{S}_{B^\star}}|||_* - \left|||\Delta^B_{\mathcal{S}^\perp_{B^\star}}\right|||_* + \frac{\lambda_C}{\lambda_B}\left(\|\Delta^C_{\mathcal{J}_{C^\star}}\|_1 - \left\|\Delta^C_{\mathcal{J}^c_{C^\star}}\right\|_1 - \left\|C^\star_{\mathcal{J}^\star_C}\right\|_1\right) \\ &= |||\Delta^B_{\mathcal{S}_{B^\star}}|||_* + \frac{\lambda_C}{\lambda_B}\|\Delta^C_{\mathcal{J}_{C^\star}}\|_1 - \left(\left|||\Delta^B_{\mathcal{S}^\perp_{B^\star}}\right|||_* + \frac{\lambda_C}{\lambda_B}\left\|\Delta^C_{\mathcal{J}^c_{C^\star}}\right\|_1\right) \\ &= \mathcal{Q}(\Delta^B_{\mathcal{S}_{B^\star}}, \Delta^C_{\mathcal{J}_{C^\star}}) - \mathcal{Q}(\Delta^B_{\mathcal{S}^\perp_{B^\star}}, \Delta^C_{\mathcal{J}^c_{C^\star}}).\end{aligned}$$

■

Lemma 22 *Under the conditions of Theorem 15, the following bound holds:*

$$\frac{1}{T}|||\mathfrak{W}_0(\Delta^B_{aug} + \Delta^C_{aug})|||^2_F \ge \frac{\alpha_{RSC}}{2}(|||\Delta^B|||^2_F + |||\Delta^C|||^2_F) - \frac{\lambda_B}{2}\mathcal{Q}(\Delta^B, \Delta^C).$$

Proof This lemma directly follows from Lemma 2 in Agarwal et al. (2012), by setting $\Theta^\star = B^\star$, $\Gamma^\star = C^\star$, with the regularizer $\mathcal{R}(\cdot)$ being the element-wise ℓ_1 norm. Note that $\sigma_j(B^\star) = 0$ for $j = r+1, \cdots, \min\{p_1, p_2\}$ since $\mathrm{rank}(B) = r$. For our problem, it suffices to set $\mathbb{M}^\perp$ as $\mathcal{J}^c_{C^\star}$, and therefore $\|C^\star_{\mathcal{J}^c_{C^\star}}\|_1 = 0$. ■

Lemma 23 *Consider the two centered Gaussian processes $\{X_t\} \in \mathbb{R}^{p_1}$ and $\{Z_t\} \in \mathbb{R}^{p_2}$, and denote their cross covariance matrix by $\Gamma_{X,Z}(h) = (X_t, Z_{t+h}) = \mathbb{E}(X_t Z'_{t+h})$. Let $\mathcal{X}$ and $\mathcal{Z}$ denote the data matrix. There exist positive constants $c_i > 0$ such that whenever $T \gtrsim c_3(p_1 + p_2)$, with probability at least*

$$1 - c_1 \exp[-c_2(p_1 + p_2)],$$

the following bound holds:

$$\frac{1}{T}\left|||\mathcal{X}'\mathcal{Z}|||_{op} \le \mathbb{Q}_{X,Z}\sqrt{\frac{p_1 + p_2}{T}} + 4|||\Gamma_{X,Z}(0)|||_{op},\right.$$

where

$$\mathbb{Q}_{X,Z} = c_0\left[\mathcal{M}(f_X) + \mathcal{M}(f_Z) + \mathcal{M}(f_{X,Z})\right].$$

Proof The main structure of this proof follows from that of Lemma 3 in Negahban and Wainwright (2011), and here we focus on how to handle the temporal dependency present in our problem. Let $S^p = \{u \in \mathbb{R}^p | \|u\| = 1\}$ denote the p-dimensional unit sphere. The operator norm has the following variational representation form:

$$\frac{1}{T}\left|||\mathcal{X}'\mathcal{Z}|||_{op} = \frac{1}{n}\sup_{u \in S^{p_1}}\sup_{v \in S^{p_2}} u'\mathcal{X}'\mathcal{Z}v.\right.$$

For positive scalars s_1 and s_2, define

$$\Psi(s_1, s_2) = \sup_{u \in s_1 S^{p_1}}\sup_{v \in s_2 S^{p_2}}\langle \mathcal{X}u, \mathcal{Z}v\rangle,$$

and the goal is to establish an upper bound for $\Psi(1,1)/T$. Let $\mathcal{A} = \{u^1, \cdots, u^A\}$ and $\mathcal{B} = \{v^1, \cdots, v^B\}$ denote the 1/4 coverings of S^{p_1} and S^{p_2}, respectively. Negahban and Wainwright (2011) showed that

$$\Psi(1,1) \le 4\max_{u^a \in \mathcal{A}, v^b \in \mathcal{B}}\langle \mathcal{X}u^a, \mathcal{Z}v^b\rangle,$$

and by Anderson et al. (1998) and Anderson (2011), there exists a 1/4 covering of S^{p_1} and S^{p_2} with at most $A \le 8^{p_1}$ and $B \le 8^{p_2}$ elements, respectively. Consequently,

$$\mathbb{P}\left[\left|\frac{1}{T}\Psi(1,1)\right| \ge 4\delta\right] \le 8^{p_1+p_2}\max_{u^a, v^b}\mathbb{P}\left[\frac{|(u^a)'\mathcal{X}\mathcal{Z}(v^b)|}{T} \ge \delta\right].$$

What remains to be bounded is

$$\frac{1}{T}u'\mathcal{X}'\mathcal{Z}v, \qquad \text{for an arbitrary fixed pair of } (u, v) \in S^{p_1} \times S^{p_2}.$$

By Lemma 20, we have

$$\mathbb{P}\left[\left|u'\left(\frac{\mathcal{X}'Z}{T}\right)v\right| > 2\pi\left(\mathcal{M}(f_X) + \mathcal{M}(f_Z) + \mathcal{M}(f_{X,Z})\right)\eta + |||\Gamma_{X,Z}(0)|||_{op}\right] \le 6\exp\left(-cT\min\{\eta, \eta^2\}\right).$$

Therefore, we have

$$\mathbb{P}\left[\left|\frac{1}{T}\Psi(1,1)\right| \ge 8\pi\left(\mathcal{M}(f_X) + \mathcal{M}(f_Z) + \mathcal{M}(f_{X,Z})\right)\eta + 4|||\Gamma_{X,Z}(0)|||_{op}\right] \le 6\exp\left[(p_1 + p_2)\log 8 - cT\min\{\eta, \eta^2\}\right].$$

With the specified choice of sample size T, the probability vanishes by choosing $\eta = c_0\sqrt{\frac{p_1+p_2}{T}}$, for c_0 large enough, and we yield the conclusion in Lemma 23. ■

Lemma 24 *Let $\{X_t\}$ and $\{\varepsilon_t\}$ be two generic processes, where $\varepsilon_t = (U'_t, V'_t)'$. Suppose the spectral density of the joint process (X'_t, ε'_t) exists. Then, the following inequalities hold*

$$\mathfrak{m}(f_{X,V}) \ge \mathfrak{m}(f_{X,\varepsilon}), \qquad \mathcal{M}(f_{X,V}) \le \mathcal{M}(f_{X,\varepsilon}).$$

Proof By definition, the spectral density $f_{X,\varepsilon}(\theta)$ can be written as

$$\begin{aligned}f_{X,\varepsilon}(\theta) &= \left(\frac{1}{2\pi}\right)\sum_{\ell=-\infty}^{\infty}\Gamma_{X,\varepsilon}(\ell)e^{-i\ell\theta}, \qquad \theta \in [-\pi, \pi] \\ &= \left(\frac{1}{2\pi}\right)\sum_{\ell=-\infty}^{\infty}\left(\mathbb{E}X_t U_{t+\ell}, \;\; \mathbb{E}X_t V_{t+\ell}\right)e^{-i\ell\theta} \\ &= \left(f_{X,U}(\theta), \;\; f_{X,V}(\theta)\right).\end{aligned}$$

It follows that

$$\mathcal{M}(f_{X,\varepsilon}) = \operatorname*{ess\,sup}_{\theta \in [-\pi,\pi]}\sqrt{\Lambda_{\max}(H(\theta))},$$

where

$$H(\theta) = \begin{bmatrix} f^*_{X,U}(\theta) \\ f^*_{X,V}(\theta) \end{bmatrix} \begin{bmatrix} f_{X,U}(\theta) & f_{X,V}(\theta) \end{bmatrix} = \begin{bmatrix} f^*_{X,U}(\theta) f_{X,U}(\theta) & f^*_{X,U}(\theta) f_{X,V}(\theta) \\ f^*_{X,V}(\theta) f_{X,U}(\theta) & f^*_{X,V}(\theta) f_{X,V}(\theta) \end{bmatrix}.$$

Note that

$$\mathcal{M}(f_{X,V}) = \operatorname*{ess\,sup}_{\theta \in [-\pi,\pi]} \sqrt{\Lambda_{\max}(f^*_{X,V}(\theta) f_{X,V}(\theta))}.$$

By Lemma **??**, $\forall \theta$, $\Lambda_{\min}(f^*_{X,V}(\theta) f_{X,V}(\theta)) \geq \Lambda_{\min}(H(\theta))$ and $\Lambda_{\max}(f^*_{X,V}(\theta) f_{X,V}(\theta)) \leq \Lambda_{\max}(H(\theta))$, hence

$$\mathfrak{m}(f_{X,V}) \geq \mathfrak{m}(f_{X,\varepsilon}), \qquad \mathcal{M}(f_{X,V}) \leq \mathcal{M}(f_{X,\varepsilon}).$$

■

Appendix D. Proof of Proposition(s).

Proof [**Proof of Proposition 9**] The joint process $W_t = \{(X_t', Z_t')'\}$ is a stationary VAR(1) process, and it follows that

$$S_w(h) := \begin{bmatrix} S_x(h) & S_{x,z}(h) \\ S_{z,x}(h) & S_z(h) \end{bmatrix} = \frac{1}{T} \sum_{t=1}^{T} w_t w_{t+h}' \xrightarrow{p} \Gamma_W(h) := \mathbb{E} W_t W_{t+h}', \quad \text{as} \quad T \to \infty,$$

which implies

$$S_x \xrightarrow{p} \Gamma_X, \quad S_z \xrightarrow{p} \Gamma_Z, \quad S_{x,z} \xrightarrow{p} \Gamma_{X,Z}, \quad S_{x,z}(1) \xrightarrow{p} \Gamma_{X,Z}(1).$$

Note that sample partial regression residual covariances can be obtained by

$$S_{00} = S_z - S_z(1) S_z^{-1} S_z'(1), \qquad S_{11} = S_x - S_{x,z} S_z^{-1} S_{x,z}', \qquad S_{10} = S_{x,z}(1) - S_z(1) S_z^{-1} S_{x,z}'.$$

An application of the Continuous Mapping Theorem yields

$$S_{00} \xrightarrow{p} \Sigma_{00}, \qquad S_{10} \xrightarrow{p} \Sigma_{10}, \qquad S_{11} \xrightarrow{p} \Sigma_{11}.$$

By Hsu (1941a,b), the limiting behavior of $T\Psi_r$ is given by

$$T\Psi_r \sim \chi^2_{(p_1-r)(p_2-r)}, \qquad \text{as} \quad T \to \infty.$$

Note that since μ is of multiplicity one and the ordered eigenvalues are continuous functions of the matrices, the following holds:

$$\phi_k \xrightarrow{p} \mu_k, \qquad \forall\, k = 1, \ldots, \min(p_1, p_2).$$

Abstract

Distributed learning is an effective way to analyze big data. In distributed regression, a typical approach is to divide the big data into multiple blocks, apply a base regression algorithm on each of them, and then simply average the output functions learnt from these blocks. Since the average process will decrease the variance, not the bias, bias correction is expected to improve the learning performance if the base regression algorithm is a biased one. Regularization kernel network is an effective and widely used method for nonlinear regression analysis. In this paper we will investigate a bias corrected version of regularization kernel network. We derive the error bounds when it is applied to a single data set and when it is applied as a base algorithm in distributed regression. We show that, under certain appropriate conditions, the optimal learning rates can be reached in both situations.

Keywords: Distributed learning, kernel method, regularization, bias correction, error bound

1. Introduction

Data acquisition become much faster and easier as the development of technology. In this big data era, distributed learning has received considerable attention and is shown to be an effective way to analyze data that is so big and cannot be handled by a single machine. Among various distributed learning paradigms, a simple one is to divide the whole data set into multiple blocks, apply a base learning algorithm to each block, and then average the results from different blocks (Rosenblatt and Nadler, 2016; Zhang et al., 2015). This process, though simple, has some advantages. First, it is computationally efficient because the second stage can be easily parallelized. Second, because no mutual communication is required, the data security or confidentiality can be well protected. Last, recent research shows this method is consistent and sometimes reaches optimal learning rate (Zhang et al., 2015; Lin et al., 2017). Thus its asymptotic effectiveness is theoretically guaranteed.

In distributed learning the performance highly depends on the selection of the base algorithm in the second stage. Assume a big data set D of N observations is randomly divided into m blocks, $D_1, D_2, \ldots, D_m$, which are assumed to be of the same size at the moment so that D_i are independent and identically distributed if the entire sample set D is independently drawn from some unknown distribution ρ. Let $\hat{f}_1, \hat{f}_2, \ldots, \hat{f}_m$ be the estimators obtained by applying a base algorithm on these data blocks. Assume each estimator $\hat{f}_i$ has bias b and variance v . Then the mean squared error of $\hat{f}_i$ is $\mathrm{mse}(\hat{f}_i) = b^2+v$ while the average estimator

$$\bar{f} = \frac{1}{m}\sum_{i=1}^{m} \hat{f}_i$$

has $\mathrm{mse}(\bar{f}) = b^2 + \frac{v}{m}$. On a single data block the algorithm usually trades off the bias and variance well to achieve the optimal performance. In distributed learning, however, the variance shrinks fast when m is large but the bias keeps unchanging during the average process. In this case, the bias may dominate the learning performance. An algorithm (or a model selection strategy) that is optimal for a single block is not necessarily still optimal for distributed learning. Instead, distributed learning prefers algorithms of small bias as the base learning algorithm on each block. Therefore, when a base learning algorithm is biased, bias correction is expected to play a role to improve the performance. The purpose of this paper is to investigate the application of biased corrected regularization kernel network for distributed regression analysis.

In regression analysis, the data $D = \{(x_1, y_1), (x_2, y_2), \ldots, (x_{|D|}, y_{|D|})\}$ is a set of observations collected for input variable X of predictors and a scalar response variable Y, where $|D|$ is the sample size of the data set D. Assume they are linked by

$$y_i = f^*(x_i) + \epsilon_i, \qquad i = 1, 2, \ldots, |D|,$$

where x_i comes from a compact metric space (e.g., a bounded subset in $\mathbb{R}^p$), $y_i \in \mathbb{R}$, and ϵ_i is a zero-mean noise. The target is to recover the unknown true model f^* as accurate as possible to understand the impact of predictors and predict the response on unobserved data. Numerous regression methods have been developed in the literature, e.g. ridge regression, LASSO, and regularization kernel network (RKN). Among them, the regularization kernel network is a popular kernel method for nonlinear regression analysis. Its predictive consistency has been extensively studied in a vast literature; see e.g. Evgeniou et al. (2000); Bousquet and Elisseeff (2002); Zhang (2003); De Vito et al. (2005); Wu et al. (2006); Bauer et al. (2007); Caponnetto and De Vito (2007); Smale and Zhou (2007); Sun and Wu (2009); Steinwart et al. (2009); Guo et al. (2017b) and the references therein. Its applications were also extensively explored and shown successful in many problem domains. More recently, a bias corrected version for RKN, or BCRKN for short, was proposed in Wu (2017) to improve the performance of block wise data processing. In Wu (2017), the asymptotic bias and variance of BCRKN on a single data set was characterized, which indicates BCRKN has smaller bias than RKN and thus implies its efficiency in learning with block wise data intuitively. Empirical study also confirmed this. However, without rigorous analysis of the error bounds, there is lack of theoretical guarantee. In this paper, we will derive the error bounds and learning rates of BCKRN both for a single data set and for distributed

regression. This will provide a theoretical guarantee for the use of BCRKN from a learning theory perspective.

The rest of this paper will be arranged as follows. In Section 2 we will describe the BCRKN algorithm and state our main results. In particular, we show that BCRKN can achieve the minimax optimal rates in both single data learning and distributed learning. Moreover, BCRKN relaxes the saturation effect of RKN. In Section 3 we discuss the relations of our results with existing work and conduct some comparisons. The proofs of our results are given in Sections 4-8.

2. Main results

Let $\mathcal{X}$ denote the input space which is assumed to be a compact metric space. A Mercer kernel on $\mathcal{X}$ is a continuous, symmetric, and positive-semidefinite function $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$. The function class spanned by $\{K_x = K(x,\cdot) : x \in \mathcal{X}\}$ and equipped with the inner product satisfying $\langle K_x, K_t\rangle_K = K(x,t)$ forms a pre-Hilbert space. Its completion is called a reproducing kernel Hilbert space (RKHS) $\mathcal{H}_K$ associated to the kernel K, with the name coming after the reproducing property $f(x) = \langle f, K(x,\cdot)\rangle_K$, $\forall f \in \mathcal{H}_K$. Note that $|f(x)| \le \sqrt{K(x,x)}\|f\|_K$ for all $f \in \mathcal{H}_K$. Consequently, with $\kappa = \sup_{x\in\mathcal{X}}\sqrt{K(x,x)} < \infty$, $\mathcal{H}_K$ can be embedded into $C(\mathcal{X})$ and $\|f\|_\infty \le \kappa\|f\|_K$. More other properties of RKHS that will not be used in this paper can be found in Aronszajn (1950).

Given the data D and the RKHS $\mathcal{H}_K$, RKN estimates the true model by

$$f_{D,\lambda} = \arg\min_{f\in\mathcal{H}_K} \frac{1}{|D|}\sum_{i=1}^{|D|}(y_i - f(x_i))^2 + \lambda\|f\|_K^2, \tag{1}$$

where $\lambda > 0$ is a regularization parameter that trades off the fitting error and model complexity. The well known representer theorem (Wahba, 1990) tells that

$$f_{D,\lambda}(x) = \sum_{i=1}^{|D|} c_i K(x_i, x)$$

with the coefficients $\mathbf{c} = (c_1, \ldots, c_{|D|})^\top$ satisfying $(\lambda|D|I + \mathbf{K})\mathbf{c} = \mathbf{y}_D$ where I represents an identity matrix (or operator), $\mathbf{K} = (K(x_i, x_j))_{i,j=1}^{|D|}$ is the kernel matrix on the input data $\mathbf{x}_D = \{x_1, \ldots, x_{|D|}\}$ and $\mathbf{y}_D = (y_1, \cdots, y_{|D|})^\top$ is the vector of the response data. Let $S_D : \mathcal{H}_K \to \mathbb{R}^{|D|}$ be the sampling operator defined by

$$S_D f = (f(x_1), \ldots, f(x_{|D|}))^\top, \qquad \forall\ f \in \mathcal{H}_K.$$

Its dual operator S_D^* is given by

$$S_D^*\mathbf{c} = \sum_{i=1}^{|D|} c_i K_{x_i} \in \mathcal{H}_K, \qquad \forall\ \mathbf{c} \in \mathbb{R}^{|D|}.$$

Then $f_{D,\lambda}$ has the following operator representation (Smale and Zhou, 2007)

$$f_{D,\lambda} = \tfrac{1}{|D|}\left(\lambda I + \tfrac{1}{|D|}S_D^* S_D\right)^{-1} S_D^*\mathbf{y}_D. \tag{2}$$

Note that the operator $\frac{1}{|D|}S_D^* S_D$ is a sample version of the integral operator

$$L_K f(x) = \mathbf{E}_t\left[K(x,t)f(t)\right] = \int_{\mathcal{X}} K(x,t)f(t)\mathrm{d}\rho_{\mathcal{X}}(t)$$

where $\rho_{\mathcal{X}}$ is the marginal distribution of ρ on $\mathcal{X}$. Recall that L_K defines a compact, symmetric, and positive operator on $\mathcal{H}_K$. In the sequel we also use the notation $L_{K,D} = \frac{1}{|D|}S_D^* S_D$ and write

$$f_{D,\lambda} = (\lambda I + L_{K,D})^{-1}\left(\tfrac{1}{|D|}S_D^*\mathbf{y}_D\right).$$

By the aid of operator representation (2), the asymptotic bias of RKN can be characterized as $-\lambda(\lambda I + L_K)^{-1}f^*$. The bias corrected regularization kernel network (BCRKN) is defined by subtracting a plug-in estimator of the bias (Wu, 2017)

$$f_{D,\lambda}^\sharp = f_{D,\lambda} + \lambda\left(\lambda I + L_{K,D}\right)^{-1} f_{D,\lambda}. \tag{3}$$

It is also verified in Wu (2017) that

$$f_{D,\lambda}^\sharp(x) = \sum_{i=1}^{n} c_i^\sharp K(x_i, x)$$

with $\mathbf{c}^\sharp = \mathbf{c} + \lambda\left(\lambda I + \frac{1}{n}\mathbf{K}\right)^{-1}\mathbf{c}$. The effectiveness of BCRKN has been tested empirically by a variety of simulations and real applications in Wu (2017). The main purpose of this paper is to verify its effectiveness in distributed regression from a learning theory perspective.

To perform rigorous error analysis and present our main results, we need some notations and assumptions that are used throughout the paper. Firstly, we assume $|y| \le M$ almost surely for some constant $M > 0$. This implies the true regression function f^* satisfies $\|f^*\|_\infty \le M$.

Note that we can extend the domain of L_K to $L^2_{\rho_{\mathcal{X}}}$ and obtain a compact, symmetric, and positive operator on $L^2_{\rho_{\mathcal{X}}}$, which will be denoted by L. We can in turn say L_K is the restriction of L on $\mathcal{H}_K$. So $Lf = L_K f$ for $f \in \mathcal{H}_K$ and we do not need to differentiate them when operating on functions in $\mathcal{H}_K$. Our second assumption is a regularity condition on the true model:

$$f^* = L^r(u^*) \ \text{ for some } r > 0 \text{ and } u^* \in L^2_{\rho_{\mathcal{X}}}. \tag{4}$$

This assumption has been widely used in the literature of learning theory to characterize the approximation ability of $\mathcal{H}_K$; see e.g. De Vito et al. (2005); Smale and Zhou (2007); Bauer et al. (2007); Zhang et al. (2015) and many references therein. Recall that $L^{\frac{1}{2}}$ is an isomorphism from $\overline{\mathcal{H}_K}$ onto $\mathcal{H}_K$, i.e.

$$\|f\|_{L^2_{\rho_{\mathcal{X}}}} = \|L^{\frac{1}{2}}f\|_K, \qquad \text{for } f \in \overline{\mathcal{H}_K}, \tag{5}$$

where $\overline{\mathcal{H}_K}$ is the closure of $\mathcal{H}_K$ in $L^2_{\rho_{\mathcal{X}}}$. So if $r \ge \frac{1}{2}$, the condition (4) implies $f^* \in \mathcal{H}_K$.

We shall use the effective dimension $\mathcal{N}(\lambda) = \mathrm{Tr}((L_K + \lambda I)^{-1}L_K)$, that is, the trace of $(L_K + \lambda I)^{-1}L_K$, to measure the complexity of $\mathcal{H}_K$ with respect to $\rho_{\mathcal{X}}$. We assume that there exist a constant $C_0 > 0$ and some $0 < \beta \le 1$ such that for all $\lambda > 0$

$$\mathcal{N}(\lambda) \le C_0\lambda^{-\beta}. \tag{6}$$

Again this is a natural and widely used assumption in the literature; see e.g. De Vito et al. (2005); Caponnetto and De Vito (2007); Zhang et al. (2013); Lin et al. (2017).

Assume $\kappa \geq 1$ without loss of generality for otherwise all our statements and proofs are still valid by defining $\kappa = \max\{1, \sup_{x\in\mathcal{X}} \sqrt{K(x,x)}\}$. Denote

$$\mathcal{B}_{|D|,\lambda} = \frac{2\kappa}{\sqrt{|D|}} \left\{ \frac{\kappa}{\sqrt{|D|\lambda}} + \sqrt{\mathcal{N}(\lambda)} \right\}.$$

The consistency of RKN as well as BCRKN generally requires the regularization parameter λ to be chosen according to the sample size and satisfy $\lambda \to 0$ and $\lambda|D| \to \infty$ as $|D| \to \infty$. This implies λ is upper bounded by an absolute constant. So, in the sequel, we will assume $\lambda \leq 1$ without loss of generality to simplify our notations and presentations.

As the performance of distributed learning highly depends on the base algorithm, we will conduct a thorough error analysis of BCRKN for a single data set first and then turn to the distributed regression.

2.1 Error bound for learning with a single data set

We derive the following error bounds and learning rates for BCRKN when it is applied on a single data set.

Theorem 1 *If the regularity condition* (4) *holds with* $0 < r \leq 2$ *and* $0 < \lambda \leq 1$*, then for any* $0 < \delta < 1$*, with confidence at least* $1 - \delta$*,*

$$\|f_{D,\lambda}^\sharp - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq C \left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}} + 1 \right)^3 \left(\mathcal{B}_{|D|,\lambda} + \lambda^r \right) \left(\log \frac{4}{\delta} \right)^4, \tag{7}$$

where C *is a constant independent of* $|D|$ *or* δ*. Consequently, we have*

$$\mathbf{E}\left[\|f_{D,\lambda}^\sharp - f^*\|^2_{L^2_{\rho_\mathcal{X}}} \right] \leq 4\Gamma(9) C^2 \left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}} + 1 \right)^6 \left(\mathcal{B}_{|D|,\lambda} + \lambda^r \right)^2. \tag{8}$$

Corollary 2 *Assume the regularity condition* (4) *holds with* $0 < r \leq 2$ *and* (6) *holds with* $0 < \beta \leq 1$*.*

(i) If $0 < r < \frac{1}{2}$*, choose* $\lambda = |D|^{-\frac{1}{1+\beta}}$*. Then for any* $0 < \delta < 1$*, with confidence at least* $1 - \delta$*, we have*

$$\|f_{D,\lambda}^\sharp - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq C_1 |D|^{-\frac{r}{1+\beta}} \left(\log \frac{4}{\delta} \right)^4,$$

where C_1 *is a constant independent of* $|D|$ *or* δ*. Consequently,*

$$\mathbf{E}\left[\|f_{D,\lambda}^\sharp - f^*\|^2_{L^2_{\rho_\mathcal{X}}} \right] = \mathcal{O}\left(|D|^{-\frac{2r}{1+\beta}} \right).$$

(ii) If $\frac{1}{2} \leq r \leq 2$*, choose* $\lambda = |D|^{-\frac{1}{2r+\beta}}$*. Then for any* $0 < \delta < 1$*, with confidence at least* $1 - \delta$*, we have*

$$\|f_{D,\lambda}^\sharp - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq C_2 |D|^{-\frac{r}{2r+\beta}} \left(\log \frac{4}{\delta} \right)^4,$$

where C_2 *is a constant independent of* $|D|$ *or* δ*. Consequently,*

$$\mathbf{E}\left[\|f_{D,\lambda}^\sharp - f^*\|^2_{L^2_{\rho_\mathcal{X}}} \right] = \mathcal{O}\left(|D|^{-\frac{2r}{2r+\beta}} \right).$$

Recall that the minimax optimal learning rate under the assumptions (4) and (6) is $\mathcal{O}\left(|D|^{-\frac{2r}{2r+\beta}} \right)$. Theorem 1 tells that, when $r \geq \frac{1}{2}$, BCRKN achieves the minimax optimal learning rate on a single data set.

Since $f^* \in \mathcal{H}_K$ when $r \geq \frac{1}{2}$, we can also measure the convergence of $f_{D,\lambda}^\sharp$ to f^* in $\mathcal{H}_K$. As pointed out in Smale and Zhou (2007), the convergence in $\mathcal{H}_K$ implies the convergence in $C^s(\mathcal{X})$ if $K \in C^{2s}(\mathcal{X}\times\mathcal{X})$, here $C^s(\mathcal{X})$ is the space of all functions on $\mathcal{X} \subset \mathbb{R}^p$ whose partial derivatives up to order s are continuous with $\|f\|_{C^s(\mathcal{X})} = \sum_{|\alpha|\leq s} \|D^\alpha f\|_\infty$. So the convergence in $\mathcal{H}_K$ is much stronger. It is not only for the target function itself, but also for its derivatives.

Theorem 3 *If the regularity condition* (4) *holds with* $\frac{1}{2} < r \leq 2$*, then for any* $0 < \delta < 1$ *with confidence at least* $1 - \delta$*,*

$$\|f_{D,\lambda}^\sharp - f^*\|_K \leq C_K \left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}} + 1 \right)^2 \left(\lambda^{-\frac{1}{2}} \mathcal{B}_{|D|,\lambda} + \lambda^{r-\frac{1}{2}} \right) \left(\log \frac{4}{\delta} \right)^3, \tag{9}$$

where C_K *is a constant independent of* $|D|$ *or* δ*. If* (6) *holds with* $0 < \beta \leq 1$ *and* $\lambda = |D|^{-\frac{1}{2r+\beta}}$*, then for any* $0 < \delta < 1$*, with confidence at least* $1 - \delta$*, we have*

$$\|f_{D,\lambda}^\sharp - f^*\|_K \leq \tilde{C}_K |D|^{-\frac{r-\frac{1}{2}}{2r+\beta}} \left(\log \frac{4}{\delta} \right)^3, \tag{10}$$

where $\tilde{C}_K$ *is a constant independent of* $|D|$ *or* δ*. Moreover,*

$$\mathbf{E}\left[\|f_{D,\lambda}^\sharp - f^*\|^2_K \right] = \mathcal{O}\left(|D|^{-\frac{2r-1}{2r+\beta}} \right). \tag{11}$$

Under the assumptions (4) with $r > \frac{1}{2}$ and (6) with $0 < \beta \leq 1$, the minimax optimality of the bound $\mathcal{O}\left(|D|^{-\frac{2r-1}{2r+\beta}} \right)$ in the $\mathcal{H}_K$-metric has been proved in Guo et al. (2016). Theorem 3 indicates that the stronger convergence of BCRKN is also rate optimal in the minimax sense.

When $0 < r < \frac{1}{2}$, we are unfortunately not able to obtain the minimax rate by the integral operator technique under the assumption (6). Note that if $\mathcal{H}_K$ is finite dimensional the range of L^r is exactly $\mathcal{H}_K$ for all $r > 0$. The assumption (4) always implies $f^* \in \mathcal{H}_K$. So the situation $0 < r < \frac{1}{2}$ makes sense only when $\mathcal{H}_K$ is infinite dimensional. In this case, L_K has infinite positive eigenvalues which converge to 0. This imposes the main difficulty of error analysis via integral technique – although $L_{K,D}$ converges well to L_K at a rate $\mathcal{O}(|D|^{-1/2})$, the difference of $(\lambda I + L_{K,D})^{-1}$ and $(\lambda I + L_K)^{-1}$ cannot be well bounded when $\lambda \to 0$. Actually, even for RKN which has been exhaustedly studied in the literature, it is an open problem to obtain the minimax rate under the assumptions (4) and (6). However, if there is sufficient amount of unlabeled data which helps to improve the estimate of the integral operator, minimax rate can be achieved, as has been verified in

Blanchard and Krämer (2010). For this purpose we propose the following semi-supervised approach. Assume, in addition to the labeled data D, we have a sequence of unlabelled data $x_{|D|+1}, \ldots, x_{|D'|}$. We create a fully labeled data set

$$D' = \{(x_1, y_1'), \cdots, (x_{|D|}, y_{|D|}'), (x_{|D|+1}, 0), \cdots, (x_{|D'|}, 0)\},$$

where $y_i' = \frac{|D'|}{|D|} y_i$ for $1 \le i \le |D|$. We can apply RKN and BCRKN on D' to obtain semi-supervised estimators $f_{D',\lambda}$ and $f^\sharp_{D',\lambda}$. Note that $D = D'$ when $|D'| = |D|$. So the semi-supervised method can be regarded as an extension of the supervised method while the supervised method is a special case of the semi-supervised method with no unlabeled data. The next theorem confirms that BCRKN can achieve the minimax rate for $0 < r < \frac{1}{2}$ when there are enough unlabeled data.

Theorem 4 *Assume the regularity condition* (4) *with* $0 < r < \frac{1}{2}$. *For any* $0 < \delta < 1$, *we have with confidence at least* $1 - \delta$,

$$\|f^\sharp_{D',\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}} \le \left(\frac{2M}{\kappa} + 4\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\right) \left(\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} + 1\right)^3 \left(\mathcal{B}_{|D|,\lambda} + \lambda^r\right) \left(\log \frac{4}{\delta}\right)^3. \tag{12}$$

If in addition (6) *holds with* $0 < \beta \le 1$ *and* $r + \beta \ge \frac{1}{2}$, $\lambda = |D|^{-\frac{1}{2r+\beta}}$, $|D'| \ge |D|^{\frac{1+\beta}{2r+\beta}}$, *then for any* $\delta \in (0,1)$, *with confidence at least* $1 - \delta$, *there holds*

$$\|f^\sharp_{D',\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}} \le C' |D|^{-\frac{r}{2r+\beta}} \left(\log \frac{4}{\delta}\right)^3 \tag{13}$$

where the constant C' *is independent of* δ, $|D|$ *or* $|D'|$ *and will be given explicitly in the proof.*

2.2 Error bound of distributed regression with BCRKN

When BCRKN is used as a base algorithm for distributed regression, a big data set D is split into m blocks $D_1, D_2, \ldots, D_m$. On each block D_j, BCRKN is applied to produce an estimator $f^\sharp_{D_j,\lambda}$, and the weighted average of $f^\sharp_{D_j,\lambda}$,

$$\overline{f}^\sharp_{D,\lambda} = \sum_{j=1}^m \frac{|D_j|}{|D|} f^\sharp_{D_j,\lambda}, \tag{14}$$

is used for the purposes of prediction and inference. For this divide-and-conquer approach, we first give a general error bound for an arbitrary m. Here we do not require each block to have the same sample size.

Theorem 5 *If the regularity condition* (4) *holds with* $\frac{1}{2} \le r \le 2$ *and* $\lambda \le 1$, *then there exists a constant* $\bar{C}$ *independent of* m *or* $|D_j|$ *such that*

$$\mathbf{E}\left[\|\overline{f}^\sharp_{D,\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right] \le \bar{C} \sum_{j=1}^m \frac{|D_j|}{|D|} \left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}} + 1\right)^6 \left(\frac{|D_j|}{|D|} \mathcal{B}^2_{|D_j|,\lambda} + \frac{\lambda^2 \mathcal{N}(\lambda)}{|D|} + \lambda^{2r}\right).$$

We next show that the distributed BCRKN (14) can achieve the optimal learning rate provided that m is not too large.

Theorem 6 *Assume the regularity condition* (4) *with* $\frac{1}{2} \le r \le 2$. *If* (6) *holds with* $0 < \beta \le 1$, $|D_1| = |D_2| = \cdots = |D_m|$, $\lambda = |D|^{-\frac{1}{2r+\beta}}$, *and the number of the local machines satisfies*

$$m \le |D|^{\min\left\{\frac{2}{2r+\beta}, \frac{2r-1}{2r+\beta}\right\}}, \tag{15}$$

then

$$\mathbf{E}\left[\|\overline{f}^\sharp_{D,\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right] = \mathcal{O}\left(|D|^{-\frac{2r}{2r+\beta}}\right).$$

3. Relations to existing work and discussions

The minimax analysis of regularized least square algorithm has received attention in statistics and learning theory literature (DeVore et al., 2004; Györfi et al., 2006; Temlyakov, 2008; Caponnetto and De Vito, 2007; Steinwart et al., 2009). In particular, assume L_K admits an eigendecomposition $L_K = \sum_{i=1}^\infty \tau_i \phi_i \otimes \phi_i$, where $\tau_i \ge 0$ and ϕ_i are the eigenvalues and eigenfunctions of L_K, respectively. It is proved in Caponnetto and De Vito (2007) that, if the regularity condition (4) holds with some $r \ge \frac{1}{2}$ and the eigenvalues satisfy $\tau_i \sim i^{-2\alpha}$ for some $\alpha > \frac{1}{2}$, then the minimax optimal learning rate of regularized least square algorithm is $\mathcal{O}(|D|^{-\frac{2\alpha}{4\alpha r+1}})$. It is also proved that RKN can achieve minimax rate if $\frac{1}{2} < r \le 1$. When $r = \frac{1}{2}$, they obtained a suboptimal rate $\mathcal{O}\left(\left(\frac{\log |D|}{|D|}\right)^{-\frac{2\alpha}{2\alpha+1}}\right)$. In Steinwart et al. (2009), under the additional restriction

$$\|f\|_\infty \le C \|f\|_K^{\frac{1}{2\alpha}} \|f\|^{1-\frac{1}{2\alpha}}_{L^2_{\rho_\mathcal{X}}}, \qquad \forall\, f \in \mathcal{H}_K,$$

it is proved that the projected (or clipped) RKN estimator can achieve the minimax learning rate. More recently, Lin et al. (2017) proved that RKN can achieve minimax learning rate for r in the whole range of $[\frac{1}{2}, 1]$ without any restrictions except for the conditions (4) and $\tau_i \sim i^{-2\alpha}$. It improves the results in Caponnetto and De Vito (2007); Steinwart et al. (2009). When $r \ge 1$, RKN suffers the saturation effect and the learning rate will not improve. Note our condition (6) on the effective dimension is nearly equivalent to $\tau_i \sim i^{-2\alpha}$ with $\beta = \frac{1}{2\alpha}$. The result in Corollary 2 tells that BCRKN can achieve the minimax learning rate for $r \in [\frac{1}{2}, 2]$ and thus relaxes the saturation effect of RKN.

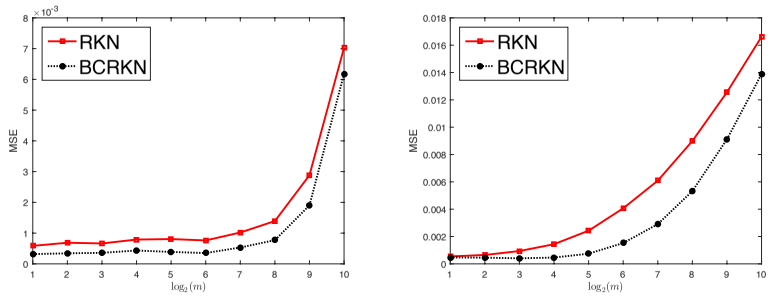
For distributed regression problem, assume all data blocks D_i, $i = 1, \ldots, m$, are of equal size. If RKN is used as the base algorithm, under the assumptions that $\mathbf{E}[|\phi_i(x)|^{2k}] \le A^{2k}$ for some $k > 2$ and constant $A < \infty$, $\lambda_i \le a i^{-2\alpha}$, and $f^* \in \mathcal{H}_K$ (i.e. $r = \frac{1}{2}$), it is proved in Zhang et al. (2015) that the optimal learning rate of $\mathcal{O}(n^{-\frac{2\alpha}{2\alpha+1}})$ can be achieved by choosing $\lambda = |D|^{-\frac{2\alpha}{2\alpha+1}}$ and restricting the number of local processors

$$m \le c_\alpha \left(\frac{|D|^{\frac{2(k-4)\alpha-k}{2\alpha+1}}}{A^{4k} \log^k |D|}\right)^{\frac{1}{k-2}}.$$

Later in Lin et al. (2017) the regularity condition (4) was taken into consideration and it is proved that the distributed regression can achieve the minimax optimal rate for all $r \in [\frac{1}{2}, 1]$ if

$$m \leq |D|^{\min\{\frac{6\alpha(2r-1)+1}{5(4\alpha r+1)}, \frac{2\alpha(2r-1)}{4\alpha r+1}\}}. \tag{16}$$

The method suffers from the saturation effect inherited from RKN. So the learning rate cannot improve with $r > 1$. When BCRKN is applied as the base algorithm for distributed regression, the saturation effect is relaxed and the minimax optimal learning rate can be achieved for the whole range $r \in [\frac{1}{2}, 2]$ as in the single data learning case. Compare (15) with (16) and we see our analysis also relaxes the restriction on the number m of local processors.



When $r < 1$ we notice that distributed regression with RKN and BCRKN both reach the optimal rates by underregularization, that is, selecting the regularization parameter according to the number of all observations $|D|$, not the number of observations in each block $|D_i|$. But due to the reduced bias the parameter selection of BCRKN is less sensitive and thus could be advantageous in practice. We show this by an illustrative example used in Zhang et al. (2015). Consider the model $f^*(x) = \min\{x, 1-x\}$ with $x \sim \text{Uniform}[0,1]$ and the noise $\epsilon \sim N(0, \sigma^2)$ with $\sigma^2 = \frac{1}{5}$. Let $K(x,t) = 1 + \min\{x,t\}$. Then $f^* \in \mathcal{H}_K$ and $\|f^*\|_K = 1$. We first compare the distributed RKN and the distributed BCRKN when $\lambda = |D|^{-2/3}$, a theoretically optimal choice. We generate $|D| = 4098$ sample points and use number of partitions $m \in \{2, 4, 8, 16, 32, 64, 128, 256, 512, 1024\}$. The mean squared errors of two methods are plotted in Figure 1 (a). We see BCRKN slightly outperforms RKN for all m.

Recall that the analyses in Zhang et al. (2015); Lin et al. (2017) and this paper indicate the optimal choice of the regularization parameter is $\lambda = |D|^{-\theta}$ with θ an index depending on the regularity of the true target function f^* and the effective dimension of the integral operator L_K. Clearly both are unknown in practice and thus a theoretical optimal choice of the regularization parameter is actually not available. At the same time, in a big data setting where distributed regression is necessary globally tuning the optimal parameter is either impossible or too time consuming. A reasonable way is to tune the parameter locally to get optimal choice $\lambda_i = |D_i|^{-\theta}$ on D_i and then underregularize it using

$$\lambda = \lambda_i^{\frac{\log|D|}{\log|D_i|}} = |D|^{-\theta}.$$

So we next compare the use of RKN and BCRKN in distributed regression when this parameter selection strategy is used. The results are shown in Figure 1 (b). We see the requirement on the number of local processors becomes more restrictive for both methods, indicating that underregularizing locally optimal parameter does not lead to globally optimal parameter. BCRKN significantly outperforms RKN as m increases, indicating it is less sensitive to the parameter selection when a globally optimal parameter is not available.

Note that the upper bounds on the number of local processors are constrained by the analysis techniques, not necessarily reflect the true limit on the number of local processors allowed in practice. Also, since underregularization is necessary in distributed regression but globally tuning the optimal parameter is impractical, the impact of parameter selection strategy on the number of local processors is unknown. Further investigation on these issues is of great interest in future research.

(a) (b)

Figure 1: MSE of distributed RKN and distributed BCRKN. (a) $\lambda = |D|^{-2/3}$ is used. (b) λ is first tuned locally and the underregularized.

Finally, it is worth mentioning that debiasing techniques have also been developed to improve the accuracy of statistical inference of distributed lasso and received considerable attention recently (Bühlmann, 2013; Zhang and Zhang, 2014; Javanmard and Montanari, 2014; Lee et al., 2017; Battey et al., 2015).

4. Preliminary lemmas

The following lemmas can be found in Lin et al. (2017); Guo et al. (2017a).

Lemma 7 *Let D be a sample drawn independently according to ρ and g be a measurable bounded function on $\mathcal{Z}$ and ξ_g be a random variable with values on $\mathcal{H}_K$ given by $\xi_g(z) = g(z)K_x$ for $z = (x,y) \in \mathcal{Z}$. For any $0 < \delta < 1$, with confidence at least $1-\delta$, there holds*

$$\left\| (\lambda I + L_K)^{-\frac{1}{2}} \left(\frac{1}{|D|} \sum_{z \in D} \xi_g(z) - \mathbf{E}[\xi_g] \right) \right\|_K \leq \frac{\|g\|_\infty \log\frac{2}{\delta}}{\kappa} \mathcal{B}_{|D|,\lambda}.$$

Lemma 8 *Let D be a sample drawn independently according to ρ. If $|y| \leq M$ almost surely, then with confidence at least $1-\delta$, there holds*

$$\left\| (\lambda I + L_K)^{-\frac{1}{2}} (\tfrac{1}{|D|} S_D^* \mathbf{y}_D - L_{K,D} f^*) \right\|_K \leq 2M \mathcal{B}_{|D|,\lambda} \log\frac{2}{\delta}.$$

Lemma 9 *Let D be a sample drawn independently according to ρ. If $|y| \leq M$ almost surely, then for any $0 < \delta < 1$, with confidence at least $1-\delta$, there holds*

$$\Xi_D := \|(\lambda I + L_K)^{-\frac{1}{2}} (L_K - L_{K,D})\| \leq \mathcal{B}_{|D|,\lambda} \log\frac{2}{\delta}, \tag{17}$$

If A and B are invertible operators on a Banach space, then by the second order operator decomposition proposed in Lin et al. (2017), we have

$$A^{-1} - B^{-1} = B^{-1}(B-A)B^{-1}(B-A)A^{-1} + B^{-1}(B-A)B^{-1}. \tag{18}$$

This implies the following decomposition of the operator product

$$BA^{-1} = (B-A)B^{-1}(B-A)A^{-1} + (B-A)B^{-1} + I. \tag{19}$$

With $A = L_{K,D}+\lambda I$ and $B = L_K+\lambda I$ in (19), and applying Lemma 9, we have the following bound for $\|(L_K+\lambda I)(L_{K,D}+\lambda I)^{-1}\|$; for the detailed proof see Guo et al. (2017a).

Proposition 10 *For any $0<\delta<1$, with confidence at least $1-\delta$, there holds*

$$\Omega_D := \|(L_K+\lambda I)(L_{K,D}+\lambda I)^{-1}\| \le \left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{2}{\delta}}{\sqrt{\lambda}}+1\right)^2.$$

Moreover, the confidence set is the same as that in Lemma 9.

Lemma 11 *Let Q be positive random variable. If there are constants $a>0, b>0, \tau>0$ such that for any $0<\delta\le 1$, with confident at least $1-\delta$, there holds $Q \le a(\log\frac{b}{\delta})^\tau$, then for any $s>0$ we have $\mathbf{E}[Q^s] \le a^s b\Gamma(\tau s+1)$.*

Proof Note the condition implies that for all $t>0$ there is

$$\Pr\left[Q^{\frac{1}{\tau}} > t\right] \le b\exp\left(-\frac{t}{a^{1/\tau}}\right).$$

So we have

$$\begin{aligned}\mathbf{E}[Q^s] &= \mathbf{E}\left[\left(Q^{1/\tau}\right)^{\tau s}\right] = \tau s\int_0^\infty t^{\tau s-1}\Pr\left[Q^{\frac{1}{\tau}}>t\right]dt\\ &\le \tau s b\int_0^\infty t^{\tau s-1}\exp\left(-\frac{t}{a^{1/\tau}}\right)dt\\ &= b\tau s\Gamma(\tau s)a^s = a^s b\Gamma(\tau s+1).\end{aligned}$$

This proves the lemma. ∎

5. Error analysis of BCRKN in $L^2_{\rho_{\mathcal{X}}}$ when $r \ge \frac{1}{2}$

We will split the proof of Theorem 1 into three cases: $0<r<\frac{1}{2}$, $\frac{1}{2}\le r\le\frac{3}{2}$, and $\frac{3}{2}<r\le 2$. In this section we prove it for the second and third cases while leave the first case to Section 7. Denote $\Delta_D = \frac{1}{|D|}S_D^*(\mathbf{y}_D - S_D f^*)$.

Proposition 12 *If $\frac{1}{2}\le r\le\frac{3}{2}$, we have*

$$\|f^\sharp_{D,\lambda} - f^*\|_{L^2_{\rho_{\mathcal{X}}}} \le 2\Omega_D\left\|(\lambda I+L_K)^{-\frac{1}{2}}\Delta_D\right\|_K + \lambda^r(\Omega_D)^r\|u^*\|_{L^2_{\rho_{\mathcal{X}}}}.$$

Proof By the triangle inequality, we have

$$\left\|f^\sharp_{D,\lambda} - f^*\right\|_{L^2_{\rho_{\mathcal{X}}}} \le \left\|f^\sharp_{D,\lambda} - \mathbf{E}^*[f^\sharp_{D,\lambda}]\right\|_{L^2_{\rho_{\mathcal{X}}}} + \left\|\mathbf{E}^*[f^\sharp_{D,\lambda}] - f^*\right\|_{L^2_{\rho_{\mathcal{X}}}}, \tag{20}$$

where $\mathbf{E}^*[f^\sharp_{D,\lambda}] = (2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-2}L_{K,D}f^*$ is the conditional expectation with respect to $\mathbf{y}_D$ given $\mathbf{x}_D$.

For the first term $\left\|f^\sharp_{D,\lambda} - \mathbf{E}^*[f^\sharp_{D,\lambda}]\right\|_{L^2_{\rho_{\mathcal{X}}}}$, noting that $2\lambda I+L_{K,D}$ and $(\lambda I+L_{K,D})^{-1}$ commute, we have

$$\begin{aligned}&\left\|f^\sharp_{D,\lambda} - \mathbf{E}^*[f^\sharp_{D,\lambda}]\right\|_{L^2_{\rho_{\mathcal{X}}}} = \left\|L_K^{\frac{1}{2}}(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-2}\Delta_D\right\|_K\\ \le\ &\left\|(\lambda I+L_K)^{\frac{1}{2}}(\lambda I+L_{K,D})^{-\frac{1}{2}}\right\|\left\|(\lambda I+L_{K,D})^{-\frac{1}{2}}(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-\frac{1}{2}}\right\|\\ &\times\left\|(\lambda I+L_{K,D})^{-\frac{1}{2}}(\lambda I+L_K)^{\frac{1}{2}}\right\|\left\|(\lambda I+L_K)^{-\frac{1}{2}}\Delta\right\|_K\\ \le\ &2\Omega_D\left\|(\lambda I+L_K)^{-\frac{1}{2}}\Delta_D\right\|_K,\end{aligned} \tag{21}$$

here we have used the fact (Blanchard and Krämer, 2010) that

$$\|A^sB^s\| \le \|AB\|^s, \qquad 0\le s\le 1,$$

for positive operators A and B on Hilbert spaces.

For the second term, we have

$$\mathbf{E}^*[f^\sharp_{D,\lambda}] - f^* = [(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-2}L_{K,D} - I]f^* = \lambda^2(\lambda I+L_{K,D})^{-2}f^*.$$

By the regularity condition (4),

$$\begin{aligned}\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}] - f^*\right\|_{L^2_{\rho_{\mathcal{X}}}} &= \lambda^2\left\|(\lambda I+L_{K,D})^{-2}L^r u^*\right\|_{L^2_{\rho_{\mathcal{X}}}}\\ &\le \lambda^2\left\|(\lambda I+L_K)^{\frac{1}{2}}(\lambda I+L_{K,D})^{-2}L_K^{r-\frac{1}{2}}L^{\frac{1}{2}}u^*\right\|_K\\ &\le \lambda^2\left\|(\lambda I+L_K)^{\frac{1}{2}}(\lambda I+L_{K,D})^{-\frac{1}{2}}\right\|\left\|(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|\left\|L^{\frac{1}{2}}u^*\right\|_K\\ &\le \lambda^2(\Omega_D)^{\frac{1}{2}}\left\|(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|\|u^*\|_{L^2_{\rho_{\mathcal{X}}}}.\end{aligned} \tag{22}$$

Since $\frac{1}{2}\le r\le\frac{3}{2}$, we have

$$\begin{aligned}&\left\|(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|\\ =\ &\left\|(\lambda I+L_{K,D})^{r-2}(\lambda I+L_{K,D})^{-r+\frac{1}{2}}(\lambda I+L_K)^{r-\frac{1}{2}}(\lambda I+L_K)^{-r+\frac{1}{2}}L_K^{r-\frac{1}{2}}\right\|\end{aligned}$$

$$\leq \left\|(\lambda I+L_{K,D})^{r-2}\right\|\left\|(\lambda I+L_{K,D})^{-r+\frac{1}{2}}(\lambda I+L_K)^{r-\frac{1}{2}}\right\|\left\|(\lambda I+L_K)^{-r+\frac{1}{2}}L_K^{r-\frac{1}{2}}\right\|$$
$$\leq \lambda^{r-2}(\Omega_D)^{r-\frac{1}{2}}.$$

Therefore,

$$\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\right\|_{L^2_{\rho_\mathcal{X}}}\leq \lambda^r(\Omega_D)^r\|u^*\|_{L^2_{\rho_\mathcal{X}}}. \tag{23}$$

Then the conclusion follows by combining (21) and (23). ■

Proposition 13 *If $\frac{3}{2}<r\leq 2$, we have*

$$\|f^\sharp_{D,\lambda}-f^*\|_{L^2_{\rho_\mathcal{X}}}\leq 2\Omega_D\left\|(\lambda I+L_K)^{-\frac{1}{2}}\Delta_D\right\|_K+\lambda\Xi_D(\Omega_D)^{\frac{3}{2}}\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}+\lambda^r\Omega_D\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

Proof The proof is similar to Proposition 12. First, $\|f^\sharp_{D,\lambda}-f^*\|_{L^2_{\rho_\mathcal{X}}}$ can be divided into two terms by (20). The first term has been estimated in Proposition 12 as (21). We now focus on the second term. To this end, by (22), we only need to estimate $\left\|(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|$. When $\frac{3}{2}\leq r<2$, we have

$$\begin{aligned}
&(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\\
=\;&(\lambda I+L_{K,D})^{-\frac{1}{2}}\left[(\lambda I+L_{K,D})^{-1}-(\lambda I+L_K)^{-1}\right]L_K^{r-\frac{1}{2}}\\
&+(\lambda I+L_{K,D})^{-\frac{1}{2}}(\lambda I+L_K)^{-1}L_K^{r-\frac{1}{2}}\\
=\;&(\lambda I+L_{K,D})^{-\frac{1}{2}}(\lambda I+L_K)^{-1}(L_K-L_{K,D})(\lambda I+L_{K,D})^{-1}(\lambda I+L_K)(\lambda I+L_K)^{-1}L_K^{r-\frac{1}{2}}\\
&+(\lambda I+L_{K,D})^{-\frac{1}{2}}(\lambda I+L_K)^{\frac{1}{2}}(\lambda I+L_K)^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}.
\end{aligned}$$

By the bounds $\left\|(\lambda I+L_{K,D})^{-\frac{1}{2}}\right\|\leq\frac{1}{\sqrt{\lambda}}$, $\left\|(\lambda I+L_K)^{-\frac{1}{2}}\right\|\leq\frac{1}{\sqrt{\lambda}}$, and $\|L_K\|\leq\kappa^2$, we have,

$$\begin{aligned}
&\left\|(\lambda I+L_{K,D})^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|\\
\leq\;&\frac{1}{\lambda}\left\|(\lambda I+L_K)^{-\frac{1}{2}}(L_K-L_{K,D})\right\|\left\|(\lambda I+L_{K,D})^{-1}(\lambda I+L_K)\right\|\left\|(\lambda I+L_K)^{-1}L_K^{r-\frac{1}{2}}\right\|\\
&+\left\|(\lambda I+L_{K,D})^{-\frac{1}{2}}(\lambda I+L_K)^{\frac{1}{2}}\right\|\left\|(\lambda I+L_K)^{-\frac{3}{2}}L_K^{r-\frac{1}{2}}\right\|\\
\leq\;&\lambda^{-1}\Omega_D\left\|(\lambda I+L_K)^{-\frac{1}{2}}(L_K-L_{K,D})\right\|\kappa^{2r-3}+\lambda^{r-2}(\Omega_D)^{\frac{1}{2}}.
\end{aligned}$$

Therefore, putting the above bound back into (22) yields

$$\begin{aligned}
\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\right\|_{L^2_{\rho_\mathcal{X}}}\leq\;&\lambda\left\|(\lambda I+L_K)^{-\frac{1}{2}}(L_K-L_{K,D})\right\|(\Omega_D)^{\frac{3}{2}}\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\
&+\lambda^r\Omega_D\|u^*\|_{L^2_{\rho_\mathcal{X}}}.
\end{aligned}\tag{24}$$

Now the conclusion follows by plugging (21) and (24) into (20). ■

Now we are ready to prove Theorem 1 and Corollary 2 for $r\geq\frac{1}{2}$.

Proof of Theorem 1: Case $\frac{1}{2}\leq r\leq 2$. By Lemma 8, we have with confidence at least $1-\frac{\delta}{2}$,

$$\left\|(\lambda I+L_K)^{-\frac{1}{2}}\Delta_D\right\|_K\leq 2M\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}. \tag{25}$$

By Lemma 9 and Proposition 10, we obtain that, with confidence at least $1-\frac{\delta}{2}$,

$$\Xi_D=\|(\lambda I+L_K)^{-\frac{1}{2}}(L_K-L_{K,D})\|\leq\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta} \tag{26}$$

and

$$\Omega_D=\|(L_K+\lambda I)(L_{K,D}+\lambda I)^{-1}\|\leq\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^2 \tag{27}$$

hold simultaneously.

When $\frac{1}{2}\leq r\leq\frac{3}{2}$, we apply (25) and (27) to Proposition 12 and obtain

$$\begin{aligned}
\|f^\sharp_{D,\lambda}-f^*\|_{L^2_{\rho_\mathcal{X}}}\leq\;&4M\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^2\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}+\lambda^r\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^{2r}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\
\leq\;&(4M+\|u^*\|_{L^2_{\rho_\mathcal{X}}})\left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}}+1\right)^3(\mathcal{B}_{|D|,\lambda}+\lambda^r)\left(\log\frac{4}{\delta}\right)^4
\end{aligned}$$

When $\frac{3}{2}<r\leq 2$, we apply (25), (26) and (27) to Proposition 13 and obtain

$$\begin{aligned}
\|f^\sharp_{D,\lambda}-f^*\|_{L^2_{\rho_\mathcal{X}}}\leq\;&4M\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^2\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}\\
&+\lambda\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^3\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\
&+\lambda^r\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^2\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\
\leq\;&(4M+2\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}})\left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}}+1\right)^3(\mathcal{B}_{|D|,\lambda}+\lambda^r)\left(\log\frac{4}{\delta}\right)^4.
\end{aligned}$$

So (7) is proved for all $\frac{1}{2}\leq r\leq 2$. Applying Lemma 11 with $b=4$, $\tau=4$, and $s=2$, we obtain the desired estimation in (8). ■

Proof of Corollary 2 (ii). With $\frac{1}{2}\leq r\leq 2$ and the choice of $\lambda=|D|^{-\frac{1}{2r+\beta}}$, we have

$$B_{|D|,\lambda}\leq\frac{2\kappa}{\sqrt{|D|}}\left\{\frac{\kappa|D|^{\frac{1}{2(2r+\beta)}}}{\sqrt{|D|}}+\sqrt{C_0}|D|^{\frac{\beta}{2(2r+\beta)}}\right\}\leq 2\kappa\left(\kappa+\sqrt{C_0}\right)|D|^{-\frac{r}{2r+\beta}} \tag{28}$$

and

$$\frac{B_{|D|,\lambda}}{\sqrt{\lambda}}+1\le 2\kappa(\kappa+\sqrt{C_0})|D|^{-\frac{r}{2r+\beta}}|D|^{\frac{1}{2r+\beta}}+1\le 2\kappa\left(\kappa+\sqrt{C_0}\right)+1. \tag{29}$$

Then the conclusions follow from Theorem 1. ■

6. Error analysis in $\mathcal{H}_K$

In this section, we derive the error bound for $\|f^\sharp_{D,\lambda}-f^*\|_K$ and prove the convergence of BCRKN in $\mathcal{H}_K$. It is similar to the error analysis in $L^2_{\rho_\mathcal{X}}$.

Proposition 14 *If $r\in[\frac12,\frac32]$, we have*

$$\|f^\sharp_{D,\lambda}-f^*\|_K\le 2\lambda^{-\frac12}(\Omega_D)^{\frac12}\left\|(\lambda I+L_K)^{-\frac12}\Delta_D\right\|_K+\lambda^{r-\frac12}(\Omega_D)^{r-\frac12}\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

If $r\in(\frac32,2]$, we have

$$\begin{aligned}\|f^\sharp_{D,\lambda}-f^*\|_K &\le 2\lambda^{-\frac12}(\Omega_D)^{\frac12}\left\|(\lambda I+L_K)^{-\frac12}\Delta_D\right\|_K+\lambda^{\frac12}\Xi_D\Omega_D\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\ &\quad+\lambda^{r-\frac12}\Omega_D\|u^*\|_{L^2_{\rho_\mathcal{X}}}.\end{aligned}$$

Proof By the triangle inequality in $\mathcal{H}_K$, we have

$$\|f^\sharp_{D,\lambda}-f^*\|_K\le\|f^\sharp_{D,\lambda}-\mathbf{E}^*[f^\sharp_{D,\lambda}]\|_K+\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\|_K.$$

To estimate the first term, we see that

$$f^\sharp_{D,\lambda}-\mathbf{E}^*[f^\sharp_{D,\lambda}]=(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-2}\Delta_D.$$

Then

$$\begin{aligned}&\left\|f^\sharp_{D,\lambda}-\mathbf{E}^*[f^\sharp_{D,\lambda}]\right\|_K=\|(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-2}\Delta_D\|_K\\ \le\ &\left\|(2\lambda I+L_{K,D})(\lambda I+L_{K,D})^{-\frac32}\right\|\left\|(\lambda I+L_{K,D})^{-\frac12}(\lambda I+L_K)^{\frac12}\right\|\left\|(\lambda I+L_K)^{-\frac12}\Delta_D\right\|_K\\ \le\ &2\lambda^{-\frac12}(\Omega_D)^{\frac12}\left\|(\lambda I+L_K)^{-\frac12}\Delta_D\right\|_K.\end{aligned}$$

For the second term, we have

$$\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\right\|_K=\left\|\lambda^2(\lambda I+L_{K,D})^{-2}L^ru^*\right\|_K\le\lambda^2\|(\lambda I+L_{K,D})^{-2}L_K^{r-\frac12}\|\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

Following the same idea as in the proof of Proposition 12, we obtain for $r\in[\frac12,\frac32]$,

$$\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\right\|_K\le\lambda^{r-\frac12}(\Omega_D)^{r-\frac12}\|u^*\|_{L^2_{\rho_\mathcal{X}}}$$

and following the idea in the proof of Proposition 13, we obtain for $r\in(\frac32,2]$,

$$\left\|\mathbf{E}^*[f^\sharp_{D,\lambda}]-f^*\right\|_K\le\lambda^{\frac12}\Xi_D\Omega_D\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}+\lambda^{r-\frac12}\Omega_D\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

The desired error bounds now follow by combining the estimates for both terms. ■

Proof of Theorem 3. Note that (25), (26) and (27) hold simultaneously with probability at least $1-\delta$. Therefore, when $\frac12\le r\le\frac32$, we have with confidence at least $1-\delta$

$$\begin{aligned}\|f^\sharp_{D,\lambda}-f^*\|_K &\le 2\lambda^{-\frac12}\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac4\delta}{\sqrt{\lambda}}+1\right)2M\mathcal{B}_{|D|,\lambda}\log\frac4\delta\\ &\quad+\lambda^{r-\frac12}\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac4\delta}{\sqrt{\lambda}}+1\right)^{2r-1}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\ &\le (4M+\|u^*\|_{L^2_{\rho_\mathcal{X}}})\left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}}+1\right)^2(\lambda^{-\frac12}\mathcal{B}_{|D|,\lambda}+\lambda^{r-\frac12})\left(\log\frac4\delta\right)^3\end{aligned}$$

and, when $\frac32<r\le2$,

$$\begin{aligned}\|f^\sharp_{D,\lambda}-f^*\|_K &\le 2\lambda^{-\frac12}\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac4\delta}{\sqrt{\lambda}}+1\right)2M\mathcal{B}_{|D|,\lambda}\log\frac4\delta\\ &\quad+\lambda^{\frac12}\mathcal{B}_{|D|,\lambda}\log\frac4\delta\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac4\delta}{\sqrt{\lambda}}+1\right)^2\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\ &\quad+\lambda^{r-\frac12}\left(\frac{\mathcal{B}_{|D|,\lambda}\log\frac4\delta}{\sqrt{\lambda}}+1\right)^2\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\ &\le \left(4M+2\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\right)\left(\frac{\mathcal{B}_{|D|,\lambda}}{\sqrt{\lambda}}+1\right)^2(\lambda^{-\frac12}\mathcal{B}_{|D|,\lambda}+\lambda^{r-\frac12})\left(\log\frac4\delta\right)^3.\end{aligned}$$

This proves the error bound (9). Then (10) follows from estimates (28) and (29), and (11) follows by applying Lemma 11. ■

7. Improve the error analysis by unlabelled data

The error analysis for the semi-supervised approach is more involved. Before we move on, notice that Theorem 1 with $0<r<\frac12$ is a special case of Theorem 4 with $D'=D$ when there is no unlabeled data. So upon finishing Theorem 4, we also obtain Theorem 1 with $0<r<\frac12$.

We need to introduce an intermediate function. Recall L is a compact operator on $L^2_{\rho_\mathcal{X}}$. Let $\{\tau_i\}_{i=1}^\infty$ and $\{\psi_i\}_{i=1}^\infty$ be the eigenvalues and eigenfunctions of L. Then $\{\psi_i\}_{i=1}^\infty$ form an orthonormal basis of $L^2_{\rho_\mathcal{X}}$. Let P_λ be the projection operator on $L^2_{\rho_\mathcal{X}}$ that projects each $f\in L^2_{\rho_\mathcal{X}}$ onto the subspace spanned by $\{\psi_i:\tau_i\ge\lambda\}$, i.e.

$$P_\lambda f=\sum_{\{i:\tau_i\ge\lambda\}}\langle\psi_i,f\rangle_{L^2_{\rho_\mathcal{X}}}\psi_i,\qquad\forall\ f\in L^2_{\rho_\mathcal{X}}.$$

By the isomorphism property (5) of $L^{\frac{1}{2}}$, $\{\phi_i = \sqrt{\tau_i}\psi_i : \sigma_i > 0\}$ form an orthonormal basis of $\mathcal{H}_K$. Since $\{i : \tau_i \geq \lambda\}$ is a finite set, it is obvious $P_\lambda f \in \mathcal{H}_K$ for all $f \in L^2_{\rho_\mathcal{X}}$. Define $f^{tr}_\lambda = P_\lambda f^*$. We can bound $\|f^\sharp_{D',\lambda} - f^*\|_{L^2_{\rho_\mathcal{X}}}$ as follows.

Proposition 15 *We have*

$$\|f^\sharp_{D',\lambda} - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq I_1 + I_2 + I_3,$$

where

$$\begin{aligned} I_1 &= \left\|(\lambda I + L_K)^{\frac{1}{2}}(2\lambda I + L_{K,D'})(\lambda I + L_{K,D'})^{-2}\left(\tfrac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K \\ I_2 &= \left\|\lambda^2(\lambda I + L_K)^{\frac{1}{2}}(\lambda I + L_{K,D'})^{-2}f^{tr}_\lambda\right\|_K, \\ I_3 &= \|f^{tr}_\lambda - f^*\|_{L^2_{\rho_\mathcal{X}}}. \end{aligned}$$

Proof Note that

$$\|f^\sharp_{D',\lambda} - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq \|f^\sharp_{D',\lambda} - f^{tr}_\lambda\|_{L^2_{\rho_\mathcal{X}}} + \|f^{tr}_\lambda - f^*\|_{L^2_{\rho_\mathcal{X}}}. \tag{30}$$

Since $f^\sharp_{D',\lambda} - f^{tr}_\lambda \in \mathcal{H}_K$, by the isometry property (5) of $L^{\frac{1}{2}} = L_K^{\frac{1}{2}}$, we have

$$\|f^\sharp_{D',\lambda} - f^{tr}_\lambda\|_{L^2_{\rho_\mathcal{X}}} = \|L_K^{\frac{1}{2}}(f^\sharp_{D',\lambda} - f^{tr}_\lambda)\|_K \leq \|(\lambda I + L_K)^{\frac{1}{2}}(f^\sharp_{D',\lambda} - f^{tr}_\lambda)\|_K. \tag{31}$$

Recall that

$$f^\sharp_{D',\lambda} = f_{D',\lambda} + \lambda(\lambda I + L_{K,D'})^{-1}f_{D',\lambda} = (2\lambda I + L_{K,D'})(\lambda I + L_{K,D'})^{-2}\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'}.$$

It is easy to check that

$$\begin{aligned} f^\sharp_{D',\lambda} - f^{tr}_\lambda &= (2\lambda I + L_{K,D'})(\lambda I + L_{K,D'})^{-2}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right) \\ &\quad -\lambda^2(\lambda I + L_{K,D'})^{-2}f^{tr}_\lambda. \end{aligned}$$

Putting this in (31) we have $\|f^\sharp_{D',\lambda} - f^{tr}_\lambda\|_{L^2_{\rho_\mathcal{X}}}$ bounded by $I_1 + I_2$. Together with (30), we obtain the desired conclusion. ■

Next we estimate the three terms respectively. The third term I_3 can be easily bounded by the following lemma, which has been proved in Caponnetto (2006).

Lemma 16 *We have* $\|f^{tr}_\lambda - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq \lambda^r\|u^*\|_{L^2_{\rho_\mathcal{X}}}$ *and* $\|f^{tr}_\lambda\|_K \leq \lambda^{-\frac{1}{2}+r}\|u^*\|_{L^2_{\rho_\mathcal{X}}}$.

For the first term I_1, we have the following bound.

Proposition 17 *For any $\delta \in (0,1)$, with confidence at least $1-\delta$, there holds*

$$I_1 \leq \left(\frac{2M}{\kappa} + 2\|u^*\|_{L^2_{\rho_\mathcal{X}}}\right)\left(\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} + 1\right)^3\left(\mathcal{B}_{|D|,\lambda} + \lambda^r\right)\left(\log\frac{4}{\delta}\right)^3.$$

Proof Since $2\lambda I + L_{K,D'}$ and $(\lambda I + L_{K,D'})^{-1}$ commute, we have

$$\begin{aligned} I_1 &= \left\|(\lambda I + L_K)^{\frac{1}{2}}(2\lambda I + L_{K,D'})(\lambda I + L_{K,D'})^{-2}\left(\tfrac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K \\ &\leq \left\|(\lambda I + L_K)^{\frac{1}{2}}(\lambda I + L_{K,D'})^{-\frac{1}{2}}\right\|\left\|(2\lambda I + L_{K,D'})(\lambda I + L_{K,D'})^{-1}\right\| \\ &\quad \times\left\|(\lambda I + L_{K,D'})^{-\frac{1}{2}}(\lambda I + L_K)^{\frac{1}{2}}\right\|\left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\tfrac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K \\ &\leq 2\Omega_{D'}\left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\tfrac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K. \end{aligned}$$

Proposition 10 ensures that, with confidence at least $1-\frac{\delta}{2}$,

$$\Omega_{D'} \leq \left(\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} + 1\right)^2\left(\log\frac{4}{\delta}\right)^2. \tag{32}$$

Now it suffices to consider the term $\left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K$. We further divide it into three parts as follows

$$\begin{aligned} \left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\| &\leq \left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_Kf^*\right)\right\|_K \\ &\quad + \left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_Kf^* - L_Kf^{tr}_\lambda)\right\|_K \\ &\quad + \left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_K - L_{K,D'})f^{tr}_\lambda\right\|_K. \end{aligned}$$

By the definition of y'_i, it is easy to check that $\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} = \frac{1}{|D|}S^*_D\mathbf{y}_D$. Applying Lemma 7 with $\xi_g(z) = yK_x$, we obtain, with confidence at least $1-\frac{\delta}{2}$,

$$\left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_Kf^*\right)\right\|_K \leq \frac{M\log\frac{4}{\delta}}{\kappa}\mathcal{B}_{|D|,\lambda}.$$

By Lemma 16, we have

$$\left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_Kf^* - L_Kf^{tr}_\lambda)\right\|_K \leq \|f^* - f^{tr}_\lambda\|_{L^2_{\rho_\mathcal{X}}} \leq \lambda^r\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

For $\left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_K - L_{K,D'})f^{tr}_\lambda\right\|_K$, observe that

$$\left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_K - L_{K,D'})f^{tr}_\lambda\right\|_K \leq \left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_K - L_{K,D'})\right\|\|f^{tr}_\lambda\|_K.$$

By Lemma 16, we have $\|f^{tr}_\lambda\|_K \leq \lambda^{-\frac{1}{2}+r}\|u^*\|_{L^2_{\rho_\mathcal{X}}}$. By Lemma 9, we have with confidence at least $1-\frac{\delta}{2}$,

$$\left\|(\lambda I + L_K)^{-\frac{1}{2}}(L_K - L_{K,D'})f^{tr}_\lambda\right\|_K \leq \lambda^r\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}}\|u^*\|_{L^2_{\rho_\mathcal{X}}}\log\frac{4}{\delta},$$

with the confidence set the same as that for (32). Combining the above estimations together yields

$$\left\|(\lambda I + L_K)^{-\frac{1}{2}}\left(\frac{1}{|D'|}S^*_{D'}\mathbf{y}_{D'} - L_{K,D'}f^{tr}_\lambda\right)\right\|_K$$
$$\leq \left(\frac{M}{\kappa} + \|u^*\|_{L^2_{\rho_\mathcal{X}}}\right)\left(\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} + 1\right)\left(\mathcal{B}_{|D|,\lambda} + \lambda^r\right)\log\frac{4}{\delta}. \quad (33)$$

Then our desired result follows by (32) and (33). ■

Proposition 18 *For any $\delta \in (0,1)$, we have, with confidence at least $1 - \frac{\delta}{2}$,*

$$I_2 \leq \left(\frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} + 1\right)\lambda^r\|u^*\|_{L^2_{\rho_\mathcal{X}}}\log\frac{4}{\delta}$$

with the confidence set the same as that for (32).

Proof We have

$$\begin{aligned} I_2 &= \|\lambda^2(\lambda I + L_K)^{\frac{1}{2}}(\lambda I + L_{K,D'})^{-2}f^{tr}_\lambda\|_K \\ &= \lambda^2\left\|(\lambda I + L_K)^{\frac{1}{2}}(\lambda I + L_{K,D'})^{-\frac{1}{2}}(\lambda I + L_{K,D'})^{-\frac{3}{2}}f^{tr}_\lambda\right\|_K \\ &\leq \lambda^2\|(\lambda I + L_K)^{\frac{1}{2}}(\lambda I + L_{K,D'})^{-\frac{1}{2}}\|\|(\lambda I + L_{K,D'})^{-\frac{3}{2}}\|\|f^{tr}_\lambda\|_K \\ &\leq \lambda^r(\Omega_{D'})^{\frac{1}{2}}\|u^*\|_{L^2_{\rho_\mathcal{X}}}, \end{aligned}$$

where we used the bounds $\|(\lambda I + L_{K,D'})^{-\frac{3}{2}}\| \leq \lambda^{-\frac{3}{2}}$ and $\|f^{tr}_\lambda\|_K \leq \lambda^{r-\frac{1}{2}}\|u^*\|_{L^2_{\rho_\mathcal{X}}}$. By (32), we obtain the desired bound and confidence set. ■

Now we can prove Theorem 4.

Proof of Theorem 4. Plugging the bounds of I_1, I_2, and I_3 into Proposition 15, we obtain the error bound for $\|f^\sharp_{D',\lambda} - f^*\|_{L^2_{\rho_\mathcal{X}}}$ in (12).

If $\lambda = |D|^{-\frac{1}{2r+\beta}}$ with $0 < r \leq \frac{1}{2}$ and $\mathcal{N}(\lambda) \leq C_0\lambda^{-\beta}$, we have

$$B_{|D|,\lambda} \leq \frac{2\kappa}{\sqrt{|D|}}\left\{\kappa|D|^{-\frac{1}{2}}|D|^{\frac{1}{2(2r+\beta)}} + \sqrt{C_0}|D|^{\frac{\beta}{2(2r+\beta)}}\right\} \leq 2\kappa(\kappa + \sqrt{C_0})|D|^{-\frac{r}{2r+\beta}}.$$

Under the condition $|D'| \geq |D|^{\frac{1+\beta}{2r+\beta}}$, we have

$$\begin{aligned} \frac{\mathcal{B}_{|D'|,\lambda}}{\sqrt{\lambda}} &= \frac{2\kappa}{\sqrt{|D'|\lambda}}\left\{\frac{\kappa}{\sqrt{|D'|\lambda}} + \sqrt{\mathcal{N}(\lambda)}\right\} \\ &\leq \frac{2\kappa}{\sqrt{|D'|}}|D|^{\frac{1}{2(2r+\beta)}}\left\{\kappa|D'|^{-\frac{1}{2}}|D|^{\frac{1}{2(2r+\beta)}} + \sqrt{C_0}|D|^{\frac{\beta}{2(2r+\beta)}}\right\} \end{aligned}$$

$$\begin{aligned} &\leq \frac{2\kappa}{\sqrt{|D'|}}|D|^{\frac{1}{2(2r+\beta)}}(\kappa + \sqrt{C_0})|D|^{\frac{\beta}{2(2r+\beta)}} \\ &\leq 2\kappa(\kappa + \sqrt{C_0}). \end{aligned}$$

Applying these two estimates to (12), we have for any $\delta \in (0,1)$, with confidence at least $1 - \delta$,

$$\|f^\sharp_{D',\lambda} - f^*\|_{L^2_{\rho_\mathcal{X}}} \leq C_1|D|^{-\frac{r}{2r+\beta}}\left(\log\frac{4}{\delta}\right)^3$$

where

$$C_1 = \left(\frac{2M}{\kappa} + 4\|u^*\|_{L^2_{\rho_\mathcal{X}}}\right)\left[2\kappa(\kappa + \sqrt{C_0}) + 1\right]^3\left[2\kappa(\kappa + \sqrt{C_0}) + 1\right].$$

This completes the proof of Theorem 4. ■

Note we also proved Theorem 1 with $0 < r < \frac{1}{2}$ because it is a special case of Theorem 4 with $D' = D$. So we are in position to prove Corollary 2 (i).

Proof of Corollary 2 (i). When $0 < r \leq \frac{1}{2}$, take $\lambda = |D|^{-\frac{1}{1+\beta}}$. Then

$$\begin{aligned} B_{|D|,\lambda} &\leq \frac{2\kappa}{\sqrt{|D|}}\left\{\frac{\kappa|D|^{\frac{1}{2(1+\beta)}}}{\sqrt{|D|}} + \sqrt{C_0}|D|^{\frac{\beta}{2(1+\beta)}}\right\} \\ &\leq 2\kappa(\kappa + \sqrt{C_0})|D|^{-\frac{1}{2(1+\beta)}} \leq 2\kappa(\kappa + \sqrt{C_0})|D|^{-\frac{r}{1+\beta}} \end{aligned}$$

and

$$\frac{B_{|D|,\lambda}}{\sqrt{\lambda}} \leq 2\kappa(\kappa + \sqrt{C_0})|D|^{-\frac{1}{2(1+\beta)}}|D|^{\frac{1}{2(1+\beta)}} = 2\kappa(\kappa + \sqrt{C_0}).$$

Plugging them into the estimation (7) we obtain the desired learning rate. ■

8. Error analysis for distributed BCRKN

The following lemma is analogous to Guo et al. (2017a, Proposition 4).

Lemma 19 *Let $\overline{f}^\sharp_{D,\lambda}$ be defined by* (14). *We have*

$$\mathbf{E}\left[\|\overline{f}^\sharp_{D,\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right] \leq \sum_{j=1}^m \frac{|D_j|^2}{|D|^2}\mathbf{E}\left[\|f^\sharp_{D_j,\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right] + \sum_{j=1}^m \frac{|D_j|}{|D|}\left\|\mathbf{E}[f^\sharp_{D_j,\lambda}] - f^*\right\|^2_{L^2_{\rho_\mathcal{X}}}. \quad (34)$$

Proof of Theorem 5. By Theorem 1, for each fixed $j \in \{1, 2, \ldots, m\}$,

$$\mathbf{E}\left[\|f^\sharp_{D_j,\lambda} - f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right] \leq 4\Gamma(9)C^2\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}} + 1\right)^6\left(\mathcal{B}_{|D_j|,\lambda} + \lambda^r\right)^2.$$

Then the first term on the right of (34) can be estimated as

$$\sum_{j=1}^{m}\frac{|D_j|^2}{|D|^2}\mathbf{E}\left[\|f^\sharp_{D_j,\lambda}-f^*\|^2_{L^2_{\rho_\mathcal{X}}}\right]\le 4\Gamma(9)C^2\sum_{j=1}^{m}\frac{|D_j|^2}{|D|^2}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\left(\mathcal{B}_{|D_j|,\lambda}+\lambda^r\right)^2. \quad (35)$$

To estimate the second term on the right of (34), for each fixed $j\in\{1,2,\dots,m\}$, by Jensen's inequality, we have

$$\left\|\mathbf{E}[f^\sharp_{D_j,\lambda}]-f^*\right\|_{L^2_{\rho_\mathcal{X}}}\le\mathbf{E}\left[\|\mathbf{E}^*[f^\sharp_{D_j,\lambda}]-f^*\|_{L^2_{\rho_\mathcal{X}}}\right].$$

We will bound the second term in two different ways according to the range of r. First consider the case when $\frac{1}{2}\le r\le\frac{3}{2}$. The bound (23) in the proof of Proposition 12 tells us that

$$\left\|\mathbf{E}^*[f^\sharp_{D_j,\lambda}]-f^*\right\|_{L^2_{\rho_\mathcal{X}}}\le\lambda^r\Omega^r_{D_j}\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

It follows that

$$\|\mathbf{E}[f^\sharp_{D_j,\lambda}]-f^*\|_{L^2_{\rho_\mathcal{X}}}\le\lambda^r\|u^*\|_{L^2_{\rho_\mathcal{X}}}\mathbf{E}\left[\Omega^r_{D_j}\right]. \quad (36)$$

Applying Proposition 10 to each fixed $j\in\{1,\dots,m\}$, with confidence at least $1-\frac{\delta}{2}$, there holds

$$\Omega_{D_j}\le\left(\frac{\mathcal{B}_{|D_j|,\lambda}\log\frac{4}{\delta}}{\sqrt{\lambda}}+1\right)^2\le\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^2\left(\log\frac{4}{\delta}\right)^2.$$

By Lemma 11, this implies that for any $s>0$,

$$\mathbf{E}\left[\Omega^s_{D_j}\right]\le 2\Gamma(2s+1)\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^{2s}. \quad (37)$$

Applying (37) with $s=r$ to (36) yields

$$\|\mathbf{E}[f^\sharp_{D_j,\lambda}]-f^*\|_{L^2_{\rho_\mathcal{X}}}\le 2\Gamma(2r+1)\|u^*\|_{L^2_{\rho_\mathcal{X}}}\lambda^r\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^{2r}. \quad (38)$$

Combining (34), (35) and (38), we have

$$\begin{aligned}\mathbf{E}[\|\overline{f}^\sharp_{D,\lambda}-f^*\|^2_{L^2_{\rho_\mathcal{X}}}] &\le 4\Gamma(9)C^2\sum_{j=1}^{m}\frac{|D_j|^2}{|D|^2}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\left(\mathcal{B}_{|D_j|,\lambda}+\lambda^r\right)^2\\ &\quad+4\Gamma^2(2r+1)\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\lambda^{2r}\sum_{j=1}^{m}\frac{|D_j|}{|D|}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^{4r}.\end{aligned}$$

This proves the desired bound for $\frac{1}{2}\le r\le\frac{3}{2}$.

For $\frac{3}{2}<r\le 2$, by the bound (24) in the proof of Proposition 13, we have

$$\|\mathbf{E}^*[f^\sharp_{D_j,\lambda}]-f^*\|_{L^2_{\rho_\mathcal{X}}}\le\lambda\Xi_{D_j}\Omega^{\frac{3}{2}}_{D_j}\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}+\lambda^r\Omega_{D_j}\|u^*\|_{L^2_{\rho_\mathcal{X}}}.$$

So,

$$\begin{aligned}\mathbf{E}[\|\mathbf{E}^*[f^\sharp_{D_j,\lambda}]-f^*\|_{L^2_{\rho_\mathcal{X}}}] &\le \lambda\mathbf{E}\left[\Xi_{D_j}(\Omega_D)^{\frac{3}{2}}\right]\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}+\lambda^r\mathbf{E}[\Omega_{D_j}]\|u^*\|_{L^2_{\rho_\mathcal{X}}}\\ &\le \lambda\left(\mathbf{E}\left[\Xi^2_{D_j}\right]\right)^{\frac{1}{2}}\left(\mathbf{E}\left[\Omega^3_{D_j}\right]\right)^{\frac{1}{2}}\kappa^{2r-3}\|u^*\|_{L^2_{\rho_\mathcal{X}}}+\lambda^r\mathbf{E}[\Omega_{D_j}]\|u^*\|_{L^2_{\rho_\mathcal{X}}}.\end{aligned}$$

From Lin et al. (2017, Lemma 17), we know

$$\mathbf{E}\left[\left\|(\lambda I+L_K)^{-\frac{1}{2}}(L_K-L_{K,D})\right\|^2\right]\le\frac{\kappa^2\mathcal{N}(\lambda)}{|D|}$$

and by (37) with $s=3$, we have

$$\mathbf{E}\left[\Omega^3_{D_j}\right]\le 2\Gamma(7)\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6.$$

Therefore,

$$\begin{aligned}&\|\mathbf{E}[f^\sharp_{D_j,\lambda}]-f^*\|^2_{L^2_{\rho_\mathcal{X}}}\\ \le\;& 2\lambda^2\mathbf{E}\left[\Xi^2_{D_j}\right]\mathbf{E}\left[\Omega^3_{D_j}\right]\kappa^{4r-6}\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}+2\lambda^{2r}(\mathbf{E}[\Omega_{D_j}])^2\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\\ \le\;& 2\lambda^2\frac{\kappa^2\mathcal{N}(\lambda)}{|D_j|}2\Gamma(7)\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\kappa^{4r-6}\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\\ &+32\lambda^{2r}\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^4\\ \le\;& \left(4\Gamma(7)\kappa^{4r-4}+32\right)\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\left(\frac{\lambda^2\mathcal{N}(\lambda)}{|D_j|}+\lambda^{2r}\right). \quad (39)\end{aligned}$$

Combining (34), (35) and (39), we have

$$\begin{aligned}&\mathbf{E}[\|\overline{f}^\sharp_{D,\lambda}-f^*\|^2_{L^2_{\rho_\mathcal{X}}}]\\ \le\;& 4\Gamma(9)C^2\sum_{j=1}^{m}\frac{|D_j|^2}{|D|^2}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\left(\mathcal{B}_{|D_j|,\lambda}+\lambda^r\right)^2\\ &+\left(4\Gamma(7)\kappa^{4r-4}+32\right)\|u^*\|^2_{L^2_{\rho_\mathcal{X}}}\sum_{j=1}^{m}\frac{|D_j|}{|D|}\left(\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}}+1\right)^6\left(\frac{\lambda^2\mathcal{N}(\lambda)}{|D_j|}+\lambda^{2r}\right).\end{aligned}$$

This proves the conclusion for $\frac{3}{2}<r\le 2$. ■

Next let us turn to the special case that the local machines are assigned the same number of observations, i.e., $|D_1|=|D_2|=\cdots=|D_m|$.

Proof of Theorem 6. For $\frac{1}{2}\le r\le 2$, we choose $\lambda=|D|^{-\frac{1}{2r+\beta}}$. Then by the capacity assumption (6), restriction on the number of local machines $m\le|D|^{\min\{\frac{2r-1}{2r+\beta},\frac{2}{2r+\beta}\}}$, and the

fact $|D_1| = |D_2| = \ldots = |D_m| = \frac{|D|}{m}$, we have

$$\frac{\mathcal{N}(\lambda)}{\lambda |D_j|} \leq C_0 m N^{\frac{1-2r}{2r+\beta}} \leq C_0.$$

It follows that, for each $j = 1, \ldots, m$,

$$\frac{\mathcal{B}_{|D_j|,\lambda}}{\sqrt{\lambda}} = \frac{2\kappa}{\sqrt{\lambda |D_j|}} \left\{ \frac{\kappa}{\sqrt{|D_j|\lambda}} + \sqrt{\mathcal{N}(\lambda)} \right\} \leq 2\kappa(\kappa + \sqrt{C_0})$$

and

$$\frac{|D_j|}{|D|} \mathcal{B}^2_{|D_j|,\lambda} \leq 8\kappa^2 \left(\frac{\kappa^2}{|D||D_j|\lambda} + \frac{\mathcal{N}(\lambda)}{|D|} \right) \leq 8\kappa^2(\kappa^2 + C_0)|D|^{-\frac{2r}{2r+\beta}}$$

and

$$\frac{\lambda^2 \mathcal{N}(\lambda)}{|D_j|} \leq \frac{C_0 |D|^{-\frac{2}{2r+\beta}} |D|^{\frac{\beta}{2r+\beta}} m}{|D|} \leq C_0 |D|^{-\frac{2r}{2r+\beta}}.$$

Then by Theorem 5,

$$\mathbf{E}\left[\|\bar{f}^\sharp_{D,\lambda} - f^*\|^2_{L^2_{\hat{\rho}_\mathcal{X}}} \right] \leq \bar{C} \left(2\kappa(\kappa + \sqrt{C_0}) + 1 \right)^6 \left(16\kappa^2(\kappa^2 + C_0) + C_0 + 1 \right) |D|^{-\frac{2r}{2r+\beta}}.$$

This completes the proof of Theorem 6. ■

Editor: Mark Schmidt

Abstract

In deterministic optimization, line searches are a standard tool ensuring stability and efficiency. Where only stochastic gradients are available, no direct equivalent has so far been formulated, because uncertain gradients do not allow for a strict sequence of decisions collapsing the search space. We construct a probabilistic line search by combining the structure of existing deterministic methods with notions from Bayesian optimization. Our method retains a Gaussian process surrogate of the univariate optimization objective, and uses a probabilistic belief over the Wolfe conditions to monitor the descent. The algorithm has very low computational cost, and no user-controlled parameters. Experiments show that it effectively removes the need to define a learning rate for stochastic gradient descent.

Keywords: stochastic optimization, learning rates, line searches, Gaussian processes, Bayesian optimization

1. Introduction

This work substantially extends the work of Mahsereci and Hennig (2015) published at NIPS 2015. Stochastic gradient descent (SGD, Robbins and Monro, 1951) is currently the standard in machine learning for the optimization of highly multivariate functions if their gradient is corrupted by noise. This includes the online or mini-batch training of neural networks, logistic regression (Zhang, 2004; Bottou, 2010) and variational models (e.g. Hoffman et al., 2013; Hensman et al., 2012; Broderick et al., 2013). In all these cases, noisy gradients arise because an exchangeable loss-function $\mathcal{L}(x)$ of the optimization parameters $x \in \mathbb{R}^D$, across a large dataset $\{d_i\}_{i=1\ldots,M}$, is evaluated only on a subset $\{d_j\}_{j=1,\ldots,m}$:

$$\mathcal{L}(x) := \frac{1}{M}\sum_{i=1}^{M} \ell(x, d_i) \approx \frac{1}{m}\sum_{j=1}^{m} \ell(x, d_j) =: \hat{\mathcal{L}}(x) \qquad m \ll M. \tag{1}$$

If the indices j are i.i.d. draws from $[1, M]$, by the Central Limit Theorem, the error $\hat{\mathcal{L}}(x) - \mathcal{L}(x)$ is unbiased and approximately normal distributed. Despite its popularity and its low cost per step, SGD has well-known deficiencies that can make it inefficient, or at least tedious to use in practice. Two main issues are that, first, the gradient itself, even without noise, is not the optimal search *direction*; and second, SGD requires a *step size* (learning rate) that has drastic effect on the algorithm's efficiency, is often difficult to choose well, and virtually never optimal for each individual descent step. The former issue, adapting the search direction, has been addressed by many authors (see George and Powell, 2006, for an overview). Existing approaches range from lightweight 'diagonal preconditioning' like Adam (Kingma and Ba, 2014), AdaGrad (Duchi et al., 2011), and 'stochastic meta-descent' (Schraudolph, 1999), to empirical estimates for the natural gradient (Amari et al., 2000) or the Newton direction (Roux and Fitzgibbon, 2010), to problem-specific algorithms (Rajesh et al., 2013), and more elaborate estimates of the Newton direction (Hennig, 2013). Most of these algorithms also include an auxiliary adaptive effect on the learning rate. Schaul et al. (2013) provided an estimation method to explicitly adapt the learning rate from one gradient descent step to another. Several very recent works have proposed the use of reinforcement learning and 'learning-to-learn' approaches for parameter adaption (Andrychowicz et al., 2016; Hansen, 2016; Li and Malik, 2016). Mostly these methods are designed to work well on a specified subset of optimization problems, which they are also trained on; they thus need to be re-learned for differing objectives. The corresponding algorithms are usually orders of magnitude more expensive than the low-level black box proposed here, and often require a classic optimizer (e.g SGD) to tune their internal hyper-parameters.

None of the mentioned algorithms change the size of the *current* descent step. Accumulating statistics across steps in this fashion requires some conservatism: If the step size is initially too large, or grows too fast, SGD can become unstable and 'explode', because individual steps are not checked for robustness at the time they are taken.

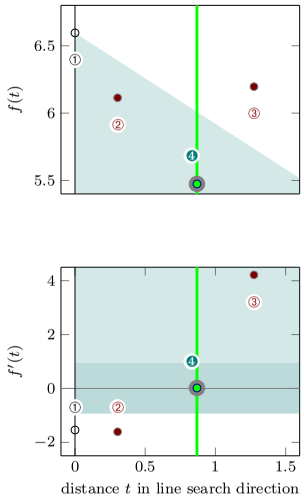

Figure 1: Sketch: The task of a *classic line search* is to tune the step taken by an optimization algorithm along a univariate search direction. The search starts at the endpoint ① of the previous line search, at $t = 0$. The *upper* plot shows function values, the *lower* plot corresponding gradients. A sequence of extrapolation steps ②,③ finds a point of positive gradient at ③. It is followed by interpolation steps until an acceptable point ❹ is found. Points of insufficient decrease, above the line $f(0) + c_1 t f'(0)$ (white area in upper plot) are excluded by the Armijo condition W-I, while points of steep negative gradient (white area in lower plot) are excluded by the curvature condition W-II (the strong extension of the Wolfe conditions also excludes the light green area in the lower plot). Point ❹ is the first to fulfill both conditions, and is thus accepted.

In essence, the same problem exists in deterministic (noise-free) optimization problems. There, providing stability is one of several tasks of the *line search* subroutine. It is a standard constituent of algorithms like the classic nonlinear conjugate gradient (Fletcher and Reeves, 1964) and BFGS (Broyden, 1969; Fletcher, 1970; Goldfarb, 1970; Shanno, 1970)

methods (Nocedal and Wright, 1999, §3).[1] In the noise-free case, line searches are considered a solved problem (Nocedal and Wright, 1999, §3). But the methods used in deterministic optimization are not stable to noise. They are easily fooled by even small disturbances, either becoming overly conservative or failing altogether. The reason for this brittleness is that existing line searches take a sequence of hard decisions to shrink or shift the search space. This yields efficiency, but breaks hard in the presence of noise. Section 3 constructs a probabilistic line search for noisy objectives, stabilizing optimization methods like the works cited above. As line searches only change the length, not the direction of a step, they could be used in combination with the algorithms adapting SGD's direction, cited above. In this paper we focus on parameter tuning of the SGD algorithm and leave other search directions to future work.

2. Connections

2.1 Deterministic Line Searches

There is a host of existing line search variants (Nocedal and Wright, 1999, §3). In essence, though, these methods explore a univariate domain 'to the right' of a starting point, until an 'acceptable' point is reached (Figure 1). More precisely, consider the problem of minimizing $\mathcal{L}(x) : \mathbb{R}^D \to \mathbb{R}$, with access to $\nabla\mathcal{L}(x) : \mathbb{R}^D \to \mathbb{R}^D$. At iteration i, some 'outer loop' chooses, at location x_i, a search direction $s_i \in \mathbb{R}^D$ (e.g. by the BFGS-rule, or simply $s_i = -\nabla\mathcal{L}(x_i)$ for gradient descent). It will *not* be assumed that s_i has unit norm. The line search operates along the univariate domain $x(t) = x_i + ts_i$ for $t \in \mathbb{R}_+$. Along this direction it collects scalar function values and projected gradients that will be denoted $f(t) = \mathcal{L}(x(t))$ and $f'(t) = s_i^\intercal \nabla\mathcal{L}(x(t)) \in \mathbb{R}$. Most line searches involve an initial extrapolation phase to find a point t_r with $f'(t_r) > 0$. This is followed by a search in $[0, t_r]$, by interval nesting or by interpolation of the collected function and gradient values, e.g. with cubic splines.[2]

2.1.1 The Wolfe Conditions for Termination

As the line search is only an auxiliary step within a larger iteration, it need not find an exact root of f'; it suffices to find a point 'sufficiently' close to a minimum. The *Wolfe conditions* (Wolfe, 1969) are a widely accepted formalization of this notion; they consider t acceptable if it fulfills

$$f(t) \leq f(0) + c_1 t f'(0) \quad \text{(W-I)} \qquad \text{and} \qquad f'(t) \geq c_2 f'(0) \quad \text{(W-II)}, \tag{2}$$

using two constants $0 \leq c_1 < c_2 \leq 1$ chosen by the designer of the line search, not the user. W-I is the *Armijo* or *sufficient decrease* condition (Armijo, 1966). It encodes that acceptable functions values should lie below a linear extrapolation line of slope $c_1 f'(0)$. W-II is the *curvature condition*, demanding a decrease in slope. The choice $c_1 = 0$ accepts any value below $f(0)$, while $c_1 = 1$ rejects all points for convex functions. For the curvature condition,

1. In these algorithms, another task of the line search is to guarantee certain properties of the surrounding estimation rule. In BFGS, e.g., it ensures positive definiteness of the estimate. This aspect will not feature here.
2. This is the strategy in `minimize.m` by C. Rasmussen, which provided a model for our implementation. At the time of writing, it can be found at `http://learning.eng.cam.ac.uk/carl/code/minimize/minimize.m`

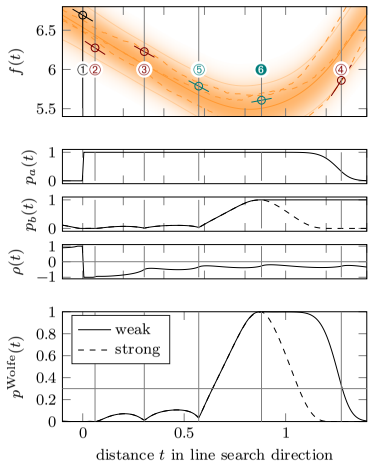

Figure 2: Sketch of a *probabilistic line search*. As in Fig. 1, the algorithm performs extrapolation (②,③,④) and interpolation (⑤,❻), but receives unreliable, noisy function and gradient values. These are used to construct a GP posterior (top. solid posterior mean, thin lines at 2 standard deviations, local pdf marginal as shading, three dashed sample paths). This implies a bivariate Gaussian belief (§3.3) over the validity of the weak Wolfe conditions (middle three plots. $p_a(t)$ is the marginal for W-I, $p_b(t)$ for W-II, $\rho(t)$ their correlation). Points are considered acceptable if their joint probability $p^{\text{Wolfe}}(t)$ (bottom) is above a threshold (gray). An approximation (§3.3.1) to the strong Wolfe conditions is shown dashed.

$c_2 = 0$ only accepts points with $f'(t) \geq 0$; while $c_2 = 1$ accepts any point of greater slope than $f'(0)$. W-I and W-II are known as the *weak* form of the Wolfe conditions. The *strong* form replaces W-II with $|f'(t)| \leq c_2|f'(0)|$. This guards against accepting points of low function value but large positive gradient. Figure 1 shows a conceptual sketch illustrating the typical process of a line search, and the weak and strong Wolfe conditions. The exposition in §3.3 will initially focus on the weak conditions, which can be precisely modeled probabilistically. Section 3.3.1 then adds an approximate treatment of the strong form.

2.2 Bayesian Optimization

A recently blossoming sample-efficient approach to global optimization revolves around modeling the objective f with a probability measure $p(f)$; usually a Gaussian process (GP). Searching for extrema, evaluation points are then chosen by a utility functional $u[p(f)]$. Our line search borrows the idea of a Gaussian process surrogate, and a popular acquisition function, *expected improvement* (Jones et al., 1998). Bayesian optimization (BO) methods are often computationally expensive, thus ill-suited for a cost-sensitive task like a line search. But since line searches are governors more than information extractors, the kind of sample-efficiency expected of a Bayesian optimizer is not needed. The following sections develop a lightweight algorithm which adds only minor computational overhead to stochastic optimization.

3. A Probabilistic Line Search

We now consider minimizing $f(t) = \hat{\mathcal{L}}(x(t))$ from Eq. 1. That is, the algorithm can access only noisy function values and gradients y_t, y'_t at location t, with Gaussian likelihood

$$p(y_t, y'_t \mid f) = \mathcal{N}\left(\begin{bmatrix} y_t \\ y'_t \end{bmatrix}; \begin{bmatrix} f(t) \\ f'(t) \end{bmatrix}, \begin{bmatrix} \sigma_f^2 & 0 \\ 0 & \sigma_{f'}^2 \end{bmatrix}\right). \tag{3}$$

The Gaussian form is supported by the Central Limit argument at Eq. 1. The function value y_t and the gradient y'_t are assumed independent for simplicity; see §3.4 and Appendix A regarding estimation of the variances $\sigma_f^2, \sigma_{f'}^2$, and some further notes on the independence assumption of y and y'. Each evaluation of $f(t)$ uses a newly drawn mini-batch.

Our algorithm is modeled after the classic line search routine `minimize.m`[2] and translates each of its building blocks one-by-one to the language of probability. The following table illustrates these four ingredients of the probabilistic line search and their corresponding classic parts.

building block	**classic**	**probabilistic**
1) 1D surrogate for objective $f(t)$	piecewise cubic splines	GP where the mean are piecewise cubic splines
2) candidate selection	*one* local minimizer of cubic splines *xor* extrapolation	local minimizers of cubic splines *and* extrapolation
3) choice of best candidate	———	BO acquisition function
4) acceptance criterion	classic Wolfe conditions	prob. Wolfe conditions

The table already motivates certain design choices, for example the particular choice of the GP-surrogate for $f(t)$, which strongly resembles the classic design. Probabilistic line searches operate in the same scheme as classic ones: 1) they construct a surrogate for the underlying 1D-function 2) they select candidates for evaluation which can interpolate between datapoints or extrapolate 3) a heuristic chooses among the candidate locations and the function is evaluated there 4) the evaluated points are checked for Wolfe-acceptance. The following sections introduce all of these building blocks with greater detail: A robust yet lightweight Gaussian process surrogate on $f(t)$ facilitating analytic optimization (§ 3.1); a simple Bayesian optimization objective for exploration (§ 3.2); and a probabilistic formulation of the Wolfe conditions as a termination criterion (§ 3.3). Appendix D contains a detailed pseudocode of the probabilistic line search; Algorithm 1 very roughly sketches the structure of the probabilistic line search and highlights its essential ingredients.

3.1 Lightweight Gaussian Process Surrogate

We model information about the objective in a probability measure $p(f)$. There are two requirements on such a measure: First, it must be robust to irregularity (low and high variability) of the objective. And second, it must allow analytic computation of discrete candidate points for evaluation, because a line search should not call yet another optimization subroutine itself. Both requirements are fulfilled by a once-integrated Wiener process, i.e. a zero-mean Gaussian process prior $p(f) = \mathcal{GP}(f; 0, k)$ with covariance function

$$k(t, t') = \theta^2 \left[\tfrac{1}{3} \min^3(\tilde{t}, \tilde{t}') + \tfrac{1}{2} |t - t'| \min^2(\tilde{t}, \tilde{t}') \right]. \tag{4}$$

Algorithm 1 probLineSearchSketch(f, y_0, y'_0, σ_{f_0}, $\sigma_{f'_0}$)

```

end while

return observed point in T with lowest GP mean since no Wolfe-point found
```

Here $\tilde{t} := t + \tau$ and $\tilde{t}' := t' + \tau$ denote a shift by a constant $\tau > 0$. This ensures this kernel is positive semi-definite, the precise value τ is irrelevant as the algorithm only considers positive values of t (our implementation uses $\tau = 10$). See §3.4 regarding the scale θ^2. With the likelihood of Eq. 3, this prior gives rise to a GP posterior whose mean function is a cubic spline[3] (Wahba, 1990). We note in passing that regression on f and f' from N observations of pairs (y_t, y'_t) can be formulated as a filter (Särkkä, 2013) and thus performed in $\mathcal{O}(N)$ time. However, since a line search typically collects < 10 data points, generic GP inference, using a Gram matrix, has virtually the same, low cost.

Because Gaussian measures are closed under linear maps (Papoulis, 1991, §10), Eq. 4 implies a Wiener process (linear spline) model on f':

$$p(f; f') = \mathcal{GP}\left(\begin{bmatrix} f \\ f' \end{bmatrix}; \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} k & k^{\partial} \\ \partial k & \partial k \partial \end{bmatrix}\right), \tag{5}$$

3. Eq. 4 can be generalized to the 'natural spline', removing the need for the constant τ (Rasmussen and Williams, 2006, §6.3.1). However, this notion is ill-defined in the case of a single observation, as in the line search.

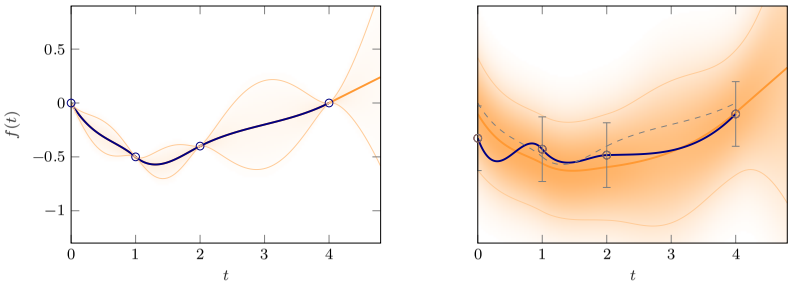

Figure 3: *Integrated Wiener process:* GP marginal posterior of function values; posterior mean in solid orange and, two standard deviations in thinner solid orange, local pdf marginal as shading; function value observations as gray circles (corresponding gradients not shown). Classic interpolation by piecewise cubic spline in dark blue. *Left:* observations are exact; the mean of the GP and the cubic spline interpolator of a classic line search coincide. *Right:* same observations with additive Gaussian noise (error-bars indicate ± 1 standard deviations); noise free interpolator in dashed gray for comparison. The classic interpolator in dark blue, which exactly matches the observations, becomes unreliable; the GP reacts robustly to noisy observations; the GP-mean still consists of piecewise cubic splines.

with (using the indicator function $\mathbb{I}(x) = 1$ if x, else 0)

$$\begin{aligned} k^{\partial}{}_{tt'} &:= \frac{\partial k(t,t')}{\partial t'} &&= \theta^2 \left[\mathbb{I}(t < t')\frac{\tilde{t}^2}{2} + \mathbb{I}(t \geq t')\left(\tilde{t}\tilde{t}' - \frac{\tilde{t}'^2}{2}\right)\right] \\ {}^{\partial}k_{tt'} &:= \frac{\partial k(t,t')}{\partial t} &&= \theta^2 \left[\mathbb{I}(t' < t)\frac{\tilde{t}'^2}{2} + \mathbb{I}(t' \geq t)\left(\tilde{t}\tilde{t}' - \frac{\tilde{t}^2}{2}\right)\right] \\ {}^{\partial}k^{\partial}{}_{tt'} &:= \frac{\partial^2 k(t,t')}{\partial t' \partial t} &&= \theta^2 \min(\tilde{t}, \tilde{t}'). \end{aligned} \tag{6}$$

Given a set of evaluations $(\boldsymbol{t}, \boldsymbol{y}, \boldsymbol{y}')$ (vectors, with elements t_i, y_{t_i}, y'_{t_i}) with independent likelihood 3, the posterior $p(f \mid \boldsymbol{y}, \boldsymbol{y}')$ is a GP with posterior mean function μ and covariance function $\tilde{k}$ as follows:

$$\begin{bmatrix} \mu(t) \\ \mu'(t) \end{bmatrix} = \underbrace{\begin{bmatrix} k_{t\boldsymbol{t}} & k^{\partial}{}_{t\boldsymbol{t}} \\ {}^{\partial}k_{t\boldsymbol{t}} & {}^{\partial}k^{\partial}{}_{t\boldsymbol{t}} \end{bmatrix} \begin{bmatrix} k_{\boldsymbol{tt}} + \sigma_f^2 \boldsymbol{I} & k^{\partial}{}_{\boldsymbol{tt}} \\ {}^{\partial}k_{\boldsymbol{tt}} & {}^{\partial}k^{\partial}{}_{\boldsymbol{tt}} + \sigma_{f'}^2 \boldsymbol{I} \end{bmatrix}^{-1}}_{=:\boldsymbol{g}^{\intercal}(t)} \begin{bmatrix} \boldsymbol{y} \\ \boldsymbol{y}' \end{bmatrix} \tag{7}$$

$$\begin{bmatrix} \tilde{k}(t,t') & \tilde{k}^{\partial}(t,t') \\ {}^{\partial}\tilde{k}(t',t) & {}^{\partial}\tilde{k}^{\partial}(t,t') \end{bmatrix} = \begin{bmatrix} k_{tt'} & k^{\partial}{}_{tt'} \\ {}^{\partial}k_{t't} & {}^{\partial}k^{\partial}{}_{tt'} \end{bmatrix} - \boldsymbol{g}^{\intercal}(t) \begin{bmatrix} k_{\boldsymbol{t}t'} & k^{\partial}{}_{\boldsymbol{t}t'} \\ {}^{\partial}k_{t'\boldsymbol{t}} & {}^{\partial}k^{\partial}{}_{\boldsymbol{t}t'} \end{bmatrix}$$

The posterior marginal variance will be denoted by $\mathbb{V}(t) = \tilde{k}(t,t)$. To see that μ is indeed piecewise cubic (i.e. a cubic spline), we note that it has at most three non-vanishing

derivatives[4], because

$$\begin{aligned} {}^{\partial^2}k_{tt'} &:= \frac{\partial^2 k(t,t')}{\partial t^2} = \theta^2 \mathbb{I}(t \leq t') & {}^{\partial^3}k_{tt'} &:= \frac{\partial^3 k(t,t')}{\partial t^3} = \theta^2 \mathbb{I}(t \leq t')(t' - t) \\ {}^{\partial^2}k^{\partial}{}_{tt'} &:= \frac{\partial^4 k(t,t')}{\partial t^2 \partial t'} = -\theta^2 \mathbb{I}(t \leq t') & {}^{\partial^3}k^{\partial}{}_{tt'} &:= \frac{\partial^4 k(t,t')}{\partial t^3 \partial t'} = 0. \end{aligned} \tag{8}$$

This piecewise cubic form of μ is crucial for our purposes: having collected N values of f and f', respectively, all local minima of μ can be found analytically in $\mathcal{O}(N)$ time in a single sweep through the 'cells' $t_{i-1} < t < t_i$, $i = 1, \ldots, N$ (here $t_0 = 0$ denotes the start location, where (y_0, y'_0) are 'inherited' from the preceding line search. For typical line searches $N < 10$, c.f. §4. In each cell, $\mu(t)$ is a cubic polynomial with at most one minimum in the cell, found by an inexpensive quadratic computation from the three scalars $\mu'(t_i), \mu''(t_i), \mu'''(t_i)$. This is in contrast to other GP regression models—for example the one arising from a squared exponential kernel—which give more involved posterior means whose local minima can be found only approximately. Another advantage of the cubic spline interpolant is that it does not assume the existence of higher derivatives (in contrast to the Gaussian kernel, for example), and thus reacts robustly to irregularities in the objective. In our algorithm, after each evaluation of (y_N, y'_N), we use this property to compute a short list of *candidates* for the next evaluation, consisting of the $\leq N$ local minimizers of $\mu(t)$ and one additional *extrapolation* node at $t_{\max} + \alpha$, where $t_{\max}$ is the currently largest evaluated t, and α is an extrapolation step size starting at $\alpha = 1$ and doubled after each extrapolation step.[5]

A conceptual (rather than algorithmic) motivation for using the integrated Wiener process as surrogate for the objective, as well as for the described candidate selection, are classic line searches. There, the 1D-objective is modeled by piecewise cubic interpolations between neighboring datapoints. In a sense, this is a non-parametric approach, since a new spline is defined, when a datapoint is added. Classic line searches always only deal with one spline at a time, since they are able to collapse all other parts of the search space. Indeed, for noise free observations, the mean of the posterior GP is identical to the classic cubic interpolations, and thus candidate locations are identical as well; this is illustrated in Figure 3. The non-parametric approach also prevents issues of over-constrained surrogates for more than two datapoints. For example, unless the objective is a perfect cubic function, it is impossible to fit a parametric third order polynomial to it, for more than two noise free observations. All other variability in the objective would need to be explained away by artificially introducing noise on the observations. An integrated Wiener process very naturally extends its complexity with each newly added datapoint without being overly assertive – the encoded assumption is that the objective has *at least* one derivative (which is also observed in this case).

4. There is no well-defined probabilistic belief over f'' and higher derivatives—sample paths of the Wiener process are almost surely non-differentiable almost everywhere (Adler, 1981, §2.2). But $\mu(t)$ is always a member of the reproducing kernel Hilbert space induced by k, thus piecewise cubic (Rasmussen and Williams, 2006, §6.1).
5. For the integrated Wiener process and heteroscedastic noise, the variance *always* attains its maximum exactly at the mid-point between two evaluations; including the variance into the candidate selection biases the existing candidates towards the center (additional candidates might occur between evaluations without local minimizer, even for noise free observations/classic line searches). We did not explore this further since the algorithm showed very good sample efficiency already with the adopted scheme.

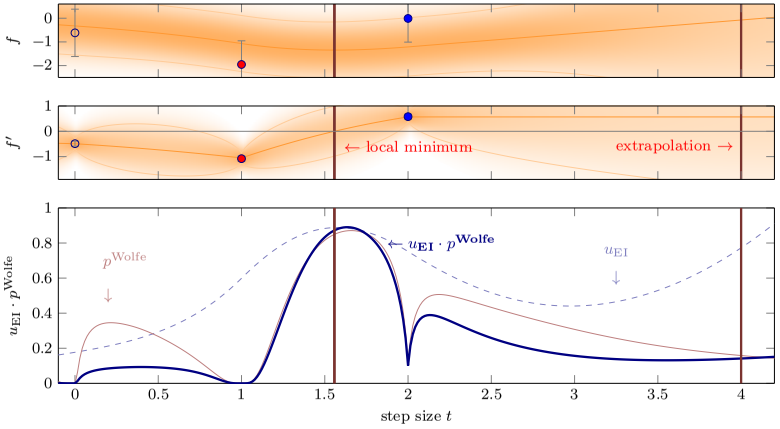

Figure 4: *Candidate selection* by Bayesian optimization. *Top:* GP marginal posterior of function values. Posterior mean in solid orange and, two standard deviations in thinner solid orange, local pdf marginal as shading. The red and the blue point are evaluations of the objective function, collected by the line search. *Middle:* GP marginal posterior of corresponding gradients. Colors same as in top plot. In all three plots the locations of the *two* candidate points (§3.1) are indicated as vertical dark red lines. The left one at about $t_1^{\mathrm{cand}} \approx 1.54$ is a local minimum of the posterior mean in between the red and blue point (the mean of the gradient belief (solid orange, middle plot) crosses through zero here). The right one at $t_2^{\mathrm{cand}} = 4$ is a candidate for extrapolation. *Bottom:* Decision criterion in arbitrary scale: The expected improvement u_{EI} (Eq. 9) is shown in dashed light blue, the Wolfe probability p^{Wolfe} (Eq. 14 and Eq. 16) in light red and their decisive product in solid dark blue. For illustrative purposes all criteria are plotted for the whole t-space. In practice solely the values at t_1^{cand} and t_2^{cand} are computed, compared, and the candidate with the higher value of $u_{\mathrm{EI}} \cdot p^{\mathrm{Wolfe}}$ is chosen for evaluation. In this example this would be the candidate at t_1^{cand}.

3.2 Choosing Among Candidates

The previous section described the construction of $< N+1$ discrete candidate points for the next evaluation. To decide at which of the candidate points to actually call f and f', we make use of a popular acquisition function from Bayesian optimization. *Expected improvement* (Jones et al., 1998) is the expected amount, under the GP surrogate, by which the function $f(t)$ might be smaller than a 'current best' value η (we set $\eta = \min_{i=0,\ldots,N}\{\mu(t_i)\}$, where t_i

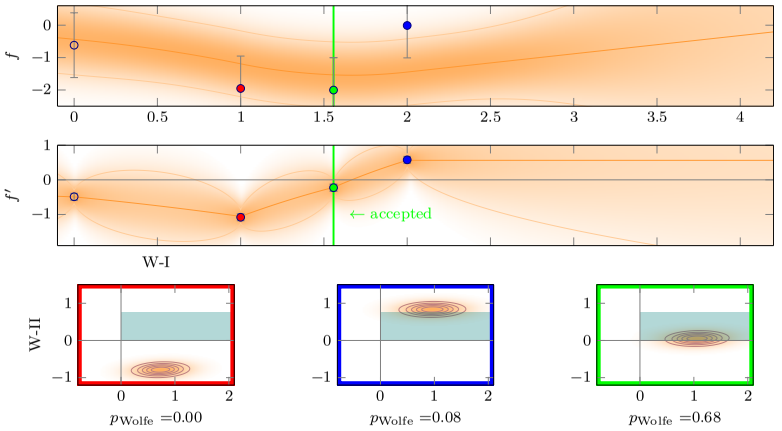

Figure 5: *Acceptance procedure. Top and middle:* plot and colors as in Figure 4 with an additional 'green' observation. *Bottom:* Implied bivariate Gaussian belief over the validity of the Wolfe conditions (Eq. 11) at the red, blue and green point respectively. Points are considered acceptable if their Wolfe probability p_t^{Wolfe} is above a threshold $c_W = 0.3$; this means that at least 30% of the orange 2D Gauss density must cover greenish shaded area. Only the green point fulfills this condition and is therefore accepted.

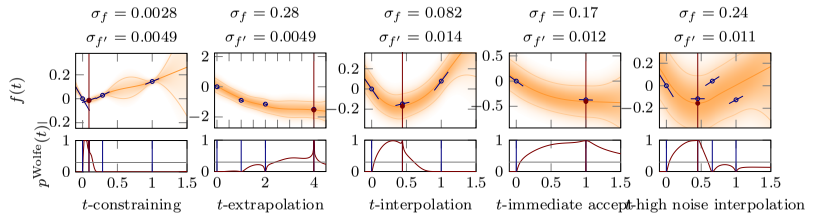

Figure 6: *Curated snapshots* of line searches (from N-I on MNIST), showing variability of the objective's shape and the decision process. *Top row:* GP marginal posterior of function values and evaluations, *bottom row:* approximate p^{Wolfe} over strong Wolfe conditions. Accepted point marked red.

are observed locations),

$$u_{\text{EI}}(t) = \mathbb{E}_{p(f_t \,|\, \boldsymbol{y}, \boldsymbol{y}')}[\min\{0, \eta - f(t)\}] \\ = \frac{\eta - \mu(t)}{2}\left(1 + \operatorname{erf}\frac{\eta - \mu(t)}{\sqrt{2\mathbb{V}(t)}}\right) + \sqrt{\frac{\mathbb{V}(t)}{2\pi}}\exp\left(-\frac{(\eta - \mu(t))^2}{2\mathbb{V}(t)}\right). \tag{9}$$

The next evaluation point is chosen as the candidate maximizing the product of Eq. 9 and Wolfe probability p^{Wolfe}, which is derived in the following section. The intuition is that p^{Wolfe} precisely encodes properties of desired points, but has poor exploration properties; u_{EI} has better exploration properties, but lacks the information that we are seeking a point with low curvature; u_{EI} thus puts weight on (by W-II) clearly ruled out points. An illustration of the candidate proposal and selection is shown in Figure 4.

In principle other acquisition functions (e.g. the upper-confidence bound, GP-UCB (Srinivas et al., 2010)) are possible, which might have a stronger explorative behavior; we opted for u_{EI} since exploration is less crucial for line searches than for general BO and some (e.g. GP-UCB) had one additional parameter to tune. We tracked the sample efficiency of u_{EI} instead and it was very good (low); the experimental Subsection 4.3 contains further comments and experiments on the alternative choices of u_{EI} and p^{Wolfe} as standalone acquisition functions; they performed equally well (in terms of loss and sample efficiency) to their product on the tested setups.

3.3 Probabilistic Wolfe Conditions for Termination

The key observation for a probabilistic extension of the Wolfe conditions W-I and W-II is that they are positivity constraints on two variables a_t, b_t that are both linear projections of the (jointly Gaussian) variables f and f':

$$\begin{bmatrix} a_t \\ b_t \end{bmatrix} = \begin{bmatrix} 1 & c_1 t & -1 & 0 \\ 0 & -c_2 & 0 & 1 \end{bmatrix} \begin{bmatrix} f(0) \\ f'(0) \\ f(t) \\ f'(t) \end{bmatrix} \geq 0. \tag{10}$$

The GP of Eq. (5) on f thus implies, at each value of t, a bivariate Gaussian distribution

$$p(a_t, b_t) = \mathcal{N}\left(\begin{bmatrix} a_t \\ b_t \end{bmatrix}; \begin{bmatrix} m_t^a \\ m_t^b \end{bmatrix}, \begin{bmatrix} C_t^{aa} & C_t^{ab} \\ C_t^{ba} & C_t^{bb} \end{bmatrix}\right), \tag{11}$$

$$\text{with} \quad m_t^a = \mu(0) - \mu(t) + c_1 t \mu'(0)$$

$$m_t^b = \mu'(t) - c_2 \mu'(0) \tag{12}$$

$$\text{and} \quad C_t^{aa} = \tilde{k}_{00} + (c_1 t)^2 {}^{\partial}\tilde{k}_{00}^{\partial} + \tilde{k}_{tt} + 2[c_1 t({}^{\partial}\tilde{k}_{00}^{\partial} - {}^{\partial}\tilde{k}_{0t}) - \tilde{k}_{0t}]$$

$$C_t^{bb} = c_2^2 {}^{\partial}\tilde{k}_{00}^{\partial} - 2c_2 {}^{\partial}\tilde{k}_{0t}^{\partial} + {}^{\partial}\tilde{k}_{tt}^{\partial} \tag{13}$$

$$C_t^{ab} = C_t^{ba} = -c_2({}^{\partial}\tilde{k}_{00}^{\partial} + c_1 t {}^{\partial}\tilde{k}_{00}^{\partial}) + c_2 {}^{\partial}\tilde{k}_{0t} + {}^{\partial}\tilde{k}_{t0} + c_1 t {}^{\partial}\tilde{k}^{\partial}{}_{0t} - \tilde{k}_{tt}^{\partial}.$$

The quadrant probability $p_t^{\text{Wolfe}} = p(a_t > 0 \wedge b_t > 0)$ for the Wolfe conditions to hold, is an integral over a bivariate normal probability,

$$p_t^{\text{Wolfe}} = \int_{-\frac{m_t^a}{\sqrt{C_t^{aa}}}}^{\infty} \int_{-\frac{m_t^b}{\sqrt{C_t^{bb}}}}^{\infty} \mathcal{N}\left(\begin{bmatrix} a \\ b \end{bmatrix}; \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 & \rho_t \\ \rho_t & 1 \end{bmatrix}\right) da\, db, \tag{14}$$

with correlation coefficient $\rho_t = C_t^{ab}/\sqrt{C_t^{aa} C_t^{bb}}$. It can be computed efficiently (Drezner and Wesolowsky, 1990), using readily available code.[6] The line search computes this probability for all evaluation nodes, after each evaluation. If any of the nodes fulfills the Wolfe conditions with $p_t^{\text{Wolfe}} > c_W$, greater than some threshold $0 < c_W \leq 1$, it is accepted and returned. If several nodes simultaneously fulfill this requirement, the most recently evaluated node is returned; there are additional safeguards for cases where e.g. no Wolfe-point can be found, which can be deduced from the pseudo-code in Appendix D; they are similar to standard safeguards of classic line search routines (e.g. returning the node of lowest mean). Section 3.4.1 below motivates fixing $c_W = 0.3$. The acceptance procedure is illustrated in Figure 5.

3.3.1 Approximation for Strong Conditions:

As noted in Section 2.1.1, deterministic optimizers tend to use the strong Wolfe conditions, which use $|f'(0)|$ and $|f'(t)|$. A precise extension of these conditions to the probabilistic setting is numerically taxing, because the distribution over $|f'|$ is a non-central χ-distribution, requiring customized computations. However, a straightforward variation to 14 captures the spirit of the strong Wolfe conditions that large positive derivatives should not be accepted: Assuming $f'(0) < 0$ (i.e. that the search direction is a descent direction), the strong second Wolfe condition can be written exactly as

$$0 \leq b_t = f'(t) - c_2 f'(0) \leq -2c_2 f'(0). \tag{15}$$

The value $-2c_2 f'(0)$ is bounded to 95% confidence by

$$-2c_2 f'(0) \lesssim 2c_2(|\mu'(0)| + 2\sqrt{\mathbb{V}'(0)}) =: \bar{b}. \tag{16}$$

Hence, an approximation to the strong Wolfe conditions can be reached by replacing the infinite upper integration limit on b in Eq. 14 with $(\bar{b} - m_t^b)/\sqrt{C_t^{bb}}$. The effect of this adaptation, which adds no overhead to the computation, is shown in Figure 2 as a dashed line.

3.4 Eliminating Hyper-parameters

As a black-box inner loop, the line search should not require any tuning by the user. The preceding section introduced six so-far undefined parameters: $c_1, c_2, c_W, \theta, \sigma_f, \sigma_{f'}$. We will now show that c_1, c_2, c_W, can be fixed by hard design decisions: θ can be eliminated by standardizing the optimization objective within the line search; and the noise levels can be estimated at runtime with low overhead for finite-sum objectives of the form in Eq. 1. The result is a parameter-free algorithm that effectively *removes* the one most problematic parameter from SGD—the learning rate.

3.4.1 Design Parameters c_1, c_2, c_W

Our algorithm inherits the Wolfe thresholds c_1 and c_2 from its deterministic sibling. We set $c_1 = 0.05$ and $c_2 = 0.5$. This is a standard setting that yields a 'lenient' line search, i.e. one

6. e.g. `http://www.math.wsu.edu/faculty/genz/software/matlab/bvn.m`

that accepts most descent points. The rationale is that the stochastic aspect of SGD is not always problematic, but can also be helpful through a kind of 'annealing' effect.

The acceptance threshold c_W is a new design parameter arising only in the probabilistic setting. We fix it to $c_W = 0.3$. To motivate this value, first note that in the noise-free limit, all values $0 < c_W < 1$ are equivalent, because p^{Wolfe} then switches discretely between 0 and 1 upon observation of the function. A back-of-the-envelope computation, assuming only two evaluations at $t = 0$ and $t = t_1$ and the same fixed noise level on f and f' (which then cancels out), shows that function values barely fulfilling the conditions, i.e. $a_{t_1} = b_{t_1} = 0$, can have $p^{\text{Wolfe}} \sim 0.2$ while function values at $a_{t_1} = b_{t_1} = -\epsilon$ for $\epsilon \rightarrowtail 0$ with 'unlucky' evaluations (both function and gradient values one standard-deviation from true value) can achieve $p^{\text{Wolfe}} \sim 0.4$. The choice $c_W = 0.3$ balances the two competing desiderata for precision and recall. Empirically (Fig. 6), we rarely observed values of p^{Wolfe} close to this threshold. Even at high evaluation noise, a function evaluation typically either clearly rules out the Wolfe conditions, or lifts p^{Wolfe} well above the threshold. A more in-depth analysis of c_1, c_2, and c_W is done in the experimental Section 4.2.1.

3.4.2 Scale θ

The parameter θ of Eq. 4 simply scales the prior variance. It can be eliminated by scaling the optimization objective: We set $\theta = 1$ and scale $y_i \leftarrowtail (y_i - y_0)/|y_0'|, y_i' \leftarrowtail y_i'/|y_0'|$ within the code of the line search. This gives $y(0) = 0$ and $y'(0) = -1$, and typically ensures the objective ranges in the single digits across $0 < t < 10$, where most line searches take place. The division by $|y_0'|$ causes a non-Gaussian disturbance, but this does not seem to have notable empirical effect.

3.4.3 Noise Scales $\sigma_f, \sigma_{f'}$

The likelihood 3 requires standard deviations for the noise on both function values (σ_f) and gradients ($\sigma_{f'}$). One could attempt to learn these across several line searches; but the resulting estimator would be biased. In exchangeable models as captured by Eq. 1, however, the variance of the loss and its gradient can be estimated locally and unbiased, directly for the mini-batch, at low computational overhead—an approach already advocated by Schaul et al. (2013). We collect the empirical statistics

$$\hat{S}(x) := \frac{1}{m}\sum_j^m \ell^2(x, y_j), \quad \text{and} \quad \hat{\nabla S}(x) := \frac{1}{m}\sum_j^m \nabla\ell(x, y_j)^{\odot 2} \tag{17}$$

(where $^{\odot 2}$ denotes the element-wise square) and estimate, at the beginning of a line search from x_k,

$$\sigma_f^2 = \frac{1}{m-1}\left(\hat{S}(x_k) - \hat{\mathcal{L}}(x_k)^2\right) \text{ and } \sigma_{f'}^2 = s_i^{\odot 2\intercal}\left[\frac{1}{m-1}\left(\hat{\nabla S}(x_k) - (\nabla\hat{\mathcal{L}}(x_k))^{\odot 2}\right)\right]. \tag{18}$$

This amounts to the assumption that noise on the gradient is independent (see also Appendix A). We finally scale the two empirical estimates as described in Section §3.4.2: $\sigma_f \leftarrowtail \sigma_f/|y'(0)|$, and ditto for $\sigma_{f'}$. The overhead of this estimation is small if the computation of $\ell(x, y_j)$ itself is more expensive than the summation over j. In the neural network examples N-I and N-II of the experimental Section 4, the additional steps added only $\sim 1\%$ cost overhead to the evaluation of the loss. This is rather at the lower end for these models; A more general statement about memory and time requirements for neural networks can be found in Sections 3.6 and 3.7. Estimating noise separately for each input dimension captures the often inhomogeneous structure among gradient elements, and its effect on the noise along the projected direction. For example, in multi-layer models, gradient noise is typically higher on weights between the input and first hidden layer, hence line searches along the corresponding directions are noisier than those along directions affecting higher-level weights.

3.4.4 Propagating Step Sizes Between Line Searches

As will be demonstrated in §4, the line search can find good step sizes even if the length of the direction s_i is mis-scaled. Since such scale issues typically persist over time, it would be wasteful to have the algorithm re-fit a good scale in each line search. Instead, we propagate step lengths from one iteration of the search to another: We set the initial search direction to $s_0 = -\alpha_0\nabla\hat{\mathcal{L}}(x_0)$ with some initial learning rate α_0. Then, after each line search ending at $x_i = x_{i-1} + t_* s_i$, the next search direction is set to $s_{i+1} = -\alpha_{\text{ext}} \cdot t_* \alpha_0 \nabla\hat{\mathcal{L}}(x_i)$ (with $\alpha_{\text{ext}} = 1.3$). Thus, the next line search starts its extrapolation at 1.3 times the step size of its predecessor (Section 4.2.2 for details).

3.5 Relation to Bayesian Optimization and Noise-Free Limit

The probabilistic line search algorithm is closely related to Bayesian optimization (BO) since it approximately minimizes a 1D-objective under potentially noisy function evaluations. It thus uses notions of BO (e.g. a GP-surrogate for the objective, and an acquisition function to discriminate locations for the next evaluation of the loss), but there are some differences concerning the aim, requirements on computational efficiency, and termination condition, which are shortly discussed here: (i) *Performance measure:* The final performance measure in BO is usually the lowest found value of the objective function. Line searches are subroutines inside of a greedy, iterative optimization machine, which usually performs several thousand steps (and line searches); many, very approximate steps often performs better than taking less, but preciser steps. (ii) *Termination:* The termination condition of a line search is imposed from the outside in the form of the Wolfe conditions. Stricter Wolfe conditions do not usually improve the performance of the outer optimizer, thus, no matter if a better (lower) minimum could be found, any Wolfe-point is acceptable at all times. (iii) *Sample efficiency:* Since the last evaluation from the previous line search can be re-used in the current line search, only one additional value and gradient evaluation is enough to terminate the procedure. This 'immediate-accept' is the desired behavior if the learning rate is currently well calibrated. (iv) *Locations for evaluation:* BO, usually calls an optimizer to maximize some acquisition function, and the preciseness of this optimization is crucial for performance. Line searches just need to find a Wolfe-acceptable point; classic line searches suggest that it is enough to look at plausible locations, like minimizer of a local interpolator, or some rough extrapolation point; this inexpensive heuristic usually works rather well. (v) *Exploration:* BO needs to solve an intricate trade-off problem in between exploring enough of the parameters space for possible locations of minima, and exploiting locations around them further. Since line searches are only concerned with finding

a Wolfe-point, they do not need to explore the parameter space of possible step sizes to that extend; crucial features are rather the possibility to explore somewhat larger steps than previous ones (which is done by extrapolation-candidates), and likewise to shorted steps (which is done by interpolation-candidates).

In the limit of noise free observed gradients and function values ($\sigma_f = \sigma_{f'} = 0$) the probabilistic line search behaves like its classic parent, except for very slight variations in the candidate choice (building block 3): The GP-mean reverts to the classic interpolator; all candidate locations are thus identical, but the probabilistic line search might propose a second option, since (even if there is a local minimizer) it *always* also proposes an extrapolation candidate. This is illustrated in the following table.

building block	**classic**	**probabilistic (noise free)**
1) 1D surrogate for objective $f(t)$	piecewise cubic splines	GP-mean identical to classic interpolator
2) candidate selection	local minimizer of cubic splines *xor* extrapolation	local minimizer of cubic splines *or* extrapolation
3) choice of best candidate	———	BO acquisition function
4) acceptance criterion	classic Wolfe conditions	p^{Wolfe} identical to classic Wolfe conditions

3.6 Computational Time Overhead

The line search routine itself has little memory and time overhead; most importantly it is independent of the dimensionality of the optimization problem. After every call of the objective function, the GP (§3.1) needs to be updated which, at most, is at the cost of inverting a $2N \times 2N$-matrix, where N usually is equal to $1, 2$, or 3 but never > 10. In addition, the bivariate normal integral p_t^{Wolfe} of Eq. 14 needs to be computed at most N times. On a laptop, one evaluation of p_t^{Wolfe} costs about 100 microseconds. For the choice among proposed candidates (§3.2), again at most N, for each, we need to evaluate p_t^{Wolfe} and $u_{\text{EI}}(t)$ (Eq. 9) where the latter comes at the expense of evaluating two error functions. Since all of these computations have a fixed cost (in total some milliseconds on a laptop), the relative overhead becomes less the more expensive the evaluation of $\nabla\hat{\mathcal{L}}(x)$.

The largest overhead actually lies outside of the actual line search routine. In case the noise levels σ_f and $\sigma_{f'}$ are not known, we need to estimate them. The approach we took is described in Section 3.4.3 where the variance of $\nabla\hat{\mathcal{L}}$ is estimated using the sample variance of the mini-batch, each time the objective function is called. Since in this formulation the variance estimation is about half as expensive as one backward pass of the net, the time overhead depends on the relative cost of the feed forward and backward passes (Balles et al., 2017). If forward and backward pass are the same cost, the most straightforward implementation of the variance estimation would make each function call < 1.3 times as expensive. This is an *upper bound* and the actual cost is usually lower.[7] At the same time though, *all* exploratory experiments which very considerably increase the time spend when

7. It is desirable to decrease this value in the future reusing computation results or by approximation but this is beyond this discussion.

using SGD with a hand tuned learning rate schedule need not be performed anymore. In Section 4.1 we will also see that SGD using the probabilistic line search often needs less function evaluations to converge, which might lead to overall faster convergence in wall clock time than classic SGD in a single run.

3.7 Memory Requirement

Vanilla SGD, at all times, keeps around the current optimization parameters $x \in \mathbb{R}^D$ and the gradient vector $\nabla\hat{\mathcal{L}}(x) \in \mathbb{R}^D$. In addition to this, the probabilistic line search needs to store the estimated gradient variances $\Sigma'(x) = (1-m)^{-1}(\hat{\nabla}S(x) - \nabla\hat{\mathcal{L}}(x)^{\odot 2})$ (Eq. 18) of same size. The memory requirement of SGD+probLS is thus comparable to AdaGrad or Adam. If combined with a search direction other than SGD always one additional vector of size D needs to be stored.

4. Experiments

This section reports on an extensive set of experiments to characterise and test the line search. The overall evidence from these tests is that the line search performs well and is relatively insensitive to the choice of its internal hyper-parameters as well the mini-batch size. We performed experiments on two multi-layer perceptrons N-I and N-II; both were trained on two well known datasets MNIST and CIFAR-10.

- N-I: fully connected net with 1 hidden layer and 800 hidden units + biases, and 10 output units, sigmoidal activation functions and a cross entropy loss. Structure without biases: 784-800-10. Many authors used similar nets and reported performances.[8]
- N-II: fully connected net with 3 hidden layers and 10 output units, tanh-activation functions and a squared loss. Structure without biases: 784-1000-500-250-10. Similar nets were also used for example in Martens (2010) and Sutskever et al. (2013).
- MNIST (LeCun et al., 1998): multi-class classification task with 10 classes: hand-written digits in gray-scale of size 28×28 (numbers '0' to '9'); training set size 60 000, test set size 10 000.
- CIFAR-10 (Krizhevsky and Hinton, 2009): multi-class classification task with 10 classes: color images of natural objects (horse, dog, frog,...) of size 32×32; training set size 50 000, test set size 10 000; like other authors, we only used the "batch 1" sub-set of CIFAR-10 containing 10 000 training examples.

In addition we train logistic regressors with sigmoidal output (N-III) on the following binary classification tasks:

- Wisconsin Breast Cancer Dataset (WDBC) (Wolberg et al., 2011): binary classification of tumors as either 'malignant' or 'benign'. The set consist of 569 examples of which we used 169 to monitor generalization performing; thus 400 remain for the training set; 30 features describe for example radius, area, symmetry, et cetera. In comparison

8. `http://yann.lecun.com/exdb/mnist/`

to the other datasets and networks, this yields a very low dimensional optimization problem with only 30 (+1 bias) input parameters as well as just a small number of datapoints.

- GISETTE (Guyon et al., 2005): binary classification of the handwritten digits '4' and '9'. The original 28×28 images are taken from the MNIST datset; then the feature set was expanded and consists of the original normalized pixels, plus a randomly selected subset of products of pairs of features, which are slightly biased towards the upper part of the image; in total there are 5000 features, instead of 784 as in the original MNIST. The size of the training set and test set is 6000 and 1000 respectively.
- EPSILON: synthetic dataset from the PASCAL Challenge 2008 for binary classification. It consists of 400 000 training set datapoint and 100 000 test set datapoints, each having 2000 features.

In the text and figures, SGD using the probabilistic line search will occasionally be denoted as SGD+PROBLS. Section 4.1 contains experiments on the sensitivity to varying gradient noise levels (mini-batch sizes) performed on both multi-layer perceptrons N-I and N-II, as well as on the logistic regressor N-III. Section 4.2 discusses sensitivity to the hyper-parameters choices introduced in Section 3.4 and Section 4.3 contains additional diagnostics on step size statistics. Each single experiment was performed 10 times with different random seeds that determined the starting weights and the mini-batch selection and seeds were shared across all experiments. We report all results of the 10 instances as well as means and standard deviations.

4.1 Varying Mini-batch Sizes

The noise level of the gradient estimate $\nabla\hat{\mathcal{L}}(x)$ and the loss $\hat{\mathcal{L}}(x)$ is determined by the mini-batch size m and ultimately there should exist an optimal m that maximizes the optimizer's performance in wall-clock-time. In practice of course the cost of computing $\nabla\hat{\mathcal{L}}(x)$ and $\hat{\mathcal{L}}(x)$ is not necessarily linear in m since it is upper bounded by the memory capacity of the hardware used. We assume here that the mini-batch size is chosen by the user; thus we test the line search with the default hyper-parameter setting (see Sections 3.4 and 4.2) on four different mini-batch sizes:

- $m = 10, 100, 200$ and 1000 (for MNIST, CIFAR-10, and EPSILON)
- $m = 10, 50, 100$, and 400 (for WDBC and GISETTE)

which correspond to increasing signal-to-noise ratios. Since the training set of WDBC only consists of 400 datapoints, the run with the larges mini-batch size of 400 in fact runs full-batch gradient descent on WDBC; this is not a problem, since—as discussed above—the probabilistic line search can also handle noise free observations.[9] We compare to SGD-runs using a fixed step size (which is typical for these architectures) and an annealed step size with annealing schedule $\alpha_t = \alpha_0/t$. Because annealed step sizes performed much worse than

9. Since the dataset size M of WDBC is very small, we used the factor $(M-m)/(mM)$ instead of $1/m$ to scale the sample variances of Eq. 17. The former encodes sampling mini-batches $\mathcal{B}$ with replacement, the latter without replacement; for $m \ll M$ both factors are nearly identical.

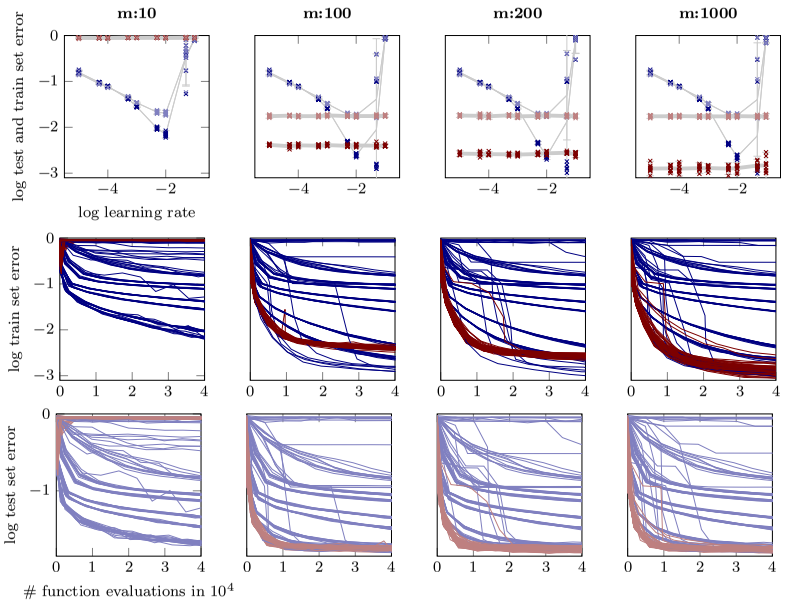

Figure 7: Performance of N-II on MNIST for *varying mini-batch sizes*. *Top:* final logarithmic test set and train set error after 40 000 function evaluations of training versus a large range of learning rates each for 10 different initializations. SGD-runs with fixed learning rates are shown in light blue (test set) and dark blue (train set); SGD+PROBLS-runs in light red (test set) and dark red (train set); means and two standard deviations for each of the 10 runs in gray. *Columns* from left to right refer to different mini-batch sizes m of 10, 100, 200 and 1000 which correspond to decreasing relative noise in the gradient observations. Not surprisingly the performance of SGD-runs with a fixed step size are very sensitive to the choice of this step size. SGD using the probabilistic line search adapts initially mis-scaled step sizes and performs well across the whole range of initial learning rates. *Middle and bottom:* Evolution of the logarithmic test and train set error respectively for all SGD-runs and SGD+PROBLS-runs versus # function evaluations (colors as in top plot). For mini-batch sizes of $m = 100, 200$ and 1000 *all* instances of SGD using the probabilistic line search reach the same best test set error. Similarly a good train set error is reached very fast by SGD+PROBLS. Only very few instances of SGD with a fixed learning rate reach a better train set error (and this advantage usually does not translate to test set error). For very small mini-batch sizes ($m = 10$, first column) the line search performs poorly on this architecture, most likely because of the variance estimation becoming too inaccurate.

SGD+fixed step size, we will only report on the latter results in the plots.[10] Since classic SGD without the line search needs a hand crafted learning rate we search on exhaustive logarithmic grids of

$$\alpha_{\text{SGD}}^{\text{N-I}} = [10^{-5}, 5\cdot 10^{-5}, 10^{-4}, 5\cdot 10^{-4}, 10^{-3}, 5\cdot 10^{-3}, 10^{-2}, 5\cdot 10^{-2}, 10^{-1}, 5\cdot 10^{-1}]$$
$$\alpha_{\text{SGD}}^{\text{N-II}} = [\alpha_{\text{SGD}}^{\text{N-I}},\ 1.0,\ 1.5,\ 2.0,\ 2.5,\ 3.0,\ 3.5,\ 4.0]$$
$$\alpha_{\text{SGD}}^{\text{N-III}} = [10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}].$$

We run 10 different initialization for each learning rate, each mini-batch size and each net and dataset combination ($10\cdot 4\cdot(2\cdot 10+2\cdot 17+3\cdot 11)=3480$ runs in total) for a large enough budget to reach convergence; and report all numbers. Then we perform the same experiments using the same seeds and setups with SGD using the probabilistic line search and compare the results. For SGD+probLS, α_{SGD} is the initial learning rate which is used in the very first step. After that, the line search automatically adapts the learning rate, and shows no significant sensitivity to its initialization.

Results of N-I and N-II on both, MNIST and CIFAR-10 are shown in Figures 7, 14, 15, and 16; results of N-III on WDBC, GISETTE and EPSILON are shown in Figures 18, 17, and 19 respectively. All instances (SGD and SGD+probLS) get the same computational budget (number of mini-batch evaluations) and not the same number of optimization steps. The latter would favour the probabilistic line search since, on average, a bit more than one mini-batch is evaluated per step. Likewise, all plots show performance measure versus the number of mini-batch evaluations, which is proportional to the computational cost.

All plots show similar results: While classic SGD is sensitive to the learning rate choice, the line search-controlled SGD performs as good, close to, or sometimes even better than the (in practice unknown) optimal classic SGD instance. In Figure 7, for example, SGD+probLS converges much faster to a good test set error than the best classic SGD instance. In all experiments, across a reasonable range of mini-batch sizes m and of initial α_{SGD} values, the line search quickly identified good step sizes α_t, stabilized the training, and progressed efficiently, reaching test set errors similar to those reported in the literature for tuned versions of these kind of architectures and datasets. The probabilistic line search thus effectively removes the need for exploratory experiments and learning-rate tuning.

Overfitting and training error curves: The training error of SGD+probLS often plateaus earlier than the one of vanilla SGD, especially for smaller mini-batch sizes. This does not seem to impair the performance of the optimizer on the test set. We did not investigate this further, since it seemed like a nice natural annealing effect; the exact causes are unclear for now. One explanation might be that the line search does indeed improve overfitting, since it tries to measure descent (by Wolfe conditions which rely on the *noise-informed* GP). This means that, if—close to a minimum—successive acceptance decisions can not identify a descent direction anymore, diffusion might set in.

4.2 Sensitivity to Design Parameters

Most, if not all, numerical methods make implicit or explicit choices about their hyper-parameters. Most of these are never seen by the user since they are either estimated at run

10. An example of annealed step size performance can be found in Mahsereci and Hennig (2015).

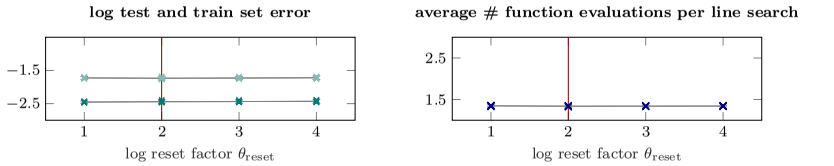

Figure 8: *Sensitivity to varying hyper-parameters* θ_{reset}. Plot and color coding as in Figure 9. Adopted parameter in dark red at $\theta_{\text{reset}}=100$. Resetting the GP scale occurs very rarely. For example for $\theta_{\text{reset}}=100$ the reset occurred in 0.02% of all line searches.

time, or set by design to a fixed, approximately insensitive value. Well known examples are the discount factor in ordinary differential equation solvers (Hairer et al., 1987, §2.4), or the Wolfe parameters c_1 and c_2 of classic line searches (§3.4.1). The probabilistic line search inherits the Wolfe parameters c_1 and c_2 from its classical counterpart as well as introducing two more: The Wolfe threshold c_W and the extrapolation factor α_{ext}. c_W does not appear in the classical formulation since the objective function can be evaluated exactly and the Wolfe probability is binary (either fulfilled or not). While c_W is thus a natural consequence of allowing the line search to model noise explicitly, the extrapolation factor α_{ext} is the result of the line search favoring shorter steps, which we will discuss below in more detail, but most prominently because of bias in the line search's first gradient observation.

In the following sections we will give an intuition about the task of the most influential design parameters c_2, c_W, and α_{ext}, discuss how they affect the probabilistic line search, and validate good design choices through exploring the parameter space and showing insensitivity to most of them. All experiments on hyper-parameter sensitivity were performed training N-II on MNIST with mini-batch size $m=200$. For a full search of the parameter space c_W-c_2-α_{ext} we performed 4950 runs in total with 495 different parameter combinations. All results are reported.

4.2.1 Wolfe II Parameter c_2 and Wolfe Threshold c_W

As described in Section 3.4, c_2 encodes the strictness of the curvature condition W-II. Pictorially speaking, a larger c_2 extends the range of acceptable gradients (green shaded are in the lower part of Figure 5) and leads to a lenient line search while a smaller value of c_2 shrinks this area, leading to a stricter line search. c_W controls how certain we want to be that the Wolfe conditions are actually fulfilled (pictorially, how much mass of the 2D-Gauss need to lie in the green shaded area). In the extreme case of complete uncertainty about the collected gradients and function values (roughly $\det[\text{cov}[a,b]]\to\infty$) p^{Wolfe} will always be ≤ 0.25, if the strong Wolfe conditions are imposed. In the limit of certain observations ($\sigma_f, \sigma_{f'}\to 0$) p^{Wolfe} is binary and reverts to the classic Wolfe criteria. An overly strict line search, therefore (e.g. $c_W=0.99$ and/ or $c_2=0.1$), will still be able to optimize the objective function well, but will waste evaluations at the expense of efficiency. Figure 10 explores the c_2-c_W parameter space (while keeping α_{ext} fixed at 1.3). The left column shows final test and train set error, the right column the average number of function evaluations

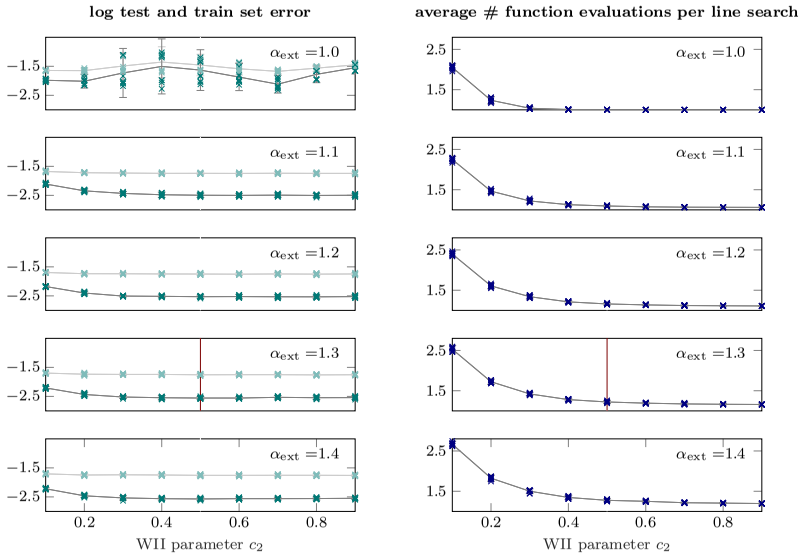

Figure 9: *Sensitivity to varying hyper-parameters* c_2, and α_{ext}. Runs were performed training N-II on MNIST with mini-batch size $m = 200$. For each parameter setting 10 runs with different initializations were performed. *Left column:* logarithmic test set error (light green) and train set error (dark green) after 40 000 function evaluations; mean and ± two standard deviations of the 10 runs in gray. *Right Column:* average number of function evaluations per line search. A low number indicates an efficient line search procedure (perfect efficiency at 1). For most parameter combinations this lies around $\approx 1.3 - 1.5$. Only at extreme parameter values, for example $\alpha_{\text{ext}} = 1.0$, which amounts to no extrapolation at all in between successive line searches, the line search performs poorer. The hyper-parameters adopted in the line search implementation are indicated as vertical dark red line at $\alpha_{\text{ext}} = 1.3$ and $c_2 = 0.5$.

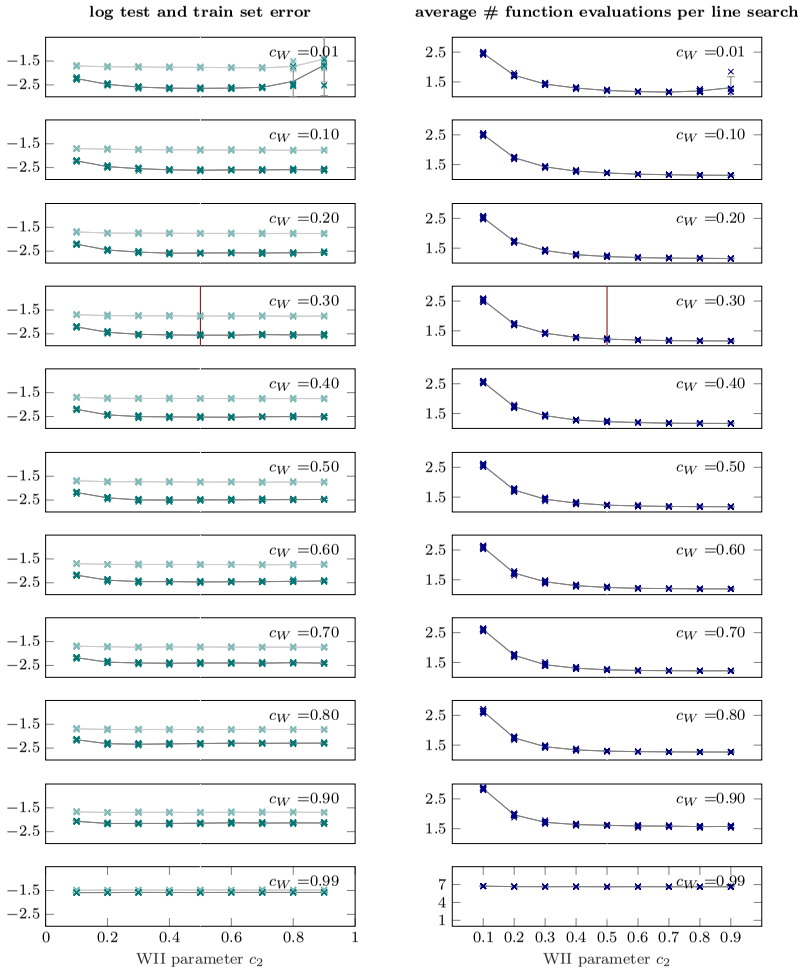

Figure 10: *Sensitivity to varying hyper-parameters* c_2, and c_W. Plot and color coding as in Figure 9 but this time for varying c_W instead of α_{ext}. *Right Column:* Again a low number indicates an efficient line search procedure (perfect efficiency at 1). For most parameter combinations this lies around $\approx 1.3 - 1.5$. Only at extreme parameter values for example $c_W = 0.99$, which amounts to imposing nearly absolute certainty about the Wolfe conditions, the line search becomes less efficient. Adopted parameters again in dark red at $c_W = 0.3$ and $c_2 = 0.5$

per line search, both versus different choices of Wolfe parameter c_2. The left column thus shows the overall performance of the optimizer, while the right column is representative for the computational efficiency of the line search. Intuitively, a line search which is minimally invasive (only corrects the learning rate, when it is really necessary) is preferred. Rows in Figure 10 show the same plot for different choices of the Wolfe threshold c_W.

The effect of strict c_2 can be observed clearly in Figure 10 where for smaller values of $c_2 <\approx 0.2$ the average number of function evaluations spend in one line search goes up slightly in comparison to looser restrictions on c_2, while still a very good perfomace is reached in terms of train and test set error. Likewise, the last row of Figure 10 for the extreme value of $c_W = 0.99$ (demanding 99% certainty about the validity if the Wolfe conditions), shows significant loss in computational efficiency having an average number of 7 function evaluations per line search. Besides loosing efficiency, it is still optimizing the objective well. Lowering this threshold a bit to 90% increases the computational efficiency of the line search to be nearly optimal again.

Ideally, we want to trade off the desiderata of being strict enough to reject too small and too large steps that prevent the optimizer to converge, but being lenient enough to allow all other reasonable steps, thus increasing computational efficiency. The values $c_W = 0.3$ and $c_2 = 0.5$, which are adopted in our current implementation are marked as dark red vertical lines in Figure 10.

4.2.2 Extrapolation Factor α_{EXT}

The extrapolation parameter α_{ext}, introduced in Section 3.4.4, pushes the line search to try a larger learning rate first, than the one which was accepted in the previous step. Figure 9 is structured like Figure 10, but this time explores the line search sensitivity in the c_2-α_{ext} parameter space (abscissa and rows respectively) while keeping c_W fixed at 0.3. Unless we choose $\alpha_{\text{ext}} = 1.0$ (no step size increase between steps) in combination with a lenient choice of c_2 the line search performs well. For now we adopt $\alpha_{\text{ext}} = 1.3$ as default value which again is shown as dark red vertical line in Figure 9.

The introduction of α_{ext} might seem arbitrary at first, but is a necessity and well-working fix because of a few shortcomings of the current design. First, the curvature condition W-II is the single condition that prevents too small steps and pushes optimization progress. On the other hand both W-I and W-II simultaneously penalize too large steps (see Figure 1 for a sketch). This is not a problem in case of deterministic observation ($\sigma_f, \sigma_{f'} \to 0$), where W-II undoubtedly decides if a gradient is still too negative. Unless W-II is chosen very tightly (small c_2) or c_W unnecessarily large (both choices, as discussed above, are undesirable), in the presence of noise, p^{Wolfe} will thus be more reliable in preventing overshooting than pushing progress. The first row of Figure 9 illustrates this behavior, where the performance drops somewhat if no extrapolation is done ($\alpha_{\text{ext}} = 1.0$) in combination with a looser version of W-II (larger c_2).

Another factor that contributes towards accepting small rather than larger learning rates is a bias introduced in the first observation of the line search at $t = 0$. Observations $y'(t)$ that the GP gets to see are projections of the gradient sample $\nabla\hat{\mathcal{L}}(t)$ onto the search direction $s = -\nabla\hat{\mathcal{L}}(0)$. Since the first observations $y'(0)$ is computed from the same mini-batch as the search direction (not doing this would double the optimizer's computational cost) an

inevitable bias is introduced of approximate size of $\cos^{-1}(\gamma)$ (where γ is the expected angle between gradient evaluations from two independent mini-batches at $t = 0$). Since the scale parameter θ of the Wiener process is implicitly set by $y'(0)$ (§3.4.2), the GP becomes more uncertain at unobserved points than it needs to be; or alternatively expects the 1D-gradient to cross zero at smaller steps, and thus underestimates a potential learning rate. The posterior *at* observed positions is little affected. The over-estimation of θ rather pushes the posterior towards the likelihood (since there is less model to trust) and thus still gives a reliable measure for $f(t)$ and $f'(t)$. The effect on the Wolfe conditions is similar. With $y'(0)$ biased towards larger values, the Wolfe conditions, which measure the drop in projected gradient norm, are thus prone to accept larger gradients combined with smaller function values, which again is met by making small steps. Ultimately though, since candidate points at $t^{\text{cand}} > 0$ that are currently queried for acceptance, are always observed and unbiased, this can be controlled by an appropriate design of the Wolfe factor c_2 (§3.4.1 and §4.2.1) and of course α_{ext}.

4.2.3 Full Hyper-Parameter Search: c_W-c_2-α_{EXT}

An exhaustive performance evaluation on the whole c_W-c_2-α_{ext}-grid is shown in Appendix C in Figures 20-24 and Figures 25-35. As discussed above, it shows the necessity of introducing the extrapolation parameter α_{ext} and shows slightly less efficient performance for obviously undesirable parameter combinations. In a large volume of the parameter space, and most importantly in the vicinity of the chosen design parameters, the line search performance is stable and comparable to carefully hand tuned learning rates.

4.2.4 Safeguarding Mis-scaled GPs: θ_{RESET}

For completeness, we performed an additional experiment on the threshold parameter which is denoted by θ_{reset} in the pseudo-code (Appendix D) and safeguards against GP mis-scaling. The introduction of noisy observations necessitates to model the variability of the 1D-function, which is described by the kernel scale parameter θ. Setting this hyper-parameter is implicitly done by scaling the observation input, assuming a similar scale than in the previous line search (§3.4.2). If, for some reason, the previous line search accepted an unexpectedly large or small step (what this means is encoded in θ_{reset}) the GP scale θ for the next line search is reset to an exponential running average of previous scales (α_{stats} in the pseudo-code). This occurs very rarely (for the default value $\theta_{\text{reset}} = 100$ the reset occurred in 0.02% of all line searches), but is necessary to safeguard against extremely mis-scaled GP's. θ_{reset} therefore is not part of the probabilistic line search model as such, but prevents mis-scaled GPs due to some unlucky observation or sudden extreme change in the learning rate. Figure 8 shows performance of the line search for $\theta_{\text{reset}} = 10, 100, 1000$ and 10 000 showing no significant performance change. We adopted $\theta_{\text{reset}} = 100$ in our implementation since this is the expected and desired multiplicative (inverse) factor to maximally vary the learning rate in one single step.

4.3 Candidate Selection and Learning Rate Traces

In the current implementation of the probabilistic line search, the choice among candidates for evaluation is done by evaluating an acquisition function $u_{\text{EI}}(t_i^{\text{cand}}) \cdot p^{\text{Wolfe}}(t_i^{\text{cand}})$ at every

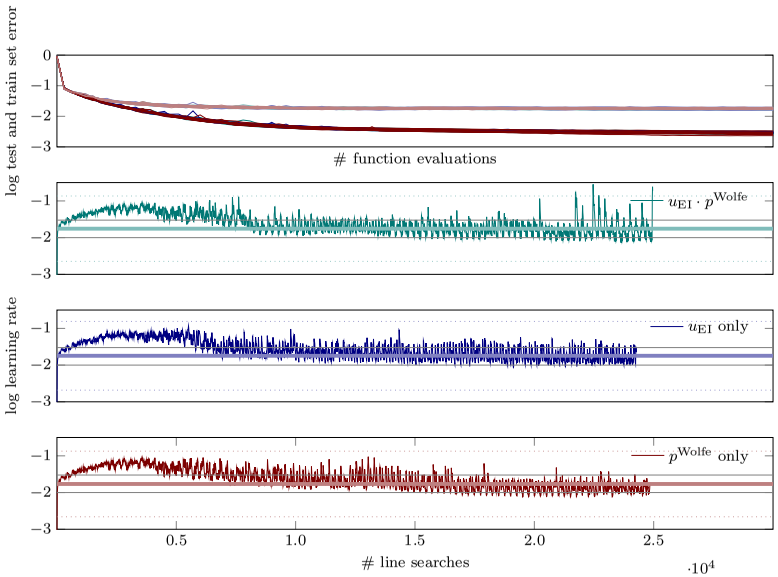

Figure 11: *Different choices of acquisition function.* We compare between using expected improvement u_{EI} (blue), the Wolfe probability p^{Wolfe} (red) and their product $u_{\text{EI}} \cdot p^{\text{Wolfe}}$ (green) which is the default in our code. *Top:* evolution of logarithmic test and train set error. Different lines of the same color correspond to different seeds. *Rows 2-4:* learning rate traces of a single seed (colors same as in top plot). For plotting purposes the curves were smoothed and thinned out. The thick light green, light red and light blue horizontal lines show the mean of the raw (non-smoothed) values of accepted learning rates across the whole optimization process, the dotted lines show ± two standard deviations and the gray solid lines mark a range of well performing constant learning rates.

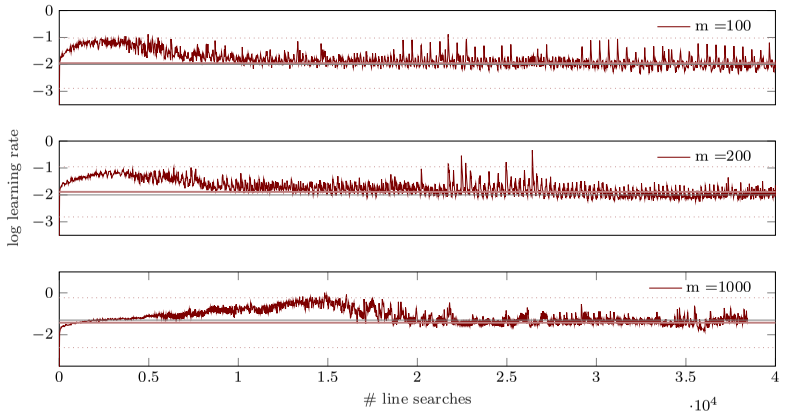

Figure 12: Traces of *accepted logarithmic learning rates*. All runs are performed with default design parameters. Different rows show the same plot for different mini-batch sizes of $m = 100, 200$ and 1000; plots and smoothing as in rows 2-4 of Figure 11 (details in text).

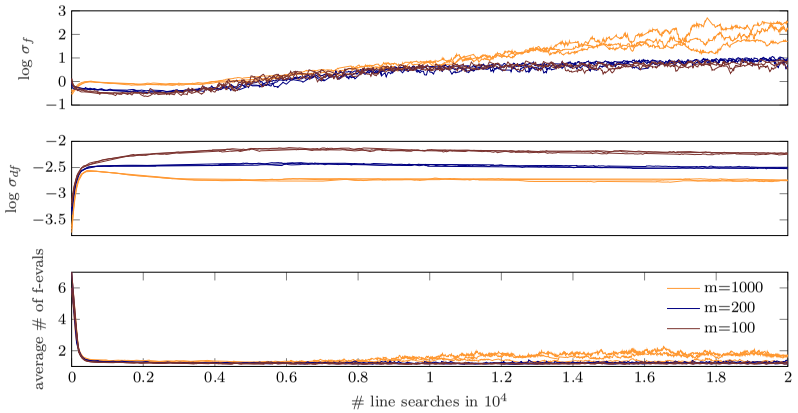

Figure 13: Traces of *logarithmic noise levels* σ_f (top), $\sigma_{f'}$ (middle) and average number of function evaluations per line search (bottom). Setup and smoothing as in Figure 12. Different colors correspond to different mini-batch sizes (see legend). Curves of the same color correspond to different seeds (3 shown).

candidate point t_i^{cand}; then choosing the one with the highest value for evaluation of the objective (§3.2). The Wolfe probability p^{Wolfe} actually encodes precisely what kind of point we want to find and incorporates both (W-I and W-II) conditions about the function value *and* to the gradient (§3.3). However p^{Wolfe} does not have very desirable exploration properties. Since the uncertainty of the GP grows to 'the right' of the last observation, the Wolfe probability quickly drops to a low, approximately constant value there (Figure 4). Also p^{Wolfe} is partially allowing for undesirably short steps (§4.2.2). The expected improvement u_{EI}, on the other hand, is a well studied acquisition function of Bayesian optimization trading off exploration and exploitation. It aims to globally find a point with a function value lower than a current best guess. Though this is a desirable property also for the probabilistic line search, it is lacking the information that we are seeking a point that also fulfills the W-II curvature condition. This is evident in Figure 4 where p^{Wolfe} significantly drops at points where the objective function is already evaluated but u_{EI} does not. In addition, we do not need to explore the positive t space to an extend, the expected improvement suggests, since the aim of a line search is just to find *a* good, acceptable point at positive t and not the globally best one. The product of both acquisition function $u_{\text{EI}} \cdot p^{\text{Wolfe}}$ is thus a trade-off between exploring enough, but still preventing too much exploitation in obviously undesirable regions. In practice, though, we found that all three choices ((i) $u_{\text{EI}} \cdot p^{\text{Wolfe}}$, (ii) u_{EI} only, (iii) p^{Wolfe} only) perform comparable. The following experiments were all performed training N-II on MNIST; only the mini-batch size might vary as indicated.

Figure 11 compares all three choices for mini-batch size $m = 200$ and default design parameters. The top plot shows the evolution of the logarithmic test and train set error (for plot and color description see Figure caption). All test and train set error curves respectively bundle up (only lastly plotted clearly visible). The choice of acquisition function thus does not change the performance here. Rows 2-4 of Figure 11 show learning rate traces of a single seed. All three curves show very similar global behavior. First the learning rate grows, then drops again, and finally settles around the best found constant learning rate. This is intriguing since *on average* a larger learning rate seems to be better at the beginning of the optimization process, then later dropping again to a smaller one. This might also explain why SGD+probLS in the first part of the optimization progress outperforms vanilla SGD (Figure 7). Runs that use just slightly larger constant learning rates than the best performing constant one (above the gray horizontal lines in Figure 11) were failing after a few steps. This shows that there is some non-trivial adaptation going on, not just globally, but locally at every step.

Figure 12 shows traces of accepted learning rates for different mini-batch sizes $m = 100, 200, 1000$. Again the global behavior is qualitatively similar for all three mini-batch sizes on the given architecture. For the largest mini-batch size $m = 1000$ (last row of Figure 12) the probabilistic line search accepts a larger learning rate (on average and in absolute value) than for the smaller mini-batch sizes $m = 100$ and 200, which is in agreement with practical experience and theoretical findings (Hinton (2012, §4 and 7), Goodfellow et al. (2016, §9.1.3), Balles et al. (2016)).

Figure 13 shows traces of the (scaled) noise levels σ_f and $\sigma_{f'}$ and the average number of function evaluations per line search for different noise levels ($m = 100, 200, 1000$; same colors show the same setup but different seeds). The average number of function evaluations rises very slightly to $\approx 1.5 - 2$ for mini-batch size $m = 1000$ towards the end of the optimization

process, in comparison to ≈ 1.5 for $m = 100, 200$. This seems counter intuitive in a way, but since larger mini-batch sizes also observe smaller value and gradients (especially towards the end of the optimization process), the relative noise levels might actually be larger. (Although the curves for varying m are shown versus the same abscissa, the corresponding optimizers might be in different regions of the loss surface, especially $m = 1000$ probably reaches regions of smaller absolute gradients). At the start of the optimization the average number of function evaluations is high, because the initial default learning rate is small (10^{-4}) and the line search extends each step multiple times.

5. Conclusion

The line search paradigm widely accepted in deterministic optimization can be extended to noisy settings. Our design combines existing principles from the noise-free case with ideas from Bayesian optimization, adapted for efficiency. We arrived at a lightweight "black-box" algorithm that exposes no parameters to the user. Empirical evaluations so far show compatibility with the SGD search direction and viability for logistic regression and multi-layer perceptrons. The line search effectively frees users from worries about the choice of a learning rate: Any reasonable initial choice will be quickly adapted and lead to close to optimal performance. Our matlab implementation can be found at `http://tinyurl.com/probLineSearch`.

Appendix A. – Noise Estimation

Section 3.4.3 introduced the statistical variance estimators

$$\begin{aligned}\Sigma'(x) &= (1-m)^{-1}(\hat{\nabla S}(x) - \nabla\hat{\mathcal{L}}(x)^{\odot 2}) \\ \Sigma(x) &= (1-m)^{-1}(\hat{S}(x) - \hat{\mathcal{L}}(x)^2)\end{aligned} \tag{19}$$

of the function and gradient estimate $\hat{\mathcal{L}}(x)$ and $\nabla\hat{\mathcal{L}}(x)$ at position x. The underlying assumption is that $\hat{\mathcal{L}}(x)$ and $\nabla\hat{\mathcal{L}}(x)$ are distributed according to

$$\begin{bmatrix}\hat{\mathcal{L}}(x) \\ \nabla\hat{\mathcal{L}}(x)\end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix}\hat{\mathcal{L}}(x) \\ \nabla\hat{\mathcal{L}}(x)\end{bmatrix}; \begin{bmatrix}\mathcal{L}(x) \\ \nabla\mathcal{L}(x)\end{bmatrix}, \begin{bmatrix}\Sigma(x) & 0_{D\times 1} \\ 0_{1\times D} & \operatorname{diag}\Sigma'(x)\end{bmatrix}\right) \tag{20}$$

which implies Eq 3

$$\begin{bmatrix}\hat{\mathcal{L}}(x) \\ s(x)'\cdot\nabla\hat{\mathcal{L}}(x)\end{bmatrix} = \begin{bmatrix}y(x) \\ y'(x)\end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix}f(x) \\ f'(x)\end{bmatrix}, \begin{bmatrix}\sigma_f(x) & 0 \\ 0 & \sigma_{f'}(x)\end{bmatrix}\right). \tag{21}$$

where $s(x)$ is the possibly new search direction at x. This is an approximation since the true covariance matrix is in general not diagonal. A better estimator for the projected gradient noise would be (dropping x from the notation)

$$\begin{aligned}\eta_{f'} &= s^\intercal\left[\frac{1}{m-1}\frac{1}{m}\sum_{k=1}^{m}(\nabla\ell^k - \nabla\hat{\mathcal{L}})(\nabla\ell^k - \nabla\hat{\mathcal{L}})^\intercal\right]s \\ &= \sum_{i,j=1}^{D} s_i s_j \frac{1}{m-1}\frac{1}{m}\sum_{k=1}^{m}\left(\nabla\ell_i^k - \nabla\hat{\mathcal{L}}_i\right)\left(\nabla\ell_j^k - \nabla\hat{\mathcal{L}}_j\right) \\ &= \frac{1}{m-1}\sum_{i,j=1}^{D} s_i s_j\left(\frac{1}{m}\sum_{k=1}^{m}\nabla\ell_i^k\nabla\ell_j^k - \nabla\hat{\mathcal{L}}_i\nabla\hat{\mathcal{L}}_j - \nabla\hat{\mathcal{L}}_j\nabla\hat{\mathcal{L}}_i + \nabla\hat{\mathcal{L}}_i\nabla\hat{\mathcal{L}}_j\right) \\ &= \frac{1}{m-1}\left(\frac{1}{m}\sum_{k=1}^{m}\sum_{i,j=1}^{D} s_i\nabla\ell_i^k s_j\nabla\ell_j^k - \sum_{i,j=1}^{D} s_j\nabla\hat{\mathcal{L}}_j s_i\nabla\hat{\mathcal{L}}_i\right) \\ &= \frac{1}{m-1}\left(\frac{1}{m}\sum_{k=1}^{m}(s'\cdot\nabla\ell^k)^2 - (s'\cdot\nabla\hat{\mathcal{L}})^2\right).\end{aligned} \tag{22}$$

Comparing to $\sigma_{f'}$ yields

$$\begin{aligned}\eta_{f'} &= \frac{1}{m-1}\sum_{i,j=1}^{D} s_i s_j\left(\frac{1}{m}\sum_{k=1}^{m}\nabla\ell_i^k\nabla\ell_j^k - \nabla\hat{\mathcal{L}}_j\nabla\hat{\mathcal{L}}_i\right) \\ &= \frac{1}{m-1}\sum_{i=1}^{D} s_i^2\left(\frac{1}{m}\sum_{k=1}^{m}(\nabla\ell_i^k)^2 - \nabla\hat{\mathcal{L}}_i^2\right) \\ &\quad + \frac{1}{m-1}\sum_{i\neq j=1}^{D} s_i s_j\left(\frac{1}{m}\sum_{k=1}^{m}\nabla\ell_i^k\nabla\ell_j^k - \nabla\hat{\mathcal{L}}_j\nabla\hat{\mathcal{L}}_i\right) \\ \eta_{f'} &= \sigma_{f'} + \frac{1}{m-1}\sum_{i\neq j=1}^{D} s_i s_j\left(\frac{1}{m}\sum_{k=1}^{m}\nabla\ell_i^k\nabla\ell_j^k - \nabla\hat{\mathcal{L}}_j\nabla\hat{\mathcal{L}}_i\right).\end{aligned} \tag{23}$$

From Eq 22 we see that, in order to effectively compute $\eta_{f'}$, we need an efficient way of computing the inner product $(s'\cdot\nabla\ell^k)$ for all k. In addition, we need to know the search direction $s(x)$ of the potential next step (if x was accepted) at the time of computing $\eta_{f'}$. This is possible e.g. for the SGD search direction where $s(x) = -\frac{1}{m}\sum_{k=1}^{m}\nabla\ell^k(x)$ but potentially not possible or practical for arbitrary search directions. For all experiments in this paper we used the approximate variance estimator $\sigma_{f'}$.

The following paragraph is concerned with the independence assumption of gradient and function value y and y' (in contrast to independence among gradient elements). In general y and y' are not independent since the algorithm draws them from the same mini-batch; the likelihood including the correlation factor ρ reads

$$p(y_t, y_t' \mid f) = \mathcal{N}\left(\begin{bmatrix}y_t \\ y_t'\end{bmatrix}; \begin{bmatrix}f(t) \\ f'(t)\end{bmatrix}, \begin{bmatrix}\sigma_f^2 & \rho \\ \rho & \sigma_{f'}^2\end{bmatrix}\right). \tag{24}$$

The noise covariance matrix enters the GP only in the inverse of the sum with the kernel matrix of the observations. We can compute it analytically for one datapoint at position t, since it is only a 2×2 matrix. For $\rho = 0$, define:

$$\begin{aligned}det_{\rho=0} &:= [k_{tt}+\sigma_f^2][{}^\partial k^\partial{}_{tt} + \sigma_{f'}^2] - k^\partial{}_{tt}{}^\partial k_{tt} \\ G_{\rho=0}^{-1} &:= \begin{bmatrix}k_{tt}+\sigma_f^2 & k^\partial{}_{tt} \\ {}^\partial k_{tt} & {}^\partial k^\partial{}_{tt}+\sigma_{f'}^2\end{bmatrix}^{-1} = \frac{1}{det_{\rho=0}}\begin{bmatrix}{}^\partial k^\partial{}_{tt}+\sigma_{f'}^2 & -k^\partial{}_{tt} \\ -{}^\partial k_{tt} & k_{tt}+\sigma_f^2\end{bmatrix}.\end{aligned} \tag{25}$$

For $\rho \neq 0$ we thus get:

$$\begin{aligned}det_{\rho\neq 0} &:= [k_{tt}+\sigma_f^2][{}^\partial k^\partial{}_{tt}+\sigma_{f'}^2] - [k^\partial{}_{tt}+\rho][{}^\partial k_{tt}+\rho] \\ &= det_{\rho=0} - \rho({}^\partial k_{tt} + k^\partial{}_{tt}) - \rho^2 \\ G_{\rho\neq 0}^{-1} &:= \begin{bmatrix}k_{tt}+\sigma_f^2 & k^\partial{}_{tt}+\rho \\ {}^\partial k_{tt}+\rho & {}^\partial k^\partial{}_{tt}+\sigma_{f'}^2\end{bmatrix}^{-1} = \frac{1}{det_{\rho\neq 0}}\begin{bmatrix}{}^\partial k^\partial{}_{tt}+\sigma_{f'}^2 & -(k^\partial{}_{tt}+\rho) \\ -({}^\partial k_{tt}+\rho) & k_{tt}+\sigma_f^2\end{bmatrix} \\ &= \frac{det_{\rho=0}}{det_{\rho\neq 0}}G_{\rho=0}^{-1} - \frac{\rho}{det_{\rho\neq 0}}\begin{bmatrix}0 & 1 \\ 1 & 0\end{bmatrix}\end{aligned} \tag{26}$$

The fraction ${}^{det_{\rho=0}}/_{det_{\rho\neq 0}}$ in the first term of the last row, is a positive scalar that scales all element of $G_{\rho=0}^{-1}$ equally (since $G_{\rho=0}$ and $G_{\rho\neq 0}$ are positive definite matrices, we know that $det_{\rho=0} > 0$, $det_{\rho\neq 0} > 0$). If $|\rho|$ is small in comparison to the determinant $det_{\rho=0}$, then $det_{\rho\neq 0} \approx det_{\rho=0}$ and the scaling factor is approximately one. The second term corrects off-diagonal elements in $G_{\rho\neq 0}$ and is proportional to ρ; if $|\rho| \ll det_{\rho=0}$ this term is small as well.

In might be possible to estimate ρ as well from the mini-batch in a similar style to the estimation of σ_f and $\sigma_{f'}$; it is not clear, however, if the additional computational cost would justify the improvements in the GP-inference.

Appendix B. – Noise Sensitivity

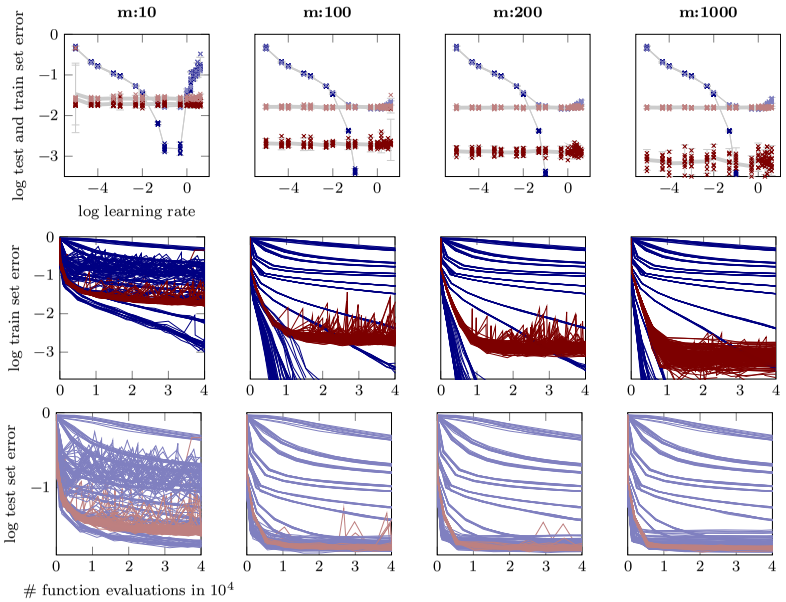

Figure 14: Performance of N-I on MNIST for *varying mini-batch sizes*; plots and colors same as in Figure 7 (middle plots cropped for readability).

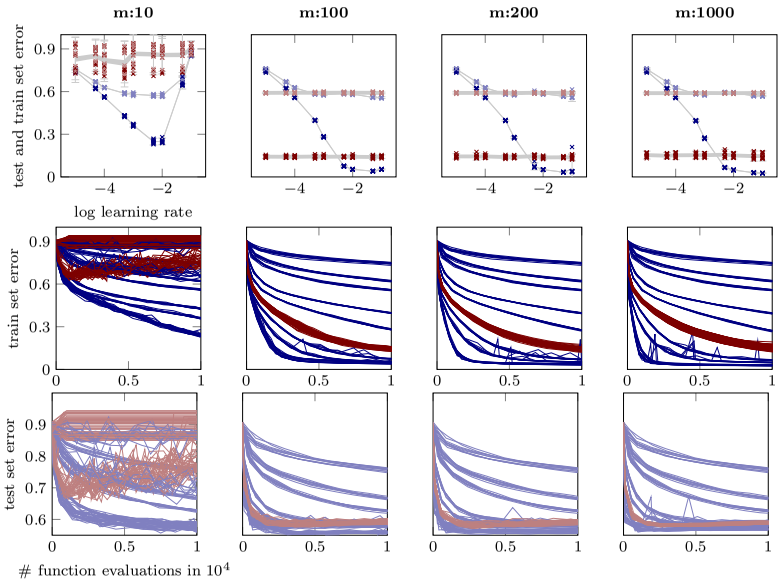

Figure 15: Performance of N-II on CIFAR-10 for *varying mini-batch sizes*; plots and colors same as in Figure 7, except the scaling of the y-axis which is not logarithmic here.

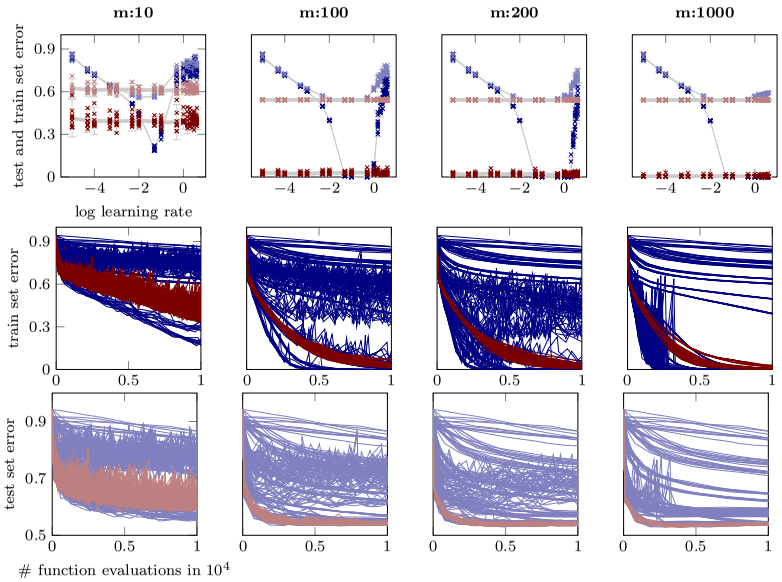

Figure 16: Performance of N-I on CIFAR-10 for *varying mini-batch sizes*; plots and colors same as in Figure 15.

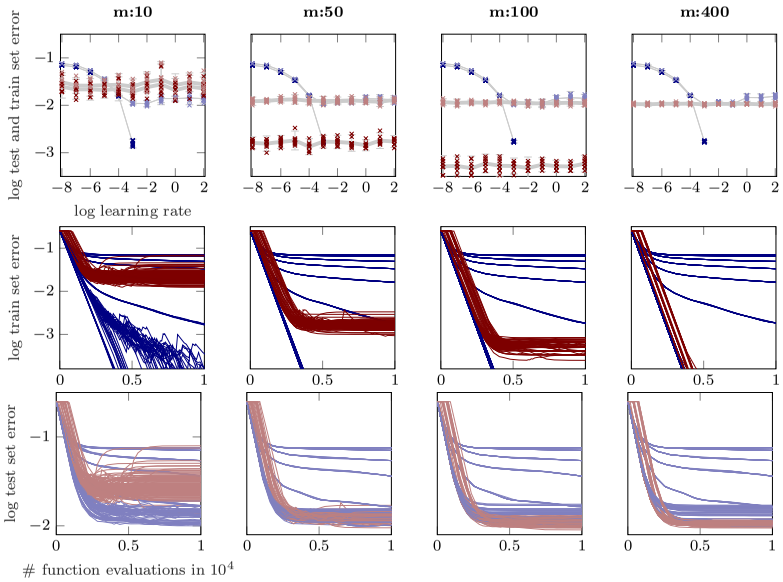

Figure 17: Performance of N-III on GISETTE for *varying mini-batch sizes*; plots and colors same as in Figure 15 (middle plots cropped for readability).

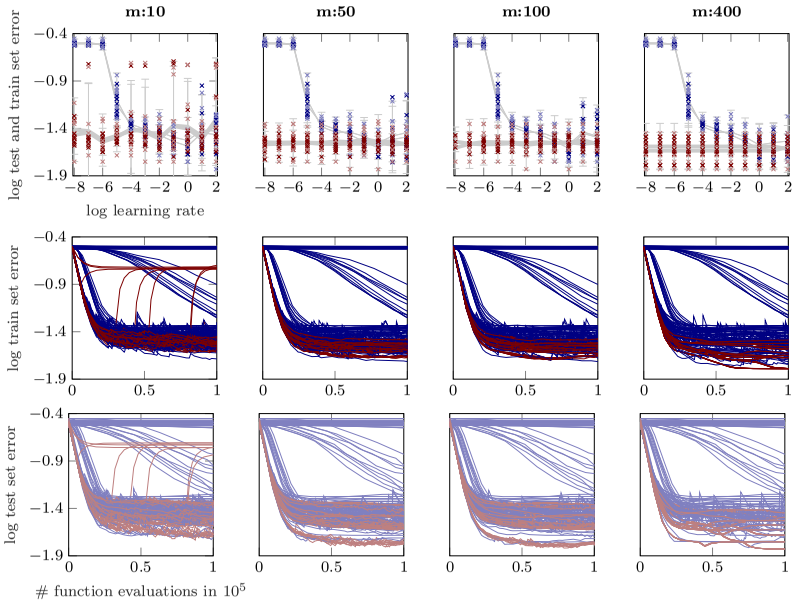

Figure 18: Performance of N-III on WDBC for *varying mini-batch sizes*; plots, colors, and description same as in Figure 17. *Remark:* since the training set is of size 400, the most right column ($m = 400$) in fact runs full-batch gradient descent; this is not a problem, since the probabilistic line search can handle noise free observations as well.

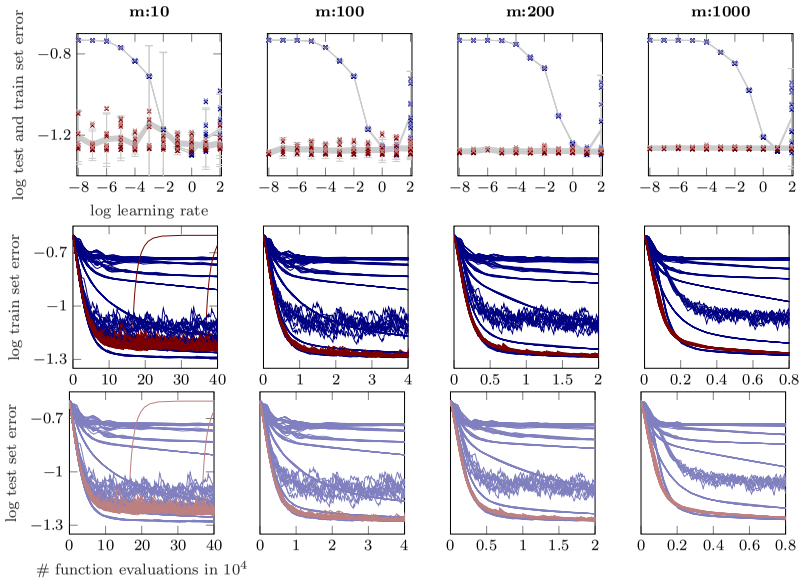

Figure 19: Performance of N-III on EPSILON for *varying mini-batch sizes*; plots, colors, and description same as in Figure 17. EPSILON is the largest dataset that was used in the experiments (400k samples); this did not seem to impair the performance of the line search or variance estimator.

Appendix C. – Parameter Sensitivity

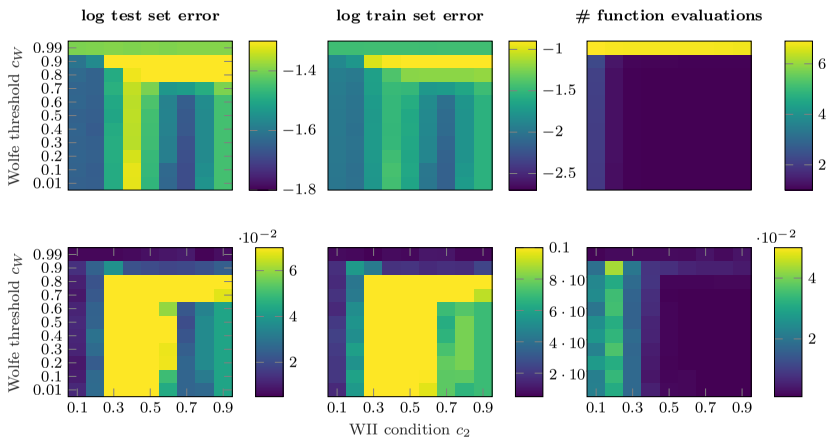

Figure 20: *Sensitivity to varying hyper-parameters* c_2, and c_W and *fixed* $\alpha_{\text{ext}} = 1.0$. Experimental setup as in Figures 9 and 10. *Top row* from left to right: logarithmic test set error, train set error, and average number of function evaluations per line search averaged over 10 different initializations. *Bottom row:* corresponding relative standard deviations. In all plots darker colors are better. For extrapolation parameters $\alpha_{\text{ext}} > 1$ (see Figures 21, 22, 23, and 24) the different parameter combinations all result in similar good performance. Only at extreme choices, for example $\alpha_{\text{ext}} = 1.0$ (this figure), which amounts to no extrapolation at all in between successive line searches, the line search performs poorer. At the extreme value of $c_W = 0.99$, which amounts to imposing nearly absolute certainty about the Wolfe conditions, the line search becomes less efficient. In Figure 23 the default values adopted in the line search implementation ($c_W = 0.3$, $c_2 = 0.5$, and $\alpha_{\text{ext}} = 1.3$) are indicated as red dots.

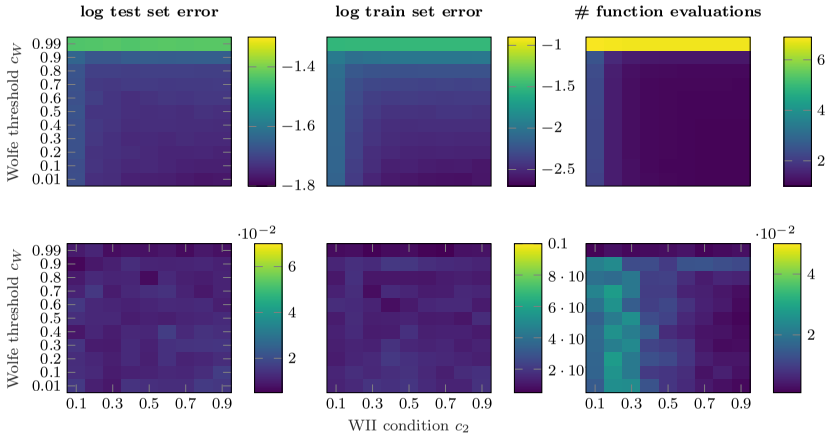

Figure 21: Same as Figure 20 but for *fixed* $\alpha_{\text{ext}} = 1.1$

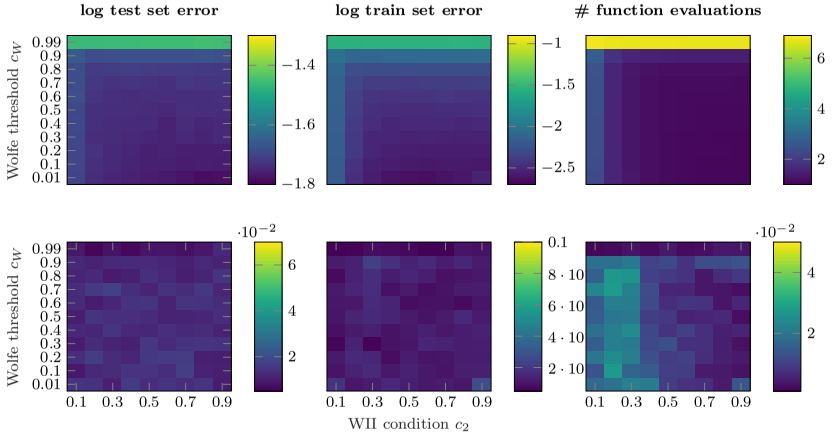

Figure 22: Same as Figure 20 but for *fixed* $\alpha_{\text{ext}} = 1.2$

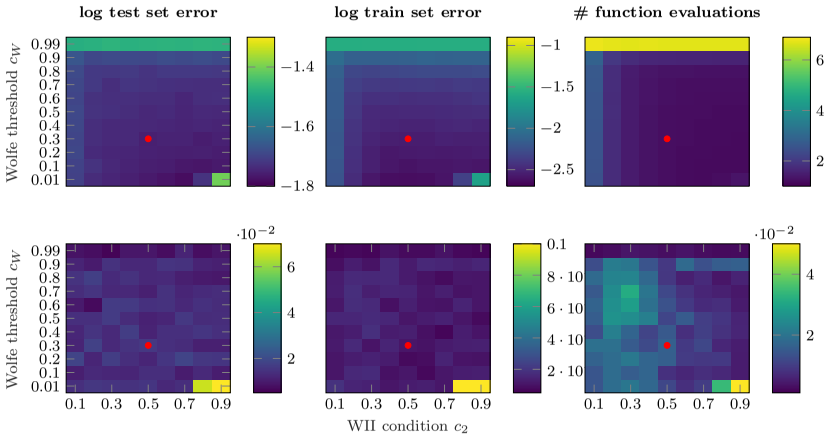

Figure 23: Same as Figure 20 but for *fixed* $\alpha_{\text{ext}} = 1.3$. The default values adopted in the line search implementation ($c_W = 0.3$, $c_2 = 0.5$, and $\alpha_{\text{ext}} = 1.3$) are indicated as red dots.

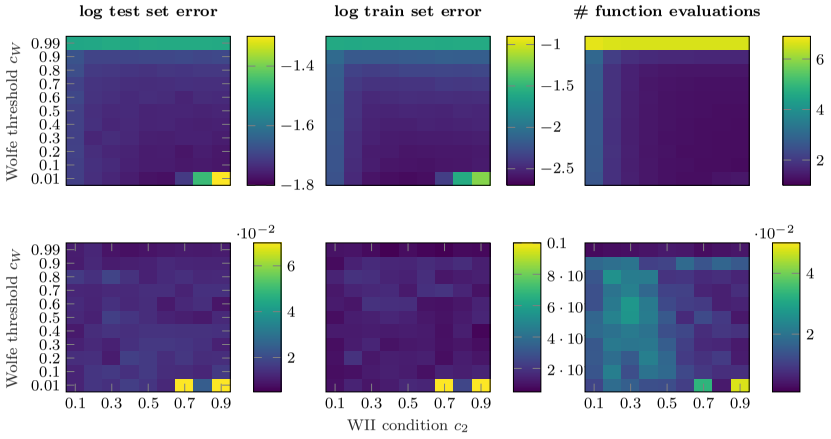

Figure 24: Same as Figure 20 but for *fixed* $\alpha_{\text{ext}} = 1.4$

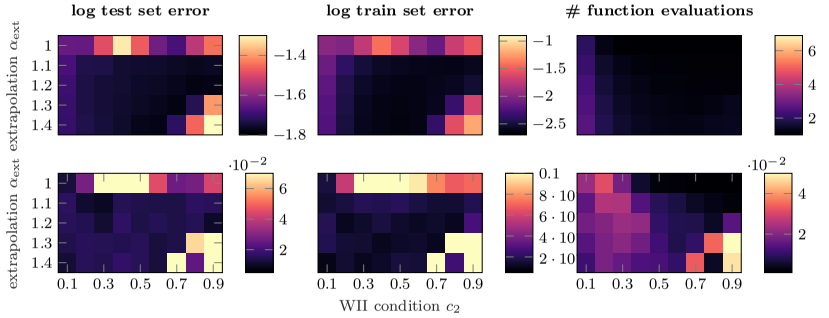

Figure 25: *Sensitivity to varying hyper-parameters* c_2, and α_{ext} and *fixed* $c_W = 0.01$. Experimental setup as in Figures 9 and 10 and plots like in Figure 20. In all plots darker colors are better. All choices of c_W result in good performance though very tight choices of $c_W = 0.99$ (Figure 35), which amounts to imposing nearly absolute certainty about the Wolfe conditions, are less efficient. As described in Figure 20, for a dropped extrapolation factor ($\alpha_{\text{ext}} \to 1$) in combination with a loose curvature condition (large c_2) the line searches performs poorer (top row, right half of columns in Figures 25–34). In Figure 28 the default values adopted in the line search implementation ($c_W = 0.3$, $c_2 = 0.5$, and $\alpha_{\text{ext}} = 1.3$) are indicated as red dots.

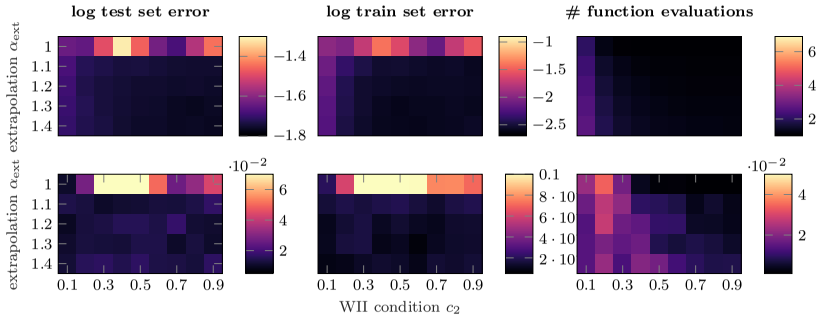

Figure 26: Same as Figure 25 but for *fixed* $c_W = 0.10$.

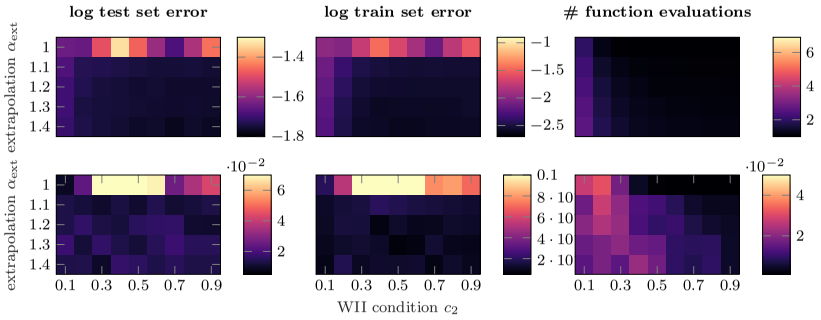

Figure 27: Same as Figure 25 but for *fixed* $c_W = 0.20$.

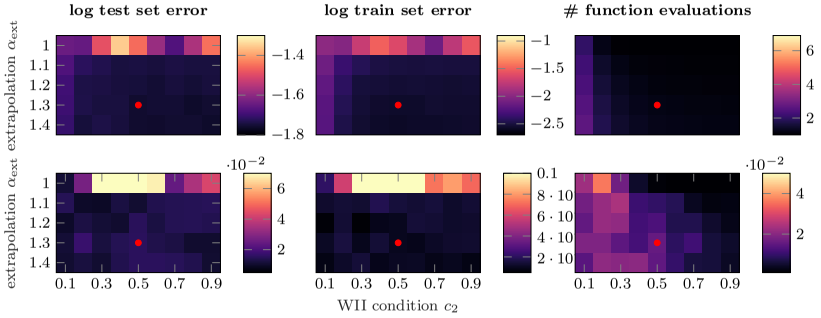

Figure 28: Same as Figure 25 but for *fixed* $c_W = 0.30$. The default values as red dots.

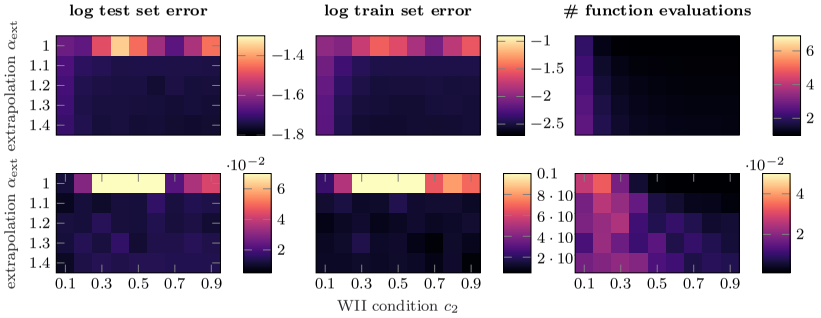

Figure 29: Same as Figure 25 but for *fixed* $c_W = 0.40$.

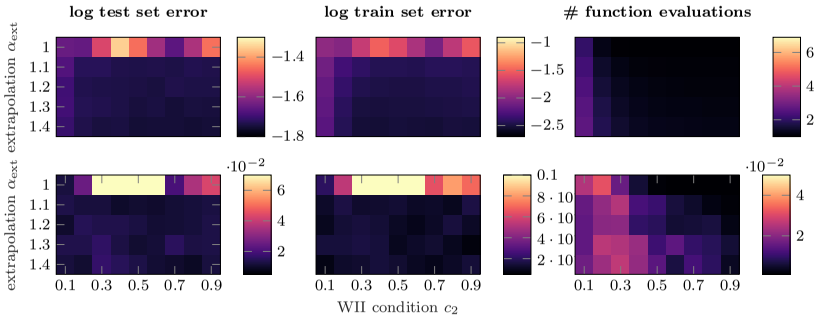

Figure 30: Same as Figure 25 but for *fixed* $c_W = 0.50$.

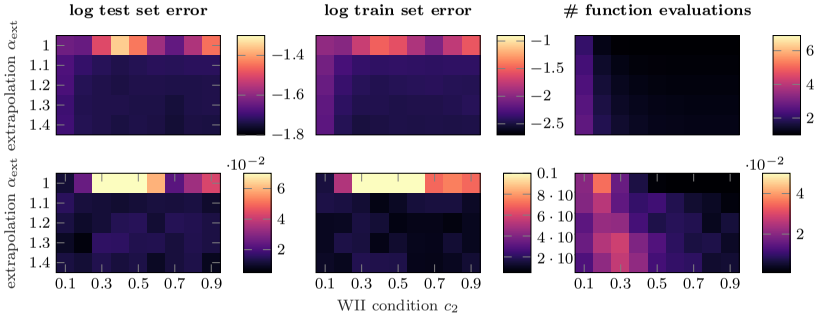

Figure 31: Same as Figure 25 but for *fixed* $c_W = 0.60$.

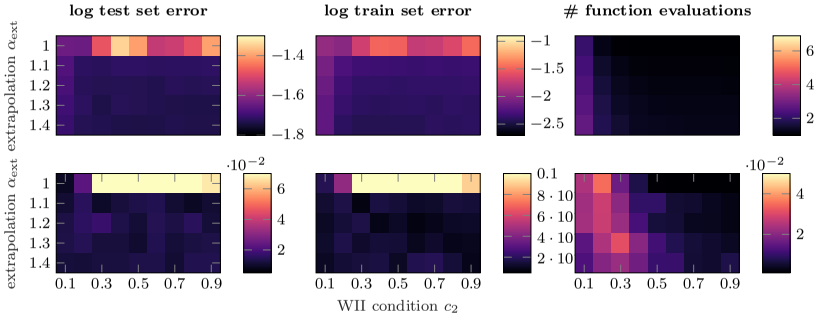

Figure 32: Same as Figure 25 but for *fixed* $c_W = 0.70$.

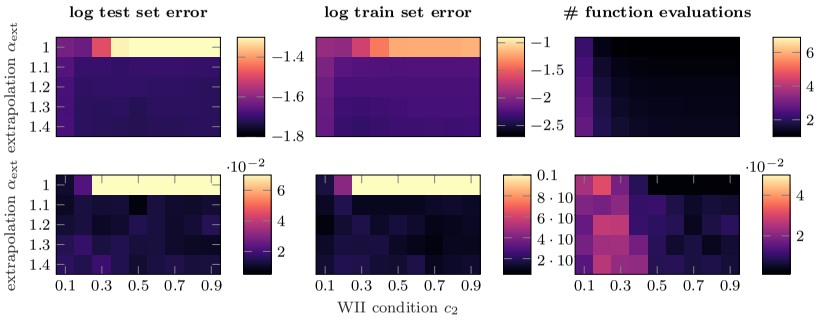

Figure 33: Same as Figure 25 but for *fixed* $c_W = 0.80$.

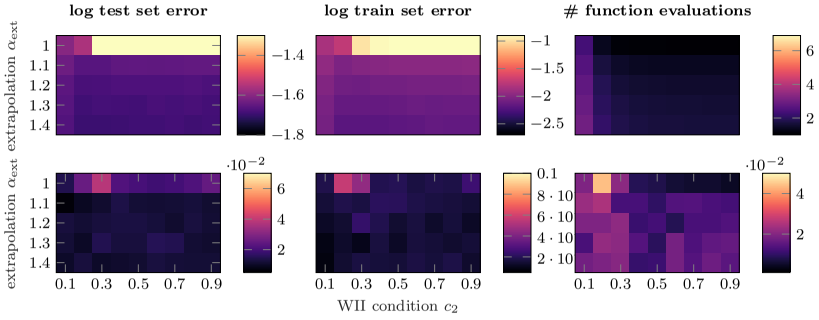

Figure 34: Same as Figure 25 but for *fixed* $c_W = 0.90$.

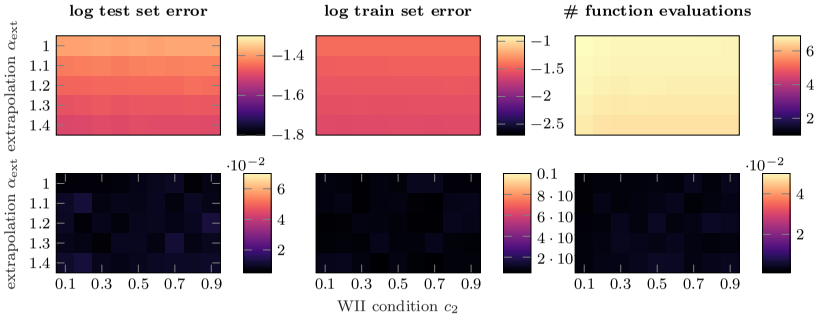

Figure 35: Same as Figure 25 but for *fixed* $c_W = 0.99$.

Appendix D. – Pseudocode

Algorithm 1 of Section 3 roughly sketches the structure of the probabilistic line search and its main ingredients. This section provides a detailed pseudocode which can be used for re-implementation. It is based on the code which was used for the experiments in this paper. A matlab implementation including a minimal example can be found at `http://tinyurl.com/probLineSearch`. The actual line search routine is called probLineSearch below and is quite short. Most of the pseudocode is occupied with comments, helper function that define the kernel of the GP, the GP-update or Gauss cdf and pdf which we printed here for completeness such that a detailed re-implementation is possible. For better readability of the pseudocode we use the following color coding:

- blue: comments
- green: variables of the integrated Wiener process.
- red: most recently evaluated observation (noisy loss and gradient). If the line search terminates, these will be returned as 'accepted'.
- orange: inputs from the main solver procedure and unchanged during each line search.

Notation and operators:

operator or function	definition
$A \odot B$	elementwise multiplication
$A \oslash B$	elementwise division
$A^{\odot b}$	elementwise power of b
A'	transpose of A
$A \cdot B$	scalar-scalar, scalar-matrix or matrix-matrix multiplication
A/B	right matrix division, the same as $A \cdot B^{-1}$
$A\backslash B$	left matrix division, the same as $A^{-1} \cdot B$
$\text{sign}(a)$	sign of scalar a
$\text{erf}(x)$	error function $\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$
$\max(A)$	maximum element in A
$\min(A)$	minimum element in A
$\lvert a \rvert$	absolute value of scalar a
$A < B$	elementwise 'less' comparison
$A \leq B$	elementwise 'less-or-equal' comparison
$A > B$	elementwise 'greater' comparison
$A \geq B$	elementwise 'greater-or-equal' comparison
$[a, b, c] \leftarrow f(x)$	function f called at x returns the values a, b and c

For better readability and to avoid confusion with transposes, we denote derivatives for example as dy and df (instead of y' and f' as in the main text).

function SGDSolver(f)
  ▶ f – function handle to objective. Usage: $[y, dy, \Sigma_f, \Sigma_{df}] \leftarrow f(x)$.

  ▶ initial weights
  $x \leftarrow$initial weights

  ▶ initial step size (rather small to avoid over-shooting in very first step)
  $\alpha \leftarrow e.g. \approx 10^{-4}$
  $\alpha_{\text{stats}} \leftarrow \alpha$

  ▶ initial function evaluation at x
  $[y, dy, \Sigma_f, \Sigma_{df}] \leftarrow f(x)$

  ▶ initial search direction
  $d \leftarrow -dy$

  ▶ loop over line searches
  while budget not used do

    ▶ line search finds step size
    $[\alpha, \alpha_{\text{stats}}, x, y, dy, \Sigma_f, \Sigma_{df}] \leftarrow$probLineSearch$(x, d, y, dy, \Sigma_f, \Sigma_{df}, \alpha, \alpha_{\text{stats}}, f)$

    ▶ set new search direction
    $d \leftarrow -dy$
  end while

  return x
end function

function probLineSearch$(x_0, d, f_0, df_0, \Sigma_{f_0}, \Sigma_{df_0}, \alpha_0, \alpha_{stats}, f)$
  ▶ x_0 – current weights $[D \times 1]$
  ▶ f – function handle to objective.
  ▶
  ▶ d – search direction $[D \times 1]$ (does not need to be normalized)
  ▶ f_0 – function value at start, $f_0 = f(x_0)$
  ▶ df_0 – gradient at start, $df_0 = \nabla f(x_0)$ $[D \times 1]$
  ▶ Σ_{f_0} – sample variance of f_0
  ▶ Σ_{df_0} – sample variances of df_0, $[D \times 1]$
  ▶ α_0 – initial step size

  ▶ set maximum # of f evaluations per line search
  $L \leftarrow 6$

  ▶ scaling and noise level of GP
  $\beta \leftarrow |d' \cdot \Sigma_{df_0}|$ ▷ scale factor
  $\sigma_f \leftarrow \sqrt{\Sigma_{f_0}/(\alpha_0 \cdot \beta)}$ ▷ scaled sample variance of f_0
  $\sigma_{df} \leftarrow \sqrt{((d^{\odot 2})' \cdot \Sigma_{df_0})/\beta}$ ▷ scaled and projected sample variances of df_0

  ▶ initialize counter and non-fixed parameters
  $N \leftarrow 1$ ▷ size of GP$= 2 \cdot N$
  $t_{\text{ext}} \leftarrow 1$ ▷ scaled step size for extrapolation
  $tt \leftarrow 1$ ▷ scaled position of first function evaluation

  ▶ initialize storage for GP. Dynamic arrays of maximum size $[L + 1 \times 1]$
  $T \leftarrow [0]$ ▷ scaled positions along search direction
  $Y \leftarrow [0]$ ▷ scaled function values at T
  $dY \leftarrow [(df_0' \cdot d)/\beta]$ ▷ scaled projected gradients at T

  ▶ initialize GP with observation at start
  $[G, A] \leftarrow$updateGP$(T, Y, dY, N, \sigma_f, \sigma_{df})$

  ▶ loop until budged is used or acceptable point is found
  for N **from** 2 **to** $L + 1$ **do**

    ▶ evaluate objective function at tt.
    $[y, dy, \Sigma_f, \Sigma_{df}, T, Y, dY, N] \leftarrow$evaluateObjective$(tt, x_0, \alpha_0, d, T, Y, dY, N, \beta, f)$

    ▶ update the GP which is now of size $2 \cdot N$.
    $[G, A] \leftarrow$updateGP$(T, Y, dY, N, \sigma_f, \sigma_{df})$

    ▶ initialize storage for candidates. Dynamic arrays of maximum size $[N \times 1]$.
    $T_{\text{cand}} \leftarrow [\,]$ ▷ scaled position of candidates
    $M_{\text{cand}} \leftarrow [\,]$ ▷ GP mean of candidates
    $S_{\text{cand}} \leftarrow [\,]$ ▷ GP standard deviation of candidates

    ▶ current point is above the Wolfe threshold? If yes, accept point and return.
    if probWolfe(tt, T, A, G) **then**
      $output \leftarrow$rescaleOutput$(x_0, f_0, \alpha_0, d, tt, y, dy, \Sigma_f, \Sigma_{df}, \beta)$
      return $output$
    end if

    ▶ Wolfe conditions not satisfied at this point.
    ▶ find suitable candidates for next evaluation.

    ▶ GP mean of function values and corresponding gradients at points in T.
    $M \leftarrow$ map function m$(_, T, A)$ over T
    $dM \leftarrow$ map function d1m$(_, T, A)$ over T

```
    ▶ candidates 1: local minima of GP mean.
    T_sorted ⇐ sort T in ascending order
    T_Wolfes ⇐[ ]                                   ▷ prepare list of acceptable points

    ▶ iterate through all N − 1 cells, compute locations of local minima.
    for n from 1 to N − 1 do
        T_n ⇐ value of T_sorted at n
        T_{n+1} ⇐ value of T_sorted at n + 1

        ▶ add a little offset for numerical stability
        t_rep ⇐ T_n + 10^{−6} · (T_{n+1} − T_n)

        ▶ compute location of cubic minimum in n^th cell
        t_cubMin ⇐cubicMinimum(t_rep, T, A, N)

        ▶ add point to candidate list if minimum lies in between T_n and T_{n+1}
        if t_cubMin > T_n and t_cubMin < T_{n+1} then
            if (not isnanOrIsinf(t_cubMin)) and (t_cubMin > 0) then

    $m_b \leftarrow \mathrm{D1M}(t) - c_2 \cdot dm_0$
    $V_{bb} \leftarrow {c_2}^2 \cdot dVd_0 - 2 \cdot c_2 \cdot \mathrm{VD0DF}(t) + \mathrm{DVD}(t)$

    ▶ covariance between conditions
    $V_{ab} \leftarrow -c_2 \cdot (Vd_0 + c_1 \cdot t \cdot dVd_0) + c_2 \cdot \mathrm{VD0F}(t) + \mathrm{V0DF}(t) + c_1 \cdot t \cdot \mathrm{VD0DF}(t) - \mathrm{VD}(t)$

    ▶ extremely small variances → very certain (deterministic evaluation)
    if $V_{aa} \leq 10^{-9}$ **and** $V_{bb} \leq 10^{-9}$ **then**
        $p_{\text{Wolfe}} \leftarrow (m_a \geq 0) \cdot (m_b \geq 0)$

        ▶ accept?
        $p_{\text{acc}} \leftarrow p_{\text{Wolfe}} > c_W$
        return p_{acc}
    end if

    ▶ zero or negative variances (maybe something went wrong?)
    if $V_{aa} \leq 0$ **or** $V_{bb} \leq 0$ **then**
        return 0
    end if

    ▶ noisy case (everything is alright)
    ▶ correlation
    $\rho \leftarrow V_{ab} / \sqrt{V_{aa} \cdot V_{bb}}$

    ▶ lower and upper integral limits for Armijo condition
    $low_a \leftarrow -m_a / \sqrt{V_{aa}}$
    $up_a \leftarrow +\infty$

    ▶ lower and upper integral limits for curvature condition
    $low_b \leftarrow -m_b / \sqrt{V_{bb}}$
    $up_b \leftarrow \left(2 \cdot c_2 \cdot \left(|dm_0| + 2 \cdot \sqrt{dVd_0}\right) - m_b\right) / \sqrt{V_{bb}}$

    ▶ compute Wolfe probability
    $p_{\text{Wolfe}} \leftarrow \mathrm{BVN}(low_a, up_a, low_b, up_b, \rho)$

    ▶ accept?
    $p_{\text{acc}} \leftarrow p_{\text{Wolfe}} > c_W$
    return p_{acc}

The function $\mathrm{BVN}(low_a, up_a, low_b, up_b, \rho)$ evaluates the 2D-integral

$$\int_{low_a}^{up_a} \int_{low_b}^{up_b} \mathcal{N}\left(\begin{bmatrix} a \\ b \end{bmatrix}; \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}\right) da db.$$

end function

function gaussCDF(z)
    ▶ Gauss cumulative density function
    return $0.5 \odot \left(1 + \mathrm{erf}(z/\sqrt{2})\right)$
end function

Abstract

Learning a causal effect from observational data requires strong assumptions. One possible method is to use instrumental variables, which are typically justified by background knowledge. It is possible, under further assumptions, to discover whether a variable is structurally instrumental to a target causal effect $X \to Y$. However, the few existing approaches are lacking on how general these assumptions can be, and how to express possible equivalence classes of solutions. We present instrumental variable discovery methods that systematically characterize which set of causal effects can and cannot be discovered under local graphical criteria that define instrumental variables, without reconstructing full causal graphs. We also introduce the first methods to exploit non-Gaussianity assumptions, highlighting identifiability problems and solutions. Due to the difficulty of estimating such models from finite data, we investigate how to strengthen assumptions in order to make the statistical problem more manageable.

Keywords: causality, causal discovery, instrumental variables

1. Contribution

Given observational data for a treatment variable X, an outcome Y, and a set of observed covariates $\mathbf{O}$ that precede X an Y causally, we present methods to estimate the causal effect of X on Y when hidden common causes between X and Y cannot be blocked by conditioning on observed variables. The main methodology consists of discovering *instrumental variables* among $\mathbf{O}$, which informally can be described as surrogate experiments on X that do not affect Y directly. This complements approaches where hidden common causes can be blocked. We will assume that the model is linear, although this assumption can be relaxed to some extent, as discussed in the conclusion. Much of the contribution is theoretical, and intended to describe what to the best of our knowledge is the first graphical account of the limits of what can be discovered about instrumental variables from constraints in the observational distribution. We also discuss a pragmatic implementation of such ideas and clarify their practical limitations.

Consider a linear graphical causal model (Spirtes et al., 2000; Pearl, 2000) where, given a directed acyclic graph (DAG) $\mathcal{G}$ with vertex set $\mathbf{V}$, we define a joint distribution in terms of conditional relationships between each variable V_i and its given *parents* in $\mathcal{G}$:

$$V_i = \sum_{V_j \in par_{\mathcal{G}}(i)} \lambda_{ij} V_j + e_i. \quad (1)$$

That is, each random variable V_i corresponds to a vertex in $\mathcal{G}$, where $par_{\mathcal{G}}(i)$ are the parents of V_i in $\mathcal{G}$ and e_i is an independent error term. Equation (1) is called a *structural equation* in the sense that it encodes a relationship that remains stable under a *perfect intervention* on other variables. Following the notation of Pearl (2000), we use the index "$do(V_k = v_k)$" to denote the regime under which variable V_k is fixed to some level v_k by an external agent. If V_k is a parent of V_i, the *(differential) causal effect* of V_k on V_i is defined as:

$$\frac{\partial \mathbb{E}[V_i \mid do(V_k = v_k)]}{\partial v_k} = \lambda_{ik}. \quad (2)$$

Each λ_{ik} will be referred to as a *structural coefficient*. Our goal is to estimate the differential causal effect of some treatment X on some outcome Y from observational data. If the common hidden causes of these two variables can be blocked by other observable variables, a formula such as the back-door adjustment of Pearl (2000) or the Prediction Algorithm of Spirtes et al. (2000) can be used to infer it. In general, unmeasured confounders of X and Y might remain unblocked.

When unmeasured confounding remains, and where it is reasonable to assume the linear structure (1), a possibility is to exploit an *instrumental variable* (or *instrument*, or *IV*; Morgan and Winship, 2015): some observable variable W that is not an effect of either X and Y, it is unconfounded with Y, and has no direct effect on Y.

Figure 1 illustrates one possible DAG containing an instrument. Let σ_{ab} represent the covariance of two variables A and B. The parameterization in (1) implies $\sigma_{wx} = \lambda_{xw}\sigma_{ww}$ and $\sigma_{wy} = \lambda_{yx}\lambda_{xw}\sigma_{ww}$. It follows that $\lambda_{yx} = \sigma_{wy}/\sigma_{wx}$. We can estimate σ_{wy} and σ_{wx} from observations, allowing for a consistent estimate of λ_{yx}. Notice that $\sigma_{wx} \neq 0$ is required. W in this case is called an instrumental variable for the causal relationship $X \to Y$.

It is not possible to test whether some observable variable is an IV from its joint distribution with X and Y alone. IV assumptions can nevertheless be falsified by exploiting constraints in the joint distribution of multiple observable variables (Chu et al., 2001; Brito and Pearl, 2002; Kuroki and Cai, 2005), where such constraints are necessary but not sufficient to identify IVs and the corresponding causal effects. Our contribution are IV discovery algorithms for causal effect estimation. We characterize in which ways such algorithms can find the correct causal effect, and in which sense they will fail. We also introduce variations of the assumptions that are needed for practical reasons, complementing existing methods that rely on other sets of assumptions. Some of the ideas used in our methods are based on principles from causal discovery in linear non-Gaussian models (Shimizu et al., 2006).

The structure of the paper is as follows. In Section 2, we discuss the challenges of inferring causal effects when treatment and outcome are confounded by unobserved variables, and

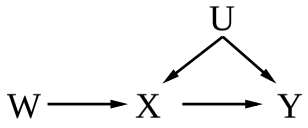

Figure 1: A graph illustrating a possible IV structure. X and Y have an unmeasured confounder U. W is an instrument as it is unconfounded with Y, has no direct effect on it, and causes X. In this paper, variables named "U" will denote hidden variables.

provide an overview of our approach. In Section 3, we discuss the theory behind two classes of testable constraints that can be detected from data. The resulting algorithm has several practical issues, and a more realistic alternative is provided in Section 4, which is then validated experimentally in Section 5. Other related approaches are discussed in Section 6.

2. Outline of Methodology: Learning under Unmeasured Confounding

We assume that the system of interest is a linear causal model which is Markov with respect to an unknown DAG $\mathcal{G}$ with vertices $\mathbf{V} \equiv \mathbf{O} \cup \mathbf{U} \cup \{X, Y\}$. Set $\mathbf{O}$ is the set of observable variables besides *treatment* variable X and *outcome* variable Y. Set $\mathbf{U}$ is the set of unobservable (also called *latent*, or *hidden*) variables. X and Y do not precede any element of $\mathbf{V} \backslash \{X, Y\}$. Y does not precede X. The task is to estimate the differential causal effect of X on Y. Our problems of interest are formulated so that all have a *target causal effect* λ_{yx} corresponding to edge $X \to Y$. To avoid constant repetition, in several results that appear in this paper, we will often refer to vertices and edges of a (possibly unnamed) causal graph $\mathcal{G}$ while implicitly assuming the structural assumptions and notation introduced in this paragraph.

Focusing on a single λ_{yx} is common in applied sciences: in particular, scenarios where we have a target causal effect $X \to Y$ to be estimated, and a set $\mathbf{O}$ of covariates preceding X and Y is available. Morgan and Winship (2015) provide several examples. This is in contrast to the more familiar causal structure discovery tasks in the machine learning literature, where an equivalence class of a whole causal system is learned from data, and where some causal queries may or may not be identifiable (Spirtes et al., 2000). The focus here in on quantifying the strength of a particular causal effect λ_{yx}, as opposed to unveiling the directionalities and connections of a causal graph. This allows more focused algorithms that bypass a full graph estimation. This philosophy was exploited by Entner et al. (2012) in the task of finding possible sets of observable variables that can block the effect of any hidden common cause of X and Y.

However, the approach by Entner et al. will not provide a causal effect estimate if such a set does not exist. For instance, in Figure 1, if U is a latent variable, their algorithm will provide no answer concerning the causal effect of X on Y. *Our goal is to cover this scenario, which complements approaches that require unmeasured confounding to be blocked.* The methodological framework to accomplish this task is by discovering candidate instru-

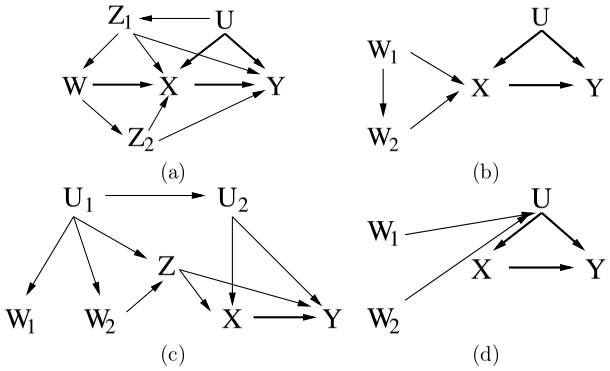

Figure 2: (a) Variable W is an instrument for the relation $X \to Y$ conditioning on $\{Z_1, Z_2\}$. This can be verified by noticing that W is d-separated from Y given $\{Z_1, Z_2\}$ in the graph obtained by removing edge $X \to Y$ from the given figure. (b) Both W_1 and W_2 are instruments conditioning on the empty set $\emptyset$. (c) The typical covariance constraints ("tetrads") that are implied by instrumental variables also happen in the case where no instruments exist, implying that rank constraints in the covariance matrix are not enough information to discover IVs. (d) A case that is difficult even when considering information from non-Gaussian distributions.

mental variables without prior knowledge of the causal structure, besides the stated ordering assumptions about $\{X, Y\}$. The challenge is that we cannot guarantee which candidate instrumental variables are actual instruments without further assumptions.

We will make use of structural characterizations of causality using graphical models (Pearl, 2000; Spirtes et al., 2000). Prior exposure to causal graphical models is assumed, with key definitions summarized in Section 2.1. In Section 2.2, we outline the challenges and explain the general concept of *equivalence class of causal effects*, a concept adapted from the work of Maathuis et al. (2009) to the instrumental variable case. Finally, in Section 2.3 we provide a road map of the steps used in our approach.

2.1 Graphical Terminology

Directed acyclic graphs (DAGs) encode independencies among vertices, which correspond to independencies among random variables. This follows from the usual one-to-one relationship between vertices in a graph and random variables in a distribution. In a DAG, any two vertices $\{V_i, V_j\}$ can be connected by up to one *directed edge*. Given an edge $V_i \to V_j$, we say that V_i is the *tail* and V_j is the *head* of the edge. We also say that V_i and V_j are *endpoints* of edge $V_i \to V_j$ where V_i is a *parent* of V_j and V_j is a *child* or V_i.

A *path* in a graph is a sequence of edges, where any two consecutive edges in the sequence share a common endpoint. Paths are *simple* if no vertex appears twice, and *non-simple*

otherwise. For instance, $W \to X \leftarrow U \to Y$ is a path in Figure 1. An example of a non-simple path is $W \to X \leftarrow U \to X \leftarrow U \to Y$. For most of our presentation, it is sufficient to just assume that the paths referred to are simple unless stated otherwise. A *collider* in a path is a vertex that is common to two consecutive edges such that this vertex is the head of both edges. For instance, X is a collider in the path given in the previous example, while U is not. A vertex V is an *endpoint of a path* P if it is one of the endpoints of the first or last edge E in the path, and V is not shared with the (possible) edge next to E in P. For instance, W and Y are the endpoints of $W \to X \leftarrow U \to Y$.

A path P is *between* vertices V_i and V_j if V_i and V_j are the endpoints of P. A *trek* is a path with no colliders. For instance, $W \to X \leftarrow U \to Y$ is not a trek, but $X \leftarrow U \to Y$ and $W \to X \to Y$ are. A trek P must have an unique *source*, the vertex in P that is not the head of any edge in P. A special case of a trek is a *directed path*, which is a trek where the source is one of the endpoints. For instance, $W \to X \to Y$ is a directed path between W and Y where W is the source. We also say that this path is *from* source (W) *into* the other endpoint (Y). The source V_i in a directed path P is an *ancestor* of all elements V_j in P, while V_j is a *descendant* of V_i. It is possible that $V_i = V_j$, so V_i is an ancestor and descendant of itself. A *non-directed path* is a path that is not directed.

A *back-door (path)* between V_i and V_j is a trek that is into V_i and V_j. For instance, $X \leftarrow U \to Y$ is a back-door between X and Y.

A vertex V is *active on a path* with respect to some vertex set $\mathbf{S}$ if it is either (i) a collider in this path and itself or one of its descendants is in $\mathbf{S}$; or (ii) not a collider and not in $\mathbf{S}$. A path is *active* if all of its vertices are active, *blocked* otherwise. The notion of active and blocked paths will be important in the sequel, as activation has implications on which variables can be considered to be an instrument with respect to which conditioning sets.

These definitions lead to the concept of *d-separation* (Pearl, 2000). A vertex V_i is d-separated from a vertex V_j given a set $\mathbf{S}$ if and only if every path between V_i and V_j is blocked by $\mathbf{S}$. The interpretation of this definition is explained at length in the graphical modeling literature and we will assume familiarity with it. We say a probabilistic model $\mathcal{M}$ is *Markov* with respect to a DAG $\mathcal{G}$ if every d-separation in $\mathcal{G}$ corresponds to a conditional independence constraint in $\mathcal{M}$. A model $\mathcal{M}$ is *faithful* to $\mathcal{G}$ if every d-separation in $\mathcal{G}$ corresponds to a conditional independence constraint in $\mathcal{M}$ and vice-versa. We sometimes use the notation $V_i \perp\!\!\!\perp V_j \mid \mathbf{S}$ (Dawid, 1979) to denote conditional independence of V_i and V_j given $\mathbf{S}$ in a distribution, and also to denote d-separation when applied to vertex sets in a graph.

2.2 Scope and Fundamental Challenges

The identification of structural coefficients from given causal graphs is a classical problem in the structural equation modeling literature (Bollen, 1989). Much progress has been achieved on describing increasingly intricate combinations of structural features that lead to the identification of such coefficients (Brito and Pearl, 2002; Foygel et al., 2011; Chen et al., 2014). As these sophisticated criteria also lead to constraints which are hard to detect from data, we focus instead on the class of structures that corresponds to classical accounts of instrumental variables (Angrist and Pischke, 2009) as described by Brito and Pearl (2002).

Brito and Pearl's criteria are as follows. Given the causal graph $\mathcal{G}$ of a system that includes an edge $X \to Y$, a vertex W is a (conditional) instrument variable for $X \to Y$ given $\mathbf{Z}$ if and only if:

1. $\mathbf{Z}$ does not d-separate W from X in $\mathcal{G}$, and
2. $\mathbf{Z}$ d-separates W from Y in the graph obtained by removing the edge $X \to Y$ from $\mathcal{G}$, and
3. $\mathbf{Z}$ are non-descendants of X and Y in $\mathcal{G}$.

For the rest of the paper, we will call the above conditions the *graphical criteria for instrumental variable validity*, or simply "Graphical Criteria." Notice that the validity of a vertex as an IV is dependent on which set $\mathbf{Z}$ we condition on. That is, if in the corresponding causal graph we find some set $\mathbf{Z}$ that blocks all and only the paths relevant to the Graphical Criteria, then we can identify λ_{yx} as $\sigma_{wy.\mathbf{z}}/\sigma_{wx.\mathbf{z}}$, where $\sigma_{ab.\mathbf{s}}$ represents the partial covariance[1] of two variables A and B given some set $\mathbf{S}$. Figure 2(a) illustrates a case.

Unless strong background knowledge is available, the relevant structure needs to be learned from the data. As an example, consider Figure 1. When U is unobserved and the distribution is faithful to the graph, the absence of the edge $W \to Y$ is not testable (Chu et al., 2001). However, in a situation such as Figure 2(b), the *simultaneous* lack of edges $W_1 \to Y$ and $W_2 \to Y$ has a testable implication, as the absence of each edge implies $\lambda_{yx} = \sigma_{w_1 y}/\sigma_{w_1 x}$ and $\lambda_{yx} = \sigma_{w_2 y}/\sigma_{w_2 x}$, respectively. This leads to a *tetrad constraint*,

$$\sigma_{w_1 y}\sigma_{w_2 x} - \sigma_{w_1 x}\sigma_{w_2 y} = 0, \tag{3}$$

which can be tested using observable data. Unfortunately, the tetrad constraint is necessary, but not sufficient, to establish that both elements in this pair of variables are instrumental. As an example, consider Figure 2(c). It is not hard to show that $\sigma_{w_1 y.z}\sigma_{w_2 x.z} - \sigma_{w_1 x.z}\sigma_{w_2 y.z} = 0$. However, the Graphical Criteria for IVs are not satisfied as W_1 is not d-separated from Y given Z if we remove edge $X \to Y$. This is because path $W_1 \leftarrow U_1 \to U_2 \to Y$ is active. Indeed, in this case λ_{yx} can be much different from $\sigma_{w_1 y.z}/\sigma_{w_1 x.z}$. A major component of our contribution is to characterize graphically in which ways the solution is not unique.

We can summarize the main identification challenge as follows. In the Graphical Criteria, the challenging condition is the second, as the first is easily testable by faithfulness and the third is given by assumption. Another way of phrasing condition 2, with respect to conditioning set $\mathbf{Z}$, is as follows:

2a. there is no active non-directed path between W and Y that does not include X (that is, no active back-door path nor any active path that includes a collider), and

2b. there is no active directed path from W to Y that does not include X.

While we will be able to check 2a, we will not be able to verify 2b, learning to multiple candidate causal effects.

1. Analogous to the (more widely used) notion of partial correlation, we define partial covariance as the covariance between the residuals of the least-squares regression of A and B on $\mathbf{S}$, given by $\sigma_{ab.\mathbf{s}} \equiv \sigma_{ab} - \Sigma_{ab,\mathbf{s}}\Sigma_{\mathbf{ss}}^{-1}\Sigma_{\mathbf{s},ba}$, where Σ is the joint covariance matrix and $\sigma_{ij} \equiv \Sigma_{ij}$ for scalars i, j.

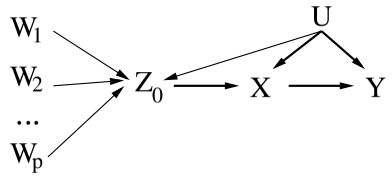

Figure 3: In this model, variables $W_1, \dots W_p$ are instrumental variables conditioning on the empty set. However, conditioning on Z_0 will introduce an active path from each W_i to Y via U, destroying their validity. This is particularly an issue for algorithms such as sisVIVE (Kang et al., 2016) and IV-BY-MAJORITY$_\infty$ (Section 3), where each variable is either deemed an IV or a conditioning variable. An algorithm such as IV-TETRAD$_\infty$ (Section 3) is able to avoid this mistake, although the computational cost can be high.

2.3 Roadmap

In general, the best we can do is to provide a *set* of candidate causal effects, one of which will be correct if at least two instrumental variables (under the same conditioning set) are present in the true graph. In this case, the set can be used, for instance, to provide lower and upper bounds on the causal effect. We will discuss our methods in the context of different assumptions about the existence of instruments, particularly about the *number* of instruments that exist in the true unknown graph.

That is, we propose algorithms that in theory return *equivalence classes of causal effects*. Such a class of algorithms will be sound in this equivalence class sense of returning a set of candidate effects that includes the true effect *if* there are instrumental variables, but will be incorrect otherwise. Following Cooper (1997), Mani et al. (2006) and Entner et al. (2012), we will not need to discover full graphs in order to identify the causal effect, but we will not also find all causal effects that are identifiable from faithfulness assumptions. In particular, we will consider in which sense our algorithms are complete: that is, if there are instrumental variables satisfying the Graphical Criteria, we will characterize under which conditions we will find them. Computational considerations are relevant here.

In the next section, we introduce algorithms that return an equivalence class of causal effects using tetrad constraints, which are complemented by non-Gaussianity assumptions. Motivated by simplicity of presentation, all approaches in Section 3 assume that the distribution of the population is known and that computational resources are unbounded. We do not claim these algorithms are practical —the goal is to use them as a theoretical basis to choose and justify stronger assumptions that achieve practical learning. In Section 4, we discuss practical methods for learning from data and the computational and identification compromises we adopt.

A roadmap for all algorithms introduced in this paper is shown in Table 1. In the table, we provide the main assumptions used by each method and whether or not the algorithm

Algorithm	Main Assumptions	Tractable
1: IV-BY-MAJORITY$_\infty$	there exists a set $\mathbf{W} \subseteq \mathbf{O}$, of size larger than $\lvert\mathbf{O}\rvert/2$, such that each $W \in \mathbf{W}$ is a valid IV given $\mathbf{O}\backslash\{W\}$.	Yes
2: IV-TETRAD$_\infty$	there exists a set $\mathbf{W} \subseteq \mathbf{O}$, of size at least 2, and a set $\mathbf{Z} \subseteq \mathbf{O}\backslash\mathbf{W}$, such that each $W \in \mathbf{W}$ is a valid IV given $\mathbf{Z}$.	No
3: IV-TETRAD$^+_\infty$	the assumptions of IV-TETRAD$_\infty$, plus the assumption that no non-directed paths between each W and Y are active given $\mathbf{Z} \cup \mathbf{W}\backslash\{W\}$, and that the distribution is non-Gaussian.	No
4: IV-TETRAD$^+$	the assumptions of IV-TETRAD$^+_\infty$, plus the assumptions that $\mathbf{Z} = \mathbf{O}\backslash\mathbf{W}$ and $\lvert\mathbf{W}\rvert \geq K$ for some given $K \geq 2$.	Yes
5: IV-TETRAD^{++}	the assumptions of IV-TETRAD$^+$.	Yes (by MCMC)

Table 1: All algorithms introduced in this paper, along with their main assumptions and whether they are computationally tractable. Algorithms 2-5 assume also a form of faithfulness discussed in Section 3. Further assumptions can be added on top of the assumptions listed below in order to reduce the size of the equivalence class returned, as discussed in Sections 3 and 4.

is tractable as a function of $|\mathbf{O}|$, the number of observed variables other than treatment X and outcome Y. The relationship among these algorithms is a follows.

Algorithm 1, introduced at the beginning of Section 3, is inspired by current approaches for learning instrumental variables. One of its main requirements is the existence of a large number of valid instruments, which grows with $|\mathbf{O}|$. It does not, however, require faithfulness.

Algorithms 2 and 3, introduced in Sections 3.1 and 3.3 respectively, are motivated by the requirement of only two valid instruments. Also, there is no requirement concerning a special choice for the respective conditioning set: it can be a strict subset of the remaining variables. The two algorithms, however, assume a variant of faithfulness explained in the next section. Algorithm 3 requires stronger assumptions than Algorithm 2, but as it will be shown, it will return an equivalence class no larger than Algorithm 2 while sometimes guaranteeing a strictly smaller equivalence class.

Unlike the previous algorithms, Algorithm 4, introduced in Section 4, is aimed at practical learning with finite sample sizes and limited computational resources. That is, here computational tractability and the handling of statistical variability are important issues to be considered. We achieve a reduction on statistical variability by enforcing a stronger constraint: the unknown true model must contain a set of valid IVs no smaller than K,

Algorithm 1 IV-BY-MAJORITY$_\infty$

1: **Input:** set of random variables $\mathbf{O} \cup \{X, Y\}$ with known joint distribution
2: **Output:** the causal effect of X on Y, or a value (NA) indicating lack of knowledge
3: **for** each $W_i \in \mathbf{O}$ **do**
4: $\quad \mathbf{Z}_i \leftarrow \mathbf{O} \backslash \{W_i\}$
5: $\quad \beta_i \leftarrow \sigma_{w_i y.\mathbf{z}_i} / \sigma_{w_i x.\mathbf{z}_i}$
6: **end for**
7: **if** more than half of set $\{\beta_i\}$ is equal to the same finite value β **then**
8: $\quad$ **return** β
9: **end if**
10: **return** NA

a user-defined parameter. We achieve tractability, and also a further reduction on statistical variability, by requiring the conditioning set to be automatically determined given a candidate choice of IVs, as in Algorithm 1.

Finally, Algorithm 5 is introduced late in Section 5.3.2 as an example of a Bayesian variation of Algorithm 4. The goal is to illustrate how variations of Algorithm 4 can be created to respond to particular needs of an individual application, such as the provision of Bayesian measures of uncertainty of our estimates. The algorithm is still tractable assuming Markov chain Monte Carlo (MCMC) can be reliably run on an acceptable amount of time.

Although it seems that we take a step backwards in Algorithm 4, by enforcing back assumptions about $\mathbf{Z}$ that are similar to Algorithm 1, we will explain in Section 4 that these are not fundamental. However, practical learning with finite sample sizes is hard to achieve otherwise.

3. From Structural Constraints to Instruments and Causal Effects

Consider Algorithm 1 as a method for learning causal effects given the distribution of the population (hence, the "∞" symbol in the name of the algorithm, indicating that this is equivalent to having infinite sample sizes). If W_i is an IV conditioned on $\mathbf{Z}_i \equiv \mathbf{O} \backslash W_i$, then $\beta_i \equiv \sigma_{w_i y.\mathbf{z}_i} / \sigma_{w_i x.\mathbf{z}_i} = \lambda_{yx}$, the true causal effect. Without knowing whether W_i is a conditional IV with respect to $\mathbf{Z}_i$, we cannot make claims about the causal effect.

However, if more than half of the elements $W_i \in \mathbf{O}$ are conditional IVs given the respective $\mathbf{Z}_i$, then it follows that more than half of the elements in set $\{\beta_i\}$ will be equal, and equal to λ_{yx}. This is the same core assumption introduced by Kang et al. (2016). It sidesteps the problems introduced by models such as the one in Figure 2(c) by assuming that more than half of $\mathbf{O}$ are "valid" IVs. That is, we can partition $\mathbf{O}$ into two sets, $\mathbf{O} = \mathbf{W} \cup \mathbf{Z}$, such that each $W \in \mathbf{W}$ is a conditional IV given $\mathbf{Z} \cup \mathbf{W} \backslash \{W\}$. This is done without knowledge of which variables are valid and which are not. As discussed by Kang et al. (2016), there are situations where this assumption is plausible, or at least weaker than in standard approaches, as in some genetic studies where $\mathbf{O}$ are genetic features of a cell and X, Y are phenotypes. Kang et al. (2016) introduced the sisVIVE algorithm ("some invalid, some

Algorithm 2 IV-TETRAD$_\infty$

1: **Input:** set of random variables $\mathbf{O} \cup \{X, Y\}$ with known joint distribution
2: **Output:** $\mathcal{C}$, a set of candidate differential causal effects of X on Y
3: Initialize $\mathcal{C} \leftarrow \emptyset$
4: **for** each pair $\{W_i, W_j\} \subseteq \mathbf{O}$ **do**
5: $\quad$ **for** every set $\mathbf{Z} \subseteq \mathbf{O} \backslash \{W_i, W_j\}$ **do**
6: $\quad\quad$ **if** $\sigma_{w_i x.\mathbf{z}} = 0$ **or** $\sigma_{w_j x.\mathbf{z}} = 0$ **then**
7: $\quad\quad\quad$ **next**
8: $\quad\quad$ **end if**
9: $\quad\quad$ **if** $\sigma_{w_i x.\mathbf{z}} \sigma_{w_j y.\mathbf{z}} \neq \sigma_{w_i y.\mathbf{z}} \sigma_{w_j x.\mathbf{z}}$ **then**
10: $\quad\quad\quad$ **next**
11: $\quad\quad$ **end if**
12: $\quad\quad$ $\mathcal{C} \leftarrow \mathcal{C} \cup \{\sigma_{w_i y.\mathbf{z}} / \sigma_{w_i x.\mathbf{z}}\}$
13: $\quad$ **end for**
14: **end for**
15: **return** $\mathcal{C}$

valid IV estimator") which, although very different[2] from Algorithm 1, relies on the same fundamental assumptions and as such will be used in our benchmark methods in Section 5.

However, this assumption can be false even when nearly all of $\mathbf{O}$ are possibly valid instruments. Consider Figure 3 where we have an arbitrary number of IVs $W_1, \ldots, W_p$ that are valid by conditioning on the empty set. *None* of them are valid by conditioning on Z_0. In this situation, IV-BY-MAJORITY$_\infty$ will return NA and sisVIVE loses its guarantees, potentially performing badly. We will characterize how this happens by using faithfulness.

3.1 Structural Signatures of Tetrad Constraints and the Graphical Criteria

Consider Algorithm 2 as a method for learning causal effects, disregarding for now its computational complexity. The idea is to find triplets $(W_i, W_j, \mathbf{Z})$ such that $(W_i, \mathbf{Z})$ and $(W_j, \mathbf{Z})$ both satisfy the Graphical Criteria. Under the assumption of *linear faithfulness* (Spirtes et al., 2000), Line 6 of the algorithm is equivalent to item 1 of the Graphical Criteria. To characterize what Algorithm 2 can say about item 2 of the Graphical Criteria, we will need other, less usual, graphical definitions introduced in the next section.

Algorithm 2 is simple, but to the best of our knowledge is has not been described in the literature. A possible reason for the absence of this algorithm in the literature is that characterizing its limitations is not straightforward. One of the main contributions of this paper is the analysis of IV-TETRAD$_\infty$ in Section 3.2, for which we will first need the following theory.

2. sisVIVE uses a modified sparse regression method that is arguably more statistically elegant than using, for instance, hypothesis testing to decide which estimated λ_i are statistically the same. The method remains computationally efficient. We introduced Algorithm 1 because it is closely related to the other algorithms discussed in this paper and hence provides more direct insights on the interplay between different assumptions and identification issues. Notice, however, that sisVIVE never returns NA as it assumes there is always a majority.

3.1.1 t-Separation and Rank Constraints

In this section, we describe the notion of *t-separation* (Sullivant et al., 2010), the most important graphical concept in our approach. Readers familiar with this concept can skip this section.

Recall the basic definition of a trek from Section 2.1. Another way of describing a trek T is by ordering its endpoints (such that a trek is "from" V_i "to" V_j), implying an ordered pair of (possibly empty) directed paths $(P_1; P_2)$ where: P_1 has *sink* (vertex without children in T) V_i; P_2 has sink V_j; and P_1, P_2 have the same *source* (vertex in T without parents in T).

Definition 1 (t-separation) *The ordered pair of vertex sets* $(\mathbf{C_A}; \mathbf{C_B})$ t-separates *vertex set* $\mathbf{A}$ *from vertex set* $\mathbf{B}$ *if, for every trek* $(P_1; P_2)$ *from a vertex in* $\mathbf{A}$ *to a vertex in* $\mathbf{B}$*, either* P_1 *contains a vertex in* $\mathbf{C_A}$ *or* P_2 *contains a vertex in* $\mathbf{C_B}$*.*

Spirtes (2013) and Sullivant et al. (2010) discuss a generalization of this notion and further examples. As the definition is somewhat complex, later in this section we provide some basic examples of this concept in the context of instrumental variables.

Like d-separation, t-separation is relevant if it implies testable implications that decrease the set of graphical structures compatible with the data (Spirtes et al., 2000). While we will see that t-separation can also imply independence constraints among observable variables, this would be of limited interest as d-separation can also imply such constraints. The importance of t-separation is the possibility of implying testable consequence of d-separations *given unobserved variables*. This is done under the assumption of linearity, which will lead to rank constraints (Spirtes, 2013).

Definition 2 (rank constraint) *A* rank constraint *in a matrix* M *is any constraint of the type* $rank(M) \leq r$*, where* r *is some constant and* $rank(M)$ *is the rank of matrix* M*.*

If M is the cross-covariance submatrix given by variables $\{V_i, V_j\}$ indexing the rows, and by $\{V_k, V_l\}$ indexing the columns, then the rank constraint $rank(M) \leq 1$ implies $\sigma_{ik}\sigma_{jl} - \sigma_{il}\sigma_{jk} = 0$. That is, the determinant of M is zero, and a corresponding tetrad constraint holds.

Let $\Sigma_{\mathbf{AB}}$ be the cross-covariance matrix of set $\mathbf{A}$ (rows) and set $\mathbf{B}$ (columns). The DAG Trek Separation Theorem of Sullivant et al. (2010) says:

Theorem 3 (Trek Separation for DAGs) *Let* $\mathcal{G}$ *be a DAG with vertex set* $\mathbf{V}$*. Let* $\mathbf{A}$ *and* $\mathbf{B}$ *be subsets of* $\mathbf{V}$*. We have* $rank(\Sigma_{\mathbf{AB}}) \leq r$ *in all linear structural equation models with graph* $\mathcal{G}$ *if and only if there exist subsets* $\mathbf{C_A}$ *and* $\mathbf{C_B}$ *of* $\mathbf{V}$ *with* $|\mathbf{C_A}| + |\mathbf{C_B}| \leq r$ *such that* $(\mathbf{C_A}; \mathbf{C_B})$ *t-separates* $\mathbf{A}$ *from* $\mathbf{B}$*.*

To jump from (testable) rank constraints to (unobservable) structural constraints in $\mathcal{G}$, we assume our model distribution $\mathcal{P}$ is *rank-faithful* to a DAG $\mathcal{G}$ (Spirtes, 2013):

Definition 4 ((linear) rank-faithfulness) *Distribution* $\mathcal{P}$ *is* rank-faithful *to a DAG* $\mathcal{G}$ *if every rank constraint holding on a covariance (sub)matrix derived from* $\mathcal{P}$ *is entailed by every linear structural equation model Markov with respect to* $\mathcal{G}$*.*

One implication of rank-faithfulness is that $|\Sigma_{\mathbf{ZZ}}| > 0$ for any set $\mathbf{Z}$ of vertices in $\mathcal{G}$, a fact which we will make use of in some proofs.

Unlike d-separation, t-separation is defined by a pair of conditioning sets. Moreover, when we say that V_i is t-separated from V_j given some ordered pair $(\mathbf{C}_I; \mathbf{C}_J)$, the order of the sets in the conditioning pair matters. These two sets do not need to be disjoint and can also contain V_i and V_j.

Example 1 *Consider Figure 1 again. In this example,* X *alone cannot d-separate* W *from* Y*, due to the active path* $W \to X \leftarrow U \to Y$*. We need also to condition on* U*, but we cannot directly test the respective conditional independence if* U *is a latent variable. It is however the case that if* $\mathbf{A} \equiv \{W\}$ *and* $\mathbf{B} \equiv \{Y\}$*, then* $(\emptyset; \{X\})$ *t-separates* $\mathbf{A}$ *from* $\mathbf{B}$*: using the notation of Definition 1, the only trek between* W *and* Y *is* $(\emptyset; W \to X \to Y)$*.* $\mathbf{C_A} = \emptyset$ *and* $\mathbf{C_B} = \{X\}$ *will suffice to imply the t-separation.*

Moreover, by Theorem 3, cross-covariance matrix $\Sigma_{\mathbf{AB}}$ has rank at most $|\emptyset| + |\{X\}| = 1$. Notice, however, that this is true regardless or not this t-separation holds. Therefore, without knowing the graph, we still cannot exclude edge $W \to Y$.

If we try to redefine the problem such that $\mathbf{A} \equiv \{W, X\}$ and $\mathbf{B} \equiv \{X, Y\}$, hoping to show that $\Sigma_{\mathbf{AB}}$ will not be full rank, then this will not work either. This is because $(\emptyset, X)$ does not imply the t-separation anymore, as there is now the trek $(X \leftarrow U; U \to Y)$ between $\mathbf{A}$ and $\mathbf{B}$. Pair $(\emptyset; \{X\})$ does not block this trek. We need the conditioning set pair to be $(\{X\}, \{X\})$. By the notation of Theorem 3, this means $\mathbf{C_A} = \mathbf{C_B} = \{X\}$ and all the theorem implies is that $\Sigma_{\mathbf{AB}}$ has rank at most $|\{X\}| + |\{X\}| = 2$. Once again, this is true regardless of the absence of the edge $W \to Y$. □

Example 2 *Consider Figure 2(b) again. Pair* $\mathbf{A} \equiv \{W_1, W_2\}$ *is t-separated from* $\mathbf{B} \equiv \{X, Y\}$ *by* $(\emptyset, \{X\})$*.*

To check this, enumerate all simple treks $(P_1; P_2)$ such that path P_1 has its sink in $\{W_1, W_2\}$ and path P_2 has its sink in $\{X, Y\}$. We obtain:

- $(P_1^{[1]}; P_2^{[1]}) \equiv (\emptyset; W_1 \to X)$,
- $(P_1^{[2]}; P_2^{[2]}) \equiv (\emptyset; W_1 \to X \to Y)$,
- $(P_1^{[3]}; P_2^{[3]}) \equiv (\emptyset; W_1 \to W_2 \to X)$,
- $(P_1^{[4]}; P_2^{[4]}) \equiv (\emptyset; W_1 \to W_2 \to X \to Y)$,
- $(P_1^{[5]}; P_2^{[5]}) \equiv (\emptyset; W_2 \to X)$,
- $(P_1^{[6]}; P_2^{[6]}) \equiv (\emptyset; W_2 \to X \to Y)$,
- $(P_1^{[7]}; P_2^{[7]}) \equiv (W_2 \leftarrow W_1; W_1 \to X)$,
- $(P_1^{[8]}; P_2^{[8]}) \equiv (W_2 \leftarrow W_1; W_1 \to X \to Y)$.

We can then verify that, for each case, it is indeed true that $\{X\}$ blocks all paths $P_2^{[1]}, \ldots, P_2^{[8]}$,. Since $|\emptyset| + |\{X\}| = 1$, then $|\Sigma_{\mathbf{AB}}|$ has rank at most 1. This constraint is *not* satisfied under rank-faithfulness if, for instance, edge $W_1 \to Y$ were to be present. That is, even though X does not d-separate $\{W_1, W_2\}$ from Y, it alone is responsible for a t-separation and no hidden variable is evoked in its testable claim of $rank(\Sigma_{\mathbf{AB}}) \leq 1$. □

Example 3 *Consider Figure 2(c) again. Using standard d-separation, we can verify that Z alone does not d-separate $\{W_1, W_2\}$ from $\{X, Y\}$. Instead, $\{U_1, Z\}$, or $\{U_2, Z\}$, should be used instead. In the absence of the causal graph, we cannot discover this d-separation by directly testing the corresponding conditional independence given a latent variable. We need indirect evidence for this d-separation that uses observable variables only.*

That is where *conditional* tetrad constraints play a role. Assuming Z is observable, we could de-activate all directed paths from $\{W_1, W_2\}$ to $\{X, Y\}$ that go through Z and consider the *partial* cross-covariance matrix of $\{W_1, W_2\}$ against $\{X, Y\}$ given Z. The Trek Separation Theorem for DAGs, however, says nothing explicit about conditional cross-covariances. The independence model given by conditioning on a variable is sometimes a DAG itself, but this is not true in general (Richardson and Spirtes, 2002). Sullivant et al. (2010) present versions of the theorem for some classes of DAGs under conditioning, but not in a completely general way, as further explained in Appendix A.

Fortunately, for our purposes, conditioning can be easily dealt with: let us simply introduce the conditioning variables in both sets $\mathbf{A}$ and $\mathbf{B}$. In this example, define $\mathbf{A} \equiv \{W_1, W_2, Z\}$ and $\mathbf{B} \equiv \{X, Y, Z\}$. Then it is not hard to verify that $(\emptyset; \{U_1, Z\})$ t-separates $\mathbf{A}$ from $\mathbf{B}$: this follows by first verifying that all treks between $\{W_1, W_2, Z\}$ and $\{X, Y, Z\}$ include U_1 or Z.[3] Cross-covariance $\Sigma_{\mathbf{AB}}$ is now rank-deficient since $|\emptyset| + |\{U_1, Z\}| = 2 < 3$, which means its determinant is zero. Because its determinant can be written as $\sigma_{zz}(\sigma_{w_1x.z}\sigma_{w_2y.z} - \sigma_{w_1y.z}\sigma_{w_2x.z})$ and we assume $\sigma_{zz} \neq 0$, the (conditional) tetrad constraint will hold. This means that without observing U_1 we can make claims about the conditional structure between $\{W_1, W_2\}$ and $\{X, Y\}$. □

Like d-separation, it is possible that more than one conditioning set pair implies t-separation between two sets $\mathbf{A}$ and $\mathbf{B}$. In the last example, it is also the case that $(\emptyset; \{U_2, Z\})$ implies t-separation.

In Appendix A, we provide further examples of t-separation. *Linear faithfulness*, the assumption that vanishing partial correlations hold in the distribution if and only if a corresponding d-separation also holds in $\mathcal{G}$ (Spirtes et al., 2000), is a special case of rank faithfulness since t-separation subsumes d-separation (Sullivant et al., 2010), as also discussed in Appendix A.

3.2 Analysis of Algorithm 2

The algorithm searches for rank constraints among quartets $\{W_i, W_j\} \times \{X, Y\}$ where X is the treatment and Y is the outcome.[4] We need to characterize which structures are

3. The "trivial trek Z," composed of the single vertex Z and no edges, does not violate this statement, as Z is t-separated from itself by $(\emptyset; \{U_1, Z\})$ if we define this trivial trek to be $(\emptyset; Z)$.
4. For simplicity, we assume that there is an edge $X \to Y$ corresponding to a non-zero coefficient λ_{yx}. Otherwise, if W_i satisfies the Graphical Criteria for $X \to Y$ given $\mathbf{Z}$, then under unmeasured confounding between treatment and outcome we have that the lack of an edge $X \to Y$ implies $W_i \perp\!\!\!\perp Y \mid \mathbf{Z}$ and $W_i \not\perp\!\!\!\perp Y \mid \mathbf{Z} \cup \{X\}$. This corresponds to the collider orientation rule of the FCI algorithm (Spirtes et al., 2000) that implies $\lambda_{yx} = 0$. If on top of the lack of edge $X \to Y$ we have that there is no unblocked unmeasured confounding between X and Y, then $X \perp\!\!\!\perp Y \mid \mathbf{Z}$, which again by faithfulness will allow us to infer $\lambda_{yx} = 0$ (Spirtes et al., 2000). Algorithm 2 is assumed to be invoked only if the FCI algorithm and the method of Entner et al. (2012) do not provide any results.

compatible with the Trek Separation Theorem and, among those, which satisfy the Graphical Criteria. We start with the following observation.

Proposition 5 *In Line 9 of Algorithm 2, under rank-faithfulness the conditional tetrad constraint is equivalent to*

$$rank(\Sigma_{\mathbf{AB}}) \leq |\mathbf{Z}| + 1, \tag{4}$$

for $\mathbf{A} = \{W_i, W_j\} \cup \mathbf{Z}$ and $\mathbf{B} = \{X, Y\} \cup \mathbf{Z}$.

Proof of Proposition 5. As in Example 2, the determinant $|\Sigma_{\mathbf{AB}}| = |\Sigma_{\mathbf{ZZ}}|(\sigma_{w_ix.\mathbf{Z}}\sigma_{w_jy.\mathbf{Z}} - \sigma_{w_iy.\mathbf{Z}}\sigma_{w_jx.\mathbf{Z}})$ is zero if and only if the conditional tetrad constraint $\sigma_{w_ix.\mathbf{Z}}\sigma_{w_jy.\mathbf{Z}} = \sigma_{w_iy.\mathbf{Z}}\sigma_{w_jx.\mathbf{Z}}$ holds, as $|\Sigma_{\mathbf{ZZ}}| > 0$ by rank-faithfulness. Hence, $\Sigma_{\mathbf{AB}}$ is not full rank, that is, its rank is strictly less than $\min(|\mathbf{A}|, |\mathbf{B}|) = |\mathbf{Z}| + 2$. □

If the constraint holds, by Theorem 3 it follows that there is some pair $(\mathbf{C_A}; \mathbf{C_B})$ that t-separates $\{W_i, W_j\} \cup \mathbf{Z}$ from $\{X, Y\} \cup \mathbf{Z}$. It is required that $\mathbf{Z} \subseteq \mathbf{C_A} \cup \mathbf{C_B}$, since $\mathbf{Z}$ is contained in both $\mathbf{A}$ and $\mathbf{B}$. This implies the lower bound $|\mathbf{C_A}| + |\mathbf{C_B}| \geq |\mathbf{Z}|$ so that at most one element of $\mathbf{Z}$ belongs to $\mathbf{C_A} \cap \mathbf{C_B}$, and at most one element not in $\mathbf{Z}$ can belong to $\mathbf{C_A} \cup \mathbf{C_B}$. The main result of this section is a characterization of the ways this may happen such that we fail to discover the correct causal effect.

Consider the case where there exists a trek T, containing no element of $\mathbf{Z}$, which is between some $W \in \{W_i, W_j\}$ and $\{X, Y\}$. $\mathbf{C_A} \cup \mathbf{C_B}$ must contain an element of T for the t-separation to hold. Since by (4) and Theorem 3 we have that $|\mathbf{C_A}| + |\mathbf{C_B}| \leq |\mathbf{Z}| + 1$, then we can use exactly one (possibly latent) element out of $\mathbf{Z}$ but in $\mathbf{C_A} \cup \mathbf{C_B}$ to explain this t-separation. Moreover, since $\mathbf{Z} \subseteq \mathbf{C_A} \cup \mathbf{C_B}$, no vertex can appear in both $\mathbf{C_A}$ and $\mathbf{C_B}$, or otherwise $|\mathbf{C_A}| + |\mathbf{C_B}| > |\mathbf{Z}| + 1$. That is, the existence of T implies $\mathbf{C_A} \cap \mathbf{C_B} = \emptyset$.

We call any vertex in T satisfying the definition below a *conditional choke point*. A conditional choke point can be a "left" or "right" choke point:

Definition 6 (left conditional choke point) *In a causal DAG $\mathcal{G}$ with vertex set $\mathbf{V}$, V_0 is a* left conditional choke point *for pairs $\{W_i, W_j\} \times \{X, Y\}$ given $\mathbf{Z}$, where $\{V_0, W_i, W_j, X, Y\} \cup \mathbf{Z} \subseteq \mathbf{V}$, if*

1. *some $(\mathbf{C_A}; \mathbf{C_B})$ t-separates $\{W_i, W_j\}$ from $\{X, Y\}$ in $\mathcal{G}$, such that $V_0 \in \mathbf{C_A} \backslash \{\mathbf{Z} \cup \mathbf{C_B}\}$, $\mathbf{C_A} \cup \mathbf{C_B} = \mathbf{Z} \cup \{V_0\}$, $\mathbf{C_A} \cap \mathbf{C_B} = \emptyset$, and*
2. *for any trek $(P_1; P_2)$ from a vertex in $\{W_i, W_j\}$ to a vertex in $\{X, Y\}$ in $\mathcal{G}$ that contains no member of $\mathbf{Z}$, P_1 contains V_0, and*
3. *there exists at least one such a trek.*

A "right conditional choke point" follows an equivalent definition with respect to $\mathbf{C_B}$ and P_2. The literature has characterizations of *unconditional* choke points (Shafer et al., 1993; Sullivant et al., 2010), relating them to unconditional tetrad constraints. To the best of our knowledge, this is the first time that conditional choke points are explicitly defined and used. The reason for the name "choke point" is explained later in this section.

A second category of choke point, now for vertices in $\mathbf{Z}$, will be defined as follows:

Definition 7 (collider choke point) *In a causal DAG $\mathcal{G}$ with vertex set $\mathbf{V}$, Z_0 is a* collider choke point *for pairs $\{W_i, W_j\} \times \{X, Y\}$ given $\mathbf{Z}$, where $\{W_i, W_j, X, Y\} \cup \mathbf{Z} \subseteq \mathbf{V}$, if*

1. *some $(\mathbf{C_A}; \mathbf{C_B})$ t-separates $\{W_i, W_j\}$ from $\{X, Y\}$ in $\mathcal{G}$, such that $Z_0 \in \mathbf{Z}$, $\mathbf{C_A} \cup \mathbf{C_B} = \mathbf{Z}$, $\mathbf{C_A} \cap \mathbf{C_B} = Z_0$, and*
2. *for any (possibly non-simple) path P from a vertex in $\{W_i, W_j\}$ to a vertex in $\{X, Y\}$ in $\mathcal{G}$ that contains a collider in $\mathbf{Z}$, P contains Z_0, and*
3. *there exists at least one such a path.*

The same vertex can be a conditional and a collider choke point depending on the conditioning set. For instance, Z_0 is a (right) conditional choke point in Figure 3 for each $\{W_i, W_j\} \times \{X, Y\}$ given the empty set, since $(\emptyset; Z_0)$ t-separates each pair in $\{W_1, \dots W_p\} \times \{X, Y\}$ and it lies on all of such treks. The tetrad constraint $\sigma_{w_i x}\sigma_{w_j y} = \sigma_{w_i y}\sigma_{w_j x}$ holds, and we can recover the correct causal effect from $\sigma_{w_i y}/\sigma_{w_i x}$ as the Graphical Criteria is satisfied. On the other hand, if we take the conditioning set to be Z_0 itself, then the conditional tetrad constraint $\sigma_{w_i x.z_0}\sigma_{w_j y.z_0} = \sigma_{w_i y.z_0}\sigma_{w_j x.z_0}$ *also* holds, as well as the corresponding t-separation. However, there is no conditional choke point as all treks in $\{W_i, W_j\} \times \{X, Y\}$ contain an element of the conditioning set, Z_0 itself. Z_0 is now a collider choke point, as it lies as a collider on all active paths between $\{W_1, \dots, W_p\}$ and $\{X, Y\}$. Notice that the Graphical Criteria does not hold as W_1 is not d-separated from Y given Z_0 in the graph that modifies Figure 3 by removing edge $X \to Y$.

Choke points do not need to be unique, in the same way that t-separation between sets may be implied by more than one conditioning pair. For instance, both U_1 and U_2 are right conditional choke points in Figure 2(c), corresponding to the different choices of $\mathbf{C_B}$ discussed in Example 3.

We are now ready to characterize when Algorithm 2 may provide an incorrect value for the target causal effect. The proof of this result is given in Appendix B.

Theorem 8 *Let $\mathcal{C}$ be the outcome of Algorithm 2 as applied to a distribution which is rank-faithful to some causal DAG $\mathcal{G}$. Let $\beta_i \in \mathcal{C}$, and let $(W_i, W_j, \mathbf{Z})$ be the respective triplet that generated β_i by passing the check in Line 9. Then $(W_i, W_j, \mathbf{Z})$ fails to satisfy the Graphical Criteria if and only if exactly one of these is true:*

(i) there is at least one trek between $\{W_i, W_j\}$ and Y that do not contain any member of $\mathbf{Z} \cup \{X\}$, and all of those treks intersect at the same conditional choke point V_0;

(ii) there is at least one (possibly non-simple) active path between $\{W_i, W_j\}$ and Y that contains a collider in $\mathbf{Z}$ and does not contain X, and all of those paths intersect at the same collider choke point Z_0.

Moreover, it is not possible that for $(W_i, W_j, \mathbf{Z})$ both a conditional choke point and a collider choke point exist in $\mathcal{G}$ regardless of whether the Graphical Criteria hold.

That is, if a candidate triplet $(W_i, W_j, \mathbf{Z})$ does not correspond to valid (conditional) instrumental variables, then *all offending paths that avoid X and connect the candidate instruments to Y must pass through a single variable $V \in \mathbf{V} \backslash \{X\}$*. If V is in the conditioning set $\mathbf{Z}$, then this variable must be a collider in all of the offending paths. For instance, U is a conditional choke point with respect to $\mathbf{Z} = \emptyset$ in Figure 2(d) and Z_0 is a collider choke point for $\mathbf{Z} = \{Z_0\}$ in Figure 3. The difference between valid and invalid instruments that imply tetrad constraints is that, in the former, X is a conditional choke point. Although this is not used by Algorithm 2, if conditional tetrad constraints hold for all pairs in some set $\mathbf{W} \equiv \{W_1, \dots, W_p\}$ given $\mathbf{Z}$, it follows that all offending paths from $\mathbf{W}$ to Y go through a common variable V. As a matter of fact, the name "choke point," originally coined by Spirtes et al. (2000) for the special case $\mathbf{Z} = \emptyset$, comes from this idea of having all connecting paths (treks only, in the original case) between two sets passing through a single variable.

We can formalize a sufficient assumption that guarantees that Algorithm 2 does not return a incorrect causal effect as follows:

Corollary 9 *Let $\mathcal{G}$ be a causal DAG with observable vertices $\mathbf{O}$, treatment vertex X and outcome vertex Y. For all $\{W_i, W_j\} \cup \mathbf{Z} \subset \mathbf{O}$ where a tetrad constraint $\sigma_{w_i x.\mathbf{Z}}\sigma_{w_j y.\mathbf{Z}} = \sigma_{w_i y.\mathbf{Z}}\sigma_{w_j x.\mathbf{Z}}$ holds, if X is a corresponding conditional choke point in $\mathcal{G}$, then the output set of Algorithm* TETRAD-IV$_\infty$ *will not contain an incorrect causal effect.*

The result above allows for an empty output set $\mathcal{C}$, which will happen if no valid pair of instrumental variables exists. However, even if all elements of $\mathcal{C}$ are equal to some $\lambda_{\mathcal{C}}$, it does not mean that $\lambda_{\mathcal{C}} = \lambda_{yx}$ in case the assumptions of Corollary 9 fail. It is impossible to distinguish, based on tetrad relations, the graph in Figure 2(b) from the one in 2(d). In the former, X can take the role of a conditional choke point explaining the tetrad constraint. In the latter, X cannot take this role because of the active trek $W_1 \to U \to Y$, but vertex U can, resulting on a tetrad constraint but on invalid IVs. In general, we will have problems in a graph which includes an intermediate latent variable that is a common ancestor of X and Y and blocks all treks from W_1 and W_2 to X. As another example, vertex U_1 takes the role of a conditional choke point given Z in Figure 2(c), while X cannot take this role because of the active trek $W_1 \leftarrow U_1 \to U_2 \to Y$.

One might argue that the assumptions of Corollary 9 are not too restrictive, as failing them require that all offending paths intersect at an unique vertex. If two disjoint paths from W_1 to Y via latent variables exist, for instance, then no tetrad constraint will hold and at worst we would be conservative and not return any causal effect. However, we argue that these assumptions should not be taken lightly. The whole motivation for including a conditioning set $\mathbf{Z}$ is to block paths such that a "desirable" choke point emerges: treatment X. The assumptions that make the presence of an instrumental variable possible are the same that make the presence of undesirable choke points plausible.

Instead, the output of IV-TETRAD$_\infty$ is better interpreted as an *equivalence class of causal effects*, differing from the usual output of causal discovery algorithms such as the PC algorithm (Spirtes et al., 2000): the PC algorithm returns a set of graphs of which some graphical features might be the same (for instance, they all share the same directed edge),

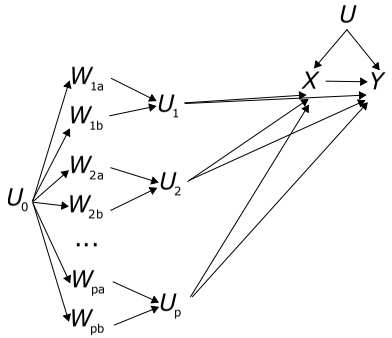

Figure 4: Vertices named $U_\star$ are latent variables, with X being the treatment and Y being the outcome. When given as input to algorithms for finding locally covariance equivalent solutions, the result will include a (potentially different) causal effect candidate for each of the pairwise groupings $\{W_{ia}, W_{ib}\}$, $i = 1, 2, \ldots, p$, where $p = |\mathbf{O}|/2$.

and where some causal effects might be identified based on the common features. That is, the PC algorithm either gives (in the limit of infinite data) the correct answer, or it answers "I don't know." The same is true of the method introduced by Entner et al. (2012).

In contrast, IV-TETRAD$_\infty$ may return an empty set of solutions, but at the same time *all* solutions in a non-empty output set $\mathcal{C}$ may be wrong in case the assumptions of Corollary 9 do not hold. The need to report an equivalence class is illustrated by the following result.

Proposition 10 *There exist problems where the output of* IV-TETRAD$_\infty$ *will contain* $\mathcal{O}(|\mathbf{O}|)$ *different elements, none of which is the correct solution* λ_{yx}.

Proof of Proposition 10. This is illustrated by Figure 4: given $\mathbf{O} = \{W_{1a}, W_{1b}, W_{2a}, \ldots, W_{pb}\}$, $p = |\mathbf{O}|/2$, the structure shown in the Figure will generate solutions for all pairs $\{W_{ia}, W_{ib}\} \times \{X, Y\}$ with corresponding conditioning set $\mathbf{Z}_i \equiv \mathbf{O} \backslash \{W_{ia}, W_{ib}\}$. For parameters generated randomly and independently, it is clear each resulting λ_i will be unique. The corresponding choke point in each case is U_i, and none of the returned causal effects will in general be correct. □

For practical purposes, one should be willing to to assume that *at least one* solution exists, that is, there exists at least one pair of IVs conditioned on the same set $\mathbf{Z}$. Under this condition, we obtain the following guarantee:

Corollary 11 *Let* $\mathcal{C}$ *be the output of* IV-TETRAD$_\infty$ *as applied to a distribution which is rank-faithful to a causal DAG* $\mathcal{G}$ *with observable vertices* $\mathbf{O} \cup \{X, Y\}$ *and target edge* $X \to Y$. *Let* λ_{yx} *be the corresponding true causal effect. Assuming that there exists at least one set* $\{W_i, W_j\} \cup \mathbf{Z} \subseteq \mathbf{O}$ *where* $\{W_i, W_j\}$ *satisfies the Graphical Criteria conditioned on* $\mathbf{Z}$, *then the minimum and maximum elements of* $\mathcal{C}$ *will provide lower and upper bounds on* λ_{yx}.

The proof of this Corollary is immediate from the previous discussions. Summaries other than lower bounds and upper bounds are possible: for instance, if the maximum of $\mathcal{C}$ is much larger than the second largest element, and background knowledge says that such a large value is unlikely, we may opt to exclude it or to reweight elements of $\mathcal{C}$ according to some prior. More of that is discussed in Section 5.

Assuming that one solution exists is a much weaker assumption than the one in IV-BY-MAJORITY / sisVIVE. However, it does require rank-faithfulness and it can only provide bounds and other summaries of an equivalence class. If in the application of the algorithm we have that all elements of $\mathcal{C}$ are the same, then from the assumption that there is at least one valid tuple it follows that we found the true causal effect. A discussion of what further assumptions are necessary in practical learning is postponed to Section 4.

The *soundness* of Algorithm IV-TETRAD$_\infty$ can be defined in terms of the bounds given by Corollary 11, or other summaries of interest, provably capturing the true λ_{yx}. Soundness is however of limited value if the equivalence class is too large or trivial (that is, if there is a lack of *specificity* in the constraints chosen to distinguish possible models), or if the algorithm cannot find all elements of the equivalence class (a lack of *completeness*). While soundness and completeness are a matter of mathematical proof, specificity must be argued in the context of the scientific plausibility of assumptions and practical matters of computational and statistical tractability.

The Markov equivalence class used by various causal discovery algorithms has a natural specificity, as independence constraints are nonparametric restrictions that require no further assumptions about the probability distribution underlying the causal model. The motivation for the specificity of our method is less clear and discussed by first formally defining the following concept:

Definition 12 (locally covariance equivalent causal effect) *We say that two ratios* $\beta_{i(\mathbf{z})} \equiv \sigma_{w_i y \cdot \mathbf{Z}} / \sigma_{w_i x \cdot \mathbf{Z}}$ *and* $\beta_{j(\mathbf{z}')} \equiv \sigma_{w_j y \cdot \mathbf{Z}'} / \sigma_{w_j x \cdot \mathbf{Z}'}$ *are locally covariance equivalent causal effects if there is some pair* $\{W_k, W_l\}$, $W_i \neq W_k$, $W_j \neq W_l$, *where* $\beta_{i(\mathbf{z})} = \beta_{k(\mathbf{z})}$ *and* $\beta_{j(\mathbf{z}')} = \beta_{l(\mathbf{z}')}$.

IV-TETRAD$_\infty$ is sound and complete in the sense that by construction it returns all and only locally covariance equivalent causal effects. The effects are "local" in the sense that it does not use covariance information from the joint distribution of $\{W_i, W_j, W_k, W_l\} \cup \mathbf{Z} \cup \mathbf{Z}'$ beyond what is found in the marginals $\{W_i, W_k\} \cup \mathbf{Z}$ and $\{W_j, W_l\} \cup \mathbf{Z}'$. This is motivated by the following desiderata:

Desiderata 1 (Local Covariance Discovery) *We say that an algorithm obeys the* local covariance discovery *desiderata if it follows these conditions:*

1. *only substructures where two or more variables follow the Graphical Criteria conditioned on a common set* $\mathbf{Z} \subset \mathbf{O}$ *can be used to select conditional instrumental variables;*

2. *only covariance information is used.*

Algorithm 3 IV-TETRAD$^{+}_{\infty}$

1: **Input:** set of zero-mean random variables $\mathbf{O} \cup \{X, Y\}$ with known joint distribution
2: **Output:** $\mathcal{C}$, a set of candidate differential causal effects of X on Y
3: Initialize $\mathcal{C} \leftarrow \emptyset$
4: **for** each pair $\{W_i, W_j\} \subseteq \mathbf{O}$ **do**
5: **for** every set $\mathbf{Z} \subseteq \mathbf{O} \backslash \{W_i, W_j\}$ **do**
6: **if** $\sigma_{w_i x.\mathbf{z}} = 0$ **or** $\sigma_{w_j x.\mathbf{z}} = 0$ **then**
7: **next**
8: **end if**
9: **if** $\sigma_{w_i x.\mathbf{z}} \sigma_{w_j y.\mathbf{z}} \neq \sigma_{w_i y.\mathbf{z}} \sigma_{w_j x.\mathbf{z}}$ **then**
10: **next**
11: **end if**
12: $r_{W_i} \leftarrow \text{resProj}(W_i, \mathbf{Z} \cup \{W_j\})$
13: $r_{W_j} \leftarrow \text{resProj}(W_j, \mathbf{Z} \cup \{W_i\})$
14: $r_Y \leftarrow \text{resProj}(Y, \mathbf{Z} \cup \{W_i, W_j\})$
15: **if** $r_{W_i} \perp\!\!\!\perp r_Y$ **and** $r_{W_j} \perp\!\!\!\perp r_Y$ **then**
16: $\mathcal{C} \leftarrow \mathcal{C} \cup \{\sigma_{w_i y.\mathbf{z}} / \sigma_{w_i x.\mathbf{z}}\}$
17: **end if**
18: **end for**
19: **end for**
20: **return** $\mathcal{C}$

The requirement for covariance information only allows us to use only second moments, which is relatively statistically efficient. This will be relaxed in the next section. The need for "two or more" variables in condition 1 is necessary, since the Graphical Criteria provides no testable implications for a single instrument, as discussed in the introduction. It is also desirable, as it considers variables that are jointly instrumental by conditioning on the same set $\mathbf{Z}$. To drop this criterion is to require a search space where different conditioning sets are required for each IV, resulting in an algorithm that effectively reconstructs a "non-local" graphical substructure that will require the identification of structural coefficients other than λ_{yx}. This is what is done, for instance, in one of the first published extensions of the Graphical Criteria (Brito and Pearl, 2002). However, identification of causal effects using given IVs is an easier problem than discovering IVs from limited structure information. Inferring structure from data is statistically challenging, and we claim that restricting a method to the desiderata above provides a baseline where stronger assumptions, and computational and statistical costs, can be exchanged for greater specificity of the solutions returned.

3.3 Exploiting Non-Gaussianity Assumptions

This Section introduces a variant of IV-TETRAD$_{\infty}$ that can verify the validity of item 2a of the Graphical Criteria, as discussed in Section 2.3. We assume our causal model is a *LiNGAM model*, a linear structural equation model with independent, non-Gaussian error terms, which may include latent variables (Shimizu et al., 2006). We call this Algorithm IV-TETRAD$^{+}_{\infty}$, which is shown in Algorithm 3. We will also discuss the difficulties posed by 2b even under the assumption of non-Gaussianity. The motivation is to reduce the size of the

equivalence class by trading it off with the addition of more assumptions (non-Gaussianity) and a weakening of completeness (some solutions might be missed, as we will characterize).

In Algorithm 3, function $\text{resProj}(V, \mathbf{S})$ is a function that returns the residual of the least-squares projection of V into the set of random variables $\mathbf{S}$ rearranged as a column vector,

$$\text{resProj}(V, \mathbf{S}) \equiv V - \mathbb{E}[\mathbf{S}^{\intercal} V]\mathbb{E}[\mathbf{S}\mathbf{S}^{\intercal}]^{-1}\mathbf{S},$$

which is itself a random variable. We assume that V and $\mathbf{S}$ have zero mean.

3.3.1 Main Result

The validity of Algorithm 3 holds "almost everywhere," in the sense it holds for all but a (Lebesgue) measure zero subset of the set of possible structural coefficients λ_{ij} and variances[5] ω_i of each respective error term e_i, $\theta_{\mathcal{G}} \equiv \{\lambda_{ij} \mid V_j \in par_{\mathcal{G}}(i)\} \cup \{\omega_i\}$. The motivation for this concept is analogous to the different variations of faithfulness, see the discussion on generic identifiability by Foygel et al. (2011) and Sullivant et al. (2010).

The main result of this section is the following:

Theorem 13 *Let $\mathbf{O} \cup \{Y\}$ be a subset of the variables in a zero-mean LiNGAM model with graph $\mathcal{G}$, where Y has no descendants in $\mathcal{G}$. Let $O_i \in \mathbf{O}$ and $\mathbf{Z} \subseteq \mathbf{O} \backslash \{O_i\}$, and let $r_i \equiv O_i - \mathbf{a}^{\intercal}\mathbf{Z}$ be the residual of the least-squares regression of O_i on $\mathbf{Z}$, with $\mathbf{a}$ being the corresponding least-squares coefficients. Analogously, let $r_y \equiv Y - b_i O_i - \mathbf{b}^{\intercal}\mathbf{Z}$ be the residual of the corresponding least-squares regression. Then, almost everywhere, $r_i \perp\!\!\!\perp r_y$ if and only if there are no active non-directed paths between O_i and Y conditioned on $\mathbf{Z}$*

The proof is given in Appendix B. This generalizes the main result of Entner et al. (2012), which considers the case where $\mathbf{Z}$ contains no descendant of O_i.

Even under non-Gaussianity, we will see that it is still possible for conditional choke points in the true graph to add incorrect causal effect estimates to the output of Algorithm 3. However, only the following special case can occur:

Definition 14 (downstream conditional choke point) *In a causal DAG $\mathcal{G}$ with vertex set $\mathbf{V}$, V_0 is a* downstream conditional choke point *for pairs $\{W_i, W_j\} \times \{X, Y\}$ given $\mathbf{Z}$, where $\{V_0, W_i, W_j, X, Y\} \cup \mathbf{Z} \subseteq \mathbf{V}$, if V_0 is a conditional choke point which is a descendant of $\{W_i, W_j\}$ in $\mathcal{G}$, an ancestor of both X and Y, such that no active back-door paths between V_0 and $\{W_i, W_j\}$ exist in $\mathcal{G}$.*

This implies that collider choke points are now ruled out, as shown in the following result proved in Appendix B:

Theorem 15 *Let $\mathcal{C}$ be the outcome of Algorithm 3 as applied to a distribution which is rank-faithful to some causal DAG $\mathcal{G}$. Let $\beta_i \in \mathcal{C}$, and let $(W_i, W_j, \mathbf{Z})$ be the respective triplet that generated β_i by passing the check in Line 15. Then $(W_i, W_j, \mathbf{Z})$ fails to satisfy the Graphical Criteria if and only if: there is at least one directed path between $\{W_i, W_j\}$ and Y that does not contain any member of $\mathbf{Z} \cup \{X\}$, and all of those directed paths intersect at the same downstream conditional choke point V_0.*

5. As error terms are non-Gaussian, other parameters are expected to exist, but our results are agnostic with respect to them.

By further restricting the set of possible choke points, we refine the explanation of possible disparities obtained by Algorithm 3 compared to Algorithm 2. By knowing that there is a *single* choke point per pair which is *unconfounded* with the candidate IVs, *and* which lies on all unblocked directed paths from $\{W_i, W_j\}$ to Y, the output of the algorithm, combined with background knowledge, can be analyzed to exploit this piece of information. For example, any downstream conditional choke point must be a latent confounder of X and Y, which is itself caused by $\{W_i, W_j\}$: efforts might be directed to try to interpret and measure such confounders as possible explanations for the disparities in the output of Algorithm 3.

Examples of advantages and remaining limitations of IV-TETRAD$^+_\infty$ are as follows.

Example 4 *Consider Figure 2(c) again. As discussed before, t-separation between* $\{W_1, W_2, Z\}$ *and* $\{X, Y, Z\}$ *holds given* $(\emptyset; \{U_1, Z\})$*. However, there is an active path between* W_1 *and* Y *that does not include* X*. Algorithm 2 will include the candidate causal effect corresponding the invalid IV triplet* (W_1, W_2, Z) *in its output. In contrast, Algorithm 3 will detect the active back-door path* $W_1 \leftarrow U_1 \rightarrow U_2 \rightarrow Y$ *by the residual test of Line 15 and reject* (W_1, W_2, Z)*.* □

Example 5 *Consider Figure 2(d) again. T-separation between* $\{W_1, W_2\}$ *and* $\{X, Y\}$ *holds given* $(\emptyset; U)$*. However, there are active paths between* $\{W_1, W_2\}$ *and* Y *that do not include* X *and intersect at the downstream conditional choke point* U*. Algorithm 3 will not detect these offending paths and will incorrectly include a value different from* λ_{yx} *in its output set.* □

Example 6 *Consider Figure 3 again. T-separation between* $\{W_1, W_2, Z_0\}$ *and* $\{X, Y, Z_0\}$ *holds given* $(\emptyset; \{Z_0\})$*. Algorithm 2 will include the candidate causal effect corresponding the invalid IV triplet* (W_i, W_j, Z_0) *in its output. In contrast, Algorithm 3 will detect the active non-directed paths* $W_i \rightarrow Z_0 \leftarrow U \rightarrow Y$ *by the residual test of Line 15.* □

Example 7 *Figure 5 shows a more complex example where a latent variable* U *invalidates one particular set of candidate IVs (*$\{V_1, V_2\}$ *given* V_6*). Meanwhile, in the same graph, conditioning on* V_2 *is essential to validate another set of candidate IVs. These two cases cannot be distinguished by Algorithm 2 but can be by Algorithm 3.* □

Notice that Lines 12-14 in IV-TETRAD$^+_\infty$ include W_j in the conditioning set for W_i and vice-versa. Including W_j in the conditioning set for W_i is acceptable, given that if W_i and W_j each satisfy the Graphical Criteria with respect to $X \rightarrow Y$ given $\mathbf{Z}$, then W_i satisfies the Graphical Criteria with respect to $X \rightarrow Y$ given $\mathbf{Z} \cup \{W_j\}$:

Proposition 16 *If* W_i *and* W_j *each satisfy the Graphical Criteria with respect to* $X \rightarrow Y$ *given* $\mathbf{Z}$*, then* W_i *satisfies the Graphical Criteria with respect to* $X \rightarrow Y$ *given* $\mathbf{Z} \cup \{W_j\}$*.*

Proof of Proposition 16. Given $\mathbf{Z}$, both W_i and W_j are d-separated from Y in the graph where edge $X \rightarrow Y$ has been removed. If $\mathbf{Z} \cup \{W_j\}$ d-connected W_i to Y in this mutilated graph, then there should be an active path from W_i to Y where W_j is a collider. But this would imply an active path from W_j to Y given $\mathbf{Z}$, contrary to our assumption. □

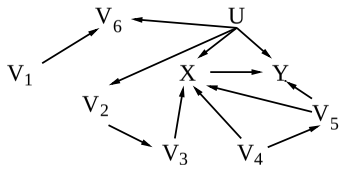

Figure 5: In this system, $\mathbf{W} \equiv \{V_1, V_2\}$ satisfies the conditional tetrad constraints $\{V_1, V_2\} \times \{X, Y\}$ given $\mathbf{Z} \equiv \{V_3, V_6\}$. The same is true for $\mathbf{W}' \equiv \{V_3, V_4\}$ for $\mathbf{Z}' \equiv \{V_2, V_5\}$. Only $\mathbf{W}'$ represents a set of (conditionally) valid IVs. The non-Gaussianity criteria of IV-TETRAD$^+_\infty$ helps to rule out the former.

The motivation for including W_j in the conditioning set of W_i is that, if W_i and W_j share a hidden common cause that is independent of X and Y and W_j is an unblocked ancestor of X, then not conditioning on W_j will induce an active back-door between W_i and X that will make the algorithm unnecessarily remove $\sigma_{w_i y.\mathbf{z}.}/\sigma_{w_i x.\mathbf{z}.}$ from the output.

3.3.2 Implications to Completeness

The following result is a direct consequence of the assumptions and the exhaustive search done by IV-TETRAD$^+_\infty$. The proof of this result follows immediately from Theorem 13 and the existence of edge $X \rightarrow Y$:

Proposition 17 *If there is a pair of observable variables* $\{W_i, W_j\}$ *which are IVs conditioned on some* $\mathbf{Z}$ *according to the Graphical Criteria, and some* $W \in \{W_i, W_j\}$ *has an active non-directed path with* X *given* $\mathbf{Z}$*, and* X *is a parent of* Y*, then Algorithm 3 will not include* $\{W_i, W_j\}$ *in its output.*

The implication of this is as follows. A positive property of IV-TETRAD$^+_\infty$ is that it will exclude from the equivalence class some candidate IVs that do not obey the Graphical Criteria but which are returned by IV-TETRAD$_\infty$. However, IV-TETRAD$_\infty$ was complete in the sense of always including in its output the correct causal effect, under the assumption that at least one pair of valid IVs existed given a common conditioning set. This assumption is not strong enough in the case of IV-TETRAD$^+_\infty$. As an example, suppose that there exists only one pair $\{W_i, W_j\}$ of valid IVs, and its conditioning set $\mathbf{Z}$ does not block all back-doors into X. IV-TETRAD$^+_\infty$ may return a non-empty set but it will not include the correct causal effect.

Example 8 W *is a valid IV in the model with paths* $W \rightarrow X \rightarrow Y$*,* $W \leftarrow U_1 \rightarrow X \leftarrow U_2 \rightarrow Y$*, but* W *will be discarded due to the back-door path between* W *and* Y *that is unblocked by not conditioning on* X*.* □

As a result, the following is a modification of Corollary 11 to the alternative algorithm IV-TETRAD$^+_\infty$. The proof follows immediately from the previous results.

Algorithm 4 IV-TETRAD$^+$

1: **Input:** $\mathcal{D}$, a sample from the joint distribution of random variables $\mathbf{O} \cup \{X, Y\}$; K, number of instruments to consider
2: **Output:** two sets of estimates of the differential causal effect of X on Y
3: Remove from $\mathbf{O}$ any element that is not in the Markov blanket of either X or Y, and also any element which is marginally uncorrelated with X or Y
4: Let $\hat{\lambda}_i \leftarrow \hat{\sigma}_{w_i y.\mathbf{O}\setminus i}/\hat{\sigma}_{w_i x.\mathbf{O}\setminus i}$ for each $W_i \in \mathbf{O}$
5: Initialize $\mathcal{C}$ and $\mathcal{C}_R$ as empty sets, and $\mathbf{W}$ as $\mathbf{O}$
6: **while** $|\mathbf{W}| \geq K$ **do**
7: Sort $\mathbf{W}$ as $W^{(1)}, \ldots, W^{(|\mathbf{W}|)}$ according to the corresponding $\{\hat{\lambda}\}$
8: Find $j \in \{1, 2, \ldots, |\mathbf{W}|\}$ that minimizes ScoreTetrads$(W^{(j:j+K-1)}, \mathbf{O}, X, Y, \mathcal{D})$
9: $\mathbf{W}_j \leftarrow$ ExpandTetrads$(j, K, \mathbf{W}, \mathbf{O}, X, Y, \mathcal{D})$
10: **if** TestTetrads$(\mathbf{W}_j, \mathbf{O}, X, Y, \mathcal{D})$ **then**
11: $\hat{\lambda}_{TSLS} \leftarrow$ TSLS$(\mathbf{W}_j, \mathbf{O}\setminus\mathbf{W}_j, X, Y, \mathcal{D})$
12: **if** TestResiduals$(\mathbf{W}_j, \mathbf{O}, X, Y, \mathcal{D})$ **then**
13: $\mathcal{C} \leftarrow \mathcal{C} \cup \hat{\lambda}_{TSLS}$
14: **else**
15: $\mathcal{C}_R \leftarrow \mathcal{C}_R \cup \hat{\lambda}_{TSLS}$
16: **end if**
17: **end if**
18: $\mathbf{W} \leftarrow \mathbf{W}\setminus\mathbf{W}_j$
19: **end while**
20: **return** $(\mathcal{C}, \mathcal{C}_R)$

Corollary 18 *Let $\mathcal{C}$ be the output of* IV-TETRAD$^+_\infty$ *as applied to a distribution which is rank-faithful to a causal DAG $\mathcal{G}$ with observable vertices $\mathbf{O}\cup\{X, Y\}$ and target edge $X \to Y$. Let λ_{yx} be the corresponding true causal effect. Assuming that there exists at least one set $\{W_i, W_j\} \cup \mathbf{Z} \subseteq \mathbf{O}$ where $\{W_i, W_j\}$ satisfies the Graphical Criteria conditioned on $\mathbf{Z}$, and that no non-directed path between $\{W_i, W_j\}$ and X is active given $\mathbf{Z}$, then the minimum and maximum elements of $\mathcal{C}$ will provide lower and upper bounds on λ_{yx}.*

The trade-off between IV-TETRAD$_\infty$ and IV-TETRAD$^+_\infty$ can be implemented in different ways within a practical algorithm, as we shall see next.

4. Practical Learning from Data

Testing tetrad constraints from data is difficult in practice, particularly without assuming Gaussianity and under conditioning. In order to search for candidate IVs, we will first adopt the stronger (but falsifiable) assumption that, if any set of valid conditional IVs exist, then there is at least one such set $\mathbf{W}$ of size K, which remains valid by conditioning on $\mathbf{O}\setminus\mathbf{W}$. One motivation is to avoid a combinatorial search for conditioning sets, while still having the option of rejecting a solution if confounding or collider biases remain by doing a test at the end. The other motivation is the statistical unreliability of candidate sets of small size: in a large system where the treatment may have many observed causes, instruments will in

general be weakly associated with the treatment, leading to high variance estimates. This issue of "weak instruments" is pervasive in real problems and one mitigation is to consider instrument sets of a minimum size.

The algorithm, IV-TETRAD$^+$, is shown in Algorithm 4. Its implementation diverges from a direct adaptation of IV-TETRAD$^+_\infty$ where hypothesis testing would be used to to check the required constraints. This is because we found that, in simulations, directly testing conditional tetrad constraints is not a very robust strategy. Instead, IV-TETRAD$^+$ includes intermediate steps along the lines of a "score-based approach" (Cooper, 1999) for causal discovery. In the algorithm, we search for a window of K estimated causal effects $\{\hat{\lambda}\}$ within a sorted list, scoring this set according to a particular measure of variability of its elements. Ideally, a perfect score of 0 is obtained when all $\hat{\lambda}$ in this window are equal. *This corresponds to an alternative view of Line 9 of* IV-TETRAD$^+_\infty$*, where we find a set of K variables W_i with corresponding ratios $\hat{\sigma}_{w_i y.\mathbf{O}\setminus i}/\hat{\sigma}_{w_i x.\mathbf{O}\setminus i}$ as close as possible to each other, in a formal sense defined below.*

The algorithm makes use of TSLS$(\mathbf{W}, \mathbf{Z}, X, Y, \mathcal{D})$, the two-stage least squares (TSLS) estimator for some set of conditional instruments $\mathbf{W}$ and conditioning set $\mathbf{Z}$, given a data set $\mathcal{D}$. The TSLS estimator[6] $\hat{\lambda}_{TSLS}$ is motivated by the redundant ways of estimating λ_{yx} if we have more than one instrument. For instance, we could have used either $\sigma_{w_i y.\mathbf{Z}}/\sigma_{w_i x.\mathbf{Z}}$ or $\sigma_{w_j y.\mathbf{Z}}/\sigma_{w_j x.\mathbf{Z}}$ in the previous algorithms without any difference. When finite sample covariance matrices are used instead of population covariance matrices, differences will appear. The TSLS is a classic way of combining all postulated instruments into a single estimator (Angrist and Pischke, 2009). This is particularly relevant in IV-TETRAD$^+$, where we use more than two instruments in each causal effect estimate inside function ScoreTetrads, as explained in the next paragraphs.

The output of the algorithm is a pair of two sets, $\mathcal{C}$ and $\mathcal{C}_R$, where the latter excludes from $\mathcal{C}$ all elements that correspond to each W_i detected to be connected to Y via an active non-directed path, as in IV-TETRAD$^+_\infty$.

4.1 Interpretation

The details of the algorithm are as follows:

- In Line 3, we remove variables from $\mathbf{O}$ that are considered to be conditionally independent of X or Y. *The deletion of variables outside the Markov blanket of X correspond to Line 6 in* IV-TETRAD$^+_\infty$. As discussed in the beginning of this section, we assume that if valid IVs exist, then $\mathbf{O}$ can be partitioned into instrument set $\mathbf{W}$ and conditioning set $\mathbf{Z} \equiv \mathbf{O}\setminus\mathbf{W}$. By Proposition 16, $W_i \in \mathbf{W}$ remains a valid IV if the conditioning set is $\mathbf{O}_i \equiv \mathbf{O}\setminus\{W_i\}$. We remove also variables which are statistically independent of Y given the remaining variables in $\mathbf{O}$. This is motivated by the instability of the ratio of estimates $\hat{\sigma}_{w_i y.\mathbf{Z}}/\hat{\sigma}_{w_i x.\mathbf{Z}}$ when both are close to zero. If W is d-connected to X and edge $X \to Y$ exists, then in theory we will not remove any valid IV by doing this test.

6. Assuming $\mathcal{D}$ is centered to have zero empirical mean, this is defined as follows: let $\mathbf{R}_W$, $\mathbf{R}_X$, $\mathbf{R}_Y$ denote the corresponding empirical residuals of the least-squares regression of $\mathbf{W}$, X and Y on $\mathbf{Z}$. The projection matrix $P_{\mathbf{W}}$ is defined as $\mathbf{R}_W(\mathbf{R}_W^\top\mathbf{R}_W)^{-1}\mathbf{R}_W^\top$. Let $\hat{\mathbf{R}}_X$ denote the predicted value $\hat{\mathbf{R}}_X \equiv P_{\mathbf{W}}\mathbf{R}_X$. The two-stage least squares coefficient is then given by the least-squares regression of $\mathbf{R}_Y$ on $\hat{\mathbf{R}}_X$, resulting in $\hat{\lambda}_{TSLS} \equiv (\mathbf{R}_X^\top P_{\mathbf{W}}\mathbf{R}_X)^{-1}\mathbf{R}_X^\top P_{\mathbf{W}}\mathbf{R}_Y$.

In our experiments in the next Section, Line 3 is implemented by running LARS (Efron et al., 2004), regressing separately X on $\mathbf{O}$ and Y on $\mathbf{O}$. We then remove from $\mathbf{O}$ any element that is given a coefficient of value zero in either regression.

Moreover, we also remove from $\mathbf{O}$ any element marginally uncorrelated with X or Y by a test of vanishing Spearman correlations at a 0.05 level;[7]

- In Line 4, each $\hat{\sigma}_{ab.\mathbf{z}}$ is an estimated partial covariance as given by the empirical covariance matrix derived from $\mathcal{D}$, and $\mathbf{O}_{\setminus i} \equiv \mathbf{O} \setminus \{W_i\}$.
- The loop that starts in Line 6 will search for a subset of $\mathbf{W}$ of size at least K that respects desirable tetrad and residual independence constraints. Every time a set of minimum size is found, it is removed from $\mathbf{W}$ and the process repeats;
- In Line 8, function ScoreTetrads($W^{(j:j+K-1)}, \mathbf{V}, X, Y, \mathcal{D}$) returns the median of the absolute differences between $\hat{\lambda}_{TSLS}$ and each $\hat{\lambda}^{(j)}, \dots \hat{\lambda}^{(j+K-1)}$, where $\hat{\lambda}_{TSLS} \equiv$ TSLS $(\{W^{(j)}, \dots, W^{(j+K-1)}\}, \mathbf{V} \setminus \{W^{(j)}, \dots, W^{(j+K-1)}\}, X, Y, \mathcal{D})$;
- In Line 9, function ExpandTetrads performs a greedy search to optimize ScoreTetrads by expanding the current set $\{W^{(j)}, \dots, W^{(j+K-1)}\}$ as either $\{W^{(j-1)}, \dots, W^{(j+K-1)}\}$ or $\{W^{(j)}, \dots, W^{(j+K)}\}$. This is done until a local maximum for ScoreTetrads is found;
- At the end of Line 9, we have a set of proposed instrumental variables which are found to approximately imply the same causal effect, as defined by Line 4. This also implies approximately satisfying the corresponding tetrad constraints. In Line 10, we formally check the validity of this candidate set by performing Wishart tests of conditional tetrad constraints (Wishart, 1928; Spirtes et al., 2000) for every possible pair in $\mathbf{W}_j$ against pair $\{X, Y\}$.[8] Function TestTetrads returns true if and only if more than half of the tested pairs return a test p-value greater than a particular pre-defined level. In our experiments in the next section, this level was set at 0.05. *This step has therefore a direct correspondence to the tetrad checks in* IV-TETRAD$^+_\infty$*, augmented with a pre-selection of pairs*;
- Finally, in Line 12, for each $W \in \mathbf{W}_j$, function TestResiduals is defined such that we first obtain the residual r_W of the least-squares regression of W on $\mathbf{O} \setminus W$, as well as the residual r_X of the regression of X on $\mathbf{O}$ (alternatively we could calculate r_Y, but we expect X to be more strongly associated with W as in theory there is no edge between W and Y). We perform a marginal independence test of these two residuals using HSIC (Gretton et al., 2007). As with the tetrad tests, TestResiduals will return true if and only if more than half of the p-values are above a particular threshold (again 0.05 in our experiments).

7. Although this rules out possible IVs which are dependent on X only if we condition in some other observed variable (for instance, if the only path between W_i and X is $W_i \to Z \leftarrow U_z \to X$ for some $Z \in \mathbf{Z}$ and $U_z \in \mathbf{U}$), in preliminary runs we found this to provide more stable outputs.
8. We ignore that the test distribution in Wishart's test assumes Gaussianity and marginal covariances. As discussed by Spirtes (2013), there is evidence that tests without Gaussianity assumptions (Bollen, 1990) have no clear advantage compared to Wishart's.

The rationale for Algorithm 4 is as follows. In the limit of infinite data, any set of K variables which satisfies the corresponding tetrad constraints will return a value of zero for ScoreTetrads, which will then be expanded by ExpandTetrads to include any remaining candidate IVs that imply the same ratio λ. Sets of size K that satisfy the Graphical Criteria will contribute with the true causal effect to $\mathcal{C}$, as will also sets of size K or larger corresponding to locally covariance equivalent causal effects. The algorithm can fail to produce information that a more exhaustive algorithm would produce if subsets of conditioning sets $\mathbf{O} \setminus W_i$ were considered instead (for instance, in the limit of infinite data, IV-TETRAD$^+$ will return an empty $\mathcal{C}_R$ for data generated by the model in Figure 3, which is in theory avoidable).

The separation between $\mathcal{C}$ and $\mathcal{C}_R$ is due to the fact that full automation of effect discovery is not recommended, as there are unidentifiability trade-offs. Recall that in the graph where W_1 and W_2 are valid IVs, but where W_1 and X share an unmeasured confounder, that the residual test will asymptotically reject this candidate pair. It is to remind the user of this possibility that the algorithm separates, in a second set, the outcomes filtered by a more stringent criteria. The price to be paid is the stronger assumption concerning the existence of a partition $(\mathbf{W}, \mathbf{Z})$ of $\mathbf{O}$ such that $\mathbf{W}$ are valid IVs given $\mathbf{Z}$ and that $|\mathbf{W}| \geq K$. If this existence criteria also includes that no elements in $\mathbf{W}$ has an active non-directed path with Y given $\mathbf{Z}$, then $\mathcal{C}_R$ will be no larger and sometimes smaller than $\mathcal{C}$. Both sets can be summarized in many ways, including using them to provide lower and upper bounds to λ_{yx} in a way analogous to Corollaries 11 and 18.

4.2 Further Comments

IV-TETRAD$^+$ can in principle be expanded to include a greedy search over sets $\mathbf{Z}$ which are strict subsets of $\mathbf{O} \setminus \{W_i\}$. Some non-trivial theory on how to do it with formal guarantees and non-trivial assumptions is left as future work. The most immediate modification of IV-TETRAD$^+$ would be to include a further outer loop, where other conditioning sets are used instead of $\mathbf{O}_{\setminus i}$, starting from the empty set. The outer loop would increase this set by one element at a time, optimizing ScoreTetrads. As this is a relatively straightforward heuristic without any insightful theory behind it, and the statistical variance of the final result will just increase considerably, we do not discuss it further. Our preferred solution is to let the algorithm return an empty set if no tetrad constraints and residual tests are satisfied, ignoring the search for a more specific conditioning set. The theory behind IV-TETRAD$^+_\infty$ is used in IV-TETRAD$^+$ to provide guarantees about $\mathcal{C}_R$. It also provides the explanation of what can go wrong by improperly conditioning on a covariate. This theory can be combined with background knowledge to manually select a pre-defined set of conditioning sets that are believed to be adequate for finding instruments, in case the default $\mathbf{O}_{\setminus i}$ is deemed insufficient.

The choice of K is not a straightforward question. This decision is a bias-variance trade-off: smaller K means weaker assumptions but higher variance. We do not provide a domain-free rule of thumb: our recommendation is to set K as high as possible according to knowledge from the domain of interest. Notice that, unlike sisVIVE, this number does not need to grow with $|\mathbf{O}|$. Sensitivity analysis, where different values of K are attempted, can be a valuable tool to diagnose the impact of this choice.

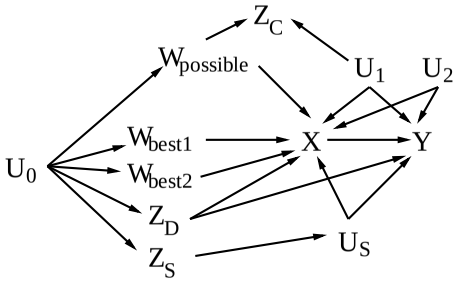

Figure 6: Example of a synthetic graph generated by the template used in Section 5. W_{best_1}, W_{best_2} and $W_{possible}$ are valid IVs conditioned on Z_D and Z_S only, as conditioning on Z_C activates the path $W_{possible} \rightarrow Z_C \leftarrow U_1 \rightarrow Y$, which invalidates that instrument. However, W_{best_1} and W_{best_2} remain valid even after conditioning on all other observed variables.

5. Experiments

We assess how IV-TETRAD$^+$ compares to other methods in a series of simulations. We then provide an example on how the method can be used in an empirical study and assess its robustness.

5.1 Synthetic Studies for Finding a Single Causal Effect Assuming IVs Exist

We generate synthetic models of particular structures, intended to capture features such as confounding and collider bias that should be avoided by proper conditioning. In order to allow for a direct a comparison of IV-TETRAD$^+$ against alternative methods that return a single causal effect estimate, we pragmatically force our algorithm to choose a single element in each output $\mathcal{C} \cup \mathcal{C}_R$ for the sake of simplifying comparisons.[9] The choice is the effect estimate corresponding to the set $\mathbf{W}_j$ that minimizes ScoreTetrads at the end of Line 9, which is then contrasted against the true effect.[10]

Simulations are performed as follows. Treatment X and outcome Y have two latent parents, U_1 and U_2. U_1 is connected to observed covariates as described below, so its variance decreases by conditioning. U_2 is not directly connected to the observed covariates. We then generate synthetic graphs by splitting the observed covariates in different groups.

9. Also, in this setup, the non-Gaussianity test of Line 12 does not play a role in the final output.
10. It is theoretically possible that this criterion will make IV-TETRAD$^+$ return the wrong causal effect in the limit of infinite data, as by design we introduce locally covariance equivalent causal effects. However, with finite data this criterion typically chooses solutions corresponding to correct IVs: in our setup, the non-IV vertices that imply locally covariance equivalent effects tend to be more weakly associated with outcome Y than the true IVs, as paths from such vertices to outcome Y pass through latent choke points. This inflates the variance of the corresponding $\hat{\lambda}_i$, leading to higher disparity compared to the effect estimated by two-stage least squares.

Table 2: Experimental results for 8 methods as described in the text, including three oracle competitors that illustrate idealized scenarios where parts of the structure are known. Two experimental parameters are varied: sample size N and the amount $\lambda_{xu} = \lambda_{yu}$ of unmeasured confounding between X and Y. For each pair of method and experimental condition, we report the summarized performance over 100 trials in two ways: the median absolute difference between the estimated causal effect and true λ_{yx} (the smaller, the better); and the proportion in which the sign of the estimated effect and the sign of the true effect agree (the higher, the better). IV-TETRAD$^+$ beats all non-oracle competitors at sample size 10000, with a p-value $p < 0.001$ according to a binomial test (in bold). Notice that NAIVE2 is actually the closer competitor to IV-TETRAD$^+$, while in this particular setup sisVIVE does not improve even with large sample sizes.

Group $\mathbf{W}$ are variables which can be used as conditional IVs. This group has two subgroups, $\mathbf{W}_{best}$ and $\mathbf{W}_{possible}$. The former remains a set of valid IVs conditioned on all other observed covariates. The latter will have active collider paths with treatment X that can be in principle deactivated by a combinatorial search, which is not performed by any algorithm in our benchmark. Group $\mathbf{Z}_S$ is a set of covariates with a common latent child U_S which is also a parent of X and Y, making U_S a spurious choke point between $\mathbf{Z}_S$ and $\{X, Y\}$. Group $\mathbf{Z}_D$ is a set of covariates which are parents of both X and Y and as such are not blocked by choke points, latent or not. Group $\mathbf{Z}_C$ are variables which are children of $\mathbf{W}_{possible}$ and U_1. Finally, all variables in $\mathbf{WZ} \equiv \mathbf{W} \cup \mathbf{Z}_S \cup \mathbf{Z}_D$ have a common latent parent U_0, making conditioning on $\mathbf{WZ} \backslash W$ required for $W \in \mathbf{W}_{best}$ to be a valid IV. Figure 6 shows an example where $|\mathbf{W}_{best}| = 2, |\mathbf{W}_{possible}| = 1, |\mathbf{Z}_S| = 2, |\mathbf{Z}_D| = 1$ and $|\mathbf{Z}_C| = 1$.

The methods we compare against are:

1. NAIVE1, the least-squares regression coefficient of Y on X;
2. NAIVE2, two-stage least squares (TSLS) of Y on X using all variables $\mathbf{O} = \mathbf{W} \cup \mathbf{Z}_S \cup \mathbf{Z}_C \cup \mathbf{Z}_D$ as instruments;
3. NAIVE3, least-squares regression of Y on X and $\mathbf{O}$;

4. ORACLE, TSLS estimation using the correct set of IVs $\mathbf{W}$ and correct adjustment set $\mathbf{Z}_S \cup \mathbf{Z}_D$;

5. W-ORACLE, TSLS using $\mathbf{W}$ as IVs, but conditioning on all of the other variables $\mathbf{Z}_S \cup \mathbf{Z}_D \cup \mathbf{Z}_C$;

6. S-ORACLE, the algorithm of Kang et al. (2016) executed by first correctly removing the set $\mathbf{Z}_C$ from the input;

7. SISVIVE, the algorithm of Kang et al. (2016) executed in the standard way, by taking all variables $\mathbf{O}$ as input;

8. IV-TETRAD$^+$, our method, using all variables $\mathbf{O}$ as input and $K = 10$.

All error variables and latent variables are zero-mean Laplacian distributed, and coefficients are sampled from standard Gaussians and re-scaled such that the observed variables have a variance of 1. A simulation is rejected until $|\lambda_{yx}| > 0.05$. Coefficients between $\{X, Y\}$ and latent variables $\{U_1, U_2\}$ are set such that $\lambda_{xu_1} = \lambda_{yu_1} = \lambda_{yu_2} = \lambda_{yu_2}$, at two levels, $(0.125, 0.25)$. The difficulty of the problem increases with λ_{xu_1}, as this makes unmeasured confounding stronger. Comparisons are shown in Table 2, with the setup $|\mathbf{W}_{best}| = 15$, $|\mathbf{W}_{possible}| = 10$, $|\mathbf{Z}_S| = 10$, $|\mathbf{Z}_D| = 5$, $|\mathbf{Z}_C| = 10$. This satisfies the criterion of $|\mathbf{W}|$ being half the number of remaining variables, although only the 15 variables $\mathbf{Z}_S \cup \mathbf{Z}_D$ should be used as a conditioning set.

We generate 100 synthetic problems with a data set of 10,000 points each and assess methods using also subsets of size 1000 and 5000. For $\lambda_{xu} = 0.125$, the empirical distribution of effects λ_{yx} had a median of 0.34, an upper quartile of 0.55 and a maximum of 1.05. For $\lambda_{yu} = 0.25$, a median of 0.35, an upper quartile of 0.75 and a maximum of 1.28. For assessment, we use two measures that summarize absolute deviance from λ_{yx} and agreement with its sign.

The message in Table 2 is as follows. The parameter estimation problem is easy if one knows the correct IVs and background variables (ORACLE), but it shows already its challenges if one has potentially correct IVs but conditions on the wrong set (W-ORACLE). sisVIVE can work very well if one knows in advance which conditioning variables to discard (S-ORACLE). In general we will not have this knowledge, and sisVIVE can potentially behave badly, even worse than a naïve method (compare NAIVE3 to SISVIVE). The large contrast between S-ORACLE and SISVIVE is a warning against ignoring the effects of incorrect conditioning. Of all non-oracle methods, IV-TETRAD$^+$ is the clear winner, although as expected it is a high variance estimator and should be advantageous only for relatively large sample sizes. In Section 5.3 we illustrate ways in which the uncertainty of this estimator can be assessed.

5.2 Residual Test Assessment

We assess the robustness of the residual test validations of IV-TETRAD$^+$ in a series of simulations. We designed three scenarios as illustrated in Figure 7, where $\{U_0, U\}$ are latent variables:

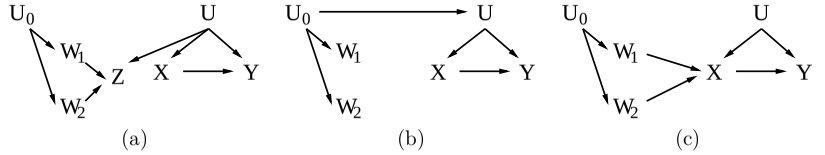

Figure 7: The three different configurations used in the assessment performed in Section 5.2.

S_1: The graph is given by Figure 7(a). The ideal output is to falsify the null hypothesis of residual independence between W_1 and X given $\{W_2, Z\}$, and W_2 and X given $\{W_1, Z\}$.

S_2: The graph is given by Figure 7(b). The ideal output is to falsify the null hypothesis of residual independence between W_1 and X given W_2, and W_2 and X given W_1.

S_3: The graph is given by Figure 7(c). The ideal output is *not* to falsify the null hypothesis of residual independence between W_1 and X given W_2, and W_2 and X given W_1.

In each scenario, we simulate 100 synthetic problems and generate a data set of size 10,000 from each. The simulation of parameters is similar to Section 5.1, also including two levels of confounding by setting $\lambda_{xu} = \lambda_{yu}$ to either 0.125 or 0.25. We also increase the non-Gaussianity of the error terms: each error term is generated by sampling a Laplace distributed random variable as before, and then raising it to the power of 1.5, preserving the sign, and rescaling it back to have the same variance required so that each latent and observed variable has a marginal variance of 1. We do not claim that the tests proposed are particularly strong when the sample size is not large or the random variables are not clearly non-Gaussian. We do illustrate that, according to the theory, we should get better decisions with increasing sample sizes.

A joint decision is given for the pair of variables $\{W_1, W_2\}$, as in the definition of TestResiduals used in Algorithm 4. This is done by voting: for each candidate IV $W \in \{W_1, W_2\}$, we test the independence of r_W against r_X using HSIC (Gretton et al., 2007) conditioning on the remaining observed variables. If more than half of the candidate IVs result in a corresponding p-value greater than the chosen level of 0.05 (in our setup, this means that both W_1 and W_2 pass the test), then the model passes the test and the IVs are not falsified. Otherwise, the model is rejected. In our simulation, we are correct in each simulated instance if we reject the candidate instrument pair in scenarios S_1 and S_2, or if we do not reject it in scenario S_3.

We use a Shapiro-Wilk test of Gaussianity followed by the HSIC test as implemented in the R package dHSIC,[11] both at a level 0.05. That is, if for candidate instrument W the Gaussianity assumption cannot be rejected for the residuals r_W or r_X, then W by default is

11. Available at the Comprehensive R Archive Network, CRAN, `https://cran.r-project.org/`.

Confounding	$N = 1000$			$N = 5000$			$N = 10000$

$\lambda_{yu} = 0.25$	0.63	0.59	0.79	0.85	0.98	0.83	0.86	1.00	0.83

Table 3: Experimental results for assessing the detection of invalid instrument candidates based on the dependencies between least-squares residuals of instruments and treatments on a common pool of covariates. Within each sample size and amount of confounding, we show the proportion of times we correctly decided whether the corresponding pair of candidate IVs are indeed valid or not (out of 100 simulations). The three problems S_1, S_2 and S_3 are discussed in the main text. The correct decisions are to reject the candidates in problems of type S_1 and S_2, and not reject them in S_3.

not rejected as a plausible instrument.[12] Only default dHSIC hyperparameters were used to make the results more conservative: we believe better results can be obtained by more sophisticated approaches for hyperparameter selection. Similarly, the p-value threshold of 0.05 should not be seen the level of the test but as a regularization parameter, and should be adapted as the sample size increases (Kalisch and Bühlmann, 2007). Results are summarized in Table 3.

As expected, correctly rejecting the model in scenarios S_1 and S_2 is easier when confounding is stronger, which is precisely when we would like to be more conservative regarding our choice of instruments. Scenario S_2 is particularly hard under smaller sample sizes, as correlations quickly go to zero given a single path of length 3 between candidate instruments and treatment/outcome. The performance in Scenario S_3 plateaus, meaning that in this particular simulated distribution of parameters we still erroneously reject the valid IVs approximately 17% of the time. The Type I error probability is not that straightforward to calculate due to the voting mechanism and the dependency of the least-squares rejection estimates and the residual estimates. However, as it is known, in any constraint-based search algorithm we should decrease the test level hyperparameter from 0.05 towards zero as sample size increases if we want consistency. This is analogous to the behavior of other algorithms such as the PC algorithm (Spirtes et al., 2000).

To conclude, despite the noted shortcomings of requiring detectable non-Gaussianity and large sample sizes, the tests do provide a validation of proposed instruments as advertised. Moreover, they are expected to be more effective in discarding possibly invalid IVs as unmeasured confounding gets stronger, which is a desired behavior. However, we still recommend that we output candidate effects both with and without the residual independence tests as done by IV-TETRAD$^+$, for the reasons explained.

12. In theory the goal is to save computational time. In this cases the independence assumption is likely not to be rejected anyway, but the HSIC test can be costly if done many times so we want to avoid performing it whenever possible.

5.3 Empirical Illustration

We consider the application of our method to the study by Sachs et al. (2005). That study collected cell activity measurements (concentration of proteins and lipids) for single cell data under a variety of conditions. While searching for instrumental variables under a combination of experimental conditions is an interesting topic, we will focus on a single condition (described in the paper as stimulation with anti-CD3 and anti-CD28). There are 11 variables and 853 data points, of which we selected the manipulation of concentration levels of molecule *Erk* as the treatment, and concentration of *Akt* as the outcome. We use as background knowledge the model inference result shown as Figure 3A presented by Sachs et al. (2005), encoding that the other 9 cell products are not causally affected by either *Erk* or *Akt*. Although previously unknown, evidence for this causal link was also given support by an experiment performed by Sachs et al. (2005).

The data shows some weak correlations, but we will assume for simplicity that no conditional independencies will hold between the treatment variable and the remaining 10 variables. The motivation for Step 3 in Algorithm 4 was primary as a variance reduction technique. Instead, here we will be primarily concerned about illustrating how we could assert uncertainty in our estimates using the modified Bayesian approach introduced by Silva and Kalaitzis (2015).

Running the standard regression adjustment NAIVE3 on this data, we get a differential causal effect of 1.36. sisVIVE reports an effect of 1.58, where all variables were chosen as instruments and as such this estimate here is the same as NAIVE2. This suggests that unmeasured confounding may be weakening the association between treatment and outcome, but sampling variability may be high as discussed in the next section. We run IV-TETRAD$^+$ as in Section 5.1 (and skipping Step 3), where a single effect of 1.43 is returned by minimizing ScoreTetrads. For this run we chose a window size $K = 3$, as $K = 2$ is in general too noisy of a choice since it cannot exploit any redundancies of the tetrad constraints implied by the candidate instrument sets. TestResiduals does not reject any candidate set proposed by the tetrad search. For $K = 4$ and $K > 4$ the results were 1.38 and 1.58 respectively, illustrating some of the difficulties of working with a relatively small sample size (853 points) using an algorithm that has been shown to require large samples. To illustrate what a practitioner should do in this case, we describe ways of assessing the uncertainty of the output of IV-TETRAD$^+$.

5.3.1 Exploration with the Bootstrap

First, we show a simple comparison based on the bootstrap: we sample the data with replacement and show the corresponding (bootstrapped) sampling distribution of the estimates obtained by NAIVE3, sisVIVE and the single-output IV-TETRAD$^+$ with $K = 3$. A smoothed estimate of the respective bootstrapped outcomes is shown in Figure 8. It is evident that as the method gets more flexible, the entropy of the respective sampling distribution of the estimates also increases. There is some evidence of bimodality of the sampling distribution, with IV-TETRAD$^+$ being particularly more extreme.

Bootstrap can in principle be used to find confidence intervals for the corresponding causal effects. However, it is relevant also to discuss Bayesian approaches for quantifying uncertainty. This is particularly interesting for a method like IV-TETRAD$^+$, which po-

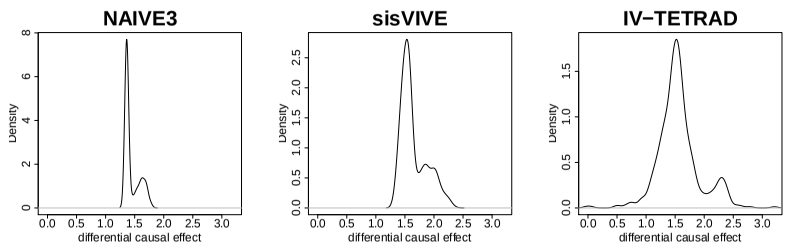

Figure 8: Smoothed sampling distribution of the estimated causal effects for the three discussed methods using 500 bootstrapped samples and kernel density estimation.

tentially returns sets of causal effects of varying sizes. It is not clear what a confidence interval (or confidence set) would be here. Returning a summary such as the minimum and maximum elements of the set, and building confidence intervals on bounds of the causal effect, may be too conservative and not very robust to outliers. In the next section, we will show a Bayesian solution to that problem. First, let us start by still considering the case where IV-TETRAD$^+$ returns a single element as chosen by ScoreTetrads.

Obtaining a posterior distribution over the causal effect of interest requires a likelihood function that includes all observed variables. The usual Bayesian approach for graphical modeling would require exploring a space of conditional tetrad and residual independence constraints, where any chosen set of constraints defines a model. We would then evaluate the marginal likelihood of each model and search for the maximum a posteriori or list several models of high probability. Alternatively, we in principle could perform Markov chain Monte Carlo (MCMC) sampling in the space of parameters and model constraints. A very different algorithm from IV-TETRAD$^+$ would be necessary, as it does not search among complete models. Such an algorithm would be computationally very intense, and it is not clear how to parameterize a joint likelihood for any given set of constraints, whether latent variables are explicitly introduced or not.

5.3.2 Learning by Bayesian Projections

Instead, we adopt the much simpler "Bayesian projections" approach suggested by Silva and Kalaitzis (2015), which has a relation to several other approaches for model selection that avoid introducing constraints directly in the likelihood function, such as the one by Goutis and Robert (1998). We define a black-box non-Gaussian likelihood function for the observed variables, generate posterior samples from it by MCMC, and perform a causal effect search algorithm similar to IV-TETRAD$^+$. The main difference here is that instead of performing statistical tests, we instead reject constraints if they violate a threshold of misfit.

To make it more explicit, we define an algorithm which we will call IV-TETRAD^{++}. In this algorithm, we are given M posterior samples of the model parameters from a black-box

mixture of Gaussians likelihood. Within each sample $1 \leq m \leq M$, we run IV-TETRAD$^+$ with the following modifications:

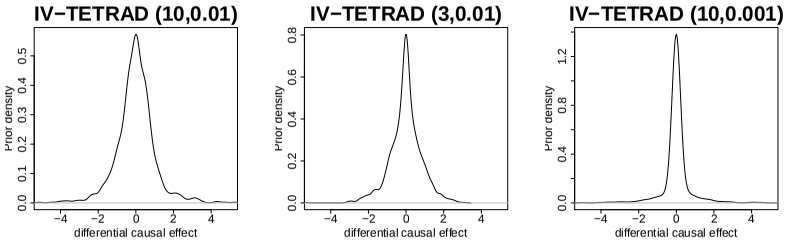
1. Empirical covariances $\hat{\sigma}_{ab.\mathbf{s}}$ are replaced with the corresponding model covariances $\sigma^{(m)}_{ab.\mathbf{s}}$, which can be computed analytically for a mixture of Gaussians model;
2. We ignore Line 3 of IV-TETRAD$^+$, the one where we originally estimated Markov blankets. Instead, we discard every λ_i such that $|\lambda_i| > \alpha_{cut}$. Hyperparameter α_{cut} is given as an input, implying the removal from the output of unusually high causal effects, including some of those resulting from variables V_i such that $\sigma_{v_i x.\mathbf{v}_{\setminus i}} \approx 0$.
3. TestTetrads is modified to reject a tetrad constraint if
$$|\rho^{(m)}_{w_i x.\mathbf{o}_{\setminus i}} \rho^{(m)}_{w_j y.\mathbf{o}_{\setminus j}} - \rho^{(m)}_{w_j i y.\mathbf{o}_{\setminus i}} \rho^{(m)}_{w_j x.\mathbf{o}_{\setminus j}}| > \tau,$$
where $\rho_{ab.\mathbf{s}}$ is the partial correlation of A and B given $\mathbf{S}$. Hyperparameter τ is given as an input, and provides the rule that decides on whether a tetrad constraint fits the model given by the m-th MCMC sample with model partial correlations $\rho^{(m)}_{ab.\mathbf{s}}$.
4. For simplicity, we do not perform TestResiduals. It could in principle be implemented by sampling a large synthetic data set from model m, estimating a measure of dependence between the residuals, and rejecting independence with this measure is larger than a given hyperparameter. Due to its computational cost and the fact it does not change the message of this section, we will ignore this step.

A more formal description of the algorithm is given in Appendix C.

Silva and Kalaitzis (2015) discuss the shortcomings of algorithms based on Bayesian projections compared to a traditional Bayesian approach where the likelihood enforces constraints explicitly. However, the computational advantages are major, as sampling from the posterior of a more standard black-box model is much simpler than searching within a complex likelihood space. As a matter of fact, at the present time it is not known how to define such a likelihood function. A Bayesian projection approach has some similarities to frequentist bootstrap, where a black-box object (the empirical distribution, in the nonparametric bootstrap case) provides the source of variability (the sampling distribution, in the bootstrap case). This allows us to leverage constraint-based algorithms with few modifications.

The most delicate design choices are the choice of α_{cut} and τ. One possibility to assess its impact is by sampling from the prior and plotting the implied distribution on differential causal effects. This is done in Figure 9, where the black-box distribution is a mixture of 5 Gaussians with the following priors: the mixing distribution is given a Dirichlet prior with hyperparameter $(2, 2, 2, 2, 2)$; the covariance matrix Σ_c of each mixture component c is given an inverse Wishart prior with $\nu = 11 + 3$ degrees of freedom and a $\nu\mathbf{I}$ scale matrix, with $\mathbf{I}$ being the 11×11 identity matrix; the mean vector μ_c of each component is given a multivariate Gaussian prior with zero mean and covariance matrix Σ_c.

Given the prior for the base distribution, Figure 9 shows a smoothed depiction of 1000 samples from the priors defined by sampling the mixture model parameters from the base distribution and passing them through IV-TETRAD^{++}, where we choose the single element that minimizes ScoreTetrads. To generate the figure, we used the the following configurations: i. $(\alpha_{cut} = 10, \tau = 0.01)$; ii. $(\alpha_{cut} = 3, \tau = 0.01)$ and iii. $(\alpha_{cut} = 10, \tau = 0.001)$.



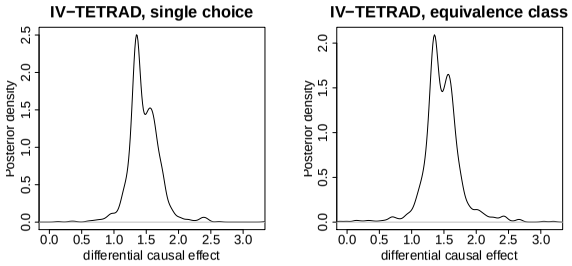


Figure 9: Examples of the implied prior on the differential causal effect using the Bayesian projections algorithm IV-TETRAD^{++} with three choices of hyperparameters ($\alpha_{cut} = 10, \tau = 0.01$), ($\alpha_{cut} = 3, \tau = 0.01$) and ($\alpha_{cut} = 10, \tau = 0.001$).

(a) (b)

Figure 10: (a) The posterior distribution when a single value is chosen as the output of IV-TETRAD^{++}. (b) The resulting posterior where we uniformly sample one of the elements of the equivalence class.

As expected, decreasing these two hyperparameters makes the prior narrower. At the same time, since the effect is given by the ratio of covariance entries, we expect the implied prior to be heavy-tailed. For illustration purposes, we proceed to analyze the Sachs et al. data by choosing ($\alpha_{cut} = 10, \tau = 0.01$) as the prior configuration.

5.3.3 Results

Figure 10(a) shows the resulting posterior after running MCMC for the mixture of Gaussians for 10,000 iterations and thinning it down to 1000 samples. The evidence that 5 mixture components is enough is given by the fact that the component of smallest posterior probability was assigned almost zero mass. The figure illustrates the difficulty of the problem and

why a single point estimate might not be a good summary of the outcome even in the case where a single causal effect is returned.

More interestingly, the Bayesian approach allows us to generate posteriors over equivalence classes in a relatively simple way, without resorting to potentially uninformative summaries based on bounds. This however requires subject matter information, as the data cannot distinguish the elements in an equivalence class. Following the philosophy of Richardson et al. (2011), we separate priors for elements which are informed by the data (equivalence class) from priors for elements which cannot be distinguished (the choice *within* the equivalence class, given the equivalence class). Figure 10(b) shows the posterior distribution that, for each sample m of the Markov chain, generates a sample causal effect by sampling uniformly at random from the elements in the corresponding equivalence class of sample m. That is, the extra information here is the uniform prior, which may be taken as a default choice. In principle, another prior can be used. For instance, if it is agreed that the choice should be made based, for instance, on a distribution that assigns mass in a way that is inversely proportional to the magnitude of each element in the class (this assumes that smaller effects are more likely than large effects). In any case, the important lesson is the understanding that this final component of the posterior is independent of the data given the equivalence class.[13] The conclusion from Figure 10(b) is that the bimodality is explained not only by the data, but also by the indeterminacy of the solution, in contrast to the bimodality found in Figure 8, which is an artefact of the sampling distribution of the corresponding estimators.

6. Related Work

The notion of "equivalence class of causal effects" is not new, even if not previously named as such. Hoyer et al. (2008) discuss how causal effects in LiNGAM models can be partially identified if the number of latent confounders is known. Their method also returns sets of causal effects, but without any need for further covariates and instruments. However, the size of the equivalence class of causal effects grows rapidly with the number of assumed latent variables and it is unclear how to determine the number of unmeasured confounders. Maathuis et al. (2009) present extensions of the PC algorithm which return sets of causal effects that follow from different members of an equivalence class of DAGs compatible with the observable independence constraints.

Didelez and Sheehan (2007) present a survey on instrumental variables from the point of view of applications in Mendelian randomization. A complementary method to sisVIVE based on similar assumptions, but performing estimation by the reweighted median of covariance ratios, is discussed by Bowden et al. (2016). The difficulty of estimating effects with weak instruments is well-known in the statistics literature. A review that covers some background on the estimation with weak instruments is provided by Burgess et al. (2017).

A different way of inducing "approximate" instrumental variables was introduced by Silva and Evans (2016). In that case, only (approximate) independence constraints are exploited. The same machinery in principle could include approximate tetrad constraints, although

13. This idea could also be adapted to the case where the empty set is returned in some of the MCMC samples: the posterior would be a mixture model with positive mass on the empty set and the remaining mass spread over the values found.

further research on that would be necessary. The problem of equivalence class of causal effects is also present in that approach. In such a scenario, however, there are infinitely many alternatives, which can be represented as an interval. The width of the interval is typically large and uninformative in classical bounding methods for instrumental variables (Didelez and Sheehan, 2007), but the approach introduced by Silva and Evans (2016) allows for the introduction of stronger assumptions as a way of reducing the size of the equivalence class. This borrows some concepts from earlier work such as the one Ramsahai (2012).

The use of tetrad constraints for testing the validity of particular edge exclusions in linear causal models has a long history, dating back at least to Spearman (1904). Although the generalizations discussed by Sullivant et al. (2010) were presented in the context of Gaussian models, this distributional assumption is not necessary, with their rank constraint results exploited even in the context of partially non-linear models by Spirtes (2013). More recently, tetrad constraints have been used in the discovery of latent variable model structure (Silva et al., 2006; Spirtes, 2013), where structures such as Figure 2(c) emerge but no direct relationships among observables (such as $X \to Y$) are discoverable. The combination of tetrad constraints and non-Gaussianity assumptions has been exploited by Shimizu et al. (2009), again with the target being relationships among latent variables. Tetrad tests for the validity of postulated IVs were discussed by Kuroki and Cai (2005).

The literature on learning algorithms allowing for latent variables has been growing steadily, including the Fast Causal Inference algorithm of Spirtes et al. (2000) and more recent methods that exploit constraints other than independence constraints (Tashiro et al., 2014; Nowzohour et al., 2015), but none of these methods allow for the estimation of the causal effect of X and Y when there is an unblocked unmeasured confounder between them. Phiromswad and Hoover (2013) introduced an algorithm for IV discovery, but it does not take into account unidentifiability issues that can be solved by exploring constraints other than covariance matrix constraints. It also returns equivalence classes of graphs and requires searching for multiple causal effects at the same time, contrary to our goal of focusing on a given causal effect λ_{yx}.

7. Conclusion

Finding instrumental variables is one of the most fundamental problems in causal inference. To the best of our knowledge, this paper provides the first treatment on how this can be systematically achieved by exploiting rank constraints and clarifying to which extent an equivalence class of solutions remains. We then proceeded to show how non-Gaussianity can be exploited in a pragmatic way, by adapting a state-of-the-art algorithm. Finally, we illustrated how empirical improvement can be obtained.

We expect that theoretical challenges in instrumental variable discovery can be further tackled by building on the findings shown here. In particular, as also hinted by Kang et al. (2016), some of the ideas here raised extend to non-linear (additive), heterogeneous effects and binary models. Methods developed by Peters et al. (2014) can potentially provide a starting point on how to allow for non-linearities in the context of instrumental variables. As discussed by Spirtes (2013), linearity is only really needed "downstream" of the choke point: that is, it would be enough that only the structural equation for outcome Y is

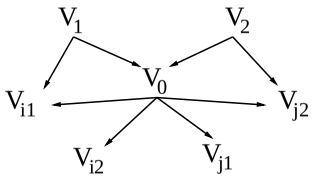

Figure 11: The graph used in Appendix A for more complex examples of t-separation. We are interested on making claims about this structure by observing some, but not all, of its vertices.

linear. Theoretical details need to be sorted out, but IV-TETRAD$^+$ should in principle be practically applicable to non-linear models with linearity for Y only.

More sophisticated graphical criteria for the identification of causal effects in linear systems were introduced by Brito and Pearl (2002). Further work has led to rich graphical criteria to identify causal effects in confounded pairs (Foygel et al., 2011), going beyond the IV criteria discussed here. This opens up the possibility elaborated discovery algorithms where back-door blocking (Entner et al., 2012) and the methods in this paper cannot provide a solution. How to perform this task in a computationally and statistically tractable way remains an open question.

Code for all experiments is available at `http://www.homepages.ucl.ac.uk/~ucgtrbd/code/iv_discovery`.

Acknowledgments

We thank Robin Evans, Peter Spirtes and Kun Zhang for several useful discussions. Part of the discussions were possible by travel funding supporting the attendance of RS and SS in the Short Thematic Program "Statistical Causal Inference and Applications to Genetics" organized and sponsored by the Centre the Recherches Mathématiques, University of Montreal, Canada. RS's visit was also partially supported by a grant from Adobe Research. RS also acknowledges travel support from the Center for Causal Discovery in Pittsburgh, PA, where part of the discussions that originated this paper took place. This work was partially supported by the Alan Turing Institute under the EPSRC grant EP/N510129/1.

This manuscript has strongly benefited from suggestions and clarification questions raised by three anonymous reviewers.

Appendix A. More about T-separation

We start with a few more examples of t-separation. Consider Figure 11. Vertex V_0 does not d-separate V_{i1} from V_{j2}. However, *pair* $(V_0; V_0)$ t-separates V_{i1} from V_{j2}. To see that, let us list all three (simple) treks between V_{i1} and V_{j2}:

- $(P_1^{[1]}; P_2^{[1]}) \equiv (V_{i1} \leftarrow V_1; V_1 \rightarrow V_0 \rightarrow V_{j2})$
- $(P_1^{[2]}; P_2^{[2]}) \equiv (V_{i1} \leftarrow V_0; V_0 \rightarrow V_{j2})$
- $(P_1^{[3]}; P_2^{[3]}) \equiv (V_{i1} \leftarrow V_0 \leftarrow V_2; V_2 \rightarrow V_{j2})$

In the first trek, V_0 is contained in $P_2^{[1]}$; in the second case, both paths in the trek satisfy the criterion of containing V_0; in the final trek, $P_1^{[3]}$ plays this role. Notice that $(V_0; \emptyset)$ does not t-separate V_{i1} from V_{j2} (first trek remains "unblocked") and neither does $(\emptyset; V_0)$ (third trek remains "unblocked").

That V_{i1} is t-separated from V_{j2} given $(V_0; V_0)$, however, brings out no useful implication about the cross-covariance matrix $\Sigma_{\mathbf{AB}}$ of ($\mathbf{A} \equiv \{V_{i1}\}$, $\mathbf{B} \equiv \{V_{j2}\}$): all it says is that $rank(\Sigma_{\{V_{i1}\}\{V_{j2}\}}) \leq 2$, which is a vacuous claim. We may attempt to introduce V_0 in the two sets $\mathbf{A}$ and $\mathbf{B}$, assuming V_0 is observable, as this is compatible with the notion that V_0 can t-separate itself from itself. Unfortunately, there is nothing to be gained, as $rank(\Sigma_{\{V_{i1}V_0\}\{V_{j2}V_0\}}) \leq 2$, which is again a vacuous claim.

Pair $(\emptyset; V_0)$ does t-separate V_{i1} and V_{i2} with a testable implication $rank(\Sigma_{\{V_{i1}V_0\}\{V_{i2}V_0\}}) \leq 1$, but this does not provide anything useful to a structure learning algorithm, as d-separation of V_{i1} and V_{i2} given V_0 can be tested directly instead.

Consider now $\mathbf{A} \equiv \{V_{i1}, V_{i2}\}$, $\mathbf{B} \equiv \{V_{j1}, V_{j2}\}$. To be useful, we need a conditioning pair $(\mathbf{C_A}; \mathbf{C_B})$ where $|\mathbf{C_A}|+|\mathbf{C_B}| \leq 1$. Following the previous examples, it should be clear that no such a pair will exist out of the given variables. However, we could consider de-activating the path $V_{i1} \leftarrow V_1 \rightarrow V_0$ by considering the *partial* cross-covariance matrix of $\{V_{i1}, V_{i2}\}$ against $\{V_{j1}, V_{j2}\}$ given V_1. The Trek Separation Theorem for DAGs, however, says nothing explicit about partial cross-covariances. Sullivant et al. (2010) present versions of the theorem for some classes of DAGs under conditioning, but not in a completely general way. Theorem 2.17 of Sullivant et al. (2010) assumes that conditioning can be encoded by undirected edges so that no vertices adjacent to an undirected edge can also be at the arrowhead endpoint of a directed edge. Although one can show this does not affect the Markov properties of general DAGs under conditioning, as ancestral graphs (Richardson and Spirtes, 2002) are a special case of this, it is not immediately obvious how this affects parametric constraints.

Fortunately, even in the conditioning case we do not need to consider anything but DAGs: simply introduce the conditioning variables in both sets $\mathbf{A}$ and $\mathbf{B}$. In this example, define $\mathbf{A} \equiv \{V_{i1}, V_{i2}, V_1\}$ and $\mathbf{B} \equiv \{V_{j1}, V_{j2}, V_1\}$. Then it is not hard to verify that $(V_0; V_1)$ t-separates $\mathbf{A}$ from $\mathbf{B}$ (recall that V_1 "t-separates itself from itself" using the conditioning set pair $(\emptyset; V_1)$). Cross-covariance $\Sigma_{\mathbf{AB}}$ is rank-deficient, which means its determinant is zero. Because its determinant can be written as $\sigma_{11}(\sigma_{i1j1.1}\sigma_{i2j2.1} - \sigma_{i1j2.1}\sigma_{i2j1.1})$ and we assume $\sigma_{11} \neq 0$, the (conditional) tetrad constraint will hold.

The relationship between t-separation and d-separation is given by Theorem 2.11 of Sullivant et al. (2010). Namely, d-separation between set $\mathbf{A}$ and set $\mathbf{B}$ given set $\mathbf{C}$ holds if and only if we can partition $\mathbf{C}$ as two sets $\mathbf{C_A}$ and $\mathbf{C_B}$ such that $(\mathbf{C_A}; \mathbf{C_B})$ t-separates $\mathbf{A} \cup \mathbf{C_A}$ from $\mathbf{B} \cup \mathbf{C_B}$. That is, any d-separation can be cast as some type of t-separation. However, as t-separation of $\mathbf{A} \cup \mathbf{C_A}$ from $\mathbf{B} \cup \mathbf{C_B}$ implies t-separation of $\mathbf{A}$ from $\mathbf{B}$, this allows us to derive rank constraints using the marginal distribution of $\mathbf{A} \cup \mathbf{B}$ only, unlike the conditional independence constraints directly implied by conditioning on $\mathbf{C}$. If $\mathbf{C}$ contains

hidden variables, this is another way of understanding how t-separation implies testable constraints that cannot be achieved directly by testing for conditional independencies.

Appendix B. Proofs

We being by proving the main result of Section 3.2.

Proof of Theorem 8. If $(W_i, W_j, \mathbf{Z})$ satisfies the Graphical Criteria, then there should be no active path between any element of $\{W_i, W_j\}$ and Y that does not include X. Hence, neither point (i) nor point (ii) in the theorem statement are possible.

Assume now that $(W_i, W_j, \mathbf{Z})$ does not satisfy the Graphical Criteria. Then there must be at least one active path, conditioned on $\mathbf{Z}$, connecting some $W \in \{W_i, W_j\}$ to Y which does not contain X. Otherwise, if all active paths contained X, then they would all be interrupted by the removal of edge $X \rightarrow Y$, as all other edges adjacent to X are into X, and X is not in the conditioning set $\mathbf{Z}$.

Suppose one of these active paths is a trek T, which should not contain any member of $\mathbf{Z}$ or otherwise it would not be active. $\{W_i, W_j, \mathbf{Z}\}$ must be t-separated from $\{X, Y, \mathbf{Z}\}$ by some $(\mathbf{C_A}; \mathbf{C_B})$, as implied by Theorem 3 and the conditional tetrad constraint detected in Line 9. As argued in the discussion leading to the definition of conditional choke point, $\mathbf{C_A} \cup \mathbf{C_B} = \mathbf{Z} \cup \{V_0\}$ for some conditional choke point V_0 not in $\mathbf{Z}$. If there is some other trek that is active and contains no member of $\mathbf{Z} \cup \{V_0\}$, then this would imply the existence of another element of $\mathbf{C_A} \cup \mathbf{C_B}$ not in $\mathbf{Z} \cup \{V_0\}$, contrary to the fact that $|\mathbf{C_A}|+|\mathbf{C_B}| \leq |\mathbf{Z}|+1$. Hence, scenario (i) in the theorem statement will happen if we do not satisfy the Graphical Criteria and there exists an active trek between $\{W_i, W_j\}$ and Y.

Assume that there exists a active path C' with endpoints $W \in \{W_i, W_j\}$ and Y, and which contains at least one collider in $\mathbf{Z}$. Allowing this path to be non-simple, we have that all colliders in this path must be in $\mathbf{Z}$, and no non-colliders are in $\mathbf{Z}$. Let $Z_1, Z_2, \ldots, Z_K$ be the colliders in C' as we move from W towards Y. Then the trek $(P_1^K; P_2^K)$ linking Z_K to Y is such that Z_K is the sink of P_1^K and hence $Z_K \in \mathbf{C_A}$. Likewise, Z_1 will be the sink of P_2^1 in the trek $(P_1^1; P_2^1)$ between W and Z_1, so that $Z_1 \in \mathbf{C_B}$. As we move from Z_1 towards Z_K in C', we will be forced to make one element of $\mathbf{Z}$ to belong to both $\mathbf{C_A}$ and $\mathbf{C_B}$, as and we cannot have all consecutive treks $Z_i \leftarrow \cdots \rightarrow Z_{i+1}$ such that Z_i and Z_{i+1} are both only in $\mathbf{C_A}$ or only in $\mathbf{C_B}$. This is illustrated in Figure 12. Therefore, there exists some $Z' \in \mathbf{C_A} \cap \mathbf{C_B}$. Since $|\mathbf{C_A}| + |\mathbf{C_B}| \leq |\mathbf{Z}| + 1$, we cannot have both (i) and (ii) being true, as Z' must be counted twice and $\mathbf{Z} \subseteq \mathbf{C_A} \cup \mathbf{C_B}$ (as we have seen, if there is a conditional choke point then $\mathbf{C_A} \cap \mathbf{C_B} = \emptyset$). Moreover, we cannot have another path C'' satisfying the properties of C' but which does not contain Z', as the existence of another $Z'' \neq Z'$ would again violate $|\mathbf{C_A}| + |\mathbf{C_B}| \leq |\mathbf{Z}| + 1$.

As all active paths connecting $\{W_i, W_j\}$ to Y must be either treks or paths where all colliders are ancestors of $\mathbf{Z}$, then these two cases cover all possibilities. □

We now proof the other core result from Section 3.3:

Proof of Theorem 15. By the same reasoning of Theorem 8, passing Line 9 leaves us with the two possible scenarios of that theorem. However, scenario (ii) cannot take place since, by Theorem 13 and Line 15, there must be no active non-directed paths between $\{W_i, W_j\}$

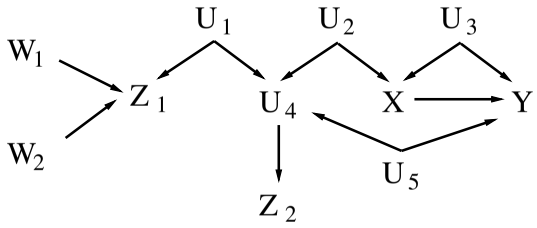

Figure 12: Path $W_1 \to Z_1 \leftarrow U_1 \to U_4 \to Z_2 \leftarrow U_4 \leftarrow U_5 \to Y$ is an example of a (non-simple) active path from some vertex in $\{W_1, W_2\}$ to Y given $\mathbf{Z} \equiv \{Z_1, Z_2\}$ where both Z_1 and Z_2 are colliders in this path. Here, Z_2 is on the "left side" of the trek $Z_2 \leftarrow U_4 \leftarrow U_5 \to Y$ than links an element of $\mathbf{A} \equiv \{W_1, W_2, Z_1, Z_2\}$ to $\mathbf{B} \equiv \{X, Y, Z_1, Z_2\}$. Z_1 is on the "right side" of the trek $W_1 \to Z_1$ that links an element of $\mathbf{A}$ to an element of $\mathbf{B}$. Trek $Z_1 \leftarrow U_1 \to U_4 \to Z_2$ also links en element of $\mathbf{A}$ to an element of $\mathbf{B}$. If we use Z_1 to block this trek, then Z_1 is now on the "left side" of a trek. If we use Z_2, then Z_2 is now on the "right side" of a trek. Hence, in order to t-separate $\mathbf{A}$ from $\mathbf{B}$, we need either $(\{Z_2\}; \{Z_1, Z_2\})$ or $(\{Z_1, Z_2\}; \{Z_1\})$, both of size 3 even though only two vertices are used.

and Y. For the same reasons, choke point V_0 cannot lie on an active non-directed path between $W \in \{W_i, W_j\}$ and Y, nor it can be in an active back-door path with endpoints in W and Y. As Y is not an ancestor of any vertex, V_0 must be a descendant of $\{W_i, W_j\}$ and an ancestor or Y. What is left is showing that V_0 is also an ancestor of X.

There must be an active path between W and X given $\mathbf{Z}$ by linear faithfulness and Line 6 of the algorithm. Assume V_0 is not an ancestor of X. There must be an active path between W and X which is not a trek or otherwise it would be blocked by $\mathbf{Z} \cup \{V_0\}$. However, using the same argument as in Theorem 8, this path with colliders in $\mathbf{Z}$ would also require a member of $\mathbf{Z}$ to be in both sets of the conditioning set pair $(\mathbf{C_A}; \mathbf{C_B})$, contradicting that $|\mathbf{C_A}| + |\mathbf{C_B}| \leq |\mathbf{Z}| + 1$. Therefore, this makes V_0 also an ancestor or X, fulfilling all requirements of a downstream choke point. □

The result for Theorem 13 depends on this standard theorem (Darmois, 1953; Skitovitch, 1953):

Theorem 19 (Darmois-Skitovitch Theorem) *Let $e_1, \ldots, e_n$ be independent random variables, $n \geq 2$. Let $v_1 = \sum_{i=1}^{n} \alpha_i e_i$, $v_2 = \sum_{i=1}^{n} \beta_i e_i$ for some coefficients $\{\alpha_i\}$, $\{\beta_i\}$. If v_1 and v_2 are independent, then those e_j for which $\alpha_j \neq 0$, $\beta_j \neq 0$ are Gaussian.*

The idea is that if we assume $\{e_i\}$ are not Gaussian, $\{V_1, V_2\}$ share a common source if and only if they are dependent. Shimizu et al. (2006) and Entner et al. (2012) present a deeper discussion on how this theorem is used in causal discovery.

For the main results, we will assume that particular algebraic (polynomial) identities implied by the model graph do not vanish at the particular parameter values of the given model (which we called "almost everywhere" results in the theorem). We will in particular consider ways of "expanding" the structural equations of each vertex according to *exogenous* variables, that is, any variable which is either an error term or latent variable (assuming without loss of generality that latent variables have no parents).

For each vertex V_k in the model, and each exogenous ancestor E_m of V_k, let $\mathcal{P}_{km}$ be the set of all directed paths from E_m to V_k. For each path $p \in \mathcal{P}_{km}$, define $\phi_{kmp} = \prod_j \lambda_{jj'}$, the product of all coefficients along this path for $V_j \in \mathbf{V} \cap p$ where $V_{j'} = p \cap par_{\mathcal{G}}(j)$ (that is, $V_{j'}$ is the parent of V_j in this path. We multiply coefficients following a sequence $E_m \to \cdots \to V_{j'} \to V_j \to \cdots \to V_k$). From this,

$$V_k = \sum_{E_m \in \mathcal{A}_{\mathcal{G}}(k)} \sum_{p \in \mathcal{P}_{km}} \phi_{kmp} E_m, \tag{5}$$

where $A_{\mathcal{G}}(k)$ is the set of exogenous ancestors of V_k, where for $E_m = e_k$ we have $\phi_{kmp} \equiv 1$ and path p is given by the single edge $e_k \to V_k$. We refer to the idea of expansion a few times in the proofs as a way of describing how models can be written as polynomial functions of the parameters $\theta_{\mathcal{G}} = \{\lambda_{ij} \mid V_j \in par_{\mathcal{G}}(i)\} \cup \{\omega_i\}$.

Overall, for a LiNGAM model $\mathcal{M}$ with DAG $\mathcal{G}$, we denote by $\mathcal{X}_{\mathcal{G}}$ the set of exogenous variables of $\mathcal{M}$, and by the *expanded graph* of $\mathcal{M}$ the graph $\mathcal{G}$ augmented with the error terms and the corresponding edges $e_i \to V_i$ for all observable vertices V_i in $\mathcal{G}$.

The main result used in the proof of Theorem 13 comes from the following Lemma. Notice that the non-Gaussianity assumption and the Darmois-Skitovitch Theorem are not necessary for its proof.

Lemma 20 *Let $\mathbf{O} \cup \mathbf{U}$ be the set of variables in a zero-mean LiNGAM model $\mathcal{M}$ with graph $\mathcal{G}$, where $\mathbf{U}$ are the latent variables of the model. Let $\mathbf{O}_{\setminus i} \equiv \mathbf{O} \setminus \{O_i\}$ for any $O_i \in \mathbf{O}$. Let $r_i \equiv O_i - \mathbf{a}^{\intercal}\mathbf{O}_{\setminus i}$ be the residual of the least-squares regression of O_i on $\mathbf{O}_{\setminus i}$, with $\mathbf{a}$ being the corresponding least-squares coefficients. Then, almost everywhere, r_i can be written as a linear function of the exogenous variables of $\mathcal{M}$, $r_i = \sum_{E_m \in \mathcal{X}_{\mathcal{G}}} c_m E_m$, where $c_m \neq 0$ if and only if O_i is d-connected to E_m given $\mathbf{O}_{\setminus i}$ in the expanded graph of $\mathcal{M}$.*

Proof of Lemma 20. Without loss of generality, assume that each latent variable in $\mathbf{U}$ has no parents. We will sometimes use X_k as another representation of any particular model variable (observable, latent or error term), with the index k indicating particular variables in $\mathbf{O} \cup \mathbf{U}$ and error terms, depending on the context.

Choose some $O_i \in \mathbf{O}$. One way of obtaining r_i is by first performing least-squares regression of each model variable X_k on O_j, for some $O_j \neq O_i$ in $\mathbf{O}$, and calculating residuals $X_k^{(1)}$. Among model variables in $\mathbf{O}$, define $\mathbf{O}^{(1)}$ as the set of all residuals $\{O_k^{(1)}\}$, $k \neq j$. That is, the superscript (1) here denotes that we have regressed all observable variables on one arbitrary observable $O_j \neq O_i$, collecting the residuals $O_k^{(1)}$ of the regression of O_k on O_j for all variables other than O_j. We will repeat the process while incrementing the superscript and removing one element out of $\mathbf{O}^{(m)}$ at a time for $m = 2, 3, \ldots, n-1$, where n is the size of $\mathbf{O}$. This is done by the process of picking some $O_{j'}^{(1)} \in \mathbf{O}^{(1)} \setminus \{O_i^{(1)}\}$ and regressing

$\{O^{(1)}_{k\neq j'}\}$ on $O^{(1)}_{j'}$ to obtain $\mathbf{O}^{(2)}$, iterating until we are left with $\mathbf{O}^{(n-1)}$ containing the single element $O^{(n-1)}_i$, resulting in $O^{(n-1)}_i = r_i$. The elimination sequence can be arbitrary.

Let O_j be a vertex in $\mathbf{O}_{\setminus i}$. Let λ_{km} be the structural coefficient between O_k and any $X_m \in \mathbf{O} \cup \mathbf{U}$. We define $\lambda_{km} \equiv 0$ if X_m is not a parent of O_k in $\mathcal{G}$. Since

$$O_k = \lambda_{kj} O_j + \sum_{X_m \in par_{\mathcal{G}}(k) \setminus O_j} \lambda_{km} X_m + e_k,$$

we have

$$\sigma_{kj} = \lambda_{kj}\sigma_{jj} + \sum_{X_m \in par_{\mathcal{G}}(k) \setminus O_j} \lambda_{km}\sigma_{mj} + \sigma_{e_k j},$$

where $\sigma_{e_k j}$ is the covariance of e_k and O_j and σ_{mj} here represents the covariance of X_m and O_j. Dividing both sides by σ_{jj} implies

$$a^{(1)}_{kj} = \lambda_{kj} + \sum_{X_m \in par_{\mathcal{G}}(k) \setminus O_j} \lambda_{km} a^{(1)}_{mj} + a^{(1)}_{e_k j}, \tag{6}$$

where $a^{(1)}_{e_k j}$ is the least-squares regression coefficient of e_k on O_j. This means $O^{(1)}_k = O_k - a^{(1)}_{kj} O_j$ can be written as

$$O^{(1)}_k = \sum_{X_m \in par_{\mathcal{G}}(k) \setminus O_j} \lambda_{km} X^{(1)}_m + e^{(1)}_k \tag{7}$$

with $X^{(1)}_m$ and $e^{(1)}_k$ defined analogously.

We can iterate this process until we are left with r_i:

$$r_i = \sum_{U_k \in par_{\mathcal{G}}(i) \cap \mathbf{U}} \lambda_{ik} U^{(n-1)}_k + e^{(n-1)}_i. \tag{8}$$

Variable $U^{(n-1)}_k$ is the residual of the regression of U_k on $\mathbf{O}_{\setminus i}$, similarly for $e^{(n-1)}_i$.

What we will show next is that within (8) each $U^{(n-1)}_k$ and $e^{(n-1)}_i$ can be expanded as polynomial functions of $\theta_{\mathcal{G}}$ and $\mathcal{X}_{\mathcal{G}}$, and the end result will contain non-vanishing monomials that are a (linear) function of only the exogenous variables E_m which are d-connected to O_i given $\mathbf{O}\setminus O_i$ in the expanded graph of $\mathcal{M}$. Since the monomials cannot vanish except for a strict subset of lower dimensionality than that of the set of possible $\theta_{\mathcal{G}}$, the result will hold almost everywhere.

Since we are free to choose the elimination ordering leading to r_i, as they all lead to the same equivalent relation (8), let us define it in a way that a vertex can be eliminated at stage t only when its has no ancestors in $\mathbf{O}^{(t-1)}$ (where $\mathbf{O}^{(0)} \equiv \mathbf{O}_{\setminus i}$). We will define the meaning of the ancestral relationship for elements of $\mathbf{O}^{(t)}$ shortly in terms of DAGs $\mathcal{G}^{(t)}$, but for $t = 0$ it is the one implied by the expanded version of $\mathcal{G}$.

For $t = 1$, the only exogenous variables which will have a non-zero coefficient multiplying O_j in the least-squares regression are the parents of O_j in the expanded graph, since O_j has

no other ancestors.[14] Let $U^{(1)}_k$ be the residual of some latent parent of O_j,

$$U^{(1)}_k = U_k - a_{kj} \left(\sum_{E_m \in \mathcal{A}_{\mathcal{G}}(j)} \sum_{p \in \mathcal{P}_{jm}} \phi_{jmp} E_m \right), \tag{9}$$

where $\phi_{jmp} \equiv \lambda_{jm}$ if E_m is a latent variable, or 1 if $E_m = e_j$. Moreover, $a_{kj} = \lambda_{jk}\omega_{kk}/\sigma_{jj}$, where ω_{kk} is the variance parameter of U_k and σ_{jj} is a polynomial function of $\theta_{\mathcal{G}}$. We can multiply both sides of the equation above by σ_{jj} (as well all equations referring to any $O^{(1)}_k$ or $X^{(1)}_m$ such as (7)) to get a new system of variables that is polynomial in $\theta_{\mathcal{G}}$. We will adopt this step implicitly and claim that from (9) we have that $U^{(1)}_k$ can be expanded as parameters that are polynomial functions of $\theta_{\mathcal{G}}$. Moreover, it is clear from (9) that there will be at least one non-vanishing monomial containing each E_m. In what follows, we refer to any expression analogous to (9) as the *expansion* of $U^{(t)}_k$ for $t = 1, 2, \ldots, n-1$.

We define a DAG $\mathcal{G}^{(1)}$ with vertices $\{X^{(1)}_m\}$, where the children of $X^{(1)}_m$ are defined as all and only the $O^{(1)}_k$ such that X_m is a parent of O_k in the original extended graph of the model. That is, $\mathcal{G}^{(1)}$ is the extended graph over residuals after the first regression. The respective model $\mathcal{M}^{(1)}$ is given by equations of type (7) with parameters coming from $\theta_{\mathcal{G}}$.[15]

For any $t > 1$, let $O^{(t)}_j$ be the vertex being eliminated. Each $U^{(t)}_k$ in which $U^{(t-1)}_k$ is a parent of $O^{(t-1)}_j$ in $\mathcal{G}^{(t-1)}$ will be a polynomial function of $\theta_{\mathcal{G}}$ and a linear function of the union of the exogenous variables present in the expansion of each parent of $O^{(t-1)}_j$: the expansion analogous to (9) in the new model will always introduce new symbols $\lambda_{j\star}$ into existing monomials, or create new monomials with e_j, as vertex $O^{(t-1)}_j$ had no eliminated descendants up to iteration t. As such, no exogenous variable will be eliminated from the algebraic expansion of the respective $U^{(t)}_k$.

Finally, the expansion of $\lambda_{ik}U^{(n-1)}_k$ in (8) will not cancel any monomial in the expansion of some other $\lambda_{ik'}U^{(n-1)}_{k'}$: since U_k and $U_{k'}$ are both parents of O_i, no monomial in the expansion of U_k can differ from a monomial in the expansion of $U_{k'}$ by a factor of $\lambda_{ik}\lambda_{ik'}$. So (8) will depend algebraically on the union of the exogenous terms leading to each $U^{(n-1)}_k$.

To prove the Lemma, we start by pointing out that $U^{(n-1)}_k$ will have a latent/error parent of some O_j in its expansion if and only if there is at least one sequence of vertices $(O_c, \ldots, O_j)$ where O_c is an observable child of U_k and any two consecutive elements in this sequence have at least one common latent parent in $\mathcal{G}$ (the sequence can be a singleton, $O_c = O_j$). To see this, notice that the different $U^{(t)}_k$ form an equivalence relation: each $U^{(t)}_k$ with a $O^{(t-1)}_j$ child which is being eliminated at iteration t will include into its expansion the exogenous variables found in the expansion of the other parents of $O^{(t-1)}_j$. This partitions $\mathbf{O}_{\setminus i}$ into sets in which each vertex O_j can "reach" some other vertex O_k by first moving to some $O_{j'}$ which shares a latent parent with O_j and which can "reach" O_k. The latent parents of $\mathbf{O}$ are then partitioned according to their observed children.

14. Assuming O_j is not a child of O_i. In this case, without loss of generality we assume that the parents of O_i are added to the parents of O_j, and remove O_i from the model at any iteration t.
15. To be more precise, polynomial functions of such parameters, as we are implicitly multiplying each equation by σ_{jj}.

To finalize the proof, suppose O_i is d-separated from a latent/error parent E_m of O_j given $\mathbf{O}\backslash O_i$. This happens if and only if all latent parents of O_i (and e_i) are d-separated from E_m given $\mathbf{O}\backslash O_i$. Let U_k be a latent parent of O_i (or its error term). Then $U_k^{(n-1)}$ cannot have E_m in its expansion. If this was the case, by the previous paragraph U_k would be d-connected to all latent parents of O_j, meaning O_i would be d-connected to them. This implies $c_m = 0$. Conversely, suppose O_i is d-connected to the error term or a latent parents of O_j given $\mathbf{O}\backslash O_i$. Then again by the previous paragraph, for any latent parent U_k of O_i, $U_k^{(n-1)}$ will have the latent parents of O_j as terms in its expansion, implying $c_m \neq 0$ almost everywhere. □

We can now prove Theorem 13.

Proof of Theorem 13. Considering the system for $\{O_i, Y\} \cup \mathbf{Z}$, we can represent the model in an equivalent way where all other variables are latent variables, and all latent variables are exogenous. Applying Lemma 20 to both r_i and r_y, and by Theorem 19, these variables will be dependent if and only if they are a non-trivial linear function of at least one common exogenous variable E_m in the model. Again by Lemma 20, this happens if and only if O_i is d-connected to E_m given $\mathbf{Z}$, and Y is d-connected to E_m given O_i and $\mathbf{Z}$. If Y is d-connected to E_m given $\mathbf{Z}$ only, we can create an active non-directed path between O_i and Y given $\mathbf{Z}$ by the concatenation of the (O_i, E_m) path with (Y, E_m) path: since E_m is exogenous, the path is non-directed as it should include the subpath $V \leftarrow E_m \rightarrow V'$ for some V, V'. If Y is not d-connected to E_m given $\mathbf{Z}$ only —that is, we must condition on O_i also to d-connect them— then Y must be d-connected to O_i given $\mathbf{Z}$ by a path that is into O_i. This path is non-directed as Y is not an ancestor of O_i by assumption, and the claim again follows. □

Remarks: The assumptions are stronger than, for instance, the ones used in the proofs of Tashiro et al. (2014). A closely related result in that paper is its Lemma 2, a result identifying the dependence between the residual of the regression of a variable on its children. It does not use any variation of the faithfulness assumption. This is because, in their context, it is enough to detect the dependence between the residual and *some* children. So if some path cancellations take place, some other path cancellations cannot occur. But we need the dependence of our r_i and every relevant error term, because we cannot claim that r_i depends on *some* error terms or latent variables, while r_y depends on *some* error terms or latent variables, if these two sets do not overlap. Although some of the ideas by Tashiro et al. (2014) could be used in our context to build partial models and from them deduce instrumental variables, it goes against our framework of solving a particular prediction problem (causal effect of a target treatment-outcome) directly, instead of doing it by recovering parts of a broader causal graph.

Finally, we have not provided an explicit discussion on how to validate the non-Gaussianity assumption by testing the non-Gaussianity of the residuals, as done by Entner et al. (2012). Or, more precisely, showing which assumptions are necessary so that testing non-Gaussianity of the residuals is equivalent to testing non-Gaussianity of the error terms. This is left as future work.

Algorithm 5 IV-TETRAD^{++}

Input: $\mathcal{D}$, a sample from the joint distribution of random variables $\mathbf{O} \cup \{X, Y\}$; K, number of instruments to consider; S, the number of mixture components; M, the number of MCMC iterations; π, a prior for a mixture of Gaussian model for $\mathbf{O} \cup \{X, Y\}$ with M components; α_{cut} and τ, two threshold parameters
Output: a distribution over equivalence classes of differential causal effect of X on Y
Initialize $\mathcal{C}_{Bayes}$ as the empty set
Run a MCMC algorithm to obtain M samples from the posterior distribution of a Bayesian mixture of S Gaussians model with data $\mathcal{D}$ and prior π
for $m = 1, 2, \ldots, M$ **do**
  Let $\Sigma^{(m)}$ be the m-th MCMC sample of the covariance matrix of $\mathbf{O} \cup \{X, Y\}$
  Let $\hat{\lambda}_i \leftarrow \sigma^{(m)}_{w_i y.\mathbf{O}_{\backslash i}} / \sigma^{(m)}_{w_i x.\mathbf{O}_{\backslash i}}$ for each $W_i \in \mathbf{O}$
  Discard all $\hat{\lambda}_i$ such that $|\hat{\lambda}_i| > \alpha_{cut}$
  Initialize $\mathcal{C}^{(m)}$ as the empty set, and $\mathbf{W}$ as $\mathbf{O}$
  while $|\mathbf{W}| \geq K$ **do**
    Sort $\mathbf{W}$ as $W^{(1)}, \ldots, W^{(|\mathbf{W}|)}$ according to the corresponding $\{\hat{\lambda}\}$
    Find $j \in \{1, 2, \ldots, |\mathbf{W}|\}$ that minimizes $\textsc{ScoreTetrads}^{\star}(W^{(j:j+K-1)}, \mathbf{O}, X, Y, \Sigma^{(m)})$
    $\mathbf{W}_j \leftarrow \textsc{ExpandTetrads}^{\star}(j, K, \mathbf{W}, \mathbf{O}, X, Y, \Sigma^{(m)})$
    if $\textsc{TestTetrads}^{\star}(\mathbf{W}_j, \mathbf{O}, X, Y, \Sigma^{(m)})$ **then**
      $\hat{\lambda}_{TSLS} \leftarrow \text{TSLS}^{\star}(\mathbf{W}_j, \mathbf{O}\backslash\mathbf{W}_j, X, Y, \Sigma^{(m)})$
      $\mathcal{C} \leftarrow \mathcal{C} \cup \hat{\lambda}_{TSLS}$
    end if
    $\mathbf{W} \leftarrow \mathbf{W}\backslash\mathbf{W}_j$
  end while
  Add set $\mathcal{C}^{(m)}$ as an element of $\mathcal{C}_{Bayes}$
end for
return $\mathcal{C}_{Bayes}$

Appendix C. A Bayesian Projections Variation of IV-TETRAD^{+}

Algorithm 5 is a method that relies on substituting hypothesis testing by a thresholding mechanism over posterior samples of an unconstrained distribution. This algorithm is referred to in Section 5.3.2.

TestTetrads* takes the correlation matrix implied by $\Sigma^{(m)}$ and returns false if

$$|\rho^{(m)}_{w_i x.\mathbf{O}_{\backslash i}} \rho^{(m)}_{w_j y.\mathbf{O}_{\backslash j}} - \rho^{(m)}_{w_i y.\mathbf{O}_{\backslash i}} \rho^{(m)}_{w_j x.\mathbf{O}_{\backslash j}}| > \tau.$$

ExpandTetrads* and TSLS* are just the straightforward variations of the original functions that take a covariance matrix instead of a data set as input.

Abstract

We introduce two algorithms that learn to classify Symbolic and Scalar Time Sequences (SSTS); an extension of multivariate time series. An SSTS is a set of *events* and a set of *scalars*. An *event* is defined by a symbol and a time-stamp. A *scalar* is defined by a symbol and a function mapping a number for each possible time stamp of the data. The proposed algorithms rely on temporal patterns called Graph of Temporal Constraints (GTC). A GTC is a directed graph in which vertices express occurrences of specific events, and edges express temporal constraints between occurrences of pairs of events. Additionally, each vertex of a GTC can be augmented with numeric constraints on scalar values. We allow GTCs to be cyclic and/or disconnected. The first of the introduced algorithms extracts sets of co-dependent GTCs to be used in a voting mechanism. The second algorithm builds decision forest like representations where each node is a GTC. In both algorithms, extraction of GTCs and model building are interleaved. Both algorithms are closely related to each other and they exhibit complementary properties including complexity, performance, and interpretability. The main novelties of this work reside in direct building of the model and efficient learning of GTC structures. We explain the proposed algorithms and evaluate their performance against a diverse collection of 59 benchmark data sets. In these experiments, our algorithms come across as highly competitive and in most cases closely match or outperform state-of-the-art alternatives in terms of the computational speed while dominating in terms of the accuracy of classification of time sequences.

Keywords: classification, temporal data, sequential data, graphical constraint models, decision forests, symbolic and scalar time sequences, supervised learning

1. Introduction

Learning to classify from labeled training data is one of the flagship capabilities of machine learning. Classification is commonly used to model flat-table data, and in applications involving more complex representations such as (time) sequences or graphs, the information is typically "featurized" or "flattened" to fit the flat-table representation paradigm, so that standard classification algorithms can be readily applicable. In the case of symbolic time-stamped sequences, popular featurization techniques include representing time-since-previous-occurrence of an event, or computing frequency of occurrence (or other statistics or measures) over moving windows of time. Perhaps, a preferable alternative is to instead use classification algorithms capable of natively handling the temporal aspects of time-stamped sequences.

In this paper we introduce two parametric algorithms that belong to that specialized class. Both algorithms are designed to classify Symbolic and Scalar Time Sequences (SSTS); an expressive extension of the Time Series (TS) representation that remedies some of its limitations. In particular, SSTS extends the standard TS model by allowing non-uniform and asynchronous sampling, representing instantaneous sparse events as well as dense numeric sequences, and scaling well to highly-dimensional (multi-channel) application scenarios.

Both algorithms rely on a simple but expressive graphical pattern model for SSTS data called Graph of Temporal Constraints (GTC). A GTC is a conjunction of three types of conditions: (1) Existence of an event, (2) Constraint on the timestamp difference between two given events, and (3) Inequality constraints on the numerical values of a numerical time sequence at a time defined by a given event. Each GTC defines a Boolean function on an SSTS (or a TS).

The first algorithm presented in this paper, called the "GTC-Set", bootstraps training SSTSs and extracts fitting GTCs to form an ensemble model. Unlike methods relying on extracting all possible patterns and then applying a feature selection, our first algorithm directly build a final set co-dependent discriminant GTCs (all extracted GTC are used and no feature selection is applied). For this reason, the set of build GTCs is much smaller than the set of all possible GTCs. At the end of the learning process, each thusly extracted GTC is used as an individual "voter" in the classification procedure.

The second algorithm, called "GTC-DF", builds a bootstrapped decision forest where the condition in each decision node is defined as a GTC. Path of inference through each decision tree in this forest depends on whether a query STSS fulfills the constraints of the particular node's GTC or not. Here again, the GTC attached to each node is directly constructed on-the-fly instead of being selected from a pool of existing GTCs.

To assess performance of the GTC-Set and the GTC-DF algorithms, we evaluated them on a diverse collection of 59 temporal sequence classification data sets (all of them are available publicly), and compared against 13 alternative algorithms found in the literature. Results show that our algorithms are highly competitive and in most cases outperform state-of-the-art considered alternatives, both in terms of computing speed and accuracy of classification. Our algorithms are especially competitive for unaligned temporal sequence data, i.e. the data for which the value of an observation at a particular time t has no distinct predictive value, or in other words: classification performance does not depend on when we start observing the data. We also show how the users can interpret learned models based on the proposed GTC representation. Interpretability is often an important factor that determines practical usability of machine learning solutions in the real world, and our presented framework satisfies this requirement well.

This paper is structured as follows: Section 2 describes the SSTS representation and formalizes the classification problem for SSTS. Section 3 discusses related work and proposes a three-category taxonomy of time series classification algorithms. Sections 4 and 5 introduce the GTC representation and the GTC-Set/DF models. Section 6 presents and details our two classification algorithms. Section 7 summarizes results of empirical evaluations and comparisons, and Subsection 7.7 shows how a user can interpret a GTC-Set model. Concluding remarks wrap up the paper in Section 8.

2. Problem Definition

A Symbolic and Scalar Time Sequence (SSTS) is a temporal data set representation with a high power of expression. It is defined as follows:

Let $E = \{e_1, \ldots, e_n\}$ be a set of n distinct symbols called *event symbols*. Let $S = \{s_1, \ldots, s_m\}$ be a set of m distinct symbols called *scalar symbols*. An *event* is a tuple $\langle e_i, x\rangle$ where $x \in \mathbb{R}$ is a timestamp. A *scalar mapping* is a tuple $\langle s_i, f_i\rangle$ where f_i is a function $\mathbb{R} \mapsto \mathbb{R}; t \to v$ that maps each time-stamp t to a value v. Finally, a *symbolic and scalar time sequence* $d = \langle P, Q\rangle$ is a tuple where P is a set of events and Q is a set of scalar mapping. By convention, an event of type e_i is said to "happen" at time t if $\langle e_i, t\rangle \in P$, and the value of the scalar s_j at time t is $f_i(t)$ with $\langle s_i, f_i\rangle \in Q$. Figure 1 shows an example of SSTS. Note that an SSTS can contain several events with the same (event) symbol.

The SSTS classification problem is defined as follows: Given a set of labeled SSTSs and a set of unlabeled SSTSs drawn from the same underlying distribution, infer the labels of the unlabeled SSTSs.

3. Related Work

Published research into temporal data classification can be grouped into three categories: *distance based methods*, *flattening methods* and *model based methods*. This categorization does not take into account possible data pre-processing steps.

Distance based methods rely on a definition of a distance between pairs of time series, and the use of a distance-based classification algorithm (such as e.g. k-nearest neighbors). If the distance metric requires tuning of its parameters to optimize the data fit, the observations available for training are split into separate training and validation samples. Methods falling into this category include nearest neighbor and Euclidean distance (NN+ED) (Ding et al., 2008), NN+L1 (Ding et al., 2008), NN+Linf (Ding et al., 2008), DTW (Berndt and Clifford, 1994), LCSS (Vlachos et al., 2002), ERP (Chen et al., 2005), EDR (Chen and Ng, 2004), DISSIM (Frentzos et al., 2007), SWALE (Morse and Patel, 2007), TQUEST (Aßfalg et al., 2006).

Flattening methods work in two steps. Firstly, temporal data is transformed into a flat table in which each time series is decomposed into a set of features and then it is represented by a single row of the table. Secondly, a standard classification algorithm is applied to thusly prepared flat-table data (Random Forest (Breiman, 2001), SVM (Meyer et al., 2003), Artificial Neural Networks, or AdaBoost (Freund and Schapire, 2009) have all been used in this context). Types of features that are commonly used for flattening include basic

statistics of the temporal data computed over moving time windows (mean, standard deviation, skewness, kurtosis, etc.), parameters prevalent in forecasting applications (trends, periodicity), and popular temporal signal projections (Fourier Transform, Wavelet Transforms, Singular Value Decomposition, etc.). Methods that rely on extracting a large amount of patterns from raw data followed by either applying feature selection and/or applying one of the classification algorithms to identify combinations of patterns that are effective on the task, fall into this category (Guillame-Bert and Dubrawski, 2014; Batal et al., 2012; Liu et al., 1998; Li et al., 2001). In this case, large amount of patterns are extracted according to user defined constraints (e.g. minimum support) and scores (e.g. F1), before being fed into a classifier. However, these methods are often slow because of the large amount of patterns to extract. And because discriminant power for classification does not always imply high score for a pattern, the methods may miss important patterns.

Finally, *direct-model-based methods* directly extract from data a model that contains temporal information. Examples of such methods include Rodríguez and Alonso (2004) and Deng et al. (2013) who have modified the decision forest framework (Breiman, 2001) to handle time series. In these approaches, conditions in the non-leaf nodes of the decision trees are of the form $f_i(t_1, t_2) < \alpha$ with $f_i(t_1, t_2)$ function computing a predefined statistic on all time series points between t_1 and t_2. For Rodríguez and Alonso (2004), $f_i(t_1, t_2)$ is the mean, standard deviation or the dynamic time warping distance to a template time series. For Deng et al. (2013), f is either the mean, standard deviation, or an estimation of the slope. Methods presented in Rodriguez et al., Deng et al. and Ye and Keogh (2009) do not fit the flattening paradigm because the features or conditions are determined at the time when the model is built instead of at a separate pre-processing stage. Inductive Logic Programming (Muggleton, 1991) (ILP) is a general framework that is capable to express many temporal patterns. Rodriguez et al. (2000) has shown an example of how to use ILP to classify time series. However, from our experience and because of their general nature, it is unclear how ILP solvers could learn efficiently temporal patterns containing time constraints which are not predefined by the users. The two algorithms proposed in this paper fall in this last category of methods.

One of the two proposed algorithms (GTC-Set) extracts large amount of GTC patterns (see definition in section 4), and use them with a simple voting mechanism (each active pattern casts a vote—the most represented class is predicted). This algorithm can be described trough the pattern-based classification framework described by Bringmann et al. Bringmann et al. (2011). In this framework, a pattern-based classification algorithm is divided into three parts: (1) The extraction of a pool of patterns, (2) the selection of a subset of patterns, and (3) the training of a classifier based on the patterns. The class of an algorithm is define by whether or not the labels are used in the stage (1) and (2) i.e. supervised or non-supervised pattern extraction and pattern selection: The main advantages of using labels in early stages is to "direct" the pattern extraction and selection, and to generate a smaller and more specialized (and hopefully more performant) set of patterns. On the other hand, not using labels in the first stage allows the use well studied of frequent pattern mining algorithms (e.g. frequent itemset mining (Agrawal and Srikant, 1994; Han et al., 2004), frequent sequence mining (Srikant and Agrawal, 1996; Zaki, 2001; Pei et al., 2001), frequent graph mining (Yan et al., 2008; Nowozin et al., 2007)). In this framework, the GTC-Set algorithm we propose is a "Model-dependent iterative mining"

algorithm (i.e. the labels are used in the pattern extraction stage), and it does not contains a pattern selection nor training of a classifier stages: All extracted patterns are directly and independently used. Such simple application of extracted patterns is only possible because of the specific extraction of the GTC-Set algorithm. For example, directly and independently applying all patterns extracted from a frequent itemset mining algorithm would lead to poor results.

Supervised Descriptive Rule Discovery (Novak et al., 2009) (proposed as a unification of Contrast Set Mining (Bay and Pazzani, 2001), Emerging Pattern Mining (Dong and Li, 1999), and Subgroup Discovery (Klösgen, 1996)) is the supervised extraction of association rules from labeled transactional data sets for the purpose of user interpretation and data discovery. Rules are extracted to maximize a user defined interest score often measuring a lift-life measure or a statistical distance from a null-space model. Unlike pattern-based classification, these rules are not designed to be used for classification. In section 7.7, we discuss how to extract a small but representative subset of GTC patterns from set of patterns extracted by the GTC-Set algorithm. While being less performant for the classification task than the original set of patterns, the selected set of patterns aims to be easier to interpret by a user. The GTC-Set algorithm conjugated with pattern selection method can be seen as a solution to Supervised Descriptive Rule Discovery on SSTS. Interestingly, and contrary to most of the Supervised Descriptive Rule Discovery literature, the proposed method build an interpretable model from a classifier.

Unlike itemset mining, sequential mining allows for the definition and use of a relation of order in between items. This order is often used to represent the temporal sequence of the items: One item can be anterior, posterior or concurrent to another item. However, time distance is not taken into account by sequential mining, and in many dynamical systems, relations such as the time distance or the overlapping between items is discriminant.

In the literature, learning algorithms dealing with temporally discrete data (e.g. time point events) face the challenge of representing and extracting temporal constraints between pairs of time points. In most of the literature such constraints are represented with a subset C of $\mathbb{R}$: Given two data points with timestamps respectively t_1 and t_2, the constraint is satisfied if and only if $t_2 - t_1 \in C$.

This formulation has a high power of expression, but it can be prone to over-fitting given the potentially infinite number of candidate patterns and many available and applicable algorithms for pattern extraction are intractable. Solutions found in the literature rely on two principles: Constraining possible values of C, and/or defining an inexpensive to optimize score function on C. The simplest and the most popular solution is to require for the user to specify a small set of candidates for C (Mannila et al., 1997). Rodríguez and Alonso (2004) and Rodriguez et al. (2000) only consider segments of the form $[2^i, 2^j]$ where i and j are integers. Deng et al. (2013) consider a small number of randomly generated segments. Ye and Keogh (2009) show the use of a decision tree where node conditions are expressed as thresholds on the distance between the signal and a subset of a time series called "shapelet". During training, candidate shapelets are extracted from all possible subsets of training data, and pruning-based optimization is used to ensure tractability. Dousson and Vu Duong (1999) consider all segments. Recursively, the algorithm selects the segment $[a, b]$ that minimizes the surface $b - a$ while holding a user-defined minimum support. Guillame-Bert (2012) considers all possible unions from a large set of segments

defined by the user $\{[ai + b, a(i + 1) + b]\}_{i\in[m,n]}$. Recursively, the algorithm selects the set of segments that maximizes information gain. The maximization problem is solved approximately using a forward or backward gradient descent optimization. The resulting constraint is not necessarily a contiguous segment. Guillame-Bert and Dubrawski (2014) consider all combinations $[b_i, b_j]$ where $\{b_i\}$ are provided by the user, and i and j are selected to maximize information gain. All possible combinations of i and j can be evaluated thanks to an efficient specialized data encoding.

The algorithms proposed in this work rely on learning constraints of the type $[a, b]$ (a and b are not constrained). a and b are selected to maximize information gain. This is a strict improvement over Guillame-Bert and Dubrawski (2014). Efficient and exact, according to the information gain criterion, extraction of a and b is one of the main results of this work.

4. Graphs of Temporal Constraints

A Graph of Temporal Constraints (GTC) is a set of temporal constraints represented as a graph.

Definition 1 *A GTC is defined by a set of* tests $Q = \{q_1, \ldots, q_n\}$ *and a set of* constraints $C = \{c_1, \ldots, c_m\}$.

A test q_i is defined by an event symbol*, a positive or negative* flag*, and a (possibly empty) set of* scalar tests*. A q_i test with a positive flag is true at time t if an event with the given event symbol exists at time t, and if all its scalar tests are true at time t. A test with a negative flag is true if and only if the same test with a positive flag is impossible to satisfy.*

A scalar test *is an inequality constraint based on a scalar mapping value at a time t defined by the node. In this work, scalar tests are restricted to be inequalities between a single scalar mapping term and a threshold value.*

A constraint c_k *is defined by two tests q_i and q_j, a positive or negative flag, and $R \subset \mathbb{R}$ (a subset of the real numbers). A constraint with a positive flag is true if its both tests are true respectively at time t_i and t_j and if $t_j - t_i \in R$. A constraint with a negative flag is true if and only if the same constraint with a positive flag is false. In other words, a negative constraint $[a, b]$ is equivalent to the disjunctive constraint $]-\inf, a[\cup]b, +\inf[$. Additionally, we restrict GTC not to have conditions/edges starting from a negative test/node.*

This restriction is similar to the apriori constraint for association rule mining, and it guaranties that if built iteratively, the GTCs at successive steps have decreasing support.

A GTC can be seen as a directed graph were each vertex expresses the existential condition for an event (conditioned by a symbol), i.e. a test, and where each edge expresses a temporal constraint between the vertices it connects, i.e. a constraint. A GTC can contain undirected cycles and disconnected components. Fig. 2 shows two examples of GTCs.

Let us now introduce some aspects of notation used for describing GTCs. A GTC instance $\{k_i\}_{i\in1,\ldots,n}$ assigns times k_i to each of the tests q_i of GTC A so that all tests and all constraints of A are true. By convention, $A(d)$ denotes the set of instances of A in an SSTS d. Note that different instances can partially overlap with each other. By convention, A is true in an SSTS d if d contains at least one instance of A, i.e. $|A(d)| > 0$. Trace $T(q_i, d)$ of the test q_i of A on the SSTS d is defined as the set of timestamps associated

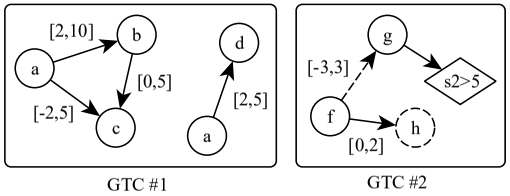

Figure 2: Two examples of GTCs. Dashed vertex (or edge) represents a vertex (or edge) with a negative flag. Diamond shapes represent scalar tests.

with the test q_i for any instances of A on d: $T(q_i, d) = \{k_i \mid \forall\{k_1, \ldots, k_i, \ldots, k_n\} \in A(d)\}$. Given a set of SSTS $D = \{d_1, \ldots, d_n\}$, $A(D)$ is the subset of SSTS for which A is true: $A(D) = \{d_i \mid d_i \in D \text{ with } |A(d_i)| > 0\}$. By convention, a GTC without tests is always true. Finally, given a set of SSTS D, the support of A is the fraction of SSTS where A is true: $supp(A) = |A(D)|/|D|$.

Testing the existence of a GTC in an SSTS (i.e. computing the existence of instances) can be done by (1) Extracting a set of spanning trees of the GTC (one tree for each of the GTCs disconnected components), (2) Independently matching each tree to the SSTS records while continuously, and (3) Checking any additional constraints that were not the part of the spanning trees. The cost of testing a GTC is polynomial with the number of events and exponential with the number of nodes. The smaller the surfaces of the temporal constraints between nodes, the less extensive the exploration, and the faster the GTC matching. However, in practice (cf. Experimental evaluation section below), the cost of testing GTCs is insignificant in comparison to the cost of learning these GTCs. It appears that because the constraints on the edges are selected to be discriminant, they tend to be restrictive and help in pruning large parts of the exploration space.

To the best of our knowledge, GTC is a novel representation, but it can be related to some existing temporal pattern representation frameworks. The closest are the Temporal Constraint Network (TCN) of Dechter (1991), the Chronicles of Dousson and Vu Duong (1999) and the Tita rules of Guillame-Bert (2012). TCN and Chronicles can be seen as reduced cases of GTCs in which tests and constraints do not have negative flags and in which there are no scalar tests. Tita rules allow node negation but do not allow undirected cycles or disjoint components.

5. Classification with GTCs

In this section, we introduce two SSTS classification models that use GTCs as their building blocks. The first model we call *GTC-Set*. A GTC-Set is an unstructured set of labeled (assigned to represent a particular unique class of STSS) GTCs. Given an unlabeled SSTS d, the predicted label for d is the most common label among all of the GTCs that are true on d. Note that this model would perform poorly if it were to contain all possible GTCs (even with a support constraint). Figure 3 shows an example of a GTC-Set.

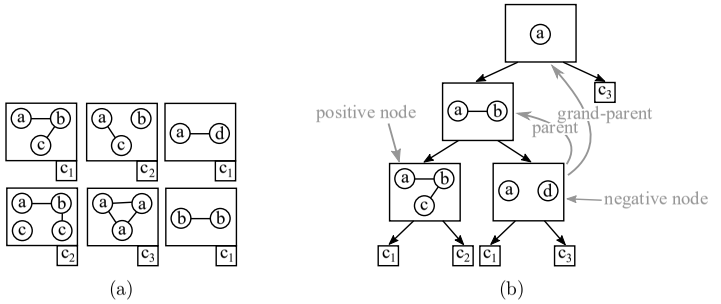

Figure 3: Examples of a GTC-Set (a) and a tree in a GTC-DF (b). Class labels in the leaf nodes are denoted with c_i.

The second model we call *GTC Decision Forest* (GTC-DF). A GTC-DF is a set of decision trees where each non-leaf node is associated with a particular GTC and it has two children. Additionally, the GTC attached to a decision tree node is constrained to be directly derived from the GTC of the parent node if connected by a positive decision tree branch, and from the grandparent node otherwise. This constraint is important and it will be discussed and justified in the next section. When applying a GTC-DF to classify a query in the form of a STSS, the decision trees are independently traversed in a familiar way. Upon arrival in a node, its associated GTC is tested for fitness to the data and the result of this test determines the direction of further traversal. As in the original decision forest algorithm (Breiman, 2001), class label distributions are agglomerated across the final active leaf nodes of each component tree, in order to obtain the joint prediction. Figure 3 shows an example of a tree in a GTC-DF.

Independence of components in GTC-Sets makes these models somewhat easier to interpret by the users than GTC Decision Forests because each of them can be considered individually. Conversely, interpretation of a GTC Decision Forest model, as well as its inference process in response to a particular query, requires consideration of GTCs corresponding to the subsequent nodes in each tree.

6. Learning Temporal Patterns

We introduce two algorithms to respectively extract GTC-Sets and GTC-DFs from a set of labeled SSTS instances. Both algorithms share the same sub-routines but differ in the structure of their main loops and therefore in the structure of the extracted GTCs. These algorithms can be seen as complementary. Experimentation shows that extracting GTC-DF is on average 40% faster, and it yields less complex models which typically perform slightly better when compared to GTC-Set models obtained from the same data (cf. Section 7.6). On the other hand, GTC-Sets allow easier interpretation of the results and the models themselves by the users (Section 7.7).

Both algorithms build GTCs by recursively applying constructive operations. In the process, selection of the next operation to apply is guided by maximizing the local information gain. This section presents GTC building operations, defines the concept of information gain of an operation, presents how to efficiently identify the operation with the highest information gain, and details the main loops of the two algorithms. Our proposed solution to how to efficiently extract optimal temporal constraints for the edges in GTCs is one of the main novelties of this work.

6.1 Constructive Operations on GTCs

Constructive operations on a GTC include:
O1: Addition of a new test (i.e. addition of a vertex),
O2: Addition of a constraint between two existing tests (i.e. addition of an edge),
O3: Addition of a scalar test to an existing test,
O4: Addition of a new test and addition of a constraint between this test and an already existing test.

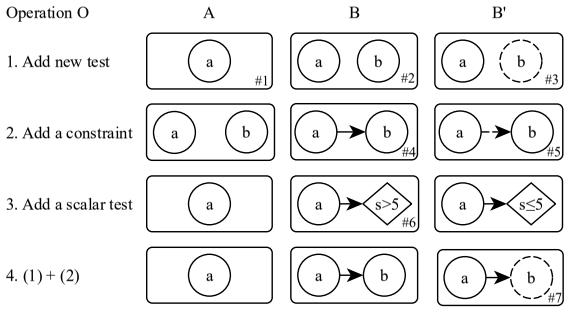
Each operation requires specific parameters. O1 requires an event symbol and a positive/negative flag. O2 requires two existing tests, a flag and a subset of $\mathbb{R}$. O3 requires an existing test and a scalar test defined by a scalar symbol, a threshold value and an inequality direction ($<$ or $\geq$). O4 requires a combination of arguments of O1 and O2. Note that, because of the threshold value of the scalar test in O3, and because the need for a subset of $\mathbb{R}$ in O2 and O4, these operations have an infinite number of possible parameter values. Operation O4 is equivalent to operations 1 and 2 combined. We justify its existence later.

Both proposed algorithms require for the set of positive SSTS according to a GTC to be monotone decreasing when applying operations: Given a set D of SSTSs, a GTC A, an operation O and B the result of O on A. Algorithms require for the set of positive SSTSs according to B to be contained in the set of positive SSTSs according to A i.e. $B(D) \subset A(D)$. This implies that each operation reduces (albeit not strictly) the support of the GTC it is applied to. For this reason, operations O2-O4 cannot be applied on negative nodes.

The result of the negation of an operation O on a GTC A is a GTC B' such that $\forall d \in D, A(d) \Rightarrow (B(d) \Leftrightarrow \neg B'(d))$ and $\neg A(d) \Rightarrow (\neg B(d) \wedge \neg B'(d))$, where B is the result of O on A. Note: $\Leftrightarrow$ and $\neg$ are respectively the logical equivalence and logical negation. Except for trivial cases, the GTC resulting from the negation of an operation is more complex than the result of the operation. In the case of fully connected GTCs, the size of the GTC resulting from the negative operation is twice the size of the result from the direct operation. Instead, we define the approximate result of the negation of an operation. This approximation is not exact but it provides reasonable results as presented in Section 7.

Whether to use or not the approximate negation is the main difference between the two proposed algorithms. Figure 4 illustrates these operations and their associated approximate negations. Adding a constraint to a test with a negative flag would violate the support reduction property and it is therefore forbidden. The goal of O4 is to allow creating a connected test with a negative flag without violating the support reduction requirement.

As a simple example, consider the four GTCs shown in figure 5a. B is the result of an operation of type $O4$ on A. B' is the result of the negation of this operation. B'' is the



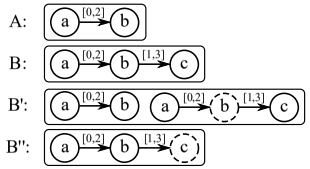


Figure 4: Illustration of the constructive operations on GTCs. Each row of graphs represents a specific operation. Column A represents the initial GTC. Column B shows the result of executing the particular operation on the initial GTC. Column B' depicts the result of the approximate negation of the operation. Dashed nodes and edges represent respectively tests and constraints with negative flags. Diamonds represent scalar tests. Description of the GTCs: #1: An event of type a is present. #2: An event of type a and an event of type b are present. #3: An event of type a is present, but no event of type b is present. #4: An event of type a and an event of type b are present, and they satisfy the constraint of the edge. #5: An event of type a and an event of type b are present, and they satisfy the complementary constraint of the edge. #6: An event of type a is present at time t such that the scalar s value is greater than 5 at time t. #7: An event of type a is present at time t_a such that there is no event b at time t_b such that t_a and t_b satisfy the constraint.

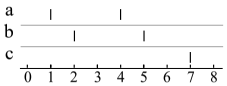

approximate result of the negation of this operation. A expresses that "There is an event a followed by an event b between 0 and 2 time units". B expresses that "There is an event a followed by an event b between 0 and 2 time units, itself followed by an event c between 1 and 3 time units". B' expresses that "There is an event a followed by an event b between 0 and 2 time units, but there is not an event a followed by an event b between 0 and 2 time units, itself followed by an event c between 1 and 3 time units". B'' expresses that "There is an event a followed by an event b between 0 and 2 time units, itself not followed by an event c between 1 and 3 time units". Figure 5b shows an SSTS B'' is true but where B' is not.

6.2 Information Gain Maximization

Both of the proposed GTC extraction algorithms are driven by the information gain maximization criterion. We define entropy H of a set of labeled SSTS D as the entropy of the

(a) Suppose a GTC A. B is the result of an operation of type $O4$ on A. B' is the result of the negation of this operation. B'' is the approximate result of the negation of this operation.

(b) Example of SSTS with B' false but B'' true.

Figure 5: Illustration of the negation and the approximate negation of an operation.

distribution of their labels

$$H(D) = \sum_i -p_i(D) \log p_i(D)$$

, with $p_i(D)$ representing the relative frequency of label i in D. Additionally, we assert $0 \log 0 = 0$.

Given a set of SSTSs $D = d_1, \ldots, d_n$, a GTC A such that A is true for all d_i, and an operation O, if B is the result of O on A, then information gain IG of the operation O on A can be defined as

$$IG = H(D) - \frac{|B(D)|}{|D|} H(B(D)) - \frac{|D \setminus B(D)|}{|D|} H(D \setminus B(D))$$

, where $H(D)$ is commonly called the initial (prior) entropy, and the rest of the right hand side of the formula is the weighed final (posterior) entropy.

During the training stage, given a GTC A, both algorithms rely on finding such constructive operation and its parameters that maximize the information gain. Except for operation O1, testing and evaluating the information gain over the range of possible parameter values is in most cases infeasible because of the infinite number of tests it might involve. We propose a solution based on the following four considerations: (1) Instead of considering all subsets of $\mathbb{R}$ (operations O2 and O3), we only consider contiguous segments of $\mathbb{R}$; (2) Since each finite data set consists of a finite number of SSTSs, and each SSTS is composed of a finite number of events, there is only a finite number of parameter values that need to be considered; (3) The procedure of extracting a plausible threshold for an operation O3, and the corresponding segments of $\mathbb{R}$, can be optimized for computational speed with an appropriate algorithm and an appropriate internal data structure; and (4) Random sampling can be used as an option to further speed up the extraction of the optimum threshold and the optimum segments of $\mathbb{R}$.

The next two subsections show how to build decision forests and sets of GTCs models using information gain maximization. Subsection 6.5 shows how to compute efficiently the threshold of operation O3 that maximize their information gain. Subsection 6.6 shows how to compute efficiently the segment of R that maximize their information gain for operations O2 and O4.

6.3 Learning Decision Trees and Forests of GTCs

We build decision trees and forests of GTCs similarly to how standard decision trees and forests are built (Quinlan, 1993; Breiman, 2001). The two differences are that: (1) Each decision node of a GTC tree is assigned a GTC instead of a single threshold condition on a single data feature as it is the case of the standard model; and (2) The structure of a GTC representing a node of a GTC tree is heavily constrained by the structure of the GTCs of its parent and grand-parent nodes.

The algorithm for training a GTC tree starts with a single empty GTC and it looks for the operation on it that yields the highest information gain. This operation is then applied, and the resulting GTC is used to define the root node constraint. The root node constraint is used to split the training SSTSs into two complementary subsets. The same procedure is further recursively applied to these subsets and additional nodes are appended to the tree until a stopping criterion is met. The GTC of a positive node of the decision tree will be derived by applying a single operation on the GTC attached to its parent. The GTC of a negative node of the decision tree will be derived by applying a single operation on the GTC attached to its grand-parent. This restriction has three benefits: (1) Search space for the new GTC is limited and therefore fast to explore. (2) The new GTC is constrained and therefore the risk for it to over-fit is mitigated. (3) GTCs of an arbitrary complexity can still be derived. A GTC Decision Forest (GTC-DF) can be obtained by bootstrapping data for GTC decision tree learning from the training set of SSTSs. Note that we typically also bootstrap the GTC-Set models and in fact use ensembles of GTC-Sets, cf. Algorithm 2. Pseudocode in Algorithm 1 provides details.

Algorithm 1: Extraction of a GTC decision forest from data.

input : D: A set of SSTSs
b: The number of bootstrap iterations (e.g. 20)
l: The minimum number of times a GTC is used (e.g. 5)
output: M: The set of extracted labeled GTCs
Algorithm
  for $i \leftarrow 1$ **to** b **do**
    $A \leftarrow$ an empty GTC
    `recursive_build`(D, A)
Subroutine `recursive_build`(D,*reference to* A)
  $M \leftarrow M \cup A$
  if $|A(D)| < l$ **then**
    $label(A) \leftarrow$ most frequent class in D with A true
    return
  $o \leftarrow$ find the operation on A with the highest information gain
  $B_2 \leftarrow A$
  $A \leftarrow$ result of O on A
  $B_1 \leftarrow A$
  set B_1 and B_2 to be respectively the positive and negative children of A
  `recursive_build`$(B_1(D), B_1)$
  `recursive_build`$(D \setminus B_2(D), B_2)$

6.4 Learning Sets of GTCs

This sub-section introduces the algorithm to extract a GTC set from data. This algorithm starts with a single empty GTC A and looks for the operation with the maximum information gain to extend its structure. This operation and the approximate negation of it are applied to the GTC A to create two new GTCs, respectively B_1 and B_2. A is then removed. The same process is next recursively applied to both B_1 and B_2 until a stopping criterion is met. Finally, each remaining (i.e. non removed) GTC is assigned to the most common class of the SSTS where it is true. Note that because of the approximated negation $B_1(D)$ and $B_2(D)$ are not necessary disjoint (the last line of the Algorithm 2).

Algorithm 2: Extraction of a GTC set.

input : D: A set of SSTSs
b: The number of bootstrap iterations to execute (e.g. 20)
l: The minimum number of times a GTC is used (e.g. 5)
output: M: The set of extracted labeled GTCs
Algorithm
  $A \leftarrow$ an empty GTC
  for $i \leftarrow 1$ **to** b **do**
    $M \leftarrow M \cup$ `recursive_build`(D, A)
Subroutine `recursive_build(D,A)`
  if $|D(A)| < l$ **then**
    $label(A) \leftarrow$ most frequent class in D with A true
    return A
  $o_1 \leftarrow$ find the operation on A with the highest information gain
  $o_2 \leftarrow$ approximate negation of o_1
  $B_1 \leftarrow$ result of o_1 on A
  $B_2 \leftarrow$ result of o_2 on A
  return `recursive_build`$(B_1(D), B_1) \cup$ `recursive_build`$(B_2(D), B_2)$ `// Note that it is not required nor expected that` $B_1(D) \cap B2(D) = \emptyset$

6.5 Finding the Optimal Scalar Tests

A scalar test is defined by an existing test q_i, a scalar symbol s_j, a threshold value α and the direction of inequality ($<$ or $\geq$). The problem of finding the optimal threshold value is different but related to the problem of finding the optimal threshold in the decision tree learning algorithm C4.5 (Quinlan, 1993). Unlike C4.5, our algorithms need to consider several scalar values for each observation/SSTS: one scalar value for each GTC instance on a given SSTS.

To identify the optimal scalar test, the algorithm considers all possible existing tests q_i with a positive flag, every scalar symbol s_j, and both inequality directions $<$ and $\geq$. For each of these values, the algorithm computes the optimal threshold value α as follows. Consider a GTC A, the set of training SSTS $D = \{d_i\}_{1..n}$, the scalar symbol s_j, the existing test q_i of A, and the inequality direction $<$ or $\geq$. We first compute a $n \times 2$ matrix L defined as follows:

$$L[j,1] = \left\{ \begin{array}{ll} \min(\{s_j(x) | \forall i, x \in T(q_j, d_i)\}) & \text{if the inequality is } < \\ \max(\{s_j(x) | \forall i, x \in T(q_j, d_i)\}) & \text{if the inequality is } \geq \end{array} \right\}$$
$$L[j,2] = \text{label}(d_j)$$

where $T(q_j, d_i)$ is the trace of the test q_j on the SSTS d_i (see the definition in Section 4). Next, this matrix is sorted according to its first column and all possible threshold values are evaluated in a sequence. α is defined as the threshold with the highest information gain. Algorithm 3 shows the details of these operations:

Algorithm 3: Finding the optimal threshold value α for a new scalar test.

input : L: A $n \times 2$ matrix as described in section 6.5.
output: α: the optimal threshold
Sort L according to the first column values
$h' \leftarrow +\infty$; $i' \leftarrow 0$; $w \leftarrow false$
$X \leftarrow \{0\} \times C$ with C the number of classes
$Y \leftarrow$ such that Y_i is the number of SSTS of class c_i
for $i \leftarrow 1$ **to** $n-1$ **do**
  $X_{L[i,2]} \leftarrow X_{L[i,2]} + 1$
  $Y_{L[i,2]} \leftarrow Y_{L[i,2]} - 1$
  if $L[i+1,1] \neq L[i,1] \wedge (L[i+1,2] \neq L[i,2] \vee w)$ **then**
    $w \leftarrow false$
    $h \leftarrow entropy(X)i + entropy(Y)(n-i)$
    if $h < h'$ **then**
      $h' \leftarrow h$; $i' \leftarrow i$
  else
    $w \leftarrow true$
$\alpha \leftarrow (L[i',1] + L[i'+1,1])/2$

6.6 Finding the Optimal Segment of R

Operations O2 and O4 require specification of a time constraint. In this work, we restrict time constraints to be contiguous segments $[a, b] \in \mathbb{R}$, albeit in general this restriction can be lifted without harm. The data set being finite, the number of meaningful candidate boundaries for a and b is also finite.

Given a GTC A and an operation O2 or O4 to apply, we define $M(d_k) \subset \mathbb{R}$ as follows. For operation O2, given two tests q_i and q_j of A, M is defined as $M(d_k) = \{x_1 - x_2 | \forall x_1 \in T(q_i, d_k), x_2 \in T(q_j, d_k)\}$. For operation O4, given an existing test q_i of A and an event symbol e_j, M is defined as $M(d_k) = \{x_1 - x_2 | \forall x \in T(q_i, d_k), \exists \langle e_j, x_2 \rangle \in d_k\}$. Note that M is computed from the trace T that is itself computed during the GTC evaluation.

By design, (1) If A is not valid on an SSTS d_k, then $M(d_k)$ is empty; and (2) If A is valid on an SSTS d_k, then the GTC resulting from applying the current operation with constraint $[a, b]$ on A is valid on d_k if and only if $\exists x \in M(d_k)$ such that $x \in [a, b]$.

We define $Y = \bigcup_k M(d_k)$, and Y_i to be the i^{th} smallest element of Y. Finally, we define Z as the set of all candidate boundaries (i.e. $a, b \in Z$) as $Z_i = \{(Y_i + Y_{i+1})/2\}_{i \in [1, |Y|]} \cup$

$\{Y_1\} \cup \{Y_{|Y|}\}$. In case of large data sets, or in case of small data sets with high risk of over-fitting, the set of candidate Z can be randomly sampled down. Such down sampling is in essence equivalent to attribute sampling used e.g. in Random Forest. In practice, this significantly speeds up the search for the optimal time constraint without reducing the model accuracy because of the redundant nature of the decision tree or decision set models. We observed experimentally that limiting Z to 40 elements (i.e. 40^2 interval candidates) does not impact the models' empirical accuracy.

Finding the segment $[a, b]$ that maximizes the information gain is an optimization problem in a finite and countable two dimensional space. The naive and direct solution to this problem requires evaluating a GTC on each SSTS for each unique point in the search space (i.e. for each possible $(a, b) \in Z^2$ with $a < b$). This solution leads to the worst case computational cost of $O(|Z|^2 nE)$ with n being the number of SSTSs and E the computational cost to compute the instances of a GTC on an SSTS. This cost may easily become prohibitively expensive for any realistically complex application. An alternative, more efficient solution is to iterate over M to evaluate application of the GTC. This solution only requires evaluating the initial GTC once, it does not require evaluating the resulting GTC, and it has a computational cost of $O(|Z|^2 n + En)$. It allows us to handle much larger problems than when using the naive approach.

Instead of these two implementations, we propose a third solution with a time complexity of $O(|Z|^2 + nE)$ (instead of $O(|Z|^2 nE)$ of $O(|Z|^2 n + En)$, as above). This new approach relies on the two following properties: (1) If $h \in M(d_k)$, then the GTC resulting from the current operation with the time constraint $[h, h]$ is true on the SSTS d_k; (2) If the GTC with the new constraint $[a, b]$ is true on the SSTS d_k, then all GTCs with a time constraint $[a', b'] \supset [a, b]$ will also be true on the SSTS d_k.

The last solution relies on building a $|Z| \times |Z| \times (C-1)$ matrix P where C is the number of classes in the classification problem. After being built, each element of $P[x, y, z]$ represents the number of SSTSs in training data which belong to class z and that match the GTC A after it was subjected to the new operation with the time constraint $[Z_x, Z_y]$. Once the matrix P is computed, search for the optimal time constraint can be done in one pass over P by iterating over x and y, then over z in the inner loop. Algorithm 4 shows how to efficiently construct matrix P. Note that in practice, search for the optimal time constraint can be merged with the last "for" loop of the algorithm. Figure 6 illustrates the Algorithm 4 step by step using a small example. Also note that while we use P to optimize information gain, P can be used to optimize any metric that relies on GTC matching counts.

7. Experimental Evaluation

In this section we report and discuss performance of the two proposed algorithms (GTC-DF and GTC-Set) as compared to a wide variety of alternative approaches found in literature. The algorithms are evaluated on a collection of 59 unique data sets described below. All these data sets are publicly available online.

7.1 Synthetic Data (1 set)

The synthetic data set is composed of a relatively simple collection of 200 computer-generated, purely symbolic SSTSs. Each of them contains one instance of each type of

Algorithm 4: Building matrix P.

input : Z: The set of candidate boundaries.
M: The "meet" sets.
output: P: Matrix P.

```
// a. Initialization
P ← a |Z| × |Z| × (C − 1) matrix filled with zeros
for k = 1 to |D| do
    k ← −1; c ← class of d_k
    if c = C then continue
    m ← M(d_k) // m_i is the i^th smallest element of m.
    for i = 1 to |m| do
        j ← such that Z_j ≤ m_i < Z_{j+1} // Note: i ↦ j is monotonically increasing
        P[j, j, c] ← P[j, j, c] + 1
        if k ≠ −1 then P[j, k, c] ← P[i, k, c] − 1
        k ← i
// b. Vertical upward spread
for i = 1 to |Z| do
    X ← {0} × (C − 1)
    for j = i to |Z| do
        X ← X + P[j, i, _]
        P[j, i, _] ← X
// c. Horizontal left spread
for i = 1 to |Z| do
    X ← {0} × (C − 1)
    for j = i to 1 do
        X ← X + P[i, j, _]
        // Note: Here X contains the class distribution for the candidate GTC
           with time constraints [Z_j, Z_i].
        P[i, j, _] ← X
```

events from the set A, B and C, respectively at times t_a, t_b and t_c. For each SSTS, t_a is sampled uniformly from $[0, 200]$, and t_b and t_c are sampled uniformly from $[t_a - 15, t_a + 15]$. If $|t_a - t_b| < 10$ and $|t_a - t_c| < 10$ and $|t_b - t_c| < 10$, then the SSTS is labeled as class 1. Else, if $|t_a - t_b| < 10$, then the SSTS is labeled as class 2. If none of these conditions are valid, the SSTS is labeled as class 3. This data set aims to evaluate our algorithm capability of correctly learning temporal constraints from data. The synthetic data set as well as a Python script used to generate it are available at *mathieu.guillame-bert.com/dataset*.

7.2 UCR Time Series Classification Repository (41 UCR Data Sets)

The University of California at Riverside (UCR) benchmark data is a collection of 41 diverse data sets representing time series classification problems of varying complexity. These data sets have the particularity to be *aligned* i.e. given a data set, the i-th observations of all time series reflect the same phenomenon observed at the same moment of time. Because of this alignment, "visual" measures of distance between instances of such data (e.g. Euclidean or

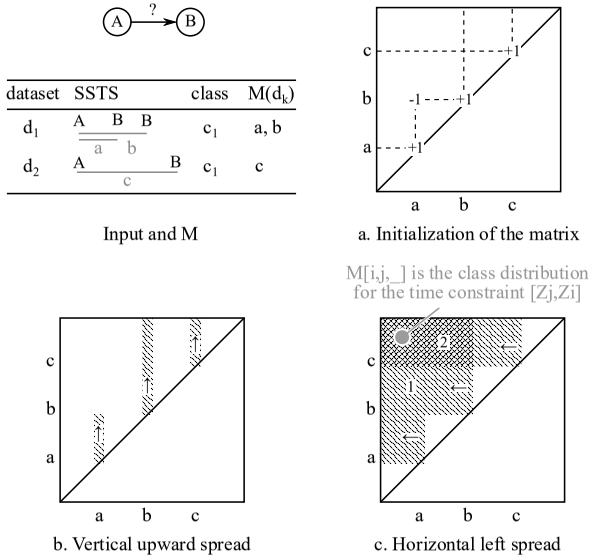

Figure 6: Step by step illustration of Algorithm 4 to construct M, matrix P, and the optimal time interval constraint.

Dynamic Time Warping (DTW) restricted to a very small shift coupled with one nearest neighbor) and algorithms designed for "flat" data sets (such as e.g. SVM) can be very competitive. The UCR data sets are organized into two groups: Group 1 (18 sets) and Group 2 (23 sets). The number of classes, number of time series, and their lengths, vary in these data sets respectively from-to $[2, 50]$, $[56, 7164]$ and $[60, 637]$ for Group 1, and $[2, 25]$, $[322, 9236]$ and $[28, 1882]$ for Group 2. It appears that the sets in Group 2 are on average larger than sets of Group 1. These data are available at *http://www.cs.ucr.edu/∼eamonn/time_series_data*.

7.3 16 Rotated UCR Data Sets

The UCR data sets are *aligned*, and it is likely that some classification models applied to them may rely on and benefit from this alignment. These data sets also contain rich local patterns. We propose to modify the UCR data by breaking their alignment in order evaluate the ability of classification algorithms to learn discriminative local patterns. In this way, the modified UCR collection can be used to evaluate algorithms on the significant problem of classifying non-aligned time series and SSTSs. One such scenario involves problems where the starting point of time series observation is arbitrary, which is the case of many practical applications in which we may not have the luxury of observing a modeled process from a

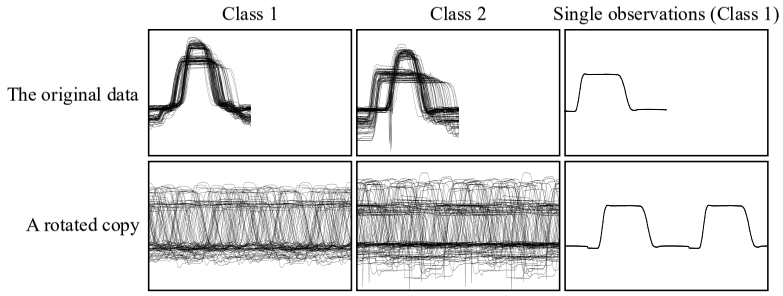

Figure 7: The original and one rotated copy of the UCR Gun Point data set.

well-defined initial setting. We call this modified collection of benchmark data the "Rotated UCR data sets".

The rotation is performed as follows: We break any potentially pre-existing alignment of a data set by randomly and independently shifting each time series in it versus others. Given a time series $X = [x_1, \ldots, x_n]$, the rotated copy is defined as $X' = [x_i, \ldots, x_n, x_1, \ldots, x_n, x_1, \ldots, x_{i-1}]$ with i being a uniformly random integer drawn from the range $[1, n]$ and unique to each time series. In order to avoid disturbing local patterns (if they exist), the rotated series are doubled in length with regard to the originals. To enable comprehensive evaluation, we independently generate 10 rotated copies for each of the originals and use each of these copies independently in experiments. The reported classification performance will be computed by averaging the results obtained from the 10 rotated copies. To avoid excessive computation costs, we chose to rotate all but two UCR Group 1 sets. As an example, Figure 7 shows the original UCR Gun Point data and one of its rotated copies.

7.4 Internal Bleeding Detection Data Set (1 Set)

Undetected internal bleeding during and after surgical procedures is a major medical concern. Early and reliable detection of internal bleeding is therefore considered a significant medical research problem. We assembled the *Bleeding Detection Data Set* from vital signs measured at high frequency (250Hz) using a bed-side hemodynamic monitoring system. The collected measurements include arterial blood pressure, central venous pressure, and airway pressure. The data has been collected from a cohort of 52 healthy pigs subjected to induced slow bleeding. Each animal has been sedated, instrumented, left to rest for half an hour, and then bled at the fixed rate of 20mL/min. From the vital sign records of each pig, we randomly sampled two 30 second long segments of data: One from the resting period before and one approximately 2 minutes into the bleeding. Pre- and post-bleeding segments are respectively labeled as negative and positive. Unlike in the UCR data sets, the SSTSs (vital signs) are not temporally aligned: The starting point of observation is effectively arbitrary. Moreover, the data is multivariate.

For reference, current clinical practice is usually unable to detect internal bleeding earlier than 10 to 15 minutes after the onset of a slow internal bleeding episode. We try to push

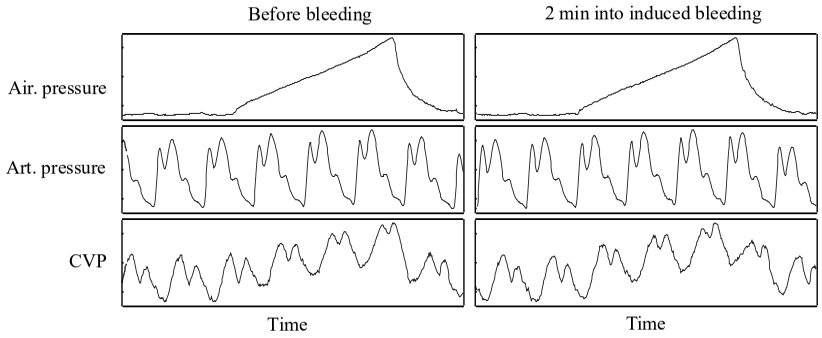

Figure 8: Four second samples of vital sign time series collected from one pig in pre-bleed phase (left) and 2 minutes into the induced bleeding (right). Note that in practice, vital signs of different animals tend to look less similar than vital signs of a same animal before and after bleeding. Air. pressure stands for Airway pressure. Art. pressure stands for arterial blood pressure, and CVP stands for central venous pressure.

that limit by considering SSTSs observed at a 2 minute mark into bleeding, when the data is not yet visually differentiable to expert clinicians. Figure 8 shows small parts of the pre-bleed and 2-minutes-in snapshots of vital signs data observed for one animal. The internal bleeding detection data set is available at *mathieu.guillame-bert.com* [Guillame-Bert].

7.5 Experimental Setup

Purposive featurization of time sequence data can sometimes significantly impact performance of the resulting models. In order to avoid obfuscating the relative performance of various algorithms being compared in this paper, we decided to not invest time and effort to produce advanced and potentially informative algorithm-specific featurizations of raw data. Instead, we relied on two basic statistics (moving averages and moving standard deviations), and we marked easily detectable peaks manifesting in the scalar data using a simple threshold criterion on the signal's second order derivative.

All considered algorithms have been implemented (or re-implemented) in C++ to ensure fairness of comparison. The computation times reported include training and evaluation over the complete 10-fold cross-validation cycles. This allows fair comparisons of lazy (e.g. 10NN) and non-lazy (e.g. our methods) algorithms. Experiments have been performed on a 3.4GHz i7 8-core processor with 16GB of main memory. Multiple algorithms were slow when applied on the UCR data set *StarLightCurves* (StarLC). Algorithms taking more than one day of computation for the 10-fold cross-validation were stopped and the expected total computation cost was estimated from the completed iterations. For this reason, results on *StarLightCurves* data are not used in computation of the global rankings.

7.6 Results

We compare our two algorithms against 13 related and relevant alternative classification algorithms for time series. The reference list includes: *ED+NN*: Euclidean Distance (i.e. L_2 distance) with Single Nearest Neighbor (Ding et al., 2008), *ED+kNN*: Euclidean Distance with k Nearest Neighbors (k is specified by the user), *ED+CVkNN*: Euclidean Distance with k Nearest Neighbors (k is determined through an internal loop 10-fold cross-validation executed on each training fold of the main 10-fold cross-validation loop), *DTW+NN*: Dynamic Time Warping (Berndt and Clifford, 1994) with Single Nearest Neighbor, *DTWC+NN*: Dynamic Time Warping with Constrained Warping Window (Berndt and Clifford, 1994) with Single Nearest Neighbor, *EDR+NN*: Edit Distance on Real Sequence (Chen and Ng, 2004) with Single Nearest Neighbor, *ERP+NN*: Edit Distance with Real Penalty (Chen et al., 2005) with Single Nearest Neighbor, *LCSS+NN*: Longest Common Subsequence (Vlachos et al., 2002) with Single Nearest Neighbor, *LCSSC+NN*: Longest Common Subsequence with Constrained Warping Window (Vlachos et al., 2002) with Single Nearest Neighbor, *L-1+NN*: L_1 distance with Single Nearest Neighbor, *L-inf+NN*: L_∞ distance with Single Nearest Neighbor, *RF*: Random Decision Forest (Breiman, 2001), *SVM*: Support Vector Machine Meyer et al., 2003, *Default*: Always return the most frequent class.

Algorithm parameters have not been tuned and were assigned to their meaningful default settings (except for k in *ED+kNNCV*), as follows. *RF*: maxNumTrees(30), minNumObservations(5), maxDepth(10). *LCSS+NN*: e(0.05 standard deviation). *EDR+NN*: e(0.25 standard deviation). *LCSSC+NN*: The maximum window is set to 25% of the data set length. It is worth noting that one could argue that the maximum window setting (c) of 25% is too high to operate DTWC and LCSSC on the UCR data sets, but we have chosen that for the three following reasons. Firstly, we have not tuned any algorithm parameters for specific data sets except for k in *ED+kNNCV*. Secondly, we have evaluated Euclidean Distance method being equivalent to DTWC with c=0%, and DTW being equivalent to DTWC with c=100%. Thirdly, c is a constraint parameter that only and strictly expands search space of the closest element when increased. We have experimented with alternative settings of this parameter and we have indeed obtained slight variations of empirical accuracy of DTWC, but these variations have not materially changed performance rankings reported below. We therefore chose to evaluate DTWC+NN (and other constrained dynamic programming distances) with c=25% for consistency. It is significant to remark that we evaluated the original implementation of DTW (Berndt and Clifford, 1994). Several pruning criteria have been studied to reduce the computation time without impacting the classification performances, including the work of Keogh and Ratanamahatana (2005). *DTWC+NN*: The maximum window is set to 25% of the data set length. *ED+CVkNN*: k is searched between 1 and 10. It is likely that optimizing parameters of each algorithm using internal cross-validation might improve their results, but it would significantly increase the computation time.

All reported results have been computed using the same 10-fold partitioning of data. In the case of the rotated UCR data sets, the 10-fold cross-validation is repeated for each of the 10 rotations of each rotated data set (e.g. each reported error rate is computed from 100 train and test experiments). In Bleeding Detection Data Set, we ensure that the

complete record for each animal is either entirely used for training or for testing in each cross-validation iteration.

Reported evaluation figures for the UCR data sets are not directly comparable with figures reported by Ding et al. (2008) or the figures available on the UCR Time Series web page: In Ding et al. (2008), evaluation results are computed with a "reversed cross-validation" where each of the n folds is successively used for training while the remaining $n-1$ folds are used for testing. On the UCR Time Series web page, evaluation is performed with a train and test protocol.

Tables 1 and 3 respectively compile the observed classification errors of all algorithms on the UCR data sets and rotated UCR data sets. The average rank and median rank are also reported for each algorithm. Table 2 shows the cumulative computation times of training and testing cycles for each algorithm. Table 4 shows the accuracy, classification error, AUC scores and computation times of each algorithm when applied to the Bleeding Detection Data Set. Figure 9 shows the ROC of the GTC-DF and Random Forest models obtained for this data set.

First, both our algorithms show a 100% accuracy on the synthetic data. This simple experiment validates their ability to identify explicit temporal sequence patterns when they exist.

The experiments on the UCR data, rotated UCR data, and Bleeding Detection Data Set (Tables 1, 3 and 4), show consistently high performance of our algorithms in comparison to state-of-the-art alternatives. On the original UCR data, and when considering 13 other methods, GTC-DF and GTC-Set have the highest average and median ranks of accuracy (respectively a median rank of 2 and 2.5 for Group 1, and 2.5 and 2.5 for Group 2). The next best methods are ERP+NN (med. rank of 4.8) and DTW+NN (med. rank of 6) for Group 1, and SVM (med.rank of 4.5) and ERP+NN (med. rank of 5) for Group 2. It is worth noting that since the original UCR data sets are internally aligned, methods that rely on basic distance metrics (e.g. Euclidean Distance or DTWC with very strong constraints e.g. c=0.5%) tend to perform relatively well and are also cheap to compute.

The Wilcoxon signed-rank test (Demšar, 2006) was applied to evaluate the significance of differences of performance between each algorithms. The resulting p-values are reported in Table 5. GTC-DF performs significantly better than all the other evaluated methods (including GTC-Set). Additionally, GTC-Set, while performing significantly worse than GTC-DF, performs significantly better than all the other evaluated methods.

Table 1: Empirical classification error rates observed for the algorithms under consideration on the UCR data sets from Groups 1 and 2. The first column contains the acronym names of the algorithms (our methods are labeled GTC-DF and GTC-Set), and the next two columns show average rank and median rank of each algorithm based on their accuracy performance measured on the individual data sets. The algorithms are sorted according to their average rank, and the two proposed methods top the sorted list.

(a) Error rates for the UCR Group 1 data sets.

JMLR 18(121):1-34, 2017

Table 2: Computing times of training and testing on the UCR data sets from Groups 1 and 2. Sorting of algorithms is the same as in Table 1b. Note that our algorithms very often remain competitive in terms of computational costs when compared to the most accurate alternatives. The ordering of the algorithms in this table is the same as in Table 1b. The bottom part of each table summarizes basic statistics of the data sets. Color is used to indicate value of each cell and it is normalized separately for each column.

Table 3: Classification error rates observed on the rotated UCR data sets. "O." stands for the original and "R." for the rotated data. The average and median ranks only reflect the rotated results. Algorithms are sorted according to their average rank on the rotated data sets. Note that GTC-DF and GTC-Set are consistently the highest on average ranking algorithms, while the runner-ups change when compared to the non-rotated data results.

Table 4: Classification error, accuracy, computation time (of the complete 10-fold cross-validation cycle), and AUC obtained on the bleeding detection data set. GTC methods are by far the top performers on this data.

The rotated UCR data sets are harder to classify than the original, aligned UCR data sets. In most cases, the error rates on the rotated data sets are higher for the same algorithm than the rates observed on the non-rotated counterparts (see Table 3). The experiment shows that GTC-DF and GTC-Set are substantially less impacted by this randomization than any other of the evaluated methods, and that GTC-DF and GTC-Set remain the top performers in terms of the average and median ranks (respectively an average and median rank of 2.9 and 2 for GTC-DF, and 3.6 and 2.5 for GTC-Set (Table 3). As expected, GTC-DF and GTC-Set yield similar error rates, and therefore their ranking impact each other. Removing one of these two algorithms from the ranking would further increase the ranking difference between the remaining proposed algorithm and the other state of the art methods under consideration.

Finally, on the Bleeding Detection Data Set, GTC-DF shows an Area Under the Receiver Operating Characteristic Curve (AUC) score of 96.2% and the accuracy at the default sensitivity set point (50%) of 91.3%, while all other evaluated methods show performance very close to random based on their empirical AUC scores (Table 4). This last result is encouraging as it may allow developing effective cardio-respiratory monitors tailored to detect specific hard-to-discern conditions.

In addition to overall highly competitive performance, learning of GTC-DF and GTC-Set models is reasonably fast, even though these algorithms are not uniformly faster than all of the evaluated alternatives. The 10-fold cross-validation on the Yoga data set (the largest of the considered sets from Group 1) takes our approaches approximately 27 and 37 minutes respectively, while the next best on accuracy models require approximately 15 hours (ERP+NN and DTW+NN, Table 2).

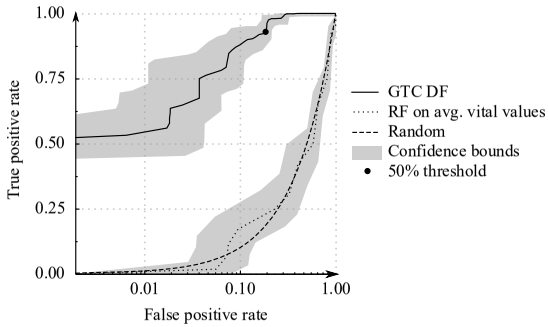

Figure 9: Receiver Operating Characteristic obtained for GTC-DF algorithm on the bleeding detection data set compared to the performance of the Random Forest algorithm on the flattened variant of the same data. False positive rate is scaled logarithmically.

Table 5: P-values of the Wilcoxon signed-rank test on the 41 UCR data sets and between each pair of the evaluated algorithms. Gray background is indicative of a positive significance of performances with a .05% error. A "+1NN" suffix has been removed from column labels for brevity.

7.7 Interpretability of Models

The ability to interpret a trained machine learning model typically improves understanding of the studied process, it may lead to useful discoveries, and it generally improves the acceptance of the model by its end-users. Many of the most powerful machine learning algorithms belong to the informal class of black (or opaque) box algorithms and specifically lack this useful ability. In our work, a single GTC is a graph of a usually small size (typically less than five tests, this number can however be controlled and further reduced

if needed). The resulting complexity of a single GTC is therefore manageable and the model can practically be read by a typical trained user. However, the large amount and the redundancy of GTCs in large GTC-DF or a GTC-Set models may still make it difficult for the user to comprehend and interpret their structures. In this section, we present a two straightforward methods to extract a small but representative subset of interpretable GTCs from a GTC-Set model.

The first method is a non-weighed coverage algorithm guided by immediate information gain. At each step of the process, all GTCs are evaluated and the one with the highest information gain is selected. Next, all SSTSs correctly classified by this selected GTC are removed form data. This sequence is repeated until all SSTSs have been removed, or until no remaining GTC has a strictly positive information gain, or until a user-specified number of GTCs have been extracted. We refer to this method as the "Coverage selection method".

This method is similar in nature to the feature selection steps in CBA (Liu et al., 1998) and CMAR (Li et al., 2001) algorithms. However, while the CBA and the CMAR use feature selection to build a classifier from a pool of already extracted patterns, our algorithms use the method presented below to extract an interpretable and informative set of patterns from an already existing and functional classifier.

The application of p boolean patterns as a list of exception rules defines $p + 1$ combinations (e.g. the second rule is only tested if the first one does not apply). However, the independent application of p boolean patterns defines 2^p combinations. The second method is a greedy forward selection guided by the immediate information gain from all the considered patterns i.e. by the 2^p combinations. This second method is more likely to over fit than the first method when a large number of patterns is selected. But it gives an equal importance to all the patterns and observations. We refer to this method as the "Combination selection method".

The primary goal of the extracted patterns is not to perform predictions but to help the user interpret the models. As shown below, the selected GTCs typically show reduced classification performance but lower complexity than the corresponding full GTC-Sets.

Figure 10 shows the first two selected GTCs by the Combination selection method on the first cross-validation folds of a few UCR data sets (Coffee, CBF, ECG200, Wager, Yoga) and the Bleeding Detection Data Set. Figure 11 shows the empirical class distribution of the held-out test data classified by these top GTCs (the held-out test sets have not been used either for training or selection of the GTCs). We can see a very good effectiveness of just the first two (or just one for the Coffee data set) greedily selected GTCs at expressing output class distributions. For instance, in case of the CBF data set using the first selected GTC enables perfect separation of class 2 from the rest of the data, and adding the second greedily selected GTC discriminates class 1 from class 3 data in the remainder. Other results shown in Figure 11 indicate a very strong, even if not perfect, utility of just the top 2 GTCs to express class distributions in data. This suggests a potential for obtaining highly interpretable and simple models with impressive classification performance if that is attainable, and gradually adding complexity as required to achieve desired accuracy of classification while limiting overall complexity of the resulting models and maintaining their interpretability.

Figure 12 illustrates an example of application of the single top GTC extracted for the first SSTS of the first test fold of the UCR Coffee data set. The time series graph depicts

the original scalar time series of the original data and the panel above it depicts occurrences of the discrete events extracted from it. This particular GTC requires that the standard deviation of the raw signal computed on a trailing time window 16 time units wide ought to peak-up (show a local maximum over time) during period between 226 and 252 time units from the time of occurrence of the starting event labeled as "begin". This is the positive node plotted in the graph diagram in the right part of Figure 12. Concurrently, this GTC also requires that no event of the standard deviation of the raw time series computed over the trailing window 16 time units wide increase, crossing the threshold of 0.75 units, during time interval between 103 and 109 time units from "begin" (the negative node in the GTC diagram) will occur. If these conditions are met, the GTC is matched, and using just this GTC to perform classification of the underlying time series would be predicted as an instance of class 1.

Interestingly, the class distribution of the first fold of the Coffee data set can be explained perfectly with just a single GTC of a relatively small size (Fig. 6). It only consists of three tests (Fig. 10). We conclude that this data set appears to be quite simple to handle. The first fold of the CBF data set can be explained perfectly and entirely with just two GTCs. In the ECG200 data set, the top two GTCs can classify correctly 90% of the held-out test data. Yoga appears to be the most complex of the data sets considered in Fig. 10). The top two GTCs extracted from its fist cross-validation fold are significantly more complex than in the case of other data sets, with 10 tests each. These two GTCs can correctly classify 76% of the held-out data. Interestingly, this finding is somewhat intuitive since for all evaluated algorithms this data takes the longest to process due to its inherent complexity. For Yoga data set, the GTC models achieve prevailing accuracy but they require more GTCs of greater complexity to accomplish that.

Table 6 summarizes the aggregated classification performance obtained with the two selection methods, when varying the number of GTCs used per data set, and compared to the results obtained when using the complete GTC-Set. We use UCR Group 1 and Bleeding Detection Data Set. The results reflect average performance from 10-fold cross-validation, so the extracted GTCs may vary between folds. In terms of error rates, UCR:Trace, UCR:Lighting2, UCR:ECG200, UCR:Coffee and UCR:Beef data are are well handled by the top two GTCs in comparison to the fully developed GTC-Set. On the other hand, performance revealed on UCR:2Patterns and UCR:Synthetic data substantially diminishes when just the simple two-GTC models are used. Finally, The Combination selection method performs better that the Coverage selection method on most data sets (16 over 18 for two selected GTCs, and 14 over 18 for four selected GTCs).

8. Conclusion

We introduced Graphs of Temporal Constraints (GTC), a new expressive model for temporal pattern representation. We also presented two methods (GTC-DF and GTC-Set) of inferring GTCs from data to enable classification of Symbolic and Scalar Time Sequences (SSTS). Our methods stand-out from previously known approaches because: (1) They offer a high power of expression, enabled by the parametric and structural nature of the proposed representation; (2) The computational cost of learning and applying these models is manageable and often competitive when compared to the most potent alternatives; (3) The

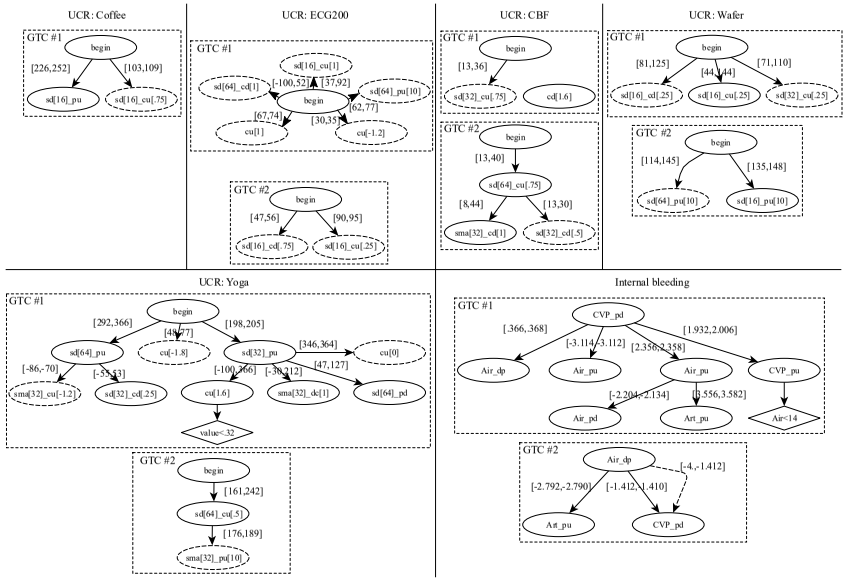

Figure 10: Graphical representations of the first two selected GTCs for the first cross-validation fold of a few evaluation data sets with the Combination selection method. Meaning of the event and scalar names: **begin**: begin of the SSTS, **sd[x]**: standard deviation over the trailing window x time units wide, **cd[x]**: signal crosses-down a threshold value x, **cu[x]**: signal crosses-up a threshold value x, **sma[x]**: simple moving average over the trailing window x time units wide, **pu**: peak up (local maximum over time), **pd**: peak down (local minimum over time), **CVP**: central venous pressure, **Air**: airway pressure, **Art**: arterial blood pressure.

users can read and interpret the models; and (4) In many cases, the users can easily project any new SSTS data and pursue its meaningful interpretation using only a handful of the most informative GTCs.

A wide range of experiments have been conducted to evaluate the proposed algorithms against a rich and diverse collection of benchmark data, and they have been compared to state-of-the-art alternative methods of temporal data classification. Experiments have shown that the proposed algorithms on average decisively outperform previously known best methods in terms accuracy of their predictions, while remaining highly competitive in terms of overall computational costs. Additionally, we have shown how easy it is to interpret the resulting models and we have presented a simple greedy procedure that in many cases yields a manageably small yet highly expressive and highly accurate models

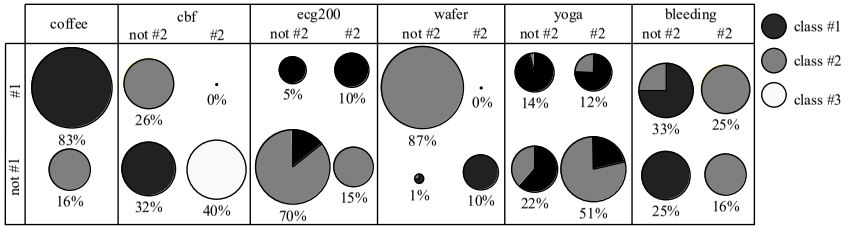

Figure 11: Held-out set empirical class separation achieved by simultaneously using the top two greedily selected GTCs for each of the considered data sets by the Combination selection method. For Coffee data set, only one GTC is needed to achieve the perfect class separation on the particular subset of testing data. The surface of each area represents the proportion of data it represents. This proportion is also shown with the percentage value beneath each graph. Pie charts are used to show distributions of target classes.

Abstract

We study the round complexity of minimizing the average of convex functions under a new setting of distributed optimization where each machine can receive two subsets of functions. The first subset is from a random partition and the second subset is randomly sampled with replacement. Under this setting, we define a broad class of distributed algorithms whose local computation can utilize both subsets and design a distributed stochastic variance reduced gradient method belonging to in this class. When the condition number of the problem is small, our method achieves the optimal parallel runtime, amount of communication and rounds of communication among all distributed first-order methods up to constant factors. When the condition number is relatively large, a lower bound is provided for the number of rounds of communication needed by any algorithm in this class. Then, we present an accelerated version of our method whose the rounds of communication matches the lower bound up to logarithmic terms, which establishes that this accelerated algorithm has the lowest round complexity among all algorithms in our class under this new setting.

1. Introduction

In this paper, we consider the *distributed optimization* problem of minimizing the average of N convex functions $f_i : \mathbb{R}^d \to \mathbb{R}$ for $i = 1, \ldots, N$, i.e.,

$$\min_{x\in\mathbb{R}^d} \left\{ f(x) := \frac{1}{N}\sum_{i=1}^{N} f_i(x) \right\} \tag{1}$$

using m machines. For simplicity of notation, we assume $N = mn$ for an integer n but all of our results can be easily generalized for an arbitrary N. In this paper, the norm $\|\cdot\|$ represents the Euclidean norm and $\langle\cdot,\cdot\rangle$ represents the inner product in $\mathbb{R}^d$. Throughout the whole paper, we make the following standard assumptions on problem (1).

Assumption 1 *The functions f_i for $i = 1, \ldots, N$ in (1) satisfy the following properties:*

- *Each function f_i is convex and L-smooth, which means f_i is differentiable and its gradient ∇f_i is L-Lipschitz continuous, i.e., $\|\nabla f_i(x) - \nabla f_i(y)\| \le L\|x-y\|$, $\forall x, y \in \mathbb{R}^d$.*
- *The average function f is μ-convex with $\mu \ge 0$, i.e., $f(x) \ge f(y) + \langle \nabla f(y), x - y\rangle + \frac{\mu}{2}\|x-y\|^2$, $\forall x, y \in \mathbb{R}^d$.*

When $\mu > 0$, f is *μ-strongly convex* and we call $\kappa = \frac{L}{\mu}$ the *condition number* of f. Note that the function f itself can be L_f-smooth, namely, $\|\nabla f(x) - \nabla f(y)\| \le L_f\|x-y\|$, $\forall x, y \in \mathbb{R}^d$, for a constant $L_f \le L$. Let x^* be an optimal solution of (1) and a deterministic solution $\hat{x}$ is called an *ϵ-optimal solution* to (1) if $f(\hat{x}) - f(x^*) \le \epsilon$. If $\hat{x}$ is a random variable generated by a stochastic algorithm, we call it an ϵ-optimal solution if $\mathbb{E}[f(\hat{x}) - f(x^*)] \le \epsilon$.

One of the most important applications of problem (1) is *empirical risk minimization* (ERM) in statistics and machine learning. Let $\{\xi_1, \xi_2, \ldots, \xi_N\}$ be a set of i.i.d. samples from an unknown distribution D. A regularized ERM problem with can be formulated as

$$\min_{x\in\mathbb{R}^d} \left\{ f(x) = \frac{1}{N}\sum_{i=1}^{N} \phi(x, \xi_i) + r(x) \right\}, \tag{2}$$

where x represents a vector of parameters of a predictive model, $\phi(x, \xi)$ is a loss function, and $r(x)$ is a regularization term. Note that (2) has the form of (1) with $f_i(x) = \phi(x, \xi_i) + r(x)$. A commonly used regularization term is $r(x) = \frac{\lambda}{2}\|x\|^2$ and the regularization parameter λ significantly influences μ and κ. The value of λ is typically in the order of $\Theta(1/\sqrt{N}) = \Theta(1/\sqrt{mn})$ as justified by Shamir and Srebro (2014), Shamir et al. (2014), Shalev-Shwartz et al. (2009) and Zhang and Lin (2015). For simplicity, in the rest of the paper, we will call f_i the ith data point or the ith function interchangeably.

We consider a situation where all N functions are initially stored in a large storage space that has limited computation power. Then, these N functions are partitioned, sampled and distributed to m machines where the main computation is performed for solving (1). One common practice under a classical setting is to randomly and evenly partition the N functions into subsets $S_1, S_2, \ldots, S_m$ with $|S_j| = \frac{N}{m} = n$ and store S_j in machine j. In this paper, we consider a *new setting* where an extra set of functions R_j with $|R_j| \le O(|S_j|)$ is sampled with replacement from these N functions so that the set $S_j \cup R_j$ is stored in

machine j for the local computation. Since no machine can access all N functions, we consider solving (1) by synchronized distributed algorithms that alternate between a local computation procedure at each machine, and a round of communication to share information among the machines.

One contribution of this paper is to develop a distributed algorithm for (1) under this new setting. Compared to the previous methods where only S_j is stored in machine j, our method requires more storage space or machines but significantly fewer rounds of communication to achieve an ϵ-optimal solution for (1) when the problem's parameters are in a practical regime, showing the advantage of the new setting. Moreover, we define a broad class of distributed algorithms for (1) under the new setting, which includes the proposed method, and establish a lower bound for the number of rounds of communication needed by any algorithm in this class to find an ϵ-optimal solution. This lower bound matches the number of rounds required by the proposed method up to logarithmic factors, indicating that our lower bound is tight and the proposed method is nearly optimal in this class.

1.1 Performance Metrics

In the design of distributed algorithms, one often needs to consider more performance metrics than in the single-machine scenario. A priori, the most important performance metric is the total runtime of algorithm—the time difference between the start of the first machine and the end of the last machine. However, there are other factors than the machines' CPU time that affect the total runtime such as the communication between machines. Moreover, the latency in initiating communication is also non-negligible, and often the bottleneck of the entire system.

We use the following synchronous message passing model from the distributed computation literature, e.g., Gropp et al. (1996) and Dean and Ghemawat (2008): We assume the communication occurs in rounds—in each round, machines exchanges messages with each other and, between two rounds, machines only perform computation based on their local information (local data points and messages received before). Under this model, three metrics are of main interests to us:

- **Parallel runtime**: The longest running time of the m machines spent in local parallel computation. In distributed first-order optimization methods, we measure it by the number of gradient computations, i.e., $\nabla f_i(x)$ computed for any i and x, in parallel.
- **The amount of communication**: The total amount of communication among m machines, measured by the number of bits transmitted through the network. It does not include the bits of the communication for distributing functions to machines before an algorithm starts. For the algorithms that only communicate iterates x and gradients $\nabla f_i(x)$, the amount of communication can be measured by the number of vectors of size $O(d)$ transmitted through the network.
- **The number of rounds of communication**: How many times m machines have to pause their local computation and initiate a round of communication to exchange messages. We also refer it as "rounds" or "round complexity" for simplicity.

Typically, trade-offs exist among these three metrics and algorithms need to be designed with a balance of these metrics. In this paper, we mostly focus on the third metric, the

number of rounds of communication an algorithm needs for solving (1), which has a significant impact on the total runtime of an algorithm when the speed of network transmission is slow or initiating the communication between machines in each round is time consuming.

1.2 Main Contributions

Distributed algorithms with low round complexity: First, we propose a *distributed stochastic variance reduced gradient* (DSVRG) method in the new distributed setting where machine j has access to two subsets of $\{f_i\}_{i\in[N]}$: a subset S_j of size n from a random partition of $\{f_i\}_{i\in[N]}$ and a subset R_j of size αn with $\alpha > 0$ sampled with replacement from $\{f_i\}_{i\in[N]}$. This method is a simple distributed implementation of the single-machine stochastic variance reduced gradient (SVRG) method (Johnson and Zhang, 2013; Mahdavi et al., 2013; Xiao and Zhang, 2014; Konečnỳ and Richtárik, 2017). We show in Theorem 14 that the DSVRG method with $\alpha = \Theta(1)$ requires $O\left(\left(\frac{\kappa}{n}\right)\log\left(\frac{1}{\epsilon}\right)\right)$ rounds of communication to find an ϵ-optimal solution for (1) in a realistic regime of ϵ and κ that contains most of ERM problems in practices.

Second, using the acceleration techniques developed by Frostig et al. (2015) and Lin et al. (2015), we propose a *distributed accelerated stochastic variance reduced gradient* (DASVRG) method that further improves the theoretical performance of DSVRG. In a practical regime of ϵ and κ similar to DSVRG, we show in Theorem 16 that DASVRG with $\alpha = \Theta(1)$ requires only $O\left(\left(\sqrt{\frac{\kappa}{n}}\right)\log\left(\frac{\kappa}{n}\right)\log\left(\frac{1}{\epsilon}\right)\right)$ rounds of communication to find an ϵ-optimal solution, which is lower than the round complexity of many existing techniques in the traditional setting with $R_j = \emptyset$, showing the advantage of the new distributed setting. The proposed algorithms may require more machines than previous approaches in order to have extra space for storing R_j in additional to S_j. However, when $\alpha = \Theta(1)$ (e.g., $\alpha = 1$), the required number of machines will increase only by a constant factor under the new setting.

Round complexity lower bounds: We also contribute to the answer of a fundamental question about the round complexity for solving (1) under the new setting:

When each machine receives functions from both random partition and sampling with replacement, what is the minimum number of rounds of communication a distributed optimization algorithm needs in order to obtain an ϵ-optimal solution for (1)?

Since different algorithms utilize different operations in local computation which may influence how many rounds are needed, a class of algorithms must be specified before we can answer the question above affirmatively. Hence, we define a broad class of algorithms called *distributed (extended) first-order algorithm*, denoted by $\mathcal{F}_\alpha$ (see Definition 1).

In $\mathcal{F}_\alpha$ with $\alpha \geq 0$, machine j has access to the subsets S_j and R_j of $\{f_i\}_{i\in[N]}$ as described in the DSVRG and DASVRG methods above with $|R_j| = \alpha n$. One realistic setting is when $\alpha \leq O(1)$ so that the memory space required in each machine remains $|R_j| + |S_j| = \Theta(|S_j|) = \Theta(n)$. It is only interesting to consider $\alpha < m - 1$, since, otherwise, $|R_j| + |S_j| \geq N$ which means the memory space of machine j is large enough to store all the N functions so that distributed computing is no longer needed. In $\mathcal{F}_\alpha$, each machine locally maintains a set of vectors W which can be shared with other machines and merged the W sets sent from other machines during a round of communication. Between the rounds of communication, machine j can add to W arbitrarily many linear combinations of the vectors in W and the (proximal) gradients of the functions in $S_j \cup R_j$ evaluated on the

vectors in W. With flexible schemes of communication and computation, the class $\mathcal{F}_\alpha$ with $\alpha = 0$ (i.e., $R_j = \emptyset$) covers many exist methods in the classical setting. When $\alpha > 0$, the class $\mathcal{F}_\alpha$ covers the proposed DSVRG and DASVRG methods.

We show that, when f is μ-strongly convex ($\mu > 0$), any algorithm in $\mathcal{F}_\alpha$ needs at least $\tilde{\Omega}\Big(\sqrt{\frac{\kappa/n+\alpha}{(\alpha+1)^3}}\log\big(\frac{1}{\epsilon}\big)\Big)$ rounds of communication in order to find an ϵ-optimal solution. Here and elsewhere in the paper, $\tilde{\Omega}(\cdot)$ and $\tilde{O}(\cdot)$ hide a logarithmic factor of m. In the scenario where $\alpha \leq O(1)$, this lower bound becomes $\tilde{\Omega}\left(\sqrt{\frac{\kappa}{n}}\log\big(\frac{1}{\epsilon}\big)\right)$, which suggests that the round complexity of DASVRG with $\alpha = \Theta(1)$ is nearly optimal and our lower bound is tight up to logarithmic factors for a practical regime of parameters. Briefly speaking, this lower bound is proved by carefully designing the "worst" $\{f_i\}_{i\in[N]}$ such that, with a high probability, the random subset $S_j \cup R_j$ in any single machine j does not contain enough (first-order) information of f in (1) so that many rounds of communication must be performed. Since this proof is much more challenging than the round complexity analysis of the DSVRG and DASVRG methods and is the main technical result of this paper, we provide it first in the main body of the paper before introducing the new algorithms.

Optimal parallel runtime, amount of communication, and rounds: In some practical regime of parameters, we show that our DSVRG algorithm can be tuned so that it achieves the optimal parallel runtime, the optimal amount of communication, and the optimal number of rounds of communication *simultaneously* for solving (1). Concretely, when $\kappa = O(n^{1-2\delta})$ with a constant $0 < \delta < \frac{1}{2}$, with appropriate choices of the control parameters (shown in Proposition 15), DSVRG finds an ϵ-optimal solution with a parallel runtime of $O(n)$, an $O(m)$ amount of communication and $O(1)$ rounds of communication for any $\epsilon = \Omega(\frac{1}{n^s})$ where s is any universal positive constant.

Note that $\kappa = O(n^{1-2\delta})$ is a common setting for machine learning applications. For example, as argued in Shamir and Srebro (2014), Shamir et al. (2014), Shalev-Shwartz et al. (2009) and Zhang and Lin (2015), ERM often has the condition number κ in the order of $\Theta(\sqrt{N}) = \Theta(\sqrt{mn})$. Therefore, when the number of machines m is not too large, e.g., when $m \leq n^{0.8}$, we have that $\kappa = \Theta(\sqrt{mn}) \leq n^{0.9}$ (so that $\delta = 0.05$).[1] Moreover, $\epsilon = n^{-10}$ (so that $s = 10$) is certainly a high enough accuracy for most machine learning applications since it exceeds the statistically optimal accuracy.

These performance guarantees of DSVRG, under the specific setting where $\kappa = O(n^{1-2\delta})$ and $\epsilon = \Omega(\frac{1}{n^s})$, are optimal up to constant factors among all the distributed first-order methods. First, to solve (1), all m machines together need to compute at least $\Omega(N)$ gradients (Agarwal and Bottou, 2015) in total so that each function in $\{f_i\}_{i\in[N]}$ can be accessed at least once. Therefore, at least one machine needs to compute at least $\Omega(n)$ gradients in serial given any possible allocation of functions. Second, the amount of communication is at least $\Omega(m)$ for even simple Gaussian mean estimation problems (Braverman et al., 2016), which can be solved as optimization (1). Third, at least $O(1)$ rounds of communication is needed to integrate the computation results from machines into a final output.

Extension to non-strongly convex problem: Although we mainly focus on strongly convex problems, some of our results can be extended to the non-strongly convex case. Using a similar approach to the strongly convex case, we show that when $\mu = 0$, any algorithm in $\mathcal{F}_\alpha$ needs at least $\tilde{\Omega}\Big(\sqrt{\frac{L}{(\alpha+1)^3 n\epsilon}}\Big)$ rounds of communication to find an

1. If $n = 10^5$, then $n^{0.8} = 10^4$ which is already much more than the number of machines in most clusters.

ϵ-optimal solution for (1). In the scenario where $\alpha \leq O(1)$, this lower bound becomes $\tilde{\Omega}\Big(\sqrt{\frac{L}{n\epsilon}}\Big)$. To achieve of this lower bound, we apply DASVRG to the strongly convex problem $\min_{x\in\mathbb{R}^d}\{f(x) + \frac{\sigma_\epsilon}{2}\|x\|^2\}$ with $\sigma_\epsilon = \Theta(\epsilon)$. According to the round complexity of DASVRG in the strongly convex case, we show in Theorem 17 that, in a certain regime of ϵ and κ, an ϵ-optimal solution can be found by DASVRG with $\alpha = \Theta(1)$ in $O\Big(\Big(\sqrt{\frac{L}{n\epsilon}}\Big)\log\Big(\frac{L}{n\epsilon}\Big)\log\big(\frac{1}{\epsilon}\big)\Big)$ rounds of communication, showing that our lower bound is tight up to logarithmic factors in that regime.

1.3 Notations and Outline

For a positive integer K, let $[K]$ denote the set $\{1, 2, \ldots, K\}$. We define a *multi-set* as a collection of items where some items can be repeated. We say two multi-sets are equal if they contain the same sets of unique elements and each unique element appears for the same number of times in both multi-sets. For a multi-set R, the notation $R\backslash\{i\}$ represents a multi-set identical to R except that the occurrence of i, if $i \in R$, is reduced by one. The union of a regular set S and a multi-set R, denoted by $S \cup R$, is defined as a regular set consisting of the items in either S or R without repetition. Let $A \otimes B$ denote the Kronecker product of matrices A and B and let $\mathbf{1}_n$ denotes the all-one vector in $\mathbb{R}^n$.

The rest of this paper is organized as follows. In Section 2, we review the related literature and compare the theoretical performance of our methods with existing work in distributed optimization. In Section 3, we define a broad family of distributed optimization algorithms and state our main results on the lower bounds for the rounds of communication for this family. In Section 4, we provide the proof of the main results. In Section 5 and Section 6, we present the DSVRG and DASVRG algorithms, respectively, and show their theoretical guarantees. We briefly describe how to apply DASVRG to non-strongly convex problems in Section 7. Finally, we present some numerical results in Section 8 and conclude the paper in Section 9.

2. Related Work

The work most closely related to our paper is Arjevani and Shamir (2015), where a lower bound for the rounds of communication was established for solving

$$\min_{x\in\mathbb{R}^d}\left\{\frac{1}{m}\sum_{j=1}^{m}\bar{f}_j(x)\right\} \tag{3}$$

using a broad class of distributed algorithms when machine j has only access to the local function $\bar{f}_j(x)$ for $j = 1, 2, \ldots, m$. To connect (3) to (1), we can define the local function as

$$\bar{f}_j(x) := \frac{1}{|S_j|}\sum_{i\in S_j} f_i(x) \tag{4}$$

for a given partition $\{S_j\}_{j\in[m]}$ of $\{f_i\}_{i\in[N]}$. Arjevani and Shamir (2015) proved that, if the local functions $\{\bar{f}_j\}_{j\in[m]}$ are δ-related (see Arjevani and Shamir (2015) for the definition) and f is strongly convex, the class of algorithms they considered needs at least $\Omega\big(\big(\sqrt{\delta\kappa}\big)\log\big(\frac{1}{\epsilon}\big)\big)$

rounds of communication to find an ϵ-optimal solution for (3). When $\delta = \Omega(1)$, their lower bound can be achieved by a straightforward centralized distributed implementation of accelerated gradient methods. In a specific context of linear regression with functions in S_j being a i.i.d. sample, it was shown by Shamir et al. (2014) that $\delta = O(\frac{1}{\sqrt{n}})$. In this case, the lower bound by Arjevani and Shamir (2015) becomes $O(\frac{\sqrt{\kappa}}{n^{.25}}\log(\frac{1}{\epsilon}))$, which has already been achieved by DISCO (Zhang and Lin, 2015) and AIDE (Reddi et al., 2016).

With our notation, the aforementioned algorithms all belong to the family $\mathcal{F}_0$ where each machine only receives the subset S_j from the random partition of $\{f_i\}_{i\in[N]}$. Unlike all previous work, the DSVRG and DASVRG algorithms we propose belong to $\mathcal{F}_\alpha$ with $\alpha > 0$ so that each machine has access to a subset R_j sampled with replacement from $\{f_i\}_{i\in[N]}$ in addition to S_j. Moreover, in the setting of Arjevani and Shamir (2015), machine j processes the entire local average function $\bar{f}_j$ in (4) in the local computation while machine j in our algorithms can process each individual function in $S_j \cup R_j$. Because of these key differences, DSVRG and DASVRG do not fall into the class of algorithms subject to the lower bound in Arjevani and Shamir (2015). That's why the communication lower bound we establish for $\mathcal{F}_\alpha$ and the communication upper bound ensured by DASVRG can be both lower than the lower bound by Arjevani and Shamir (2015). The "worst" set of functions $\{f_i\}_{i\in[N]}$ constructed in our main proof is a generalization of the set of functions in Arjevani and Shamir (2015). Chen et al. (2017) established lower bounds for the round complexity when the data is partitioned on features which is different from the setting in our paper and Arjevani and Shamir (2015) where the data is partitioned on samples.

Recently, there have been many distributed optimization algorithms proposed for problem (1) when f is strongly convex. We list several of them, including a distributed implementation of the accelerated gradient method (Accel Grad) by Nesterov (2013), in Table 1 and present their rounds and key assumptions for a clear comparison. Except DSVRG and DASVRG, all algorithms in Table 1 belong to $\mathcal{F}_0$ (i.e., $R_j = \emptyset$).

The $O(\sqrt{\kappa_f}\log(\frac{1}{\epsilon}))$ rounds of communication ($\kappa_f := \frac{L_f}{\mu}$) of Accel Grad in Table 1 is directly from the iteration complexity of the single-machine accelerated gradient method, and the $O(\sqrt{\kappa}\log(\frac{1}{\epsilon}))$ round complexity of centralized ADMM was given by Deng and Yin (2016). The distributed dual coordinate ascent method, including DisDCA (Yang, 2013), CoCoA (Jaggi et al., 2014) and CoCoA+ (Ma et al., 2015), is a class of distributed coordinate optimization algorithms which can be applied to the conjugate dual formulation of (2) when $f_i(x) = \phi(x, \xi_i) = \phi_i(\xi_i^T x)$ for ϕ_i on $\mathbb{R}^1$. By Ma et al. (2015) and Jaggi et al. (2014), CoCoA+ requires $O(\kappa\log(1/\epsilon))$ rounds of communication to find an ϵ-optimal solution.[2] Therefore, when applicable, both DSVRG and DASVRG with $\alpha = \Theta(1)$ require fewer rounds of communication than the methods mentioned above.

Assuming the problem (1) has the form of (2) with ξ_i's i.i.d. sampled from a distribution D (denoted by $\xi_i \overset{iid}{\sim} D$), the DANE (Shamir et al., 2014) and DISCO (Zhang and Lin, 2015) algorithms require $O((1+\frac{\sqrt{\kappa}}{n^{.25}})\log(1/\epsilon))$ and $O((1+\frac{\kappa^2}{n})\log(1/\epsilon))$ rounds of communication, respectively. Hence, DSVRG uses fewer rounds of communication than DANE and fewer than DISCO when $\kappa \le n^{1.5}$. If applicable, DASVRG always uses fewer rounds of communication than DISCO and DANE. Furthermore, DANE only has the theoretical guarantee

2. CoCoA+ has a better theoretical performance than CoCoA. According to Ma et al. (2015), CoCoA+ is equivalent to DisDCA with "practical updates" (Yang, 2013) under certain choices of parameters.

Algorithm	Rounds	Settings (when Assumption 1 holds)
DSVRG	$(1+\frac{\kappa}{n})\log\frac{1}{\epsilon}$	$\kappa\log\left(\frac{1}{\epsilon}\right) \le O(N)$, $\alpha = \Theta(1)$
DASVRG	$(1+\sqrt{\frac{\kappa}{n}})\log(1+\frac{\kappa}{n})\log\frac{1}{\epsilon}$	$(1+\sqrt{\frac{\kappa}{n}})\log(1+\frac{\kappa}{n})\log\frac{1}{\epsilon} \le O(m)$, $\alpha = \Theta(1)$
DISCO	$(1+\frac{\sqrt{\kappa}}{n^{.25}})\log\frac{1}{\epsilon}$ $d^{.25}\left((1+\frac{\sqrt{\kappa}}{n^{.25}})\log\frac{1}{\epsilon} + \frac{\kappa^{1.5}}{n^{.75}}\right)$	(2) with $\xi_i \overset{iid}{\sim} D$ and quadratic $\phi(x,\xi_i)$ (2) with $\xi_i \overset{iid}{\sim} D$
DANE	$\delta^2\kappa^2\log\frac{1}{\epsilon}$ $(1+\frac{\kappa^2}{n})\log\frac{1}{\epsilon}$ $\kappa_f\log\frac{1}{\epsilon}$	δ-related $\{\bar{f}_j\}_{j\in[m]}$ (2) with $\xi_i \overset{iid}{\sim} D$ and quadratic $\phi(x,\xi_i)$
AIDE	$\sqrt{\delta\kappa}\log\frac{1}{\epsilon}$ $(1+\frac{\sqrt{\kappa}}{n^{.25}})\log\frac{1}{\epsilon}$ $\sqrt{\kappa_f}\log\frac{1}{\epsilon}$	δ-related $\{\bar{f}_j\}_{j\in[m]}$ (2) with $\xi_i \overset{iid}{\sim} D$ and quadratic $\phi(x,\xi_i)$
CoCoA+	$\kappa\log\frac{1}{\epsilon}$	(2) with $\phi(x,\xi_i) = \phi_i(\xi_i^T x)$
Accel Grad	$\sqrt{\kappa_f}\log\frac{1}{\epsilon}$	
ADMM	$\sqrt{\kappa}\log\frac{1}{\epsilon}$	μ-strongly convex f_i

Table 1: Rounds and settings of different distributed optimization algorithms. Except DSVRG and DASVRG, all algorithms in this table only require $\alpha = 0$ (i.e., they do not require a subset R_j sampled with replacement).

mentioned above when it is applied to quadratic problems. Also, DISCO only applies to self-concordant functions with easily computed Hessian[3] and makes strong statistical assumptions on the data points. On the contrary, DSVRG and DASVRG works for a more general problem (1) and do not assume $\xi_i \overset{iid}{\sim} D$ for (2).

In each iteration, DANE requires solving a non-trivial sub-problem to optimality. Reddi et al. (2016) proposed an InexactDane algorithm that is similar to DANE but only needs to solve the sub-problem approximately and still achieves the same round complexity as DANE up to a logarithmic factor. Applying the acceleration techniques developed by Frostig et al. (2015) and Lin et al. (2015) to InexactDane, Reddi et al. (2016) further proposed an Accelerated Inexact DanE (AIDE) algorithm that matches the round complexity of DISCO up to a logarithmic factor.

Shamir (2016) consider a without-replacement SVRG which, if implemented in a distributed way, is similar to the DSVRG proposed here. The main difference between his method and DSVRG is that his method sequentially accesses the data points in S_j while while DSVRG accesses the data points in R_j for the local update. Since Shamir (2016) assumes that the concatenation of $\{S_j\}_{j\in[m]}$ forms a random permutation of $\{f_i\}_{[N]}$, his method essentially performs the iterative update of SVRG by sampling from $\{f_i\}_{[N]}$ without replacement. When κ is smaller than N and ϵ is not extremely small (the same as what DSVRG requires), his method obtains the same round complexity as DSVRG. However, his complexity analysis only applies for quadratic $\{f_i\}_{[N]}$. Konečný et al. (2016) proposed a

3. The examples in Zhang and Lin (2015) all take the form of $f_i(x) = \phi_i(\xi_i^T x)$ for some function ϕ_i on $\mathbb{R}^1$, which is more specific than $\phi(x,\xi_i)$, so that it is relatively easy to compute the Hessian of f_i.

Federated SVRG algorithm which is also a distributed implementation of SVRG and can be viewed as a special case of InexactDane with specific choices of parameters (Reddi et al., 2016). However, the performance analysis of InexactDane under those specific choices of parameters is only available when $\{f_i\}_{[N]}$ are quadratic and δ-related.

The methods in comparison in Table 1 are centralized methods which are typically implemented in a star network with a center server. There also exist many distributed (sub)gradient methods (Nedić and Ozdaglar, 2007, 2009; Duchi et al., 2012; Jakovetić et al., 2012; Chen and Ozdaglar, 2012; Jakovetić et al., 2014; Beck et al., 2014; Shi et al., 2015a,b; Aybat et al., 2015) and distributed ADMM methods (Boyd et al., 2011; Wei and Ozdaglar, 2012; Mota et al., 2013; Shi et al., 2014; Chang et al., 2015; Makhdoumi and Ozdaglar, 2017; Deng and Yin, 2016; Mokhtari et al., 2016) for decentralized optimization over general networks. In general, the decentralized distributed methods require more rounds of communication than the centralized ones. For example, the number of communication rounds needed by the decentralized ADMM in Makhdoumi and Ozdaglar (2017) is $O(\sqrt{\kappa}\log(\frac{1}{\epsilon}))$ multiplied by a network-dependent factor that is typically greater than one.

3. Lower Bounds on Rounds of Communication

In this section, we first define a broad family of distributed (extended) first-order methods which contains many existing distributed optimization algorithms in the literature. Then, we prove the lower bounds for the round complexity for this family of algorithms to find an ϵ-optimal solution for (1) under Assumption 1 with $\mu > 0$ and $\mu = 0$, respectively.

The algorithms in the family we consider consist of a data distribution stage where the functions $\{f_i\}_{i\in[N]}$ are distributed onto m machines, and a distributed computation stage where, in each round, machines can not only use first-order information of the functions stored locally but also apply preconditioning using local second-order information.

Definition 1 (Distributed (extended) first-order algorithms $\mathcal{F}_\alpha$) *Suppose there is a stage of data distribution where $\{f_i\}_{i\in[N]}$ are distributed to m machines such that:*

1. *The index set $[N]$ is randomly and evenly partitioned into $S_1, S_2, \ldots, S_m$ with $|S_j| = n$ for $j = 1, \ldots, m$.*

2. *A multi-set R_j of size αn is created by sampling with replacement from $[N]$ for $j = 1, \ldots, m$, where $\alpha \geq 0$ is a constant. When $\alpha = 0$, we have $R_j = \emptyset$ for all j.*

3. *Let $S'_j = S_j \cup R_j$. Machine j acquires functions in $\{f_i\}_{i\in S'_j}$ for $j = 1, \ldots, m$.*

We say an algorithm $\mathcal{A}$ for solving (1) belongs to the family $\mathcal{F}_\alpha$ ($\mathcal{A} \in \mathcal{F}_\alpha$) of distributed (extended) first-order algorithms if the machines do the following operations in rounds:

1. *Machine j maintains a local working set of vectors $W_j \subset \mathbb{R}^d$ initialized to be $W_j = \{\mathbf{0}\}$, where $\mathbf{0}$ is the all-zero vector in $\mathbb{R}^d$.*

2. *In each round, for arbitrarily many times, machine j can add any $w \in \mathbb{R}^d$ to W_j if w satisfies (c.f. Arjevani and Shamir (2015))*

$$\gamma w + \nu \nabla F_j(w) \in span\Big\{ w', \nabla F_j(w'), (\nabla^2 F_j(w') + D)w'', (\nabla^2 F_j(w') + D)^{-1} w'' \Big| \\ w', w'' \in W_j, D \text{ is diagonal}, \nabla^2 F_j(w') \text{ and } (\nabla^2 F_j(w') + D)^{-1} \text{ exist} \Big\} \quad (5)$$

   for some constants $\gamma \geq 0$ and $\nu \geq 0$ with $\gamma\nu \neq 0$, where $F_j = \sum_{i\in U_j \subset S'_j} f_i$ with an arbitrary subset U_j of S'_j.

3. *At the end of the round, all machines can simultaneously send any vectors in W_j to any other machines, and each machine can add the vectors received from other machines to its local working set.*

4. *The final output is a vector in the linear span of W_j for any j.*

We use $\mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$ to represent the output vector of $\mathcal{A}$ when it is applied to (1) for H rounds with the inputs $\{f_i\}_{i\in[N]}$ and the sets $\{S'_j\}_{j\in[m]}$ generated in the data distribution stage described above.

Besides the randomness due to the data distribution stage, the algorithm $\mathcal{A}$ itself can be a randomized algorithm. Hence, the output $\mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$ can be a random vector. Next, we provide some discussions on this class of algorithms.

In $\mathcal{F}_\alpha$, machines can only share iterates but not data points explicitly. Therefore, the sets $\{S'_j\}_{j\in[m]}$ will not be changed during the algorithm. The class $\mathcal{F}_\alpha$ allows gradient update $w = w' - \eta\nabla F_j(w')$ with $\eta > 0$ in local computation, which corresponds to (5) with $\gamma = 1, \nu = 0$. It also allows proximal mapping update $w = \arg\min_v \frac{1}{2\eta}\|v - w'\|^2 + F_j(v)$ with $\eta > 0$ in local computation, which has an optimality condition $w + \eta\nabla F_j(w) = w'$ and thus corresponds to (5) with $\gamma = 1, \nu = \eta$. As a result, the class $\mathcal{F}_0$ covers distributed Accel Grad, ADMM, DANE and AIDE. Although the algorithms in $\mathcal{F}_\alpha$ can use the local second-order information like $\nabla^2 f_i(x)$ in each machine, Newton's method is still not contained in $\mathcal{F}_\alpha$ since Newton's method requires the access to the global second-order information such as $\nabla^2 f(x)$ (machines are not allowed to share Hessian matrices with each other). That being said, one can still use a distributed iteration method which can multiply $\nabla^2 f_i(x)$ to a local vector in order to solve the inversion of $\nabla^2 f(x)$ approximately. This scheme will lead to a distributed inexact Newton method such as DISCO, which also belongs to $\mathcal{F}_0$. The DSVRG and DASVRG algorithms proposed in this paper belong to $\mathcal{F}_\alpha$ with $\alpha > 0$.

We are ready to present the lower bounds for the rounds of communications.

Theorem 2 *Suppose $m \geq (e + 4\max\{1, \alpha\})^2$ and there exists an algorithm $\mathcal{A} \in \mathcal{F}_\alpha$ with the following property:*

"For any $\epsilon > 0$ and any N convex functions $\{f_i\}_{i\in[N]}$ satisfying Assumption 1 with $\mu > 0$ and $\kappa \geq 1.5n$, there exists H_ϵ such that the output $\hat{x} = \mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H_\epsilon)$ satisfies $\mathbb{E}[f(\hat{x}) - f(x^*)] \leq \epsilon$, where the sets $\{S'_j\}_{j\in[m]}$ are generated as in Definition 1."

Then, with $k \equiv \lceil (e + 4\max\{1, \alpha\})\log m \rceil$, we must have

$$H_\epsilon \geq \left(\frac{\sqrt{2\kappa/(3n) + k - 1} - \sqrt{k}}{4k\sqrt{k}} \right) \log\left(\left(1 - \frac{1}{e}\right) \frac{\mu\|x^*\|^2}{4\epsilon} \right) \geq \tilde{\Omega}\left(\sqrt{\frac{\kappa/n + \alpha}{(\alpha+1)^3}} \log\left(\frac{\mu\|x^*\|^2}{\epsilon} \right) \right).$$

In the definition of $\mathcal{F}_\alpha$, we allow the algorithm to access both randomly partitioned data and independently sampled data, and allow the algorithm to use local Hessian for preconditioning. This makes our lower bounds in Theorem 2 **stronger**: Even with more options in distributing data and with algorithms more powerful than first-order methods (in terms of the class of operations it can take), the number of rounds needed to find an ϵ-optimal solution still cannot be reduced.

The $\kappa \geq 1.5n$ condition is not critical because, when $\kappa \leq \frac{n^{1-2\delta}}{32} < 1.5n$ for a constant $0 < \delta < \frac{1}{2}$, we will show in Proposition 15 in Section 5.2 that DSVRG only needs $O(\frac{\log(1/\epsilon)}{\delta \log n})$ rounds, which almost meets the trivial lower bound $\Omega(1)$.

A similar result can be obtained for the non-strongly convex case.

Theorem 3 *Suppose $m \geq (e + 4\max\{1, \alpha\})^2$ and there exists an algorithm $\mathcal{A} \in \mathcal{F}_\alpha$ with the following property:*

"For any $\epsilon > 0$ and any N convex functions $\{f_i\}_{i\in[N]}$ satisfying Assumption 1 with $\mu = 0$, there exists H_ϵ such that the output $\hat{x} = \mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H_\epsilon)$ satisfies $\mathbb{E}[f(\hat{x}) - f(x^*)] \leq \epsilon$, where the sets $\{S'_j\}_{j\in[m]}$ are generated as in Definition 1."

Then, with $k \equiv \lceil (e + 4\max\{1, \alpha\}) \log m \rceil$, we must have $H_\epsilon \geq \sqrt{(1 - \frac{1}{e}) \frac{L\|x^*\|^2}{64k^3 n\epsilon}}$.

4. Proofs of Main Results

In this section, we will provide the proofs for Theorem 2 and 3. Before presenting all technical details, we will first give an informal sketch of the proofs.

4.1 Sketch of Proof for Main Results

We will only provide an informal proof sketch for Theorem 2. The proof of Theorem 3 follows a similar strategy.

Let k be an integer with $k = \Theta(\log(m))$, $\mu' = n\mu$ and $\kappa' = \frac{L}{\mu'}$. For simplicity, we assume $\frac{m}{k}$ is an integer in this proof sketch although Theorem 2 and 3 hold without this assumption. Let $E_0 = \{\mathbf{0}\}$ where $\mathbf{0}$ is the all-zero vector in $\mathbb{R}^b$ and let E_t be the subspace of $\mathbb{R}^b$ consisting of the vectors whose non-zero values only appear in the first t coordinates.

Motivated by the proof for the lower bound of the iteration complexity of first-order methods (Nesterov, 2013), we construct a convex quadratic function $\bar{p} : \mathbb{R}^b \to \mathbb{R}$ and represent it as the average of k convex quadratic functions $p_s : \mathbb{R}^b \to \mathbb{R}$ for $s = 1, 2, \ldots, k$. In particular, we construct $\bar{p}(w) = \frac{1}{2}w^T\Sigma w + q^T w + \frac{\mu'}{2}\|w\|^2 = \frac{1}{k}\sum_{s=1}^k p_s$, where $\bar{p}_s(w) = \frac{1}{2}w^T\Sigma_s w + q_s^T w + \frac{\mu'}{2}\|w\|^2$ for $s = 1, 2, \ldots, k$. We are able to choose Σ, Σ_s, q and q_s here such that the following properties are satisfied

1. The matrix $\Sigma = \frac{1}{k}\sum_{s=1}^k \Sigma_s$. The matrix Σ is tridiagonal and the matrix Σ_s is block diagonal with a 2×2 block and $k - 2$ consecutive zero entries alternatively appearing along its diagonal. The sparsity patterns of Σ and Σ_s can be seen in Figure 1 in an example with $b = 15$ and $k = 3$.

2. The vector $q = \frac{1}{k}\sum_{s=1}^k q_s$ with $q, q_s \in E_1$ for $s = 1, \ldots, k$.

3. Each p_s is L-smooth and $\bar{p}$ is μ'-strongly convex.

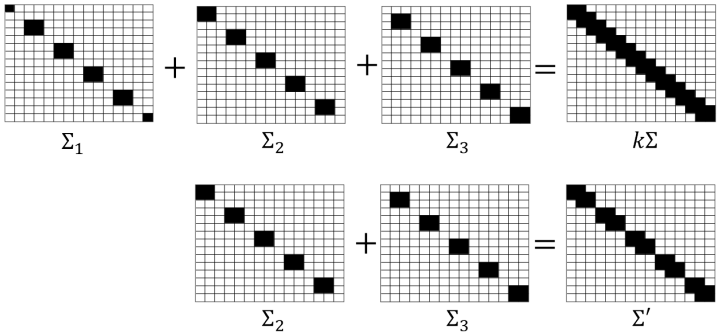

Figure 1: The sparsity pattern of Σ and Σ' when $U = \{2, 3\}$, $b = 15$ and $k = 3$.

4. The vector $w^* = \arg\min_w \bar{p}(w)$ is non-zero in all coordinates and, when b is sufficiently larger than t, $\|\hat{w} - w^*\|^2 \geq \Omega((1 - \frac{1}{\sqrt{\kappa'}})^{2t})$ for any $\hat{w} \in E_t$.

Because the gradient $\nabla\bar{p}(w) = (\Sigma + \mu' I)w + q$, where Σ is tridiagonal and $q \in E_1$, if a first-order method is applied to $\min_w \bar{p}(w)$ with an initial solution of $\mathbf{0}$, the solution will stay in E_t after t iterations. According to the 4th property above, a large number of iterations is needed for the first-order method to achieve an ϵ-optimal solution. We will use a similar argument to show that, when $\min_w \bar{p}(w)$ is solved by a distributed first-order method but each machine does not have a full collection of $\{p_s\}_{s\in[k]}$, a large number of rounds of communication is needed in order to find an ϵ-optimal solution.

Suppose a machine can only locally access the functions in $\{p_s\}_{s\in U}$ with $U \subsetneqq [k]$. By the sparsity patterns of Σ and Σ_s, $\Sigma' = \sum_{s\in U}\Sigma_s$ will be block diagonal with the size of each block being at most $(k + 1) \times (k + 1)$. The sparsity patterns of Σ' can be seen in Figure 1 for an example with $U = \{2, 3\}$, $b = 15$ and $k = 3$. Since $q, q_s \in E_1$, if the local computation of this machine starts with an initial solution in E_t and the solution is updated only using linear combinations of gradients $\nabla p_s(w) = (\Sigma_s + \mu' I)w + q_s$ for $s \in U$, this machine can only produce a solution in E_{t+k} no matter how many local iterations are performed. According to the 4th property above, this machine has to receive a solution outside E_{t+k} from other machines in order to make progress in approximting w^*. Hence, if no machine in a distributed first-order method has a full collection of $\{p_s\}_{s\in[k]}$, many rounds of communication is needed in order to generate an ϵ-optimal solution for $\min_w \bar{p}(w)$.

Since $\bar{p}$ is the average of only $k = \Theta(\log(m))$ functions while the communication lower bound is given for minimizing the average of N functions, we will make a few copies of $\{p_s\}_{s\in[k]}$ and add some zero functions to them. In particular, let $v = \frac{m}{k}$ and $\{g_i\}_{i\in[N]}$ be the multi-set of functions on $\mathbb{R}^b$ that consists of v copies of $\{p_s\}_{s\in[k]}$ and $N - vk$ zero functions. Therefore, $\bar{g}(w) \equiv \frac{1}{N}\sum_{i=1}^N g_i(w) = \frac{\bar{p}(w)}{n}$ so that $w^* = \arg\min_w \bar{g}(w)$. In addition, each g_i is L-smooth due to the 3rd property above and g is $\frac{\mu'}{n}$-strongly (i.e., μ-strongly) convex because m g_i's are μ'-strongly convex and $N - m$ g_i's are zero.

Suppose an algorithm in $\mathcal{F}_\alpha$ is applied to $\min_w \bar{g}(w)$ with the initial solution $\mathbf{0}$. Each machine will receives n functions from $\{g_i\}_{i\in[N]}$ by random partition and another αn func-

tions from $\{g_i\}_{i\in[N]}$ by random sampling with replacement. Since $k = \Theta(\log(m))$ and $\{g_i\}_{i\in[N]}$ contains only $vk = m$ functions from $\{p_s\}_{s\in[k]}$ and $N - m$ zero functions, we can show that, with a high probability, no machine will receive k or more functions from $\{p_s\}_{s\in[k]}$. According to the previous discussion, the number of non-zero coordinate in the solution generated by the algorithm will only increase by at most k between two consecutive rounds of communication. In other words, if $\hat{w}$ is the solution found by $\mathcal{F}_\alpha$ after H rounds of communication, we must have $\hat{w} \in E_t$ with $t = Hk$. By the 4th property above, the distance $\|\hat{w} - w^*\|^2 \geq \Omega((1 - \frac{1}{\sqrt{\kappa'}})^{2t})$. Since $\bar{g}$ is strongly convex, this distance implies an objective function gap of $\bar{g}(\hat{w}) - \bar{g}(w^*) \geq \Omega((1 - \frac{1}{\sqrt{\kappa'}})^{2t})$. Hence, in order to ensure $\bar{g}(\hat{w}) - \bar{g}(w^*) \leq \epsilon$, with a high probably, the rounds of communication must satisfy $H = \frac{t}{k} \geq \Omega(\sqrt{\kappa'}) \log\left(\frac{1}{\epsilon}\right) = \Omega(\sqrt{\frac{\kappa}{n}}) \log\left(\frac{1}{\epsilon}\right)$. This provides the lower bounds for the rounds of communication we found in this paper. Finally, we show that the same lower bound can be proved without having any zero function in the N functions. To do so, we raise the dimension of the problem from b to $d = nb$ by constructing a problem like (1), where $\{f_i\}_{i\in[N]}$ consists of vn copies of $\{p_s\}_{s\in[k]}$ with the first v copies defined on the first b coordinates of x, the second v copies defined on the second b coordinates of x and so on. Problem (1) with such $\{f_i\}_{i\in[N]}$ can be solved as n independent problems on $\mathbb{R}^b$ with each problem equivalent to $\min_w \bar{g}(w)$ so that the same communication lower bound can be obtained.

4.2 Some Definitions and Lemmas

Before we start the formal proof for Theorem 2, some definitions and technical lemmas are provided in this section. Given a vector $x \in \mathbb{R}^d$ and a set of indices $D \subset [d]$, we use x_D to represent the sub-vector of x that consists of the coordinates of x indexed by D.

Definition 4 *A function $f : \mathbb{R}^d \to \mathbb{R}$ is **decomposable** with respect to a partition $D_1, \ldots, D_r$ of coordinates $[d]$ if $f(x) = g^1(x_{D_1}) + \cdots + g^r(x_{D_r})$ with $g^l : \mathbb{R}^{|D_l|} \to \mathbb{R}$ for $l = 1, \ldots, r$. A set of functions $\{f_i\}_{i\in[N]}$ is **simultaneously decomposable** with respect to a partition $D_1, \ldots, D_r$ if each f_i is decomposable with respect to $D_1, \ldots, D_r$.*

It follows the Definition 1 and Definition 4 straightforwardly that:

Proposition 5 *Suppose the functions $\{f_i\}_{i\in[N]}$ in (1) are simultaneously decomposable with respect to a partition $D_1, \ldots, D_r$ so that $f_i(x) = \sum_{l=1}^r g_i^l(x_{D_l})$ with $g_i^l : \mathbb{R}^{|D_l|} \to \mathbb{R}$ for $i = 1, \ldots, N$ and $l = 1, \ldots, r$. Let x^* be the optimal solution of (1). We must have*

$$x^*_{D_l} \in \arg\min_{w\in\mathbb{R}^{|D_l|}} \left\{ \bar{g}^l(w) \equiv \frac{1}{N} \sum_{i=1}^N g_i^l(w) \right\}, \text{ for } l = 1, 2, \ldots, r. \tag{6}$$

Moreover, any algorithm $\mathcal{A} \in \mathcal{F}_\alpha$, when applied to $\{f_i\}_{i\in[N]}$, becomes decomposable with respect to the same partition $D_1, \ldots, D_r$ in the following sense: For $l = 1, \ldots, r$, there exists an algorithm $\mathcal{A}_l \in \mathcal{F}_\alpha$ such that, after any number of rounds H,

$$\mathbb{E}[f(\hat{x}) - f(x^*)] = \sum_{l=1}^r \mathbb{E}[\bar{g}^l(\hat{w}^l) - \bar{g}^l(x^*_{D_l})],$$

where $\hat{x} = \mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H) \in \mathbb{R}^d$ and $\hat{w}^l = \mathcal{A}_l(\{g_i^l\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H) \in \mathbb{R}^{|D_l|}$ for $l = 1, 2, \ldots, r$ and $\{S'_j\}_{j\in[m]}$ is generated as in Definition 1.

Proof The proof of this proposition is straightforward. Since $\{f_i\}_{i\in[N]}$ in (1) are simultaneously decomposable with respect to a partition $D_1, \ldots, D_r$, we have

$$f(x) = \frac{1}{N} \sum_{i=1}^N \sum_{l=1}^r g_i^l(x_{D_l}) = \sum_{l=1}^r \bar{g}^l(x_{D_l})$$

so that the problem (1) can be solved by solving (6) for each l separately and $x^*_{D_l}$ must be the solution of the l-th problem in (6).

In addition, the function F_j in Definition 1 is also decomposable with respect to the same partition $D_1, \ldots, D_r$. As a result, its gradient $\nabla F_j(x)$ also has a decomposed structure in the sense that the block $[\nabla F_j(x)]_{D_l}$ only depends on x_{D_l}. Similarly, its Hessian matrix $\nabla^2 F_j(x)$ is a block diagonal matrix with r blocks and the l-th block only depends on x_{D_l}. These properties ensure that each operation $\mathcal{A}$ is able to apply (as in Definition 1) to some $x \in \mathbb{R}^d$ can be decomposed into r independent operations applied on $x_{D_1}, x_{D_2}, \ldots, x_{D_r}$ separately. Hence, given the sets $\{S'_j\}_{j\in[m]}$, the sequence of operations conducted by $\mathcal{A}$ on x_{D_l} can be viewed as an algorithm $\mathcal{A}_l \in \mathcal{F}_\alpha$ applied to $\{g_i^l\}_{i\in[N]}$ so that $\hat{w}^l = \mathcal{A}_l(\{g_i^l\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$ is indeed the sub-vector $\hat{x}_{D_l}$ of the vector $\hat{x} = \mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$ for $l = 1, 2, \ldots, r$ and any H. ■

Because $m \geq (e + 4\max\{1, \alpha\})^2$ and $k \equiv \lceil (e + 4\max\{1, \alpha\}) \log m \rceil$, we can show that

$$\frac{m}{k} \geq \frac{m}{1.25(e + 4\max\{1, \alpha\}) \log m} \geq \frac{e + 4\max\{1, \alpha\}}{2.5 \log(e + 4\max\{1, \alpha\})} \geq \frac{e + 4}{2.5 \log(e + 4)} > 3$$

for any $\alpha \geq 0$, where we use the fact that $1.25x \geq \lceil x \rceil$ for $x \geq 4$ and the fact that $\frac{x}{\log x}$ is monotonically increasing on $[e, +\infty)$. In the rest of the paper, we define

$$v \equiv \left\lfloor \frac{m}{k} \right\rfloor \text{ and } \theta \equiv \frac{vk}{m}.$$

It is easy to show that $\frac{2}{3} < 1 - \frac{k}{m} < \theta \leq 1$, where the first inequality is because $\frac{m}{k} > 3$ and the second and the last inequalities are by the definitions of v and θ.

4.3 Proof for Theorem 2

Now we are ready to give the proof for Theorem 2 in this subsection. Let

$$\mu' \equiv \frac{\mu n}{\theta}, \quad \kappa' \equiv \frac{L}{\mu'} = \frac{\theta\kappa}{n} > \frac{2\kappa}{3n} \geq 1. \tag{7}$$

We first generalize the machinery by Arjevani and Shamir (2015) to construct k functions on $\mathbb{R}^b$ where $b = uk$ for some integers $k, u \geq 1$. The values of k and u will be specified later. In particular, for $i, j = 1, \ldots, b$, let $\delta_{i,j}$ be an $b \times b$ matrix with its (i, j) entry being one and others being zeros. Let $M_0, M_1, \ldots, M_{b-1}$ be $b \times b$ matrices defined as

$$M_i = \begin{cases} \delta_{1,1} & \text{for } i = 0 \\ \delta_{i,i} - \delta_{i,i+1} - \delta_{i+1,i} + \delta_{i+1,i+1} & \text{for } 1 \leq i \leq b-2 \\ \delta_{b-1,b-1} - \delta_{b-1,b} - \delta_{b,b-1} + \frac{\sqrt{\kappa'+k-1}+3\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}} \delta_{b,b} & \text{for } i = b-1. \end{cases} \tag{8}$$

For $s \in [k]$, let

$$\Sigma_s = \sum_{i=0}^{u-1} M_{ik+s-1}. \tag{9}$$

For example, when $u = 2$ and $k = 3$ (so $b = 6$), the matrices Σ_s's are given as follows

$$\Sigma_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \Sigma_2 = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

$$\Sigma_3 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & -1 & \mathcal{K} \end{bmatrix},$$

where $\mathcal{K} = \frac{\sqrt{\kappa'+k-1}+3\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}}$.

We define k functions $p_1, \ldots, p_k : \mathbb{R}^b \to \mathbb{R}$ as follows

$$p_s(w) = \begin{cases} \frac{L}{4}\left[\left(1-\frac{\mu'}{L}\right)\frac{w^T\Sigma_1 w}{2} - \left(1-\frac{\mu'}{L}\right)e_1^\top w\right] + \frac{\mu'}{2}\|w\|^2 & \text{for } s = 1 \\ \frac{L}{4}\left[\left(1-\frac{\mu'}{L}\right)\frac{w^T\Sigma_s w}{2}\right] + \frac{\mu'}{2}\|w\|^2 & \text{for } s = 2, \ldots, k, \end{cases} \tag{10}$$

where $e_1 = (1, 0, \ldots, 0)^T \in \mathbb{R}^b$, and denote their average by

$$\bar{p} \equiv \frac{1}{k}\sum_{s=1}^{k} p_s = \frac{L-\mu'}{4k}\left[\frac{1}{2}w^T\left(\sum_{s=1}^{k}\Sigma_s\right)w - e_1^T w\right] + \frac{\mu'}{2}\|w\|^2. \tag{11}$$

According to (7), we have $1 - \frac{\mu'}{L} > 0$ so that p_s for any $s \in [k]$ and $\bar{p}$ are all μ'-strongly convex functions. It is also easy to show that, for each s, $\lambda_{\max}(\Sigma_s) \leq 4$ so that ∇p_s has a Lipschitz continuity constant of $L\left(1-\frac{\mu'}{L}\right) + \mu' = L$ and p_s is L-smooth.

Next, we characterize the optimal solution of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$.

Lemma 6 *Let $h \in \mathbb{R}$ be the smaller root of the equation $h^2 - 2\left(\frac{\kappa'-1+2k}{\kappa'-1}\right)h + 1 = 0$, namely, $h \equiv \frac{\sqrt{\kappa'+k-1}-\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}}$. Then, $w^* = (w_1^*, w_2^*, \ldots, w_b^*)^T \in \mathbb{R}^b$ with*

$$w_j^* = h^j, \text{ for } j = 1, 2, \ldots, b \tag{12}$$

is the optimal solutions of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$.

Proof By (9), we have

$$\sum_{s=1}^{k}\Sigma_s = \begin{bmatrix} 2 & -1 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & -1 & \frac{\sqrt{\kappa'+k-1}+3\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}} \end{bmatrix}.$$

With this tridiagonal structure in its Hessian matrix, $\bar{p}(w)$ is related to but different from the functions constructed by Nesterov (2013) and Lan and Zhou (2017) to establish the iteration lower bound for single-machine first-order algorithms. We can show that the optimal solution of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$ must satisfy the following optimality conditions

$$\begin{aligned} w_2^* - 2\left(\frac{\kappa'-1+2k}{\kappa'-1}\right)w_1^* + 1 &= 0 \\ w_{j+1}^* - 2\left(\frac{\kappa'-1+2k}{\kappa'-1}\right)w_j^* + w_{j-1}^* &= 0, \text{ for } j = 2, 3, \ldots, b-1 \\ -\left(\frac{\sqrt{\kappa'+k-1}+3\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}} + \frac{4k}{\kappa'-1}\right)w_b^* + w_{b-1}^* &= 0. \end{aligned} \tag{13}$$

We can easily verify that $w_j^* = h^j$ for $j = 1, 2, \ldots, b$ satisfy all equations in (13) such that w^* is the optimal solution of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$. ■

We claim that $\{p_s\}_{s\in[k]}$ in (10) has the following property according to our construction.

Lemma 7 *Suppose U is a* **strict** *subset of $\{p_s\}_{s\in[k]}$ defined in (10), and q is an arbitrary linear combination of some functions p_s in U. The Hessian of q is a block diagonal matrix where each block is a square matrix of a size at most k.*

Proof There must exist some $s' \in [k]$ with $p_{s'} \notin U$. Since q is a linear combination of p_s's in U, according to the construction in (10), the Hessian of q is a tridiagonal matrix because it is a linear combination of a diagonal matrix (the Hessian of $\frac{\mu'}{2}\|w\|^2$) and all the matrices Σ_s defined in (9) except $\Sigma_{s'}$. We note that $\Sigma_{s'}$ is the only matrix among all Σ_s's that has non-zero entries in the positions $(s'-1+ik, s'+ik)$ and $(s'+ik, s'-1+ik)$ for $i = 0, 1, \ldots, u-1$ and both the row and column indices of these positions are equally spaced with a gap of k. Therefore, without $\Sigma_{s'}$ involved in the linear combination, the tridiagonal Hessian of q becomes block diagonal with each block of a size at most k. ■

To complete the proof of Theorem 2, the following lemma is critical. This lemma tells us that the property given by Lemma 7 forces the machines to perform a large number of rounds of communication in order to minimize $\bar{p}$ whenever $\{p_s\}_{s\in[k]}$ do not appear together in any machine.

Lemma 8 *For any $b = uk$ with integers $k, u \geq 1$, let $\{g_i\}_{i\in[N]}$ be the multi-set of functions on $\mathbb{R}^b$ that consists of v copies of $\{p_s\}_{s\in[k]}$ defined as (10) and $N - vk$ zero functions. More specifically,*

$$g_i(w) = \begin{cases} p_s(w) & \text{if } i = s, s+k, s+2k, \ldots, s+(v-1)k, \\ 0 & \text{if } i \geq vk+1. \end{cases} \tag{14}$$

Suppose an algorithm $\mathcal{A} \in \mathcal{F}_\alpha$ is applied to $\{g_i\}_{i\in[N]}$ to solve

$$\min_{w\in\mathbb{R}^b} \bar{g}(w) \equiv \frac{1}{N}\sum_{i=1}^N g_i \tag{15}$$

and the sets $\{S'_j\}_{j\in[m]}$ are generated as in Definition 1. Let $\mathcal{E}$ be the random event that none of the m machines has all functions in $\{p_s\}_{s\in[k]}$. Let $\hat{w} = \mathcal{A}(\{g_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$. Then, for any $\epsilon > 0$ and $k \geq 1$, there exist u and $b = uk$ such that $\mathbb{E}[g(\hat{w}) - g(w^*)|\mathcal{E}] \leq \epsilon$ only if $H \geq \left(\frac{\sqrt{\kappa'+k-1}-\sqrt{k}}{4k\sqrt{k}}\right)\log\left(\frac{\mu\|w^*\|^2}{4\epsilon}\right)$.

Proof Let $w^* \in \mathbb{R}^b$ defined as (12). Since $\bar{g} = \frac{1}{N}\sum_{i=1}^N g_i = \frac{v}{N}\sum_{s=1}^k p_s = \frac{\theta\bar{p}}{n}$, we have $w^* = \arg\min_{w\in\mathbb{R}^b}\bar{p}(w) = \arg\min_{w\in\mathbb{R}^b}\bar{g}(w)$ by Lemma 6.

Let $E_0 = \{\mathbf{0}\}$, where $\mathbf{0}$ is the all-zero vector in $\mathbb{R}^b$ and let E_t be the linear space in $\mathbb{R}^b$ spanned by the unit vectors $e_1, \ldots, e_t$ for $t = 1, \ldots, b$, where $e_s \in \mathbb{R}^b$ has one in its s-th component and zeros in other components.

Because $\mathcal{A}$ is applied to (15), by Definition 1, the working set W_j in machine j in each round can be updated for arbitrarily many times by including a vector w such that

$$\gamma w + \nu\nabla F_j(w) \in \text{span}\Big\{ w', \nabla F_j(w'), (\nabla^2 F_j(w') + D)w'', (\nabla^2 F_j(w') + D)^{-1}w'' \Big| \\ w', w'' \in W_j, D \text{ is diagonal}, \nabla^2 F_j(w') \text{ and } (\nabla^2 F_j(w') + D)^{-1} \text{ exist} \Big\} \tag{16}$$

for some constants $\gamma \geq 0$ and $\nu \geq 0$ with $\gamma\nu \neq 0$, where $F_j = \sum_{i\in U_j\subset S'_j} g_i$ with an arbitrary subset U_j of S'_j. Suppose event $\mathcal{E}$ happens such that S'_j does not contain all functions in $\{p_s\}_{s\in[k]}$ for any j. The set U_j in (16) will be a strict subset of $\{p_s\}_{s\in[k]}$ so that, according to Lemma 7, the Hessian matrix $\nabla^2 F_j$ in (16) is block-diagonal with a block size at most k. Because F_j is always a quadratic function, such a property of its Hessian matrix means, as long as W_j is contained by E_t, any vector w satisfying (16) will be in E_{t+k}. Therefore, we can show that, at the beginning of round ℓ in algorithm $\mathcal{A}$, if $\cup_j W_j \subset E_t$, then at the end of round ℓ (and at the beginning of round $\ell+1$), we have $\cup_j W_j \subset E_{t+k}$. Using this finding and the fact that $\cup_j W_j = \{\mathbf{0}\} = E_0$ initially, we conclude that, after H rounds in $\mathcal{A}$, we must have $\cup_j W_j \subset E_{Hk}$. Let $t = Hk$. Since $\hat{w} = \mathcal{A}(\{g_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$, we must have $\hat{w} \in E_t$ if $\mathcal{E}$ happens.

By (12), we can show that

$$\|w^*\|^2 = \sum_{j=1}^b (w_j^*)^2 = \sum_{j=1}^b h^{2j} = \frac{h^2(1-h^{2b})}{1-h^2}. \tag{17}$$

Because $\bar{p}$ defined in (11) is μ'-strong convex, we have

$$\frac{2}{\mu'}\mathbb{E}[\bar{p}(\hat{w}) - \bar{p}(w^*)|\mathcal{E}] \geq \mathbb{E}[\|\hat{w} - w^*\|^2|\mathcal{E}] \geq \sum_{j=t+1}^b \mathbb{E}[(w_j^*)^2|\mathcal{E}] \geq \frac{h^{2t+2}(1-h^{2b-2t})}{1-h^2} \geq \frac{\|w^*\|^2(h^{2t}-h^{2b})}{1-h^{2b}}$$

where the second inequality is because $\hat{w} \in E_t$ and the third inequality is due to (17). For any $k \geq 1$, when u is large enough so $b = uk$ is large enough, the inequality above implies $\mathbb{E}[\bar{p}(\hat{w}) - \bar{p}(w^*)|\mathcal{E}] \geq \frac{\mu'\|w^*\|^2 h^{2t}}{4} = \frac{\mu'\|w^*\|^2}{4}\left(\frac{\sqrt{\kappa'+k-1}-\sqrt{k}}{\sqrt{\kappa'+k-1}+\sqrt{k}}\right)^{2t}$. Based on this inequality, when $\mathbb{E}[\bar{g}(\hat{w}) - \bar{g}(w^*)|\mathcal{E}] \leq \epsilon$, or equivalently, when $\mathbb{E}[\bar{p}(\hat{w}) - \bar{p}(w^*)|\mathcal{E}] \leq \frac{n\epsilon}{\theta}$, we must have $\log\left(\frac{\mu'\theta\|w^*\|^2}{4n\epsilon}\right) \leq 2t\log\left(1 + \frac{2\sqrt{k}}{\sqrt{\kappa'+k-1}-\sqrt{k}}\right) \leq \frac{4t\sqrt{k}}{\sqrt{\kappa'+k-1}-\sqrt{k}}$, which further implies $H = \frac{t}{k} \geq \left(\frac{\sqrt{\kappa'+k-1}-\sqrt{k}}{4k\sqrt{k}}\right)\log\left(\frac{\mu\|w^*\|^2}{4\epsilon}\right)$. ■

In Lemma 8, the requirement of a large enough $b = uk$ is necessary since, if b is fixed and the number of rounds H satisfies $Hk \geq b$, the solution $\hat{w} = \mathcal{A}(\{g_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$ can be non-zero in all dimensions so that it may equal w^*. If this happens, $g(\hat{w}) - g(w^*) \leq \epsilon$ for any ϵ so that the lower bound for H in Lemma 8 does not hold. Because the communication lower bound we study does not depend on the dimension of the problem, we construct the functions with a dimension higher than Hk so that there are dimensions that will not be reached by the generated solutions so that the optimality gap has to reduce to zero slowly.

We now complete the proof of Theorem 2 by constructing N special functions $\{f_i\}_{i\in[N]}$ on $\mathbb{R}^d$ with $d = nb$ and $b = uk$ for a sufficiently large u based on $\{p_s\}_{s\in[k]}$ defined as (10), so that any algorithm $\mathcal{A} \in \mathcal{F}_\alpha$, when applied to $\{f_i\}_{i\in[N]}$, will need at least the targeted amount of rounds of communication.

For a large enough u, we partition the set of indices $[d] = \{1, \ldots, d\}$ into n disjoint subsets $D_1, D_2, \ldots, D_n$ with $|D_l| = b$ and $D_l = \{b(l-1)+1, , b(l-1)+2, \ldots, bl\}$. For any $l \in [n]$ and $s \in [k]$, let $q_{l,s}(x)$ be a function on $\mathbb{R}^d$ defined as

$$q_{l,s}(x) \equiv p_s(x_{D_l}), \tag{18}$$

where $\{p_s\}_{s\in[k]}$ is defined as (10). By its definition, the function $q_{l,s}(x)$ only depends on the b coordinates of x indexed by D_l. Therefore, we obtain nk different functions $\{q_{l,s}\}_{l\in[n],s\in[k]}$. Finally, we define $\{f_i\}_{i\in[N]}$ to be a set that consists of v copies of $\{q_{l,s}\}_{l\in[n],s\in[k]}$ and $N - vkn$ zero functions. In other words, the non-zero functions in the set $\{f_i\}_{i\in[N]}$ we constructed in this way constitutes a multi-set as follows

$$\left\{\begin{matrix} p_1(x_{D_1}), & p_2(x_{D_1}), & \cdots, & p_k(x_{D_1}), & \cdots, & p_1(x_{D_1}), & p_2(x_{D_1}), & \cdots, & p_k(x_{D_1}) \\ p_1(x_{D_2}), & p_2(x_{D_2}), & \cdots, & p_k(x_{D_2}), & \cdots, & p_1(x_{D_2}), & p_2(x_{D_2}), & \cdots, & p_k(x_{D_2}) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ p_1(x_{D_n}), & p_2(x_{D_n}), & \cdots, & p_k(x_{D_n}), & \ldots, & p_1(x_{D_n}), & p_2(x_{D_n}), & \cdots, & p_k(x_{D_n}) \end{matrix}\right\}, \tag{19}$$

where the l-th row consists of v copies of $\{p_s\}_{s\in[k]}$ applied on x_{D_l}.

Because of Lemma 6 and the fact that

$$f(x) = \frac{1}{N}\sum_{i=1}^N f_i(x) = \frac{v}{N}\sum_{l=1}^n\sum_{s=1}^k q_{l,s}(x) = \frac{v}{N}\sum_{l=1}^n\sum_{s=1}^k p_s(x_{D_l}) = \frac{\theta}{n}\sum_{l=1}^n \bar{p}(x_{D_l}), \tag{20}$$

the optimal solution x^* for (1) with $\{f_i\}_{i\in[N]}$ constructed as (19) is $x^* = \mathbf{1}_n \otimes w^* = (w^*, w^*, \ldots, w^*)^T$ where $w^* \in \mathbb{R}^d$ is defined as (12) and repeated for n times in x^*.

Now, we want to verify that the functions $\{f_i\}_{i\in[N]}$ satisfy our assumptions. In fact, we have shown that p_s is L-smooth for each $s \in [k]$. Since f_i is either a zero function or equals $p_s(x_{D_l})$ for some $l \in [n]$ and $s \in [k]$, the function f_i is L-smooth for each $i \in [N]$ as well. Since $\bar{p}$ is μ'-strongly convex (on $\mathbb{R}^b$) and $\mu' = \frac{n\mu}{\theta}$, the function f defined in (1) must be μ-strongly convex (on $\mathbb{R}^d$) according to the relationship (20).

According to its construction, $\{f_i\}_{i\in[N]}$ are simultaneously decomposable with respect to the partition $D_1, \ldots, D_n$ with $D_l = \{b(l-1)+1, b(l-1)+2, \ldots, bl\}$ (see Definition 4). In fact, $f_i(x) = p_s(x_{D_l})$ for some $s \in [k]$ and $l \in [n]$ so that $f_i(x)$ can be represented as

$$f_i(x) = \sum_{l=1}^{n} g_i^l(x_{D_l}), \tag{21}$$

where $g_i^l \in \{p_s\}_{s\in[k]}$ for exactly one $l \in [n]$ and $g_i^l \equiv 0$ for other l's. Moreover, for any $l \in [n]$, the following equality holds between the two multi-sets

$$\{g_i^l\}_{i\in[N]} = \{g_i\}_{i\in[N]}, \tag{22}$$

where $\{g_i\}_{i\in[N]}$ are defined as (14).[4] By Proposition 5, $\mathcal{A}$ can be decomposed with respective to the same partition $D_1, D_2, \ldots, D_n$ into $\mathcal{A}_1, \ldots, \mathcal{A}_n \in \mathcal{F}_\alpha$ and $\mathcal{A}_l$ is applied to

$$\min_{w\in\mathbb{R}^b} \left\{ \bar{g}^l \equiv \frac{1}{N}\sum_{i=1}^{N} g_i^l = \frac{1}{N}\sum_{i=1}^{N} g_i = \bar{g} \right\}, \tag{23}$$

which is exactly the problem (15) and has the form of (1). Recall Definition 1 for the procedure of generating $S_j' = S_j \cup R_j$, When $\{f_i | i \in S_j'\}$ is allocated to machine j for algorithm $\mathcal{A}$, what happens at the same time is that $\{g_i^l | i \in S_j'\}$ is allocated to machine j for algorithm $\mathcal{A}_l$ for $l = 1, 2, \ldots, n$.

We now focus on the solution generated by $\mathcal{A}_l$ for some l. For machine j in $\mathcal{A}_l$, let $Y_{1,j}$ be the number of functions in $\{p_s\}_{s\in[k]}$ (repetitions counted) that are contained in S_j and $Y_{2,j}$ be the number of functions in $\{p_s\}_{s\in[k]}$ (repetitions counted) that are contained in R_j.

Due to (14) and (22), exactly vk functions in $\{g_i^l\}_{i\in[N]}$ are from $\{p_s\}_{s\in[k]}$ and the other $N - vk$ functions are zero. Hence, $Y_{1,j}$ has a hypergeometric distribution where $\text{Prob}(Y_{1,j} = r)$ equals the probability of r successes in n draws, without replacement, from a population of size N that contains vk successes. Let $r = e\log m$. According to Chvatal (1979) and

4. The equation (22) does not means $g_i^l = g_i$ for any l and i. It only means, for any l and i, there exists an $i' \in [N]$ so that $g_i^l = g_{i'}$.

$\frac{vk}{N} \le \frac{1}{n}$, we have $\text{Prob}(Y_{1,j} \ge r) \le \left(\frac{vkn}{Nr}\right)^r \left(\frac{n-vkn/N}{n-r}\right)^{n-r} \le \left(\frac{1}{r}\right)^r \left(\frac{n-1}{n-r}\right)^{n-r}$, which implies

$$\begin{aligned}
\text{Prob}(Y_{1,j} \ge e\log m) &\le \left(\frac{1}{e\log m}\right)^{e\log m} \left(\frac{n-1}{n-e\log m}\right)^{n-e\log m} \\
&= \left(\frac{1}{e\log m}\right)^{e\log m} \left(1 + \frac{e\log m - 1}{n - e\log m}\right)^{n-e\log m} \\
&< \left(\frac{1}{e\log m}\right)^{e\log m} e^{e\log m - 1} = \frac{1}{e}\left(\frac{1}{\log m}\right)^{e\log m} \\
&\le \frac{1}{e}\left(\frac{1}{2\log(e+1)}\right)^{e\log m} \le \frac{1}{em^2},
\end{aligned} \tag{24}$$

where the second inequality is because $(1 + \frac{1}{x})^x < e$, the third inequality is because $m \ge (e + 4\max\{1,\alpha\})^2 \ge (e+1)^2$, and the last inequality is because $(2\log(e+1))^e > e^2$.

On the other hand, we have $Y_{2,j} = 0$ when $\alpha = 0$ and $Y_{2,j} = \sum_{i\in R_j} \mathbf{1}_{g_i^l \in \{p_s\}_{s\in[k]}}$ when $\alpha > 0$, where $\mathbf{1}_{g_i^l\in\{p_s\}_{s\in[k]}}$ for $i \in R_j$ are αn i.i.d. binary random variables which equal one with a probability of $\frac{vk}{N}$ and zero with a probability of $1 - \frac{vk}{N}$. Suppose $\alpha > 0$. The mean and the variance of $\mathbf{1}_{g_i^l\in\{p_s\}_{s\in[k]}}$ are $\frac{\theta}{n}$ and $\frac{\theta}{n}(1-\frac{\theta}{n})$, respectively. Hence, by Bernstein inequality (Uspensky, 1937), we have

$$\begin{aligned}
\text{Prob}(Y_{2,j} \ge 4\max\{1,\alpha\}\log m) &\le \text{Prob}(Y_{2,j} > \alpha\theta + 3\max\{1,\alpha\}\log m) \\
&\le \exp\left(\frac{-\frac{1}{2}(3\max\{1,\alpha\}\log m)^2}{\alpha\theta\left(1-\frac{\theta}{n}\right) + \max\{1,\alpha\}\log m}\right) \\
&\le \exp\left(\frac{-\frac{1}{2}(3\max\{1,\alpha\}\log m)^2}{2\max\{1,\alpha\}\log m}\right) \\
&\le \exp\left(-2\max\{1,\alpha\}\log m\right) \le \frac{1}{m^2},
\end{aligned} \tag{25}$$

where the first inequality is because $\max\{1,\alpha\}\log m > \alpha\theta$ and the third inequality is because $\max\{1,\alpha\}\log m \ge \alpha\theta\left(1-\frac{\theta}{n}\right)$. Suppose $\alpha = 0$. (25) holds trivially.

Combining (24) and (25) for $j = 1, 2, \ldots, m$ and using the union bound, we have

$$\text{Prob}(Y_{1,j} + Y_{2,j} < (e + 4\max\{1,\alpha\})\log m \text{ for } j = 1, 2, \ldots, m) \ge 1 - \frac{2}{m}.$$

Therefore, we have shown that, with a probability of at least $1 - \frac{2}{m}$, the multi-set $\{g_i^l | i \in S_j'\}$ contains fewer than $(e+4\max\{1,\alpha\})\log m \le k$ functions from $\{p_s\}_{s\in[k]}$ (repetition counted) for any $j \in [m]$. In other words, with a probability of at least $1 - \frac{2}{m}$, no machine in $\mathcal{A}_l$ has all of the functions in $\{p_s\}_{s\in[k]}$. If the event that "*none of the m machines has all functions in $\{p_s\}_{s\in[k]}$*" (same as the event $\mathcal{E}$ in Lemma 8) indeed happens in $\mathcal{A}_l$, we call $\mathcal{A}_l$ *bad*. Then, since $m \ge (e + 4\max\{1,\alpha\})^2$, we have actually proved

$$\text{Prob}(\mathcal{A}_l \text{ is bad}) \ge 1 - \frac{2}{m} \ge 1 - \frac{1}{e}. \tag{26}$$

By Proposition 5, after H rounds, the solutions $\hat{x} = \mathcal{A}(\{f_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H) \in \mathbb{R}^d$ and $\hat{w}^l = \mathcal{A}_l(\{g_i^l\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H) \in \mathbb{R}^{|D_l|}$ for $l = 1, 2, \ldots, n$ satisfy

$$\begin{aligned}\mathbb{E}[f(\hat{x}) - f(x^*)] &= \sum_{l=1}^{n} \mathbb{E}[\bar{g}^l(\hat{w}^l) - \bar{g}^l(x^*_{D_l})] = \sum_{l=1}^{n} \mathbb{E}[\bar{g}(\hat{w}^l) - \bar{g}(x^*_{D_l})] \\ &\geq \sum_{l=1}^{n} \mathbb{E}[\bar{g}(\hat{w}^l) - \bar{g}(x^*_{D_l})|\mathcal{A}_l \text{ is bad}]\text{Prob}(\mathcal{A}_l \text{ is bad}) \\ &\geq \sum_{l=1}^{n} \mathbb{E}[\bar{g}(\hat{w}^l) - \bar{g}(x^*_{D_l})|\mathcal{A}_l \text{ is bad}] \left(1 - \frac{1}{e}\right).\end{aligned}$$

Therefore, if $\mathbb{E}[f(\hat{x}) - f(x^*)] \leq \epsilon$, there must exist an $l \in [n]$ such that

$$\mathbb{E}[\bar{g}(\hat{w}^l) - \bar{g}(x^*_{D_l})|\mathcal{A}_l \text{ is bad}] \left(1 - \frac{1}{e}\right) \leq \frac{\epsilon}{n}. \tag{27}$$

When $\mathcal{A}_l$ is bad, none of the m machines in $\mathcal{A}_l$ has all functions in $\{p_s\}_{s\in[k]}$. By Lemma 8, there exist u and $b = uk$ such that (27) happens only if

$$\begin{aligned}H &\geq \left(\frac{\sqrt{\kappa' + k - 1} - \sqrt{k}}{4k\sqrt{k}}\right) \log\left(\left(1 - \frac{1}{e}\right) \frac{\mu n \|w^*\|^2}{4\epsilon}\right) \\ &= \left(\frac{\sqrt{\kappa' + k - 1} - \sqrt{k}}{4k\sqrt{k}}\right) \log\left(\left(1 - \frac{1}{e}\right) \frac{\mu \|x^*\|^2}{4\epsilon}\right), \\ &\geq \left(\frac{\sqrt{\kappa' - 1}}{4\sqrt{2}k\sqrt{k}}\right) \log\left(\left(1 - \frac{1}{e}\right) \frac{\mu \|x^*\|^2}{4\epsilon}\right),\end{aligned}$$

which is the desired lower bound after applying $\kappa' \geq \frac{2\kappa}{3n}$.

4.4 Proof for Theorem 3

We provide the proof for Theorem 3 in this subsection by following a similar argument to the proof of Theorem 2. Some notations in the previous sections will be used here but defined differently.

We first use the machinery developed in Section 2.1.1 by Nesterov (2013) to construct k functions on $\mathbb{R}^b$ where $b = uk$ for some integers $k, u \geq 1$. In particular, for $i, j = 1, \ldots, b$, let $\delta_{i,j}$ be an $b \times b$ matrix with its (i, j) entry being one and others being zeros. Let $M_0, M_1, \ldots, M_{b-1}$ be $b \times b$ matrices defined as

$$M_i = \begin{cases} \delta_{1,1} & \text{for } i = 0 \\ \delta_{i,i} - \delta_{i,i+1} - \delta_{i+1,i} + \delta_{i+1,i+1} & \text{for } 1 \leq i \leq b-1. \end{cases} \tag{28}$$

Here, only the M_{b-1} in (28) is different from the M_{b-1} in (8). For $s \in [k]$, let $\Sigma_s = \sum_{i=0}^{u-1} M_{ik+s-1}$ which has the same form as (9) but with a different M_{b-1}. For example,

when $u = 2$ and $k = 3$ (so $b = 6$), the matrices Σ_s's are given as follows.

$$\Sigma_1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \Sigma_2 = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

$$\Sigma_3 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & -1 & 1 \end{bmatrix}.$$

We define k functions $p_1, \ldots, p_k : \mathbb{R}^b \to \mathbb{R}$ as follows

$$p_s(w) = \begin{cases} \frac{L}{4}\left[\frac{w^T \Sigma_1 w}{2} - e_1^\top w\right] & \text{for } s = 1 \\ \frac{L}{4}\left[\frac{w^T \Sigma_s w}{2}\right] & \text{for } s = 2, \ldots, k, \end{cases} \tag{29}$$

where $e_1 = (1, 0, \ldots, 0)^T \in \mathbb{R}^b$, and denote their average by

$$\bar{p} \equiv \frac{1}{k}\sum_{s=1}^{k} p_s = \frac{L}{4k}\left[\frac{1}{2} w^T \left(\sum_{s=1}^{k} \Sigma_s\right) w - e_1^T w\right]. \tag{30}$$

It is also easy to show that $\lambda_{\max}(\Sigma_s) \leq 4$ so that ∇p_s has a Lipschitz continuity constant of L so that p_s is L-smooth.

Observing that

$$\sum_{s=1}^{k} \Sigma_s = \begin{bmatrix} 2 & -1 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & -1 & 2 \end{bmatrix},$$

we note that the function $\bar{p}(w)$ defined in (30) is the one studied in Section 2.1.2 by Nesterov (2013) for establishing the lower bound for the iteration complexity for single-machine first-order methods. Following Section 2.1.2 by Nesterov (2013), the optimal solution and the optimal value of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$ can be characterized as follows.

Lemma 9 (Nesterov (2013)) *The vector $w^* = (w_1^*, w_2^*, \ldots, w_b^*)^T \in \mathbb{R}^b$ with*

$$w_j^* = 1 - \frac{j}{b+1}, \text{ for } j = 1, 2, \ldots, b \tag{31}$$

is the optimal solution of $\min_{w\in\mathbb{R}^b} \bar{p}(w)$. Moreover, $\|w^*\|^2 \leq \frac{b+1}{3}$ and $\bar{p}(w^*) = \frac{L}{8k}\left(-1 + \frac{1}{b+1}\right)$.

The following lemma can be extracted from Section 2.1.2 in Nesterov (2013) which characterizes the optimal value of $\bar{p}$ when restricted in the subspace of first t coordinates.

Lemma 10 (Nesterov (2013)) *Let $\bar{p}$ defined as (30). We have*

$$\min_{(w_1,\ldots,w_t)\in\mathbb{R}^t} \bar{p}(w_1,\ldots,w_t,0,\ldots,0) = \frac{L}{8k}\left(-1+\frac{1}{t+1}\right).$$

We can show that $\{p_s\}_{s\in[k]}$ defined in (29) has the following properties.

Lemma 11 *Suppose U is a* **strict** *subset of $\{p_s\}_{s\in[k]}$ defined in (10), and q is an arbitrary linear combination of some functions p_s in U. The Hessian of q is a block diagonal matrix where each block is a square matrix of a size at most k.*

Proof Same as the proof of Lemma 7. ■

Lemma 12 *For any $b = uk$ with integers $k, u \geq 1$, let $\{g_i\}_{i\in[N]}$ be the multi-set of functions on $\mathbb{R}^b$ that consists of v copies of $\{p_s\}_{s\in[k]}$ defined as (29) and $N - vk$ zero functions. More specifically, $\{g_i\}_{i\in[N]}$ is defined as (14) but with $\{p_s\}_{s\in[k]}$ defined as (29). Suppose an algorithm $\mathcal{A} \in \mathcal{F}_\alpha$ is applied to (15) and the sets $\{S'_j\}_{j\in[m]}$ are generated as in Definition 1. Let $\mathcal{E}$ be the random event that none of the m machines has all functions in $\{p_s\}_{s\in[k]}$. Let $\hat{w} = \mathcal{A}(\{g_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$. Then, for any $\epsilon > 0$ and $k \geq 1$, there exist u and $b = uk$ such that $\mathbb{E}[g(\hat{w}) - g(w^*)|\mathcal{E}] \leq \epsilon$ only if $H \geq \sqrt{\frac{3L\|w^*\|^2}{128k^3n\epsilon}}$.*

Proof Let $u = 2H+1$, $b = 2Hk+k$ and $w^* \in \mathbb{R}^b$ defined as (31). Since $\bar{g} = \frac{1}{N}\sum_{i=1}^N g_i = \frac{v}{N}\sum_{s=1}^k p_s = \frac{\theta\bar{p}}{n}$, we have $w^* = \arg\min_{w\in\mathbb{R}^b} \bar{p}(w) = \arg\min_{w\in\mathbb{R}^b} \bar{g}(w)$ by Lemma 9.

Let E_t defined as in the proof of Lemma 8. Following the same argument as in the proof of Lemma 8, we can show that, if $\mathcal{E}$ happens, after H rounds in algorithm $\mathcal{A}$, we must have $\cup_j W_j \subset E_{Hk}$, where W_j is the working set of machine j by Definition 1. Let $t = Hk$. Since $\hat{w} = \mathcal{A}(\{g_i\}_{i\in[N]}, \{S'_j\}_{j\in[m]}, H)$, we must have $\hat{w} \in E_t$ if $\mathcal{E}$ happens. According to Lemma 10, we have

$$\bar{p}(\hat{w}) \geq \min_{(w_1,\ldots,w_t)\in\mathbb{R}^t} \bar{p}(w_1,\ldots,w_t,0,\ldots,0) = \frac{L}{8k}\left(-1+\frac{1}{Hk+1}\right),$$

which, together with Lemma 9, implies

$$\mathbb{E}\left[\frac{\bar{p}(\hat{w})-\bar{p}(w^*)}{\|w^*\|}\Big|\mathcal{E}\right] \geq \frac{\frac{L}{8k}\left(-1+\frac{1}{Hk+1}+1-\frac{1}{b+1}\right)}{\frac{1}{3}(b+1)} \geq \frac{3L}{32k^3(H+1)^2} \geq \frac{3L}{128k^3H^2}.$$

Based on this inequality, when $\mathbb{E}[\bar{g}(\hat{w}) - \bar{g}(w^*)|\mathcal{E}] \leq \epsilon$, or equivalently, when $\mathbb{E}[\bar{p}(\hat{w}) - \bar{p}(w^*)|\mathcal{E}] \leq \frac{n\epsilon}{\theta} \leq \frac{3n\epsilon}{2}$, we must have $H \geq \sqrt{\frac{L\|w^*\|^2}{64k^3n\epsilon}}$. ■

The rest of the proof of Theorem 3 is almost identical to that of Theorem 2 so we will only provide a brief sketch. In particular, we will construct N special non-strongly convex functions $\{f_i\}_{i\in[N]}$ on $\mathbb{R}^d$ with $d = nb$ for a sufficiently large b based on $\{p_s\}_{s\in[k]}$ defined as (29), and show that any algorithm $\mathcal{A} \in \mathcal{F}_\alpha$ will need at least the targeted amount of rounds of communication when it is applied to $\{f_i\}_{i\in[N]}$.

For a large enough u and $b = uk$, we partition the set of indices $[d] = \{1,\ldots,d\}$ into n disjoint subsets $D_1, D_2, \ldots, D_n$ with $|D_l| = b$ and $D_l = \{b(l-1)+1, b(l-1)+2, \ldots, bl\}$.

For any $l \in [n]$ and $s \in [k]$, let $q_{l,s}(x)$ be a function on $\mathbb{R}^d$ defined as (18) where $\{p_s\}_{s\in[k]}$ is defined as (29). We define $\{f_i\}_{i\in[N]}$ to be a set that consists of v copies of $\{q_{l,s}\}_{l\in[n],s\in[k]}$ and $N - vkn$ zeros functions. In other words, the set of non-zero functions in $\{f_i\}_{i\in[N]}$ is defined as (19) with $\{p_s\}_{s\in[k]}$ given as (29). It is easy to verify that the each function in $\{f_i\}_{i\in[N]}$ is L-smooth.

Because of Lemma 9 and (20), the optimal solution x^* for (1) with $\{f_i\}_{i\in[N]}$ constructed as above is $x^* = \mathbf{1}_n \otimes w^* = (w^*, w^*, \ldots, w^*)^T$ where $w^* \in \mathbb{R}^d$ is defined as (31).

By its construction, $\{f_i\}_{i\in[N]}$ are simultaneously decomposable with respect to the partition $D_1, \ldots, D_n$ with $D_l = \{b(l-1)+1, b(l-1)+2, \ldots, bl\}$. In fact, $f_i(x) = p_s(x_{D_l})$ for some $s \in [k]$ and $l \in [n]$ with $\{p_s\}_{s\in[k]}$ defined as (29) so that $f_i(x)$ can be represented as (21) where $g_i^l \in \{p_s\}_{s\in[k]}$ for exactly one $l \in [n]$ and $g_i^l \equiv 0$ for other l's. Moreover, for any $l \in [n]$, the equality (22) holds with $\{g_i\}_{i\in[N]}$ defined as (14) and $\{p_s\}_{s\in[k]}$ defined as (29).

By Proposition 5, $\mathcal{A}$ can be decomposed with respective to the partition $D_1, D_2, \ldots, D_n$ into $\mathcal{A}_1, \ldots, \mathcal{A}_n \in \mathcal{F}_\alpha$ and $\mathcal{A}_l$ is applied to (23) (the same as (15)). Let $S'_j = S_j \cup R_j$ generated as in Definition 1. When $\{f_i | i \in S'_j\}$ is allocated to machine j for algorithm $\mathcal{A}$, the set $\{g_i^l | i \in S'_j\}$ is allocated to machine j for algorithm $\mathcal{A}_l$ for $l = 1, 2, \ldots, n$. We still call $\mathcal{A}_l$ *bad* if none of the m machines in algorithm $\mathcal{A}_l$ has all functions in $\{p_s\}_{s\in[k]}$. Then, following exactly the same argument as in Theorem 2, we can obtain (26) which indicates that $\mathcal{A}_l$ can be *bad* with a constant probability for each l. As a result, if $\mathbb{E}[f(\hat{x}) - f(x^*)] \leq \epsilon$, there must exist an $l \in [n]$ such that (27) holds.

When $\mathcal{A}_l$ is bad, after the data distribution stage, none of the m machines in $\mathcal{A}_l$ has all functions in $\{p_s\}_{s\in[k]}$. According to Lemma 12, there exists b such that (27) happens only if $H \geq \sqrt{\left(1-\frac{1}{e}\right)\frac{L\|x^*\|^2}{64k^3n\epsilon}}$, which is the desired lower bound.

5. Distributed SVRG

In this section, we consider a *distributed stochastic variance reduced gradient* (DSVRG) method that is based on a parallelization of the stochastic variance reduced gradient (SVRG) method (Johnson and Zhang, 2013; Mahdavi et al., 2013; Xiao and Zhang, 2014; Konečnỳ and Richtárik, 2017). SVRG works in multiple stages and, in each stage, one batch gradient is computed using all N data points and $O(\kappa)$ iterative updates are performed with only one data point processed in each iterative update.

Our DSVRG algorithm randomly partitions the N data points into m subsets $\{S_j\}_{j\in[m]}$ with $|S_j| = n$ and S_j is allocated to machine j in order to parallelize the computation of the batch gradient in SVRG. Then, we let the m machines conduct the iterative update of SVRG in serial in a "round-robin" scheme, namely, let all machine stay idle except one machine that performs a certain steps of iterative updates of SVRG using its local data and pass the solution to the next machine. However, the only caveat in this idea is that the iterative update of SVRG requires an unbiased estimator of $\nabla f(x)$ which can be constructed by sampling over the whole data set. However, the unbiasedness will be lost if each machine can only sample over S_j. To address this issue, we let machine j sample with replacement from the whole data set to construct a second set R_j with $|R_j| = \alpha n$ for $\alpha > 0$ during the data allocation. In each iterative update, if each machine samples over R_j, the unbiased

Algorithm 1 Distributed SVRG (DSVRG)

Input: An initial solution $\tilde{x}^0 \in \mathbb{R}^d$, data $\{f_i\}_{i\in[N]}$, the number of machines m, a step length $\eta < \frac{1}{4L}$, the number of stages K, the number of iterations T in each stage, and a parameter $\alpha \geq \frac{TK}{N}$.

Output: $\tilde{x}^K$

1: Generate (a) a random partition $\{S_j\}_{j\in[m]}$ of $[N]$, (b) m multi-sets $\{R_j\}_{j\in[m]}$ with $|R_j| = \alpha n$ uniformly sampled with replacement from $[N]$, and (c) data $\{f_i \mid i \in S_j \cup R_j\}$ stored on machine j.
2: $k \leftarrow 1$
3: **for** $\ell = 0, 1, 2, \ldots, K-1$ **do**
4: Center sends $\tilde{x}^\ell$ to each machine
5: **for** machine $j = 1, 2, \ldots, m$ **in parallel do**
6: Compute $h_j^\ell = \sum_{i\in S_j} \nabla f_i(\tilde{x}^\ell)$ and send it to center
7: **end for**
8: Center computes $h^\ell = \frac{1}{N}\sum_{j=1}^m h_j^\ell$ and send it to machine k
9: $(\tilde{x}^{\ell+1}, \{R_j\}_{j\in[m]}, k) \leftarrow \text{SS-SVRG}(\tilde{x}^\ell, \{f_i\}_{i\in[N]}, h^\ell, \{R_j\}_{j\in[m]}, k, \eta, T)$
10: **end for**

estimator will be still available so that the convergence property can be inherited from the single-machine SVRG.

5.1 DSVRG Algorithm and Its Round Complexity

Let $\alpha > 0$. We first randomly partition $[N]$ into subsets $\{S_j\}_{j\in[m]}$ with $|S_j| = \frac{N}{m} = n$ and create m multi-sets $\{R_j\}_{j\in[m]}$ with $|R_j| = \alpha n$ by uniformly sampling with replacement from $[N]$. With the data $\{f_i | i \in S_j \cup R_j\}$ distributed on machine j for each $j \in [m]$, we describe formally each stage of this DSVRG in Algorithm 1 and the iterative update in Algorithm 2. From the definitions of S_j and R_j and the communication and computation performed, we can easily see that DSVRG belongs to the family $\mathcal{F}_\alpha$ ($\alpha > 0$) in Definition 1.

We start DSVRG in machine k with $k = 1$ initially at an initial solution $\tilde{x}^0 \in \mathbb{R}^d$. At the beginning of stage ℓ of DSVRG, all m machines participate in computing a batch gradient h^ℓ in parallel using the data indexed by $S_1, \ldots, S_m$. Within stage ℓ, in each iteration, machine k samples one data f_i from its local data indexed by R_k to construct a stochastic gradient $\nabla f_i(x_t) - \nabla f_i(\tilde{x}^\ell) + h^\ell$ and performs the *iterative update* (Line 3 of Algorithm 2). After this iteration, the index i is removed from R_k. Due to the construction of R_k, we can easily prove that this stochastic gradient is an unbiased estimation of the batch gradient $\nabla f(x_t)$.

Lemma 13 *Suppose $\tilde{x}$, x_t, $\{f_i\}_{i\in[N]}$, h, $\{R_j\}_{j\in[m]}$ and k are defined as in Algorithm 2 (SS-SVRG). In addition, suppose each element of R_j was i.i.d. sampled with replacement from $[N]$ and $h = \frac{1}{N}\sum_{i=1}^N \nabla f(\tilde{x})$. In the t-th iteration of Algorithm 2, we have*

$$\mathbb{E}[\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h | x_t, \tilde{x}] = \nabla f(x_t),$$

where the expectation is taken over i and $\{R_j\}_{j\in[m]}$.

Proof Since R_k is a multi-set that consists of indices uniformly sampled with replacement from $[N]$, the index i has a uniform distribution over $[N]$. Moreover, because each index

Algorithm 2 Single-Stage SVRG: SS-SVRG$(\tilde{x}, \{f_i\}_{i\in[N]}, h, \{R_j\}_{j\in[m]}, k, \eta, T)$

Input: A solution $\tilde{x} \in \mathbb{R}^d$, data $\{f_i\}_{i\in[N]}$, a batch gradient h, m multi-sets $\{R_j\}_{j\in[m]}$, the index of the active machine k, a step length $\eta < \frac{1}{4L}$, and the number of iterations T.

Output: The average solution $\bar{x}_T$, the updated multi-sets $\{R_j\}_{j\in[m]}$, and the updated index of active machine k.

1: $x_0 = \tilde{x}$ and $\bar{x}_0 = \mathbf{0}$
2: **for** $t = 0, 1, 2, \ldots, T-1$ **do**
3: Machine k uniformly samples an instance i from R_k and computes

$$x_{t+1} = x_t - \eta\left(\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h\right), \quad \bar{x}_{t+1} = \frac{x_{t+1} + t\bar{x}_t}{t+1}, \quad R_k \leftarrow R_k \backslash \{i\}$$

4: **if** $R_k = \emptyset$ **then**
5: x_{t+1} and $\bar{x}_{t+1}$ are sent to machine $k+1$
6: $k \leftarrow k+1$
7: **end if**
8: **end for**

sampled from R_k in the previous iteration has been removed from R_k, the set R_k at iteration t does not contain the indices in the previous iterations that determine x_t so that R_k is independent of x_t. With these facts, we can show that

$$\begin{aligned}
&\mathbb{E}[\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h | x_t, \tilde{x}] = \mathbb{E}\left[\mathbb{E}[\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h | R_k, x_t, \tilde{x}] \Big| x_t, \tilde{x}\right] \\
= \;& \mathbb{E}\left[\frac{1}{|R_k|}\sum_{i\in R_k}(\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h) \Big| x_t, \tilde{x}\right] = \mathbb{E}_{i\sim N}[\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h | x_t, \tilde{x}] = \nabla f(x_t),
\end{aligned}$$

where the third equality is because R_k is independent of x_t and the marginal distribution of each i in R_k is uniform distribution on $[N]$. ■

The m machines do the iterative updates in the order from machine 1 to machine m. Once the current active machine, say, machine k, has removed all of its samples in R_k (so that $R_k = \emptyset$), then it must pass the current solution and the running average of all solutions generated in the current stage to machine $k+1$. At any time during the algorithm, there is only one machine updating the solution x_t and the other $m-1$ machines only contribute in computing the batch gradient h^ℓ. We want to emphasize that it is important that machines should never use any samples in R_j's more than once since, otherwise, the stochastic gradient $\nabla f_i(x_t) - \nabla f_i(\tilde{x}^\ell) + h^\ell$ will lose its unbiasedness. Because one element in R_k is removed in each iterative update (Line 3) of Algorithm 2, this update cannot be performed any longer once each R_k becomes empty. Hence, a requirement for using Algorithm 1 is $TK \leq \sum_{j\in[m]} |R_j| = \alpha n m = \alpha N$.

The convergence of Algorithm 1 is established by the following theorem.

Theorem 14 *Suppose $0 < \eta < \frac{1}{4L}$ and $\mu > 0$. Algorithm 1 guarantees*

$$\mathbb{E}\left[f(\tilde{x}^K) - f(x^*)\right] \leq \left(\frac{1}{\mu\eta(1-4L\eta)T} + \frac{4L\eta(T+1)}{(1-4L\eta)T}\right)^K \left[f(\tilde{x}^0) - f(x^*)\right]. \tag{32}$$

When $\eta = \frac{1}{16L}$, $T = 96\kappa$ *and* $\alpha \geq \frac{96\kappa}{\log(9/8)N} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$, *Algorithm 1 finds an* ϵ*-optimal solution with* $K \leq \frac{1}{\log(9/8)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$ *stages and at most* $\frac{\frac{96\kappa}{\alpha n}+1}{\log(9/8)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$ *rounds of communication.*

In particular, if $\frac{96\kappa}{\log(9/8)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right) \leq O(N)$ *in addition to the previous conditions, Algorithm 1 with* $\alpha = \Theta(1)$ *finds an* ϵ*-optimal solution with at most* $O\left((\frac{\kappa}{n}+1)\log\left(\frac{1}{\epsilon}\right)\right)$ *rounds of communication.*

Proof In the iterative update given in Line 3 of Algorithm 2, a stochastic gradient $\nabla f_i(x_t) - \nabla f_i(\tilde{x}) + h$ is constructed with h being the batch gradient $\nabla f(\tilde{x})$ and i sampled from R_k in the active machine k. By Lemma 13, this stochastic gradient is unbiased estimator of $\nabla f(x_t)$. Therefore, the path of solutions $\tilde{x}^0, \tilde{x}^1, \tilde{x}^2, \ldots$ generated by Algorithm 1 has the same distribution as the ones generated by single-machine SVRG so that the convergence result for the single-machine SVRG can be directly applied to Algorithm 1. The inequality (32) has been shown in Theorem 1 in Xiao and Zhang (2014) for single-machine SVRG, which now also holds for Algorithm 1.

When $\eta = \frac{1}{16L}$ and $T = 96\kappa$, it is easy to show that

$$\frac{1}{\mu\eta(1-4L\eta)T} + \frac{4L\eta(T+1)}{(1-4L\eta)T} \leq \frac{1}{\mu\eta(1-4L\eta)T} + \frac{8L\eta}{(1-4L\eta)} = \frac{2}{9} + \frac{2}{3} = \frac{8}{9}$$

so that Algorithm 1 needs $K \leq \frac{1}{\log(9/8)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$ stages to find an ϵ-optimal solution. Since Algorithm 1 performs TK iterative updates with one element of R_k removed after each update, it requires $TK \leq \sum_{j\in[m]} |R_j| = \alpha N$, which is satisfied by the above upper bound of K, the choice of T and the assumption on α.

Since Algorithm 1 needs one round of communication to compute a batch gradient at each stage (one call of SS-SVRG) and one round after every αn iterative updates (when $R_k = \emptyset$), it needs $K + \frac{TK}{\alpha n} \leq \left(\frac{96\kappa}{\alpha n}+1\right)\frac{1}{\log(9/8)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$ rounds of communication in total to find an ϵ-optimal solution. The second part of the conclusion is a straightforward outcome from the first part. ■

By Theorem 14, to find an ϵ-optimal solution, DSVRG requires $\alpha \geq \Omega(\frac{\kappa}{N}\log(1/\epsilon))$ so that each machine must have a minimum memory space of $|S_j| + |R_j| = n + \alpha n = \Omega(n + \frac{\kappa}{m}\log(1/\epsilon))$. For ERM problem where $\kappa = \Theta(\sqrt{N})$ and ϵ is reasonably small, for example, $\epsilon = \frac{1}{n^s}$ for a constant s, the requirement becomes $\alpha \geq \Omega(\frac{\log(n)}{\sqrt{nm}})$, which can be easily satisfied with a constant α ($\alpha = \Theta(1)$). In this case, DSVRG only asks for $\Theta(n + \sqrt{\frac{n}{m}}\log(n)) = \Theta(n)$ memory space in each machine to store $S_j \cup R_j$. Note that a memory space of n is necessary in all distributed algorithms to store S_j so the space required by DSVRG is in the same order of magnitude as other distributed algorithms in this scenario. Although we use $\kappa = \Theta(\sqrt{N})$ as an example, DSVRG still applies with $\alpha = \Theta(1)$ and $\Theta(n)$ memory space when $\epsilon = \frac{1}{n^s}$ and $\kappa = \Theta(N^b)$ with $b \in (0,1)$.

Compared to other methods which use only S_j, DSVRG and DASVRG (introduced later) require additional $\Theta(\alpha N)$ amount of communication during the data allocation stage for transmitting the second data set R_j from the center to each machine. Although the

communication during the data allocation stage is not included in the total amount of communication in the performance metrics defined in Section 1.1, it will certainly affect the efficiency of an algorithm in practice. Hence, in Algorithm 4 in Appendix, we design an efficient data allocation scheme which reuses the randomness of first randomly partitioned data set S_j to construct R_j. We show in Lemma 18 that this method helps to increase the overlap between R_j and S_j so that it requires a smaller amount of communication to allocate $\{f_i | i \in S_j \cup R_j\}$ to machine j than the direct implementation. For example, when $\kappa = \Theta(\sqrt{N})$ in a typical ERM problem, with Algorithm 4, DSVRG only needs $O((\log(1/\epsilon))^2)$ more amount of communication during the data allocation stage than other methods.

5.2 Regime Where DSVRG is Optimal

In this subsection, we consider a scenario where $\kappa = O(n^{1-2\delta})$ with a constant $0 < \delta < \frac{1}{2}$ and $\epsilon = \frac{1}{n^s}$ with a constant $s > 0$. We show that with modified values of η, T and K, DSVRG can find an ϵ-optimal solution for (1) with the optimal parallel runtime, the optimal amount of communication, and the optimal number of rounds of communication *simultaneously*.

Proposition 15 *Suppose* $0 < \kappa \leq \frac{n^{1-2\delta}}{32}$ *with a constant* $0 < \delta < \frac{1}{2}$. *When* $\eta = \frac{1}{16n^\delta L}$, $T = n$ *and* $\alpha \geq \frac{1}{\log(n^\delta/2)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right)$, *Algorithm 1 finds an* ϵ*-optimal solution for (1) with* $K = O(\frac{\log(1/\epsilon)}{\log n})$ *stages,* $O(\left(\frac{1+\alpha}{\alpha}\right)\frac{\log(1/\epsilon)}{\log n})$ *rounds of communications,* $O(\frac{n\log(1/\epsilon)}{\log n})$ *parallel runtime, and* $O((m+\frac{1}{\alpha})\frac{\log(1/\epsilon)}{\log n})$ *amount of communication.*

If $\epsilon = \frac{1}{n^s}$ *with a positive constant* s *in addition to the conditions above, Algorithm 1 finds an* ϵ*-optimal solution for (1) with* $\alpha = \Theta(1)$, $O(1)$ *rounds of communications,* $O(n)$ *parallel runtime, and* $O(m)$ *amount of communication.*

Proof Since $\eta = \frac{1}{16n^\delta L} < \frac{1}{4L}$, Algorithm 1 guarantees (32) according to Theorem 14. With $T = n$ and $\eta = \frac{1}{16n^\delta L}$, we have

$$\begin{aligned}\frac{1}{\mu\eta(1-4L\eta)T} + \frac{4L\eta(T+1)}{(1-4L\eta)T} &\leq \frac{1}{\mu\eta(1-4L\eta)T} + \frac{8L\eta}{(1-4L\eta)} = \frac{16n^\delta\kappa}{(1-1/(4n^\delta))n} + \frac{1}{2n^\delta(1-\frac{1}{4n^\delta})} \\ &\leq \frac{1}{2n^\delta(1-1/(4n^\delta))} + \frac{1}{2n^\delta(1-1/(4n^\delta))} \leq \frac{2}{n^\delta}.\end{aligned}$$

Hence, $\mathbb{E}\left[f(\tilde{x}^K) - f(x^*)\right] \leq \epsilon$ is implied by (32) with $K \leq \frac{1}{\log(n^\delta/2)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right) = O(\frac{\log(1/\epsilon)}{\log n})$. The requirement $TK \leq \alpha N$ is satisfied by the above upper bound of K and the assumption on α.

Since Algorithm 1 needs one round of communication to compute a batch gradient at each stage and one round after every αn iterative updates, it needs $K + \frac{TK}{\alpha n} = O(\frac{(1+\alpha)\log(1/\epsilon)}{\alpha \log n})$ rounds of communication in total to find an ϵ-optimal solution. Since one gradient is computed in each iterative update and n gradients are computed in parallel in each stage, the parallel runtime of Algorithm 1 is $(n+T)K = O(\frac{n\log(1/\epsilon)}{\log(n)})$. Finally, each batch gradient computation requires machines sending m vectors of size $O(d)$ to the center and every αn iterative updates require sending two vectors of size $O(d)$ between machines. Hence, Algo-

rithm 1 requires $(mK + \frac{2TK}{\alpha n}) = O((m + \frac{1}{\alpha})\frac{\log(1/\epsilon)}{\log n})$ amount of communication to find an ϵ-optimal solution.[5]

We can easily obtain the second part of the conclusion after substituting ϵ in the three performance metrics above by $\frac{1}{n^s}$ with a positive constant s and using the fact that $\alpha \geq \frac{1}{\log(n^s/2)} \log\left(\frac{f(\tilde{x}^0)-f(x^*)}{\epsilon}\right) = \Theta(1)$ ■

We emphasize again that the amount of communication in Proposition 15 is measured by the number of vectors of size $O(d)$ transmitted through the network after the data distribution phase so it does not include the communication for sending S_j and R_j to machines. The justification for the scenario where $\kappa = O(n^{1-2\delta})$ and $\epsilon = \frac{1}{n^s}$ and why these performance guarantees are optimal have been discussed in Section 1.2. To apply DSVRG under this scenario, the required memory space in each machine is $O(n+\alpha n) = O(n)$ (since we are able to choose $\alpha = \Theta(1)$ in this case), which is in the same order of magnitude as the memory requirement of all distributed methods.

6. Accelerated Distributed SVRG

In this section, we use the generic acceleration techniques in Frostig et al. (2015) and Lin et al. (2015) to further improve the theoretical performance of DSVRG and obtain a *distributed accelerated stochastic variance reduced gradient* (DASVRG) method. DASVRG belongs to the family $\mathcal{F}_\alpha$ ($\alpha > 0$) in Definition 1. We will show that the lower bound given in Theorem 2 for the round complexity of $\mathcal{F}_\alpha$ is matched by the rounds needed by DASVRG with $\alpha = \Theta(1)$ up to logarithmic factors for a flexible and realistic regime of parameters.

6.1 DASVRG Algorithm and Its Round Complexity

We define the *proximal function* for $f(x)$ as

$$f_\sigma(x; y) \equiv f(x) + \frac{\sigma}{2}\|x - y\|^2 = \frac{1}{N}\sum_{i=1}^{N} f_{\sigma,i}(x; y), \tag{33}$$

where $f_{\sigma,i}(x; y) = f_i(x) + \frac{\sigma}{2}\|x - y\|^2$, σ is a positive constant to be determined later and $y \in \mathbb{R}^d$ is a *proximal point*. The condition number of this proximal function is $\kappa(f_\sigma) \equiv \frac{L+\sigma}{\mu+\sigma}$ which is always smaller than κ.

Given an algorithm, denoted by $\mathcal{A}$, that can be applied to (1), the acceleration scheme developed in Frostig et al. (2015) and Lin et al. (2015) is an iterative method that involves inner and outer loops and uses $\mathcal{A}$ as a sub-routine called in each outer loop. In particular, in the p-th outer iteration of this acceleration scheme, the algorithm $\mathcal{A}$ is applied to find a solution for the p-th proximal problem defined on a proximal point $y_p \in \mathbb{R}^d$, namely,

$$\min_{x\in\mathbb{R}^d} f_\sigma(x; y_p) \text{ for } p = 0, 1, 2, \ldots, P-1. \tag{34}$$

Since $\kappa(f_\sigma) < \kappa$, solving (34) is generally easier than solving (1). Moreover, the algorithm $\mathcal{A}$ does not need to solve (34) to optimality but only needs to generate an approximate

5. As we defined in Section 1.1, the communication used to distribute S_j and R_j to machine j is not included in the amount of communication given here.

solution $\hat{x}_{p+1}$ with an accuracy ϵ_p in the sense that

$$\mathbb{E}\left[f_\sigma(\hat{x}_{p+1}; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right] \leq \epsilon_p. \tag{35}$$

Then, the acceleration scheme uses the convex combination of $\hat{x}_{p+1}$ and another auxiliary solution z_{p+1} to construct a new proximal point y_{p+1}. After that, the $(p+1)$-th proximal problem is constructed based on y_{p+1} which will be solved in the next outer iteration while the auxiliary solution z_{p+1} will be updated by a momentum step. With an appropriately chosen value for σ, it is shown by Frostig et al. (2015) and Lin et al. (2015) that, for many existing $\mathcal{A}$ including SAG (Schmidt et al., 2017; Roux et al., 2012), SAGA (Defazio et al., 2014a), SDCA (Shalev-Shwartz and Zhang, 2013), SVRG (Johnson and Zhang, 2013) and Finito/MISO (Defazio et al., 2014b; Mairal, 2015), this acceleration scheme needs a smaller runtime for finding an ϵ-optimal solution than applying algorithm $\mathcal{A}$ directly to (1).

Given the success of this acceleration scheme in the single-machine setting, it will be promising to also apply this scheme to the DSVRG to further improve its theoretical performance. Indeed, this can be done by choosing $\mathcal{A}$ in this acceleration scheme to be DSVRG. In particular, we follow the scheme in Algorithm 2 in Frostig et al. (2015) and obtain the DASVRG method as in Algorithm 3. In the p-th outer iteration of DASVRG, DSVRG is used to solve the proximal problem (34) in a distributed way up to an accuracy ϵ_p.

Theorem 16 *When* $\mu > 0$, $\sigma = \frac{L}{n}$, $\eta = \frac{1}{16L}$, $T = 96\kappa(f_\sigma)$, $K = \frac{1}{\log(9/8)} \log\left(4\left(\frac{2\sigma+\mu}{\mu}\right)^{3/2}\right)$

$$\text{and} \quad \alpha \geq \frac{384}{\log(9/8)m}\sqrt{\frac{2\kappa}{n}+1}\log\left(4\left(\frac{2\kappa}{n}+1\right)^{3/2}\right)\log\left(\left(\frac{2\kappa}{n}+1\right)\frac{f(\hat{x}_0)-f(x^*)}{\epsilon}\right), \tag{36}$$

Algorithm 3 find an ϵ-optimal solution with $P \leq \sqrt{\frac{8\sigma+4\mu}{\mu}}\log\left(\frac{(2\sigma+2\mu)(f(\hat{x}_0)-f(x^*))}{\mu\epsilon}\right)$ outer loops and at most $\frac{\frac{384}{\alpha}+2}{\log(9/8)}\sqrt{\frac{2\kappa}{n}+1}\log\left(4\left(\frac{2\kappa}{n}+1\right)^{3/2}\right)\log\left(\left(\frac{2\kappa}{n}+1\right)\frac{f(\hat{x}_0)-f(x^*)}{\epsilon}\right)$ rounds of communication.

In particular, if the right hand side of (36) is at most $O(1)$ in addition to the previous conditions, Algorithm 1 with $\alpha = \Theta(1)$ finds an ϵ-optimal solution with at most $O\left((1+\sqrt{\frac{\kappa}{n}})\log(1+\frac{\kappa}{n})\log\frac{1}{\epsilon}\right)$ rounds of communication.

Proof Due to the way $\{R_j\}_{j\in[m]}$ is generated and Lemma 13, the solution path $\tilde{x}^0, \tilde{x}^1, \tilde{x}^2, \ldots$ generated within the p-th outer loop of Algorithm 3 has same distribution as the solution path generated by applying the single-machine SVRG to (34) with an initial solution of $\tilde{x}^0 = \hat{x}_p$. Hence, according to Theorem 1 in Xiao and Zhang (2014), the following inequality holds for the p-th outer loop of Algorithm 3

$$\mathbb{E}\left[f_\sigma(\hat{x}_{p+1}; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right] \leq \left(\frac{1}{\mu\eta(1-4L\eta)T} + \frac{4L\eta(T+1)}{(1-4L\eta)T}\right)^K \left[f_\sigma(\hat{x}_p; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right].$$

Applying the values of η and T to this inequality, the p-th outer loop of Algorithm 3 ensures

$$\mathbb{E}\left[f_\sigma(\hat{x}_{p+1}; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right] \leq \left(\frac{8}{9}\right)^K \left[f_\sigma(\hat{x}_p; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right].$$

Algorithm 3 Distributed Accelerated SVRG (DASVRG)

Input: An initial solution $\hat{x}_0 \in \mathbb{R}^d$, data $\{f_i\}_{i\in[N]}$, the number of machines m, a step length $\eta < \frac{1}{4L}$, the number of stages K in DSVRG, the number of iterations T in each stage of DSVRG, the number of outer iterations P in DASVRG, a parameter $\sigma \geq 0$, and a parameter $\alpha \geq \frac{TKP}{N}$.

Output: $\hat{x}_P$

Generate (a) a random partition $\{S_j\}_{j\in[m]}$ of $[N]$, (b) m multi-sets $\{R_j\}_{j\in[m]}$ with $|R_j| = \alpha n$ uniformly sampled with replacement from $[N]$, and (c) data $\{f_i \mid i \in S_j \cup R_j\}$ stored on machine j.
$k \leftarrow 1$
Initialize $\rho = \frac{\mu+2\sigma}{\mu}$ and $z_0 = \hat{x}_0$
for $p = 0, 1, 2, \ldots, P-1$ **do**
  Center computes $y_p = \frac{1}{1+\rho^{-1/2}}\hat{x}_p + \frac{\rho^{-1/2}}{1+\rho^{-1/2}} z_p$ and $\tilde{x}^0 = \hat{x}_p$ and sends y_p to each machine
  for $\ell = 0, 1, 2, \ldots, K-1$ **do**
    Center sends $\tilde{x}^\ell$ to each machine
    for machine $j = 1, 2, \ldots, m$ **in parallel do**
      Compute $h_j^\ell = \sum_{i\in S_j} \nabla \tilde{f}_i(\tilde{x}^\ell; y_p)$ and send it to center
    end for
    Center computes $h^\ell = \frac{1}{N}\sum_{j=1}^m h_j^\ell$ and sends it to machine k
    $(\tilde{x}^{\ell+1}, \{R_j\}_{j\in[m]}, k) \leftarrow \text{SS-SVRG}(\tilde{x}^\ell, \{f_{\sigma,i}(x; y_p)\}_{i\in[N]}, h^\ell, \{R_j\}_{j\in[m]}, k, \eta, T)$ as an example, DASVRG still applies
  end for
  Machine k computes $\hat{x}_{p+1} = \tilde{x}^K$ and sends $\hat{x}_{p+1}$ to center
  Center computes $z_{p+1} = (1-\rho^{-1/2})z_p + \rho^{-1/2}[y_p - \rho(y_p - \hat{x}_{p+1})]$
end for

By this inequality and the choice of K, we can show that the solution $\hat{x}_{p+1}$ generated from the p-th outer loop of Algorithm 3 satisfies (35) with

$$\epsilon_p = \frac{1}{4}\left(\frac{\mu}{2\sigma+\mu}\right)^{3/2}\left[f_\sigma(\hat{x}_p; y_p) - \min_{x\in\mathbb{R}^d} f_\sigma(x; y_p)\right].$$

Using this result and Lemma 3.3, 3.4, 3.5 and 3.6 in Frostig et al. (2015), we can show that

$$\mathbb{E}\left[f(\hat{x}_P) - f(x^*)\right] \leq \frac{2\sigma+2\mu}{\mu}\left(1 - \frac{1}{2}\sqrt{\frac{\mu}{2\sigma+\mu}}\right)^P \left[f(\hat{x}_0) - f(x^*)\right].$$

This means Algorithm 3 finds an ϵ-optimal solution after $P \leq 2\sqrt{\frac{2\sigma+\mu}{\mu}}\log\left(\frac{(2\sigma+2\mu)(f(\hat{x}_0)-f(x^*)}{\mu\epsilon}\right)$ outer loops.

Since Algorithm 3 performs TKP iterative updates with one element of R_k removed after each update, it requires $TKP \leq \sum_{j\in[m]}|R_j| = \alpha N$, which is satisfied by the choices of T and K, the above upper bound of P and the assumption on α.

Since Algorithm 3 needs one round of communication to compute a batch gradient at each stage (one call of SS-SVRG) and one round after every αn iterative updates (when

$R_k = \emptyset$), it needs

$$\begin{aligned} & KP + \frac{TKP}{\alpha n} = \left(\frac{T}{\alpha n} + 1\right) KP \\ \leq\ & \left(\frac{96\kappa(f_\sigma)}{\alpha n} + 1\right)\frac{2}{\log(9/8)}\sqrt{\frac{2\sigma+\mu}{\mu}}\log\left(4\left(\frac{2\sigma+\mu}{\mu}\right)^{3/2}\right)\log\left(\frac{(2\sigma+2\mu)(f(\hat{x}_0)-f(x^*)}{\mu\epsilon}\right) \\ \leq\ & \left(\frac{192}{\alpha}+1\right)\frac{2}{\log(9/8)}\sqrt{\frac{2\kappa}{n}+1}\log\left(4\left(\frac{2\kappa}{n}+1\right)^{3/2}\right)\log\left(\left(\frac{2\kappa}{n}+1\right)\frac{f(\hat{x}_0)-f(x^*)}{\epsilon}\right) \end{aligned}$$

rounds of communication in total to find an ϵ-optimal solution. In the second inequality above, we use the fact that $\sigma = \frac{L}{n}$ and $\frac{\kappa(f_\sigma)}{n} = \frac{L+\sigma}{n\mu+n\sigma} \leq \frac{n+1}{n} \leq 2$. The second conclusion is a straightforward outcome of the first conclusion. ■

According to Theorem 16, DASVRG requires $\alpha \geq \Omega(\frac{1}{m}\sqrt{\frac{\kappa}{n}+1}\log(\frac{\kappa}{n}+1)\log(1/\epsilon))$ so that each machine must have a memory space of $|S_j| + |R_j| = n + \alpha n = \Omega(n + \frac{n}{m}\sqrt{\frac{\kappa}{n}+1}\log(\frac{\kappa}{n}+1)\log(1/\epsilon))$. For ERM problem where $\kappa = \Theta(\sqrt{N})$ and $\epsilon = \frac{1}{n^s}$ for a constant s, the requirement becomes $\alpha \geq \Omega(\frac{1}{m}\sqrt{\sqrt{\frac{m}{n}}+1}\log(\sqrt{\frac{m}{n}}+1)\log(n))$, which can be easily satisfied with a constant α ($\alpha = \Theta(1)$). Moreover, in this case, DASVRG only asks for $\Theta(n + \frac{n}{m}\sqrt{\sqrt{\frac{m}{n}}+1}\log(\sqrt{\frac{m}{n}}+1)\log(n)) = \Theta(n)$ memory space in each machine to store $S_j \cup R_j$ which is in the same order of magnitude as the space required by other distributed algorithms. Although we use $\kappa = \Theta(\sqrt{N})$ as an example, DASVRG still applies with $\alpha = \Theta(1)$ and $\Theta(n)$ memory space when $\epsilon = \frac{1}{n^s}$ and $\kappa = \Theta(N^b)$ with $b \in (0, 1)$.

Furthermore, another crucial insight we obtain here is that, although in the single-machine setting, the acceleration scheme of Frostig et al. (2015) and (Lin et al., 2015) only helps to reduce the time complexity when $\kappa \geq N$ by choosing $\sigma = \Theta(N)$, in the distributed setting, it helps to reduce the rounds as long as $\kappa \geq n$ by choosing $\sigma = \Theta(n)$. This shows an interesting and new application of this generic acceleration scheme.

In DSVRG and DASVRG, the subsets $\{S_j\}_{j\in[m]}$ are only used to compute the batch gradient $\nabla f(\tilde{x}^\ell)$. Therefore, both DSVRG and DASVRG can be applied with the same theoretical guarantees under the general setting where $\{S_j\}_{j\in[m]}$ is an arbitrary (not necessarily random) partition of $\{f_i\}_{i\in[N]}$ into equal-sized subsets. Because our lower bound for the round complexity is provided for the algorithms in $\mathcal{F}_\alpha$ where $\{S_j\}_{j\in[m]}$ is a random partition, we present both DSVRG and DASVRG in the same setting to show that the theoretical lower bound is almost reachable and DASVRG is nearly optimal within $\mathcal{F}_\alpha$.

7. DASVRG for Non-Strongly Convex Problem

In this section, we consider solving (1) when f is not strongly convex ($\mu = 0$) by the standard technique of applying DASVRG to the following regularized version of (1)

$$\min_{x\in\mathbb{R}^d}\left\{f^\lambda(x) \equiv f(x) + \frac{\lambda}{2}\|x\|^2 = \frac{1}{N}\sum_{i=1}^N f_i^\lambda(x)\right\}, \tag{37}$$

where $f_i^\lambda(x) \equiv f_i(x) + \frac{\lambda}{2}\|x\|^2$ and λ is a positive constant. Note that problem (37) satisfies Assumption 1 with ∇f_i^λ being $(L+\lambda)$-Lipschitz continuous and f^λ being λ-convex. The

condition number of f^λ is $\kappa(f^\lambda) \equiv \frac{L+\lambda}{\lambda}$. With λ small enough, the ϵ-solution of (37) found by DASVRG can be an ϵ-solution for (1). Although this method is well-known, we present it here just to show that the lower bound of round complexity for non-strongly convex problems in Theorem 3 can be achieved up to logarithmic terms under some scenario.

Theorem 17 *Suppose Algorithm 3 is applied to (37) where* $\lambda = \frac{\epsilon}{D^*}$ *with* $D^* \geq \|x^*\|^2$. *When* $\sigma = \frac{L+\lambda}{n}$, $\eta = \frac{1}{16(L+\lambda)}$, $T = 96\kappa(f^\lambda_\sigma) = 96\frac{L+\lambda+\sigma}{\lambda+\sigma}$, $K = \frac{1}{\log(9/8)}\log\left(4\left(\frac{2\sigma+\lambda}{\lambda}\right)^{3/2}\right)$, *and*

$$\alpha \geq \frac{384}{\log(9/8)m}\sqrt{\frac{2D^*L}{n\epsilon}+3}\log\left(4\left(\frac{2D^*L}{n\epsilon}+3\right)^{3/2}\right)\log\left(\left(\frac{2D^*L}{n\epsilon}+3\right)\frac{f(\hat{x}_0)-f(x^*)}{\epsilon/2}\right). \quad (38)$$

Algorithm 3 find an ϵ-optimal solution of (1) with $P = \sqrt{\frac{8\sigma+4\lambda}{\lambda}}\log\left(\frac{(2\sigma+2\lambda)(f(\hat{x}_0)-f(x^*)}{\lambda\epsilon/2}\right)$ *and* $\left(\frac{192}{\alpha}+1\right)\frac{2}{\log(9/8)}\sqrt{\frac{2D^*L}{n\epsilon}+3}\log\left(4\left(\frac{2D^*L}{n\epsilon}+3\right)^{3/2}\right)\log\left(\left(\frac{2D^*L}{n\epsilon}+3\right)\frac{f(\hat{x}_0)-f(x^*)}{\epsilon/2}\right)$ *rounds of communication.*

In particular, if the right hand side of (38) is at most $O(1)$ in addition to the previous conditions, Algorithm 1 with $\alpha = \Theta(1)$ finds an ϵ-optimal solution of (1) with at most $\tilde{O}\left(\left(\sqrt{\frac{L}{n\epsilon}}\right)\log^2\left(\frac{1}{\epsilon}\right)\right)$ *rounds of communication.*

Proof Let $\hat{x}_P$ be the output of Algorithm 3 when it is applied to (37) with the specific values of η, σ, T and K given in the statement of the theorem. Because ∇f_i^λ is $(L+\lambda)$-Lipschitz continuous and f^λ is λ-convex, according to Theorem 16, $\hat{x}_P$ is an $\frac{\epsilon}{2}$-optimal solution of (37) and it is found with the number of rounds of communication stated in the conclusion. Moreover, we can easily show that

$$\begin{aligned}\mathbb{E}[f(\hat{x}_P)-f(x^*)] &\leq f(\hat{x}_P)+\frac{\lambda}{2}\|\hat{x}_P\|^2-f(x^*)-\frac{\lambda}{2}\|x^*\|^2+\frac{\lambda}{2}\|x^*\|^2\\ &\leq f^\lambda(\hat{x}_P)-\min_{x\in\mathbb{R}^d}f^\lambda(x)+\frac{\lambda}{2}\|x^*\|^2 \leq \frac{\epsilon}{2}+\frac{\epsilon}{2}=\epsilon,\end{aligned}$$

where the last inequality is because $\lambda = \frac{\epsilon}{D^*}$ with $D^* \geq \|x^*\|^2$. Hence, $\hat{x}_P$ is an ϵ-optimal solution of (1). Then, the rest of the conclusion will be proved by applying Theorem 20. ■

According to (38) in Theorem 17, we acknowledge here that DASVRG can be applied to non-strongly convex problem with $\alpha = \Theta(1)$ only under a restricted condition, for example, when $\epsilon = O(\frac{1}{N^b})$ with $b \in (0,1)$. The development in this section is mostly for the theoretical interest on the tightness of the lower bound by Theorem 3.

8. Numerical Experiments

This section presents the numerical performances of our methods in comparisons with some existing distributed optimization techniques on simulated and real data.

8.1 Experiments with Simulated Data

In this section, we conduct numerical experiments with simulated data to compare our DSVRG algorithm with DISCO (Zhang and Lin, 2015) and a distributed implementation of gradient descent (GD) method. We use a single machine to simulate the distributed environment and all methods are implemented in Matlab running on a 64-bit Microsoft Windows 10 machine with a 2.70Ghz Intel(R) i7-6820HQ CPU and 8GB of memory. We consider ridge regression, $\min_{x\in\mathbb{R}^d}\frac{1}{N}\sum_{i=1}^N(a_i^Tx-b_i)^2+\frac{\lambda}{2}\|x\|^2$, where $a_i \in \mathbb{R}^d$ and $b_i \in \mathbb{R}$ for $i \in [N]$ are the data points. We generate (a_i, b_i) following the experimental setup in Agarwal et al. (2012) by choosing a correlation parameter $\omega \in [0,1]$. Let A be the $N \times d$ matrix whose rows are a_i's. According to Agarwal et al. (2012), the eigenvalues of $\frac{1}{N}\mathbb{E}[A^TA]$ lie within the interval $\left[\frac{1}{(1+\omega)^2}, \frac{2}{(1-\omega)^2(1+\omega)}\right]$ so that the condition number κ increases when we choose ω close to 1. To make comparisons under different settings, we choose $\lambda = 10^{-4}$, $d = 50$, $N = 10^4$, $\omega \in \{0, 0.3, 0.5\}$ and $m \in \{10, 20\}$. All generated instances satisfy $\kappa = \frac{n^{1-2\delta}}{32}$ with $0 < \delta < \frac{1}{2}$ which is in the optimal regime of DSVRG (see Section 5.2).

For each instance, we compute the largest and the smallest eigenvalues of $\frac{1}{N}A^TA$ so as to compute the condition number κ and the parameters δ, η and T as in Proposition 15 for implementing DSVRG. Note that the lower bound for α given in Proposition 15 can be conservative and depends on the unknown value $f(x^*)$. In this experiment, we choose $\alpha = 1$ so that DSVRG can run for at most N iterations, which corresponds to $\frac{N}{|R_j|} = m$ rounds because $|R_j| = T = n$. In each main iteration of DISCO, an inexact Newton direction v is computed by solving a preconditioned linear system $P^{-1}\nabla^2 f(x_k)v = P^{-1}\nabla f(x_k)$ using a distributed preconditioned conjugate gradient method, where x_k in the solution in the kth main iteration. We choose $P = \nabla^2\bar{f}_1(x_k) + (\lambda + \sqrt{m}\times 0.001)I$ with $\bar{f}_1$ defined in (4) and compute P^{-1} directly. In the GD method, we use a step length of $\eta = \frac{1}{L}$.

Since DSVRG stores $|R_j| + |S_j| = (1+\alpha)n$ data points in machine j, it is meaningful to allow other methods to also store $(1+\alpha)n$ data points in each machine in the comparisons. With more local data, the round complexity of the distributed GD method is unchanged while that of DISCO will be reduced according to its round complexity $O((1+\frac{\sqrt{\kappa}}{n^{.25}})\log\frac{1}{\epsilon})$. Therefore, when implementing DISCO, we use different numbers of machines which lead to different amounts of local data. In particular, we choose $m = 2, 5$ and 10 in DISCO when $m = 10$ in DSVRG and GD and choose $m = 4, 10$ and 20 in DISCO when $m = 20$ in DSVRG and GD. Since $\alpha = 1$, DSVRG with 10 (20) machines and DISCO with 5 (10) machines store the same amount of data points in each machine.

The performance of the three methods are shown in Figure 2, where the vertical axis represents the logarithm of optimality gap (i.e., $\log(f(x_k) - f(x^*))$) and the horizon axis represents the number of rounds of communication. The values of κ and δ for each instance are shown in the figures. According to Figure 2, when δ is relatively large, DSVRG is less efficient than GD because the step length $\eta = \frac{1}{16n^\delta L}$ in DSVRG is too small and the small κ leads to a low round complexity of GD. However, when δ is relatively small, DSVRG significantly outperforms GD, which is consistent with Proposition 15. The performance of DISCO is improved when it uses more machines (and a smaller n), which is also consistent with its round complexity $O((1+\frac{\sqrt{\kappa}}{n^{.25}})\log\frac{1}{\epsilon})$. DSVRG with 10 machines is more efficient than DISCO with 10 and 5 machines for all instances here and is slightly worse than DISCO

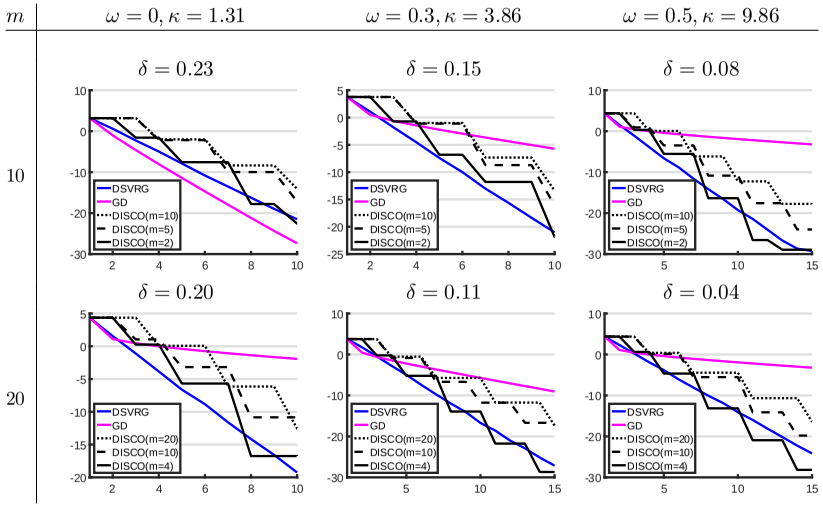

Figure 2: Comparing DSVRG implemented as in Proposition 15 with DISCO and the distributed gradient descent method (GD) in rounds. The condition number κ of each instance is in the regime where DSVRG is optimal (see Section 5.2).

with 2 machines. Recall that DSVRG with 10 machines stores the same amount of local data as DISCO with 5 machines. The results suggest that DSVRG with a small α can potentially outperform DISCO on the problems with $\kappa = O(n^{1-2\delta})$ even if the machines have access to the same amount of data in both algorithms. However, when α is large, DSVRG can be less efficient than DISCO because DISCO needs much fewer machines. The same conclusion can be made from the results where DSVRG uses 20 machines and DISCO uses 4, 10 and 20 machines.

8.2 Experiments with Real Data

In this section, we conduct numerical experiments with real data to compare our DSVRG and DASVRG algorithms with DisDSCA by Yang (2013) and a distributed implementation of the accelerated gradient method (Accel Grad) by Nesterov (2013). We apply these four algorithms to the ERM problem (2) with three data sets:[6] Covtype, Million Song and Epsilon. In particular, we solve ridge regression $\min_{x\in\mathbb{R}^d} \frac{1}{N}\sum_{i=1}^N (a_i^T x - b_i)^2 + \frac{\lambda}{2}\|x\|^2$ with Million Song data and regularized logistic regression $\min_{x\in\mathbb{R}^d} \frac{1}{N}\sum_{i=1}^N \log(1+\exp(-b_i a_i^T x)) + \frac{\lambda}{2}\|x\|^2$ with Covtype and Epsilon data. Following the previous work, we map the target variable of year from $1922 \sim 2011$ into $[0,1]$ for the Million Song data. To compare these methods in a challenging setting, we conduct experiments using random Fourier features

6. http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html

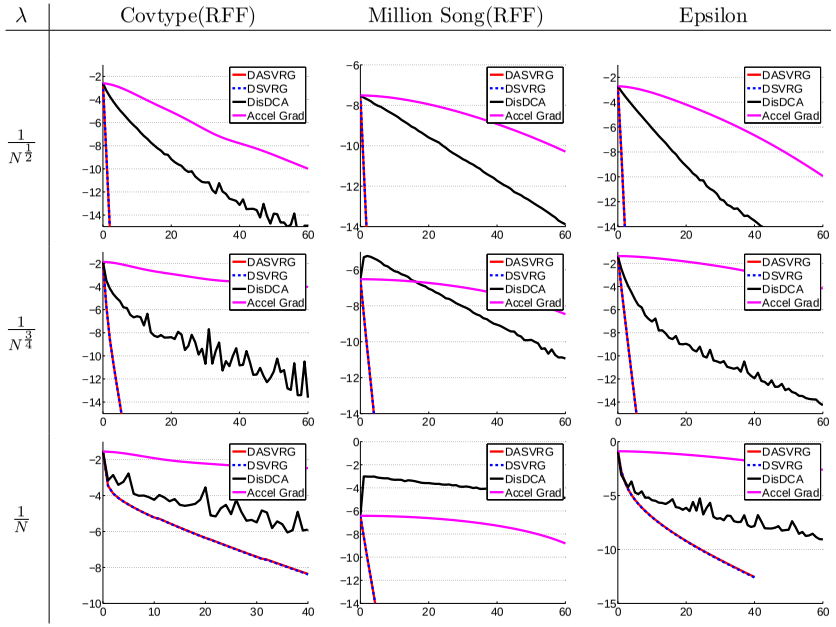

Figure 3: Comparing the DSVRG and DASVRG methods with DisDCA and the accelerated gradient method (Accel Grad) in rounds.

(RFF) (Rahimi and Recht, 2008) on Covtype and Million Song data sets. The RFF is a method for solving large-scale kernel methods by generating finite dimensional features, of which the inner product approximate the kernel similarity. We generate RFF corresponding to RBF kernel. After generating RFF, Covtype data has $N = 522,911$ examples $d = 1,000$ features and Million Song data has $N = 463,715$ examples and $d = 2,000$ features. Since the original Epsilon data is large enough (12G), we use its original features.

The experiments are conducted on a server (Intel(R) Xeon(R) CPU E5-2667 v2 3.30GHz) with multiple processes with each process simulating one machine. We choose the number of processes (machines) to be $m = 5$. To test the performances of algorithms for different condition numbers, we choose the regularization parameter λ to be $1/N^{0.5}$, $1/N^{0.75}$ and $1/N$. For each setting, L is computed as $\frac{\max_{i=1,\ldots,N}\|a_i\|^2}{\gamma} + \lambda$ where $\frac{1}{\gamma}$ is the Lipschiz continuous constant of $\nabla_x \phi(x,\xi)$ in (2), and μ is set to be λ. We implement DSVRG by choosing $\eta = \frac{1}{L}$, $T = 10,000$ and $K = \frac{N}{T}$. For DASVRG, we choose $\eta = \frac{1}{L}$, $T = 10,000$, $K = 1$ and $P = \frac{N}{T}$. In both DSVRG and DASVRG, we directly choose $R_j = S_j$ since, in practice, this implementation gives performances very similar to the performances when R_j is sampled separately. For DisDCA, we use SDCA (Shalev-Shwartz and Zhang, 2013) as

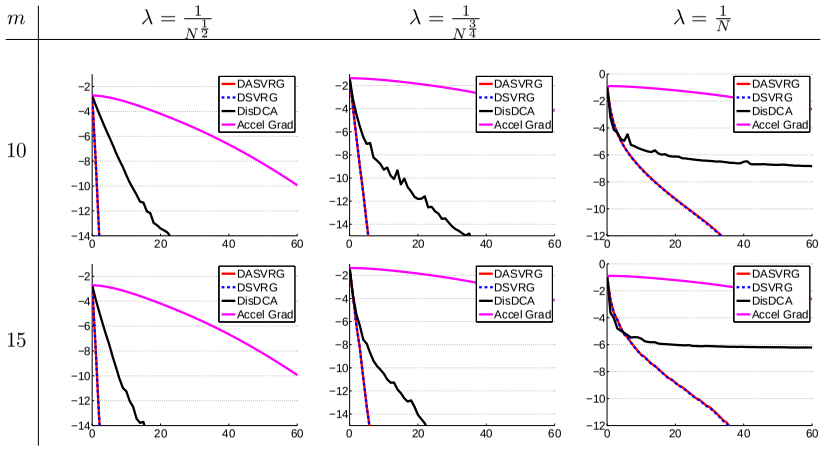

Figure 4: Comparing the DSVRG and DASVRG methods with DisDCA and the accelerated gradient method (Accel Grad) in rounds using Epsilon data.

the local solver so that it is equivalent to the implementation of CoCoA+ with $\sigma' = m$ and $\gamma = 1$ as in the experiments in Ma et al. (2015). We run SDCA for $T = 10,000$ iterations in each round of DisDCA with $\frac{N}{T}$ rounds in total.

The numerical results are presented in Figure 3, where the horizontal axis presents the number of rounds of communication conducted by algorithms and the vertical axis represents the logarithm of optimality gap. According to Figure 3, the performances of all algorithms get worse when λ decreases (so the condition number increases). We find that DSVRG and DASVRG have almost identical performances in rounds of communication and they both outperform the other two methods significantly. To compare the performances of algorithms under different values of m. We choose the $m = 10$ and 15 and repeat the same experiments on Epsilon data. The numerical results are shown in Figure 4. Similar to the case of $m = 5$, our DSVRG and DASVRG require fewer rounds to reach the same ϵ-optimal solution than the other two methods.

9. Conclusion

We study the round complexity for minimizing the average of N convex functions by distributed optimization with m machines under a new setting where each machine receives a subset of the N functions through both random partition and random sampling with replacement. Then, we propose a DSVRG algorithm under this setting which is a distributed extension of the existing SVRG algorithm. In DSVRG, the batch gradients are computed in parallel while the machines perform iterative updates in serial. DSVRG utilizes the local functions sampled with replacement to construct the unbiased stochastic gradient in each iterative update. We provide the theoretical analysis on the rounds of communication needed by DSVRG to find an ϵ-optimal solution, showing that DSVRG is optimal in terms of runtime, the amount of communication and the rounds of communication when the condition number is small. When the condition number is large, using an acceleration strategy by Frostig et al. (2015) and Lin et al. (2015), we proposed a DASVRG algorithm that requires even fewer rounds of communication than DSVRG and many existing methods that only store random partitioned data in machines, showing the advantage of the new distributed setting. Then, we define a broad family of algorithms which cover DSVRG, DASVRG and many existing methods in the literature. We provide the minimum number of rounds of communication needed by this family of algorithms for finding an ϵ-solution. The rounds of communication needed by DASVRG matches this lower bound up to logarithmic terms, and thus, is nearly optimal within this family.

Acknowledgments

Appendix A. An Efficient Data Allocation Procedure

In this section, we design an efficient data allocation scheme which requires a smaller amount of communication to allocate $\{f_i | i \in S_j \cup R_j\}$ to machine j than the direct implementation.

We assume that a random partition $S_1, \ldots, S_m$ of $[N]$ can be constructed efficiently. Let Q be the number of samples in $\{R_j\}_{j\in[m]}$ needed for the algorithm to run the desired number of iterations. In other words, $Q = TK$ in DSVRG and $Q = TKP$ in DASVRG, both of which can be much smaller than αN, the total size $\{R_j\}_{j\in[m]}$. Therefore, in practical implementation, we only need to ensure the total size of $\{R_j\}_{j\in[m]}$ equal Q by allowing $|R_j| \leq \alpha n$ or even $R_j = \emptyset$ in order to save the communication amount.

A straightforward data allocation procedure is to prepare a partition $S_1, \ldots, S_m$ of $[N]$ and then sample a sequence of Q i.i.d. indices $r_1, \ldots, r_Q$ uniformly with replacement from $[N]$. After partitioning $r_1, \ldots, r_Q$ into m multi-sets $R_1, \ldots, R_m \subset [N]$, we allocate data $\{f_i | i \in S_j \cup R_j\}$ to machine j. Note that the amount of communication in distributing $S_1, \ldots, S_m$ is exactly N which is necessary for almost all distributed algorithms. However, in the worst case, this straightforward procedure requires an extra Q amount of communication for distributing $R_j \backslash S_j$.

To improve the efficiency of data allocation, we propose a procedure which reuses the randomness of $S_1, \ldots, S_m$ to generate the indices $r_1, \ldots, r_Q$ so that the overlap between S_j and R_j can be increased which helps reduce the additional amount of communication for distributing $R_1, \ldots, R_m$. The key observation is that the concatenation of $S_1, \ldots, S_m$ is a random permutation of $[N]$ which has already provided enough randomness needed by $R_1, \ldots, R_m$. Hence, it will be easy to build the i.i.d. samples $r_1, \ldots, r_Q$ by adding a little additional randomness on top of $S_1, \ldots, S_m$. With this observation in mind, we propose our data allocation procedure in Algorithm 4.

Algorithm 4 Data Allocation : DA(N, m, Q, α)

Input: Index set $[N]$, the number of machines m, and the constant α, and the length of target sequence Q.

Output: A random partition $S_1, \ldots, S_m$ of $[N]$, indices $r_1, \ldots, r_Q \in [N]$, multi-sets $R_1, \ldots, R_m \subset [N]$, and data $\{f_i \mid i \in S_j \cup R_j\}$ stored on machine j for each $j \in [m]$.

Center samples $r_1, \ldots, r_Q$ and $R_1, \ldots, R_m$ as follows:

1: Randomly partition $[N]$ into m disjoint sets $S_1, \ldots, S_m$ of the same size $n = \frac{N}{m}$.
2: Concatenate the subsets $S_1, \ldots, S_m$ into a random permutation $i_1, \ldots, i_N$ of $[N]$ so that $S_j = \{i_{(j-1)n+1}, \ldots, i_{jn}\}$.
3: **for** $\ell = 1$ to Q **do**
4: Let

$$r_\ell = \begin{cases} i_\ell & \text{with probability } 1 - \frac{\ell-1}{N} \\ i_{\ell'} & \text{with probability } \frac{1}{N} \text{ for } \ell' = 1, 2, \ldots, \ell - 1. \end{cases}$$

5: **end for**
6: Let

$$R_j = \begin{cases} \{r_{(j-1)\alpha n+1}, \ldots, r_{j\alpha n}\} & \text{if } j = 1, \ldots, \lceil \frac{Q}{\alpha n} \rceil - 1 \\ \{r_{(\lceil \frac{Q}{\alpha n} \rceil - 1)\alpha n+1}, \ldots, r_Q\} & \text{if } j = \lceil \frac{Q}{\alpha n} \rceil \\ \emptyset & \text{if } j = \lceil \frac{Q}{\alpha n} \rceil + 1, \ldots, m. \end{cases} \tag{39}$$

Distribute data points to machines:

7: Machine j acquires data points in $\{f_i | i \in S_j \cup R_j\}$ from the storage center.

The correctness and the expected amount of communication of Algorithm 4 are characterized as follows.

Lemma 18 *The sequence $r_1, \ldots, r_Q$ generated in Algorithm 4 has the same joint distribution as a sequence of i.i.d. indices uniformly sampled with replacement from $[N]$. Moreover, the expected amount of communication for distributing $\cup_{i=1}^m \{f_i | i \in R_j \backslash S_j\}$ is at most $\frac{Q^2}{2N}$.*

Proof Conditioned on $i_1, \ldots, i_{\ell-1}$ and $r_1, \ldots, r_{\ell-1}$, the random index i_ℓ has uniform distribution over $[N] \setminus \{i_1, \ldots, i_{\ell-1}\}$. Therefore, by Line 4 in Algorithm 4, the conditional distribution of the random index r_ℓ, conditioning on $i_1, \ldots, i_{\ell-1}$ and $r_1, \ldots, r_{\ell-1}$, is a uniform distribution over $[N]$. Hence, we complete the proof of the first claim of the lemma.

To analyze the amount of communication, we note that $i_\ell \neq r_\ell$ with probability $\frac{\ell-1}{N}$. Suppose $i_\ell \in S_j$ for some j. We know that the data point f_{r_ℓ} needs to be transmitted to machine j separately from S_j only if $i_\ell \neq r_\ell$. Therefore, the expected amount of communication for distributing $\cup_{i=1}^m \{f_i | i \in R_j \backslash S_j\}$ is upper bounded by $\sum_{\ell=1}^Q \frac{\ell-1}{N} \leq \frac{Q^2}{2N}$. ■

According to Lemma 18, besides the (necessary) N amount of communication to distribute $S_1, \ldots, S_m$, Algorithm 4 needs only $\frac{Q^2}{2N}$ additional amount of communication to distribute $R_1, \ldots, R_m$ thanks to the overlaps between S_j and R_j for each j. This additional amount is less than the Q amount required by the straightforward method when $Q \leq N$.

Note that we only need $Q = O(\kappa \log(1/\epsilon))$ in the DSVRG algorithm and $Q = O(n(1 + \sqrt{\frac{\kappa}{n}}) \log(1 + \frac{\kappa}{n}) \log \frac{1}{\epsilon})$ in the DASVRG algorithm. When $\kappa = \Theta(\sqrt{N})$ in a typical ERM problem, we have $\frac{Q^2}{2N} = O((\log(1/\epsilon))^2)$ in DSVRG and $\frac{Q^2}{2N} = O(\sqrt{\frac{n}{m}}(\log(\sqrt{\frac{m}{n}}) \log(1/\epsilon))^2)$ in DASVRG, both of which are much less than the N amount of communication for distributing $S_1, \ldots, S_m$. In other words, although DSVRG and DASVRG require additional amount of communication to allocate the data compared to other algorithms, this additional amount is marginal if κ is not too large.

Although Algorithm 4 is given for allocating S_j and R_j together to machine j, it can be used to only allocate R_j to machine j when S_j has already existed in machine j beforehand. The only requirements are that $\{S_j\}_{j \in [m]}$ still forms a random partition of $[N]$ and that, after generating R_j as (39), machine j knows which machine holds i for each $i \in R_j \backslash S_j$ so that machine j can acquire data in $R_j \backslash S_j$ from that machine in Line 7 of Algorithm 4.

Abstract

We consider the kernel partial least squares algorithm for non-parametric regression with stationary dependent data. Probabilistic convergence rates of the kernel partial least squares estimator to the true regression function are established under a source and an effective dimensionality condition. It is shown both theoretically and in simulations that long range dependence results in slower convergence rates. A protein dynamics example shows high predictive power of kernel partial least squares.

Keywords: effective dimensionality, long range dependence, nonparametric regression, source condition, protein dynamics

1. Introduction

Partial least squares (PLS) is a regularized regression technique developed by Wold et al. (1984) to deal with collinearities in the regressor matrix. It is an iterative algorithm where the covariance between response and regressor is maximized at each step, see Helland (1988) for a detailed description. Regularization in the PLS algorithm is obtained by stopping the iteration process early.

Several studies showed that partial least squares algorithm is competitive with other regression methods such as ridge regression and principal component regression, needing generally fewer iterations than the latter to achieve comparable estimation and prediction, see, e.g., Frank and Friedman (1993), Krämer and Braun (2007) and Singer et al. (2016). For an overview of further properties of PLS we refer to Rosipall and Krämer (2006).

Reproducing kernel Hilbert spaces (RKHS) have a long history in probability and statistics (see, e.g., Berlinet and Thomas-Agnan, 2004). Here we focus on the supervised kernel based learning approach for the solution of non-parametric regression problems. RKHS methods are both computationally and theoretically attractive, due to the kernel trick (Schölkopf et al., 1998) and the representer theorem (Wahba, 1999), as well as its generalization (Schölkopf et al., 2001). Within the reproducing kernel Hilbert space framework one can adapt linear regularized regression techniques like ridge regression and principal component regression to a non-parametric setting, see Saunders et al. (1998) and Rosipal et al. (2000), respectively. We refer to Schölkopf and Smola (2001) for more details on the kernel based learning approach.

Kernel PLS (KPLS) was introduced in Rosipal and Trejo (2001) by using the reformulation of the PLS algorithm of Lindgren et al. (1993). The relationship to kernel conjugate gradient (KCG) methods was highlighted in Blanchard and Krämer (2010a). It can be seen in Hanke (1995) that conjugate gradient methods are well suited for handling ill-posed problems, as they arise in kernel learning, see, e.g., De Vito et al. (2006).

Rosipal (2003) investigated the performance of kernel partial least squares for non-linear discriminant analysis. Blanchard and Krämer (2010a) proved the consistency of KPLS when the algorithm is stopped early without giving convergence rates.

Caponnetto and de Vito (2007) showed that kernel ridge regression (KRR) attains optimal probabilistic rates of convergence for independent and identically distributed data, using a source and a polynomial effective dimensionality condition. A generalization of these results to a wider class of effective dimensionality conditions and extension to kernel principal component regression can be found in Dicker et al. (2017).

For independent identically distributed data Blanchard and Krämer (2010b) obtained probabilistic convergence rates for a certain kernel conjugate gradient estimator under early stopping, while Lin and Zhou (2017) considered kernel partial least squares estimators with the cross-validation stopping rule.

In contrast to existing works, we derive probabilistic convergence rates of the kernel partial least squares estimator to the true regression function when the input data are not independent and identically distributed, but rather stationary time series. To the best of our knowledge, none of the kernel regression methods have been considered for the dependent data so far. Our results can be applied to stationary dependence structures, given that certain concentration inequalities for these data hold. The derived convergence rates depend not only on the complexity of the target function and of the data mapped into the kernel space, but also on the persistence of the dependence in the data. For measuring the complexity of the data we consider general effective dimensionality conditions. In a Gaussian setting we prove that the short range dependence still leads to optimal rates, but if the dependence is more persistent, the rates become slower. We illustrate the good predictive performance of KPLS by an application to the molecular dynamics of a bacteriophage protein.

2. Kernel Partial Least Squares

Consider the non-parametric regression problem

$$y_t = f^*(X_t) + \varepsilon_t, \quad t \in \mathbb{Z}. \tag{1}$$

Here $\{X_t\}_{t\in\mathbb{Z}}$ is a d-dimensional, $d \in \mathbb{N}$, stationary time series on a probability space $(\Omega, \mathcal{A}, \mathrm{P})$ and $\{\varepsilon_t\}_{t\in\mathbb{Z}}$ is an independent and identically distributed sequence of real valued random variables with expectation zero and variance $\sigma^2 > 0$ that is independent of $\{X_t\}_{t\in\mathbb{Z}}$.

Let X be a random vector that is independent of $\{X_t\}_{t\in\mathbb{Z}}$ and $\{\varepsilon_t\}_{t\in\mathbb{Z}}$ with the same distribution as X_0. The target function we seek to estimate is $f^* \in \mathcal{L}^2\left(\mathrm{P}^X\right)$.

For the purpose of supervised learning assume that we have a training sample $\{(X_t, y_t)\}_{t=1}^n$ for some $n \in \mathbb{N}$. In the following we introduce some basic notation for the kernel based learning approach.

Define with $(\mathcal{H}, \langle\cdot,\cdot\rangle_\mathcal{H})$ the RKHS of functions on $\mathbb{R}^d$ with reproducing kernel $k : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$, i.e., it holds

$$g(x) = \langle g, k(\cdot, x)\rangle_\mathcal{H}, \quad x \in \mathbb{R}^d, g \in \mathcal{H}. \tag{2}$$

The corresponding inner product and norm in $\mathcal{H}$ is denoted by $\langle\cdot,\cdot\rangle_\mathcal{H}$ and $\|\cdot\|_\mathcal{H}$, respectively. We refer to Berlinet and Thomas-Agnan (2004) for examples of Hilbert spaces and their reproducing kernels. In the following we deal with reproducing kernel Hilbert spaces which fulfill the following, rather standard, conditions:

(K1) $\mathcal{H}$ is separable,

(K2) There exists a $\kappa > 0$ such that $|k(x, y)| \le \kappa$ for all $x, y \in \mathbb{R}^d$ and k is measurable.

Under (K1) the Hilbert-Schmidt norm $\|\cdot\|_{\mathrm{HS}}$ for operators mapping from $\mathcal{H}$ to $\mathcal{H}$ is well defined. If condition (K2) holds, all functions in $\mathcal{H}$ are bounded, see Berlinet and Thomas-Agnan (2004), chapter 2. The conditions are satisfied for a variety of popular kernels, e.g., Gaussian or triangular.

The main principle of RKHS methods is the mapping of the data X_t into $\mathcal{H}$ via the feature maps $\phi_t = k(\cdot, X_t)$, $t = 1, \ldots, n$. This mapping can be done implicitly by using the kernel trick $\langle\phi_t, \phi_s\rangle_\mathcal{H} = k(X_t, X_s)$ and thus only the $n \times n$ dimensional kernel matrix $K_n = n^{-1}[k(X_t, X_s)]_{t,s=1}^n$ is needed in the computations. Then the task for RKHS methods is to find coefficients $\alpha_1, \ldots, \alpha_n$ such that $f_\alpha = \sum_{t=1}^n \alpha_t\phi_t$ is an adequate approximation of f^* in $\mathcal{H}$, measured in the $\mathcal{L}^2\left(\mathrm{P}^X\right)$ norm $\|\cdot\|_2$.

There are a variety of different approaches to estimate the coefficients $\alpha_1, \ldots, \alpha_n$, including kernel ridge regression, kernel principal component regression and, of course, kernel partial least squares. The latter method was introduced by Rosipal and Trejo (2001) and is the focus of the current work.

It was shown by Krämer and Braun (2007) that the KPLS algorithm solves

$$\widehat{\alpha}_i = \arg\min_{v\in\mathcal{K}_i(K_n,y)} n^{-1}\|y - K_n v\|^2, \quad i = 1, \ldots, n, \tag{3}$$

with $y = (y_1, \ldots, y_n)^\mathrm{T}$. Here $\mathcal{K}_i(K_n, y) = \operatorname{span}\left\{y, K_n y, K_n^2 y, \ldots, K_n^{i-1} y\right\}$, $i = 1, \ldots, n$, is the ith order Krylov space with respect to K_n and y and $\|\cdot\|$ denotes the Euclidean norm. The dimension i of the Krylov space is the regularization parameter for KPLS.

We will introduce several operators that will be crucial for our further analysis. Define two integral operators: the kernel integral operator $T^* : \mathcal{L}^2\left(\mathrm{P}^X\right) \to \mathcal{H}, g \mapsto \mathrm{E}\{k(\cdot, X)g(X)\}$ and the change of space operator $T : \mathcal{H} \to \mathcal{L}^2\left(\mathrm{P}^X\right), g \mapsto g$, which is well defined if (K2) holds. It is easy to see that T, T^* are adjoint, i.e., for $u \in \mathcal{H}$ and $v \in \mathcal{L}^2\left(\mathrm{P}^X\right)$ it holds $\langle T^* v, u\rangle_\mathcal{H} = \langle v, Tu\rangle_2$ with $\langle\cdot,\cdot\rangle_2$ being the inner product in $\mathcal{L}^2\left(\mathrm{P}^X\right)$.

The sample analogues of T, T^* are $T_n : \mathcal{H} \to \mathbb{R}^n, g \mapsto \{g(X_1), \ldots, g(X_n)\}^\mathrm{T}$ and $T_n^* : \mathbb{R}^n \to \mathcal{H}, (v_1, \ldots, v_n)^\mathrm{T} \mapsto n^{-1}\sum_{t=1}^n v_t k(\cdot, X_t)$, respectively. Both operators are adjoint with respect to the rescaled Euclidean product $n^{-1}u^\mathrm{T}v$, $u, v \in \mathbb{R}^d$

Finally, we define the sample kernel covariance operator $S_n = T_n^* T_n : \mathcal{H} \to \mathcal{H}$ and the population kernel covariance operator $S = T^*T : \mathcal{H} \to \mathcal{H}$. Note that it holds $K_n = T_n T_n^*$. Under (K1) and (K2) S is a self-adjoint compact operator with operator norm $\|S\|_\mathcal{L} \le \kappa$, see Caponnetto and de Vito (2007).

With this notation we can restate (3) for the function f_α

$$f_{\widehat{\alpha}_i} = \arg\min_{g\in\mathcal{K}_i(S_n, T_n^* y)} n^{-1}\|y - \{g(X_1), \ldots, g(X_n)\}^\mathrm{T}\|^2 = \arg\min_{g\in\mathcal{K}_i(S_n, T_n^* y)} n^{-1}\|y - T_n g\|^2. \tag{4}$$

Hence, we are looking for functions that minimize the squared distance to y constrained to a sequence of Krylov spaces.

In the literature of ill-posed problems it is well known that without further conditions on the target function f^* the convergence rate of the conjugate gradient algorithm can be arbitrarily slow, see Hanke (1995), chapter 3.2. One common a-priori assumption on the regression function f^* is a source condition:

(S) There exist $r \ge 0$, $R > 0$ and $u \in \mathcal{L}^2\left(\mathrm{P}^X\right)$ such that $f^* = (TT^*)^r u$ and $\|u\|_2 \le R$.

If $r \ge 1/2$, then the target function $f^* \in \mathcal{L}^2\left(\mathrm{P}^X\right)$ coincides almost surely with a function $f \in \mathcal{H}$ and we can write $f^* = Tf$, see Cucker and Smale (2002). With this the kernel partial least squares estimator $f_{\widehat{\alpha}_i}$ estimates the correct target function, not only its best approximation in $\mathcal{H}$. This case is known as the inner case.

The situation with $r < 1/2$ is referred to as the outer case. Under additional assumptions, e.g., the availability of additional unlabeled data, it is still possible that an estimator of f^* converges to the true target function in $\mathcal{L}^2\left(\mathrm{P}^X\right)$ norm with optimal rates (with respect to the number n of labeled data points). See De Vito et al. (2006) for a detailed description of this semi-supervised approach for kernel ridge regression in the independent and identically distributed case. We do not treat the case $r < 1/2$ in this work.

A source condition is often interpreted as an abstract smoothness condition, see, e.g., Bissantz et al. (2007) for several examples. This can be seen as follows. Let $\eta_1 \ge \eta_2 \ge \ldots$ be the eigenvalues and $\psi_1, \psi_2, \ldots$ the corresponding eigenfunctions of the compact operator S. Then it is easy to see that the source condition (S) is equivalent to $f = \sum_{j=1}^\infty b_j\psi_j \in \mathcal{L}^2\left(\mathrm{P}^X\right)$ with b_j such that $\sum_{j=1}^\infty \eta_j^{-2(r+1/2)} b_j^2 < \infty$. Hence, the higher r is chosen the faster the sequence $\{b_j\}_{j=1}^\infty$ must converge to zero. Therefore, the sets of functions for which source conditions hold are nested, i.e., the larger r is the smaller the corresponding set will be. The set with $r = 1/2$ is the largest one and corresponds to a zero smoothness condition, i.e., $\sum_{j=1}^\infty \eta_j^{-2} b_j^2 < \infty$, which is equivalent to $f \in \mathcal{H}$. For more details we refer to Dicker et al. (2017).

3. Consistency of Kernel Partial Least Squares

The KCG algorithm as described by Blanchard and Krämer (2010b) is consistent when stopped early and convergence rates can be obtained when a source condition (S) holds. Here we will proof the same property for KPLS. Early stopping in this context means that we stop the algorithm at some $a = a(n) \le n$ and consider the estimator $f_{\widehat{\alpha}_a}$ for f^*.

The difference between KCG and KPLS is the norm which is optimized. The kernel conjugate gradient algorithm studied in Blanchard and Krämer (2010b) estimates the coefficients $\alpha \in \mathbb{R}^n$ of f_α via $\widehat{\alpha}_i^{CG} = \arg\min_{v\in\mathcal{K}_i(K_n,y)}\langle y - K_n v, K_n(y - K_n v)\rangle$. It is easy to

see that this optimization problem can be rewritten for the function f_α as

$$\min_{g\in\mathcal{K}_i(S_n,T_n^*y)} n^{-1}\|T_n^*y - S_ng\|_{\mathcal{H}}^2 = \min_{g\in\mathcal{K}_i(S_n,T_n^*y)} n^{-1}\|T_n^*\left(y - T_ng\right)\|_{\mathcal{H}}^2,$$

compared to (4) for KPLS. Thus, KCG obtains the least squares approximation g in the $\mathcal{H}$-norm for the normal equation $T_n^*y = T_n^*T_ng$ and KPLS finds a function that minimizes the residual sum of squares. In both methods the solutions are restricted to functions $g \in \mathcal{K}_i(S_n, T_n^*y)$.

An advantage of the kernel conjugate gradient estimator is that concentration inequalities can be established for both T_n^*y and S_n and applied directly as the optimization function contains both quantities. The stopping index for the regularization can be chosen by a discrepancy principle as $a^* = \min\{1 \le i \le n : \|S_nf_{\widehat{\alpha}_i^{CG}} - T_n^*y\| \le \Lambda_n\}$ with Λ_n being a threshold sequence that goes to zero as n increases.

On the other hand, the function to be optimized for KPLS contains only y and $T_ng = \{g(X_1), \ldots, g(X_n)\}^{\mathrm{T}}$ for which statistical properties are not readily available. Thus, we need to find a way to apply the concentration inequalities for T_n^*y and S_n to this slightly different problem. This leads to complications in the proof of consistency and a rather different and more technical stopping rule for choosing the optimal regularization parameter a^* is used, as can be seen in Theorem 1. This stopping rule has its origin in Hanke (1995).

In the following $\|\cdot\|_{\mathcal{L}}$ denotes the operator norm and $\|\cdot\|_{\mathrm{HS}}$ is the Hilbert-Schmidt norm.

Theorem 1 *Assume that conditions (K1), (K2), (S) hold with $r \ge 3/2$ and there are constants $C_\delta(\nu), C_\epsilon(\nu) > 0$ and a sequence $\{\gamma_n\}_{n\in\mathbb{N}} \subset [0,\infty)$, $\gamma_n \to 0$, such that we have for $\nu \in (0,1]$*

$$\mathrm{P}\left(\|S_n - S\|_{\mathcal{L}} \le C_\delta(\nu)\gamma_n\right) \ge 1 - \nu/2,$$
$$\mathrm{P}\left(\|T_n^*y - Sf\|_{\mathcal{H}} \le C_\epsilon(\nu)\gamma_n\right) \ge 1 - \nu/2.$$

Define the stopping index a^* by

$$a^* = \min\left\{1 \le a \le n : \sum_{i=0}^{a} \|S_nf_{\widehat{\alpha}_i} - T_n^*y\|_{\mathcal{H}}^{-2} \ge \left(C\gamma_n\right)^{-2}\right\}, \tag{5}$$

with $C = C_\epsilon(\nu) + \kappa^{r-1/2}(r+1/2)R\{1 + C_\delta(\nu)\}$.

Then it holds with probability at least $1-\nu$ that

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = O\left\{\gamma_n^{2r/(2r+1)}\right\},$$
$$\|f_{\widehat{\alpha}_{a^*}} - f\|_{\mathcal{H}} = O\left\{\gamma_n^{(2r-1)/(2r+1)}\right\},$$

with $f^* = Tf$.

It can be shown that the stopping rule (5) always determines a finite index, i.e., the set the minimum is taken over is not empty, see Hanke (1995), chapter 4.3.

The theorem yields two convergence results, one in the $\mathcal{H}$-norm and one in the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-norm. It holds that $\|v\|_2 = \|S^{1/2}v\|_{\mathcal{H}}$. These are the endpoints of a continuum of norms $\|v\|_\beta = \|S^\beta v\|_{\mathcal{H}}$, $\beta \in [0, 1/2]$ that were considered in Nemirovskii (1986) for the derivation of convergence rates for KCG algorithms in a deterministic setting.

The convergence rate of the kernel partial least squares estimator depends crucially on the sequence γ_n and the source parameter r. If $\gamma_n = O(n^{-1/2})$, this yields the same convergence rate as Theorem 2.1 of Blanchard and Krämer (2010b) for kernel conjugate gradient or de Vito et al. (2005) for kernel ridge regression with independent and identically distributed data. For stationary Gaussian time series we will derive concentration inequalities in the next section and obtain convergence rates depending on the source parameter r and the range of dependence. Note that Theorem 1 is rather general and it can be applied to any kind of dependence structure, as long as the necessary concentration inequalities can be established.

The next theorem derives faster convergence rates under assumptions on the effective dimensionality of operator S, which is defined as $d_\lambda = \mathrm{tr}\{(S+\lambda)^{-1}S\}$. The concept of effective dimensionality was introduced in Zhang (2003) to get sharp error bounds for general learning problems considered there. If $\mathcal{H}$ is a finite dimensional space, it was shown in Zhang (2003) that $d_\lambda \le \dim(\mathcal{H})$. For infinite dimensional spaces it describes the complexity of the interactions between data and reproducing kernel.

If $d_\lambda = O(\lambda^{-s})$ for some $s \in (0,1]$, Caponnetto and de Vito (2007) showed that the order optimal convergence rates $n^{-r/(2r+s)}$ are attained for KRR with independent and identically distributed data.

The effective dimensionality clearly depends on the behaviour of eigenvalues of S. If these converge sufficiently fast to zero, nearly parametric rates of convergence can be achieved for reproducing kernel Hilbert space methods, see, e.g., Dicker et al. (2017). In particular, the behaviour of d_λ around zero is of interest, since it determines how ill-conditioned the operator $(S+\lambda)^{-1}$ becomes. In the following theorem we set $\lambda = \lambda_n$ for a sequence $\{\lambda_n\}_{n\in\mathbb{N}} \subset (0,\infty)$ that converges to zero.

Theorem 2 *Assume that conditions (K1), (K2), (S) hold with $r \ge 1/2$ and that the effective dimensionality d_λ is known. Additionally, there are constants $C_\delta(\nu), C_\epsilon(\nu), C_\psi > 0$ and a sequence $\{\gamma_n\}_{n\in\mathbb{N}} \subset [0,\infty)$, $\gamma_n \to 0$, such that for $\nu \in (0,1]$ and n sufficiently large*

$$\mathrm{P}\left\{\|S_n - S\|_{\mathcal{L}} \le C_\delta(\nu)\gamma_n\right\} \ge 1 - \nu/3,$$
$$\mathrm{P}\left\{\|(S+\lambda_n)^{-1/2}(T_n^*y - Sf)\|_{\mathcal{H}} \le C_\epsilon(\nu)\sqrt{d_{\lambda_n}}\gamma_n\right\} \ge 1 - \nu/3,$$
$$\mathrm{P}\left\{\|(S+\lambda_n)^{1/2}(S_n+\lambda_n)^{-1/2}\|_{\mathcal{L}} \le C_\psi\right\} \ge 1 - \nu/3,$$

Here $\{\lambda_n\}_{n\in\mathbb{N}} \subset (0,\infty)$ is a sequence converging to zero such that for n large enough

$$\gamma_n \le \lambda_n^{r-1/2}. \tag{6}$$

Take $\zeta_n = \max\{\sqrt{\lambda_n d_{\lambda_n}}\gamma_n, \lambda_n^{r+1/2}\}$ Define the stopping index a^* by

$$a^* = \min\left\{1 \le a \le n : \sum_{i=0}^{a} \|S_nf_{\widehat{\alpha}_i} - T_n^*y\|_{\mathcal{H}}^{-2} \ge \left(C\zeta_n\right)^{-2}\right\}, \tag{7}$$

with $C = 4R\max\{1, C_\psi^2, (r-1/2)\kappa^{r-3/2}C_\delta(\nu), 2^{-1/2}R^{-1}C_\psi C_\epsilon(\nu)\}$.

Then it holds with probability at least $1-\nu$ *that*

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = O\left\{\lambda_n^{-1/2}\zeta_n\right\},$$
$$\|f_{\widehat{\alpha}_{a^*}} - f\|_{\mathcal{H}} = O\left\{\lambda_n^{-1}\zeta_n\right\},$$

with $f^* = Tf$.

The condition (6) holds trivially for $r = 1/2$ as γ_n converges to zero. For $r > 1/2$ the sequence λ_n must not converge to zero arbitrarily fast.

In its general form Theorem 2 does not give immediate insight in the probabilistic convergence rates of the kernel partial least squares estimator. Therefore, we state two corollaries, where the function d_λ is specified. In both corollaries we explicitly state the choice of the sequence λ_n that yield the corresponding rates.

Corollary 3 *Assume that there exists* $s \in (0,1]$ *such that* $d_\lambda = O(\lambda^{-s})$ *for* $\lambda \to 0$. *Then under conditions of Theorem 2 with* $\lambda_n = \gamma_n^{2/(2r+s)}$ *it holds with probability at least* $1-\nu$ *that*

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = O\left\{\gamma_n^{2r/(2r+s)}\right\}.$$

Polynomial decay of the effective dimensionality $d_\lambda = \operatorname{tr}\{(S+\lambda)^{-1}S\}$ occurs if the eigenvalues of S also decay polynomially fast, that is, $\mu_i = c_s i^{-1/s}$ for $s \in (0,1]$, since in this case $d_\lambda = \sum_{i=1}^{\infty}\{1+\lambda/c_s i^{1/s}\}^{-1} = O(\lambda^{-s})$. This holds, for example, for the Sobolev kernel $k(x,y) = \min(x,y)$, $x, y \in [0,1]$ and data that are uniformly distributed on $[0,1]$, see Raskutti et al. (2014).

If $\gamma_n = n^{-1/2}$, then the KPLS estimator converges in the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-norm with a rate of $n^{-r/(2r+s)}$. This rate is shown to be optimal in Caponnetto and de Vito (2007) for KRR with independent identically distributed data.

Note that the rate obtained in Theorem 1 corresponds to $\gamma_n^{-2r/(2r+s)}$ with $s = 1$, i.e., the worst case rate with respect to the parameter $s \in (0,1]$.

In the next corollary to Theorem 2 we assume that the effective dimensionality behaves in a logarithmic fashion.

Corollary 4 *Let* $d_\lambda = O\{\log(1+a/\lambda)\}$ *for* $\lambda \to 0$ *and* $a > 0$. *Then under the conditions of Theorem 2 with* $\lambda_n = \gamma_n^2\log\{\gamma_n^{-2}\}$ *and* $r = 1/2$ *it holds with probability at least* $1-\nu$ *that*

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = O\left\{\gamma_n\log(1/2\gamma_n^{-2})\right\}.$$

The effective dimensionality takes the special form considered in this corollary, for example, when the eigenvalues of S decay exponentially fast. This holds, for example, if the data are Gaussian and the Gaussian kernel is used, see Section A. If $\gamma_n = O(n^{-1/2})$, then the convergence rate is of order $O\{n^{-1}\log(n)\}$, which is nearly parametric. It is noteworthy that the source condition only impacts the choice of the sequence λ_n, not the convergence rates of the estimator in the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-norm. Therefore, we stated the corollary for $r = 1/2$,

which is a minimal smoothness condition on f^*, i.e., that $f^* = Tf$ almost surely for an $f \in \mathcal{H}$.

The rates obtained in Corollaries 3 and 4 for $\gamma_n = n^{-1/2}$ were derived in Dicker et al. (2017) for kernel ridge regression and kernel principal component regression under the assumption of independent and identically distributed data.

4. Concentration Inequalities for Gaussian Time Series

Crucial assumptions of Theorem 1 and 2 are the concentration inequalities for S_n and T_n^*y and convergence of the sequence $\{\gamma_n\}_{n\in\mathbb{N}}$. Here we establish such inequalities in a Gaussian setting for stationary time series. At the end of this section we will state explicit convergence rates for $f_{\widehat{\alpha}_{a^*}}$ that depend not only on the source parameter $r \geq 1/2$ and the effective dimensionality d_λ, but also on the persistence of the dependence in the data.

The Gaussian setting is summarized in the following assumptions

(D1) $(X_h, X_0)^{\mathrm{T}} \sim \mathcal{N}_{2d}(0, \Sigma_h)$, $h = 1, \ldots, n-1$, with

$$\Sigma_h = \begin{bmatrix}\tau_0 & \tau_h \\ \tau_h & \tau_0\end{bmatrix} \otimes \Sigma.$$

Here $\Sigma \in \mathbb{R}^{d\times d}$ and $V = [\tau_{|i-j|}]_{i,j=1}^n \in \mathbb{R}^{n\times n}$ are positive definite, symmetric matrices and $\otimes$ denotes the Kronecker product between matrices. Furthermore $X_0 \sim \mathcal{N}_d(0, \tau_0\Sigma)$.

(D2) For the autocorrelation function $\rho_h = \tau_0^{-1}\tau_h$ there exists a $q > 0$ such that $|\rho_h| \leq (h+1)^{-q}$ for $h = 0, \ldots, n-1$.

Condition (D1) is a separability condition for the covariance matrices Σ_h, $h = 0, \ldots, n-1$. Due to (D1) the effects (on the covariance) over time and between the different variables can be treated separately. Under condition (D2) it is easy to see that from $q > 1$ follows the absolute summability of the autocorrelation function ρ and thus $\{X_t\}_{t\in\mathbb{Z}}$ is a short memory process. Stationary short memory processes keep many of the properties of independent and identically distributed data, see, e.g., Brockwell and Davis (1991).

On the other hand $q \in (0,1]$ yields a long memory process, see, e.g., Definition 3.1.2 in Giraitis et al. (2012). Examples of long memory processes are the fractional Gaussian noise with an autocorrelation function that behaves like $(h+1)^{-2(1-H)}$, with $H \in [0,1)$ being the Hurst coefficient. Stationary long memory processes exhibit dependencies between observations that are more persistent, and many statistical results that hold for independent and identically distributed data, turn out to be false. See Samorodnitsky (2007) for more details.

The next theorem gives concentration inequalities for both estimators S_n and T_n^*y in a Gaussian setting with convergence rates depending on the parameter $q > 0$. These inequalities are the ones needed in Theorem 1 and Theorem 2. Recall that $d_\lambda = \operatorname{tr}\{(S+\lambda)^{-1}S\}$ denotes the effective dimensionality of S.

Theorem 5 *(i) Define* $\mathrm{d}\mu_h(x,y) = \mathrm{d}\mathrm{P}^{X_h,X_0}(x,y) - \mathrm{d}\mathrm{P}^{X_0}(x)\mathrm{d}\mathrm{P}^{X_0}(y)$. *Under Assumptions (K1) and (K2) it holds for* $\nu \in (0,1]$ *with probability at least* $1-\nu$ *that*

$$\|S_n - S\|_{\mathcal{L}}^2 \leq \frac{2\nu^{-1}}{n^2}\sum_{h=1}^{n-1}(n-h)\int\limits_{\mathbb{R}^{2d}} k^2(x,y)\mathrm{d}\mu_h(x,y) + \frac{\nu^{-1}}{n}\left[\mathrm{E}\{k^2(X_0,X_0)\} - \|S\|_{\mathrm{HS}}^2\right],$$

$$\|T_n^* y - Sf\|_{\mathcal{H}}^2 \leq \frac{2\nu^{-1}}{n^2}\sum_{h=1}^{n-1}(n-h)\int\limits_{\mathbb{R}^{2d}} k(x,y)f(x)f(y)\mathrm{d}\mu_h(x,y) + \frac{\nu^{-1}}{n}\left[\mathrm{E}\left\{k(X_0,X_0)f^2(X_0)\right\} - \|Sf\|_{\mathcal{H}}^2 + \sigma^2\mathrm{E}\{k^2(X_0,X_0)\}\right].$$

(ii) Assume that additionally to (K1), (K2) also (D1), (D2) for $q > 0$ *are fulfilled. Denote* $M = \sup_{x\in\mathbb{R}^d}|f(x)|$.

Then there exists a constant $C(q) > 0$ *such that*

$$\|S_n - S\|_{\mathcal{L}} \leq \nu^{-1/2}\{\gamma_n^2(q)\kappa C_\gamma + n^{-1}(\kappa^2 - \|S\|_{\mathrm{HS}}^2)\}^{1/2},$$
$$\|T_n^* y - Sf\|_{\mathcal{H}} \leq \nu^{-1/2}\left[\gamma_n^2(q)MC_\gamma + n^{-1}\left\{\kappa(M+\sigma^2) - \|Sf\|_{\mathcal{H}}^2\right\}\right]^{1/2},$$

for $C_\gamma = C(q)\{(2\pi)^d\det(\Sigma)\}^{-1/2}\kappa d^{1/2}(1-4^{-q})^{-1/4(d+2)}$. *The function* $\gamma_n(q)$, $q > 0$, *is defined as*

$$\gamma_n(q) = \begin{cases} n^{-1/2} & , \quad q > 1 \\ n^{-1/2}\log(1/2n) & , \quad q = 1 \\ n^{-q/2} & , \quad q \in (0,1). \end{cases}$$

(iii) Let (K1), (K2) and (S) hold. Let $\gamma_n(q)$ *be the function as defined in (ii). Then there exists a constant* $\tilde{C}_\epsilon > 0$ *such that it holds with probability at least* $1-\nu$ *for* $\lambda > 0$ *that*

$$\|(S+\lambda)^{-1/2}(T_n^* y - S_n f\|_{\mathcal{H}} \leq \nu^{-1/2}\tilde{C}_\epsilon\sigma\sqrt{d_\lambda}\gamma_n(q).$$

(iv) Let (K1), (K2), (S), (D1) and (D2) hold. Let $\lambda_n^{-1/2}d_{\lambda_n}^{1/2}\gamma_n(q) \to 0$ *for a sequence* $\lambda_n \to 0$ *and* $\gamma_n(q)$ *the function defined in (ii). Then there exists an* $n_0 = n_0(\nu,q) \in \mathbb{N}$ *such that with probability at least* $1-\nu$ *we have for all* $n \geq n_0$

$$\|(S+\lambda_n)^{1/2}(S_n+\lambda_n)^{-1/2}\|_{\mathcal{L}} \leq \sqrt{2}.$$

The first part of the theorem is general and can be used to derive concentration inequalities not only in the Gaussian setting and is of interest in itself. The convergence rate is controlled by the sums appearing on the right hand side. If these sums are of $O(n)$, then the mean squared error of both S_n and $T_n^* y$ will converge to zero with a rate of n^{-1}. On the other hand, if the sums are of order $O(n^{2-q})$ for some $q \in (0,1)$, the mean squared errors will converge with the reduced rate n^{-q}.

The second part derives explicit concentration inequalities in the Gaussian setting described by (D1) and (D2) with rates depending on the range of the dependence measured by $q > 0$. These inequalities appear in Theorem 1.

Parts (iii) and (iv) give the additional probabilistic bounds needed to apply Theorem 2. The condition $\lambda_n^{-1/2}d_{\lambda_n}^{1/2}\gamma_n(q) \to 0$ in Theorem 5 (iv) is fulfilled in the settings of Corollary 3 and Corollary 4.

Theorem 1, Corollary 3, Corollary 4 and Theorem 5 together imply

Corollary 6 *Let the conditions of Theorem 2 and (D1), (D2) hold.*

(i) Assume that there exists $s \in (0,1]$ *such that* $d_\lambda = O(\lambda^{-s})$ *for* $\lambda \to 0$. *Then with probability at least* $1-\nu$

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = \begin{cases} O\{n^{-r/(2r+s)}\}, & q > 1, \\ O\{n^{-qr/(2r+s)}\}, & q \in (0,1). \end{cases}$$

If instead of conditions of Theorem 2, conditions of Theorem 1 are assumed, then the convergence rates above have $s = 1$.

(ii) Assume that there exists $a > 0$ *such that* $d_\lambda = O\{\log(1+a/\lambda)\}$ *for* $\lambda \to 0$ *and* $r = 1/2$. *Then with probability at least* $1-\nu$

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = \begin{cases} O\{n^{-1/2}\log(1/2n)\}, & q > 1, \\ O\{n^{-q/2}\log(1/2n^q)\}, & q \in (0,1). \end{cases}$$

Hence, for $q > 1$ the kernel partial least squares algorithm achieves the same rates as if the data were independent and identically distributed. For $q \in (0,1)$ the convergence rates become substantially slower, highlighting that dependence structures that persist over a long time can influence the convergence rates of the algorithm.

5. Simulations

To validate the theoretical results of the previous sections, we conducted a simulation study. The reproducing kernel Hilbert space is chosen to correspond to the Gaussian kernel $k(x,y) = \exp(-l\|x-y\|^2)$, $x,y \in \mathbb{R}^d$, $l = 2$, for $d = 1$. Our data will also be normally distributed. We refer to Proposition 7 in Appendix A for the derivation of functions that fulfill the source condition in this setting. Proposition 8 shows that the the eigenvalues of S decay exponentially fast. Hence the effective dimensionality d_λ behaves as in Corollary 4 and thus we expect convergence rates as given by Corollary 6 (ii).

The source parameter is taken to be $r = 4.5$ and we consider the function

$$f(x) = 4.37^{-1}\{3L_4(x,-4) - 2L_4(x,3) + 1.5L_4(x,9)\}, \quad x \in \mathbb{R}.$$

The normalization constant is chosen such that f takes values in $[-0.35, 0.65]$ and L_4 is the exponential function given in Proposition 7. The function f is shown in Figure 1.

In condition (D1) we set $\sigma_x^2 = \Sigma = 4$ (recall that $d = 1$). For the matrix $V = [\tau_{|i-j|}]_{i,j=1}^n \in \mathbb{R}^{n\times n}$ we choose three different structures for $n \in \{200, 400, 1000\}$. In the first setting $\tau_h = \mathbb{I}(h = 0)$, which corresponds to independent data. The second setting with $\tau_h = 0.9^{-h}$ implies an autoregressive process of order one. Finally, the third setting with $\tau_h = (1+h)^{-q}$, $q = 1/4$, $h = 0, \ldots, n-1$ leads to the long range dependent case.

In a Monte Carlo simulation with $M = 1000$ repetitions the time series $\{X_t^{(j)}\}_{t=1}^n$ are generated via $X^{(j)} = VN^{(j)}$ with $N^{(j)} \sim \mathcal{N}_n(0, \sigma^2 I_n)$, $j = 1, \ldots, M$, where I_n is the $n \times n$-dimensional identity matrix.

The residuals $\varepsilon_1^{(j)}, \ldots, \varepsilon_n^{(j)}$ are generated as independent standard normally distributed random variables and independent of $\{X_t^{(j)}\}_{t=1}^n$. The response is defined as $y_t^{(j)} = f(X_t^{(j)}) + \eta\varepsilon_t^{(j)}$, $t = 1, \ldots, n$, $j = 1, \ldots, M$, with $\eta = 1/16$.

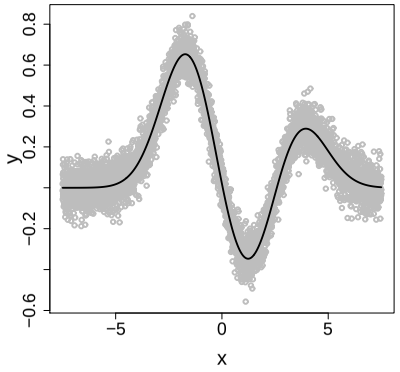

Figure 1: The function f evaluated on $[-7.5, 7.5]$ (black) and one realisation of the noisy data $y = f(x) + \varepsilon$ (grey).

The kernel partial least squares and kernel conjugate gradient algorithms are run for each sample $\{(X_t^{(j)}, y_t^{(j)})^{\mathrm{T}}\}_{t=1}^n$, $j = 1, \ldots, M$, with a maximum of 40 iteration steps. We denote the estimated coefficients with $\widehat{\alpha}_1^{(j,m)}, \ldots, \widehat{\alpha}_{40}^{(j,m)}$, $j = 1, \ldots, M$, with $m = CG$ meaning that the kernel conjugate gradient algorithm was employed and $m = PLS$ that kernel partial least squares was used to estimate $\alpha_1, \ldots, \alpha_n$.

The squared error in the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-norm is calculated via

$$\widehat{e}_{n,\tau}^{(j,m)} = \min_{a=1,\ldots,40} \left[\frac{1}{\sqrt{2\pi\sigma_x^2}} \int_{-\infty}^{\infty} \left\{ f_{\widehat{\alpha}_a^{(j,m)}}(x) - f(x) \right\}^2 \exp\left(-\frac{1}{2\sigma_x^2} x^2 \right) \mathrm{d}x \right],$$

for $j = 1, \ldots, M$, $n = 200, 400, \ldots, 1000$ and $m \in \{CG, PLS\}$.

The results of the Monte-Carlo simulations are depicted in the boxplots of Figure 2. For kernel partial least squares (left panels) one observes that independent and autoregressive dependent data have roughly the same convergence rates, although the latter have a somewhat higher error. In contrast, the long range dependent data show slower convergence with the larger interquartile range, supporting the theoretical results of Corollary 6.

The $\mathcal{L}^2\left(\mathrm{P}^X\right)$-error of kernel conjugate gradient estimators is generally slightly higher than that of kernel partial least squares. Nonetheless, both of them have a similar behaviour.

We also investigated the the stopping indices $a = 1, \ldots, 40$ for which the errors $\widehat{e}_{n,\tau}^{(j,m)}$ were attained. These are shown in Figure 3 for independent and identically distributed data. It can be seen that the optimal indices for both algorithms have a rather similar behaviour. Kernel conjugate gradient stops slightly later, but overall the differences seem negligible.

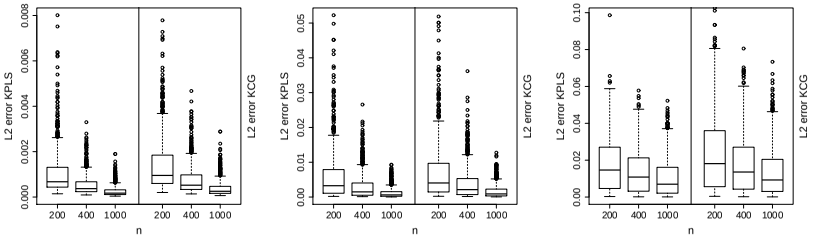

Figure 2: Boxplots of the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-errors $\{\widehat{e}_{n,\tau}^{(j,m)}\}_{j=1}^M$ of kernel partial least squares (left side of each panel) and kernel conjugate gradient (right side of each panel) for different autocovariance functions τ and $n = 200, 400, 1000$. On the left is $\tau_h = \mathbb{I}(h = 0)$, in the middle $\tau_h = 0.9^{-h}$ and on the right $\tau_h = (h+1)^{-1/4}$.

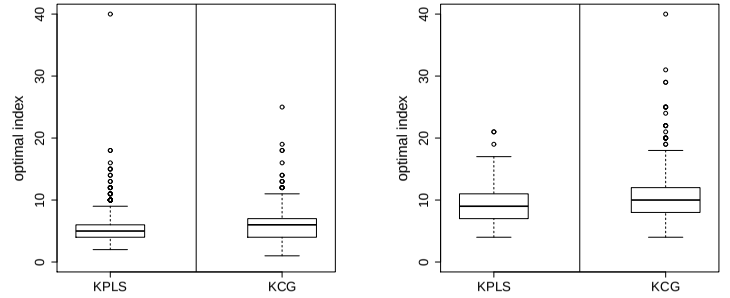

Figure 3: Boxplots of the optimal indices $a \in \{1, \ldots, 40\}$ for which the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-errors $\{\widehat{e}_{n,\tau}^{(j,m)}\}_{j=1}^M$ were attained. Kernel partial least squares is on the left of each panel and kernel conjugate gradient on the right. On the left is $n = 200$, on the right $n = 1000$. The data were assumed to be independent and identically distributed.

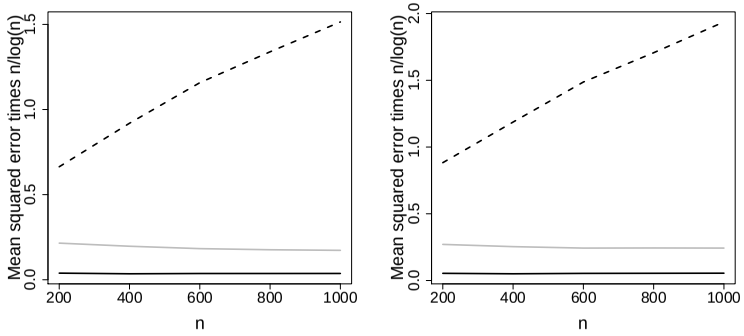

Figure 4: Mean of the $\mathcal{L}^2\left(\mathrm{P}^X\right)$-errors $\{\widehat{e}_{n,\tau}^{(j,m)}\}_{j=1}^M$ of kernel partial least squares (left) and kernel conjugate gradient (right) for $n = 200, 400, \ldots, 1000$ multiplied by $n/\log(n)$. The solid black line is for $\tau_h = \mathbb{I}(h = 0)$, the grey line for $\tau_h = 0.9^{-h}$ and the dashed black line for $\tau_h = (h+1)^{-1/4}$.

Figure 4 shows the mean (over j) of the estimated $\mathcal{L}^2\left(\mathrm{P}^X\right)$ errors $\{\widehat{e}_{n,\tau}^{(j,m)}\}_{j=1}^M$ for different n, τ and $m \in \{CG, PLS\}$. The errors were multiplied by $n/\log(n)$ to illustrate the convergence rates. According to Proposition 8 and Corollary 6 (ii) we expect the rates for the independent and autoregressive cases to be $n^{-1}\log(n)$, which is verified by the fact that the solid black and grey lines are roughly constant. For the long range dependent case we expect worse convergence rates which are also illustrated by the divergence of the dashed black line.

6. Application to Molecular Dynamics Simulations

The collective motions of protein atoms are responsible for its biological function and molecular dynamics simulations is a popular tool to explore this (Henzler-Wildman and Kern, 2007).

Typically, the $p \in \mathbb{N}$ backbone atoms of a protein are considered for the analysis with the relevant dynamics happening in time frames of nanoseconds. Although the dynamics are available exactly, the high dimensionality of the data and large number of observations can be cumbersome for regression analysis, e.g., due to the high collinearity in the columns of the covariates matrix. Many function-dynamic relationships are also non-linear (Hub and de Groot, 2009). A further complication is the fact that the motions of different backbone atoms are highly correlated, making additive non-parametric models for the target function f^* less suitable.

We consider T4 Lysozyme (T4L) of the bacteriophage T4, a protein responsible for the hydrolisis of 1,4-beta-linkages in peptidoglycans and chitodextrins from bacterial cell walls.

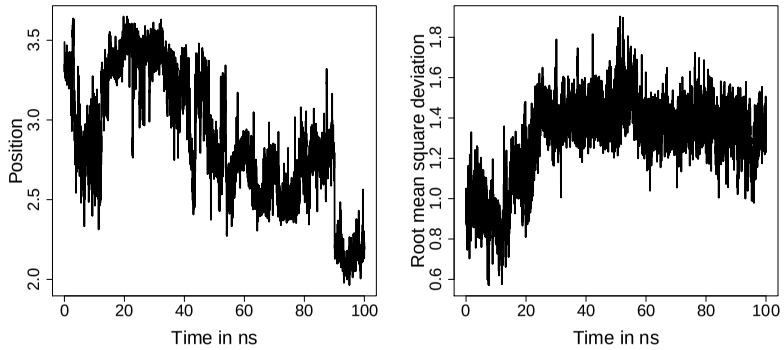

Figure 5: Time series of $X_{t,1}$, i.e., the first coordinate of the first atom T4L consists of (left) and the root mean squared deviation y_t between the protein configuration at time t and the (apo) crystal structure.

The number of available observations is $n = 4601$ and T4L consists of $p = 486$ backbone atoms.

Denote with $A_{t,i} \in \mathbb{R}^3$ the ith atom, $i = 1, \ldots, p$, at time $t = 1, \ldots, n$ and $c_i \in \mathbb{R}^3$ the ith atom in the (apo) crystal structure of T4L. A usual representation of the protein in a regression setting is the Cartesian one, i.e., we take as the covariate $X_t = (A_{1,t}^{\mathrm{T}}, \ldots, A_{p,t}^{\mathrm{T}})^{\mathrm{T}}$, $t = 1, \ldots, n$, see Brooks and Karplus (1983). The functional quantity to predict is the root mean square deviation of the protein configuration X_t at time $t = 1, \ldots, n$ from the (apo) crystal structure $C = (c_1^{\mathrm{T}}, \ldots, c_d^{\mathrm{T}})^{\mathrm{T}}$, i.e.,

$$y_t = \left\{ p^{-1} \sum_{i=1}^{p} \|X_{i,t} - C_i\|^2 \right\}^{1/2}.$$

This nonlinear function was previously considered in Hub and de Groot (2009), where it was established that linear models are insufficient for the prediction.

Figure 5 shows the time series corresponding to $X_{t,1}$ (i.e., the first coordinate of the first atom of T4L) on the left and the functional quantity y_t on the right. These plots reveal certain persistent dependence over time.

Fitting autoregressive moving average models of order $(3, 2)$ ($ARMA(3, 2)$) to y_t and $ARMA(5, 2)$ to $X_{t,1}$ shows that the smallest root of their respective characteristic polynomial is close to one (1.009 for y_t and 1.003 for $X_{t,1}$), highlighting that we are on the border of stationarity, see, e.g., Brockwell and Davis (1991).

Next, we performed an augmented Dickey Fuller test for the null hypothesis of non-stationarity against stationarity. Calculating the test statistics with 16 lags yields a p-value smaller than 0.01 for y_t and 0.0122 for $X_{t,1}$. Hence, both time series are likely stationary.

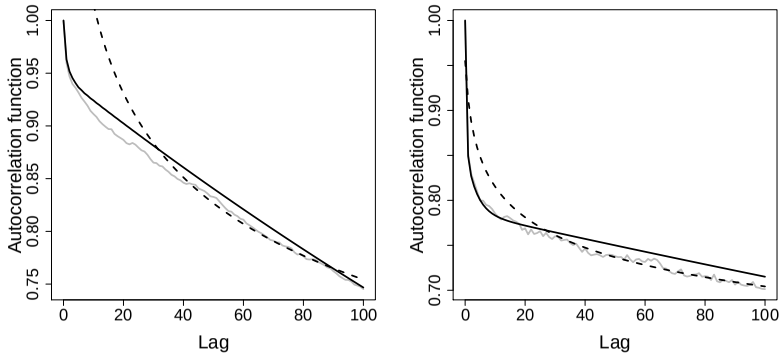

Figure 6: Autocorrelation plots of $X_{t,1}$ (left) and y_t (right). The estimated autocorrelation function is grey, the theoretical one of a fitted $ARMA(3,2)$ process is solid black and $\rho_h \propto (h+1)^{-q}$ for a suitable choice of $q > 0$ is dashed black.

Finally, to test for long range dependence, we employed the rescaled variance test of Giraitis et al. (2003). The null hypothesis of this test is the short range dependence in the data, while the alternative is the long range dependence. Calculating the test statistics with 16 lags gives the p-value for both y_t and $X_{t,1}$ smaller than 0.01, suggesting the long range dependence.

Figure 6 depicts the autocorrelation functions of $X_{t,1}$ and y_t, the theoretical autocorrelation function of the corresponding autoregressive moving average process and $\rho_h \propto (h+1)^{-q}$ for $q = 0.134$ for $X_{t,1}$ and $q = 0.066$ for y_t. The latter, as highlighted in Section 4, is an autocorrelation function for a stationary long range dependent process. These plots together with the above findings suggest that $X_{t,1}$ and y_t are stationary, long range dependent processes.

We apply kernel partial least squares to this data set with the Gaussian kernel $k(x,y) = \exp(-l\|x-y\|^2)$, $x, y \in \mathbb{R}^{3p}$, $l > 0$. The function f we aim to estimate is a distance between protein configurations, so using a distance based kernel seems reasonable. Moreover, we also investigated the impact of other bounded kernels such as triangular and Epanechnikov and obtained similar results. The first 50% of the data form a training set to calculate the kernel partial least squares estimator and the remaining data are used for testing.

The parameter $l > 0$ is calculated via cross validation on the training set. In our evaluation we obtained $l = 10.22$.

Figure 7 compares the observed response in the test set with the prediction on the test set obtained by kernel partial least squares, kernel principal component regression and linear partial least squares. Apparently, kernel partial least squares show the best performance and the kernel principal components algorithm is able to achieve comparable prediction with

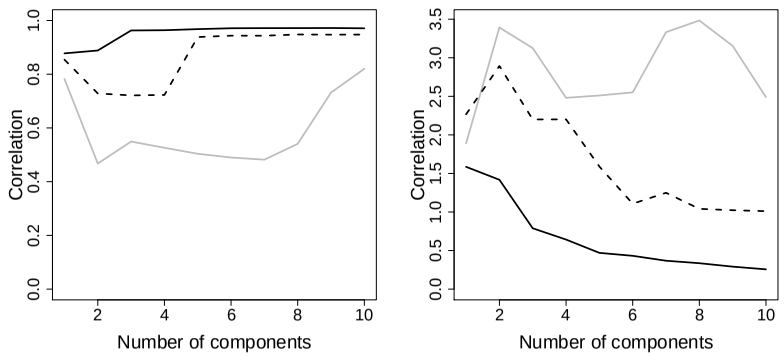

Figure 7: Correlation (left) and residual sum of squares (right) between predicted values and the observed response on the test set depending on the number of used components for kernel partial least squares (solid black), partial least squares (grey) and kernel principal component regression (dashed black).

more components. Obviously, linear partial least squares can not cope with the non-linearity of the problem.

This application highlights that kernel partial least squares still deliver a robust prediction even for long range dependent data, if enough observations are available.

Appendix A. Source Condition and Effective Dimensionality for Gaussian Kernels

The source condition (S) and the effective dimensionality d_λ are of great importance in the convergence rates derived in Section 3. Here we investigate these conditions for the reproducing kernel Hilbert space corresponding to the Gaussian kernel $k(x,y) = \exp(-l\|x-y\|^2)$, $x, y \in \mathbb{R}^d$, $l > 0$, for $d = 1$. Hence, the space $\mathcal{H}$ is the space of all analytic functions that decay exponentially fast, see Steinwart et al. (2005).

We also impose the normality conditions (D1) and (D2) on $\{X_t\}_{t\in\mathbb{Z}}$, where now $\sigma_x^2 = \Sigma \in \mathbb{R}$ due to $d = 1$. The following proposition derives a more explicit representation for $f \in \mathcal{H}$.

Proposition 7 *Assume that (K1),(K2) and (S) hold for $r \geq 1/2$. Let $d = 1$, $X_0 \sim \mathcal{N}(0, \sigma_x^2), \sigma_x^2 > 0$ and consider the Gaussian kernel $k(x,y) = \exp\{-l(x-y)^2\}$ for $x, y \in \mathbb{R}$, $l > 0$. Then f can be expressed for $\mu = r - 1/2 \in \mathbb{N}$ via $f(x) = \sum_{i=1}^{\infty} c_i L_\mu(x, z_i)$ for fixed $\{z_i\}_{i=1}^{\infty}, \{c_i\}_{i=1}^{\infty} \subset \mathbb{R}$ such that $\sum_{i,j=1}^{\infty} c_i c_j k(z_i, z_j) \leq R^2$, $R > 0$. Here we have for $x, z \in \mathbb{R}$*

$$L_\mu(x,z) = \exp\left[-1/2\left\{\frac{\det(\Lambda)(x^2+z^2) - 2l^{\mu+1}xz}{\det(\Lambda_{1:\mu})}\right\}\right],$$

with $\Lambda \in \mathbb{R}^{(\mu+1)\times(\mu+1)}$ being a tridiagonal matrix with elements

$$\Lambda_{i,j} = \begin{cases} \sigma_x^{-2} + 2l & , \quad i = j < \mu + 1 \\ l & , \quad i = j = \mu + 1 \\ -l & , \quad |i-j| = 1 \\ 0 & , \quad else \end{cases}$$

for $i, j = 1, \ldots, \mu + 1$ and $\Lambda_{1:\mu}$ is the $\mu \times \mu$-dimensional sub-matrix of Λ including the first μ columns and rows.

Conversely any function $f^* = Tf$ with f of the above form fulfills a source condition (S) with $r = \mu + 1/2$, $\mu \in \mathbb{N}$.

Hence if we fix an $r \geq 1/2$ with $r - 1/2 \in \mathbb{N}$ this theorem gives us a way to construct functions $f \in \mathcal{H}$ with $f^* = Tf$ that fulfill (S).

The next proposition derives the effective dimensionality d_λ in this setting:

Proposition 8 *Let $d = 1$, $X_0 \sim \mathcal{N}(0, \sigma_x^2)$ for some $\sigma_x^2 > 0$ and consider the Gaussian kernel $k(x,y) = \exp\{-l(x-y)^2\}$, $x, y \in \mathbb{R}$, $l > 0$.*

Then there is a constant $D > 0$ such that it holds for any $\lambda \in (0, 1]$

$$d_\lambda = \mathrm{tr}\{(S+\lambda)^{-1}S\} \leq D \log(1 + a/\lambda),$$

with $a = \sqrt{2}(1 + \beta + \sqrt{1+\beta})^{-1/2}$, $\beta = 4l\sigma_x^2$.

With the latter result Corollary 4 is applicable and we expect convergence rates for the kernel partial least squares algorithm of order $O\{\gamma_n \log(1/2\gamma_n^{-2})\}$ for a sequence $\{\gamma_n\}_n$ as in Theorem 2.

Appendix B. Proofs

B.1 Proof of Theorem 1

The proof of Theorem 1 makes use of the connection between the partial least squares and the conjugate gradient algorithm. This section is structured as follows: First we will introduce the link between kernel partial least squares and kernel conjugate gradient. We will state some key facts about orthogonal polynomials and their relationship to the algorithm in Lemma 9. Then the consistency of kernel partial least squares is shown with the help of three error bounds that are obtained in Lemmas 11 — 13.

With a slight abuse of notation we define $f_i = f_{\widehat{\alpha}_i}$ for $i = 1, \ldots, n$.

B.1.1 Orthogonal Polynomials and Some Notation

Denote with $\mathcal{P}_i$ the set of polynomials of degree at most $i = 0, \ldots, n$. For functions $\psi, \phi : \mathbb{R} \to \mathbb{R}$ and $r \in \mathbb{N}_0$ define the inner products $[\psi, \phi]_r = \langle \psi(S_n) T_n^* y, S_n^r \phi(S_n) T_n^* y \rangle_{\mathcal{H}}$. From the definition of the Krylov space it is immediate that every element $v \in \mathcal{K}_i(S_n, T_n^* y)$, $i = 1, \ldots, n$, can be represented by a polynomial $q \in \mathcal{P}_{i-1}$ via $v = q(S_n) T_n^* y$.

The following discussion is based on Hanke (1995), chapter 2. There exist two sequences of polynomials $\{p_i\}_{i=0}^n, \{q_i\}_{i=0}^n \subset \mathcal{P}_i$, such that $f_i = q_{i-1}(S_n) T_n^* y$ with $q_{-1} = 0$ and $T_n^* y - S_n f_i = p_i(S_n) T_n^* y$. Both sequences are connected by the equation $p_i(x) = 1 - x q_{i-1}(x)$, $x \in \mathbb{R}$, and the polynomials $\{p_i\}_{i=0}^n$ are orthogonal with respect to $[\cdot, \cdot]_0$.

We will also consider other sequences of polynomials, namely $\{q_i^{[r]}\}_{i=0}^n, \{p_i^{[r]}\}_{i=0}^n \subset \mathcal{P}_i$, $q_{-1}^{[r]} = 0$, such that $p_i^{[r]}(x) = 1 - x q_{i-1}^{[r]}(x)$, $x \in \mathbb{R}$, and the sequence $\{p_i^{[r]}\}_{i=0}^n$ is orthogonal with respect to $[\cdot, \cdot]_r$. This yields for every $r \in \mathbb{N}_0$ a separate conjugate gradient algorithm with solution $f_i^{[r]} = q_{i-1}^{[r]}(S_n) T_n^* y \in \mathcal{K}_i(S_n, T_n^* y)$ and residuals $T_n^* y - S_n f_i^{[r]} = p_i^{[r]}(S_n) T_n^* y$, $i = 1, \ldots, n$. The $p_i^{[r]}$, $i = 0, \ldots, n$, $r \in \mathbb{N}_0$, are called residual polynomials.

As S_n is self-adjoint, positive semi-definite and the kernel is bounded by κ we know that its spectrum is a subset of $[0, \kappa]$, see Caponnetto and de Vito (2007). This also implies that $\max\{\|S\|_{\mathcal{L}}, \|S_n\|_{\mathcal{L}}\} \leq \kappa$, with $\|\cdot\|_{\mathcal{L}}$ denoting the operator norm. The i distinct roots of $p_i^{[r]}$ will be denoted by $0 < x_{1,i}^{[r]} < \ldots x_{i,i}^{[r]} < \kappa$, $i = 1, \ldots, n$.

We will summarize some key facts about the orthogonal polynomials in the next lemma.

Lemma 9 *Let $r, s \in \mathbb{N}_0$ and $i = 1, \ldots, n$. Then we have:*

(i) The roots of consecutive orthogonal polynomials interlace, i.e., for $j = 1, \ldots, i$ it holds

$$0 < x_{j,i+1}^{[r]} < x_{j,i}^{[r]} < x_{j,i}^{[r+1]} < x_{j+1,i+1}^{[r]} < x_{j+1,i}^{[r]} < \cdots < x_{i,i}^{[r+1]} < x_{i+1,i+1}^{[r]} < \kappa,$$

(ii) the optimality property $[p_i^{[1]}, p_i^{[1]}]_0^{1/2} = \|T_n^* y - S_n f_i^{[1]}\|_{\mathcal{H}} \leq \|T_n^* y - S_n h\|_{\mathcal{H}}$ holds for all $h \in \mathcal{K}_i(S_n, T_n^* y)$,

(iii) on $x \in [0, x_{1,i}^{[r]}]$ it holds $0 \leq p_i^{[r]}(x) \leq 1$ and $q_i^{[r]}(x) \leq \left|\left(p_i^{[r]}\right)'(0)\right|$,

(iv) $p_n^{[r]} = p_n^{[s]}$,

(v) $\left(p_i^{[r]}\right)'(0) = -\sum_{j=1}^{i} \left(x_{j,i}^{[r]}\right)^{-1}$,

(vi) for $r \geq 1$ define $\phi_i(x) = p_i^{[r]}(x) \left(x_{1,i}^{[r]}\right)^{1/2} \left(x_{1,i}^{[r]} - x\right)^{-1/2}$, $x \in [0, x_{1,i}^{[r]}]$, $i = 1, \ldots, n$. Then it holds for $u \geq 0$ that $x^u \phi_i^2(x) \leq u^u \left|\left(p_i^{[r]}\right)'(0)\right|^{-u}$ with the convention $0^0 = 1$.

Proof: (i) See Hanke (1995), Corollary 2.7.

(ii) See Hanke (1995), Proposition 2.1.

(iii) Due to part (i) we know that all i roots of the polynomial $p_i^{[r]}$ are contained in $(0, \kappa)$. Furthermore $p_i^{[r]}(0) = 1 - 0 q_i^{[r]} = 1$. Thus $p_i^{[r]}$ is convex and falling in $[0, x_{1,i}^{[r]}]$ and the first assertion follows.

Because of the convexity of $p_i^{[r]}$ on $[0, x_{1,i}^{[r]}]$ we get $q_i^{[r]}(x) = x^{-1}\{1-p_i^{[r]}(x)\} \leq \left|\left(p_i^{[r]}\right)'(0)\right|$.

(iv) See the discussion in Hanke (1995) preceding Proposition 2.1 and use the facts that $T_n^* y \in \text{range}(S_n)$ and S_n is an operator of rank n.

(v) Write $p_i^{[r]}(x) = \prod_{j=1}^{i}(1 - x/x_{j,i}^{[r]})$, $x \in [0, \kappa]$, and the result is immediate.

(vi) See equation (3.10) in Hanke (1995). ■

We denote for $x \geq 0$ by P_x the orthogonal projection operator on the eigenspace corresponding to the eigenvalues of S_n that are smaller or equal x and $P_x^{\perp} = I_{\mathcal{H}} - P_x$ with $I_{\mathcal{H}} : \mathcal{H} \to \mathcal{H}$ being the identity operator.

B.1.2 Preparation for the Proof

We consider the kernel partial least squares algorithm as an optimization problem

$$f_i = \arg \min_{g \in \mathcal{K}_i(S_n, T_n^* y)} n^{-1}\|y - T_n g\|^2, \quad i = 1, \ldots, n. \tag{8}$$

This is the conjugate gradient algorithm CGNE discussed in chapter 2.2 of Hanke (1995), to which we refer for more details. Note that, for example,

$$n^{-1}\langle \phi(T_n T_n^*)y, T_n T_n^* \psi(T_n T_n^*)y\rangle = \langle \phi(S_n)T_n^* y, \psi(S_n)T_n^* y\rangle_{\mathcal{H}} = [\phi, \psi]_0,$$

for polynomials ϕ, ψ.

In the upcoming proofs we will make use of the following operator inequality:

Lemma 10 *Let $B, C : \mathcal{H} \to \mathcal{H}$ be two positive semi-definite, self-adjoint operators with $\max\{\|B\|_{\mathcal{L}}, \|C\|_{\mathcal{L}}\} \leq \kappa$. Then it holds for any $r \geq 0$ with $\zeta = \max\{r - 1, 0\}$*

$$\|B^r - C^r\|_{\mathcal{L}} \leq (\zeta + 1)\kappa^{\zeta}\|B - C\|_{\mathcal{L}}^{r-\zeta}.$$

Proof: See Blanchard and Krämer (2010b), Lemma A.6. ■

For the remainder of the proof we assume that we are on the set where it holds with probability at least $1-\nu$, $\nu \in (0, 1]$, that $\|S_n - S\|_{\mathcal{L}} \leq C_\delta(\nu)\gamma_n$ and $\|T_n^* y - Sf\|_{\mathcal{H}} \leq C_\epsilon(\nu)\gamma_n$ for a sequence $\{\gamma_n\}_n$ converging to zero and constants $C_\delta = C_\delta(\nu), C_\epsilon = C_\epsilon(\nu) > 0$.

With Lemma 2.4 in Hanke (1995) we see that the stopping iteration (5) can also be expressed as

$$a^* = \min\left\{1 \leq a \leq n : \|S_n f_a^{[1]} - T_n^* y\|_{\mathcal{H}} \leq C\gamma_n\right\}, \tag{9}$$

i.e., we stop the kernel partial least squares algorithm when a discrepancy principle for $f_a^{[1]}$ holds.

It is easy to see that from (S) it follows for $r \geq 1/2$ that

(SH) There exist $\mu \geq 0$, $R > 0$ and $u \in \mathcal{H}$ such that $f = S^{\mu}u$ and $\|u\|_{\mathcal{H}} \leq R$.

This condition is known as the Hölder source condition with $\mu = r - 1/2$.

Recall that $\mathcal{H} \subseteq \mathcal{L}^2\left(\mathrm{P}^X\right)$ and $T : \mathcal{H} \to \mathcal{L}^2\left(\mathrm{P}^X\right)$ is the change of space operator. Using the fact that T, T^* are adjoint operators, $f_{a^*} = Tf_{a^*}$ and $f^* = Tf$ for $r \geq 1/2$ we see

$$\|f_{a^*} - f^*\|_2 = \|T(f_{a^*} - f)\|_2 = \langle S(f_{a^*} - f), f_{a^*} - f\rangle_{\mathcal{H}} = \|S^{1/2}(f_{a^*} - f)\|_{\mathcal{H}}.$$

An application of Lemma 10 yields

$$\begin{aligned}\|f_{a^*} - f^*\|_2 &= \|S^{1/2}(f_{a^*} - f)\|_{\mathcal{H}} \leq \|S^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} + \|S^{1/2}(f_{a^*}^{[1]} - f)\|_{\mathcal{H}} \\ &\leq C_\delta^{1/2}\gamma_n^{1/2}\left(\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} + \|f_{a^*}^{[1]} - f\|_{\mathcal{H}}\right) + \|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} + \|S_n^{1/2}(f_{a^*}^{[1]} - f)\|_{\mathcal{H}}.\end{aligned} \tag{10}$$

The following lemmas will deal with bounding the quantities in (10) in terms of the source parameter $r = \mu + 1/2 \geq 1/2$ and the sequence γ_n. First we will derive upper bounds for the quantities containing the difference of the KPLS estimator f_{a^*} and the estimator $f_{a^*}^{[1]}$:

Lemma 11 *Assume $C_x \in (0, 1]$ such that $x_* = (C_x\gamma_n)^{1/(\mu+1)} < x_{1,a^*-1}^{[1]}$ and $C > C_\epsilon + C_x R + C_\delta(\mu + 1)\kappa^\mu R$. Under the conditions of the theorem it holds $\mu \geq 0$*

$$\begin{aligned}\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} &\leq \gamma_n^{\mu/(\mu+1)} \frac{C}{C_x^{1/(\mu+1)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]^2} \\ \|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} &\leq \gamma_n^{(2\mu+1)/(2\mu+2)} \frac{C}{C_x^{1/(2\mu+2)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]}.\end{aligned}$$

Proof: If the inner products $[\cdot, \cdot]_0$ and $[\cdot, \cdot]_1$ are the same the proof is done because both polynomial sequences are identical.

We now observe that we have for $a^* = n$ due to Lemma 9 (iv) $q_{n-1}(x) - q_{n-1}^{[1]}(x) = x^{-1}\{p_n^{[1]}(x) - p_n(x)\} = 0$, i.e., $\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} = 0$ and $\|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} = 0$ and the proof is done.

If the inner products differ and we have $0 < a^* < n$ it holds $f_{a^*} \neq f_{a^*}^{[1]}$.

Proposition 2.8 in Hanke (1995) can now be applied for $0 < a^* < n$ and yields $q_{a^*-1}(x) - q_{a^*-1}^{[1]}(x) = x^{-1}\{p_{a^*}^{[1]}(x) - p_{a^*}(x)\} = \theta_{a^*}p_{a^*-1}^{[2]}(x)$, $x \geq 0$, with $\theta_{a^*} = (p_{a^*}^{[1]})'(0) - (p_{a^*}^{[0]})'(0) > 0$. We get $f_{a^*} - f_{a^*}^{[1]} = q_{a^*-1}(S_n)T_n^* y - q_{a^*-1}^{[1]}(S_n)T_n^* y = \theta_{a^*}p_{a^*-1}^{[2]}(S_n)T_n^* y$.

Proposition 2.9 in Hanke (1995) yields $\theta_{a^*} = \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1^{-1}\left[p_{a^*}^{[1]}, p_{a^*}^{[1]}\right]_0$. The optimality property of $f_{a^*}^{[1]}$ in Lemma 9 (ii) shows that

$$\|T_n^* y - S_n f_{a^*}^{[1]}\|_{\mathcal{H}} = \|p_{a^*}^{[1]}(S_n)T_n^* y\|_{\mathcal{H}} = \left[p_{a^*}^{[1]}, p_{a^*}^{[1]}\right]_0^{1/2} \leq \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0^{1/2}. \tag{11}$$

Combining these results yields

$$\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} = \frac{\left[p_{a^*}^{[1]}, p_{a^*}^{[1]}\right]_0}{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1}\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0^{1/2} \leq \frac{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0}{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1}\|p_{a^*}^{[1]}(S_n)T_n^* y\|_{\mathcal{H}}. \tag{12}$$

Recall that $x^{[2]}_{1,a^*-1}$ denotes the first root of $p^{[2]}_{a^*-1}$. It holds for any $0 \le x \le x^{[2]}_{1,a^*-1}$ that $0 \le p^{[2]}_{a^*-1}(x) \le 1$, see Lemma 9 (iii), and thus

$$\begin{aligned}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} &\le \|P_x p^{[2]}_{a^*-1}(S_n)\{T_n^* y - Sf + Sf\}\|_{\mathcal{H}} + \|P_x^{\perp} p^{[2]}_{a^*-1}(S_n) T_n^* y\|_{\mathcal{H}} \\ &\le C_\epsilon \gamma_n + \|P_x p^{[2]}_{a^*-1}(S_n) S^{\mu+1} u\|_{\mathcal{H}} + x^{-1/2}\|P_x^{\perp} S_n^{1/2} p^{[2]}_{a^*-1}(S_n) T_n^* y\|_{\mathcal{H}} \\ &\le C_\epsilon \gamma_n + x^{\mu+1} R + \|P_x p^{[2]}_{a^*-1}(S^{\mu+1} - S_n^{\mu+1}) u\|_{\mathcal{H}} + \frac{1}{\sqrt{x}}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}.\end{aligned}$$

In the second inequality (SH) with $\mu \ge 0$ was applied.

By assumption $x_* = (C_x\gamma)^{1/(\mu+1)} \le x^{[1]}_{1,a^*-1} < x^{[2]}_{1,a^*-1}$ due to the interlacing property of the roots of the polynomials $p_i^{[r]}$, $i = 1, \dots, n$, $r \in \mathbb{N}_0$, see Lemma 9 (i).

Using Lemma 10 we get $\|S^{\mu+1} - S_n^{\mu+1}\|_{\mathcal{L}} \le (\mu+1)\kappa^\mu C_\delta \gamma_n$ and setting $x = x_*$ we get

$$\begin{aligned}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} &\le C_\epsilon\gamma_n + x_*^{\mu+1} R + C_\delta \gamma_n (\mu+1)\kappa^\mu R + x_*^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2} \\ &= \gamma_n\left\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\right\} + x_*^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}. \qquad (13)\end{aligned}$$

Due to (9) and (11) we have additionally $C\gamma_n \le \|S_n f^{[1]}_{a^*-1} - T_n^* y\|_{\mathcal{H}} = \|p^{[1]}_{a^*-1}(S_n) T_n^* y\|_{\mathcal{H}} \le \left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2}$.

Plugging this into (13) yields

$$\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} \le \frac{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R}{C}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} + \frac{1}{\sqrt{x_*}}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2},$$

or equivalently with $x_* = (C_x\gamma_n)^{1/(\mu+1)}$

$$\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} \le \gamma_n^{-1/(2\mu+2)} \frac{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}}{C_x^{1/(2\mu+2)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]}, \qquad (14)$$

where by assumption $C > C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R$ and $x_* = (C_x\gamma)^{1/(\mu+1)}$.

Combining (12), (14) and $\|p^{[1]}_{a^*}(S_n) T_n^* y\|_{\mathcal{H}} \le C\gamma_n$ due to the stopping index (9) yields

$$\begin{aligned}\|f_{a^*} - f^{[1]}_{a^*}\|_{\mathcal{H}} &\le \gamma_n^{-1/(\mu+1)} \frac{\|p^{[1]}_{a^*}(S_n) T_n^* y\|_{\mathcal{H}}}{C_x^{1/(\mu+1)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]^2} \\ &\le \gamma_n^{\mu/(\mu+1)} \frac{C}{C_x^{1/(\mu+1)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]^2}.\end{aligned}$$

For the second part of the proof we derive in the same way as (12)

$$\|S_n^{1/2}(f_{a^*} - f^{[1]}_{a^*})\|_{\mathcal{H}} \le \frac{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2}}{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}} \|p^{[1]}_{a^*}(S_n) T_n^* y\|_{\mathcal{H}}.$$

Using (14) and $\|p^{[1]}_{a^*}(S_n) T_n^* y\|_{\mathcal{H}} \le C\gamma_n$ gives

$$\|S_n^{1/2}(f_{a^*} - f^{[1]}_{a^*})\|_{\mathcal{H}} \le \gamma_n^{(2\mu+1)/(2\mu+2)} \frac{C}{C_x^{1/(2\mu+2)}\left[1 - C^{-1}\{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R\}\right]},$$

finishing the proof. ■

We now derive an upper bound on the quantities that contain $f^{[1]}_{a^*}$ and f. These contain $\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}}$, which can be controlled for $i = a^*$ by the discrepancy principle (9), and $(p_i^{[1]})'(0)$, for which we have to derive a separate bound later on.

Lemma 12 *For any $i = 1, \dots, n$ and any $0 < x \le x^{[1]}_{1,i}$ we have under the conditions of the theorem for $\mu \ge 1$*

$$\begin{aligned}\|f - f_i^{[1]}\|_{\mathcal{H}} &\le R\left\{x^\mu + C_\delta \mu \kappa^{\mu-1}\gamma_n\right\} + x^{-1}\left\{\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}} + (C_\epsilon + C_\delta\kappa^\mu R)\gamma_n\right\} \\ &\quad + (C_\epsilon + C_\delta\kappa^\mu R)\gamma_n |(p_i^{[1]})'(0)|, \\ \|S_n^{1/2}(f - f_i^{[1]})\|_{\mathcal{H}} &\le R\left\{x^{\mu+1/2} + x^{1/2} C_\delta \mu \kappa^{\mu-1}\gamma_n\right\} \\ &\quad + x^{-1/2}\left\{\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}} + (C_\epsilon + C_\delta\kappa^\mu R)\gamma_n\right\} \\ &\quad + x^{1/2}(C_\epsilon + C_\delta\kappa^\mu R)\gamma_n |(p_i^{[1]})'(0)|.\end{aligned}$$

Proof: Denote $\bar{f}_i = q^{[1]}_{i-1}(S_n) S_n f$ and consider

$$\|f - f_i^{[1]}\|_{\mathcal{H}} \le \|P_x(f - \bar{f}_i)\|_{\mathcal{H}} + \|P_x(\bar{f}_i - f_i^{[1]})\|_{\mathcal{H}} + \|P_x^{\perp}(f - f_i^{[1]})\|_{\mathcal{H}}. \qquad (15)$$

The first term of (15) can be bound by an application of Lemma 10 and (SH) with $\mu \ge 1$

$$\begin{aligned}\|P_x(f - \bar{f}_i)\|_{\mathcal{H}} &= \|P_x\{I - q^{[1]}_{i-1}(S_n) S_n\} f\|_{\mathcal{H}} = \|P_x p_i^{[1]}(S_n) f\|_{\mathcal{H}} = \|P_x p_i^{[1]}(S_n) S^\mu u\|_{\mathcal{H}} \\ &\le \|P_x p_i^{[1]}(S_n) S_n^\mu u\|_{\mathcal{H}} + \|P_x p_i^{[1]}(S_n)(S^\mu - S_n^\mu) u\|_{\mathcal{H}} \\ &\le R\left\{x^\mu + C_\delta \mu \kappa^{\mu-1}\gamma_n\right\}.\end{aligned}$$

In the last inequality we used that on $0 \le x \le x^{[1]}_{1,i}$ we have $0 \le p_i^{[1]}(x) \le 1$.

For the second term of (15) we use Lemma 9 (iii) $q_i^{[1]}(x) \le |(p_i^{[1]})'(0)|$ on $x \in [0, x^{[1]}_{1,i}]$. This yields

$$\begin{aligned}\|P_x(f_i^{[1]} - \bar{f}_i)\|_{\mathcal{H}} &= \|P_x q_i^{[1]}(S_n)(S_n f - T_n^* y)\|_{\mathcal{H}} \\ &\le \|P_x q_i^{[1]}(S_n)(Sf - T_n^* y)\|_{\mathcal{H}} + \|P_x q_i^{[1]}(S_n)(S_n - S) f\|_{\mathcal{H}} \\ &\le (C_\epsilon + C_\delta\kappa^\mu R)\gamma_n \left|\left(p_i^{[1]}\right)'(0)\right|.\end{aligned}$$

Finally, we have

$$\begin{aligned}\|P_x^{\perp}(f - f_i^{[1]})\|_{\mathcal{H}} &\le x^{-1}\|P_x^{\perp} S_n (f - f_i^{[1]})\|_{\mathcal{H}} \\ &\le x^{-1}\left\{\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}} + \|P_x(T_n^* y - S_n f)\|_{\mathcal{H}}\right\} \\ &\le x^{-1}\left\{\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}} + (C_\epsilon + C_\delta\kappa^\mu R)\gamma_n\right\}\end{aligned}$$

and thus the first inequality is proven.

For the second inequality we use

$$\|S_n^{1/2}(f-f_i^{[1]})\|_{\mathcal{H}} \le \|P_x S_n^{1/2}(f-\bar{f}_i)\|_{\mathcal{H}} + \|P_x S_n^{1/2}(\bar{f}_i - f_i^{[1]})\|_{\mathcal{H}} + \|P_x^{\perp} S_n^{1/2}(f-f_i^{[1]})\|_{\mathcal{H}}.$$

In the same way as before we derive bounds for the three terms:

$$\|P_x S_n^{1/2}(f-\bar{f}_i)\|_{\mathcal{H}} \le x^{1/2} C_\delta \mu \kappa^{\mu-1} R\gamma_n + x^{\mu+1/2} R,$$

$$\|P_x S_n^{1/2}(\bar{f}_i - f_i^{[1]})\|_{\mathcal{H}} \le x^{1/2}(C_\epsilon + C_\delta R\kappa^\mu)\gamma_n \left|\left(p_i^{[1]}\right)'(0)\right|,$$

$$\|P_x^{\perp} S_n^{1/2}(f-f_i^{[1]})\|_{\mathcal{H}} \le x^{-1/2}\{\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}} + (C_\epsilon + C_\delta \kappa^\mu R)\gamma_n\},$$

completing the proof. ■

Lemma 12 depends on $(p_i^{[1]})'(0)$ and hence an upper bound for this term is needed:

Lemma 13 *Assume that $C_x \in (0,1]$ is such that $x_* = (C_x\gamma)^{1/(\mu+1)} < x_{1,a^*-1}^{[1]}$ and $C > C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R$. Under the conditions of the theorem it holds for $\mu \ge 0$*

$$\left|\left(p_{a^*}^{[1]}\right)'(0)\right| \le \gamma_n^{-1/(\mu+1)} \left[C_x^{-1/(\mu+1)} \left\{ 1 - \frac{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R}{C} \right\}^{-2} + \left\{ \frac{(2\mu+2)^{\mu+1} R}{C - C_\delta(\mu+1)\kappa^\mu R + C_\epsilon} \right\}^{1/(\mu+1)} \right]$$

Proof: The proof is done in two steps by using the inequality $\left|\left(p_{a^*}^{[1]}\right)'(0)\right| \le \left|\left(p_{a^*-1}^{[1]}\right)'(0)\right| + \left|\left(p_{a^*}^{[1]}\right)'(0) - \left(p_{a^*-1}^{[1]}\right)'(0)\right|$.

Consider first $a^* > 1$.

We will bound $\|S_n f_{a^*-1}^{[1]} - T_n^* y\|_{\mathcal{H}}$ from above. Define $z = x_{1,a^*-1}^{[1]}$ and $\phi_i(x) = p_i^{[1]}(x)(z-x)^{-1/2} z^{1/2}$, $0 \le x \le z$. Due to Lemma 9 (vi) it holds that $\sup_{0\le x\le z} x^\nu \phi_{a^*-1}^2(x) \le \nu^\nu |(p_{a^*-1}^{[1]})'(0)|^{-\nu}$, $\nu \ge 0$. The proof of Lemma 3.7 in Hanke (1995) shows that

$$\left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0^{1/2} \le \|P_z \phi_{a^*-1}(S_n) T_n^* y\|_{\mathcal{H}}.$$

This yields with (SH)

$$\begin{aligned}
&\|S_n f_{a^*-1}^{[1]} - T_n^* y\|_{\mathcal{H}} = \left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0^{1/2} \le \|P_z \phi_{a^*-1}(S_n) T_n^* y\|_{\mathcal{H}} \\
&\le \|P_z \phi_{a^*-1}(S_n) S f\|_{\mathcal{H}} + \|P_z \phi_{a^*-1}(S_n)(T_n^* y - Sf)\|_{\mathcal{H}} \\
&\le \|P_z \phi_{a^*-1}(S_n) S f\|_{\mathcal{H}} + C_\epsilon \gamma_n \left(\sup_{0\le x\le z} \phi_{a^*-1}^2 \right)^{1/2} \\
&\le \|P_z \phi_{a^*-1}(S_n) S_n^{\mu+1} u\|_{\mathcal{H}} + \|P_z \phi_{a^*-1}(S_n)(S_n^{\mu+1} - S^{\mu+1})u\|_{\mathcal{H}} + C_\epsilon \gamma_n \\
&\le R \left\{ \left(\sup_{0\le x\le z} x^{2\mu+2} \phi_{a^*-1}^2 \right)^{1/2} + C_\delta(\mu+1)\kappa^\mu \gamma_n \left(\sup_{0\le x\le z} \phi_{a^*-1}^2 \right)^{1/2} \right\} + C_\epsilon \gamma_n \\
&\le \left| \left(p_{a^*-1}^{[1]}\right)'(0) \right|^{-\mu-1} (2\mu+2)^{\mu+1} R + \{C_\delta(\mu+1)\kappa^\mu R + C_\epsilon\}\gamma_n.
\end{aligned}$$

This gives together with $C\gamma_n \le \|S_n f_{a^*-1}^{[1]} - T_n^* y\|_{\mathcal{H}}$

$$C\gamma_n \le \left| \left(p_{a^*-1}^{[1]}\right)'(0) \right|^{-\mu-1} (2\mu+2)^{\mu+1} R + \{C_\delta(\mu+1)\kappa^\mu R + C_\epsilon\}\gamma_n.$$

If $C > C_\delta(\mu+1)\kappa^\mu R + C_\epsilon$ we finally have

$$\left|\left(p_{a^*-1}^{[1]}\right)'(0)\right| \le \gamma_n^{-1/(\mu+1)} \left\{ \frac{(2\mu+2)^{\mu+1} R}{C - C_\delta(\mu+1)\kappa^\mu R + C_\epsilon} \right\}^{1/(\mu+1)}. \tag{16}$$

If $a^* = 1$ it holds $p_{a^*-1}^{[1]} = 1$ and thus $\left|\left(p_{a^*-1}^{[1]}\right)'(0)\right| = 0$ and the inequality (16) is true as well.

We will derive an upper bound on $\left|\left(p_{a^*}^{[1]}\right)'(0) - \left(p_{a^*-1}^{[1]}\right)'(0)\right|$. Due to Corollary 2.6 of Hanke (1995) we have

$$\left|\left(p_{a^*-1}^{[1]}\right)'(0) - \left(p_{a^*}^{[1]}\right)'(0)\right| \le \frac{\left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0}{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1}. \tag{17}$$

We have $0 \le x \le x_{1,a^*-1}^{[1]} < x_{1,a^*-1}^{[2]}$ due to the interlacing property of the roots in Lemma 9 (i) and thus $0 \le p_{a^*-1}^{[2]}(x) \le 1$ for $0 \le x \le x_{1,a^*-1}^{[2]}$. With that we get with (SH)

$$\begin{aligned}
&\|p_{a^*-1}^{[1]}(S_n) T_n^* y\|_{\mathcal{H}} \le \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0^{1/2} \\
&\le \|P_x p_{a^*-1}^{[2]}(S_n) T_n^* y\|_{\mathcal{H}} + x^{-1/2} \|P_x^{\perp} S_n^{1/2} p_{a^*-1}^{[2]}(S_n) T_n^* y\|_{\mathcal{H}} \\
&\le \|P_x p_{a^*-1}^{[2]}(S_n)(T_n^* y - Sf)\|_{\mathcal{H}} + \|P_x p_{a^*-1}^{[2]}(S_n) S^{\mu+1} u\|_{\mathcal{H}} + x^{-1/2} \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1^{1/2} \\
&\le C_\epsilon \gamma_n + R\left\{C_\delta(\mu+1)\kappa^\mu \gamma_n + x^{\mu+1}\right\} + x^{-1/2} \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1^{1/2}.
\end{aligned}$$

For the choice $x_* = (C_x\gamma)^{1/(\mu+1)}$ we get

$$\left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0^{1/2} \le \gamma_n \{C_\epsilon + C_\delta(\mu+1)\kappa^\mu R + C_x\} + x_*^{-1/2} \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1^{1/2}.$$

It holds $\left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0^{1/2} = \|S_n f_{a^*-1}^{[1]} - T_n^* y\|_{\mathcal{H}} \ge C\gamma_n$. This yields with $C > C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R$

$$\left[p_{a^*-1}^{[1]}, p_{a^*-1}^{[1]}\right]_0 \le \gamma_n^{-1/(\mu+1)} C_x^{-1/(\mu+1)} \left\{ 1 - \frac{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R}{C} \right\}^{-2} \left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1.$$

Together with (17) we have

$$\left|\left(p_{a^*-1}^{[1]}\right)'(0) - \left(p_{a^*}^{[1]}\right)'(0)\right| \le \gamma_n^{-1/(\mu+1)} C_x^{-1/(\mu+1)} \left\{ 1 - \frac{C_\epsilon + C_x R + C_\delta(\mu+1)\kappa^\mu R}{C} \right\}^{-2}.$$

Combining this with (16) completes the proof. ■

B.1.3 Proof of Theorem 1

The proof is an application of Lemmas 11 — 13 to (10). First note that $r \geq 3/2$ implies $\mu \geq 1$ and thus this condition in Lemma 12 holds.

Let us choose $x_* = (C_x\gamma_n)^{1/(\mu+1)}$. Lemma 9 (v) shows that $\left|\left(p_i^{[r]}\right)'(0)\right| = \sum_{j=1}^{i}(x_{j,i}^{[r]})^{-1}$ for $i = 1, \ldots, n$, $r \in \mathbb{N}_0$. Thus it holds $\left|\left(p_i^{[1]}\right)'(0)\right|^{-1} \leq x_{1,i}^{[1]}$.

Equation (16) thus shows that C_x can be chosen small enough such that

$$x_* \leq \left|\left(p_{a^*-1}^{[1]}\right)'(0)\right|^{-1} \leq x_{1,a^*-1}^{[1]}$$

and $C_x < 1$, which makes the first condition in Lemma 11 and 13 hold true. The choice $C = C_\epsilon + (\mu+1)\kappa^\mu R(1+C_\delta)$ gives the second condition.

Now we need to check the remaining condition of Lemma 12, namely that a C_z can be chosen such that $(C_z\gamma_n)^{1/(\mu+1)} \leq x_{1,a^*}^{[1]}$ is true. Lemma 13 yields a $C_z > 0$ such that $C_z\gamma_n^{1/(\mu+1)} \leq \left|\left(p_{a^*}^{[1]}\right)'(0)\right|^{-1} \leq x_{1,a^*}^{[1]}$. Denote $z_* = (C_z\gamma_n)^{1/(\mu+1)}$ and Lemma 12 can be applied.

To ease notation we will denote everything in the derived bounds that does not depend on γ_n as a constant c_j, $j \in \mathbb{N}$. Thus we get by combining Lemmas 12 and 13 that with probability at least $1-\nu$

$$\begin{aligned}\|f - f_{a^*}^{[1]}\|_{\mathcal{H}}^2 &\leq c_1\gamma_n^{\mu/(\mu+1)} + c_2\gamma_n + c_3\gamma_n^{1-1/(\mu+1)} + c_4\gamma_n\left|\left(p_{a^*}^{[1]}\right)'(0)\right| \\ &\leq c_1\gamma_n^{\mu/(\mu+1)} + c_2\gamma_n + c_3\gamma_n^{\mu/(\mu+1)} + c_5\gamma_n^{1-1/(\mu+1)} = O\{\gamma_n^{\mu/(\mu+1)}\}\end{aligned}$$

and

$$\begin{aligned}&\|S_n^{1/2}(f - f_{a^*}^{[1]})\|_{\mathcal{H}}^2 \\ &\leq c_6\gamma_n^{(\mu+1/2)/(\mu+1)} + c_7\gamma_n^{1/(2\mu+2)}\gamma_n + c_8\gamma_n^{-1/(2\mu+2)}\gamma_n + c_9\gamma_n^{1/(2\mu+1)}\gamma_n\left|\left(p_{a^*}^{[1]}\right)'(0)\right| \\ &\leq c_6\gamma_n^{(\mu+1/2)/(\mu+1)} + c_7\gamma_n^{(2\mu+3)/(2\mu+2)} + c_8\gamma_n^{(2\mu+1)/(2\mu+2)} + c_10\gamma_n^{1+1/(2\mu+2)-1/(\mu+1)} \\ &= O\{\gamma_n^{(2\mu+1)/(2\mu+2)}\}.\end{aligned}$$

Finally Lemma 11 gives

$$\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}}^2 = O\{\gamma_n^{\mu/(\mu+1)}\}, \qquad \|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} = O\{\gamma_n^{(2\mu+1)/(2\mu+2)}\}.$$

Combining the above with (10) yields

$$\begin{aligned}&\|f - f_{a^*}\|_{\mathcal{H}}^2 = O\{\gamma_n^{\mu/(\mu+1)}\}, \\ &\|f^* - f_{a^*}\|_2^2 = O\{\gamma^{1/2}\gamma_n^{\mu/(\mu+1)}\} + O\{\gamma_n^{(2\mu+1)/(2\mu+2)}\} = O\{\gamma_n^{(2\mu+1)/(2\mu+2)}\},\end{aligned}$$

completing the proof with $\mu = r - 1/2$. ■

B.2 Proof of Theorem 2

The overall design of this proof is similar to the one of Theorem 1 and makes heavy use of results obtained in Blanchard and Krämer (2010b).

B.2.1 Preparation for the Proof

The stopping index (7) can be reformulated with $\mu = r - 1/2$ as

$$a^* = \min\{1 \leq a \leq n : \|S_n f_a^{[1]} - T_n^* y\|_{\mathcal{H}} \leq C\zeta_n\}, \tag{18}$$

with $\zeta_n = \max\{\sqrt{\lambda_n d_\lambda}\gamma_n, \lambda_n^{\mu+1}\}$.

We will derive the result in a similar way to Theorem 1. First it holds due to (10)

$$\begin{aligned}\|f_{a^*} - f^*\|_2 &= \|S^{1/2}(f_{a^*} - f)\|_{\mathcal{H}} \leq \|S^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} + \|S^{1/2}(f_{a^*}^{[1]} - f)\|_{\mathcal{H}} \\ &\leq C_\psi\lambda^{1/2}\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} + C_\psi\|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} + \|S^{1/2}(f_{a^*}^{[1]} - f)\|_{\mathcal{H}}.\end{aligned} \tag{19}$$

Now we prove the analogue versions of Lemma 11 — 13. The comments regarding those lemmas also hold here.

Lemma 14 *Let $x = C_x\lambda_n$, $C_x > 0$ such that $0 < x < x_{1,a^*-1}^{[2]}$. Choose $C > \tilde{c}_2$, with $\tilde{c}_1 = R\max\{1, C_\psi^2, \mu\kappa^{\mu-1}C_\delta\}$ and $\tilde{c}_2 = 2\max\{C_\psi C_\epsilon\sqrt{C_x+1}, \tilde{c}_1 C_x(C_x^\mu + 1)\}$. Then it holds*

$$\begin{aligned}\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} &\leq \frac{C^3}{C_x(C-\tilde{c}_2)^2}\lambda_n^{-1}\zeta_n, \\ \|S_n^{1/2}(f_{a^*} - f_{a^*}^{[1]})\|_{\mathcal{H}} &\leq \frac{C^2}{C_x^{1/2}(C-\tilde{c}_2)}\lambda_n^{-1/2}\zeta_n.\end{aligned}$$

Proof: According to the proof of Lemma 14 we can focus on the case $0 < a^* < n$. Furthermore we have due to (12)

$$\|f_{a^*} - f_{a^*}^{[1]}\|_{\mathcal{H}} \leq \frac{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0}{\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1}\|p_{a^*}^{[1]}(S_n)T_n^* y\|_{\mathcal{H}}. \tag{20}$$

Using Lemma A.3 in Blanchard and Krämer (2010b) (and the first line of its proof) we have for $0 < x < x_{1,a^*-1}^{[2]}$ with $\tilde{c}_1 = R\max\{1, C_\psi^2, \mu\kappa^{\mu-1}C_\delta\}$

$$\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_0^{1/2} \leq C_\psi C_\epsilon\sqrt{x+\lambda_n}\sqrt{d_{\lambda_n}}\gamma_n + \tilde{c}_1 x\{x^\mu + Z_\mu(\lambda_n)\} + x^{-1/2}\left[p_{a^*-1}^{[2]}, p_{a^*-1}^{[2]}\right]_1^{1/2}. \tag{21}$$

Here we define $Z_\mu(\lambda) = \lambda^\mu\mathbb{I}(\mu \leq 1) + \gamma_n\mathbb{I}(\mu > 1)$. Note that under the assumptions of the theorem it holds $Z_\mu(\lambda_n) \leq \lambda_n^\mu$.

Choosing $x = C_x\lambda_n$ yields in (21)

$$\begin{aligned}
&\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} \\
&\leq C_\psi C_\epsilon\sqrt{C_x+1}\sqrt{\lambda_n d_{\lambda_n}}\gamma_n + \tilde{c}_1 C_x(C_x^\mu+1)\lambda_n^{\mu+1} + C_x^{-1/2}\lambda_n^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2} \\
&\leq \tilde{c}_2\max\{\sqrt{\lambda_n d_{\lambda_n}}\gamma_n, \lambda_n^{\mu+1}\} + C_x^{-1/2}\lambda_n^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2} \\
&= \tilde{c}_2\zeta_n + C_x^{-1/2}\lambda_n^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2},
\end{aligned}$$

with $\tilde{c}_2 = 2\max\{C_\psi C_\epsilon\sqrt{C_x+1}, \tilde{c}_1 C_x(C_x^\mu+1)\}$. Due to the stopping condition (18) we know that

$$\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} \geq \left[p^{[1]}_{a^*-1}, p^{[1]}_{a^*-1}\right]_0^{1/2} = \|S_n f_a^{[1]} - T_n^* y\|_{\mathcal{H}} \geq C\zeta_n.$$

This gives

$$\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2} \leq \frac{C}{\sqrt{C_x}(C-\tilde{c}_2)}\lambda_n^{-1/2}\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}. \tag{22}$$

Plugging this into (20) yields together with the definition of the stopping index a^*

$$\|f_{a^*} - f^{[1]}_{a^*}\|_{\mathcal{H}} \leq \frac{C^3}{C_x(C-\tilde{c}_2)^2}\lambda_n^{-1}\zeta_n.$$

In a similar way we derive for the second case

$$\|S_n^{1/2}(f_{a^*} - f^{[1]}_{a^*})\|_{\mathcal{H}} = \frac{\left[p^{[1]}_{a^*}, p^{[1]}_{a^*}\right]_0}{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}} \leq \frac{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0^{1/2}}{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1^{1/2}}\left[p^{[1]}_{a^*}, p^{[1]}_{a^*}\right]_0.$$

An application of (22) yields

$$\|S_n^{1/2}(f_{a^*} - f^{[1]}_{a^*})\|_{\mathcal{H}} \leq \frac{C^2}{\sqrt{C_x}(C-\tilde{c}_2)}\lambda_n^{-1/2}\zeta_n.$$

■

Lemma 15 *Denote $\tilde{c}_1 = R\max\{1, C_\psi^2, \mu\kappa^{\mu-1}C_\delta\}$. For any $i = 1, \ldots, n$ and $0 < x < x^{[1]}_{1,i}$ we have under the conditions of the theorem*

$$\begin{aligned}
\|S^{1/2}(f_i^{[1]} - f)\|_{\mathcal{H}} \leq C_\psi &\left[C_\delta + \sqrt{2}C_\epsilon + \lambda_n\left\{C_\delta\left|\left(p_i^{[1]}\right)'(0)\right| + \sqrt{2}C_\epsilon x^{-1}\right\}\right]\sqrt{d_{\lambda_n}}\gamma_n \\
&+ \tilde{c}_1(\sqrt{x}+\sqrt{\lambda_n})(x^\mu + \lambda_n^\mu) + (1+\sqrt{x^{-1}\lambda_n})x^{-1/2}\|S_n f_i^{[1]} - T_n^* y\|_{\mathcal{H}}.
\end{aligned}$$

Proof: Follow the proof of Lemma A.2 in Blanchard and Krämer (2010b). Note that $Z_\mu(\lambda_n) \leq \lambda_n^\mu$. ■

Lemma 16 *Let $C > \max\{C_\psi C_\epsilon, \tilde{c}_2\}$, where $\tilde{c}_2$ is given in Lemma 14. Choose $x = C_x\lambda_n$ such that $0 < x \leq x^{[1]}_{1,a^*-1}$. Then there exists a constant $c^* > 0$ such that*

$$\left|\left(p^{[1]}_{a^*}\right)'(0)\right| \leq c^*\lambda_n^{-1}. \tag{23}$$

Proof: In analogue to Lemma 13 we will first derive an upper bound on $\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|$. Lemma A.1 in Blanchard and Krämer (2010b) yields

$$\begin{aligned}
\|S_n f^{[1]}_{a^*-1} - T_n^* y\|_{\mathcal{H}} \leq\ & R(2\mu+2)^{\mu+1}\max\{1, C_\psi^{2\mu}\}\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-\mu-1} \\
&+ 2R\mu\kappa^{\mu-1}\max\{1, C_\delta, C_\psi^{2\mu}, C_\psi^{2\mu}C_\delta\}\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1} Z_\mu(\lambda_n) \\
&+ C_\epsilon C_\psi\left\{\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1/2} + \sqrt{\lambda_n}\right\}\sqrt{d_{\lambda_n}}\gamma_n.
\end{aligned}$$

Denote $\tilde{c}_3 = R(2\mu+2)^{\mu+1}\max\{1, C_\psi^{2\mu}\}$ and $\tilde{c}_4 = 2R\mu\kappa^{\mu-1}\max\{1, C_\delta, C_\psi^{2\mu}, C_\psi^{2\mu}C_\delta\}$.

The definition of a^* gives $C\zeta_n \leq \|S_n f^{[1]}_{a^*-1} - T_n^* y\|_{\mathcal{H}}$. Combining both inequalities, setting $x = C_x\lambda_n$ and keeping $\sqrt{\lambda_n d_{\lambda_n}}\gamma_n \leq \zeta_n$ in mind gives

$$\begin{aligned}
(C - C_\psi C_\epsilon C_\lambda)\zeta_n &\leq \tilde{c}_3\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-\mu-1} + \tilde{c}_4\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1}\lambda_n^\mu \\
&\quad + C_\epsilon C_\psi\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n \\
&\leq 3\max\left\{\tilde{c}_3\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-\mu-1}, \tilde{c}_4\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1}\lambda_n^\mu,\right. \\
&\quad \left. C_\epsilon C_\psi\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right|^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n\right\}.
\end{aligned}$$

Now we assume that the maximum on the right hand side is attained in each of the three possible cases

$$\begin{aligned}
\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right| &\leq \{3(C - C_\epsilon C_\psi)^{-1}\tilde{c}_3\}^{1/(\mu+1)}\zeta_n^{-1/(\mu+1)}, \\
\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right| &\leq 3(C - C_\epsilon C_\psi)^{-1}\tilde{c}_4\zeta_n^{-1}\lambda_n^\mu, \\
\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right| &\leq 9(C - C_\epsilon C_\psi)^{-2}C_\epsilon^2 C_\psi^2\zeta_n^{-2}d_{\lambda_n}\gamma_n^2.
\end{aligned}$$

Take $\tilde{c}_5 = \max[\{3(C - C_\epsilon C_\psi)^{-1}\tilde{c}_3\}^{1/(\mu+1)}, 3(C - C_\epsilon C_\psi)^{-1}\tilde{c}_4, 9(C - C_\epsilon C_\psi)^{-2}C_\epsilon^2 C_\psi^2]$.

It is easy to see that $\zeta_n^{-1/(\mu+1)}, \zeta_n^{-1}\lambda_n^{\mu}$ and $\zeta_n^{-2} d_{\lambda_n}\gamma_n^2$ are all bound from above by λ_n^{-1}. Hence we get

$$\left|\left(p^{[1]}_{a^*-1}\right)'(0)\right| \leq \tilde{c}_5 \lambda_n^{-1}. \tag{24}$$

For the final step in the proof we have due to (17)

$$\left|\left(p^{[1]}_{a^*-1}\right)'(0) - \left(p^{[1]}_{a^*}\right)'(0)\right| \leq \frac{\left[p^{[1]}_{a^*-1}, p^{[1]}_{a^*-1}\right]_0}{\left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_1}.$$

It holds $\left[p^{[1]}_{a^*-1}, p^{[1]}_{a^*-1}\right]_0 \leq \left[p^{[2]}_{a^*-1}, p^{[2]}_{a^*-1}\right]_0$ and hence (22) yields

$$\left|\left(p^{[1]}_{a^*-1}\right)'(0) - \left(p^{[1]}_{a^*}\right)'(0)\right| \leq \frac{C^2}{C_x(C-\tilde{c}_2)^2}\lambda_n^{-1}. \tag{25}$$

The proof is complete by combining (24) and (25). ■

B.2.2 Proof of Theorem 2

We first restrict ourselves to the set where all concentration inequalities stated in the theorem hold simultaneously with probability at least $1-\nu$, $\nu \in (0,1]$. We only proof the convergence rates in the $\mathcal{L}^2$-norm, the corresponding rates in the $\mathcal{H}$-norm are done in the same way.

The theorem is proven by an application of Lemmas 14—16. To that end we need to check the conditions of those. Equation (24) and the proof of Theorem 1 show that we can take $C_x = \min\{1/2, \tilde{c}_5\}$ to fulfill $0 < x \leq x^{[1]}_{1,a^*-1}$. Furthermore we can take $C = 4R\max\{1, C_\psi^2(\nu), (r-1/2)\kappa^{r-3/2}C_\delta(\nu), 2^{-1/2}R^{-1}C_\psi(\nu)C_\epsilon(\nu)\}$ and the conditions of Lemma 14 and 16 hold. Note that $x^{[1]}_{1,a^*-1} \leq x^{[2]}_{1,a^*-1}$ due to the interlacing property of the roots, see Lemma 9 (i).

For Lemma 15 we need to find a $0 < z < x^{[1]}_{1,a^*}$. By Lemma 16 there exists a constant $c^* > 0$ such that

$$(c_*)^{-1}\lambda_n \leq \left|\left(p^{[1]}_{a^*}\right)'(0)\right|^{-1} \leq x^{[1]}_{1,a^*},$$

hence we choose $C_z = \min\{1/2, 1/c^*\}$. Now, applying Lemmas 14—16 to (19) gives the result (we again denote any constant that does not depend on n with C_i, $i \in \mathbb{N}$)

$$\begin{aligned}
&\|f_{a^*} - f^*\|_2 \leq C_\psi \lambda_n^{1/2}\|f_{a^*} - f^{[1]}_{a^*}\|_{\mathcal{H}} + C_\psi \|S_n^{1/2}(f_{a^*} - f^{[1]}_{a^*})\|_{\mathcal{H}} + \|S^{1/2}(f^{[1]}_{a^*} - f)\|_{\mathcal{H}} \\
\leq& C_1\lambda_n^{-1/2}\zeta_n + C_2\lambda_n\left|\left(p^{[1]}_i\right)'(0)\right|\sqrt{d_{\lambda_n}}\gamma_n + C_3\lambda_n^{\mu+1/2} + C_4\lambda_n^{-1/2}\|S_n f^{[1]}_{a^*} - T_n^* y\|_{\mathcal{H}}. \\
\leq& C_5\lambda_n^{-1/2}\zeta_n + C_6\sqrt{d_{\lambda_n}}\gamma_n + C_4\lambda_n^{\mu+1/2} \leq \max\{C_4, C_5, C_6\}\lambda_n^{-1/2}\zeta_n.
\end{aligned}$$

The error bound in the $\mathcal{H}$-norm is proven in an analogue fashion. ■

B.3 Proof of Corollary 3

Take $\lambda_n = \gamma_n^{2/(2r+s)}$. It is immediate that $\lambda_n^{r-1/2} = \gamma_n^{(2r-1)/(2r+s)} \geq \gamma_n$ for n sufficiently large, hence the inequality (6) holds as soon as $\gamma_n \leq 1$. Then we have by Theorem 2 that

$$\|f_{\widehat{\alpha}_{a^*}} - f^*\|_2 = O\left\{\lambda_n^{-1/2}\zeta_n(\lambda_n)\right\} = O\left\{\gamma_n^{2r/(2r+s)}\right\}.$$

■

B.4 Proof of Corollary 4

Set $\lambda_n = \gamma_n^{1/r}\log\{1/(2r)\gamma_n^{-2}\}$. It is immediate that $\lambda_n \to 0$ as γ_n converges to zero. For $r = 1/2$ condition (6) holds trivially. Let $r > 1/2$, then we have

$$\lambda_n^{r-1/2} = \gamma_n^{(r-1)/r}\log\{(r-1/2)/(2r)\gamma_n^{-2}\} \geq \gamma_n,$$

This is equivalent to $2r - 1 \geq 2\exp(\gamma_n)\gamma_n^2$, which holds for n sufficiently large and $r > 1/2$.

For the convergence rate we first show that $d_{\lambda_n}\gamma_n^2 \leq \lambda_n^{2r}$. We have

$$d_{\lambda_n}\gamma_n^2 = \log\left\{1 + \frac{a}{\gamma_n^{1/r}\log^{1/r}(1/2\gamma_n^{-1})}\right\}\gamma_n^2 \leq \log\left(\gamma_n^{-2}\right)\gamma_n^2.$$

Equivalently we need $a^r \leq \gamma_n(\gamma_n^{-2}-1)^r\log(1/2\gamma_n^{-2})$. As γ_n converges to zero $\gamma_n(\gamma_n^{-2}-1)^r$ goes to infinity for any $r > 1/2$. Hence for suitably large n it holds $\lambda_n^r \geq \sqrt{d_{\lambda_n}}\gamma_n$. Then the convergence rate is $\lambda_n^{-1/2}\zeta_n(\lambda_n) = \lambda_n^r = \gamma_n\log(1/2\gamma^{-2})$.

Because the convergence rate does not depend on $r \geq 1/2$ we can set $r = 1/2$. ■

B.5 Proof of Theorem 5

B.5.1 Preparation for the Proof

We denote with $\mathrm{tr}(A)$ the trace of a trace class operator $A : \mathcal{H} \to \mathcal{H}$ and the tensor product $(f_1 \otimes f_2)h = \langle f_1, h\rangle_{\mathcal{H}} f_2$ for functions $f_1, f_2, h \in \mathcal{H}$. We use the notation $k_t = k(\cdot, X_t)$. Note that it holds $\|A\|^2_{\mathrm{HS}} = \mathrm{tr}(A^*A)$ for a Hilbert-Schmidt operator A.

The general structure for the proof is as follows: To derive the concentration inequalities we need $\mathrm{E}\{\|S_n - S\|^2_{\mathcal{L}}\}$ as well as $\mathrm{E}\{\|T_n^* y - Sf\|^2_{\mathcal{H}}\}$ for Markov's inequality. With the help of Lemma 17 we derive representations of these expectations as sums by using the stationarity of X_t. Under normality assumptions Lemma 18 gives upper bounds for the summands in terms of the autocorrelation function of X_t using (D1). Assuming the special structure implied by (D2) Corollary 19 shows how these upper bound depend on the long range dependence coefficient $q > 0$. To get explicit convergence rates Lemma 20 gives a simple result stating how sums of these autocorrelation functions depend on q. An analogue result is given in Lemma 21 for the expectation of a warped norm.

The next technical lemma derives some simple identities for the operator S under the Hilbert-Schmidt norm, its trace and the kernel k. These will be used to find alternate representations of $\mathrm{E}\{\|S_n - S\|^2_{\mathcal{L}}\}$ and $\mathrm{E}\{\|T_n^* y - Sf\|^2_{\mathcal{H}}\}$ under stationarity.

Lemma 17 *Under the assumptions (K1) and (K2) the following hold*

(i) $\mathrm{tr}\{(k_t \otimes k_t)(k_s \otimes k_s)\} = k^2(X_t, X_s)$,

(ii) $\|S\|^2_{\mathrm{HS}} = \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} k^2(x,y)\mathrm{dP}^{X_0}(x)\mathrm{dP}^{X_0}(y)$,

(iii) $\mathrm{E}[\mathrm{tr}\{(k_0 \otimes k_0)S\}] = \|S\|^2_{\mathrm{HS}}$.

(iv) Let X' and X'' be independent and identically distributed and denote $k' = k(\cdot, X')$, $k'' = k(\cdot, X'')$. It holds for $\nu = 1, 2$ and $\lambda > 0$

$$\mathrm{E}\left[\mathrm{tr}^\nu\left\{(S+\lambda)^{-1}k' \otimes k'k'' \otimes k''\right\}\right] = \mathrm{tr}^\nu\{(S+\lambda)^{-1}S^2\}.$$

Proof: (i) Let $\{v_i\}_{i\in\mathbb{N}}$ denote an orthonormal base of $\mathcal{H}$. Then it holds due to the reproducing property (2)

$$\mathrm{tr}\left\{(k_t \otimes k_t)(k_s \otimes k_s)\right\} = \sum_{i=1}^\infty \langle v_i, k_t\rangle_{\mathcal{H}}\langle v_i, k_s\rangle_{\mathcal{H}} k(X_t, X_s) = \left\langle \sum_{i=1}^\infty \langle v_i, k_s\rangle_{\mathcal{H}} v_i, k_t \right\rangle_{\mathcal{H}} k(X_t, X_s).$$

(ii)

$$\begin{aligned}\|S\|^2_{\mathrm{HS}} &= \sum_{i=1}^\infty \langle Sv_i, Sv_i\rangle_{\mathcal{H}} = \sum_{i=1}^\infty \int_{\mathbb{R}^d} \langle Sv_i, k(\cdot,x)\rangle_{\mathcal{H}}\langle v_i, k(\cdot,x)\rangle_{\mathcal{H}}\mathrm{dP}^X(x) \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \left\langle \sum_{i=1}^\infty \langle v_i, k(\cdot,x)\rangle_{\mathcal{H}} v_i, k(\cdot,y)\right\rangle_{\mathcal{H}} k(x,y)\mathrm{dP}^X(x)\mathrm{dP}^X(y).\end{aligned}$$

The assertion follows because $\mathrm{P}^X = \mathrm{P}^{X_0}$.

(iii)

$$\begin{aligned}\mathrm{E}[\mathrm{tr}\{(k_0 \otimes k_0)S\}] &= \mathrm{E}(\langle Sk_0, k_0\rangle_{\mathcal{H}}) = \mathrm{E}\left(\int_{\mathbb{R}^d} \langle k_0, k(\cdot,x)\rangle^2_{\mathcal{H}}\mathrm{dP}^X(x)\right) \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} k^2(x,y)\mathrm{dP}^X(x)\mathrm{dP}^{X_0}(y) = \|S\|^2_{\mathrm{HS}}.\end{aligned}$$

(iv) Because S is a compact operator the spectral decomposition $S = \sum_{i=1}^\infty \mu_i \psi_i \otimes \psi_i$ holds (recall that $\{\mu_i, \psi_i\}_{i=1}^\infty$ is the eigensystem of S). Let $k(\cdot, x) = \sum_{i=1}^\infty \alpha_i(x)\psi_i$, $x \in \mathbb{R}^d$. For $\nu = 1$ we have

$$\begin{aligned}\mathrm{E}\left[\mathrm{tr}\{(S+\lambda)^{-1}k' \otimes k'k'' \otimes k''\}\right] &= \mathrm{E}\left\{k(X', X'')\sum_{i=1}^\infty \langle \psi_i, k''\rangle_{\mathcal{H}}\langle (S+\lambda)^{-1}k', \psi_i\rangle_{\mathcal{H}}\right\} \\ &= \sum_{i=1}^\infty \frac{1}{\mu_i + \lambda}\mathrm{E}\left\{k(X', X'')\langle \psi_i, k''\rangle_{\mathcal{H}}\langle \psi_i, k'\rangle_{\mathcal{H}}\right\} \\ &= \sum_{i=1}^\infty \frac{1}{\mu_i + \lambda}\sum_{j=1}^\infty \mathrm{E}\left\{\alpha_j(X')\alpha_i(X')\alpha_j(X'')\alpha_i(X'')\right\}\end{aligned}$$

On the other hand

$$\begin{aligned}\mathrm{tr}\left\{(S+\lambda)^{-1}S^2\right\} &= \mathrm{tr}\left\{(S+\lambda)^{-1}\mathrm{E}(k' \otimes k'k'' \otimes k'')\right\} \\ &= \sum_{i=1}^\infty \langle (S+\lambda)^{-1}\mathrm{E}\{k(X', X'')\langle \psi_i, k''\rangle_{\mathcal{H}}k'\}, \psi_i\rangle_{\mathcal{H}} \\ &= \sum_{i=1}^\infty \frac{1}{\mu_i + \lambda}\langle \mathrm{E}\{k(X', X'')\langle \psi_i, k''\rangle_{\mathcal{H}}k'\}, \psi_i\rangle_{\mathcal{H}} \\ &= \sum_{i=1}^\infty \frac{1}{\mu_i + \lambda}\sum_{j=1}^\infty \mathrm{E}\{\alpha_j(X')\alpha_i(X')\alpha_j(X'')\alpha_i(X'')\}\end{aligned}$$

and we are done. The proof for $\nu = 2$ is along the same lines. ■

Denote with g_h the common density of $(X_h, X_0)^{\mathrm{T}}$ and g_0 the density of X_0. The next lemma and the subsequent corollary will be used to show that the summands appearing in Theorem 5 (i) can be linked to the autocorrelation function ρ under the assumptions of normality (D1):

Lemma 18 *Under the assumptions (K1), (K2) and (D1) it holds for $h > 0$ with $\rho_h = \tau_0^{-1}\tau_h$*

$$\begin{aligned}\int_{\mathbb{R}^{2d}} k^2(x,y)\{g_h(x,y) - g_0(x)g_0(y)\}\mathrm{d}(x,y) &\le \frac{\kappa^2}{\{(4\pi\tau_0)^d \det(\Sigma)\}^{1/2}}\theta^{1/2}(\rho_h), \\ \int_{\mathbb{R}^{2d}} k(x,y)f(x)f(y)\{g_h(x,y) - g_0(x)g_0(y)\}\mathrm{d}(x,y) &\le \frac{\kappa M}{\{(4\pi\tau_0)^d \det(\Sigma)\}^{1/2}}\theta^{1/2}(\rho_h),\end{aligned}$$

with $\theta(\rho) = 1 + (1-\rho^2)^{-d/2} - 2^{d+1}(4-\rho^2)^{-d/2}$, $\rho \in [0,1)$.

Proof: We will only proof the first inequality, the second one follows in the same way.

By Jensen's inequality and (K2) we know

$$\begin{aligned}&\int_{\mathbb{R}^{2d}} k^2(x,y)\{g_h(x,y) - g_0(x)g_0(y)\}\mathrm{d}(x,y) \\ &\le \kappa^2\left[\int_{\mathbb{R}^{2d}} \left\{g_h^2(x,y) - 2g_h(x,y)g_0(x)g_0(y) + g_0^2(x)g_0^2(y)\right\}\mathrm{d}(x,y)\right]^{1/2}.\end{aligned}$$

The first and third integral term can readily be calculated as

$$\begin{aligned}\int_{\mathbb{R}^{2d}} g_h^2(x,y)\mathrm{d}(x,y) &= [(4\pi)^d(\tau_0^2 - \tau_h^2)^{d/2}\det(\Sigma)]^{-1} \\ \left\{\int_{\mathbb{R}^d} g_0^2(x)\mathrm{d}x\right\}^2 &= \{(4\pi)^d\tau_0^d\det(\Sigma)\}^{-1}.\end{aligned}$$

For the first equality we use $\det(A \otimes \Sigma) = \det(A)^d \det(\Sigma)^2$ for $A \in \mathbb{R}^{2\times 2}$ and thus

$$\int_{\mathbb{R}^{2d}} g_h(x,y) g_0(x) g_0(y) \mathrm{d}(x,y) = \frac{\int_{\mathbb{R}^{2d}} \exp\left(-1/2 z^{\mathrm{T}} G^{-1} z\right) \mathrm{d}z}{(2\pi)^{2d} \det(\Sigma)^2 \tau_0^d (\tau_0^2 - \tau_h^2)^{d/2}}, \tag{26}$$

with

$$G^{-1} = \left\{ \begin{pmatrix} \tau_0 & \tau_h \\ \tau_h & \tau_0 \end{pmatrix}^{-1} + \begin{pmatrix} \tau_0^{-1} & 0 \\ 0 & \tau_0^{-1} \end{pmatrix} \right\} \otimes \Sigma^{-1}.$$

It holds $\det(G) = (4\tau_0^2 - \tau_h^2)^{-d} (\tau_0^4 - \tau_0^2 \tau_h^2)^d \det(\Sigma)^2$. Thus we get with (26)

$$\begin{aligned} \int_{\mathbb{R}^{2d}} g_h(x,y) g_0(x) g_0(y) \mathrm{d}(x,y) &= \frac{(2\pi)^d \tau_0^d (\tau_0^2 - \tau_h^2)^{d/2} \det(\Sigma)}{(2\pi)^{2d} \det(\Sigma)^2 (4\tau_0^2 - \tau_h^2)^{d/2} \tau_0^d (\tau_0^2 - \tau_h^2)^{d/2}} \\ &= \left\{ (2\pi)^d (4\tau_0^2 - \tau_h^2)^{d/2} \det(\Sigma) \right\}^{-1}, \end{aligned}$$

completing the proof by multiplying all terms with $\tau_0^{-d} \tau_0^d$. ■

Using the special structure imposed by (D2) we can link the bounds derived in Lemma 18 to the long range coefficient $q > 0$:

Corollary 19 *Under the assumptions (K1), (K2), (D1) and (D2) it holds for all $h > 0$ and $q > 0$*

$$\int_{\mathbb{R}^{2d}} k^2(x,y) \{g_h(x,y) - g_0(x) g_0(y)\} \mathrm{d}(x,y) \leq \frac{\kappa^2 d^{1/2}}{\sqrt{(2\pi)^d \det(\Sigma)}} (1 - 4^{-q})^{-1/4(d-2)} |\rho_h|$$

$$\int_{\mathbb{R}^{2d}} k(x,y) f(x) f(y) \{g_h(x,y) - g_0(x) g_0(y)\} \mathrm{d}(x,y) \leq \frac{\kappa M d^{1/2}}{\sqrt{(2\pi)^d \det(\Sigma)}} (1 - 4^{-q})^{-1/4(d-2)} |\rho_h|.$$

Proof: Recall that $\theta(\rho) = 1 + \{1-\rho^2\}^{-d/2} - 2^{d+1}\{4-\rho^2\}^{-d/2}$ for $\rho \in [0,1)$. We seek to find bounds on θ and the corollary can be proven by an application of Lemma 18.

By assumption (D2) we know there is a ρ_* such that $\rho_h^2 \leq \rho_*^2 < 1$ for all $h > 0$. Thus consider $\rho \in [0, \rho_*]$. We start by finding a constant $C > 0$ with

$$\theta'(\rho) = \rho \left\{ (1-\rho^2)^{-d/2-1} - 2^{d+1}(4-\rho^2)^{-d/2-1} \right\} d \leq C\rho^2.$$

Thus C can be taken as $C = d\left\{(1-\rho_*^2)^{-d/2-1} - 2^{d+1}(4-\rho_*^2)^{-d/2-1}\right\}$.

Thus we know that the slope of θ is always less than that of $C\rho^2$. Finally it holds that $\theta(0) = 0$ and thus $0 \leq \theta(\rho) \leq C\rho^2$, $\rho \in [0, \rho_*]$.

Under condition (D2) it holds $\{1-\rho_*^2\}^{-d/2} \leq \{1 - 2^{-2q}\}^{-d/2}$, completing the proof by using Lemma 18. ■

Having derived bounds for the summands in Theorem 5 (i) in terms of ρ the overall behavior of the sums is still open. The next simple lemma gives insight into this and shows how the convergence rate of the sums crucially depends on $q > 0$:

Lemma 20 *Assume that condition (D2) holds. Then we have*

$$n^{-2} \sum_{h=1}^{n-1} (n-h) |\rho_h| \leq C(q) \begin{cases} n^{-1} & , \quad q > 1 \\ n^{-1} \log(n) & , \quad q = 1 \\ n^{-q} & , \quad q \in (0,1). \end{cases} \tag{27}$$

with $C(q) = \zeta(q)\mathbb{I}(q>1) + \{5 - \log(4)\}\mathbb{I}(q=1) + \{2(1-q)^{-1} - (2-q)^{-1} + (2-q)^{-1}2^{2-q}\}\mathbb{I}\{q \in (0,1)\}$. Here ζ denotes the Riemann zeta function.

Proof: Recall that by condition (D2) we have $|\rho_h| \leq (h+1)^{-q}$, $h = 0, \ldots, n-1$ for some $q > 0$.

First assume $q \in (0,1]$. The integral test for series convergence gives lower and upper bounds for the hyperharmonic series as

$$(1-q)^{-1}\{(n+1)^{1-q} - 2^{1-q}\} \leq \sum_{h=2}^{n} h^{-q} \leq 2^{-q} + (1-q)^{-1}\{n^{1-q} - 2^{1-q}\}.$$

This yields

$$\begin{aligned} n^{-2} \sum_{h=1}^{n-1} (n-h)(h+1)^{-q} &= n^{-2} \sum_{h=2}^{n} (n+1-h) h^{-q} = n^{-2} \left\{ (n+1) \sum_{h=2}^{n} h^{-q} - \sum_{h=2}^{n} h^{-(q-1)} \right\} \\ &\leq n^{-2} \left[(n+1) \left\{ 2^{-q} + (1-q)^{-1}(n^{1-q} - 2^{1-q}) \right\} - (2-q)^{-1} \left\{ (n+1)^{2-q} - 2^{2-q} \right\} \right]. \end{aligned} \tag{28}$$

Now let $q \in (0,1)$, then it holds from (28) and the fact that $n^{-2} \leq n^{-1} \leq n^{-q}$

$$\begin{aligned} & n^{-2} \sum_{h=1}^{n-1} (n-h)(h+1)^{-q} \\ \leq & \frac{n+1}{n^2} \left\{ \frac{2^{-q}(1-q) - 2^{1-q}}{1-q} \right\} + \frac{n+1}{n^{1+q}} (1-q)^{-1} - \frac{(n+1)^{2-q}}{n^2} (2-q)^{-1} + \frac{1}{n^2} \frac{2^{2-q}}{2-q} \\ \leq & n^{-q} [\{2(1-q)^{-1} - (2-q)^{-1}\} + (2-q)^{-1} 2^{2-q}], \end{aligned}$$

due to $2^{-q}(1-q) - 2^{1-q} < 0$.

For $q = 1$ we evaluate the limit

$$\begin{aligned} & \lim_{q \to 1\pm} n^{-2} \left[(n+1) \left\{ 2^{-q} + (1-q)^{-1}(n^{1-q} - 2^{1-q}) \right\} - (2-q)^{-1} \left\{ (n+1)^{2-q} - 2^{2-q} \right\} \right] \\ &= (2n^2)^{-1} [3 - \log(4) - n\{1 + \log(4)\}] + n^{-2}(n+1)\log(n) \\ &\leq \frac{\log(n)}{n} \left[5 - \log(4) \right]. \end{aligned}$$

The case $q > 1$ is clear because the zeta-function $\zeta(q)$ is defined as the hyperharmonic series with coefficient q. ■

The final preparatory result is used to derive the probablistic bound in Theorem 5 (iv) and is similar to Corollary 19:

Lemma 21 *Under the assumptions (K1), (K2), (D1) and (D2) it holds for $\lambda > 0$*

$$\int_{\mathbb{R}^{2d}} k(x,y)\langle (S+\lambda)^{-1}k(\cdot,x), k(\cdot,y)\rangle_{\mathcal{H}} \left\{f_h(x,y) - f_0(x)f_0(y)\right\} \mathrm{d}(x,y) \leq \tilde{c}|\rho_h|d_\lambda,$$

with $\tilde{c} = \sqrt{d\{1-4^{-q}\}^{-d-1}}\kappa$.

Proof: Denote $\beta(x,y) = \langle (S+\lambda)^{-1}k(\cdot,x), k(\cdot,y)\rangle_{\mathcal{H}}$. By the Cauchy-Schwarz inequality

$$\begin{aligned}\phi_h &= \int_{\mathbb{R}^{2d}} k(x,y)\beta(x,y)\left\{f_h(x,y) - f_0(x)f_0(y)\right\}\mathrm{d}(x,y) \\ &\leq \left[\int k^2(x,y)\beta^2(x,y)f_0(x)f_0(y)\mathrm{d}(x,y)\int\left\{\frac{f_h(x,y)}{\sqrt{f_0(x)f_0(y)}} - \sqrt{f_0(x)f_0(y)}\right\}^2 \mathrm{d}(x,y)\right]^{1/2}. \end{aligned} \tag{29}$$

Denote by X' and X'' two independent copies of X_0 and $k' = k(\cdot, X')$, $k'' = k(\cdot, X'')$. We start by bounding the first integral term in the product:

$$\begin{aligned}\int_{\mathbb{R}^{2d}} k^2(x,y)\beta^2(x,y)f_0(x)f_0(y)\mathrm{d}(x,y) &= \mathrm{E}\left\{k^2(X',X'')\langle (S+\lambda)^{-1}k', k''\rangle_{\mathcal{H}}^2\right\} \\ &= \mathrm{E}\left[\mathrm{tr}^2\left\{(S+\lambda)^{-1}k'\otimes k'k''\otimes k''\right\}\right] \\ &\leq \kappa^2\mathrm{tr}^2\{(S+\lambda)^{-1}S\} = \kappa^2 d_\lambda^2.\end{aligned}$$

In the second to last inequality we used Lemma 17 (iv) and the definition of d_λ.

The second integral in the product in (29) is

$$\int_{\mathbb{R}^{2d}}\left\{\frac{f_h(x,y)}{\sqrt{f_0(x)f_0(y)}} - \sqrt{f_0(x)f_0(y)}\right\}^2\mathrm{d}(x,y) = \int_{\mathbb{R}^{2d}}\frac{f_h(x,y)}{\sqrt{f_0(x)f_0(y)}}\mathrm{d}(x,y) - 1.$$

We proceed in the same way as in the proof of Lemma 18 by using properties of the Gaussian distributions at hand.

First we have

$$F_h(x,y) = \frac{f_h^2(x,y)}{f_0(x)f_0(y)} = \frac{(2\pi)^d\tau_0^d\det(\Sigma)}{(2\pi)^{2d}\det(\Sigma_{\mathrm{h}})}\exp\left[-\frac{1}{2}(x^{\mathrm{T}},y^{\mathrm{T}})\left\{2\Sigma_h^{-1} - \frac{1}{\tau_0}\begin{pmatrix}\Sigma & 0\\ 0 & \Sigma\end{pmatrix}\right\}^{-1}\begin{pmatrix}x\\ y\end{pmatrix}\right].$$

Denote $G^{-1} = 2\Sigma_h^{-1} - \tau_0^{-1}\begin{pmatrix}\Sigma & 0\\ 0 & \Sigma\end{pmatrix}$. It follows in a similar way as in the proof of Lemma 18 that $\det(G) = \tau_0^{2d}\det^2(\Sigma)$ and $\det(\Sigma_h) = (\tau_0^2-\tau_h^2)^d\det^2(\Sigma)$. Hence we have

$$\begin{aligned}\int_{\mathbb{R}^{2d}} F_h(x,y)\mathrm{d}(x,y) &= \frac{(2\pi)^d\tau_0^d\det(\Sigma)}{(2\pi)^{2d}(\tau_0^2-\tau_h^2)^d\det^2(\Sigma)}(2\pi)^d\tau_0^d\det(\Sigma) \\ &= \frac{\tau_0^{2d}}{(\tau_0^2-\tau_h^2)^d} = \frac{1}{(1-\rho_h^2)^d}.\end{aligned}$$

Under (D2) we have $\rho_h < 1$ for all $h > 0$ and there is a $\tilde{\rho} = \max_h|\rho_h| \leq 2^{-q} < 1$ and hence it holds $(1-\rho_h^2)^{-d} \leq d(1-4^{-q})^{-d-1}\rho_h^2$ and we are done. ■

B.5.2 Proof of the Theorem

First note that the the operator norm is dominated by the Hilbert-Schmidt norm. By Markov's inequality we have for $\nu \in (0,1]$

$$\begin{aligned}\mathrm{P}\left(\|S_n - S\|_{\mathrm{HS}}^2 \leq \nu^{-1}\mathrm{E}\|S_n - S\|_{\mathrm{HS}}^2\right) &\geq 1-\nu, \\ \mathrm{P}\left(\|T_n^*y - Sf\|_{\mathcal{H}}^2 \leq \nu^{-1}\mathrm{E}\|T_n^*y - Sf\|_{\mathcal{H}}^2\right) &\geq 1-\nu.\end{aligned}$$

(i) It holds due to $S_n = n^{-1}\sum_{t=1}^n k_t\otimes k_t$

$$\mathrm{E}\left(\|S_n - S\|_{\mathrm{HS}}^2\right) = \frac{1}{n^2}\sum_{t,s=1}^n\left(\mathrm{E}[\mathrm{tr}\{(k_t\otimes k_t)(k_s\otimes k_s)\}] - 2\mathrm{E}[\mathrm{tr}\{(k_0\otimes k_0)S\}] + \|S\|_{\mathrm{HS}}^2\right).$$

For the first summand we get $\mathrm{E}[\mathrm{tr}\{(k_t\otimes k_t)(k_s\otimes k_s)\}] = \mathrm{E}\{k^2(X_t,X_s)\}$, due to Lemma 17(i). Using the stationarity of $\{X_t\}_{t=1}^n$ and Lemma 17(iii) we get

$$\mathrm{E}\left(\|S_n - S\|_{\mathrm{HS}}^2\right) = \frac{1}{n}\left\{\mathrm{E}\{k^2(X_0,X_0)\} - \|S\|_{\mathrm{HS}}^2\right\} + 2\sum_{h=1}^{n-1}\frac{n-h}{n^2}\left[\mathrm{E}\{k^2(X_h,X_0)\} - \|S\|_{\mathrm{HS}}^2\right],$$

yielding the first result by an application of Lemma 17 (ii).
For the second equation we see due to the independence of $\{X_t\}_{t=1}^n$ and $\{\varepsilon_t\}_{t=1}^n$ that

$$\|T_n^*y - Sf\|_{\mathcal{H}}^2 = \sigma^2 n^{-1}\mathrm{E}\{k(X_0,X_0)\} + \mathrm{E}\left(\|S_nf - Sf\|_{\mathcal{H}}^2\right).$$

The rest follows along the same lines as the first part of the proof.

(ii) An application of part (i) of this theorem, Corollary 19 and Lemma 20 yields this result.

(iii) Because the $\{\varepsilon_t\}_{t\in\mathbb{Z}}$ are independent and identically distributed and $\{X_t\}_{t\in\mathbb{Z}}$ is stationary it holds

$$\begin{aligned}&\mathrm{E}\left\{\left\|(S+\lambda)^{-1/2}(S_nf - T_n^*y)\right\|_{\mathcal{H}}^2\right\} \\ &= \mathrm{E}\left\{\left\|(S+\lambda)^{-1/2}T_n^*\varepsilon\right\|_{\mathcal{H}}^2\right\} = n^{-2}\sum_{t,s=1}^n\mathrm{E}\left\{\left\langle\varepsilon_t(S+\lambda)^{-1}k_t, \varepsilon_sk_s\right\rangle_{\mathcal{H}}\right\} \\ &= n^{-1}\sigma^2\mathrm{E}\left\{\left\langle(S+\lambda)^{-1}k_0, k_0\right\rangle_{\mathcal{H}}\right\} = n^{-1}\sigma^2\mathrm{E}\left\{\left\|(S+\lambda)^{-1/2}k_0\right\|_{\mathcal{H}}^2\right\}.\end{aligned}$$

By the definition of d_λ we get

$$\mathrm{E}\{\|(S+\lambda)^{-1/2}k_0\|_{\mathcal{H}}^2\} = \mathrm{E}[\mathrm{tr}\{(S+\lambda)^{-1}k_0\otimes k_0\}] = \mathrm{tr}\{(S+\lambda)^{-1}S\} = d_\lambda.$$

Using $n^{-1/2} \leq \gamma_n(q)$ proves the result.

(iv) Consider first

$$\begin{aligned}\mathrm{E}\left\{\|(S+\lambda)^{-1/2}(S_n - S)\|_{\mathrm{HS}}^2\right\} &= n^{-2}\sum_{t,s=1}^n\mathrm{E}\left[\mathrm{tr}\{(S+\lambda)^{-1}(k_t\otimes k_t - S)(k_s\otimes k_s - S)\}\right] \\ &= n^{-1}\mathrm{E}\|(S+\lambda)^{-1/2}(k_0\otimes k_0 - S)\|_{\mathrm{HS}}^2 \\ &\quad + \sum_{h=1}^{n-1}\mathrm{E}\left[\mathrm{tr}\{(S+\lambda)^{-1}(k_0\otimes k_0 - S)(k_h\otimes k_h - S)\}\right].\end{aligned}$$

Continuing with the expression inside the sums we expand

$$\begin{aligned}\phi_h &= \mathrm{E}\left[\mathrm{tr}\{(S+\lambda)^{-1}(k_0\otimes k_0 - S)(k_h\otimes k_h - S)\}\right]\\ &= \mathrm{E}\left[\mathrm{tr}\{(S+\lambda)^{-1}k_0\otimes k_0 k_h\otimes k_h\}\right] - \mathrm{tr}\{(S+\lambda)^{-1}S^2\}\\ &= \mathrm{E}\left\{k(X_0,X_h)\langle(S+\lambda)^{-1}k_0,k_h\rangle_{\mathcal{H}}\right\} - \mathrm{tr}\{(S+\lambda)^{-1}S^2\}.\end{aligned}$$

Using Lemma 17 (iv) we see that

$$\mathrm{tr}\{(S+\lambda)^{-1}S^2\} = \int\limits_{\mathbb{R}^{2d}} k(x,y)\langle(S+\lambda)^{-1}k(\cdot,x),k(\cdot,y)\rangle_{\mathcal{H}}\mathrm{dP}^X(x)\mathrm{dP}^X(y).$$

Hence we have

$$\phi_h = \int\limits_{\mathbb{R}^{2d}} k(x,y)\langle(S+\lambda)^{-1}k(\cdot,x),k(\cdot,y)\rangle_{\mathcal{H}}\left\{\mathrm{dP}^{X_0,X_h}(x,y) - \mathrm{dP}^{X_0}(x)\mathrm{dP}^{X_0}(y)\right\}.$$

This can be bound by the results of Lemma 21 and together with Lemma 20 there exists a constant $C(q)>0$ such that with probability at least $1-\nu$

$$\|(S+\lambda)^{-1/2}(S_n - S)\|_{\mathcal{L}}^2 \leq \nu^{-1}C^2(q)\gamma_n^2(q)d_\lambda,$$

with $\gamma_n^2(q) = \begin{cases} n^{-1}, & q>1\\ n^{-1}\log(n), & q=1\\ n^{-q}, & q\in(0,1).\end{cases}$

This implies $\|(S+\lambda)^{-1/2}(S_n-S)(S+\lambda)^{-1/2}\|_{\mathcal{L}} \leq \nu^{-1/2}C(q)\lambda^{-1/2}\sqrt{d_\lambda}\gamma_n(q)$. Let $\lambda=\lambda_n$ be a sequence converging to zero such that $\lambda_n^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n(q)\to 0$. Let n be large enough such that $\nu^{-1/2}C(q)\lambda_n^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n(q) < 1$. Using Lemma A.5 in Blanchard and Krämer (2010b) we obtain

$$\|(S+\lambda)^{1/2}(S_n+\lambda)^{-1/2}\| \leq [1-\nu^{-1/2}C(q)\lambda_n^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n(q)]^{-1/2} \leq \sqrt{2}.$$

The latter inequality can be fulfilled for n large enough such that $\nu^{-1/2}C(q)\lambda_n^{-1/2}\sqrt{d_{\lambda_n}}\gamma_n(q) \leq 1/2$. ■

B.6 Proof of Proposition 7

Recall that $Su = \mathrm{E}\{u(X_0)k(\cdot,X_0)\}$ for $u\in\mathcal{H}$. Define the independent random variables $Y_1,\ldots,Y_\mu$ that are all distributed as X_0.

First consider the following observation for $\mu\in\mathbb{N}$:

$$\begin{aligned}S^\mu u = S(S^{\mu-1}u) &= \mathrm{E}_{Y_1}\{(S^{\mu-1}u)(Y_1)k(\cdot,Y_1)\} = \mathrm{E}_{Y_2}\mathrm{E}_{Y_1}\{(S^{\mu-2}u)(Y_2)k(Y_1,Y_2)k(\cdot,Y_1)\}\\ &= \mathrm{E}_{Y_\mu}\cdots\mathrm{E}_{Y_1}\left\{\prod_{\nu=1}^{\mu-1}k(Y_\nu,Y_{\nu+1})u(Y_\mu)k(\cdot,Y_1)\right\}. \qquad (30)\end{aligned}$$

We take $u=\sum_{i=1}^\infty c_i k(\cdot,z_i)$ for $\{z_i\}_{i\in\mathbb{N}},\{c_i\}_{i\in\mathbb{N}}\subset\mathbb{R}$ such that $\|u\|_{\mathcal{H}}^2 = \sum_{i,j=1}^\infty c_i c_j k(z_i,z_j) \leq R^2$. The fact that a function $u\in\mathcal{H}$ can be represented as a linear combination of kernel functions is due to the Moore-Aronszajn Theorem, see Berlinet and Thomas-Agnan (2004).

Define the matrix $\Gamma = [\Gamma_{i,j}]_{i,j=1}^{\mu+2}\in\mathbb{R}^{(\mu+2)\times(\mu+2)}$ via

$$\Gamma_{i,j} = \begin{cases}\sigma_x^{-2}+2l & , \quad i=j=2,\ldots,\mu+1\\ l & , \quad i=j=1,\mu+2\\ -l & , \quad |i-j|=1\\ 0 & , \quad else\end{cases}.$$

Then we have via the integration of Gaussian functions and (30)

$$\begin{aligned}f(x) &= \frac{1}{(2\pi\sigma_x^2)^{\mu/2}}\sum_{i=1}^\infty c_i\int\limits_{\mathbb{R}^\mu}\exp\left\{-1/2(x,x_1,\ldots,x_\mu,z_i)\Gamma(x,x_1,\ldots,x_\mu,z_i)^{\mathrm{T}}\right\}\mathrm{d}(x_1,\ldots,x_\mu)\\ &= \frac{1}{\sigma_x^\mu\det(\Gamma_{2:\mu+1})^{1/2}}\sum_{i=1}^\infty c_i\exp\left[-1/2\frac{\det(\Lambda_{1:\mu+1})(x^2+z_i^2)-2l^{\mu+1}xz_i}{\det(\Gamma_{2:\mu+1})}\right].\end{aligned}$$

Here we used the symmetry property $\det(\Gamma_{2:\mu+2}) = \det(\Gamma_{1:\mu+1})$ as the first and last rows and columns of Γ are identical. This concludes the proof. ■

B.7 Proof of Proposition 8

In Shi et al. (2008) it was shown that the eigenvalues of S have the form $\mu_i = ab^{i-1}$, $i=1,2,\ldots$ with

$$a = \sqrt{2}(1+\beta+\sqrt{1+\beta})^{-1/2},\quad b = (1+\beta+\sqrt{1+2\beta})^{-1}\beta.$$

and $\beta = 4l\sigma_x^2$. It is clear that $0<b<1$ and hence $0<\mu_i\leq a$. We have $d_\lambda = \sum_{i=0}^\infty\{1+a^{-1}b^{-i}\lambda\}^{-1}$. Denote $f(x) = \{1+a^{-1}b^{-x}\lambda\}^{-1}$. We want to apply the integral test to the sum. We have $\int_0^\infty f(x)\mathrm{d}x = \log^{-1}(b^{-1})\log(1+a\lambda^{-1})$. This yields the bounds

$$\frac{\log(1+a/\lambda)}{\log(b^{-1})} \leq d_\lambda \leq \frac{1}{1+\lambda/a} + \frac{\log(1+a/\lambda)}{\log(b^{-1})}.$$

On $\lambda\in(0,1]$ we get $d_\lambda \leq D\log(1+a/\lambda)$ for a constant $D>0$. This can be seen as follows: The function $g_1(\lambda) = (1+\lambda/a)^{-1}$ is bounded from above by $C_1=1$ and the function $g_2(\lambda) = (b^{-1})\log(1+a/\lambda)$ is lower bounded by $c_2 = \log(1+a)$ and has no upper bound.

Hence on the set $I = \{\lambda\in(0,1] : g_2(\lambda)\geq C_1\}$ we can choose $C=2$. On the set I^c we have on the other hand $Cg_2(x)\geq c_2C\geq g_1(x)+g_2(x)$, hence we need $C = 2c_2^{-1}C_1 = 2\log^{-1}(1+a)$. The choice $D = 2\log^{-1}(b^{-1})\max\{1,\log^{-1}(1+a)\}$ is sufficient and we have $d_\lambda \leq D\log(1+a/\lambda)$, $\lambda\in(0,1]$. ■

Abstract

We propose a novel approach to Bayesian analysis that is provably robust to outliers in the data and often has computational advantages over standard methods. Our technique is based on splitting the data into non-overlapping subgroups, evaluating the posterior distribution given each independent subgroup, and then combining the resulting measures. The main novelty of our approach is the proposed aggregation step, which is based on the evaluation of a median in the space of probability measures equipped with a suitable collection of distances that can be quickly and efficiently evaluated in practice. We present both theoretical and numerical evidence illustrating the improvements achieved by our method.

Keywords: Big data, geometric median, distributed computing, parallel MCMC, Wasserstein distance

1. Introduction

Contemporary data analysis problems pose several general challenges. One is resource limitations: massive data require computer clusters for storage and processing. Another problem occurs when data are severely contaminated by "outliers" that are not easily identified and removed. Following Box and Tiao (1968), an outlier can be defined as *"being an observation which is suspected to be partially or wholly irrelevant because it is not generated by the stochastic model assumed."* While the topic of robust estimation has occupied an important place in the statistical literature for several decades and significant progress has been made in the theory of point estimation, robust Bayesian methods are not sufficiently well-understood.

Our main goal is to take a step towards solving these problems, proposing a general Bayesian approach that is

(i) provably robust to the presence of outliers in the data without any specific assumptions on their distribution or reliance on preprocessing;

(ii) scalable to big data sets through allowing computational algorithms to be implemented in parallel for different data subsets prior to an efficient aggregation step.

The proposed approach consists in splitting the sample into disjoint parts, implementing Markov chain Monte Carlo (MCMC) or another posterior sampling method to obtain draws from each "subset posterior" in parallel, and then using these draws to obtain weighted samples from the *median posterior (or M-Posterior)*, a new probability measure which is a (properly defined) median of a collection of subset posterior distributions. We show that, despite the loss of "interactions" among the data in different groups, the final result still admits strong guarantees; moreover, splitting the data gives certain advantages in terms of robustness to outliers.

In particular, we demonstrate that the M-Posterior is a probability measure centered at the "robust" estimator of the unknown parameter, the associated credible sets are often of the same "width" as the credible sets obtained from the usual posterior distribution and admit strong "frequentist" coverage guarantees (see Section 3.2 for exact statements).

The paper is organized as follows: Section 1.1 contains an overview of the existing literature and explains the goals that we aim to achieve in this work. Section 2 introduces the mathematical background and key facts used throughout the paper. Section 3 describes the main theoretical results for the median posterior. Section 4 presents details of algorithms, implementation, and numerical performance of the median posterior for several models. The simulation study and analysis of data examples convincingly show the robustness properties of the median posterior. In particular, we have used M-Posterior for scalable nonparametric Bayesian modeling of joint dependence in the multivariate categorical responses collected by the General Social Survey (`gss.norc.org`). Proofs that are omitted in the main text are contained in the supplementary material.

1.1 Discussion of Related Work

A. Dasgupta remarks that (see the discussion following the work by Berger, 1994): "Exactly what constitutes a study of Bayesian robustness is of course impossible to define." The popular definition which also indicates the main directions of research in this area is due to Berger (1994): "Robust Bayesian analysis is the study of the sensitivity of Bayesian answers

to uncertain inputs. These uncertain inputs are typically the model, prior distribution, or utility function, or some combination thereof." Notable works on robustness of Bayesian procedures to model misspecification include Doksum and Lo (1990) and Hoff (2007) that investigate methods based on conditioning on partial information, as well as a more recent paper by Miller and Dunson (2015) who introduced the notion of the "coarsened" posterior; however, its behavior in the presence of outliers is not explicitly addressed. Outliers are typically accommodated by either employing heavy-tailed likelihoods (e.g., Svensen and Bishop, 2005) or by attempting to identify and remove them as a first step (as in Box and Tiao, 1968 or Bayarri and Berger, 1994). The common assumption in the Bayesian literature is that the distribution of the outliers can be modeled (e.g., using a t-distribution, contamination by a larger variance parametric distribution, etc). In this paper, we instead bypass the need to place a model on the outliers and do not require their removal prior to analysis; similar approach has previously been advocated by Hooker and Vidyashankar (2014). We base inference on the *median posterior*, whose robustness can be formally and precisely quantified in terms of concentration properties around the true delta measure under the potential influence of outliers and contaminations of arbitrary nature.

Also relevant is the recent progress in scalable Bayesian algorithms. Most methods designed for distributed computing share a common feature: they efficiently use the data subset available to a single machine and combine the "local" results for "global" learning, while minimizing communication among cluster machines (Smola and Narayanamurthy, 2010). A wide variety of optimization-based approaches are available for distributed learning (Boyd et al., 2011); however, the number of similar Bayesian methods is limited. One of the reasons for this limitation is that Bayesian approaches typically require an approximation to the full posterior distribution instead of just a point estimate of parameters.

Several major approaches exist for scalable Bayesian learning in a distributed setting. The first approach independently evaluates the likelihood for each data subset across multiple machines and returns the likelihoods to a "master" machine, where they are appropriately combined with the prior using conditional independence assumptions of the probabilistic model. These two steps are repeated at every MCMC iteration (see Smola and Narayanamurthy, 2010; Agarwal and Duchi, 2012). This approach is problem-specific and involves extensive communication among machines. The second approach uses a so-called stochastic approximation (SA) and successively learns "noisy" approximations to the full posterior distribution using data in small mini-batches. A group of methods based on this approach uses sampling-based techniques to explore the posterior distribution through modified Hamiltonian or Langevin dynamics (e.g., Welling and Teh, 2011; Ahn et al., 2012; Korattikara et al., 2013). Unfortunately, these methods fail to accommodate discrete-valued parameters and multimodality. Another subgroup of methods uses deterministic variational approximations and learns the variational parameters of the approximated posterior through an optimization-based approach (see Wang et al., 2011; Hoffman et al., 2013; Broderick et al., 2013). Although these techniques often have excellent predictive performance, it is well known (Bishop, 2006) that variational methods tend to substantially underestimate posterior uncertainty and provide a poor characterization of posterior dependence, while lacking theoretical guarantees.

Our approach instead falls in a class of methods which avoid extensive communication among machines by running independent MCMC chains for each data subset and obtaining draws from subset posteriors. These subset posteriors can be combined in a variety of ways. Some of these methods simply average draws from each subset (Scott et al., 2013). Other alternatives use an approximation to the full posterior distribution based on kernel density estimates (Neiswanger et al., 2013) or the so-called Weierstrass transform (Wang and Dunson, 2013). These methods have limitations related to the dimension of the parameter, moreover, their applicability and theoretical justification are restricted to parametric models. Unlike the method proposed below, none of the aforementioned algorithms are provably robust. Another closely related method is the so-called WASP (Srivastava et al., 2015b). It is scalable but still lacks robustness guarantees.

Our work was inspired by recent multivariate median-based techniques for robust estimation developed in Minsker (2015) (see also Hsu and Sabato, 2013; Alon et al., 1996; Lerasle and Oliveira, 2011; Nemirovskiĭ and David, 1983 where similar ideas were applied in different frameworks).

2. Preliminaries

We proceed by recalling key definitions and facts which will be used throughout the paper, followed by the definition of the M-Posterior distribution in Section 2.4.

2.1 Notation

In what follows, $\|\cdot\|_2$ denotes the standard Euclidean distance in $\mathbb{R}^p$ and $\langle\cdot,\cdot\rangle_{\mathbb{R}^p}$ the associated dot product.

Given a totally bounded metric space $(\mathbb{Y}, d)$, the packing number $M(\varepsilon, \mathbb{Y}, d)$ is the maximal number N such that there exist N *disjoint* d-balls $B_1, \dots, B_N$ of radius ε contained in $\mathbb{Y}$, i.e., $\bigcup_{j=1}^{N} B_j \subseteq \mathbb{Y}$.

Let $\{p_\theta,\ \theta \in \Theta\}$ be a family of probability density functions on $\mathbb{R}^p$. Let $l, u : \mathbb{R}^p \mapsto \mathbb{R}_+$ be two functions such that $l(x) \le u(x)$ for every $x \in \mathbb{R}^p$ and $d^2(l,u) := \int_{\mathbb{R}^p} (\sqrt{u} - \sqrt{l})^2(x)dx < \infty$. A bracket $[l, u]$ consists of all functions $g : \mathbb{R}^p \mapsto \mathbb{R}$ such that $l(x) \le g(x) \le u(x)$ for all $x \in \mathbb{R}^p$. For $A \subseteq \Theta$, the bracketing number $N_{[]}(\varepsilon, A, d)$ is defined as the smallest number N such that there exist N brackets $[l_i, u_i],\ i = 1, \dots, N$ satisfying $\{p_\theta,\ \theta \in A\} \subseteq \bigcup_{i=1}^{N} [l_i, u_i]$ and $d(l_i, u_i) \le \varepsilon$ for all $1 \le i \le N$.

For $y \in \mathbb{Y}$, δ_y denotes the Dirac measure concentrated at y. In other words, for any Borel-measurable B, $\delta_y(B) = I\{y \in B\}$, where $I\{\cdot\}$ is the indicator function.

We will say that $k : \mathbb{Y} \times \mathbb{Y} \mapsto \mathbb{R}$ is a *kernel* if it is a symmetric, positive definite function. Assume that $(\mathbb{H}, \langle\cdot,\cdot\rangle_{\mathbb{H}})$ is a reproducing kernel Hilbert space (RKHS) of functions $f : \mathbb{Y} \mapsto$

$\mathbb{R}$. Then k is a *reproducing kernel* for $\mathbb{H}$ if for any $f \in \mathbb{H}$ and $y \in \mathbb{Y}$, $\langle f, k(\cdot, y)\rangle_{\mathbb{H}} = f(y)$ (see Aronszajn, 1950 for details).

For a square-integrable function $f \in L_2(\mathbb{R}^p)$, $\hat{f}$ stands for its Fourier transform. For $x \in \mathbb{R}$, $\lfloor x \rfloor$ denotes the largest integer not greater than x.

Finally, given two nonnegative sequences $\{a_n\}$ and $\{b_n\}$, we write $a_n \lesssim b_n$ if $a_n \leq Cb_n$ for some $C > 0$ and all n. Other objects and definitions are introduced in the course of exposition when necessity arises.

2.2 Generalizations of the Univariate Median

Let $\mathbb{Y}$ be a normed space with norm $\|\cdot\|$, and let μ be a probability measure on $(\mathbb{Y}, \|\cdot\|)$ equipped with Borel σ-algebra. Define the *geometric median* of μ by

$$x_* = \operatorname*{argmin}_{y \in \mathbb{Y}} \int_{\mathbb{Y}} (\|y - x\| - \|x\|)\, \mu(dx).$$

In this paper, we focus on the special case when μ is a uniform distribution on a finite collection of atoms $x_1, \ldots, x_m \in \mathbb{Y}$, so that

$$x_* = \operatorname{med}_g(x_1, \ldots, x_m) := \operatorname*{argmin}_{y \in \mathbb{Y}} \sum_{j=1}^{m} \|y - x_j\|. \tag{1}$$

The geometric median exists under rather general assumptions; for example, if $\mathbb{Y}$ is a Hilbert space (this case will be our main focus; more general conditions were obtained by Kemperman, 1987). Moreover, it is well-known that in this situation $x_* \in \operatorname{co}(x_1, \ldots, x_m)$—the convex hull of $x_1, \ldots, x_m$ (meaning that there exist nonnegative α_j, $j = 1 \ldots m$, $\sum_{j=1}^{m} \alpha_j = 1$ such that $x_* = \sum_{j=1}^{m} \alpha_j x_j$).

Another useful generalization of the univariate median is defined as follows. Let $(\mathbb{Y}, d)$ be a metric space with metric d, and $x_1, \ldots, x_k \in \mathbb{Y}$. Define B_* to be the d-ball of minimal radius such that it is centered at one of $\{x_1, \ldots, x_m\}$ and contains at least half of these points. Then the median $\operatorname{med}_0(x_1, \ldots, x_m)$ of $x_1, \ldots, x_m$ is the center of B_*. In other words, let

$$\varepsilon_* := \inf\Big\{\varepsilon > 0 :\ \exists j = j(\varepsilon) \in \{1, \ldots, m\} \text{ and } I(j) \subset \{1, \ldots, m\} \text{ such that } |I(j)| > \frac{m}{2} \text{ and } \forall i \in I(j),\ d(x_i, x_j) \leq 2\varepsilon\Big\}, \tag{2}$$

$j_* := j(\varepsilon_*)$, where ties are broken arbitrarily, and set

$$x_* = \operatorname{med}_0(x_1, \ldots, x_m) := x_{j_*}. \tag{3}$$

We will say that x_* is the *metric median* of $x_1, \ldots, x_m$. Note that x_* always belongs to $\{x_1, \ldots, x_m\}$ by definition. Advantages of this definition are its generality (only metric space structure is assumed) and simplicity of numerical evaluation since only the pairwise

distances $d(x_i, x_j)$, $i, j = 1, \ldots, m$ are required to compute the median. This construction was previously employed by Nemirovskiĭ and David (1983) in the context of stochastic optimization and is further studied by Hsu and Sabato (2013). A closely related notion of the median was used by Lopuhaa and Rousseeuw (1991) under the name of the "minimal volume ellipsoid" estimator.

Finally, we recall an important property of the median (shared both by med_g and med_0) which states that it transforms a collection of independent, "weakly concentrated" estimators into a single estimator with significantly stronger concentration properties. Given q, α such that $0 < q < \alpha < 1/2$, define a nonnegative function $\psi(\alpha, q)$ via

$$\psi(\alpha, q) := (1 - \alpha) \log \frac{1 - \alpha}{1 - q} + \alpha \log \frac{\alpha}{q}. \tag{4}$$

The following result is an adaptation of Theorem 3.1 in (Minsker, 2015):

Theorem 1

a *Assume that $(\mathbb{H}, \|\cdot\|)$ is a Hilbert space and $\theta_0 \in \mathbb{H}$. Let $\hat{\theta}_1, \ldots, \hat{\theta}_m \in \mathbb{H}$ be a collection of independent random variables. Let κ be a constant satisfying $0 \leq \kappa < \frac{1}{3}$. Suppose $\varepsilon > 0$ is such that for all j, $1 \leq j \leq \lfloor (1 - \kappa)m \rfloor + 1$,*

$$\Pr\Big(\|\hat{\theta}_j - \theta_0\| > \varepsilon\Big) \leq \frac{1}{7}. \tag{5}$$

Let $\hat{\theta}_* = \operatorname{med}_g(\hat{\theta}_1, \ldots, \hat{\theta}_m)$ be the geometric median of $\{\hat{\theta}_1, \ldots, \hat{\theta}_m\}$. Then

$$\Pr\Big(\|\hat{\theta}_* - \theta_0\| > 1.52\varepsilon\Big) \leq \left[e^{(1-\kappa)\psi\left(\frac{3/7 - \kappa}{1 - \kappa}, 1/7\right)}\right]^{-m}.$$

b *Assume that $(\mathbb{Y}, d)$ is a metric space and $\theta_0 \in \mathbb{Y}$. Let $\hat{\theta}_1, \ldots, \hat{\theta}_m \in \mathbb{Y}$ be a collection of independent random variables. Let κ be a constant satisfying $0 \leq \kappa < \frac{1}{3}$. Suppose $\varepsilon > 0$ is such that for all j, $1 \leq j \leq \lfloor (1 - \kappa)m \rfloor + 1$,*

$$\Pr\Big(d(\hat{\theta}_j, \theta_0) > \varepsilon\Big) \leq \frac{1}{4}. \tag{6}$$

Let $\hat{\theta}_* = \operatorname{med}_0(\hat{\theta}_1, \ldots, \hat{\theta}_m)$. Then

$$\Pr\Big(d(\hat{\theta}_*, \theta_0) > 3\varepsilon\Big) \leq \left[e^{(1-\kappa)\psi\left(\frac{1/2 - \kappa}{1 - \kappa}, 1/4\right)}\right]^{-m}.$$

Proof See Section A.1 in the appendix. ■

Remark 2 *While we require $\kappa < 1/3$ above for clarity and to keep the constants small, we prove a slightly more general result that holds for any $\kappa < 1/2$.*

Theorem 1 implies that the concentration of the geometric median of independent estimators around the "true" parameter value improves geometrically fast with respect to the number of such estimators, while the estimation rate is preserved, up to a constant. In our case, the role of $\hat{\theta}_j$'s will be played by posterior distributions based on disjoint subsets of observations, viewed as elements of the space of signed measures equipped with a suitable distance.

Parameter κ allows taking corrupted observations into account: if the initial sample contains not more than $\lfloor \kappa m \rfloor$ outliers (of arbitrary nature), then at most $\lfloor \kappa m \rfloor$ estimators amongst $\{\theta_1, \dots, \theta_m\}$ can be affected but their median remains stable, still being close to the unknown θ_0 with high probability. To clarify the notion of "robustness" that such a statement provides, assume that $\hat{\theta}_1, \dots, \hat{\theta}_m$ are consistent estimators of θ_0 based on disjoint samples of size n/m each. If $\frac{n}{m} \to \infty$, then $\frac{\kappa m}{n} \to 0$, hence the breakdown point of the estimator $\hat{\theta}_*$ is 0 is general. However, it is able to handle a number of outliers that grows like $o(n)$ while preserving consistency, which is the best one can hope for without imposing any additional assumptions on the underlying distribution, parameter of interest or nature of the outliers.

Let us also mention that the the geometric median of a collection of points in a Hilbert space belongs to the convex hull of these points. Thus, one can think about "downweighing" some observations (potential outliers) and increasing the weight of others, and geometric median gives a way to formalize this approach. The median med_0 defined in (3) corresponds to the extreme case when all but one weight are equal to 0. Its potential advantage lies in the fact that its evaluation requires only the knowledge of pairwise distances $d(\hat{\theta}_i, \hat{\theta}_j),\ i, j = 1, \dots, m$, see (2).

2.3 Distances Between Probability Measures

Next, we discuss the special family of distances between probability measures that will be used throughout the paper. These distances provide the necessary structure to define and evaluate medians in the space of measures, as discussed above. Since one of our goals was to develop computationally efficient techniques, we focus on distances that admit accurate numerical approximation.

Assume that $(\mathbb{X}, \rho)$ is a separable metric space, and let $\mathcal{F} = \{f : \mathbb{X} \mapsto \mathbb{R}\}$ be a collection of real-valued functions. Given two Borel probability measures P, Q on $\mathbb{X}$, define

$$\|P - Q\|_{\mathcal{F}} := \sup_{f \in \mathcal{F}} \left| \int_{\mathbb{X}} f(x) d(P - Q)(x) \right|. \tag{7}$$

Important special cases include the situation when

$$\mathcal{F} = \mathcal{F}_L := \{f : \Theta \mapsto \mathbb{R} \text{ s.t. } \|f\|_L \le 1\}, \tag{8}$$

where $\|f\|_L := \sup_{x_1 \neq x_2} \frac{|f(x_1) - f(x_2)|}{\rho(x_1, x_2)}$ is the Lipschitz constant of f.

It is well-known (Dudley, 2002, Theorem 11.8.2) that in this case $\|P - Q\|_{\mathcal{F}_L}$ is equal to the Wasserstein distance (also known as the Kantorovich-Rubinstein distance)

$$d_{W_{1,\rho}}(P, Q) = \inf \Big\{ \mathbb{E}\rho(\boldsymbol{X}, \boldsymbol{Y}) : \mathcal{L}(\boldsymbol{X}) = P,\ \mathcal{L}(\boldsymbol{Y}) = Q \Big\}, \tag{9}$$

where $\mathcal{L}(\boldsymbol{Z})$ denotes the law of a random variable $\boldsymbol{Z}$ and the infimum on the right is taken over the set of all joint distributions of $(\boldsymbol{X}, \boldsymbol{Y})$ with marginals P and Q.

Another fruitful structure emerges when $\mathcal{F}$ is a unit ball in a Reproducing Kernel Hilbert Space $(\mathbb{H}, \langle \cdot, \cdot \rangle_{\mathbb{H}})$ with a reproducing kernel $k : \mathbb{X} \times \mathbb{X} \mapsto \mathbb{R}$. That is,

$$\mathcal{F} = \mathcal{F}_k := \{f : \mathbb{X} \mapsto \mathbb{R},\ \|f\|_{\mathbb{H}} := \sqrt{\langle f, f \rangle_{\mathbb{H}}} \le 1\}. \tag{10}$$

Let $\mathcal{P}_k := \{P \text{ is a probability measure, } \int_{\mathbb{X}} \sqrt{k(x,x)} dP(x) < \infty\}$, and assume that $P, Q \in \mathcal{P}_k$. Theorem 1 proven by Sriperumbudur et al. (2010) implies that the corresponding distance between measures P and Q takes the form

$$\|P - Q\|_{\mathcal{F}_k} = \left\| \int_{\mathbb{X}} k(x, \cdot) d(P - Q)(x) \right\|_{\mathbb{H}}. \tag{11}$$

It follows that $P \mapsto \int_{\mathbb{X}} k(x, \cdot) dP(x)$ is an embedding of $\mathcal{P}_k$ into the Hilbert space $\mathbb{H}$ which can be seen as an application of the "kernel trick" in our setting. The Hilbert space structure allows one to use fast numerical methods to approximate the geometric median, see Section 4 below.

Remark 3 *Note that when P and Q are discrete measures (e.g., $P = \sum_{j=1}^{N_1} \beta_j \delta_{z_j}$ and $Q = \sum_{j=1}^{N_2} \gamma_j \delta_{y_j}$), then*

$$\|P - Q\|^2_{\mathcal{F}_k} = \sum_{i,j=1}^{N_1} \beta_i \beta_j k(z_i, z_j) + \sum_{i,j=1}^{N_2} \gamma_i \gamma_j k(y_i, y_j) - 2 \sum_{i=1}^{N_1} \sum_{j=1}^{N_2} \beta_i \gamma_j k(z_i, y_j). \tag{12}$$

In this paper, we will only consider *characteristic* kernels, which means that $\|P - Q\|_{\mathcal{F}_k} = 0$ if and only if $P = Q$. It follows from Theorem 7 in Sriperumbudur et al. (2010) that a sufficient condition for k to be characteristic is its *strict positive definiteness*: we say that k is *strictly positive definite* if it is bounded, measurable, and such that for all non-zero signed Borel measures ν

$$\iint_{\mathbb{X} \times \mathbb{X}} k(x, y) d\nu(x) d\nu(y) > 0.$$

When $\mathbb{X} = \mathbb{R}^p$, a simple sufficient criterion for the kernel k to be characteristic follows from Theorem 9 in Sriperumbudur et al. (2010):

Proposition 4 *Let $\mathbb{X} = \mathbb{R}^p,\ p \ge 1$. Assume that $k(x, y) = \phi(x - y)$ for some bounded, continuous, integrable, positive-definite function $\phi : \mathbb{R}^p \mapsto \mathbb{R}$.*

1. *Let $\widehat{\phi}$ be the Fourier transform of ϕ. If $|\widehat{\phi}(x)| > 0$ for all $x \in \mathbb{R}^p$, then k is characteristic;*

2. If ϕ is compactly supported, then k is characteristic.

Remark 5 *It is important to mention that in practical applications, we often deal with empirical measures based on a collection of MCMC samples from the posterior distribution. A natural question is the following: if P and Q are probability measures on $\mathbb{R}^D$ and P_m, Q_n are their empirical versions, what is the size of the error*

$$e_{m,n} := \left| \|P - Q\|_{\mathcal{F}_k} - \|P_m - Q_n\|_{\mathcal{F}_k} \right| ?$$

For i.i.d samples, a useful and favorable fact is that $e_{m,n}$ often does not depend on D: under weak assumptions on kernel k, $e_{m,n}$ has an upper bound of order $m^{-1/2} + n^{-1/2}$ (that is, $\lim_{m,n\to\infty} \Pr\left(e_{m,n} \geq C(m^{-1/2} + n^{-1/2})\right)$ can be made arbitrarily small by choosing C big enough, see Corollary 12 in Sriperumbudur et al., 2009). On the other hand, the bound for the (stronger) Wasserstein distance is not dimension-free and is of order $m^{-1/(D+1)} + n^{-1/(D+1)}$. Similar error rates hold for empirical measures based on samples from Markov chains used to approximate invariant distributions, including MCMC samples (see Boissard and Le Gouic, 2014 and Fournier and Guillin, 2015).

If $\mathbb{X}$ is a separable Hilbert space with dot product $\langle \cdot, \cdot \rangle_{\mathbb{X}}$ and P_1, P_2 are probability measures with

$$\int_{\mathbb{X}} \|x\|_{\mathbb{X}} dP_i(x) < \infty, \ i = 1, 2,$$

it will be useful to assume that the class $\mathcal{F}$ is chosen such that the distance between the measures is lower bounded by the distance between their means, namely

$$\left\| \int_{\mathbb{X}} x dP_1(x) - \int_{\mathbb{X}} x dP_2(x) \right\|_{\mathbb{X}} \leq C \|P_1 - P_2\|_{\mathcal{F}} \tag{13}$$

for some absolute constant $C > 0$. Clearly, this holds if $\mathcal{F}$ contains the set of continuous linear functionals $\mathbb{L} = \{x \mapsto \langle u, x \rangle_{\mathbb{X}}, \ u \in \mathbb{X}, \ \|u\|_{\mathbb{X}} \leq 1/C\}$, since

$$\left\| \int_{\mathbb{X}} x dP_i(x) \right\|_{\mathbb{X}} = \sup_{\|u\|_{\mathbb{X}} \leq 1} \int_{\mathbb{X}} \langle x, u \rangle_{\mathbb{X}} \, dP_i(x), \ i = 1, 2.$$

In particular, this is true for the Wasserstein distance $d_{W_{1,\rho}}(\cdot, \cdot)$ defined with respect to the metric ρ such that $\rho(x, y) \geq c_1 \|x - y\|_{\mathbb{X}}$. Next, we will state a simple sufficient condition on the kernel $k(\cdot, \cdot)$ for (13) to hold for the unit ball $\mathcal{F}_k$.

Proposition 6 *Let $\mathbb{X}$ be a separable Hilbert space, $k_0 : \mathbb{X} \times \mathbb{X} \mapsto \mathbb{R}$ - a characteristic kernel, and define*

$$k(x, y) := k_0(x, y) + \langle x, y \rangle_{\mathbb{X}} .$$

Then k is characteristic and satisfies (13) with $C = 1$.

Proof Let $\mathbb{H}_1$ and $\mathbb{H}_2$ be two reproducing kernel Hilbert spaces with kernels k_1 and k_2 respectively. It is well-known (e.g., Aronszajn, 1950) that the space corresponding to kernel $k = k_1 + k_2$ is

$$\mathbb{H} = \{f = f_1 + f_2, \ f_1 \in \mathbb{H}_1, \ f_2 \in \mathbb{H}_2\}$$

with the norm $\|f\|^2_{\mathbb{H}} = \inf\{\|f_1\|^2_{\mathbb{H}} + \|f_2\|^2_{\mathbb{H}}, \ f_1 + f_2 = f\}$. Hence, the unit ball of $\mathbb{H}$ contains the unit balls of $\mathbb{H}_1$ and $\mathbb{H}_2$, so that for any probability measures P, Q

$$\|P - Q\|_{\mathcal{F}_k} \geq \max\left(\|P - Q\|_{\mathcal{F}_{k_1}}, \|P - Q\|_{\mathcal{F}_{k_2}} \right),$$

which easily implies the result. ■

The kernels of the form $k(x, y) = k_0(x, y) + \langle x, y \rangle_{\mathbb{X}}$ will prove especially useful in the situation when the parameter of interest is finite-dimensional (see Section 3.2 for details).

Finally, we recall the definition of the well-known Hellinger and total variation distances. Assume that P and Q are probability measures on $\mathbb{R}^D$ which are absolutely continuous with respect to Lebesgue measure with densities p and q respectively. Then the Hellinger distance between P and Q is given by

$$h(P, Q) := \sqrt{\frac{1}{2} \int_{\mathbb{R}^D} \left(\sqrt{p(x)} - \sqrt{q(x)} \right)^2 dx}.$$

The total variation distance between two probability measures defined on a σ-algebra $\mathfrak{B}$ is

$$\|P - Q\|_{\mathrm{TV}} = \sup_{B \in \mathfrak{B}} |P(B) - Q(B)|.$$

We are ready to introduce the *median posterior* (or M-Posterior) distribution.

2.4 Construction of the M-Posterior Distribution

Let $\{P_\theta, \ \theta \in \Theta\}$ be a family of probability distributions over $\mathbb{R}^D$ indexed by Θ. Suppose that for all $\theta \in \Theta$, P_θ is absolutely continuous with respect to Lebesgue measure dx on $\mathbb{R}^D$ with $dP_\theta(\cdot) = p_\theta(\cdot) dx$. In what follows, we equip Θ with a metric (that we will refer to as the "Hellinger metric")

$$\rho(\theta_1, \theta_2) := h(P_{\theta_1}, P_{\theta_2}), \tag{14}$$

and assume that the metric space (Θ, ρ) is separable.

Let k be a characteristic kernel defined on $\Theta \times \Theta$. Kernel k defines a metric on Θ via

$$\rho_k(\theta_1, \theta_2) := \|k(\cdot, \theta_1) - k(\cdot, \theta_2)\|_{\mathbb{H}} = \Big(k(\theta_1, \theta_1) + k(\theta_2, \theta_2) - 2k(\theta_1, \theta_2) \Big)^{1/2}, \tag{15}$$

where $\mathbb{H}$ is the RKHS associated to k. We will assume that (Θ, ρ_k) is separable. Note that the Hellinger metric $\rho(\theta_1, \theta_2)$ is a particular case corresponding to the kernel

$$k_H(\theta_1, \theta_2) := \left\langle \sqrt{p_{\theta_1}}, \sqrt{p_{\theta_2}} \right\rangle_{L_2(dx)} .$$

All subsequent results apply to this special case. While this is a natural metric for the problem, the disadvantage of $k_H(\cdot, \cdot)$ is that it is often difficult to evaluate numerically. Instead, we will consider metrics ρ_k that are dominated by ρ (this is formalized in assumption 1).

Let $X_1, \dots, X_n$ be i.i.d. $\mathbb{R}^D$-valued random vectors defined on a probability space $(\Omega, \mathcal{B}, P)$ with unknown distribution $P_0 := P_{\theta_0}$ for some $\theta_0 \in \Theta$. Bayesian inference of P_0 requires specifying a prior distribution Π over Θ (equipped with the Borel σ-algebra induced by ρ). The posterior distribution given the observations $\mathcal{X}_n := \{X_1, \dots, X_n\}$ is a random probability measure on Θ defined by

$$\Pi_n(B|\mathcal{X}_n) := \frac{\int\limits_B \prod_{i=1}^n p_\theta(X_i) d\Pi(\theta)}{\int\limits_\Theta \prod_{i=1}^n p_\theta(X_i) d\Pi(\theta)}$$

for all Borel measurable sets $B \subseteq \Theta$. It is known (see Ghosal et al., 2000) that under rather general assumptions the posterior distribution Π_n *contracts* towards θ_0, meaning that

$$\Pi_n(\theta \in \Theta : \rho(\theta, \theta_0) \geq \varepsilon_n | \mathcal{X}_n) \to 0$$

almost surely or in probability as $n \to \infty$ for a suitable sequence $\varepsilon_n \to 0$.

One of the questions that we address can be formulated as follows: what happens if *some* observations in $\mathcal{X}_n$ are corrupted, e.g., if $\mathcal{X}_n$ contains outliers of arbitrary nature and magnitude? Even if there is only one outlier, the usual posterior distribution might concentrate most of its mass far from the true value θ_0.

We proceed with a general description of our proposed algorithm for constructing a robust version of the posterior distribution. Let $1 \leq m \leq n/2$ be an integer. Divide the sample $\mathcal{X}_n$ into m disjoint groups $G_1, \dots, G_m$ of size $|G_j| \geq \lfloor n/m \rfloor$ each:

$$\{X_1, \dots, X_n\} = \bigcup_{j=1}^m G_j, \ G_i \cap G_l = \emptyset \text{ for } i \neq j, \ |G_j| \geq \lfloor n/m \rfloor, \ j = 1 \dots m.$$

A good choice of m efficiently exploits the available computational resource while ensuring that the groups G_js are sufficiently large.

Let Π be a prior distribution over Θ, and let

$$\left\{ \Pi^{(j)}(\cdot) := \Pi_{|G_j|}(\cdot|G_j), \ j = 1, \dots, m \right\}$$

be the family of subset posterior distributions depending on disjoint subgroups G_j, $j = 1, \dots, m$:

$$\Pi_{|G_j|}(B|G_j) := \frac{\int\limits_B \prod_{i \in G_j} p_\theta(X_i) d\Pi(\theta)}{\int\limits_\Theta \prod_{i \in G_j} p_\theta(X_i) d\Pi(\theta)}.$$

Define the M-Posterior as

$$\hat{\Pi}_{n,g} := \text{med}_g(\Pi^{(1)}, \dots, \Pi^{(m)}), \tag{16}$$

or

$$\hat{\Pi}_{n,0} := \text{med}_0(\Pi^{(1)}, \dots, \Pi^{(m)}), \tag{17}$$

where the medians $\text{med}_g(\cdot)$ and $\text{med}_0(\cdot)$ are evaluated with respect to $\|\cdot\|_{\mathcal{F}_L}$ or $\|\cdot\|_{\mathcal{F}_k}$ introduced in Section 2.2 above. Note that $\hat{\Pi}_{n,g}$ and $\hat{\Pi}_{n,0}$ are always probability measures: indeed, due to the aforementioned properties of a geometric median, there exists $\alpha_1 \geq 0, \dots, \alpha_m \geq 0, \ \sum\limits_{j=1}^m \alpha_j = 1$ such that $\hat{\Pi}_{n,g} = \sum\limits_{j=1}^m \alpha_j \Pi^{(j)}$, and $\hat{\Pi}_{n,0} \in \{\Pi^{(1)}(\cdot), \dots, \Pi^{(m)}(\cdot)\}$ by definition.

While $\hat{\Pi}_{n,g}$ and $\hat{\Pi}_{n,0}$ possess several nice properties (such as robustness to outliers), in practice they often overestimate the uncertainty about θ_0, especially when the number of groups m is large: indeed, if for example $\theta \in \mathbb{R}$ and Bernstein-von Mises theorem holds, then each $\Pi_{|G_j|}(\cdot|G_j)$ is "approximately normal" with covariance $\frac{m}{n} I^{-1}(\theta_0)$ (here, $I(\theta_0)$ is the Fisher information). However, the asymptotic covariance of the posterior distribution based on the whole sample is $\frac{1}{n} I^{-1}(\theta_0)$.

To overcome this difficulty, we propose a modification of our approach where the random measures $\Pi_n^{(j)}$ are replaced by the *stochastic approximations* $\Pi_{|G_j|,m}(\cdot|G_j), \ j = 1, \dots, m$ of the full posterior distribution. To this end, define the "stochastic approximation" based on the subsample G_j as

$$\Pi_{|G_j|,m}(B|G_j) := \frac{\int\limits_B \left(\prod_{i \in G_j} p_\theta(X_i) \right)^m d\Pi(\theta)}{\int\limits_\Theta \left(\prod_{i \in G_j} p_\theta(X_i) \right)^m d\Pi(\theta)}, \tag{18}$$

where we assume that $p_\theta^m(\cdot)$ is an integrable function for all θ. In other words, $\Pi_{|G_j|,m}(\cdot|G_j)$ is obtained as a posterior distribution given that each data point from G_j is observed m times. While each of $\Pi_{|G_j|,k}(\cdot|G_j)$ might underestimate uncertainly, the median $\hat{\Pi}_{n,g}^{\text{st}}$ (or $\hat{\Pi}_{n,0}^{\text{st}}$) of these random measures yields credible sets with much better coverage. This approach shows good performance in numerical experiments. One of our main results (see Section 3.2) provides a justification for this observation, albeit, under rather strong assumptions and for the parametric case.

3. Theoretical Analysis

We proceed with a discussion of the theoretical guarantees for the M-Posterior, starting with the contraction rates and robustness properties.

3.1 Convergence of Posterior Distribution and Robust Bayesian Inference

Our first result establishes the "weak concentration" property of the posterior distribution around the true parameter. Let $\delta_0 := \delta_{\theta_0}$ be the Dirac measure supported on $\theta_0 \in \Theta$. Recall the following version of Theorem 2.1 in Ghosal et al. (2000) (we state the result for the Wasserstein distance $d_{W_{1,\rho}}(\Pi_n(\cdot|\mathcal{X}_l), \delta_0)$ rather than the closely related contraction rate of the posterior distribution). Here, the Wasserstein distance is evaluated with respect to the "Hellinger metric" $\rho(\cdot, \cdot)$ defined in (14).

Theorem 7 *Let $\mathcal{X}_l = \{X_1, \dots, X_l\}$ be an i.i.d. sample from P_0. Assume that $\varepsilon_l > 0$ and $\Theta_l \subset \Theta$ are such that for some constant $C > 0$*

(1) *the packing number satisfies* $\log M(\varepsilon_l, \Theta_l, \rho) \le l\varepsilon_l^2$,

(2) $\Pi(\Theta \setminus \Theta_l) \le \exp(-l\varepsilon_l^2(C+4))$,

(3) $\Pi\left(\theta : \ -P_0\left(\log \frac{p_\theta}{p_0}\right) \le \varepsilon_l^2, \ P_0\left(\log \frac{p_\theta}{p_0}\right)^2 \le \varepsilon_l^2\right) \ge \exp(-Cl\varepsilon_l^2)$.

Then there exists $R = R(C)$ and a universal constant $\tilde{K}$ such that

$$\Pr\left(d_{W_{1,\rho}}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)) \ge R\varepsilon_l + e^{-\tilde{K}l\varepsilon_l^2}\right) \le \frac{1}{l\varepsilon_l^2} + 4e^{-\tilde{K}l\varepsilon_l^2}. \tag{19}$$

Proof The proof closely mimics the argument behind Theorem 2.1 in (Ghosal et al., 2000). For reader's convenience, details are outlined in Section A.2 of the appendix. ■

Conditions of Theorem 7 are standard assumptions guaranteeing that the resulting posterior distribution contracts to the true parameter θ_0 at the rate ε_n. Note that the bounds for the distance $d_{W_{1,\rho}}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)$ slightly differ from the contraction rate itself: indeed, we have

$$d_{W_{1,\rho}}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)) \le \varepsilon_l + \int\limits_{h(P_\theta, P_0) \ge \varepsilon_l} d\Pi_l(\cdot|\mathcal{X}_l),$$

hence to obtain the inequality $d_{W_{1,\rho}}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)) \lesssim \varepsilon_l$, we usually require $\int\limits_{h(P_\theta, P_0) \ge \varepsilon_l} d\Pi_l(\cdot|\mathcal{X}_l) \lesssim \varepsilon_l$, which adds an extra logarithmic factor in the parametric case.

Combination of Theorems 7 and 1 immediately yields the corollary for $\hat{\Pi}_{n,0}$. Let $\mathbb{H}$ be the reproducing kernel Hilbert space with the reproducing kernel

$$k_H(\theta_1, \theta_2) = \frac{1}{2}\left\langle \sqrt{p_{\theta_1}}, \sqrt{p_{\theta_2}} \right\rangle_{L_2(dx)}.$$

Let $f \in \mathbb{H}$ and note that, due to the reproducing property and Cauchy-Schwarz inequality, we have

$$\begin{aligned} f(\theta_1) - f(\theta_2) &= \langle f, k_H(\cdot, \theta_1) - k_H(\cdot, \theta_2)\rangle_{\mathbb{H}} \\ &\le \|f\|_{\mathbb{H}} \left\|k_H(\cdot, \theta_1) - k_H(\cdot, \theta_2)\right\|_{\mathbb{H}} = \|f\|_{\mathbb{H}} \, \rho(\theta_1, \theta_2). \end{aligned} \tag{20}$$

Therefore, $\mathcal{F}_k \subseteq \mathcal{F}_L$ and $\|P - Q\|_{\mathcal{F}_k} \le \|P - Q\|_{\mathcal{F}_L}$, where $\mathcal{F}_k$ and $\mathcal{F}_L$ were defined in (10) and (8) respectively, and the underlying metric structure is given by ρ. In particular, convergence with respect to $\|\cdot\|_{\mathcal{F}_L}$ implies convergence with respect to $\|\cdot\|_{\mathcal{F}_k}$.

Corollary 8 *Let $X_1, \dots, X_n$ be an i.i.d. sample from P_0, and assume that $\hat{\Pi}_{n,g}$ is defined with respect to the norm $\|\cdot\|_{\mathcal{F}_L}$ as in (17) above. Set $l := \lfloor n/m \rfloor$, assume that conditions of Theorem 7 hold, and, moreover, that ε_l satisfies*

$$\frac{1}{l\varepsilon_l^2} + 4e^{-(1+K/2)l\varepsilon_l^2/2} < \frac{1}{7}.$$

Then

$$\Pr\left(\left\|\delta_0 - \hat{\Pi}_{n,g}\right\|_{\mathcal{F}_{k_H}} \ge 1.52\left(R\varepsilon_l + e^{-\tilde{K}l\varepsilon_l^2}\right)\right) \le \left[e^{\psi(3/7,1/7)}\right]^{-m} < 1.27^{-m}.$$

Proof It is enough to apply part (a) of Theorem 1 with $\kappa = 0$ to the independent random measures $\Pi_n(\cdot|G_j)$, $j = 1, \dots, m$. Note that the "weak concentration" assumption (29) is implied by (19). ■

Once again, note the exponential improvement of concentration as compared to Theorem 7. It is easy to see that a similar statement holds for the median $\hat{\Pi}_{n,0}(\cdot)$ defined in (17) (even for the stronger Wasserstein distance $d_{W_{1,\rho}}(\delta_0, \hat{\Pi}_{n,0})$), modulo changes in constants.

Remark 9 *The case when the sample $\mathcal{X}_n = \{X_1, \dots, X_n\}$ contains $\lfloor \kappa m \rfloor$ outliers (which can be completely arbitrary vectors in $\mathbb{R}^D$) for some $\kappa < 1/3$ can be handled similarly. In most examples throughout the paper, we state the results for the case $\kappa = 0$ for simplicity, keeping in mind that the generalization is a trivial corollary of Theorem 1. For example, if we allow $\lfloor \kappa m \rfloor$ outliers in the setup of Corollary 8, the resulting bounds becomes*

$$\Pr\left(\left\|\delta_0 - \hat{\Pi}_{n,g}\right\|_{\mathcal{F}_{k_H}} \ge 1.52\left(R\varepsilon_l + e^{-\tilde{K}l\varepsilon_l^2}\right)\right) \le \left[e^{(1-\kappa)\psi\left(\frac{3/7-\kappa}{1-\kappa}, 1/7\right)}\right]^{-m}.$$

While the result of the previous statement is promising, numerical approximation and sampling from the "robust posterior" $\hat{\Pi}_{n,g}$ is often problematic due to the underlying geometry defined by the Hellinger metric, and the associated distance $\|\cdot\|_{\mathcal{F}_{k_H}}$ is hard to estimate in practice. Our next goal is to derive similar guarantees for the M-Posterior evaluated with respect to the computationally tractable family of distances discussed in Section 2.3 above.

To transfer the conclusions of Theorem 7 and Corollary 8 to the case of other kernels $k(\cdot, \cdot)$ and associated metrics $\rho_k(\cdot, \cdot)$, we need to guarantee the existence of tests versus the complements of the balls in these distances. Such tests can be obtained from comparison inequalities between distances.

Assumption 1 *There exists $\gamma > 0$, $r(\theta_0) > 0$ and $\tilde{C}(\theta_0) > 0$ satisfying*

$$d(\theta, \theta_0) \ge \tilde{C}(\theta_0)\rho_k^\gamma(\theta, \theta_0) \text{ whenever } d(\theta, \theta_0) \le r(\theta_0),$$

where d is the Hellinger distance or the Euclidean distance (in the parametric case).

Remark 10 *When d is the Euclidean distance, we will impose an additional mild assumption guaranteeing existence of test versus the complements of the balls (for the Hellinger distance, this is always true, see Ghosal et al., 2000). Namely, we will assume that for every n and every pair $\theta_1, \theta_2 \in \Theta$, there exists a test $\phi_n := \phi_n(X_1, \dots, X_n)$ such that for some $\gamma > 0$ and a universal constant $K > 0$*

$$\begin{aligned} \mathbb{E}_{P_{\theta_1}} \phi_n &\le e^{-Knd^2(\theta_1, \theta_2)}, \\ \sup_{d(\theta, \theta_2) < d(\theta_1, \theta_2)/2} \mathbb{E}_{P_\theta}(1 - \phi_n) &\le e^{-Knd^2(\theta_1, \theta_2)}. \end{aligned} \tag{21}$$

Below, we provide examples of kernels satisfying the stated assumption.

Example 1 (Exponential families) *Let $\{P_\theta,\ \theta \in \Theta \subseteq \mathbb{R}^p\}$ be of the form*

$$\frac{dP_\theta}{dx}(x) := p_\theta(x) = \exp\Big(\langle T(x), \Theta\rangle_{\mathbb{R}^p} - G(\theta) + q(x)\Big),$$

where $\langle \cdot, \cdot \rangle_{\mathbb{R}^p}$ is the standard Euclidean dot product. Then the Hellinger distance can be expressed as (Nielsen and Garcia, 2011)

$$h^2(P_{\theta_1}, P_{\theta_2}) = 1 - \exp\Big(-\frac{1}{2}\Big(G(\theta_1) + G(\theta_2) - 2G\Big(\frac{\theta_1+\theta_2}{2}\Big)\Big)\Big).$$

If $G(\theta)$ is convex and its Hessian $D^2G(\theta)$ satisfies $D^2G(\theta) \succeq A$ uniformly for all $\theta \in \Theta$ and some symmetric positive definite operator $A : \mathbb{R}^p \mapsto \mathbb{R}^p$, then

$$h^2(P_{\theta_1}, P_{\theta_2}) \geq 1 - \exp\Big(-\frac{1}{8}(\theta_1-\theta_2)^T A(\theta_1-\theta_2)\Big),$$

hence assumption 1 holds with d being the Hellinger distance, $\gamma = 1$, $\tilde{C} = \frac{1}{\sqrt{2}}$ and $r(\theta_0) \equiv 1$ for

$$k(\theta_1, \theta_2) := \exp\left(-\frac{1}{8}(\theta_1-\theta_2)^T A(\theta_1-\theta_2)\right).$$

For finite-dimensional models, we will be especially interested in kernels $k(\cdot,\cdot)$ such that the associated metric $\rho_k(\cdot,\cdot)$ is bounded by the Euclidean distance. The following proposition gives a sufficient condition for this to hold.

Assume that kernel $k(\cdot,\cdot)$ satisfies conditions of Proposition 4 (in particular, k is characteristic). Recall that by Bochner's theorem, there exists a finite nonnegative Borel measure ν such that $k(\theta) = \int\limits_{\mathbb{R}^p} e^{i\langle x,\theta\rangle} d\nu(x)$.

Proposition 11 *Assume that $\int\limits_{\mathbb{R}^p} \|x\|_2^2 d\nu(x) < \infty$. Then there exists $D_k > 0$ depending only on k such that for all θ_1, θ_2,*

$$\rho_k(\theta_1, \theta_2) \leq D_k \left\|\theta_1 - \theta_2\right\|_2.$$

Proof For all $z \in \mathbb{R}$, $|e^{iz} - 1 - iz| \leq \frac{|z|^2}{2}$, implying that

$$\begin{aligned}
\rho_k^2(\theta_1,\theta_2) &= \|k(\cdot,\theta_1) - k(\cdot,\theta_2)\|_{\mathbb{H}}^2 \\
&= 2k(0) - 2k(\theta_1-\theta_2) = 2\int\limits_{\mathbb{R}^p} (1 - e^{i\langle x, \theta_1-\theta_2\rangle}) d\nu(x) \\
&\leq \int\limits_{\mathbb{R}^p} \langle x, \theta_1-\theta_2\rangle_{\mathbb{R}^p}^2 \, d\nu(x) \leq \|\theta_1-\theta_2\|_2^2 \int\limits_{\mathbb{R}^p} \|x\|_2^2 d\nu(x).
\end{aligned}$$

■

Moreover, the result of the previous proposition clearly remains valid for kernels of the form

$$\tilde{k}(\theta_1,\theta_2) = k(\theta_1-\theta_2) + c\,\langle \theta_1, \theta_2\rangle_{\mathbb{R}^p}, \tag{22}$$

where $c > 0$ and k satisfies the assumptions of proposition 11. For such a kernel, we have the obvious lower bound $\rho_{\tilde{k}}(\theta_1,\theta_2) \geq \sqrt{c}\,\|\theta_1-\theta_2\|_2$, hence $\rho_{\tilde{k}}$ is equivalent (in the strong sense) to the Euclidean distance.

We are ready to state our main result for convergence with respect to the RKHS-induced distance $\|\cdot\|_{\mathcal{F}_k}$.

Theorem 12 *Assume that conditions of Theorem 7 hold with ρ being the Hellinger or the Euclidean distance, and that assumption 1 is satisfied. In addition, let prior Π be such that*

$$D_k^W := \int_\Theta \rho_k^W(\theta,\theta_0) d\Pi(\theta) < \infty$$

for a sufficiently large W (it follows from the proof that $W = \frac{4}{3} + \frac{4+2C}{3\tilde{K}}$ is sufficient, with C and $\tilde{K}$ being the constants from the statement of Theorem 7). Then there exists a sufficiently large $R = R(\theta_0,\gamma) > 0$ and an absolute constant $\tilde{K}$ such that

$$\Pr\Big(\|\delta_0 - \Pi_l(\cdot|\mathcal{X}_l)\|_{\mathcal{F}_k} \geq R\varepsilon_l^{1/\gamma} + D_k e^{-\tilde{K}l\varepsilon_l^2/2}\Big) \leq \frac{1}{l\varepsilon_l^2} + 4e^{-\tilde{K}l\varepsilon_l^2}. \tag{23}$$

Proof The result essentially follows from the combination of Theorem 7 and assumption 1, see Section A.3 for details. ■

Theorem 12 yields the "weak" estimate that is needed to obtain the stronger bound for the M-Posterior distribution $\hat{\Pi}_{n,g}$. This is summarized in the following corollary:

Corollary 13 *Let $X_1, \ldots, X_n$ be an i.i.d. sample from P_0, and assume that $\hat{\Pi}_{n,g}$ is defined with respect to the distance $\|\cdot\|_{\mathcal{F}_k}$ as in (17) above. Let $l := \lfloor n/m \rfloor$. Assume that conditions of Theorem 12 hold, and, moreover, ε_l is such that*

$$\frac{1}{l\varepsilon_l^2} + 4e^{-\tilde{K}l\varepsilon_l^2} < \frac{1}{7}.$$

Then

$$\Pr\Big(\big\|\delta_0 - \hat{\Pi}_{n,g}\big\|_{\mathcal{F}_k} \geq 1.52\left(R\varepsilon_l^{1/\gamma} + D_k e^{-\tilde{K}l\varepsilon_l^2/2}\right)\Big) \leq 1.27^{-m}. \tag{24}$$

Proof It is enough to apply parts (a) and (b) of Theorem 1 with $\kappa = 0$ to the independent random measures $\Pi_{|G_j|}(\cdot|G_j)$, $j = 1, \ldots, m$. Note that the "weak concentration" assumption (28) is implied by (23). ■

Note that if $\Theta \subseteq \mathbb{R}^p$ and kernel $k(\cdot,\cdot)$ is of the form (22), the previous corollary together with proposition 6 imply that

$$\Pr\Big(\big\|\theta_* - \theta_0\big\|_2 \geq \frac{1.52R}{c}\varepsilon_l\Big) \leq 1.27^{-m},$$

where $\theta_* = \int_\Theta \theta d\hat{\Pi}_{n,g}(\theta)$ is the mean of $\hat{\Pi}_{n,g}$. In other words, this shows that the M-Posterior mean is the robust estimator of θ_0.

3.2 Bayesian Inference Based on Stochastic Approximation of the Posterior Distribution

As we have already mentioned in Section 2.4, when the number of disjoint subgroups m is large, the resulting M-Posterior distribution is "too flat", which results in large credible sets and overestimation of uncertainty. Clearly, the source of the problem is the fact that each individual random measure $\Pi_{|G_j|}(\cdot|G_j),\ j=1,\ldots,m$ is based on sample of size $l \simeq \frac{n}{m}$ which can be much smaller than n.

One way to reduce the variance of each subset posterior distribution is to repeat each observation in G_j m times (although other alternatives, such as bootstrap, are possible; for instance, bootstrap-related techniques have been investigated by Kleiner et al. (2014) in the frequentist setting), $\tilde{G}_j = \underbrace{\{G_j,\ldots,G_j\}}_{m \text{ times}}$. Formal application of the Bayes rule in this situation yields a collection of new measures on the parameter space:

$$\Pi_{|G_j|,m}(B|G_j) := \frac{\int\limits_B \left(\prod_{i\in G_j} p_\theta(X_i)\right)^m d\Pi(\theta)}{\int\limits_\Theta \left(\prod_{i\in G_j} p_\theta(X_i)\right)^m d\Pi(\theta)},$$

where we have assumed that $p_\theta(\cdot)$ is integrable. Here, $\left(\prod_{i\in G_j} p_\theta(X_i)\right)^m$ can be viewed as an approximation of the full data likelihood. We call the random measure $\Pi_{|G_j|,m}(\cdot|G_j)$ the *j-th stochastic approximation* to the full posterior distribution.

Of course, such a "correction" negatively affects coverage properties of the credible sets associated with each measure $\Pi_{|G_j|}(\cdot|G_j)$. However, taking the median of stochastic approximations yields improved coverage of the resulting M-Posterior distribution. The main goal of this section is to establish an asymptotic statement in spirit of a Bernstein-von Mises theorem for the M-Posterior based on stochastic approximations $\Pi_{|G_j|,m}(B|G_j),\ j=1,\ldots,m$.

We will start by showing that under certain assumptions the upper bounds for the convergence rates of $\Pi_{|G_j|,m}(\cdot|G_j)$ towards δ_0 are the same as for $\Pi_{|G_j|}(\cdot|G_j)$, the "standard" posterior distribution given G_j.

For $A \subseteq \Theta$, let $N_{[]}(u,A,d)$ be the bracketing number of $\{p_\theta,\ \theta\in A\}$ with respect to the distance $d(l,u) := \int\limits_{\mathbb{R}^D} \left(\sqrt{l(x)} - \sqrt{u(x)}\right)^2 dx$, and let

$$H_{[]}(u;A) := \log N_{[]}(u,A,d)$$

be the *bracketing entropy*. In what follows, $B(\theta_0,r) := \{\theta\in\Theta:\ h(P_\theta,P_{\theta_0}) \le r\}$ denotes the "Hellinger ball" of radius r centered at θ_0.

Theorem 14 (Wong et al., 1995, Theorem 1) *There exist constants $c_j,\ j=1,\ldots,4$ and $\zeta>0$ such that if*

$$\int\limits_{\zeta^2/2^8}^{\sqrt{2}\zeta} H_{[]}^{1/2}\left(u/c_3; B(\theta_0,\zeta\sqrt{2})\right) du \le c_4\sqrt{l}\zeta^2,$$

then

$$P\left(\sup_{\theta:h(P_\theta,P_0)\ge\zeta} \prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \ge e^{-c_1 l\zeta^2}\right) \le 4e^{-c_2 l\zeta^2}.$$

In particular, one can choose $c_1 = 1/24,\ c_2 = (4/27)(1/1926),\ c_3 = 10$ and $c_4 = (2/3)^{5/2}/512$.

In "typical" parametric problems ($\Theta\subseteq\mathbb{R}^p$), the bracketing entropy can be bounded as $H_{[]}(u;B(\theta_0,r)) \le C_1\log(C_2 r/u)$, whence the minimal ζ that satisfies conditions of Theorem 14 is of order $\zeta \simeq \sqrt{\frac{1}{l}}$. In particular, it is easy to check (e.g., using Theorem 2.7.11 in van der Vaart and Wellner, 1996) that this is the case when

(a) there exists $r_0>0$ such that

$$h\left(P_\theta,P_{\theta_0}\right) \ge K_1\|\theta-\theta_0\|_2$$

whenever $h\left(P_\theta,P_{\theta_0}\right)\le r_0$, and

(b) there exists $\alpha>0$ such that for $\theta_1,\theta_2\in B(\theta_0,r_0)$,

$$|p_{\theta_1}(x) - p_{\theta_2}(x)| \le F(x)\,\|\theta_1-\theta_2\|_2^\alpha$$

with $\int_{\mathbb{R}^D} F(x)dx < \infty$.

Application of theorem 14 to the analysis of "stochastic approximations" yields the following result.

Theorem 15
Let $\varepsilon_l>0$ be such that conditions of Theorem 14 hold with $\zeta := \varepsilon_l$, and

(a) for some $C>0$

$$\Pi\left(\theta:\ -P_0\left(\log\frac{p_\theta}{p_0}\right) \le \varepsilon_l^2,\ P_0\left(\log\frac{p_\theta}{p_0}\right)^2 \le \varepsilon_l^2\right) \ge \exp(-Cl\varepsilon_l^2),$$

(b) k is a positive-definite kernel that satisfies assumption 1 for the Hellinger distance for some $\tilde{C}(\theta_0)$ and $\gamma>0$.

Then there exists $\tilde{R} = \tilde{R}(C,\tilde{C},\gamma) > 0$ such that

$$\Pr\left(\|\delta_0 - \Pi_{l,m}(\cdot|\mathcal{X}_l)\|_{\mathcal{F}_k} \ge \tilde{R}\varepsilon_l^{1/\gamma} + e^{-ml\varepsilon_l^2}\right) \le \frac{1}{l\varepsilon_l^2} + 4e^{-c_2\tilde{C}^2\tilde{R}^{2\gamma}l\varepsilon_l^2}.$$

Proof See Section A.4 in the appendix. ■

Remark 16 *Note that for the kernel $k(\cdot,\cdot)$ of the form (22), assumption 1 reduces to the inequality between the Hellinger and Euclidean distances.*

As before, Theorem 1 combined with the "weak concentration" inequality of Theorem 15 gives stronger guarantees for the median $\hat{\Pi}^{\text{st}}_{n,g}$ (or its alternative $\hat{\Pi}^{\text{st}}_{n,0}$) of

$$\Pi_{|G_1|,m}(\cdot|G_1), \ldots, \Pi_{|G_m|,m}(\cdot|G_m).$$

Exact statement is very similar in spirit to Corollary 13.

Our next goal is to obtain the result describing the asymptotic behavior of the M-Posterior distribution $\hat{\Pi}^{\text{st}}_{n,0}$ in the parametric case. We start with a result that addresses each individual stochastic approximation $\Pi_{|G_j|,m}(\cdot|G_j),\ j = 1, \ldots, m$. Assume that $\Theta \subseteq \mathbb{R}^p$ has non-empty interior. For $\theta \in \Theta$, let

$$I(\theta) := \mathbb{E}_{\theta_0}\left[\frac{\partial}{\partial\theta}\log p_\theta(X)\left(\frac{\partial}{\partial\theta}\log p_\theta(X)\right)^T\right]$$

be the Fisher information matrix (we are assuming that it is well-defined). We will say that the family $\{P_\theta,\ \theta \in \Theta\}$ is *differentiable in quadratic mean* (see Chapter 7 in van der Vaart, 2000 for details) if there exists $\dot{\ell}_{\theta_0} : \mathbb{R}^D \mapsto \mathbb{R}^p$ such that

$$\int_{\mathbb{R}^D}\left(\sqrt{p_{\theta_0+h}} - \sqrt{p_{\theta_0}} - \frac{1}{2}h^T\dot{\ell}_{\theta_0}\sqrt{p_{\theta_0}}\right)^2 = o(\|h\|_2^2)$$

as $h \to 0$; usually, $\dot{\ell}_\theta(x) = \frac{\partial}{\partial\theta}\log p_\theta(x)$. Next, define

$$\Delta_{l,\theta_0} := \frac{1}{\sqrt{l}}\sum_{j=1}^{l} I^{-1}(\theta_0)\dot{\ell}_{\theta_0}(X_j).$$

We will first state a preliminary result for each individual "subset posterior" distribution:

Proposition 17 *Let $X_1, \ldots, X_l$ be an i.i.d. sample from P_{θ_0} for some θ_0 in the interior of Θ. Assume that*

(a) the family $\{P_\theta,\ \theta \in \Theta\}$ is differentiable in quadratic mean;

(b) the prior Π has a density (with respect to the Lebesgue measure) that is continuous and positive in the neighborhood of θ_0;

(c) conditions of Theorem 14 hold with $\zeta = \frac{C}{\sqrt{l}}$ for some $C > 0$ and l large enough.

Then for any integer $m \geq 1$,

$$\left\|\Pi_{l,m}(\cdot|X_1, \ldots, X_l) - N\left(\theta_0 + \frac{\Delta_{l,\theta_0}}{\sqrt{l}}, \frac{1}{l\cdot m}I^{-1}(\theta_0)\right)\right\|_{\text{TV}} \to 0$$

in P_{θ_0}-probability as $l \to \infty$.

Proof The proof follows standard steps (e.g., Theorem 10.1 in van der Vaart, 2000), where the existence of tests is substituted by the inequality of Theorem 14. See Section A.5 in the appendix for details. ■

The implication of this result for the M-Posterior is the following: if k is the kernel of

type (22), for sufficiently regular parametric families (differentiable in quadratic mean, with "well-behaved" bracketing numbers, satisfying assumption 1 for the Euclidean distance with $\gamma = 1$) and regular priors, then

(a) the M-Posterior is well approximated by a normal distribution centered at the "robust" estimator θ^* of unknown θ_0;

(b) the estimator θ^* is a center of the confidence set of level 1.15^{-m} and diameter of order $\sqrt{\frac{m}{n}}$ (same as we would expect for this level for the usual posterior distribution - however, the bound for the M-Posterior holds for finite sample sizes).

This is formalized below:

Theorem 18

(a) Let k be the kernel of type (22), and suppose that the assumptions of Proposition 17 hold. Moreover, let the prior Π be such that $\int_{\mathbb{R}^p}\|\theta\|_2^2 d\Pi(\theta) < \infty$. Then for any fixed $m \geq 1$,

$$\left\|\hat{\Pi}^{\text{st}}_{n,0} - N\left(\theta^*, \frac{1}{n}I^{-1}(\theta_0)\right)\right\|_{\text{TV}} \to 0 \text{ as } n \to \infty,$$

in P_{θ_0}-probability when $n \to \infty$, where θ^* is the mean of $\hat{\Pi}^{\text{st}}_{n,0}$.

(b) Assume that conditions (a), (b) of Theorem 15 hold with

$$\varepsilon_l \gtrsim \frac{1}{\sqrt{l}} \simeq \sqrt{\frac{m}{n}}$$

and $\gamma = 1$. Then for all $n \geq n_0$ and $\bar{R}$ large enough,

$$\Pr\left(\|\theta^* - \theta_0\|_2 \geq \bar{R}\left(\varepsilon_l + e^{-ml\varepsilon_l^2}\right)\right) \leq 1.15^{-m}.$$

Proof (a) It is easy to see that convergence in total variation norm, together with an assumption that the prior distribution satisfies

$$\int_{\mathbb{R}^p}\|\theta\|_2^2 d\Pi(\theta) < \infty,$$

implies that the expectations converge in P_{θ_0}-probability as well:

$$\left\|\int_\Theta \theta\left(d\Pi_{l,m}(\theta|\mathcal{X}_l) - dN\left(\theta_0 + \frac{\Delta_{l,\theta_0}}{\sqrt{l}}, \frac{1}{l\cdot m}I^{-1}(\theta_0)\right)(\theta)\right)\right\|_2 \to 0 \text{ as } l \to \infty.$$

Together with an observation that the total variation distance between $N(\mu_1, \Sigma)$ and $N(\mu_2, \Sigma)$ is bounded by the multiple of $\|\mu_1 - \mu_2\|_2$, it implies that we can replace $\theta_0 + \frac{\Delta_{l,\theta_0}}{\sqrt{l}}$ by the mean

$$\bar{\theta}_{l,m}(X_1, \ldots, X_l) := \int_\Theta \theta d\Pi_{l,m}(\theta|\mathcal{X}_l),$$

in other words, the conclusion of Proposition 17 can be stated as

$$\left\| \Pi_{l,m}(\cdot|\mathcal{X}_l) - N\left(\bar{\theta}_{l,m}, \frac{1}{l\cdot m} I^{-1}(\theta_0)\right)\right\|_{\mathrm{TV}} \to 0 \text{ as } l \to \infty,$$

in P_{θ_0}-probability. Now assume that $m = \lfloor \frac{n}{l} \rfloor$ is fixed, and let $n, l \to \infty$. As before, let $G_1, \dots, G_m$ be disjoint groups of i.i.d. observations from P_{θ_0} of cardinality l each. Recall that, by the definition (3) of $\mathrm{med}_0(\cdot)$, $\Pi^{\mathrm{st}}_{n,0} = \Pi_{l,m}(\cdot|\mathcal{X}_{l_*})$ for some $l_* \le m$, and $\theta^* := \theta_{l_*,m}$ is the mean of $\Pi^{\mathrm{st}}_{n,0}$. Clearly, we have

$$\left\| \Pi^{\mathrm{st}}_{n,0} - N\left(\theta^*, \frac{1}{l\cdot m} I^{-1}(\theta_0)\right)\right\|_{\mathrm{TV}} \le$$
$$\max_{j=1,\dots,m} \left\| \Pi_{l,m}(\cdot|G_j) - N\left(\bar{\theta}_{l,m}(G_j), \frac{1}{l\cdot m} I^{-1}(\theta_0)\right)\right\|_{\mathrm{TV}} \to 0 \text{ as } n \to \infty. \tag{25}$$

(b) Let $\varepsilon_l \ge C\sqrt{\frac{1}{l}}$ where C large enough so that

$$\frac{1}{l\varepsilon_l^2} + 4e^{-c_2\tilde{C}^2\tilde{R}^2 l\varepsilon_l^2} \le \frac{1}{4},$$

where c_2, $\tilde{R}$ are the same as in Theorem 15. Applying Theorem 15, we get

$$\Pr\left(\|\delta_{\theta_0} - \Pi_{l,m}(\cdot|\mathcal{X}_l)\|_{\mathcal{F}_k} \ge \tilde{R}\varepsilon_l + e^{-ml\varepsilon_l^2}\right) \le \frac{1}{4}.$$

By part (b) of Theorem 1,

$$\left\| \hat{\Pi}^{\mathrm{st}}_{n,0} - \delta_{\theta_0}\right\|_{\mathcal{F}_{\tilde{k}}} \le 3\left(\tilde{R}\varepsilon_l + e^{-ml\varepsilon_l^2}\right)$$

with probability $\ge 1 - 1.15^{-m}$. Since kernel $\tilde{k}$ is of the type (22), proposition (6) implies that

$$\|\theta^* - \theta_0\|_2 \le \left\| \hat{\Pi}^{\mathrm{st}}_{n,0} - \delta_{\theta_0}\right\|_{\mathcal{F}_{\tilde{k}}}, \tag{26}$$

and the result follows.

■

In particular, for $m = A\log(n)$ and $\varepsilon_l \simeq \sqrt{\frac{m}{n}}$, we obtain the bound

$$\Pr\left(\|\theta^* - \theta_0\|_2 \ge \bar{R}\sqrt{\frac{A\log n}{n}}\right) \le n^{-A}.$$

for some constant $\bar{R}$ *independent* of m. Note that θ^* itself depends on m, hence this bound is *not uniform*, and holds only for a given confidence level $1 - n^{-A}$.

It is convenient to interpret this (informally) in terms of the credible sets: to obtain the credible set with "frequentist" coverage level $\ge 1 - n^{-A}$, pick $m = A\log n$ and use the $(1 - n^{-A})$ - credible set of the M-Posterior $\hat{\Pi}^{\mathrm{st}}_{n,0}$.

Algorithm 1 Evaluating the geometric median of probability distributions via Weiszfeld's algorithm

Input:

1. Discrete measures $Q_1, \dots, Q_m$;
2. The kernel $k(\cdot,\cdot) : \mathbb{R}^p \times \mathbb{R}^p \mapsto \mathbb{R}$;
3. Threshold $\varepsilon > 0$;

Initialize:

1. Set $w_j^{(0)} := \frac{1}{m}$, $j = 1 \dots m$;
2. Set $Q_*^{(0)} := \frac{1}{m}\sum_{j=1}^m Q_j$;

repeat

Starting from $t = 0$, for each $j = 1, \dots, m$:

1. Update $w_j^{(t+1)} = \frac{\|Q_*^{(t)} - Q_j\|_{\mathcal{F}_k}^{-1}}{\sum_{i=1}^m \|Q_*^{(t)} - Q_i\|_{\mathcal{F}_k}^{-1}}$; (apply (12) to evaluate $\|Q_*^{(t)} - Q_i\|_{\mathcal{F}_k}$);
2. Update $Q_*^{(t+1)} = \sum_{j=1}^m w_j^{(t+1)} Q_j$;

until $\|Q_*^{(t+1)} - Q_*^{(t)}\|_{\mathcal{F}_k} \le \varepsilon$;
Return: $w_* := (w_1^{(t+1)}, \dots, w_m^{(t+1)})$.

4. Numerical Algorithms and Examples

In this section, we consider examples and applications in which comparisons are made for the inference based on the usual posterior distribution and on the M-Posterior. One of the well-known and computationally efficient ways to find the geometric median in Hilbert spaces is the famous *Weiszfeld's algorithm*, introduced in Weiszfeld (1936). Details of implementation are described in Algorithms 1 and 2. Algorithm 1 is a particular case of Weiszfeld's algorithm applied to subset posterior distributions and distance $\|\cdot\|_{\mathcal{F}_k}$, while Algorithm 2 shows how to obtain an approximation to M-Posterior given the samples from $\Pi_{n,m}(\cdot|G_j)$, $j = 1 \dots m$. Note that the subset posteriors $\Pi_{n,m}(\cdot|G_j)$ whose "weights" $w_{*,j}$ in the expression of the M-Posterior are small (in our case, smaller than $1/(2m)$) are excluded from the analysis. Our extensive simulations show the empirical evidence in favor of this additional thresholding step.

Detailed discussion of convergence rates and acceleration techniques for Weiszfeld's method from the viewpoint of modern optimization can be found in Beck and Sabach (2013). For alternative approaches and extensions of Weiszfeld's algorithm, see Bose et al. (2003), Ostresh (1978), Overton (1983), Chandrasekaran and Tamir (1990), Cardot et al. (2012), Cardot et al. (2013), among other works.

In all numerical simulations below, we use stochastic approximations and the corresponding M-Posterior $\hat{\Pi}^{\mathrm{st}}_{n,g}$, unless noted otherwise. The posterior $\hat{\Pi}^{\mathrm{st}}_{n,0}$ based on the metric median is mainly of theoretical interest, while numerical results obtained for it are typically inferior compared to the geometric median, so we do not discuss them further.

Algorithm 2 Approximating the M-Posterior distribution

Input:

1. Samples $\{Z_{j,i}\}_{i=1}^{S_j} \sim \Pi_{n,m}(\cdot|G_j),\ j = 1 \dots m$ (see equation (18));

Do:

1. $Q_j := \frac{1}{S_j} \sum_{i=1}^{S_j} \delta_{Z_{j,i}}$, $j = 1 \dots m$ - empirical approximations of $\Pi_{n,m}(\cdot|G_j)$.
2. Apply Algorithm 1 to $Q_1, \dots, Q_m$; return $w_* = (w_{*,1} \dots w_{*,m})$;
3. For $j = 1, \dots, m$, set $\bar{w}_j := w_{*,j} I\{w_{*,j} \geq \frac{1}{2m}\}$; define $\hat{w}_j^* := \bar{w}_j / \sum_{i=1}^m \bar{w}_i$.

Return: $\hat{\Pi}_{n,g}^{\text{st}} := \sum_{i=1}^m \hat{w}_i^* Q_i$.

Before presenting the results of numerical analysis, let us remark on two important computational aspects.

Remark 19

(a) The number of subsets m appears as a "free parameter" entering the theoretical guarantees for M-Posterior. One interpretation of m (in terms of the credible sets) is given in the end of Section 3.2. Our results also imply that partitioning the data into $m = 2k + 1$ subsets guarantees robustness to the presence of k outliers of arbitrary nature.

In many applications, m is dictated by the sample size and computational resources (e.g., the number of available machines). In Section A.6, we describe a heuristic approach to selection of m that shows good practical performance. As a rule of a thumb, we recommend choosing $m \lesssim \sqrt{n}$ as larger values of m lead to an M-Posterior that overestimates uncertainty. This heuristic is supported by the numerical results presented below.

(b) It is easy to get a general idea regarding the potential improvement in computational time complexity achieved by the M-Posterior. Given the data set $\mathcal{X}_n = \{X_1, \dots, X_n\}$ of size n, let $t(n)$ be the running time of the algorithm (e.g., MCMC) that outputs a single observation from the posterior distribution $\Pi_n(\cdot|\mathcal{X}_n)$. If the goal is to obtain S samples from the posterior, then the total running time is $O(S \cdot t(n))$. Let us compare this time with the running time needed to obtain S samples from the M-posterior given that the algorithm is running on m machines in parallel. In this case, we need to generate $O(S)$ samples from each of m subset posteriors, which is done in time $O\left(S \cdot t\left(\frac{n}{m}\right)\right)$, where S is typically large and $m \ll n$. According to Theorem 7.1 in Beck and Sabach (2013), Weiszfeld's algorithm approximates the M-Posterior to degree of accuracy ε in at most $O(1/\varepsilon)$ steps, and each of these steps has complexity $O(S^2)$ (which follows from (12)), so that the total running time is

$$O\left(S \cdot t\left(\frac{n}{m}\right) + \frac{S^2}{\varepsilon}\right). \tag{27}$$

The term $\frac{S^2}{\varepsilon}$ can be refined in several ways via application of more advanced optimization techniques (see the aforementioned references). If, for example, $t(n) \simeq n^r$ for some $r \geq 1$, then $\frac{S}{m} \cdot t\left(\frac{n}{m}\right) \simeq \frac{1}{m^{1+r}} S n^r$ which should be compared to $S \cdot n^r$ required by the standard approach.

To give a specific example, consider an application of (27) in the context of Gaussian process (GP) regression. If n is the number of training samples, then GP regression has $O(n^3) + O(Sn^2)$ asymptotic time complexity to obtain S samples from the posterior distribution of GP (Rasmussen and Williams, 2006, Algorithm 2.1). Assuming we have access to m machines, the time complexity to obtain S samples from M-Posterior in GP regression is $O\left(\left(\frac{n}{m}\right)^3 + S\left(\frac{n}{m}\right)^2 + \frac{S^2}{\varepsilon}\right)$. If for example $S = cn$ for some $c > 0$ and $m^2 < n\varepsilon$, we get $O(m^2)$ improvement in running time.

(c) In many cases, replacing the "subset posterior" by the stochastic approximation does not result in increased sampling complexity: indeed, the log-likelihood in the sampling algorithm for the subset posterior is simply multiplied by m to obtain the sampler for the stochastic approximation. We have included the description of a modified Dirichlet mixture model in the supplementary material as an illustration.

4.1 Numerical Analysis: Simulated Data

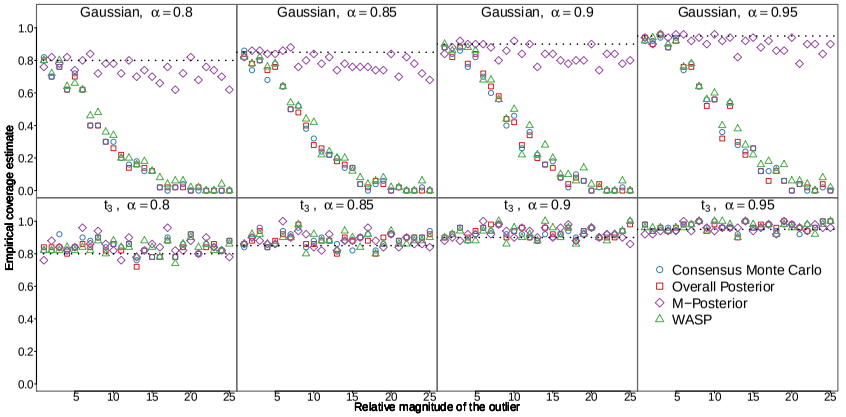

Figure 1: Effect of the outlier on empirical coverage of (1-α)100% credible intervals (CIs). The x-axis represents the outlier magnitude. The y-axis represents the empirical coverage computed from 50 simulation replications. The dotted horizontal lines show the theoretical frequentist coverage.

This section demonstrates the effect of magnitude of an outlier on the posterior distribution of the mean parameter μ. We empirically show that M-Posterior of μ is a robust alternative to the overall posterior. To this end, we used the simplest univariate Gaussian model $\{P_\mu = \mathcal{N}(\mu, 1),\ \mu \in \mathbb{R}\}$.

We simulated 25 data sets containing 200 observations each. Each data set $\mathbf{x}_i = (x_{i,1}, \dots, x_{i,200})$ contained 199 independent observations from the standard Gaussian distribution ($x_{i,j} \sim$

$\mathcal{N}(0,1)$ for $i = 1,\ldots,25$ and $j = 1,\ldots,199$). The last entry in each data set, $x_{i,200}$, was an outlier, and its value increased linearly for $i = 1,\ldots,25$: $x_{i,200} = i\max(|x_{i,1}|,\ldots,|x_{i,199}|)$. The index of outlier was unknown to every sampling algorithm. The true variance of observations was fixed at 1 and was assumed to be known. The algorithms for sampling from the subset and overall posterior distributions of μ were implemented using Stan language (Carpenter et al., 2016) based on Stan's default Gaussian prior on μ. We used two likelihoods for the data, one was the standard Gaussian likelihood and the other was a (more robust) Student's t-distribution likelihood with 3 degrees of freedom (t_3). We generated 1000 samples from each posterior distribution $\Pi_{200}(\cdot|\,\mathbf{x}_i)$ for $i = 1,\ldots,25$. Setting $m = 10$ in Algorithm 1, we generated 1000 samples from every subset posterior $\Pi_{200,10}(\cdot|G_{j,i})$, $j = 1,\ldots,10$ to form the empirical measures $Q_{j,i}$; here, $\cup_{j=1}^{10} G_{j,i} = \mathbf{x}_i$. Using these $Q_{j,i}$s, Algorithm 2 generated 10000 samples from the M-Posterior $\hat{\Pi}^{\text{st}}_{2000,g}(\cdot|\,\mathbf{x}_i)$ for each $i = 1,\ldots,25$. This process was replicated 50 times.

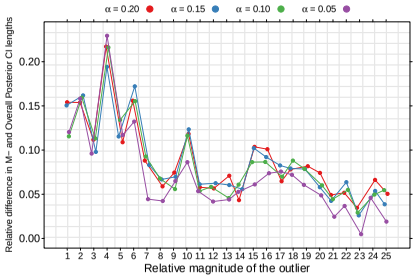

Figure 2: Calibration of uncertainty quantification of M-Posterior. The x-axis represents the outlier magnitude that increases from 1 to 25. The y-axis represents the relative difference between M-Posterior and overall posterior CI lengths. A value close to 0 represents that the M-Posterior CIs are well-calibrated.

We used Consensus MCMC (Scott et al., 2013) and WASP (Srivastava et al., 2015a) as representative methods for scalable MCMC approach, and compared their performance with M-Posterior. Across 50 simulation replications with the Gaussian and t_3 likelihood, we estimated the empirical coverage of (1-α)100% credible intervals (CIs) for the "consensus posterior", WASP, the overall posterior, and the M-Posterior for $\alpha = 0.2, 0.15, 0.10$, and 0.05. The empirical coverages of M-Posterior's CIs showed robustness to magnitude of the outlier in the Gaussian likelihood model. On the contrary, performance of the WASP, consensus posterior and overall posterior deteriorated fairly quickly across all α's leading to 0% empirical coverage as magnitude of the outlier increased from $i = 1$ to $i = 25$ (Figure 1). When the more robust t_3 likelihood was used, empirical coverages of CIs computed using the four methods were close to their theoretical values for all four α's. We compared uncertainty quantification of the M-Posterior with that of the overall posterior using relative lengths of their CIs, with zero value corresponding to identical lengths and a positive value to wider CIs of the M-Posterior. We found that widths of CIs for both posteriors were

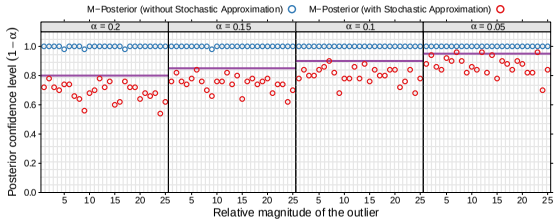

Figure 3: Effect of stochastic approximation on empirical coverage of (1-α)100% CIs. The x-axis represents the outlier magnitude that increases from 1 to 25. The y-axis represents the fraction of times the CIs of M-Posteriors with and without stochastic approximation include the true mean over 50 replications. The horizontal lines (in violet) show the theoretical frequentist coverage.

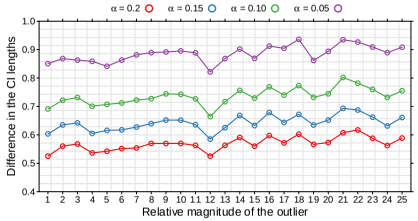

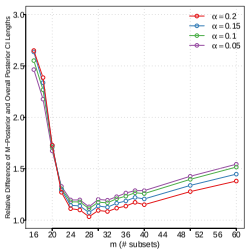

Figure 4: Effect of stochastic approximation on the length of (1-α)100% CIs. The x-axis represents the outlier magnitude that increases from 1 to 25. The y-axis represents the differences in the lengths of the CIs of M-Posteriors without and with stochastic approximation.

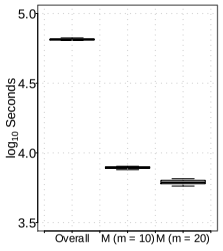

fairly similar for $i = 1,\ldots,25$, with M-Posterior's CIs being slightly wider in absence of large outliers (Figure 2).

Stochastic approximation was important for proper calibration of uncertainty quantification. The empirical coverages of (1-α)100% CIs of the M-Posterior without stochastic approximation overcompensated for uncertainty at all levels of α (Figure 3). Similarly, lengths of the CIs of M-Posterior without stochastic approximation are wider than those with stochastic approximation (Figure 4). Both these observations showed that stochastic approximation led to shorter CIs for M-Posterior that had empirical coverages close to their theoretical values.

The number of subsets m had an effect on credible interval length of the M-Posterior. We modified the simulation above and generated 1000 observations $\mathbf{x}$, with the last 10 observations in $\mathbf{x}$ being outliers with value $x_j = 25\max(|x_1|,\ldots,|x_{990}|)$, $j = 991,\ldots,1000$. The simulation setup was replicated 50 times. M-Posteriors were obtained for $m = 16, 18,\ldots,40, 50, 60$. Across all values of m, M-Posterior's CI was compared to the CI of the overall posterior

(a) Sensitivity to the choice of m

(b) Time

Figure 5: (a) Effect of m on the length of (1-α)100% CIs. The x-axis represents different choices of m. The y-axis represents the relative difference between M-Posterior and overall posterior CI lengths (median across all 25 outlier magnitudes and 50 replications). (b) Computation time to estimate overall posterior and M-Posterior (M) with $m = 10$ and $m = 20$ in real data analysis.

after removing the outliers; the relative difference of M-Posterior and the overall posterior CI lengths decreases for $m \geq 22 > 2k$, where $k = 10$ is the number of outliers, remains stable as m increases to $m = 38$, and grows for larger values of m (Figure 5a). This demonstrates that inference based on M-Posterior was not too sensitive to the choice of m for a wide range of values.

4.2 Real Data Analysis: General Social Survey

The General Social Survey (GSS; `gss.norc.org`) has collected responses to questions about evolution of American society since 1972. We selected data for 9 questions from different social topics: "happy" (happy), "Bible is a word of God" (bible), "support capital punishment" (cap), "support legalization of marijuana" (grass), "support premarital sex" (pre), "approve bible prayer in public schools" (prayer), "expect US to be in world war in 10 years" (uswar), "approve homosexual sex relations" (homo), "support abortion" (abort). These questions were in the survey since 1988 and their answers were converted to two levels: *yes* or *no*. Missing data were imputed based on the average, resulting in a data set with approximately 28,000 respondents.

We use a Dirichlet process (DP) mixture of product multinomial distributions, probabilistic parafac (p-parafac), to model the multivariate dependence among the 9 questions. Let $c_k \in \{\text{yes}, \text{no}\}$ represent the response to kth question, $k = 1, \ldots, 9$, then $\boldsymbol{\pi}_{c_1,\ldots,c_9}$ is the joint probability of response $c = (c_1, \ldots, c_9)$ for the 9 questions. Using $\boldsymbol{\pi}_{c_1,\ldots,c_9}$, we estimated the joint probability of response to two questions $\boldsymbol{\pi}_{c_i,c_j}$ for every i and j in $\{1, \ldots, 9\}$; see Section 6 of the supplementary material for the p-parafac generative model and sampling algorithms. The GSS data were randomly split into 10 test and training data sets. Samples from the overall posteriors of $\boldsymbol{\pi}_{c_i,c_j}$s were obtained using the Gibbs sampling algorithm of Dunson and Xing (2009). We chose m as 10 and 20 and estimated M-Posteriors for $\boldsymbol{\pi}_{c_i,c_j}$s in

four steps: training data were randomly split into m subsets, samples from subset posteriors were obtained after modifying the original sampler using stochastic approximation, weights of subsets posteriors were estimated using Algorithm 2, and atoms with estimated weights below $\frac{1}{2m}$ were removed.

M-Posterior had similar uncertainty quantification as the overall posterior while being more efficient. M-Posterior was at least 10 ($m = 20$) and 8 times ($m = 10$) faster than the overall posterior and it used less than 25% of the memory resources required by the overall posterior (Figure 5b). The lengths of credible intervals for $\boldsymbol{\pi}_{c_i,c_j}$s obtained using the overall posterior and the two M-Posteriors were very similar, but the overall posterior's coverage of the maximum likelihood estimators for $\boldsymbol{\pi}_{c_i,c_j}$s obtained from the test data was worse than that of the two M-Posteriors (Table 1).

Empirical Coverage of (1-α)100% Credible Intervals				
α	0.05	0.10	0.15	0.20
Overall Posterior	0.56 (0.10)	0.52 (0.01)	0.49 (0.02)	0.46 (0.02)
M-Posterior ($m = 10$)	0.71 (0.02)	0.65 (0.04)	0.62 (0.04)	0.60 (0.04)
M-Posterior ($m = 20$)	0.74 (0.03)	0.70 (0.03)	0.66 (0.03)	0.63 (0.03)
Length of (1-α)100% Credible Intervals (in 10^{-2})				
α	0.05	0.10	0.15	0.20
Overall Posterior	1.20 (0.12)	1.08 (0.11)	1.00 (0.10)	0.95 (0.10)
M-Posterior ($m = 10$)	1.70 (0.13)	1.54 (0.12)	1.43 (0.11)	1.35 (0.10)
M-Posterior ($m = 20$)	1.88 (0.11)	1.70 (0.10)	1.59 (0.09)	1.49 (0.09)

Table 1: Empirical coverage and lengths of (1-α)100% credible intervals. The results are averaged across all joint probabilities $\boldsymbol{\pi}_{c_i,c_j}$s and 10 folds of cross-validation. Monte Carlo errors are in parentheses.

Appendix A. Proofs.

A.1 Proof of Theorem 1

We will prove a slightly more general result:

Theorem 20

a *Assume that $(\mathbb{H}, \|\cdot\|)$ is a Hilbert space and $\theta_0 \in \mathbb{H}$. Let $\hat\theta_1, \dots, \hat\theta_m \in \mathbb{H}$ be a collection of independent random variables. Let the constants α, q, γ be such that $0 < q < \alpha < 1/2$, and $0 \le \gamma < \frac{\alpha - q}{1-q}$. Suppose $\varepsilon > 0$ is such that for all $j,\ 1 \le j \le \lfloor (1-\gamma)m \rfloor + 1$,*

$$\Pr\left(\|\hat\theta_j - \theta_0\| > \varepsilon\right) \le q. \tag{28}$$

Let $\hat\theta_* = \mathrm{med}_g(\hat\theta_1, \dots, \hat\theta_m)$ be the geometric median of $\{\hat\theta_1, \dots, \hat\theta_m\}$. Then

$$\Pr\left(\|\hat\theta_* - \theta_0\| > C_\alpha \varepsilon\right) \le \left[e^{(1-\gamma)\psi\left(\frac{\alpha-\gamma}{1-\gamma}, q\right)}\right]^{-m},$$

where $C_\alpha = (1-\alpha)\sqrt{\frac{1}{1-2\alpha}}$.

b *Assume that $(\mathbb{Y}, d)$ is a metric space and $\theta_0 \in \mathbb{Y}$. Let $\hat\theta_1, \dots, \hat\theta_m \in \mathbb{Y}$ be a collection of independent random variables. Let the constants q, γ be such that $0 < q < \frac{1}{2}$ and $0 \le \gamma < \frac{1/2 - q}{1-q}$. Suppose $\varepsilon > 0$ are such that for all $j,\ 1 \le j \le \lfloor (1-\gamma)m \rfloor + 1$,*

$$\Pr\left(d(\hat\theta_j, \theta_0) > \varepsilon\right) \le q. \tag{29}$$

Let $\hat\theta_* = \mathrm{med}_0(\hat\theta_1, \dots, \hat\theta_m)$. Then

$$\Pr\left(d(\hat\theta_*, \theta_0) > 3\varepsilon\right) \le e^{-m(1-\gamma)\psi\left(\frac{1/2-\gamma}{1-\gamma}, q\right)}.$$

To get the bound stated in the paper, take $q = \frac{1}{7}$ and $\alpha = \frac{3}{7}$ in part **(a)** and $q = \frac{1}{4}$ in part **b**.

We start by proving part **a**. To this end, we will need the following lemma (see lemma 2.1 in Minsker, 2015):

Lemma 21 *Let $\mathbb{H}$ be a Hilbert space, $x_1, \dots, x_m \in \mathbb{H}$ and let x_* be their geometric median. Fix $\alpha \in \left(0, \frac{1}{2}\right)$ and assume that $z \in \mathbb{H}$ is such that $\|x_* - z\| > C_\alpha r$, where*

$$C_\alpha = (1-\alpha)\sqrt{\frac{1}{1-2\alpha}}$$

and $r > 0$. Then there exists a subset $J \subseteq \{1, \dots, m\}$ of cardinality $|J| > \alpha m$ such that for all $j \in J$, $\|x_j - z\| > r$.

Assume that event $\mathcal{E} := \left\{\|\hat\theta_* - \theta_0\| > C_\alpha \varepsilon\right\}$ occurs. Lemma 21 implies that there exists a subset $J \subseteq \{1, \dots, m\}$ of cardinality $|J| \ge \alpha k$ such that $\|\hat\theta_j - \theta_0\| > \varepsilon$ for all $j \in J$, hence

$$\begin{aligned}\Pr(\mathcal{E}) \le &\Pr\left(\sum_{j=1}^m I\left\{\|\hat\theta_j - \theta_0\| > \varepsilon\right\} > \alpha m\right) \le \\ &\Pr\left(\sum_{j=1}^{\lfloor (1-\gamma)m\rfloor + 1} I\left\{\|\hat\theta_j - \theta_0\| > \varepsilon\right\} > (\alpha - \gamma)m \frac{\lfloor (1-\gamma)m\rfloor + 1}{\lfloor (1-\gamma)m\rfloor + 1}\right) \le \\ &\Pr\left(\sum_{j=1}^{\lfloor (1-\gamma)m\rfloor + 1} I\left\{\|\hat\theta_j - \theta_0\| > \varepsilon\right\} > \frac{\alpha - \gamma}{1-\gamma}\left(\lfloor (1-\gamma)m\rfloor + 1\right)\right).\end{aligned}$$

If W has Binomial distribution $W \sim B(\lfloor (1-\gamma)m\rfloor + 1, q)$, then

$$\begin{aligned}\Pr\left(\sum_{j=1}^{\lfloor (1-\gamma)m\rfloor + 1} I\left\{\|\hat\theta_j - \theta_0\| > \varepsilon\right\} > \frac{\alpha - \gamma}{1-\gamma}\left(\lfloor (1-\gamma)m\rfloor + 1\right)\right) \le \\ \Pr\left(W > \frac{\alpha - \gamma}{1-\gamma}\left(\lfloor (1-\gamma)m\rfloor + 1\right)\right)\end{aligned}$$

(see Lemma 23 in Lerasle and Oliveira, 2011 for a rigorous proof of this fact). Chernoff bound (e.g., Proposition A.6.1 in van der Vaart and Wellner, 1996), together with an obvious bound $\lfloor (1-\gamma)m\rfloor + 1 > (1-\gamma)m$, implies that

$$\Pr\left(W > \frac{\alpha - \gamma}{1-\gamma}\left(\lfloor (1-\gamma)m\rfloor + 1\right)\right) \le \exp\left(-m(1-\gamma)\psi\left(\frac{\alpha-\gamma}{1-\gamma}, q\right)\right).$$

To establish part **b**, we proceed as follows: let $\mathcal{E}_1$ be the event

$$\mathcal{E}_1 = \{\text{more than a half of events } d(\hat\theta_j, \theta_0) \le \varepsilon,\ j = 1 \dots m \text{ occur}\}.$$

Assume that $\mathcal{E}_1$ occurs. Then we clearly have $\varepsilon_* \le \varepsilon$, where ε_* is defined in equation (2.2) of the paper: indeed, for any $\theta_{j_1},\ \theta_{j_2}$ such that $d(\hat\theta_{j_i}, \theta_0) \le \varepsilon,\ i = 1, 2$, triangle inequality gives $d(\theta_{j_1}, \theta_{j_2}) \le 2\varepsilon$. By the definition of $\hat\theta_*$, inequality $d(\hat\theta_*, \hat\theta_j) \le 2\varepsilon_* \le 2\varepsilon$ holds for at least a half of $\{\hat\theta_1, \dots, \hat\theta_m\}$, hence, it holds for some $\hat\theta_{\tilde j}$ with $d(\hat\theta_{\tilde j}, \theta_0) \le \varepsilon$. In turn, this implies (by triangle inequality) $d(\hat\theta_*, \theta_0) \le 3\varepsilon$. We conclude that

$$\Pr\left(d(\hat\theta_*, \theta_0) > 3\varepsilon\right) \le \Pr(\mathcal{E}_1).$$

The rest of the proof repeats the argument of part **a** since

$$\Pr(\mathcal{E}_1^c) = \Pr\left(\sum_{j=1}^m I\left\{d(\hat\theta_j, \theta_0) > \varepsilon\right\} \ge \frac{m}{2}\right),$$

where $\mathcal{E}_1^c$ is the complement of $\mathcal{E}_1$.

A.2 Proof of Theorem 7

By the definition of Wasserstein distance d_{W_1},

$$d_{W_1,\rho}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)) = \int_\Theta \rho(\theta,\theta_0) d\Pi_l(\theta|X_1,\dots,X_l). \tag{30}$$

(recall that ρ is the Hellinger distance). Let R be a large enough constant to be determined later. Note that the Hellinger distance is uniformly bounded by 1. Using (30), it is easy to see that

$$d_{W_{1,\rho}}(\delta_0, \Pi_l(\cdot|\mathcal{X}_l)) \le R\varepsilon_l + \int\limits_{\rho(\theta,\theta_0)\ge R\varepsilon_l} d\Pi_l(\cdot|\mathcal{X}_l). \tag{31}$$

To this end, it remains to estimate the second term in the sum above. We will follow the proof of Theorem 2.1 in Ghosal et al. (2000). Bayes formula implies that

$$\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|\mathcal{X}_l) = \int\limits_{\rho(\theta,\theta_0)\ge R\varepsilon_l} \frac{\prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)}{\int\limits_\Theta \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)}.$$

Let

$$A_l = \left\{\theta : -P_0\left(\log\frac{p_\theta}{p_0}\right) \le \varepsilon_l^2, P_0\left(\log\frac{p_\theta}{p_0}\right)^2 \le \varepsilon_l^2\right\}.$$

For any $C_1 > 0$, Lemma 8.1 Ghosal et al. (2000) yields

$$\Pr\left\{\int\limits_\Theta \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) dQ(\theta) \le \exp\big(-(1+C_1)l\varepsilon_l^2\big)\right\} \le \frac{1}{C_1^2 l\varepsilon_l^2}.$$

for every probability measure Q on the set A_l. Moreover, by the assumption on the prior Π,

$$\Pi(A_l) \ge \exp\left(-Cl\varepsilon_l^2\right).$$

Consequently, with probability at least $1 - \frac{1}{C_1^2 l\varepsilon_l^2}$,

$$\int\limits_\Theta \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta) \ge \exp\Big(-(1+C_1)l\varepsilon_l^2\Big)\Pi(A_l) \ge \exp(-(1+C_1+C)l\varepsilon_l^2).$$

Define the event $B_l = \left\{\int\limits_\Theta \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta) \le \exp\Big(-(1+C_1+C)l\varepsilon_l^2\Big)\right\}$.

Let Θ_l be the set satisfying conditions of Theorem 3.1. Then by Theorem 7.1 in Ghosal et al. (2000), there exist test functions $\phi_l := \phi_l(X_1,\dots,X_l)$ and a universal constant K such that

$$\begin{aligned} &\mathbb{E}_{P_0}\phi_l \le 2e^{-Kl\varepsilon_l^2}, \\ \sup_{\theta\in\Theta_l, h(P_\theta,P_0)\ge R\varepsilon_l} &\mathbb{E}_{P_\theta}(1-\phi_l) \le e^{-KR^2\cdot l\varepsilon_l^2}, \end{aligned} \tag{32}$$

where $KR^2 - 1 > K$.

Note that

$$\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|X_1,\dots,X_l) = \Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|X_1,\dots,X_l)(\phi_l + 1 - \phi_l).$$

For the first term,

$$\mathbb{E}_{P_0}\Big[\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|X_1,\dots,X_l)\cdot\phi_l\Big] \le \mathbb{E}_{P_0}\phi_l \le 2e^{-Kl\varepsilon_l^2}. \tag{33}$$

Next, by the definition of B_l, we have

$$\begin{aligned} &\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|\mathcal{X}_l)(1-\phi_l) = \\ &\frac{\int\limits_{\rho(\theta,\theta_0)\ge R\varepsilon_l} \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l)}{\int\limits_\Theta \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)} (I\{B_l\} + I\{B_l^c\}) \\ &\le I\{B_l\} + e^{(1+C_1+C)l\varepsilon_l^2} \int\limits_{\rho(\theta,\theta_0)\ge R\varepsilon_l} \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l). \end{aligned} \tag{34}$$

To estimate the second term of last equation, note that

$$\begin{aligned} &\mathbb{E}_{P_0} \int\limits_{\rho(\theta,\theta_0)\ge R\varepsilon_l} \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l) \le \\ &\mathbb{E}_{P_0}\left(\int\limits_{\theta\in\Theta\setminus\Theta_l} \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l) + \int\limits_{\{\Theta_l\cap\rho(\theta,\theta_0)\ge R\varepsilon_l\}} \prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l)\right) \le \\ &\Pi(\Theta\setminus\Theta_l) + \int\limits_{\{\Theta_l\cap\rho(\theta,\theta_0)\}\ge R\varepsilon_l} \mathbb{E}_{P_0}\left(\prod_{i=1}^l \frac{p_\theta}{p_0}(X_i) d\Pi(\theta)(1-\phi_l)\right) \le \\ &e^{-l\varepsilon_l^2(C+4)} + e^{-KR^2\cdot l\varepsilon_l^2} \le 2e^{-l\varepsilon_l^2(C+4)} \end{aligned} \tag{35}$$

for $R \ge \sqrt{(C+4)/K}$. Set $C_1 = 1$ and note that $I\{B_l\} = 1$ with probability $P(B_l) \le 1/l\varepsilon_l^2$. It follows from (33), (34) and (35) and Chebyshev's inequality that for any $t > 0$

$$\begin{aligned} \Pr\Big(\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|\mathcal{X}_l) \ge t\Big) &\le \Pr(B_l) + \frac{2e^{-Kl\varepsilon_l^2}}{t} + \frac{2\exp\left(-2l\varepsilon_l^2\right)}{t} \\ &\le \frac{1}{l\varepsilon_l^2} + \frac{2e^{-Kl\varepsilon_l^2}}{t} + \frac{2\exp\left(-2l\varepsilon_l^2\right)}{t}. \end{aligned}$$

Finally, for a constant $\tilde{K} = \min(K/2, 1)$ and $t = e^{-\tilde{K}l\varepsilon_l^2}$, we obtain

$$\begin{aligned} \Pr\Big(\Pi_l(\theta:\rho(\theta,\theta_0)\ge R\varepsilon_l|\mathcal{X}_l) \ge t\Big) &\le \frac{1}{l\varepsilon_l^2} + 2e^{-Kl\varepsilon_l^2/2} + 2\exp\left(-l\varepsilon_l^2\right) \\ &\le \frac{1}{l\varepsilon_l^2} + 4e^{-\tilde{K}l\varepsilon_l^2}, \end{aligned}$$

which yields the result.

A.3 Proof of Theorem 12

From equation (20) in the paper and proceeding as in proof of Theorem 7, we get that

$$\|\delta_0 - \Pi_l(\cdot|\mathcal{X}_l)\|_{\mathcal{F}_k} \leq R\varepsilon_l^{1/\gamma} + \int\limits_{\rho_k(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} \rho_k(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l).$$

By Hölder's inequality,

$$\int\limits_{\rho_k(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} \rho_k(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l) \leq$$

$$\left[\int\limits_{\Theta} \rho_k^w(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l)\right]^{1/w} \left[\int\limits_{\rho_k(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} d\Pi_l(\cdot|\mathcal{X}_l)\right]^{1/q}$$

with $w > 1$ and $q = \frac{w}{w-1}$.

Define the event

$$B_l = \left\{\int\limits_{\Theta} \prod_{i=1}^{l} \frac{p_\theta}{p_0}(X_i)d\Pi(\theta) \geq \exp\Big(-(1+C_1+C)l\varepsilon_l^2\Big)\right\}.$$

Following in the proof of Theorem 3.1, we note that $\Pr(B_l) \geq 1 - \frac{1}{C_1^2 l\varepsilon_l^2}$ (where constants C, C_1 are the same as in the proof of Theorem 7). Also, note that

$$\mathbb{E}_{P_0}\left[\int_\Theta \rho_k^w(\theta,\theta_0)\prod_{i=1}^{l}\frac{p_\theta}{p_0}(X_i)d\Pi(\theta)\right] = \int_\Theta \rho_k^w(\theta,\theta_0)d\Pi(\theta)$$

Hence, with probability $\geq 1 - e^{-\tilde{K}l\varepsilon_l^2}$,

$$\int_\Theta \rho_k^w(\theta,\theta_0)\prod_{i=1}^{l}\frac{p_\theta}{p_0}(X_i)d\Pi(\theta) \leq e^{\tilde{K}l\varepsilon_l^2}\int_\Theta \rho_k^w(\theta,\theta_0)d\Pi(\theta),$$

where $\tilde{K} = \min(K/2, 1)$ is the same universal constant as in the proof of Theorem 7. Writing

$$\left[\int\limits_{\Theta} \rho_k^w(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l)\right]^{1/w} = \left[\frac{\int_\Theta \rho_k^w(\theta,\theta_0)\prod_{i=1}^{l}\frac{p_\theta}{p_0}(X_i)d\Pi(\theta)}{\int_\Theta \prod_{i=1}^{l}\frac{p_\theta}{p_0}(X_i)d\Pi(\theta)}\right]^{1/w},$$

we deduce that with probability $\geq 1 - e^{-\tilde{K}l\varepsilon_l^2} - \frac{1}{l\varepsilon_l^2}$ (where we set $C_1 := 1$),

$$\left[\int\limits_{\Theta} \rho_k^w(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l)\right]^{1/w} \leq e^{\frac{2+C+\tilde{K}}{w}l\varepsilon_l^2}\left[\int_\Theta \rho_k^w(\theta,\theta_0)d\Pi(\theta)\right]^{1/w}.$$

By Theorem 7.1 in Ghosal et al. (2000), there exist test functions $\phi_l := \phi_l(X_1,\ldots,X_l)$ and a universal constant K such that

$$\mathbb{E}_{P_0}\phi_l \leq 2e^{-Kl\varepsilon_l^2},$$
$$\sup_{\theta\in\Theta_l, d(\theta,\theta_0)\geq\tilde{R}\varepsilon_l} \mathbb{E}_{P_\theta}(1-\phi_l) \leq e^{-K\tilde{R}^2\cdot l\varepsilon_l^2},$$

where $K\tilde{R}^2 - 1 > K$ and $d(\cdot,\cdot)$ is the Hellinger or Euclidean distance. It immediately follows from Assumption 3.4 that

$$\Big\{\theta : \rho(\theta,\theta_0) \geq \tilde{C}_0(\theta_0)R^\gamma\varepsilon_l\Big\} \supseteq \Big\{\theta : \rho_k(\theta,\theta_0) \geq R\varepsilon_l^{1/\gamma}\Big\},$$

hence the test functions ϕ_l (for $\tilde{R} := \tilde{C}_0(\theta_0)R^\gamma$) satisfy

$$\mathbb{E}_{P_0}\phi_l \leq 2e^{-Kl\varepsilon_l^2}, \tag{36}$$
$$\sup_{\theta\in\Theta_l, \rho_k(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} \mathbb{E}_{P_\theta}(1-\phi_l) \leq e^{-KR^2\cdot l\varepsilon_l^2}.$$

Repeating the steps of the proof of Theorem 7, we see that if R is chosen large enough, then

$$\int\limits_{\rho_k(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} d\Pi_l(\cdot|\mathcal{X}_l) \leq e^{-\tilde{K}l\varepsilon_l^2}$$

with probability $\geq 1 - \frac{1}{l\varepsilon_l^2} - 4e^{-\tilde{K}l\varepsilon_l^2}$. Combining the bounds, we obtain that, for $w := \frac{4}{3} + \frac{4+2C}{3K}$, with probability $\geq 1 - \frac{1}{l\varepsilon_l^2} - 5e^{-\tilde{K}l\varepsilon_l^2}$,

$$\int\limits_{\rho(\theta,\theta_0)\geq R\varepsilon_l^{1/\gamma}} \rho_k(\theta,\theta_0)d\Pi_l(\cdot|\mathcal{X}_l) \leq e^{-\tilde{K}l\varepsilon_l^2/2}\left[\int_\Theta \rho_k^w(\theta,\theta_0)d\Pi(\theta)\right]^{1/w},$$

hence the result follows.

A.4 Proof of Theorem 15

The proof strategy is similar to Theorem 7. Note that

$$d_{W_{1,\rho}}(\delta_0, \Pi_{n,m}(\cdot|\mathcal{X}_l)) \leq R\varepsilon_l + \int\limits_{h(P_\theta,P_0)\geq R\varepsilon_l} d\Pi_l(\cdot|\mathcal{X}_l), \tag{37}$$

where $h(\cdot,\cdot)$ is the Hellinger distance.

Let $\mathcal{E}_l := \{\theta : h(P_\theta, P_0) \geq R\varepsilon_l\}$. By the definition of $\Pi_{n,m}$, we have

$$\Pi_{n,m}(\mathcal{E}_l|\mathcal{X}_l) = \frac{\int\limits_{\mathcal{E}_l}\Big(\prod_{j=1}^{l}\frac{p_\theta}{p_0}(X_j)\Big)^m d\Pi(\theta)}{\int\limits_{\Theta}\Big(\prod_{j=1}^{l}\frac{p_\theta}{p_0}(X_j)\Big)^m d\Pi(\theta)}. \tag{38}$$

To bound the denominator from below, we proceed as before. Let

$$\Theta_l = \left\{ \theta : -P_0 \left(\log \frac{p_\theta}{p_0} \right) \leq \varepsilon_l^2, P_0 \left(\log \frac{p_\theta}{p_0} \right)^2 \leq \varepsilon_l^2 \right\}.$$

Let B_l be the event defined by

$$B_l := \left\{ \int\limits_{\Theta_l} \left(\prod_{i=1}^{l} \frac{p_\theta}{p_0}(X_i) \right)^m dQ(\theta) \leq \exp(-2ml\varepsilon_l^2) \right\},$$

where Q is a probability measure supported on Θ_l. Lemma 8.1 in Ghosal et al. (2000) yields that $\Pr(B_l) \leq \frac{1}{l\varepsilon_l^2}$ for any Q, in particular, for the conditional distribution $\Pi(\cdot|\Theta_l)$. We conclude that

$$\int\limits_{\Theta} \left(\prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \right)^m d\Pi(\theta) \geq \Pi(\Theta_l) \exp(-2ml\varepsilon_l^2) \geq \exp(-(2m + C)l\varepsilon_l^2).$$

To estimate the numerator in (38), note that if Theorem 3.10 holds for $\gamma = \varepsilon_l$, then it also holds for $\gamma = L\varepsilon_l$ for any $L \geq 1$. This observation implies that

$$\sup_{\theta \in \mathcal{E}_l} \left(\prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \right)^m \leq e^{-c_1 R^2 ml\varepsilon_l^2}$$

with probability $\geq 1 - 4e^{-c_2 R^2 l\varepsilon_l^2}$, hence

$$\int\limits_{\mathcal{E}_l} \left(\prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \right)^m d\Pi(\theta) \leq e^{-c_1 R^2 ml\varepsilon_l^2}$$

with the same probability. Choose $R = R(C)$ large enough so that $c_1 m R^2 \geq 3m + C$. Putting the bounds for the numerator and denominator of (38) together, we get that with probability $\geq 1 - \frac{1}{l\varepsilon_l^2} - 4e^{-c_2 R^2 l\varepsilon_l^2}$,

$$\Pi_{n,m}(\mathcal{E}_l|\mathcal{X}_l) \leq e^{-ml\varepsilon_l^2}.$$

The result now follows from (37).

A.5 Proof of Proposition 17

The proof follows a standard pattern: on the first step, we show that it is enough to consider the posterior obtained from the prior restricted to a large compact set, and then proving the theorem for the prior with compact support. The second part mimics the classical argument exactly (e.g., see van der Vaart, 2000).

To show that one can restrict the prior to the compact set, it is enough to establish that for R large enough and $\mathcal{E}_l := \{\theta : \|\theta - \theta_0\| \geq \frac{R}{\sqrt{l}}\}$,

$$\Pi_{n,m}(\mathcal{E}_l|\mathcal{X}_l) = \frac{\int\limits_{\mathcal{E}_l} \left(\prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \right)^m d\Pi(\theta)}{\int\limits_{\Theta} \left(\prod_{j=1}^{l} \frac{p_\theta}{p_0}(X_j) \right)^m d\Pi(\theta)} \tag{39}$$

can be made arbitrarily small. This follows from the inclusion

$$\mathcal{E}_l \subseteq \left\{ \theta : h(P_\theta, P_{\theta_0}) \geq \tilde{C} \frac{R}{\sqrt{l}} \right\}$$

(due to the assumed inequality between Hellinger and Euclidean distances) and the bounds for the numerator and the denominator of (39) established in the proof of Theorem 15.

A.6 Selection of the optimal number of subsets m

The following heuristic approach picks the median among the candidate M-posteriors. Namely, start by evaluating the M-Posterior for each m in the range of candidate values $[m_1, m_2]$:

$$\begin{aligned} \hat{\Pi}^g_{n,m_1} &:= \mathrm{med}_g(\Pi_n^{(1)}, \ldots, \Pi_n^{(m_1)}), \\ \hat{\Pi}^g_{n,m_1+1} &:= \mathrm{med}_g(\Pi_n^{(1)}, \ldots, \Pi_n^{(m_1+1)}), \\ &\vdots \\ \hat{\Pi}^g_{n,m_2} &:= \mathrm{med}_g(\Pi_n^{(1)}, \ldots, \Pi_n^{(m_2)}) \end{aligned}$$

and choose $m_* \in [m_1, m_2]$ such that

$$\hat{\Pi}^g_{n,m_*} = \mathrm{med}_0 \left(\hat{\Pi}^g_{n,m_1}, \hat{\Pi}^g_{n,m_1+1}, \ldots, \hat{\Pi}^g_{n,m_2} \right), \tag{40}$$

where med_0 is the *metric median* defined in (3) in Section 2.2.

Abstract

The Hidden Markov Model (HMM) is one of the mainstays of statistical modeling of discrete time series, with applications including speech recognition, computational biology, computer vision and econometrics. Estimating an HMM from its observation process is often addressed via the Baum-Welch algorithm, which is known to be susceptible to local optima. In this paper, we first give a general characterization of the basin of attraction associated with any global optimum of the population likelihood. By exploiting this characterization, we provide non-asymptotic finite sample guarantees on the Baum-Welch updates and show geometric convergence to a small ball of radius on the order of the minimax rate around a global optimum. As a concrete example, we prove a linear rate of convergence for a hidden Markov mixture of two isotropic Gaussians given a suitable mean separation and an initialization within a ball of large radius around (one of) the true parameters. To our knowledge, these are the first rigorous local convergence guarantees to global optima for the Baum-Welch algorithm in a setting where the likelihood function is nonconvex. We complement our theoretical results with thorough numerical simulations studying the convergence of the Baum-Welch algorithm and illustrating the accuracy of our predictions.

Keywords: Hidden Markov Models, Baum-Welch algorithm, EM algorithm, non-convex optimization, graphical models

1. Introduction

Hidden Markov models (HMMs) are one of the most widely applied statistical models of the last 50 years, with major success stories in computational biology (Durbin, 1998), signal processing and speech recognition (Rabiner and Juang, 1993), control theory (Elliott et al., 1995), and econometrics (Kim and Nelson, 1999) among other disciplines. At a high level, a hidden Markov model is a Markov process split into an observable component and an unobserved or latent component. From a statistical standpoint, the use of latent states makes the HMM generic enough to model a variety of complex real-world time series, while the Markovian structure enables relatively simple computational procedures.

In applications of HMMs, an important problem is to estimate the state transition probabilities and the parameterized output densities based on samples of the observable component. From classical theory, it is known that under suitable regularity conditions, the maximum likelihood estimate (MLE) in an HMM has good statistical properties (Bickel et al., 1998). However, given the potentially nonconvex nature of the likelihood surface, computing the global maximum that defines the MLE is not a straightforward task. In fact, the HMM estimation problem in full generality is known to be computationally intractable under cryptographic assumptions (Terwijn, 2002). In practice, however, the Baum-Welch algorithm (Baum et al., 1970) is frequently applied and leads to good results. It can be understood as the specialization of the EM algorithm (Dempster et al., 1977) to the maximum likelihood estimation problem associated with the HMM. Despite its wide use in many applications, the Baum-Welch algorithm can get trapped in local optima of the likelihood function. Understanding when this undesirable behavior occurs—or does not occur—has remained an open question for several decades.

A more recent line of work (Mossel and Roch, 2006; Siddiqi et al., 2010; Hsu et al., 2012) has focused on developing tractable estimators for HMMs, via approaches that are distinct from the Baum-Welch algorithm. Nonetheless, it has been observed that the practical performance of such methods can be significantly improved by running the Baum-Welch algorithm using their estimators as the initial point; see, for instance, the detailed empirical study in Kontorovich et al. (2013). This curious phenomenon has been observed in other contexts (Chaganty and Liang, 2013), but has not been explained to date. Obtaining a theoretical characterization of when and why the Baum-Welch algorithm behaves well is the main objective of this paper.

1.1 Related work and our contributions

Our work builds upon a framework for analysis of EM, as previously introduced by a subset of the current authors (Balakrishnan et al., 2014); see also the follow-up work to regularized EM algorithms (Yi and Caramanis, 2015; Wang et al., 2014). All of this past work applies to models based on i.i.d. samples, and as we show in this paper, there are a number of non-trivial steps required to derive analogous theory for the dependent variables that arise for HMMs. Before doing so, let us put the results of this paper in context relative to older and more classical work on Baum-Welch and related algorithms.

Under mild regularity conditions, it is well-known that the maximum likelihood estimate (MLE) for an HMM is a consistent and asymptotically normal estimator; for instance, see Bickel et al. (1998), as well as the expository works (Cappé et al., 2004; van Handel, 2008). On the algorithmic level, the original papers of Baum and co-authors (Baum et al., 1970; Baum and Petrie, 1966) showed that the Baum-Welch algorithm converges to a stationary point of the sample likelihood; these results are in the spirit of the classical convergence analysis of the EM algorithm (Wu, 1983; Dempster et al., 1977). These classical convergence results only provide a relatively weak guarantee—namely, that if the algorithm is initialized

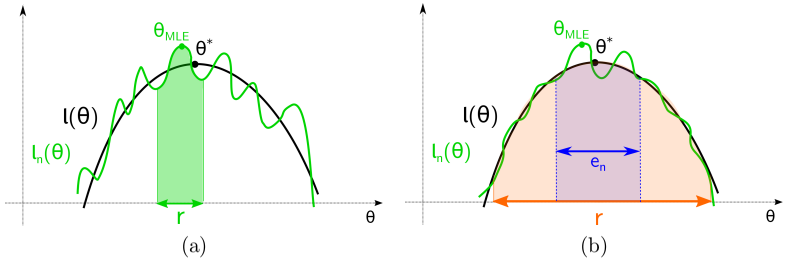

Figure 1: (a) A poorly behaved sample likelihood, for which there are many local optima at varying distances from the MLE. It would require an initialization extremely close to the MLE in order to ensure that the Baum-Welch algorithm would not be trapped at a sub-optimal fixed point. (b) A well-behaved sample likelihood, for which all local optima lie within an e_n-ball of the MLE, as well as the true parameter θ^*. In this case, the Baum-Welch algorithm, when initialized within a ball of large radius r, will converge to the ball of much smaller radius e_n. The goal of this paper is to give sufficient conditions for when the sample likelihood exhibits this favorable structure.

sufficiently close to the MLE, then it will converge to it. However, the classical analysis does not quantify the size of this neighborhood, and as a critical consequence, it *does not* rule out the pathological type of behavior illustrated in panel (a) of Figure 1. Here the sample likelihood has multiple optima, both a global optimum corresponding to the MLE as well as many local optima *far away from the MLE* that are also fixed points of the Baum-Welch algorithm. In such a setting, the Baum-Welch algorithm will only converge to the MLE if it is initialized in an extremely small neighborhood.

In contrast, the goal of this paper is to give sufficient conditions under which the sample likelihood has the more favorable structure shown in panel (b) of Figure 1. Here, even though the MLE does not have a large basin of attraction, the sample likelihood has all of its optima (including the MLE) localized to a small region around the true parameter θ^*. Our strategy to reveal this structure, as in our past work (Balakrishnan et al., 2014), is to shift perspective: instead of studying convergence of Baum-Welch updates to the MLE, we study their convergence to an ϵ_n-ball of the true parameter θ^*, and moreover, instead of focusing exclusively on the sample likelihood, we first study the structure of the population likelihood, corresponding to the idealized limit of infinite data. Our first main result (Theorem 1) provides sufficient conditions under which there is a large ball of radius r, over which the population version of the Baum-Welch updates converge at a geometric rate to θ^*. Our second main result (Theorem 2) uses empirical process theory to analyze the finite-sample version of the Baum-Welch algorithm, corresponding to what is actually implemented in practice. In this finite sample setting, we guarantee that over the ball of radius r, the Baum-Welch updates will converge to an ϵ_n-ball with $\epsilon_n \ll r$, and most importantly, this ϵ_n-ball contains the true parameter θ^*. Typically this ball also contains the MLE with high-probability, but our theory does *not* guarantee convergence to the MLE,

but rather to a point that is close to both the MLE and the true parameter θ^* and whose statistical risk is equivalent to that of the MLE upto logarithmic factors.

These latter two results are abstract, applicable to a broad class of HMMs. We then specialize them to the case of a hidden Markov mixture consisting of two isotropic components, with means separated by a constant distance, and obtain concrete guarantees for this model. It is worth comparing these results to past work in the i.i.d. setting, for which the problem of Gaussian mixture estimation under various separation assumptions has been extensively studied (e.g. (Dasgupta, 1999; Vempala and Wang, 2004; Belkin and Sinha, 2010; Moitra and Valiant, 2010)). The constant distance separation required in our work is much weaker than the separation assumptions imposed in most papers that focus on correctly labeling samples in a mixture model. Our separation condition is related to, but in general incomparable with the non-degeneracy requirements in other work (Hsu et al., 2012; Hsu and Kakade, 2013; Moitra and Valiant, 2010).

Finally, let us discuss the various challenges that arise in studying the dependent data setting of hidden Markov models, and highlight some important differences with the i.i.d. setting (Balakrishnan et al., 2014). In the non-i.i.d. setting, arguments passing from the population-based to sample-based updates are significantly more delicate. First of all, it is not even obvious that the population version of the Q-function—a central object in the Baum-Welch updates— exists. From a technical standpoint, various gradient smoothness conditions are much more difficult to establish, since the gradient of the likelihood no longer decomposes over the samples as in the i.i.d. setting. In particular, each term in the gradient of the likelihood is a function of all observations. Finally, in order to establish the finite-sample behavior of the Baum-Welch algorithm, we can no longer appeal to standard i.i.d. concentration and empirical process techniques. Nor do we pursue the approach of some past work on HMM estimation (e.g. (Hsu et al., 2012)), in which it is assumed that there are multiple independent samples of the HMM.[1] Instead, we directly analyze the Baum-Welch algorithm that practioners actually use—namely, one that applies to a single sample of an n-length HMM. In order to make the argument rigorous, we need to make use of more sophisticated techniques for proving concentration for dependent data (Yu, 1994; Nobel and Dembo, 1993).

The remainder of this paper is organized as follows. In Section 2, we introduce basic background on hidden Markov models and the Baum-Welch algorithm. Section 3 is devoted to the statement of our main results in the general setting, whereas Section 4 contains the more concrete consequences for the Gaussian output HMM. The main parts of our proofs are given in Section 5, with the more technical details deferred to the appendices.

2. Background and problem set-up

In this section, we introduce some standard background on hidden Markov models and the Baum-Welch algorithm.

1. The rough argument here is that it is possible to reduce an i.i.d. sampling model by cutting the original sample into many pieces, but this is not an algorithm that one would implement in practice.

2.1 Standard HMM notation and assumptions

We begin by defining a discrete-time hidden Markov model with hidden states taking values in a discrete space. Letting $\mathbb{Z}$ denote the integers, suppose that the observed random variables $\{X_i\}_{i\in\mathbb{Z}}$ take values in $\mathbb{R}^d$, and the latent random variables $\{Z_i\}_{i\in\mathbb{Z}}$ take values in the discrete space $[s] := \{1, \ldots, s\}$. The Markov structure is imposed on the sequence of latent variables. In particular, if the variable Z_1 has some initial distribution π_1, then the joint probability of a particular sequence $(z_1, \ldots, z_n)$ is given by

$$p(z_1, \ldots, z_n; \beta) = \pi_1(z_1; \beta) \prod_{i=1}^{n} p(z_i \mid z_{i-1}; \beta), \tag{1}$$

where the vector β is a particular parameterization of the initial distribution and Markov chain transition probabilities. We restrict our attention to the homogeneous case, meaning that the transition probabilities for step $(t-1) \to t$ are independent of the index t. Consequently, if we define the transition matrix $A \in \mathbb{R}^{s\times s}$ with entries

$$A(j, k; \beta) := p(z_2 = k \mid z_1 = j; \beta),$$

then the marginal distribution π_i of Z_i can be described by the matrix vector equation

$$\pi_i^T = \pi_1^T A^{i-1},$$

where π_i and π_1 denote vectors belonging to the s-dimensional probability simplex.

We assume throughout that the Markov chain is aperiodic and recurrent, whence it has a unique stationary distribution $\bar{\pi}$, defined by the eigenvector equation $\bar{\pi}^T = \bar{\pi}^T A$. To be clear, both $\bar{\pi}$ and the matrix A depend on β, but we omit this dependence so as to simplify notation. We assume throughout that the Markov chain begins in its stationary state, so that $\pi_1 = \bar{\pi}$, and moreover, that it is reversible, meaning that

$$\bar{\pi}(j)A(j, k) = \bar{\pi}(k)A(k, j) \tag{2}$$

for all pairs $j, k \in [s]$.

A key quantity in our analysis is the mixing rate of the Markov chain. In particular, we assume the existence of *mixing constant* $\epsilon_{\text{mix}} \in (0, 1]$ such that

$$\epsilon_{\text{mix}} \leq \frac{p(z_i|z_{i-1}; \beta)}{\bar{\pi}(z_i)} \leq \epsilon_{\text{mix}}^{-1} \tag{3}$$

for all $(z_i, z_{i-1}) \in [s] \times [s]$. This condition implies that the dependence on the initial distribution decays geometrically. More precisely, some simple algebra shows that

$$\sup_{\pi_1} \left\|\pi_1^T A^t - \pi_1^T\right\|_{\text{TV}} \leq c_0 \rho_{\text{mix}}^t \qquad \text{for all } t = 1, 2, \ldots, \tag{4}$$

where $\rho_{\text{mix}} = 1 - \epsilon_{\text{mix}}$ denotes the *mixing rate* of the process, and c_0 is a universal constant. Note that as $\epsilon_{\text{mix}} \to 1^-$, the Markov chain has behavior approaching that of an i.i.d. sequence, whereas as $\epsilon_{\text{mix}} \to 0^+$, its behavior becomes increasingly "sticky".

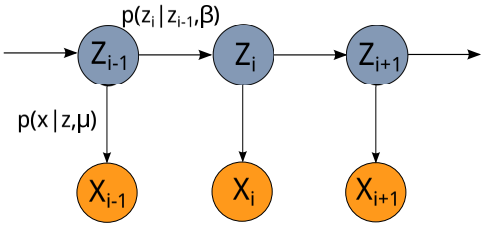

Figure 2: The hidden Markov model as a graphical model. The blue circles indicate observed variables Z_i, whereas the orange circles indicate latent variables X_i.

Associated with each latent variable Z_i is an observation $X_i \in \mathbb{R}^d$. We use $p(x_i|z_i; \mu)$ to denote the density of X_i given that $Z_i = z_i$, an object that we assume to be parameterized by a vector μ. Introducing the shorthand $x_1^n = (x_1, \ldots, x_n)$ and $z_1^n = (z_1, \ldots, z_n)$, the joint probability of the sequence (x_1^n, z_1^n) (also known as the complete likelihood) can be written in the form

$$p(z_1^n, x_1^n; \theta) = \pi_1(z_1) \prod_{i=2}^{n} p(z_i \mid z_{i-1}; \beta) \prod_{i=1}^{n} p(x_i|z_i; \mu), \tag{5}$$

where the pair $\theta := (\beta, \mu)$ parameterizes the transition and observation functions. The likelihood then reads

$$p(x_1^n; \theta) = \sum_{z_1^n} p(z_1^n, x_1^n; \theta).$$

For our convenience in subsequent analysis, we also define a form of complete likelihood including an additional hidden variable z_0 which is not associated to any observation x_0

$$p(z_0^n, x_1^n; \theta) = \pi_0(z_0) \prod_{i=1}^{n} p(z_i \mid z_{i-1}; \beta) \prod_{i=1}^{n} p(x_i|z_i; \mu), \tag{6}$$

where $\pi_0 = \bar{\pi}$. Note that it preserves the usual relationship $\sum_{z_0^n} p(z_0^n, x_1^n; \theta) = p(x_1^n; \theta)$ between the ordinary and complete likelihoods in EM problems.

A simple example: A special case helps to illustrate these definitions. In particular, suppose that we have a Markov chain with $s = 2$ states. Consider a matrix of transition probabilities $A \in \mathbb{R}^{2\times 2}$ of the form

$$A = \frac{1}{e^\beta + e^{-\beta}} \begin{bmatrix} e^\beta & e^{-\beta} \\ e^{-\beta} & e^\beta \end{bmatrix} = \begin{bmatrix} \zeta & 1-\zeta \\ 1-\zeta & \zeta \end{bmatrix}, \tag{7}$$

where $\zeta := \frac{e^\beta}{e^\beta + e^{-\beta}}$. By construction, this Markov chain is recurrent and aperiodic with the unique stationary distribution $\bar{\pi} = \begin{bmatrix}\frac{1}{2} & \frac{1}{2}\end{bmatrix}^T$. Moreover, by calculating the

eigenvalues of the transition matrix, we find that the mixing condition (4) holds with $\rho_{\mathrm{mix}} := |2\zeta - 1| = |\tanh(\beta)|$.

Suppose moreover that the observed variables in $\mathbb{R}^d$ are conditionally Gaussian, say with

$$p(x_t|z_t;\mu) = \begin{cases} \frac{1}{(2\pi\sigma^2)^{d/2}} \exp\big\{ -\frac{1}{2\sigma^2}\|x-\mu\|_2^2\big\} & \text{if } z_t = 1 \\ \frac{1}{(2\pi\sigma^2)^{d/2}} \exp\big\{ -\frac{1}{2\sigma^2}\|x+\mu\|_2^2\big\} & \text{if } z_t = 2. \end{cases} \tag{8}$$

With this choice, the marginal distribution of each X_t is a two-state Gaussian mixture with mean vectors μ and $-\mu$, and covariance matrices $\sigma^2 I_d$. We provide specific consequences of our general theory for this special case in the sequel.

2.2 Baum-Welch updates for HMMs

We now describe the Baum-Welch updates for a general discrete-state hidden Markov model. As a special case of the EM algorithm, the Baum-Welch algorithm is guaranteed to ascend on the likelihood function of the hidden Markov model. It does so indirectly, by first computing a lower bound on the likelihood (E-step) and then maximizing this lower bound (M-step).

For a given integer $n \geq 1$, suppose that we observe a sequence $x_1^n = (x_1, \ldots, x_n)$ drawn from the marginal distribution over X_1^n defined by the model (5). The rescaled log likelihood of the sample path x_1^n is given by

$$\ell_n(\theta) = \frac{1}{n} \log \Big(\sum_{z_0^n} p(z_0^n, x_1^n; \theta) \Big)$$

The EM likelihood is based on lower bounding the likelihood via Jensen's inequality. For any choice of parameter θ' and positive integers $i \leq j$ and $a < b$, let $\mathbb{E}_{Z_i^j | x_a^b, \theta'}$ denote the expectation under the conditional distribution $p(Z_i^j \mid x_a^b; \theta')$. With this notation, the concavity of the logarithm and Jensen's inequality imply that for any choice of θ', we have the lower bound

$$\begin{aligned} \ell_n(\theta) &= \frac{1}{n} \log \big[\mathbb{E}_{Z_0^n | x_1^n, \theta'} \frac{p(Z_0^n, x_1^n; \theta)}{p(Z_0^n \mid x_1^n; \theta')} \big] \\ &\geq \underbrace{\frac{1}{n} \mathbb{E}_{Z_0^n | x_1^n, \theta'} \big[\log p(Z_0^n, x_1^n; \theta) \big]}_{Q_n(\theta \,|\, \theta')} + \underbrace{\frac{1}{n} \mathbb{E}_{Z_0^n | x_1^n, \theta'} \big[-\log p(Z_0^n \mid x_1^n; \theta') \big]}_{H_n(\theta')}. \end{aligned}$$

For a given choice of θ', the E-step corresponds to the computation of the function $\theta \mapsto Q_n(\theta \mid \theta')$. The M-step is defined by the EM operator $M_n : \widetilde{\Omega} \mapsto \widetilde{\Omega}$

$$M_n(\theta') = \arg\max_{\theta \in \widetilde{\Omega}} Q_n(\theta \mid \theta'), \tag{9}$$

where $\widetilde{\Omega}$ is the set of feasible parameter vectors. Overall, given an initial vector $\theta^0 = (\beta^0, \mu^0)$, the EM algorithm generates a sequence $\{\theta^t\}_{t=0}^{\infty}$ according to the recursion $\theta^{t+1} = M_n(\theta^t)$.

This description can be made more concrete for an HMM, in which case the Q-function takes the form

$$\begin{aligned} Q_n(\theta \mid \theta') = \frac{1}{n} \mathbb{E}_{Z_0 | x_1^n, \theta'} \big[\log \pi_0(Z_0; \beta) \big] + \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{Z_{i-1}, Z_i | x_1^n, \theta'} \big[\log p(Z_i \mid Z_{i-1}; \beta) \big] \\ + \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{Z_i | x_1^n, \theta'} \big[\log p(x_i \mid Z_i; \mu) \big], \end{aligned} \tag{10}$$

where the dependence of π_0 on β comes from the assumption that $\pi_0 = \bar{\pi}$. Note that the Q-function can be decomposed as the sum of a term which is solely dependent on μ, and another one which only depends on β—that is

$$Q_n(\theta \mid \theta') = Q_{1,n}(\mu \mid \theta') + Q_{2,n}(\beta \mid \theta') \tag{11}$$

where $Q_{1,n}(\mu \mid \theta') = \frac{1}{n} \sum_{i=1}^n \mathbb{E}_{Z_i | x_1^n, \theta'} \big[\log p(x_i \mid Z_i, \mu) \big]$, and $Q_{2,n}(\beta \mid \theta')$ collects the remaining terms. In order to compute the expectations defining this function (E-step), we need to determine the marginal distributions over the singletons Z_i and pairs (Z_i, Z_{i+1}) under the joint distribution $p(Z_0^n \mid x_1^n; \theta')$. These marginals can be obtained efficiently using a recursive message-passing algorithm, known either as the forward-backward or sum-product algorithm (Kschischang et al., 2001; Wainwright and Jordan, 2008).

In the M-step, the decomposition (11) suggests that the maximization over the two components (β, μ) can also be decoupled. Accordingly, with a slight abuse of notation, we often write

$$M_n^{\mu}(\theta') = \arg\max_{\mu \in \Omega_\mu} Q_{1,n}(\mu \mid \theta'), \quad \text{and} \quad M_n^{\beta}(\theta') = \arg\max_{\beta \in \Omega_\beta} Q_{2,n}(\beta \mid \theta')$$

for these two decoupled maximization steps, where Ω_β and Ω_μ denote the feasible set of transition and observation parameters respectively and $\widetilde{\Omega} := \Omega_\beta \times \Omega_\mu$. In the following, unless otherwise stated, $\Omega_\mu = \mathbb{R}^d$, so that the maximization over the observation parameters is unconstrained.

3. Main results

We now turn to the statement of our main results, along with a discussion of some of their consequences. The first step is to establish the existence of an appropriate population analog of the Q-function. Although the existence of such an object is a straightforward consequence of the law of large numbers in the case of i.i.d. data, it requires some technical effort to establish existence for the case of dependent data; in particular, we do so using a k-truncated version of the full Q-function (see Proposition 1). This truncated object plays a central role in the remainder of our analysis. In particular, we first analyze a version of the Baum-Welch updates on the expected k-truncated Q-function for an extended sequence of observations x_{1-k}^{n+k}, and provide sufficient conditions for these population-level updates to be contractive (see Theorem 1). We then use non-asymptotic forms of empirical process theory to show that under suitable conditions, the actual sample-based EM updates—i.e., the updates that are actually implemented in practice—are also well-behaved in this region with high probability (see Theorem 2). In subsequent analysis to follow in Section 4, we show that this initialization radius is suitably large for an HMM with Gaussian outputs.

3.1 Existence of population Q-function

In the analysis of Balakrishnan et al. (2014), the central object is the notion of a population Q-function—namely, the function that underlies the EM algorithm in the idealized limit of infinite data. In their setting of i.i.d. data, the standard law of large numbers ensures that as the sample size n increases, the sample-based Q-function approaches its expectation, namely the function

$$\bar{Q}(\theta \mid \theta') = \mathbb{E}\big[Q_n(\theta \mid \theta')\big] \;=\; \mathbb{E}\big[\mathbb{E}_{Z_1|X_1,\theta'}\big[\log p(X_1, Z_1; \theta)\big]\big].$$

Here we use the shorthand $\mathbb{E}$ for the expectation over all samples X that are drawn from the joint distribution (in this case $\mathbb{E} := \mathbb{E}_{X_1^n|\theta^*}$).

When the samples are dependent, the quantity $\mathbb{E}\big[Q_n(\theta \mid \theta')\big]$ is no longer independent of n, and so an additional step is required. A reasonable candidate for a general definition of the population Q-function is given by

$$\bar{Q}(\theta \mid \theta') := \lim_{n \to +\infty} [\mathbb{E} Q_n(\theta \mid \theta')]. \tag{12}$$

Although it is clear that this definition is sensible in the i.i.d. case, it is necessary for dependent sampling schemes to prove that the limit given in definition (12) actually exists.

In this paper, we do so by considering a suitably truncated version of the sample-based Q-function. Similar arguments have been used in past work (e.g., (Cappé et al., 2004; van Handel, 2008)) to establish consistency of the MLE; here our focus is instead on the behavior of the Baum-Welch algorithm. Let us consider a sequence $\{(X_i, Z_i)\}_{i=1-k}^{n+k}$, assumed to be drawn from the stationary distribution of the overall chain. Recall that $\mathbb{E}_{Z_i^j|x_a^b,\theta}$ denotes expectations taken over the distribution $p(Z_i^j \mid x_a^b, \theta)$. Then, for a positive integer k to be chosen, we define

$$Q_n^k(\theta \mid \theta') = \frac{1}{n}\Big[\mathbb{E}_{Z_0|x_{-k}^k,\theta'} \log p(Z_1; \beta) + \sum_{i=1}^{n} \mathbb{E}_{Z_{i-1}^i|x_{i-k}^{i+k},\theta'} \log p(Z_i \mid Z_{i-1}; \beta) + \sum_{i=1}^{n} \mathbb{E}_{Z_i|x_{i-k}^{i+k},\theta'} \log p(x_i \mid Z_i; \mu)\Big]. \tag{13}$$

In an analogous fashion to the decomposition in equation (10), we can decompose Q_n^k in the form

$$Q_n^k(\theta \mid \theta') = Q_{1,n}^k(\mu \mid \theta') + Q_{2,n}^k(\beta \mid \theta').$$

We associate with this triplet of Q-functions the corresponding EM operators $M_n^k(\theta')$, $M_n^{\mu,k}(\theta')$ and $M_n^{\beta,k}(\theta')$ as in Equation (9). Note that as opposed to the function Q_n from equation (10), the definition of Q_n^k involves variables Z_i, Z_{i-1} that are not conditioned on the full observation sequence x_1^n, but instead only on a $2k$ window centered around the index i. By construction, we are guaranteed that the k-truncated population function and its decomposed analogs given by

$$\begin{aligned}\bar{Q}^k(\theta \mid \theta') &:= \lim_{n\to\infty} \mathbb{E} Q_n^k(\theta \mid \theta') = \mathbb{E} Q_{1,n}^k(\mu \mid \theta') + \lim_{n\to\infty} \mathbb{E} Q_{2,n}^k(\beta \mid \theta') \\ &:= \bar{Q}_1^k(\mu \mid \theta') + \bar{Q}_2^k(\beta \mid \theta')\end{aligned} \tag{14}$$

are well-defined. In particular, due to stationarity of the random sequences $\{p(z_i \mid X_{i-k}^{i+k})\}_{i=1}^n$ and $\{p(z_{i-1}^i \mid X_{i-k}^{i+k})\}_{i=1}^n$, the expectation over $\{(X_i, Z_i)\}_{i=1-k}^{n+k}$ is independent of the sample size n. Notice that the Baum-Welch algorithm in practice essentially corresponds to using $k = n$.

Our first result uses the existence of this truncated population object in order to show that the standard population Q-function from equation (12) is indeed well-defined. In doing so, we make use of the sup-norm

$$\|Q_1 - Q_2\|_\infty := \sup_{\theta,\theta' \in \widetilde{\Omega}} \Big|Q_1(\theta \mid \theta') - Q_2(\theta \mid \theta')\Big|. \tag{15}$$

We require in the following that the observation densities satisfy the following boundedness condition

$$\sup_{\theta \in \widetilde{\Omega}} \mathbb{E}\Big[\max_{z_i \in [s]} \big|\log p(X_i \mid z_i, \theta)\big|\Big] < \infty. \tag{16}$$

Proposition 1 *Under the previously stated assumptions, the population function $\bar{Q}$ defined in equation* (12) *exists.*

The proof of this claim is given in Appendix A. It hinges on the following auxiliary claim, which bounds the difference between $\mathbb{E} Q_n$ and the k-truncated Q-function as

$$\|\mathbb{E} Q_n - \bar{Q}^k\|_\infty \leq \frac{c\, s^4}{\epsilon_{\mathrm{mix}}^9 \overline{\pi}_{\min}^2}\big(1 - \epsilon_{\mathrm{mix}} \overline{\pi}_{\min}\big)^k + \frac{c(\overline{\pi}_{\min}, s, \epsilon_{\mathrm{mix}})}{n}, \tag{17}$$

where $\overline{\pi}_{\min} := \min_{\beta \in \Omega_\beta, j \in [s]} \overline{\pi}(j \mid \beta)$ is the minimum probability in the stationary distribution, ϵ_{mix} is the mixing constant from equation (3), and $c(\cdot)$ is a constant dependent only on the inherent model parameters. The dependencies on ϵ_{mix} and $\overline{\pi}_{\min}$ are not optimized here. Since this bound holds for all n, it shows that the population function $\bar{Q}$ can be uniformly approximated by $\bar{Q}^k$, with the approximation error decreasing geometrically as the truncation level k grows. This fact plays an important role in the analysis to follow.

3.2 Analysis of updates based on $\bar{Q}^k$

Our ultimate goal is to establish a bound on the difference between the sample-based Baum-Welch estimate and θ^*, in particular showing contraction of the Baum-Welch update towards the true parameter. Our strategy for doing so involves first analyzing the Baum-Welch iterates at the population level, which is the focus of this section.

The quantity $\bar{Q}$ is significant for the EM updates because the parameter θ^* satisfies the self-consistency property $\theta^* = \arg\max_\theta \bar{Q}(\theta \mid \theta^*)$. In the i.i.d. setting, the function $\bar{Q}$ can often be computed in closed form, and hence directly analyzed, as was done in past work Balakrishnan et al. (2014). In the HMM case, this function $\bar{Q}$ no longer has a closed form, so an alternative route is needed. Here we analyze the population version via the truncated function $\bar{Q}^k$ (14) instead, where k is a given truncation level (to be chosen in the sequel). Although θ^* is no longer a fixed point of $\bar{Q}^k$, the bound (17) combined with

the assumption of strong concavity of $\overline{Q}^k$ imply an upper bound on the distance of the maximizers of $\overline{Q}^k$ and $\overline{Q}$.

With this setup, we consider an idealized population-level algorithm that, based on some initialization $\widetilde{\theta}^0 \in \Omega = \mathbb{B}_2\big(r; \mu^*\big) \times \Omega_\beta$, generates the sequence of iterates

$$\widetilde{\theta}^{t+1} = \overline{M}^k(\widetilde{\theta}^t) := \arg\max_{\theta \in \widetilde{\Omega}} \overline{Q}^k(\theta \mid \widetilde{\theta}^t). \tag{18}$$

where $\widetilde{\Omega} = \Omega_\beta \times \Omega_\mu$ is a larger set than Ω, especially $\Omega_\mu = \mathbb{R}^d$. Since $\overline{Q}^k$ is an approximate version of $\overline{Q}$, the update operator $\overline{M}^k$ should be understood as an approximation to the idealized population EM operator $\overline{M}$ where the maximum is taken with respect to $\overline{Q}$. As part (a) of the following theorem shows, the approximation error is well-controlled under suitable conditions. We analyze the convergence of the sequence $\{\widetilde{\theta}^t\}_{t=0}^\infty$ in terms of the norm $\|\cdot\|_\star : \Omega_\mu \times \Omega_\beta \to \mathbb{R}^+$ given by

$$\|\theta - \theta^*\|_\star = \|(\mu, \beta) - (\mu^*, \beta^*)\|_\star := \|\mu - \mu^*\|_2 + \|\beta - \beta^*\|_2. \tag{19}$$

Contraction in this norm implies that both parameters μ, β converge linearly to the true parameter.

Conditions on $\overline{Q}^k$: Let us now introduce the conditions on the truncated function $\overline{Q}^k$ that underlie our analysis. For this purpose, we concentrate on a potentially smaller set

$$\Omega := \mathbb{B}_2(r; \mu^*) \times \Omega_\beta$$

with radius $r > 0$, where Ω_β is the set of allowable HMM transition parameters. The goal is to find the largest $\Omega \subset \widetilde{\Omega}$, in which said conditions are fulfilled. This set Ω is then equivalent to the basin of attraction, i.e. the set in which we can initialize the algorithm and obtain linear convergence to a good optimum.

First, let us say that the function $\overline{Q}^k(\cdot \mid \theta')$ is $(\lambda_\mu, \lambda_\beta)$-*strongly concave* in Ω if for all $\theta' \in \Omega$ we have

$$\overline{Q}_1^k(\mu_1 \mid \theta') - \overline{Q}_1^k(\mu_2 \mid \theta') - \langle \nabla_\mu \overline{Q}_1^k(\mu_2 \mid \theta'), \mu_1 - \mu_2 \rangle \leq -\frac{\lambda_\mu}{2}\|\mu_1 - \mu_2\|_2^2 \tag{20a}$$

and

$$\overline{Q}_2^k(\beta_1 \mid \theta') - \overline{Q}_2^k(\beta_2 \mid \theta') - \langle \nabla_\beta \overline{Q}_2^k(\beta_2 \mid \theta'), \beta_1 - \beta_2 \rangle \leq -\frac{\lambda_\beta}{2}\|\beta_1 - \beta_2\|_2^2 \tag{20b}$$

for all $(\mu_1, \beta_1), (\mu_2, \beta_2) \in \Omega$.

Second, we impose *first-order stability* conditions on the gradients of each component of $\overline{Q}^k$:

- For each $\mu \in \Omega_\mu, \theta' \in \Omega$, we have

$$\|\nabla_\mu \overline{Q}_1^k(\mu \mid \mu', \beta') - \nabla_\mu \overline{Q}_1^k(\mu \mid \mu^*, \beta')\|_2 \leq L_{\mu,1}\|\mu' - \mu^*\|_2 \tag{21a}$$
$$\|\nabla_\mu \overline{Q}_1^k(\mu \mid \mu', \beta') - \nabla_\mu \overline{Q}_1^k(\mu \mid \mu', \beta^*)\|_2 \leq L_{\mu,2}\|\beta' - \beta^*\|_2, \tag{21b}$$

  We refer to this condition as L_μ-FOS for short.
- Secondly, for all $\beta \in \Omega_\beta, \theta' \in \Omega$, we require that

$$\|\nabla_\beta \overline{Q}_2^k(\beta \mid \mu', \beta') - \nabla_\beta \overline{Q}_2^k(\beta \mid \mu^*, \beta')\|_2 \leq L_{\beta,1}\|\mu' - \mu^*\|_2 \tag{22a}$$
$$\|\nabla_\beta \overline{Q}_2^k(\beta \mid \mu', \beta') - \nabla_\beta \overline{Q}_2^k(\beta \mid \mu', \beta^*)\|_2 \leq L_{\beta,2}\|\beta' - \beta^*\|_2. \tag{22b}$$

We refer to this condition as L_β-FOS for short. The experienced reader may find that the (L_μ, L_β)-FOS conditions look intriguingly similar to the Lipschitz gradient conditions often encountered when proving geometric convergence for gradient descent methods. On a high level, smoothness requires function values of one function to be close for any pair of arguments that are close. Although our conditions seem to invoke Lipschitz gradients as well, it is actually of a completely different nature. The important difference arises from the existence of two parameters, as we now clarify.

As opposed to gradient descent, the EM updates optimize over the first parameter θ of a function $\overline{Q}^k(\cdot \mid \theta')$ defined by the second parameter θ' at every time step. If we could access $\overline{Q}^k(\cdot \mid \theta^*)$, EM would converge in one step to the true optimum. Therefore, if we can guarantee that $\overline{Q}^k(\cdot \mid \theta')$ and $\overline{Q}^k(\cdot \mid \theta^*)$ are close in some sense, there should be good reasons to hope that under some more regularity assumptions the maximizers are close as well, i.e. that $\overline{M}^k(\theta')$ is close to θ^*.

The (L_μ, L_β)-FOS conditions are precisely encouraging closeness of these two functions in a first-order sense. In particular, we require the gradients (with respect to the first argument θ) to be Lipschitz in the second argument θ'. Typical smoothness however is a property with respect to a *fixed* function (i.e. a fixed θ' in our case) and thus requires gradients to be Lipschitz in the first argument. Loosely speaking it upper bounds the curvature of said function, and thus is more like a second-order condition by nature. This distinction also explains why (L_μ, L_β)-FOS conditions require to be uniformly satisfied only over the first argument, while one of the second arguments can be fixed at μ^* or β^* respectively. Finally, as we show in Section 4, these conditions hold for concrete models.

Convergence guarantee for $\overline{Q}^k$-updates: We are now equipped to state our main convergence guarantee for the updates. It involves the quantities

$$L := \max\{L_{\mu_1}, L_{\mu_2}\} + \max\{L_{\beta_1}, L_{\beta_2}\}, \quad \lambda := \min\{\lambda_\mu, \lambda_\beta\} \quad \text{and} \quad \kappa := \frac{L}{\lambda}, \tag{23}$$

with κ generally required to be smaller than one, as well as the additive norm $\|\cdot\|_\star$ from equation (19).

Part (a) of the theorem controls the *approximation error* induced by using the k-truncated function $\overline{Q}^k$ as opposed to the exact population function $\overline{Q}$, whereas part (b) guarantees a *geometric rate of convergence* in terms of κ defined above in equation (23).

Theorem 1 *(a)* Approximation guarantee: *Under the mixing condition* (4)*, density boundedness condition* (16)*, and $(\lambda_\mu, \lambda_\beta)$-strong concavity condition* (20)*, there is a universal constant c_0 such that*

$$\|\overline{M}^k(\theta) - \overline{M}(\theta)\|_\star^2 \leq \underbrace{\frac{Cs^4}{\lambda\, \epsilon_{\text{mix}}^9 \overline{\pi}_{\min}^2}\big(1 - \epsilon_{\text{mix}}\overline{\pi}_{\min}\big)^k}_{=:\varphi^2(k)} \qquad \text{for all } \theta \in \Omega, \tag{24}$$

where s is the number of states, and $\overline{\pi}_{\min} := \min_{\beta \in \Omega_\beta} \min_{j \in [s]} \overline{\pi}(j; \beta)$.

(b) Convergence guarantee: *Suppose in addition that the (L_μ, L_β)-FOS conditions* (21),(22) *holds with parameter $\kappa \in (0, 1)$ as defined in* (23) *for $\theta, \theta' \in \Omega = \mathbb{B}_2\big(r; \mu^*\big) \times \Omega_\beta$, and*

that the truncation parameter k is sufficiently large to ensure that

$$\varphi(k) \leq \big(1-\kappa\big) r - \kappa \max_{\beta \in \Omega_\beta} \|\beta - \beta^*\|_2.$$

Then, given an initialization $\widetilde{\theta}^0 \in \Omega$, the iterates $\{\widetilde{\theta}^t\}_{t=0}^{\infty}$ generated by the $\overline{M}^k$ operator satisfy the bound

$$\|\widetilde{\theta}^t - \theta^*\|_\star \leq \kappa^t \|\widetilde{\theta}^0 - \theta^*\|_\star + \frac{1}{1-\kappa}\varphi(k). \tag{25}$$

Note that the subtlety here is that θ^* is no longer a fixed point of the operator $\overline{M}^k$, due to the error induced by the k^{th}-order truncation. Nonetheless, under the mixing condition, as the bounds (24) and (25) show, this approximation error is controlled, and decays exponentially in k. The proof of the recursive bound (25) is based on showing that

$$\|\overline{M}^k(\theta) - \overline{M}^k(\theta^*)\|_\star \leq \kappa \|\theta - \theta^*\|_\star \tag{26}$$

for any $\theta \in \Omega$. Inequality (26) is equivalent to stating that the operator $\overline{M}^k$ is contractive, i.e. that applying $\overline{M}^k$ to the pair θ and θ^* always decreases the distance.

Finally, when Theorem 1 is applied to a concrete model, the task is to find a big r and Ω_β such that the conditions in the theorem are satisfied, and we do so for the Gaussian output HMM in Section 4.

3.3 Sample-based results

We now turn to a result that applies to the sample-based form of the Baum-Welch algorithm—that is, corresponding to the updates that are actually applied in practice. For a tolerance parameter $\delta \in (0,1)$, we let $\varphi_n(\delta, k)$ be the smallest positive scalar such that

$$\mathbb{P}\Big[\sup_{\theta \in \Omega} \|M_n(\theta) - M_n^k(\theta)\|_\star \geq \varphi_n(\delta, k)\Big] \leq \delta. \tag{27a}$$

This quantity bounds the approximation error induced by the k-truncation, and is the sample-based analogue of the quantity $\varphi(k)$ appearing in Theorem 1(a). For each $\delta \in (0,1)$, we let $\epsilon_n^\mu(\delta, k)$ and $\epsilon_n^\beta(\delta, k)$ denote the smallest positive scalars such that

$$\begin{aligned} &\mathbb{P}\big[\sup_{\theta \in \Omega} \|M_n^{\mu,k}(\theta) - \overline{M}^{\mu,k}(\theta)\|_2 \geq \epsilon_n^\mu(\delta, k)\Big] \leq \delta, \quad \text{and} \\ &\mathbb{P}\big[\sup_{\theta \in \Omega} \|M_n^{\beta,k}(\theta) - \overline{M}^{\beta,k}(\theta)\|_2 \geq \epsilon_n^\beta(\delta, k)\Big] \leq \delta, \end{aligned} \tag{27b}$$

where $M_n^{\mu,k}(\cdot)$ and $M_n^{\beta,k}(\cdot)$ correspond to the truncated versions of $M_n^\mu(\cdot)$ and $M_n^\beta(\cdot)$. Furthermore we define $\epsilon_n(\delta, k) := \epsilon_n^\mu(\delta, k) + \epsilon_n^\beta(\delta, k)$. For a given truncation level k, these values give an upper bound on the difference between the population and sample-based M-operators, as induced by having only a finite number n of samples.

Theorem 2 (Sample Baum-Welch) *Suppose that the truncated population EM operator $\overline{M}^k$ satisfies the local contraction bound (26) with parameter $\kappa \in (0,1)$ in Ω. For a given sample size n, suppose that (k, n) are sufficiently large to ensure that*

$$\varphi_n(\delta, k) + \varphi(k) + \epsilon_n^\mu\big(\delta, k\big) \leq (1-\kappa)\, r - \kappa \max_{\beta \in \Omega_\beta} \|\beta - \beta^*\|_2. \tag{28a}$$

Then given any initialization $\widehat{\theta}^0 \in \Omega$, with probability at least $1 - 2\delta$, the Baum-Welch sequence $\{\widehat{\theta}^t\}_{t=0}^{\infty}$ satisfies the bound

$$\|\widehat{\theta}^t - \theta^*\|_\star \leq \underbrace{\kappa^t \|\widehat{\theta}^0 - \theta^*\|_\star}_{\text{Geometric decay}} + \underbrace{\frac{1}{1-\kappa}\Big\{\varphi_n\big(\delta, k\big) + \varphi(k) + \epsilon_n\big(\delta, k\big)\Big\}}_{\text{Residual error } e_n}. \tag{28b}$$

The bound (28b) shows that the distance between $\widehat{\theta}^t$ and θ^* is bounded by two terms: the first decays geometrically as t increases, and the second term corresponds to a residual error term that remains independent of t. Thus, by choosing the iteration number T larger than $\frac{\log(2r/\epsilon)}{\log \kappa}$, we can ensure that the first term is at most ϵ. The residual error term can be controlled by requiring that the sample size n is sufficiently large, and then choosing the truncation level k appropriately. We provide a concrete illustration of this procedure in the following section, where we analyze the case of Gaussian output HMMs. In particular, we can see that the residual error is of the same order as for the MLE and that the required initialization radius is optimal up to constants. Let us emphasize here that k as well as the truncated operators are purely theoretical objects which were introduced for the analysis.

4. Concrete results for the Gaussian output HMM

We now return to the concrete example of a Gaussian output HMM, as first introduced in Section 2.1, and specialize our general theory to it. Before doing so, let us make some preliminary comments about our notation and assumptions. Recall that our Gaussian output HMM is based on $s = 2$ hidden states, using the transition matrix from equation (7), and the Gaussian output densities from equation (8). For convenience of analysis, we let the hidden variables Z_i take values in $\{-1, 1\}$. In addition, we require that the mixing coefficient $\rho_{\text{mix}} = 1 - \epsilon_{\text{mix}}$ is bounded away from 1 in order to ensure that the mixing condition (3) is fulfilled. We denote the upper bound for ρ_{mix} as $b < 1$ so that $\rho_{\text{mix}} \leq b$ and $\epsilon_{\text{mix}} \geq 1 - b$. The feasible set of the probability parameter ζ and its log odds analog $\beta = \frac{1}{2}\log\big(\frac{\zeta}{1-\zeta}\big)$ are then given by

$$\Omega_\zeta = \Big\{\zeta \in \mathbb{R} \mid \frac{1-b}{2} \leq \zeta \leq \frac{1+b}{2}\Big\}, \quad \text{and} \quad \Omega_\beta = \Big\{\beta \in \mathbb{R} \;\mid\; |\beta| < \underbrace{\frac{1}{2}\log\big(\frac{1+b}{1-b}\big)}_{\beta_B}\Big\}. \tag{29}$$

4.1 Explicit form of Baum-Welch updates

We begin by deriving an explicit form of the Baum-Welch updates for this model. Using this notation, the Baum-Welch updates take the form

$$\widehat{\mu}^{t+1} = \frac{1}{n}\sum_{i=1}^{n}(2p(Z_i = 1 \mid x_1^n; \widehat{\theta}^t) - 1)x_i, \tag{30a}$$

$$\widehat{\zeta}^{t+1} = \Pi_{\Omega_\zeta}\left(\frac{1}{n}\sum_{i=1}^{n}\sum_{Z_i} p(Z_i = Z_{i+1} \mid x_1^n; \widehat{\theta}^t)\right), \text{ and} \tag{30b}$$

$$\widehat{\beta}^{t+1} = \frac{1}{2}\log\left(\frac{\widehat{\zeta}^{t+1}}{1-\widehat{\zeta}^{t+1}}\right), \tag{30c}$$

where Π_{Ω_ζ} denotes the Euclidean projection onto the set Ω_ζ. Note that the maximization steps are carried out on the decomposed Q-functions $Q_{1,n}(\cdot \mid \theta^t), Q_{2,n}(\cdot \mid \theta^t)$. In addition, since we are dealing with a one-dimensional quantity β, the projection of the unconstrained maximizer onto the interval Ω_ζ is equivalent to the constrained maximizer over the feasible set Ω_ζ. This step is in general not valid for higher dimensional transition parameters.

4.2 Population and sample guarantees

We now use the results from Section 3 to show that the population and sample-based version of the Baum-Welch updates are linearly convergent in a ball around θ^* of fixed radius. In establishing the population-level guarantee, the key conditions which need to be fulfilled—and the one that are the most technically challenging to establish— are the (L_μ, L_β)-FOS conditions (21), (22). In particular, we want to show that these conditions hold with Lipschitz constants L_μ, L_β that decrease exponentially with the separation of the mixtures. As a consequence, we obtain that for large enough separation $\frac{L}{\lambda} < 1$, i.e. the EM operator is contractive towards the true parameter.

In order to ease notation, our explicit tracking of parameter dependence is limited to the standard deviation σ and Euclidean norm $\|\mu^*\|_2$, which together determine the signal-to-noise ratio $\eta^2 := \frac{\|\mu^*\|_2^2}{\sigma^2}$ of the mixture model. Throughout this section, we therefore use c_0, c_1 to denote universal constants and C_0, C_1 for quantities that do not depend on $(\|\mu^*\|_2, \sigma)$, but may depend on other parameters such as $\overline{\pi}_{\min}$, ρ_{mix}, b, and so on.

We begin by stating a result for the sequence $\{\widetilde{\theta}^t\}_{t=0}^{\infty}$ obtained by repeatedly applying the k-truncated population-level Baum-Welch update operator $\overline{M}^k$. Our first corollary establishes that this sequence is linearly convergent, with a convergence rate $\kappa = \kappa(\eta)$ that is given by

$$\kappa(\eta) := \frac{C_1\eta^2(\eta^2+1)\,\mathrm{e}^{-c_2\eta^2}}{1-b^2}. \tag{31}$$

Corollary 1 (Population Baum-Welch) *Consider a two-state Gaussian output HMM that is mixing (i.e. satisfies equation* (3)*), and with its SNR lower bounded as $\eta^2 \geq C$ for a sufficiently large constant C. Given the radius $r = \frac{\|\mu^*\|_2}{4}$, suppose that the truncation parameter k is sufficiently large to ensure that $\varphi(k) \leq (1-\kappa)r - \kappa\max_{\beta\in\Omega_\beta}\|\beta-\beta^*\|_2$. Then for any initialization $\widetilde{\theta}^0 = (\widetilde{\mu}^0, \widetilde{\beta}^0) \in \mathbb{B}_2\big(r; \mu^*\big) \times \Omega_\beta$, the sequence $\{\widetilde{\theta}^t\}_{t=0}^{\infty}$ generated by $\overline{M}^k$ satisfies the bound*

$$\|\widetilde{\theta}^t - \theta^*\|_\star \leq \kappa^t\|\widetilde{\theta}^0 - \theta^*\|_\star + \frac{1}{1-\kappa}\varphi(k) \tag{32}$$

for all iterations $t = 1, 2, \ldots$.

From definition (31) it follows that as long as the signal-to-noise ratio η is larger than a universal constant, the convergence rate $\kappa(\eta) < 1$. The bound (32) then ensures a type of contraction and the pre-condition $\varphi(k) \leq (1-\kappa)r - \kappa\max_{\beta\in\Omega_\beta}\|\beta-\beta^*\|_2$ can be satisfied by choosing the truncation parameter k large enough. If we use a finite truncation parameter k, then the contraction occurs up to the error floor given by $\varphi(k)$, which reflects the bias introduced by truncating the likelihood to a window of size k. At the population level (in which the effective sample size is infinite), we could take the limit $k \to \infty$ so as to eliminate this bias. However, this is no longer possible in the finite sample setting, in which we must necessarily have $k \ll n$. While large k give a better truncation approximation, it allows for fewer samples which are "sufficiently independent" from each other within the sequence. We can see in the proof of Corollary 2 that $k \gtrsim \log n$ is a good choice to obtain an adequate trade-off.

Corollary 2 (Sample Baum-Welch iterates) *For a given tolerance $\delta \in (0,1)$, suppose that the sample size is lower bounded as $n \geq \frac{C_1}{\|\mu^*\|_2^2\sigma^2}(\eta^2+1)^3 d\log^8(\frac{d}{\delta})$. Then under the conditions of Corollary 1 and $\eta^2 \geq C\log\frac{1}{1-b^2}$, with probability at least $1-\delta$, we have*

$$\|\widetilde{\theta}^t - \theta^*\|_\star \leq \kappa^t\|\widehat{\theta}^0 - \theta^*\|_\star + \frac{C}{\sigma}\frac{\left(\frac{\|\mu^*\|_2^2}{\sigma^2}+1\right)^{3/2}\sqrt{\frac{d\log^8(n/\delta)}{n}}}{1-\kappa}. \tag{33}$$

Remarks: As a consequence of the bound (33), if we are given a sample size $n \gtrsim d\log^8 d$, then taking $T \approx \log n$ iterations is guaranteed to return an estimate $(\widehat{\mu}^T, \widehat{\beta}^T)$ with error of the order $\sqrt{\frac{d\log^8(n)}{n}}$.

In order to interpret this guarantee, note that in the case of symmetric Gaussian output HMMs as in Section 4, standard techniques can be used to show that the minimax rate of estimating μ^* in Euclidean norm scales as $\sqrt{\frac{d}{n}}$. If we could compute the MLE in polynomial time, then its error would also exhibit this scaling. The significance of Corollary 2 is that it shows that the Baum-Welch update achieves this minimax risk of estimation up to logarithmic factors.

Moreover, it should be noted that the initialization radius given here is essentially optimal up to constants. Because of the symmetric nature of the population log-likelihood, the all zeroes vector is a stationary point. Consequently, the maximum Euclidean radius of any basin of attraction for one of the observation parameters—that is, either μ^* or $-\mu^*$—can at most be $r = \|\mu^*\|_2$. Note that our initialization radius only differs from this maximal radius by a small constant factor.

4.3 Simulations

In this section, we provide the results of simulations that confirm the accuracy of our theoretical predictions for two-state Gaussian output HMMs. In all cases, we update the estimates for the mean vector $\widehat{\mu}^{t+1}$ and transition probability $\hat{\zeta}^{t+1}$ according to equation (30); for convenience, we update ζ as opposed to β. The true parameters are denoted by μ^* and ζ^*.

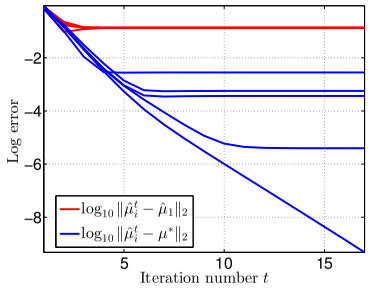

Figure 3: Plot of the convergence of the optimization error $\log\|\widehat{\mu}_i^t - \widehat{\mu}_1\|_2$, plotted in blue, and the statistical error $\log\|\widehat{\mu}_i^t - \mu^*\|_2$, plotted in red, for 5 different initializations. The parameter settings were $d = 10$, $n = 1000$, $\rho_{\mathrm{mix}} = 0.6$ and SNR $\frac{\|\mu^*\|_2}{\sigma} = 1.5$. See the main text for further details.

In all simulations, we fix the mixing parameter to $\rho_{\mathrm{mix}} = 0.6$, generate initial vectors $\widehat{\mu}^0$ randomly in a ball of radius $r := \frac{\|\mu^*\|_2}{4}$ around the true parameter μ^*, and set $\widehat{\zeta}^0 = \frac{1}{2}$. Finally, the estimation error of the mean vector μ is computed as $\log_{10}\|\hat{\mu} - \mu^*\|_2$. Since the transition parameter estimation errors behave similarly to the observation parameter in simulations, we omit the corresponding figures here.

Figure 3 depicts the convergence behavior of the Baum-Welch updates, as assessed in terms of both the optimization and the statistical error. Here we run the Baum-Welch algorithm for a fixed sample sequence X_1^n drawn from a model with SNR $\eta^2 = 1.5$ and $\zeta = 0.2$, using different random initializations in the ball around μ^* with radius $\frac{\|\mu^*\|_2}{4}$. We denote the final estimate of the $i-$th trial by $\widehat{\mu}_i$. The curves in blue depict the *optimization error*—that is, the differences between the Baum-Welch iterates $\widehat{\mu}_i^t$ using the i-th initialization, and $\widehat{\mu}_1$. On the other hand, the red lines represent the *statistical error*—that is, the distance of the iterates from the true parameter μ^*.

For both family of curves, we observe linear convergence in the first few iterations until an error floor is reached. The convergence of the statistical error aligns with the theoretical prediction in upper bound (33) of Corollary 2. The (minimax-optimal) error floor in the curve corresponds to the residual error and the e_n–region in Figure 1. In addition, the blue optimization error curves show that for different initializations, the Baum-Welch algorithm converges to *different stationary points* $\widehat{\mu}_i$; however, all of these points have roughly the same distance from μ^*. This phenomenon highlights the importance of the change of perspective

in our analysis—that is, focusing on the true parameter as opposed to the MLE. Given the presence of all these local optima in a small neighborhood of μ^*, the basin of attraction of the MLE must necessarily be much smaller than the initialization radius guaranteed by our theory.

Figure 4 shows how the convergence rate of the Baum-Welch algorithm depends on the underlying SNR parameter η^2; this behavior confirms the predictions given in Corollary 2. Lines of the same color represent different random draws of parameters given a fix SNR. Clearly, the convergence is linear for high SNR, and the rate decreases with decreasing SNR.

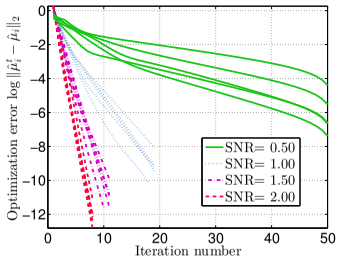

Figure 4: Plot of convergence behavior for different SNR, where for each curve, different parameters were chosen. The parameter settings are $d = 10$, $n = 1000$ and $\rho_{\mathrm{mix}} = 0.6$.

5. Proofs

In this section, we collect the proofs of our main results. In all cases, we provide the main bodies of the proofs here, deferring the more technical details to the appendices.

5.1 Proof of Theorem 1

Throughout this proof, we make use of the shorthand $\widetilde{\rho}_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$. Also we denote the separate components of the population EM operators by $\overline{M}(\theta) =: (\overline{M}^{\mu}(\theta), \overline{M}^{\beta}(\theta))^T$ and their truncated equivalents by $\overline{M}^k(\theta) =: (\overline{M}^{\mu,k}(\theta), \overline{M}^{\beta,k}(\theta))^T$. We begin by proving the bound given in part (a). Since $\overline{Q} = \lim_{n\to\infty}\mathbb{E}[Q_n]$, we have

$$\|\overline{Q} - \overline{Q}^k\|_\infty = \|\lim_{n\to\infty}\mathbb{E}[Q_n] - \overline{Q}^k\|_\infty \leq \frac{Cs^4}{\epsilon_{\mathrm{mix}}^9\overline{\pi}_{\min}^2}\widetilde{\rho}_{\mathrm{mix}}^k,$$

where we have exchanged the supremum and the limit before applying the bound (17). The same holds for the separate functions $\overline{Q}_1, \overline{Q}_2$.

Using this bound and the fact that for $\overline{Q}_1$ we have $\overline{Q}_1(\overline{M}^{\mu}(\theta) \mid \theta) \geq \overline{Q}_1(\overline{M}^{\mu,k}(\theta) \mid \theta)$, we find that

$$\overline{Q}_1(\overline{M}^{\mu}(\theta) \mid \theta) \geq \overline{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta) - \frac{Cs^4}{\epsilon_{\mathrm{mix}}^9\overline{\pi}_{\min}^2}\widetilde{\rho}_{\mathrm{mix}}^k.$$

Since $\overline{M}^{\mu,k}(\theta)$ is optimal, the first-order conditions for optimality imply that

$$\langle \bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta),\, \theta - \overline{M}^{\mu,k}(\theta)\rangle \leq 0 \qquad \text{for all } \theta \in \Omega.$$

Combining this fact with strong concavity of $\bar{Q}^k(\cdot|\theta)$ for all θ, we obtain

$$\begin{aligned}
\frac{Cs^4}{\epsilon_{\min}^9 \bar{\pi}_{\min}^2}\widetilde{\rho}_{\min}^k &\geq \bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta) - \bar{Q}_1(\overline{M}^{\mu}(\theta) \mid \theta) \\
&\geq \bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta) - \bar{Q}_1^k(\overline{M}^{\mu}(\theta) \mid \theta) - \frac{Cs^4}{\epsilon_{\min}^9 \bar{\pi}_{\min}^2}\widetilde{\rho}_{\min}^k \\
&\geq \frac{\lambda_\mu}{2}\|\overline{M}^{\mu}(\theta) - \overline{M}^{\mu,k}(\theta)\|_2^2 - \frac{Cs^4}{\epsilon_{\min}^9 \bar{\pi}_{\min}^2}\widetilde{\rho}_{\min}^k
\end{aligned}$$

and therefore $\|\overline{M}^{\mu}(\theta) - \overline{M}^{\mu,k}(\theta)\|_2^2 \leq 4\frac{Cs^4}{\lambda\epsilon_{\min}^9 \bar{\pi}_{\min}^2}\widetilde{\rho}_{\min}^k$. In particular, setting $\theta = \theta^*$ and identifiability, i.e. $\overline{M}^{\mu}(\theta^*) = \theta^*$, yields

$$\|\overline{M}^{\mu,k}(\theta^*) - \theta^*\|_2^2 \leq 4\frac{Cs^4}{\lambda_\mu \epsilon_{\min}^9 \bar{\pi}_{\min}^2}\widetilde{\rho}_{\min}^k,$$

and the equivalent bound can be obtained for $\overline{M}^{\beta,k}(\cdot)$ which yields the claim.

We now turn to the proof of part (b). Let us suppose that the recursive bound (26) holds, and use it to complete the proof of this claim. We first show that if $\widetilde{\mu}^t \in \mathbb{B}_2(r;\mu^*)$, then we must have $\widetilde{\mu}^{t+1} \in \mathbb{B}_2(r;\mu^*)$ as well. Indeed, if $\widetilde{\mu}^t \in \mathbb{B}_2(r;\mu^*)$, then we have by triangle inequality and contraction in (26)

$$\begin{aligned}
\|\overline{M}^{\mu,k}(\widetilde{\theta}^t) - \mu^*\|_2 &\leq \|\overline{M}^{\mu,k}(\widetilde{\theta}^t) - \overline{M}^{\mu,k}(\theta^*)\|_2 + \|\overline{M}^{\mu,k}(\theta^*) - \mu^*\|_2 \\
&\leq \kappa[\|\widetilde{\mu}^t - \mu^*\|_2 + \|\widetilde{\beta}^t - \beta^*\|_2] + \varphi(k) \\
&\leq \kappa(r + \max_{\beta\in\Omega_\beta}\|\beta - \beta^*\|_2) + \varphi(k) \leq r,
\end{aligned}$$

where the final step uses the assumed bound on φ. For the joint parameter update we in turn have

$$\begin{aligned}
\|\overline{M}^{k}(\widetilde{\theta}^t) - \theta^*\|_\star &\leq \|\overline{M}^{k}(\widetilde{\theta}^t) - \overline{M}^{k}(\theta^*)\|_\star + \|\overline{M}^{k}(\theta^*) - \theta^*\|_\star \\
&\leq \kappa\|\widetilde{\theta}^t - \theta^*\|_\star + \varphi(k). \qquad (34)
\end{aligned}$$

By repeatedly applying inequality (34) and summing the geometric series, the claimed bound (25) follows.

It remains to prove the bound (26). Since the vector $\overline{M}^k(\theta^*)$ maximizes the function $\theta \mapsto \bar{Q}_1^k(\theta \mid \theta^*)$, we have the first-order optimality condition

$$\langle \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta^*) \mid \theta^*),\, \overline{M}^{\mu,k}(\theta) - \overline{M}^{\mu,k}(\theta^*)\rangle \leq 0, \qquad \text{valid for any } \theta.$$

Similarly, we have $\langle \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta),\, \overline{M}^{\mu,k}(\theta^*) - \overline{M}^{\mu,k}(\theta)\rangle \leq 0$, and adding together these two inequalities yields

$$0 \leq \langle \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta^*) \mid \theta^*) - \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta),\, \overline{M}^{\mu,k}(\theta^*) - \overline{M}^{\mu,k}(\theta)\rangle$$

On the other hand, by the λ-strong concavity condition, we have

$$\lambda_\mu\|\overline{M}^{\mu,k}(\theta) - \overline{M}^{\mu,k}(\theta^*)\|_2^2 \leq \langle \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta^*) - \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta^*) \mid \theta^*),\, \overline{M}^{\mu,k}(\theta^*) - \overline{M}^{\mu,k}(\theta)\rangle$$

Combining these two inequalities with the (L_μ, L_β)-FOS condition yields

$$\begin{aligned}
\lambda_\mu\|\overline{M}^{\mu,k}(\theta) - \overline{M}^{\mu,k}(\theta^*)\|_2^2 &\leq \langle \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta^*) - \nabla\bar{Q}_1^k(\overline{M}^{\mu,k}(\theta) \mid \theta),\, \overline{M}^{\mu,k}(\theta^*) - \overline{M}^{\mu,k}(\theta)\rangle \\
&\leq \big[L_{\mu_1}\|\mu - \mu^*\|_2 + L_{\mu_2}\|\beta - \beta^*\|_2\big]\|\overline{M}^{\mu,k}(\theta) - \overline{M}^{\mu,k}(\theta^*)\|_2,
\end{aligned}$$

and similarly we obtain $\lambda_\beta\|\overline{M}^{\beta,k}(\theta) - \overline{M}^{\beta,k}(\theta^*)\|_2 \leq \big[L_{\beta_1}\|\mu - \mu^*\|_2 + L_{\beta_2}\|\beta - \beta^*\|_2\big]$. Adding both inequalities yields the claim (26).

5.2 Proof of Theorem 2

By the triangle inequality and inequality (34), we have with probability at least $1 - 2\delta$ that for any iteration

$$\begin{aligned}
\|\widehat{\theta}^{t+1} - \theta^*\|_\star &\leq \|M_n(\widehat{\theta}^t) - M_n^k(\widehat{\theta}^t)\|_\star + \|M_n^k(\widehat{\theta}^t) - \overline{M}^k(\widehat{\theta}^t)\|_\star + \|\overline{M}^k(\widehat{\theta}^t) - \theta^*\|_\star \\
&\leq \varphi_n(\delta,k) + \epsilon_n(\delta,k) + \kappa\|\widehat{\theta}^t - \theta^*\|_\star + \varphi(k).
\end{aligned}$$

In order to see that the iterates do not leave $\mathbb{B}_2\big(r;\mu^*\big)$, observe that

$$\begin{aligned}
\|\widehat{\mu}^{t+1} - \mu^*\|_2 &\leq \|M_n^\mu(\widehat{\theta}^t) - M_n^{\mu,k}(\widehat{\theta}^t)\|_2 + \|M_n^{\mu,k}(\widehat{\theta}^t) - \overline{M}^{\mu,k}(\widehat{\theta}^t)\|_2 + \|\overline{M}^{\mu,k}(\widehat{\theta}^t) - \mu^*\|_2 \\
&\leq \varphi_n(\delta,k) + \epsilon_n^\mu(\delta,k) + \kappa(\|\widehat{\mu}^t - \mu^*\|_2 + \max_{\beta\in\Omega_\beta}\|\beta - \beta^*\|_2) + \varphi(k). \qquad (35)
\end{aligned}$$

Consequently, as long as $\|\widehat{\mu}^t - \mu^*\|_2 \leq r$, we also have $\|\widehat{\mu}^{t+1} - \mu^*\|_2 \leq r$ whenever

$$\varphi_n(\delta,k) + \varphi(k) + \epsilon_n^\mu(\delta,k) \leq (1-\kappa)\,r - \kappa\max_{\beta\in\Omega_\beta}\|\beta - \beta^*\|_2.$$

Combining inequality (35) with the equivalent bound for β, we obtain

$$\|\widehat{\theta}^t - \theta^*\|_\star \leq \kappa\|\widehat{\theta}^{t-1} - \theta^*\|_\star + \varphi_n(\delta,k) + \epsilon_n(\delta,k) + \varphi(k)$$

Summing the geometric series yields the bound (28b).

5.3 Proof of Corollary 1

The boundedness condition (Assumption (16)) is easy to check since for $X \sim N(\mu^*, \sigma^2)$, the quantity $\sup_{\mu\in\mathbb{B}_2(r;\mu^*)} \mathbb{E}\big[\max\{\|X - \mu\|_2, \|X + \mu\|_2\}\big]$ is finite for any choice of radius $r < \infty$.

By Theorem 1, the k-truncated population EM iterates satisfy the bound

$$\|\widetilde{\theta}^t - \theta^*\|_\star \leq \kappa^t\|\widetilde{\theta}^0 - \theta^*\|_\star + \frac{1}{1-\kappa}\varphi(k), \qquad (36)$$

if the strong concavity (20) and FOS conditions (21), (22) hold with suitable parameters.

In the remainder of proof—and the bulk of the technical work— we show that:

- strong concavity holds with $\lambda_\mu = 1$ and $\lambda_\beta \geq \frac{2}{3}(1 - b^2)$;

- the FOS conditions hold with

$$L_{\mu,1} = c\ (\eta^2+1)\varphi_2(\epsilon_{\mathrm{mix}})\eta^2 \mathrm{e}^{-c\eta^2}, \quad \text{and} \quad L_{\mu,2} = c\sqrt{\|\mu^*\|_2^2+\sigma^2}\varphi_2(\epsilon_{\mathrm{mix}})\eta^2\mathrm{e}^{-c\eta^2}$$
$$L_{\beta,1} = c\frac{1-b}{1+b}\varphi_2(\epsilon_{\mathrm{mix}})\eta^2\mathrm{e}^{-c\eta^2} \quad \text{and} \quad L_{\beta,2} = c\sqrt{\|\mu^*\|_2^2+\sigma^2}\varphi_2(\epsilon_{\mathrm{mix}})\eta^2\mathrm{e}^{-c\eta^2},$$

where $\varphi_2(\epsilon_{\mathrm{mix}}) := \left(\frac{1}{\log(1/(1-\epsilon_{\mathrm{mix}}))} + \frac{1}{\epsilon_{\mathrm{mix}}}\right)$. Substuting these choices into the bound (36) and performing some algebra yields the claim.

5.3.1 Establishing strong concavity

We first show concavity of $\overline{Q}_1^k(\cdot \mid \theta')$ and $\overline{Q}_2^k(\cdot \mid \theta')$ separately. For strong concavity of $\overline{Q}_1^k(\cdot \mid \theta')$, observe that

$$\overline{Q}_1^k(\mu \mid \theta') = -\frac{1}{2}\mathbb{E}\left[p(z_0 = 1 \mid X_{-k}^k; \theta')\|X_0 - \mu\|_2^2 + (1 - p(z_0 = 1|X_{-k}^k; \theta'))\|X_0 + \mu\|_2^2 + c\right],$$

where c is a quantity independent of μ. By inspection, this function is strongly concave in μ with parameter $\lambda_\mu = 1$.

On the other hand, we have

$$\overline{Q}_2^k(\beta \mid \theta') = \mathbb{E}_{X_{-k}^k|\theta^*} \sum_{z_0,z_1} p(z_0, z_1 \mid X_{-k}^k; \theta') \log\left(\frac{\mathrm{e}^{\beta z_0 z_1}}{\mathrm{e}^{\beta} + \mathrm{e}^{-\beta}}\right).$$

This function has second derivative $\frac{\partial^2}{\partial\beta^2}\overline{Q}_2^k(\beta \mid \theta') = -4\frac{\mathrm{e}^{-2\beta}}{(\mathrm{e}^{-2\beta}+1)^2}$. As a function of $\beta \in \Omega_\beta$, this second derivative is maximized at $\beta = \frac{1}{2}\log\left(\frac{1+b}{1-b}\right)$. Consequently, the function $\overline{Q}_2^k(\cdot \mid \theta')$ is strongly concave with parameter $\lambda_\beta \geq \frac{2}{3}(1-b^2)$.

5.3.2 Separate FOS conditions

We now turn to proving that the FOS conditions in equations (21) and (22) hold. A key ingredient in our proof is the fact that the conditional density $p(z_{-k}^k \mid x_{-k}^k; \mu, \beta)$ belongs to the exponential family with parameters $\beta \in \mathbb{R}$, and $\gamma_i := \frac{\langle \mu, x_i\rangle}{\sigma^2} \in \mathbb{R}$ for $i = -k, \ldots, k$ which define the vector $\gamma = (\gamma_{-k}, \ldots, \gamma_k)$ (see Wainwright and Jordan (2008) for more details on exponential families.) In particular, we have

$$\underbrace{p(z_{-k}^k \mid x_{-k}^k, \mu, \beta)}_{:=p(z_{-k}^k;\gamma,\beta)} = \exp\left\{\sum_{\ell=-k}^{k}\gamma_\ell z_\ell + \beta\sum_{\ell=-k}^{k-1} z_\ell z_{\ell+1} - \Phi(\gamma,\beta)\right\}, \tag{37}$$

where the function h absorbs various coupling terms. Note that this exponential family is a specific case of the following exponential family distribution

$$\underbrace{\tilde{p}(z_{-k}^k \mid x_{-k}^k, \mu, \beta)}_{:=\tilde{p}(z_{-k}^k;\gamma,\beta)} = \exp\left\{\sum_{\ell=-k}^{k}\gamma_\ell z_\ell + \sum_{\ell=-k}^{k-1}\beta_\ell z_\ell z_{\ell+1} - \Phi(\gamma,\beta)\right\}. \tag{38}$$

The distribution in (37) corresponds to (38) with $\beta_\ell = \beta$ for all ℓ and the so-called partition function Φ is given by

$$\Phi(\gamma,\beta) = \log\sum_z \exp\left\{\sum_{\ell=-k}^{k}\gamma_\ell z_\ell + \sum_{\ell=-k}^{k-1}\beta_\ell z_\ell z_{\ell+1}\right\}.$$

The reason to view our distribution as a special case of the more general one in (38) becomes clear when we consider the equivalence of expectations and the derivatives of the cumulant function

$$\left.\frac{\partial\Phi}{\partial\gamma_\ell}\right|_{\theta'} = \mathbb{E}_{Z_{-k}^k|x_{-k}^k,\theta'}Z_\ell \quad \text{and} \quad \left.\frac{\partial\Phi}{\partial\beta_0}\right|_{\theta'} = \mathbb{E}_{Z_{-k}^k|x_{-k}^k,\theta'}Z_0Z_1, \tag{39}$$

where we recall that $\mathbb{E}_{Z_{-k}^k|x_{-k}^k,\theta'}$ is the expectation with respect to the distribution $\tilde{p}(Z_{-k}^k \mid x_{-k}^k; \mu', \beta')$ with $\beta_\ell = \beta'$. Note that in the following any value θ' for $\tilde{p}$ is taken to be on the manifold on which $\beta_\ell = \beta'$ for some β' since this is the manifold the algorithm works on. Also, as before, $\mathbb{E}$ denotes the expectation over the joint distribution of all samples X_ℓ drawn according to $p(\cdot;\theta^*)$, in this case X_{-k}^k.

Similarly to equations (39), the covariances of the sufficient statistics correspond to the second derivatives of the cumulant function

$$\left.\frac{\partial^2\Phi}{\partial\beta_\ell\partial\beta_0}\right|_{\theta} = \mathrm{cov}(Z_0Z_1, Z_\ell Z_{\ell+1} \mid X_{-k}^k, \theta) \tag{40a}$$
$$\left.\frac{\partial^2\Phi}{\partial\gamma_\ell\partial\gamma_0}\right|_{\theta} = \mathrm{cov}(Z_0, Z_\ell \mid X_{-k}^k, \theta) \tag{40b}$$
$$\left.\frac{\partial^2\Phi}{\partial\beta_\ell\partial\gamma_0}\right|_{\theta} = \mathrm{cov}(Z_0, Z_\ell Z_{\ell+1} \mid X_{-k}^k, \theta). \tag{40c}$$

In the following, we adopt the shorthand

$$\begin{aligned}\mathrm{cov}(Z_\ell, Z_{\ell+1} \mid \gamma', \beta') &= \mathrm{cov}(Z_\ell, Z_{\ell+1} \mid X_{-k}^k, \theta') \\ &= \mathbb{E}_{Z_\ell^{\ell+1}|X_{-k}^k,\theta'}(Z_\ell - \mathbb{E}_{Z_\ell^{\ell+1}|X_{-k}^k,\theta'}Z_\ell)(Z_{\ell+1} - \mathbb{E}_{Z_\ell^{\ell+1}|X_{-k}^k,\theta'}Z_{\ell+1})\end{aligned}$$

where the dependence on β is occasionally omitted so as to simplify notation.

5.3.3 Proof of inequality (21a)

By an application of the mean value theorem, we have

$$\|\nabla_\mu\overline{Q}_1^k(\mu \mid \mu', \beta') - \nabla_\mu\overline{Q}_1^k(\mu \mid \mu^*, \beta')\| \leq \underbrace{\left\|\mathbb{E}\sum_{\ell=-k}^{k}\left.\frac{\partial^2\Phi}{\partial\gamma_\ell\partial\gamma_0}\right|_{\theta=\widetilde{\theta}}(\gamma'_\ell - \gamma^*_\ell)X_0\right\|}_{T_1}$$

where $\widetilde{\theta} = \theta' + t(\theta^* - \theta')$ for some $t \in (0,1)$. Since second derivatives yield covariances (see equation (40)), we can write

$$T_1 = \left\|\sum_{\ell=-k}^{k}\mathbb{E}X_0\mathbb{E}\left[\mathrm{cov}(Z_0, Z_\ell \mid \widetilde{\gamma})\frac{\langle\mu' - \mu^*, X_\ell\rangle}{\sigma^2}\middle| X_0\right]\right\|_2,$$

so that it suffices to control the expected conditional covariance. By the Cauchy-Schwarz inequality and the fact that $\operatorname{cov}(X,Y) \leq \sqrt{\operatorname{var} X}\sqrt{\operatorname{var} Y}$ and $\operatorname{var}(Z_0 \mid X) \leq 1$, we obtain the following bound on the expected conditional covariance by using Lemma 4 (see Appendix B)

$$\begin{aligned}\mathbb{E}\left[\left|\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma}) \mid X_0\right|\right] &\leq \sqrt{\mathbb{E}\left[\operatorname{var}(Z_0 \mid \widetilde{\gamma}) \mid X_0\right]}\sqrt{\mathbb{E}\left[\operatorname{var}(Z_\ell \mid \widetilde{\gamma}) \mid X_0\right]} \\ &\leq \sqrt{\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0)}. \end{aligned} \tag{41a}$$

Furthermore, by Lemma 5 and 6 (see Appendix B), we have

$$|\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma})| \leq 2\rho_{\mathrm{mix}}^{\ell}, \quad \text{and} \quad \left\|\mathbb{E}(\operatorname{var}(Z_0|\widetilde{\gamma}_0))^{1/2} X_0 X_0^T\right\|_{op} \leq C\mathrm{e}^{-c\eta^2}. \tag{41b}$$

From the definition of the operator norm, we have

$$\begin{aligned}\|\mathbb{E}\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma}) X_0 X_\ell^T\|_{op} &= \sup_{\substack{\|u\|_2=1 \\ \|v\|_2=1}} \mathbb{E}\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma})\langle X_0,\, v\rangle\,\langle X_\ell,\, u\rangle \\ &\leq \sup_{\|v\|_2=1} \mathbb{E}|\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma})|\langle X_0,\, v\rangle^2 \\ &+ \sup_{\|u\|_2=1} \mathbb{E}|\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma})|\langle X_\ell,\, u\rangle^2 \\ &= \|\mathbb{E} X_0 X_0^T \mathbb{E}\big[|\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma}) \mid X_0\big]\|_{op} \\ &+ \|\mathbb{E} X_\ell X_\ell^T \mathbb{E}\big[\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma}) \mid X_\ell\big]\|_{op} \\ &\overset{(i)}{\leq} 2\min\{\rho_{\mathrm{mix}}^{|\ell|}\|\mathbb{E} X_0 X_0^T\|_{op}, \|\mathbb{E}\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0)^{1/2} X_0 X_0^T\|_{op}\} \\ &\overset{(ii)}{\leq} 2\min\{(\|\mu^*\|_2^2 + \sigma^2)\rho_{\mathrm{mix}}^{|\ell|}, C'\mathrm{e}^{-c\eta^2}\}, \end{aligned} \tag{42}$$

where inequality (i) makes use of inequalities (41a) and (41b), and step (ii) makes use of the second inequality in line (41b).

By inequality (42), we find that

$$\begin{aligned} T_1 &\leq \frac{\|\mu' - \mu^*\|_2}{\sigma^2} \sum_{\ell=-k}^{k} \|\mathbb{E}\operatorname{cov}(Z_0, Z_\ell \mid \widetilde{\gamma}) X_0 X_\ell^T\|_{op} \\ &\leq 2\frac{\|\mu' - \mu^*\|_2}{\sigma^2} \sum_{\ell=-k}^{k} \min\{(\|\mu^*\|_2^2 + \sigma^2)\rho_{\mathrm{mix}}^{|\ell|}, C\mathrm{e}^{-c\eta^2}\} \\ &\leq 4(\eta^2+1)\big(mC\mathrm{e}^{-c\eta^2} + \frac{\rho_{\mathrm{mix}}^m}{1-\rho_{\mathrm{mix}}}\big)\|\mu' - \mu^*\|_2. \end{aligned}$$

where $m = \frac{c\eta^2}{\log(1/\rho_{\mathrm{mix}})}$ is the smallest integer such that $\rho_{\mathrm{mix}}^m \leq C\mathrm{e}^{-c\eta^2}$ The last inequality follows from the proof of Corollary 1 in the paper Balakrishnan et al. (2014) if $\eta^2 > C$ for some universal constant C. We have thus shown that

$$\|\nabla_\mu \overline{Q}_1^k(\mu \mid \mu', \beta') - \nabla_\mu \overline{Q}_1^k(\mu \mid \mu^*, \beta')\| \leq L_{\mu,1}\|\mu' - \mu^*\|_2,$$

where $L_{\mu,1} = c\ \varphi_1(\eta)\varphi_2(\epsilon_{\mathrm{mix}})\eta^2(\eta^2+1)\mathrm{e}^{-c\eta^2}$ as claimed.

5.3.4 Proof of inequality (21b)

The same argument via the mean value theorem guarantees that

$$\|\frac{\partial}{\partial\beta}\overline{Q}_2^k(\beta \mid \mu', \beta') - \frac{\partial}{\partial\beta}\overline{Q}_2^k(\beta \mid \mu', \beta^*)\| \leq \left\|\mathbb{E}\sum_{\ell=-k}^{k} \frac{\partial^2\Phi}{\partial\beta_\ell\partial\gamma_0}\Big|_{\theta=\widetilde{\theta}}(\beta' - \beta^*)X_0\right\|_2.$$

In order to bound this quantity, we again use the equivalence (40) and bound the expected conditional covariance. Furthermore, Lemma 5 and 6 yield

$$\operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}) \overset{(i)}{\leq} 2\rho_{\mathrm{mix}}^{\ell} \quad \text{and} \quad \left\|\mathbb{E}\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0) X_0 X_0^T\right\|_{op} \overset{(ii)}{\leq} c\mathrm{e}^{-c\eta^2}. \tag{43}$$

Here inequality (ii) follows by combining inequality (54c) from Lemma 5 with the fact that $\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0) \leq 1$.

$$\begin{aligned}\|\mathbb{E} X_0 \operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma})\|_2 &= \sup_{\|u\|_2=1} \mathbb{E}\langle X_0, u\rangle \operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}) \\ &\leq \sup_{\|u\|_2=1} \mathbb{E}|\langle X_0, u\rangle|\mathbb{E}\big[|\operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma})| \mid X_0\big] \\ &\overset{(iii)}{\leq} \sup_{\|u\|_2=1} \mathbb{E}|\langle X_0, u\rangle| \min\{\rho_{\mathrm{mix}}^{|\ell|}, (\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0))^{1/2}\} \\ &\overset{(iv)}{\leq} \min\{\sup_{\|u\|_2=1} \sqrt{\mathbb{E}\langle X_0, u\rangle^2}\rho_{\mathrm{mix}}^{|\ell|}, \sup_{\|u\|_2=1} \sqrt{\mathbb{E}\langle X_0, u\rangle^2 \operatorname{var}(Z_0 \mid \widetilde{\gamma}_0))}\} \\ &\overset{(v)}{\leq} \min\{\rho_{\mathrm{mix}}^{|\ell|}\sqrt{\|\mathbb{E} X_0 X_0^T\|_{op}}, \sqrt{\|\mathbb{E}\operatorname{var}(Z_0 \mid \widetilde{\gamma}_0) X_0 X_0^T\|_{op}}\} \\ &\overset{(vi)}{\leq} \min\{\rho_{\mathrm{mix}}^{|\ell|}\sqrt{\|\mu^*\|_2^2 + \sigma^2}, C\mathrm{e}^{-c\eta^2}\} \end{aligned}$$

where step (iii) uses inequality (43); step (iv) follows from the Cauchy-Schwarz inequality; step (v) follows from the definition of the operator norm; and step (vi) uses inequality (43) again.

Putting together the pieces, we find that

$$\begin{aligned}\left\|\mathbb{E}\sum_{\ell=-k}^{k} \frac{\partial^2\Phi}{\partial\beta_\ell\partial\gamma_0} X_0\right\|_2 |\beta' - \beta^*| &\leq \sum_{\ell=-k}^{k} \|\mathbb{E} X_0 \mathbb{E}[\operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}) \mid X_0]\|_2 |\beta' - \beta^*| \\ &\leq 4\sqrt{\|\mu^*\|_2^2 + \sigma^2}\left(c\,m\,\mathrm{e}^{-c\eta^2} + \frac{\rho_{\mathrm{mix}}^m}{1-\rho_{\mathrm{mix}}}\right)|\beta' - \beta^*|. \end{aligned}$$

again with $m = \frac{c\eta^2}{\log(1/\rho_{\mathrm{mix}})}$, we find that inequality (21b) holds with $L_{\mu,2} = c\varphi_2(\epsilon_{\mathrm{mix}})\sqrt{\|\mu^*\|_2 + \sigma^2}\eta^2\mathrm{e}^{-c\eta^2}$, as claimed.

5.3.5 Proof of inequality (22a)

By the same argument via the mean value theorem, we find that

$$\|\frac{\partial}{\partial\beta}\overline{Q}_2^k(\beta \mid \beta', \mu') - \frac{\partial}{\partial\beta}\overline{Q}_2^k(\beta \mid \beta', \mu^*)\| \leq \left|\mathbb{E}\sum_{\ell=-k}^{k} \frac{\partial^2\Phi}{\partial\gamma_\ell\partial\beta_0}\Big|_{\theta=\widetilde{\theta}} \frac{\langle\mu' - \mu^*, X_\ell\rangle}{\sigma^2}\right|.$$

Equation (40) guarantees that $\frac{\partial^2 \Phi}{\partial \gamma_\ell \partial \beta_0} = \operatorname{cov}(Z_0 Z_1, Z_\ell \mid \gamma)$. Therefore, by similar arguments as in the proof of inequalities (21), we have

$$\begin{aligned} T &:= \Big| \sum_{\ell=-k}^{k} \mathbb{E}\langle \mu' - \mu^*, X_\ell \rangle \mathbb{E}[\operatorname{cov}(Z_0 Z_1, Z_\ell \mid \widetilde{\gamma}_\ell, \beta') | X_\ell] \Big| \\ &\leq \Big| \sum_{\ell=-k}^{k} \mathbb{E}|\langle \mu' - \mu^*, X_\ell \rangle| \min\{\rho_{\mathrm{mix}}^{|\ell|}, (\operatorname{var}(Z_\ell \mid \widetilde{\gamma}_\ell, \beta'))^{1/2}\} \Big| \\ &\leq \Big| \sum_{\ell=-k}^{k} \min\big\{\rho_{\mathrm{mix}}^{|\ell|}, \sqrt{\mathbb{E}\operatorname{var}(Z_\ell \mid \widetilde{\gamma}_\ell, \beta')}\big\} \sqrt{\mathbb{E}\langle \mu' - \mu^*, X_\ell \rangle^2} \Big| \\ &\leq \sqrt{\|\mu^*\|_2^2 + \sigma^2} \big(mc\, \mathrm{e}^{-c\eta^2} + 2 \sum_{\ell=m+1}^{k} \rho_{\mathrm{mix}}^{\ell} \big). \end{aligned}$$

where we have used inequality (54b) from Lemma 6. Finally, again noting that $m = \frac{c\eta^2}{\log(1/\rho_{\mathrm{mix}})}$ yields that the FOS condition holds with $L_{\beta,2} = c\sqrt{\|\mu^*\|_2 + \sigma^2}\varphi_2(\epsilon_{\mathrm{mix}})\eta^2 \mathrm{e}^{-c\eta^2}$, as claimed.

5.3.6 Proof of inequality (22b)

By the same mean value argument, we find that

$$\|\frac{\partial}{\partial \beta} \overline{Q}_2^k(\beta \mid \beta', \mu') - \frac{\partial}{\partial \beta} \overline{Q}_2^k(\beta \mid \beta^*, \mu')\| \leq \Big| \mathbb{E} \sum_{\ell=-k}^{k} \frac{\partial^2 \Phi}{\partial \beta_\ell \partial \beta_0} \Big|_{\theta = \widetilde{\theta}} (\beta' - \beta^*) \Big|.$$

By the exponential family view in equality (40) it suffices to control the expected conditional covariance. Lemma 5 and 6 guarantee that

$$|\operatorname{cov}(Z_0 Z_1, Z_\ell Z_{\ell+1} \mid X_{-k}^k, \widetilde{\gamma})| \leq \rho_{\mathrm{mix}}^{|\ell|}, \quad \text{and} \quad \mathbb{E}\operatorname{var}(Z_0 Z_1 \mid \widetilde{\gamma}_0^1, \widetilde{\beta}) \leq c\, \frac{1+b}{1-b}\, \mathrm{e}^{-c\eta^2}. \tag{44}$$

Furthermore, the Cauchy-Schwarz inequality combined with the bound (53a) from Lemma 4 yields

$$\begin{aligned} \mathbb{E}\big|\operatorname{cov}(Z_0 Z_1, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma})\big| &\leq \sqrt{\mathbb{E}\operatorname{var}(Z_0 Z_1 \mid \widetilde{\gamma}, \widetilde{\beta})} \sqrt{\mathbb{E}\operatorname{var}(Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}, \widetilde{\beta})} \\ &\leq \sqrt{\mathbb{E}\operatorname{var}(Z_0 Z_1 \mid \widetilde{\gamma}_0^1, \widetilde{\beta})} \sqrt{\mathbb{E}\operatorname{var}(Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}_\ell^{\ell+1}, \widetilde{\beta})} \\ &\leq \mathbb{E}\operatorname{var}(Z_0 Z_1 \mid \widetilde{\gamma}_0^1, \widetilde{\beta}). \end{aligned} \tag{45}$$

Combining the bounds (44) and (45) yields

$$\begin{aligned} \Big| \sum_{\ell=-k}^{k} \mathbb{E} \frac{\partial^2 \Phi}{\partial \beta_\ell \partial \beta_0} (\beta' - \beta^*) \Big| &\leq \sum_{\ell=-k}^{k} \big| \mathbb{E}\operatorname{cov}(Z_0 Z_1, Z_\ell Z_{\ell+1} \mid \widetilde{\gamma}_{-k}^k, \widetilde{\beta}) \big|\, |\beta' - \beta^*| \\ &\leq \sum_{\ell=-k}^{k} \min\Big\{ \rho_{\mathrm{mix}}^{|\ell|}, \mathbb{E}\operatorname{var}(Z_0 Z_1 \mid \widetilde{\gamma}_0^1, \widetilde{\beta}) \Big\} |\beta' - \beta^*| \\ &\leq 2 \left(c \frac{1+b}{1-b}\, m \mathrm{e}^{-c\eta^2} + \sum_{l=m+1}^{k} \rho_{\mathrm{mix}}^{\ell} \right) |\beta' - \beta^*| \\ &\leq 2c \frac{1+b}{1-b} \varphi_2(\epsilon_{\mathrm{mix}}) \eta^2 \mathrm{e}^{-c\eta^2} |\beta' - \beta^*| \end{aligned}$$

where the final inequality follows by setting $m = \frac{c\eta^2}{\log(1/\rho_{\mathrm{mix}})}$. Therefore, the FOS condition holds with $L_{\beta,1} = c\frac{1-b}{1+b}\varphi_2(\epsilon_{\mathrm{mix}})\eta^2 \mathrm{e}^{-c\eta^2}$, as claimed.

5.4 Proof of Corollary 2

In order to prove this corollary, it is again convenient to separate the updates on the mean vectors μ from those applied to the transition parameter β. Recall the definitions of φ, φ_n and ϵ_n from equations (24) and (27a) respectively, as well as $\widetilde{\rho}_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}} \overline{\pi}_{\min}$.

Using Theorem 2 we readily have that given any initialization $\widehat{\theta}^0 \in \Omega$, with probability at least $1 - 2\delta$, we are guaranteed that

$$\|\widehat{\theta}^T - \theta^*\|_\star \leq \kappa^T \|\widehat{\theta}^0 - \theta^*\|_\star + \frac{\varphi_n(\delta, k) + \epsilon_n(\delta, k) + \varphi(k)}{1 - \kappa}. \tag{46}$$

In order to leverage the bound (46), we need to find appropriate upper bounds on the quantities $\varphi_n(\delta, k)$, $\epsilon_n(\delta, k)$.

Lemma 1 *Suppose that the truncation level satisifes the lower bound*

$$k \geq \log\left(\frac{C_\epsilon n}{\delta}\right) \left(\log \frac{1}{\widetilde{\rho}_{\mathrm{mix}}}\right)^{-1} \qquad \text{where } C_\epsilon := \frac{C}{\epsilon_{\mathrm{mix}}^3 \overline{\pi}_{\min}^3}. \tag{47a}$$

Then, when the number of observations n satifies the lower bound in the assumptions of the corollary and the radius is chosen to be $r = \frac{\|\mu^*\|_2}{4}$, *we have*

$$\epsilon_n^{\mu}(\delta, k) \leq C_0 \frac{1}{\sigma} \big(\frac{\|\mu^*\|_2^2}{\sigma^2} + 1 \big)^{3/2} \log(k^2/\delta) \sqrt{\frac{k^3 d \log n}{n}}, \quad \text{and} \tag{47b}$$

$$\epsilon_n^{\beta}(\delta, k) \leq C_0\, \frac{1}{\sigma} \sqrt{\frac{\|\mu^*\|_2^2}{\sigma^2} + 1} \sqrt{\frac{k^3 \log(k^2/\delta)}{n}}. \tag{47c}$$

Lemma 2 *Suppose that* $\frac{1}{2}\frac{\log\left(C_\epsilon n/\delta\right)}{\log(1/\widetilde{\rho}_{\mathrm{mix}})} \leq k \leq C\frac{\log\left(C_\epsilon n/\delta\right)}{\log(1/\widetilde{\rho}_{\mathrm{mix}})}$ *with* $C > 1$. *Then by choosing* $r = \frac{\|\mu^*\|_2}{4}$ *and* C_1 *large enough, we have*

$$\varphi_n(\delta, k) \leq C_1 \left\{ \sqrt{\frac{d \log^2(C_\epsilon n/\delta)}{\sigma n}} + \sqrt{\frac{\|\mu^*\|_2}{\sigma} \frac{\log^2(C_\epsilon n/\delta)}{n}} + \frac{\|\mu^*\|_2}{\sigma} \sqrt{\frac{\delta}{n}} \right\}. \tag{48}$$

See Appendices C.1 and C.2, respectively, for the proofs of these two lemmas.

Note that the set for which k simultaneously satisfies the conditions in Lemma 1 and 2 is nonempty. Furtheremore, the choice of k is made purely for analysis purposes – it does not have any consequence on the Using these two lemmas, we can now complete the proof of the corollary. From the definition (31) of κ, under the stated lower bound on η^2, we can ensure that $\kappa \leq \frac{1}{2}$. Under this condition, inequality (28a) with $r = \|\mu^*\|_2/4$ reduces to showing that

$$\varphi_n(\delta, k) + \epsilon_n^{\mu}(\delta, k) + \varphi(k) \leq \frac{\|\mu^*\|_2}{8}. \tag{49}$$

Now any choice of k satisfying both conditions in Lemmas 1 and 2 guarantees that

$$\varphi_n(\delta, k) + \epsilon_n^{\mu}(\delta, k) + \epsilon_n^{\beta}(\delta, k) + \varphi(k) \leq \frac{C}{\sigma}\Big(\frac{\|\mu^*\|_2^2}{\sigma^2} + 1\Big)^{3/2}\sqrt{\frac{d\log^8(n/\delta)}{n}}. \tag{50}$$

Furthermore, as long as $n \geq \frac{C_1}{\|\mu^*\|_2^2\sigma^2}(\eta^2+1)^3 d\log^8(d/\delta)$ for a sufficiently large C_1, we are guaranteed that the bound (49) holds. Substituting the bound (50) into inequality (46) completes the proof of the corollary.

6. Discussion

In this paper, we provided general global convergence guarantees for the Baum-Welch algorithm as well as specific results for a hidden Markov mixture of two isotropic Gaussians. In contrast to the classical perspective of focusing on the MLE, we focused on bounding the distance between the Baum-Welch iterates and the true parameter. Under suitable regularity conditions, our theory guarantees that the iterates converge to an e_n-ball of the true parameter, where e_n represents a form of statistical error. It is important to note that our theory does not guarantee convergence to the MLE itself, but rather to a ball that contains the true parameter, and asymptotically the MLE as well. When applied to the Gaussian mixture HMM, we proved that the Baum-Welch algorithm achieves estimation error that is minimax optimal up to logarithmic factors. To the best of our knowledge, these are the first rigorous guarantees for the Baum-Welch algorithm that allow for a large initialization radius.

Appendix A. Proof of Proposition 1

In order to show that the limit $\lim_{n\to\infty}\mathbb{E}Q_n(\theta \mid \theta')$ exists, it suffices to show that the sequence of functions $\{\mathbb{E}Q_1, \mathbb{E}Q_2, \ldots, \mathbb{E}Q_n\}$ is Cauchy in the sup-norm (as defined previously in equation (15)). In particular, it suffices to show that for every $\epsilon > 0$ there is a positive integer $N(\epsilon)$ such that for $m, n \geq N(\epsilon)$,

$$\|\mathbb{E}Q_m - \mathbb{E}Q_n\|_\infty \leq \epsilon.$$

In order to do so, we make use of the previously stated bound (17) relating $\mathbb{E}Q_n$ to $\bar{Q}^k$. Taking this bound as given for the moment, an application of the triangle inequality yields

$$\|\mathbb{E}Q_m - \mathbb{E}Q_n\|_\infty \leq \|\mathbb{E}Q_m - \bar{Q}^k\|_\infty + \|\mathbb{E}Q_n - \bar{Q}^k\|_\infty \;\leq\; \epsilon,$$

the final inequality follows as long as we choose $N(\epsilon)$ and k large enough (roughly proportional to $\log(1/\epsilon)$).

It remains to prove the claim (17). In order to do so, we require an auxiliary lemma:

Lemma 3 (Approximation by truncation) *For a Markov chain satisfying the mixing condition* (3)*, we have*

$$\sup_{\theta'\in\Omega}\sup_{x}\sum_{z_i}|p(z_i \mid x_1^n;\theta') - p(z_i \mid x_{i-k}^{i+k};\theta')| \leq \frac{Cs^2}{\epsilon_{\text{mix}}^8\overline{\pi}_{\min}}\big(1-\epsilon_{\text{mix}}\overline{\pi}_{\min}\big)^{\min\{i,n-i,k\}} \tag{51}$$

for all $i \in [0, n]$*, where* $\overline{\pi}_{\min} = \min_{j\in[s],\beta\in\Omega_\beta}\overline{\pi}(j;\beta)$.

See Appendix D.2 for the proof of this lemma.

Using Lemma 3, let us now prove the claim (17). Introducing the shorthand notation

$$h(X_i, z_i, \theta, \theta') := \log p(X_i \mid z_i;\theta) + \sum_{z_{i-1}} p(z_i \mid z_{i-1};\theta')\log p(z_i|z_{i-1},\theta),$$

we can verify by applying Lemma 3 that

$$\begin{aligned}
&\|\mathbb{E}Q_n - \bar{Q}^k\|_\infty \qquad\qquad (52)\\
&= \Big|\sup_{\theta,\theta'}\frac{1}{n}\sum_{i=1}^n\sum_{z_i}\mathbb{E}(p(z_i \mid X_1^n,\theta') - p(z_i \mid X_{i-k}^{i+k},\theta'))h(X_i,z_i,\theta,\theta')\Big|\\
&+ \Big|\frac{1}{n}\sup_{\theta,\theta'}\mathbb{E}\sum_{z_0}p(z_0 \mid X_1^n,\theta')\log p(z_0;\theta)\Big|\\
&\leq \sup_{\theta,\theta'}\frac{1}{n}\sum_{i=1}^n\sum_{z_i}\sup_x\big|p(z_i \mid x_1^n,\theta') - p(z_i \mid x_{i-k}^{i+k},\theta')\big|\,\mathbb{E}\,|h(X_i,z_i,\theta,\theta')| + \frac{1}{n}\log\overline{\pi}_{\min}^{-1}\\
&\leq \frac{Cs^3}{\epsilon_{\text{mix}}^8\overline{\pi}_{\min}n}\Big(2\sum_{i=1}^k(1-\epsilon_{\text{mix}}\overline{\pi}_{\min})^i + (n-2k)(1-\epsilon_{\text{mix}}\overline{\pi}_{\min})^k\Big)\Big[\max_{z_i\in[s]}\mathbb{E}|h(X_i,z_i,\theta,\theta')|\Big] + \frac{1}{n}\log\overline{\pi}_{\min}^{-1}\\
&\leq \frac{Cs^3}{\epsilon_{\text{mix}}^8\overline{\pi}_{\min}}\Big(\frac{2}{n\epsilon_{\text{mix}}\overline{\pi}_{\min}} + \frac{n-2k}{n}(1-\epsilon_{\text{mix}}\overline{\pi}_{\min})^k\Big)\Big[\max_{z_i\in[s]}\mathbb{E}|h(X_i,z_i,\theta,\theta')|\Big] + \frac{1}{n}\log\overline{\pi}_{\min}^{-1}\\
&\leq \frac{Cs^4}{\epsilon_{\text{mix}}^9\overline{\pi}_{\min}^2}\big(1-\epsilon_{\text{mix}}\overline{\pi}_{\min}\big)^k + \frac{1}{n}\left(\log\overline{\pi}_{\min}^{-1} + \frac{Cs^4}{\epsilon_{\text{mix}}^{10}\overline{\pi}_{\min}^3}\right),
\end{aligned}$$

using the crude bound

$$\max_{z_i \in [s]} \mathbb{E}|h(X_i, z_i, \theta, \theta')| \leq \mathbb{E} \max_{z_i \in [s]} \big| \log p(X_i \mid z_i, \theta) \big| + s \log(\overline{\pi}_{\min} \epsilon_{\mathrm{mix}})^{-1} \leq \frac{Cs}{\overline{\pi}_{\min} \epsilon_{\mathrm{mix}}}.$$

which uses condition (16) and where C denotes generic constants which are potentially different each time they appear.

Appendix B. Technical details for Corollary 1

In this section, we collect some auxiliary bounds on conditional covariances in hidden Markov models. These results are used in the proof of Corollary 1.

Lemma 4 *For any HMM with observed-hidden states (X_i, Z_i), we have*

$$\mathbb{E}\Big[\operatorname{var}(Z_0 Z_1 \mid X_{-k}^k)\Big] \leq \mathbb{E} \operatorname{var}(Z_0 Z_1 \mid X_0^1) \tag{53a}$$

$$\mathbb{E}\Big[\operatorname{var}(Z_0 \mid X_{-k}^k) \mid X_0\Big] \leq \operatorname{var}(Z_0 \mid X_0) \tag{53b}$$

where we have omitted the dependence on the parameters.

Proof We use the law of total variance, which guarantees that $\operatorname{var} Z = \mathbb{E}\big[\operatorname{var}(Z \mid X)\big] + \operatorname{var}\mathbb{E}[Z \mid X]$. Using this decomposition, we have

$$\mathbb{E}[\operatorname{var}(Z_0 \mid X_0^1) \mid X_0] \leq \operatorname{var}(Z_0 \mid X_0)$$
$$\mathbb{E}[\operatorname{var}(Z_0 Z_1 \mid X_0^2) \mid X_0^1] \leq \operatorname{var}(Z_0 Z_1 \mid X_0^1).$$

The result then follows by induction. ∎

We now show that the expected conditional variance of the hidden state (or pairs thereof) conditioned on the corresponding observation (pairs of observations) decays exponentially with the SNR.

Lemma 5 *For a 2-state Markov chain with true parameter θ^*, we have for $\mu \in \mathbb{B}_2\big(\frac{\|\mu^*\|_2}{4}; \mu^*\big)$ and $\beta \in \Omega_\beta$*

$$\Big\| \mathbb{E} X_0 X_0^T (\operatorname{var}(Z_0 \mid \gamma_0, \beta))^{1/2} \Big\|_{op} \leq c_0 \, \mathrm{e}^{-c\eta^2} \tag{54a}$$

$$\mathbb{E} \operatorname{var}(Z_\ell \mid \gamma_\ell, \beta) \leq c_0 \, \mathrm{e}^{-c\eta^2} \tag{54b}$$

$$\mathbb{E} \operatorname{var}(Z_0 Z_1 \mid \gamma_0^1, \beta) \leq c_0 \frac{1+b}{1-b} \, \mathrm{e}^{-c\eta^2}. \tag{54c}$$

Proof By definition of the Gaussian HMM example, we have $\operatorname{var}(Z_i \mid \gamma_i) = \frac{4}{(\mathrm{e}^{\gamma_i} + \mathrm{e}^{-\gamma_i})^2}$. Moreover, following the proof of Corollary 1 in the paper Balakrishnan et al. (2014), we are guaranteed that $\mathbb{E} \operatorname{var}(Z_i \mid \gamma_i) \leq 8\mathrm{e}^{-\frac{\eta^2}{32}}$ and $\|\mathbb{E} X_i X_i^T (\operatorname{var}(Z_i|\gamma_i))^{1/2}\|_{op} \leq c_0 \mathrm{e}^{-\frac{\eta^2}{32}}$, from which inequalities (54a) and (54b) follow.

We now prove inequality (54c) for $\beta \in \Omega_\beta$ and $\mu \in \mathbb{B}_2\big(\frac{\|\mu^*\|_2}{4}; \mu^*\big)$. Note that

$$\begin{aligned}
\frac{1}{4} \operatorname{var}(Z_0 Z_1 \mid \gamma_0^1, \beta) &= \frac{\mathrm{e}^{2\gamma_1} + \mathrm{e}^{-2\gamma_1} + \mathrm{e}^{2\gamma_0} + \mathrm{e}^{-2\gamma_0}}{\big[\mathrm{e}^{\beta}(\mathrm{e}^{\gamma_0+\gamma_1} + \mathrm{e}^{-(\gamma_0+\gamma_1)}) + \mathrm{e}^{-\beta}(\mathrm{e}^{\gamma_0-\gamma_1} + \mathrm{e}^{-(\gamma_0-\gamma_1)})\big]^2} \\
&\leq \mathrm{e}^{2|\beta|} \frac{\mathrm{e}^{2\gamma_1} + \mathrm{e}^{-2\gamma_1} + \mathrm{e}^{2\gamma_0} + \mathrm{e}^{-2\gamma_0}}{(\mathrm{e}^{\gamma_0+\gamma_1} + \mathrm{e}^{-(\gamma_0+\gamma_1)} + \mathrm{e}^{\gamma_0-\gamma_1} + \mathrm{e}^{-(\gamma_0-\gamma_1)})^2} \\
&\leq \left(\frac{1+b}{1-b}\right) \left[\frac{\mathrm{e}^{|\gamma_0|}}{\mathrm{e}^{2\gamma_0} + \mathrm{e}^{-2\gamma_0}} + \frac{\mathrm{e}^{|\gamma_1|}}{\mathrm{e}^{2\gamma_1} + \mathrm{e}^{-2\gamma_1}}\right]
\end{aligned}$$

where γ are now random variables and we used

$$\begin{aligned}
&(\mathrm{e}^{\gamma_0+\gamma_1} + \mathrm{e}^{-(\gamma_0+\gamma_1)} + \mathrm{e}^{\gamma_0-\gamma_1} + \mathrm{e}^{-(\gamma_0-\gamma_1)})^2 \\
&\geq \mathrm{e}^{-|\gamma_0|}(\mathrm{e}^{-\gamma_0} + \mathrm{e}^{\gamma_0})(\mathrm{e}^{2\gamma_1} + \mathrm{e}^{-2\gamma_1}) + \mathrm{e}^{-|\gamma_1|}(\mathrm{e}^{-\gamma_1} + \mathrm{e}^{\gamma_1})(\mathrm{e}^{2\gamma_0} + \mathrm{e}^{-2\gamma_0}) \\
&\geq (\mathrm{e}^{-|\gamma_0|} + \mathrm{e}^{-|\gamma_1|})(\mathrm{e}^{2\gamma_0} + \mathrm{e}^{-2\gamma_0})(\mathrm{e}^{2\gamma_1} + \mathrm{e}^{-2\gamma_1}).
\end{aligned}$$

It directly follows that

$$\begin{aligned}
\frac{1}{4} \mathbb{E} \operatorname{var}(Z_0 Z_1 \mid \gamma_0^1, \beta) &\leq 2 \left(\frac{1+b}{1-b}\right) \mathbb{E}\left[\frac{1}{\mathrm{e}^{\gamma_0} + \mathrm{e}^{-3\gamma_0}} \mathbf{1}_{\gamma_0 \geq 0} + \frac{1}{\mathrm{e}^{3\gamma_0} + \mathrm{e}^{-\gamma_0}} \mathbf{1}_{\gamma_0 \leq 0}\right] \\
&\leq 2 \left(\frac{1+b}{1-b}\right) \left(\mathbb{E}[\mathrm{e}^{-\gamma_0} \mathbf{1}_{\gamma_0 \geq 0}] + \mathbb{E}[\mathrm{e}^{\gamma_0} \mathbf{1}_{\gamma_0 \leq 0}]\right) \\
&\leq 4 \left(\frac{1+b}{1-b}\right) \mathbb{E}[\mathrm{e}^{-\gamma_0} \mathbf{1}_{\gamma_0 \geq 0}]
\end{aligned}$$

where the last inequality follows from symmetry of the random variables X_i. One can then bound

$$\mathbb{E}[\mathrm{e}^{-\gamma_0} \mathbf{1}_{\gamma_0 \geq 0}] = \mathbb{E}\, \mathrm{e}^{-\frac{\|\mu\|_2 V_1}{\sigma^2}} \mathbf{1}_{V_1 \geq 0} \leq 2\mathrm{e}^{-\frac{\eta^2}{32}}$$

by employing a similar procedure as in the proof of Corollary 1 in Balakrishnan et al. (2014). Inequality (54c) then follows. ∎

The last lemma provides rigorous confirmation of the intuition that the covariance between any pair of hidden states should decay exponentially in their separation ℓ:

Lemma 6 *For a 2-state Markov chain with mixing coefficient ϵ_{mix} and uniform stationary distribution, we have*

$$\max\Big\{ \operatorname{cov}(Z_0, Z_\ell \mid \gamma),\ \operatorname{cov}(Z_0 Z_1, Z_\ell Z_{\ell+1} \mid \gamma),\ \operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \gamma) \Big\} \leq 2\rho_{\mathrm{mix}}^\ell \tag{55}$$

with $\rho_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}}$ for all $\theta \in \Omega$.

Lemma 6 is a mixing result and its proof is found in Section D.3.

Appendix C. Technical details for Corollary 2

In this section we prove Lemmas 1 and 2. In order to do so, we leverage the independent blocks approach used in the analysis of dependent data (see, for instance, the papers Yu (1994); Nobel and Dembo (1993)). For future reference, we state here an auxiliary lemma that plays an important role in both proofs.

Let $\{X_i\}_{i=-\infty}^{\infty}$ be a sequence sampled from a Markov chain with mixing rate $\rho_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}}$, $\overline{\pi}_{\min}$ be the minimum entry of the stationary distribution and $\widetilde{\rho}_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$. Given some functions $f_1 : \mathbb{R}^{2k} \to \mathbb{R}^d$ and $f_2 : \mathbb{R} \to \mathbb{R}^d$ in some function class $\mathcal{F}_1, \mathcal{F}_2$ respectively, our goal is to control the difference between the functions

$$g_1(X) := \frac{1}{n}\sum_{i=1}^{n} f_1(X_{i-k}^{i+k}), \qquad g_2(X) := \frac{1}{n}\sum_{i=1}^{n} f_2(X_i) \tag{56a}$$

and their expectation. Defining $m_1 := \lfloor n/4k \rfloor$ and $m_2 := \lfloor n/k \rfloor$, we say that f_1 respectively f_2 is (δ, k)-concentrated if

$$\mathbb{P}\Big[\sup_{f\in\mathcal{F}_1} \|\frac{1}{m_1}\sum_{i=1}^{m_1} f_1(\widetilde{X}_{i;2k}) - \mathbb{E}f_1(\widetilde{X}_{1;2k})\|_2 \geq \epsilon\Big] \leq \frac{\delta}{8k}, \tag{56b}$$
$$\mathbb{P}\Big[\sup_{f\in\mathcal{F}_2} \|\frac{1}{m_2}\sum_{i=1}^{m_2} f_2(\widetilde{X}_i) - \mathbb{E}f_2(\widetilde{X}_1)\|_2 \geq \epsilon\Big] \leq \frac{\delta}{2k}$$

where $\{\widetilde{X}_{i;2k}\}_{i\in\mathbb{N}}$ are a collection of i.i.d. sequences of length $2k$ drawn from the same Markov chain and $\{\widetilde{X}_i\}_{i\in\mathbb{N}}$ a collection of i.i.d. variables drawn from the same stationary distribution. In our notation, $\{\widetilde{X}_{i;2k}\}_{i\in\mathbb{N}}$ under $\mathbb{P}$ are identically distributed as $\{X_{i;2k}\}_{i\in\mathbb{N}}$ under $\mathbb{P}_0$.

Lemma 7 *Consider functions f_1, f_2 that are (δ, k)-concentrated* (56b) *for a truncation parameter $k \geq \log\left(\frac{Cn}{\overline{\pi}_{\min}^3 \epsilon_{\mathrm{mix}}^3 \delta}\right)(\log\frac{1}{\widetilde{\rho}_{\mathrm{mix}}})^{-1}$. Then the averaged functions g_1, g_2 from equation* (56a) *satisfy the bounds*

$$\mathbb{P}\Big[\sup_{g\in\mathcal{F}_1} \|g_1(X) - \mathbb{E}g_1(X)\|_2 \geq \epsilon\Big] \leq \delta \quad \text{and} \quad \mathbb{P}\Big[\sup_{g\in\mathcal{F}_2} \|g_2(X) - \mathbb{E}g_2(X)\|_2 \geq \epsilon\Big] \leq \delta. \tag{57}$$

Proof We prove the lemma for functions of the type (f_1, g_1); the proof for the case (f_2, g_2) is very similar. In order to simplify notation, we assume throughout the proof that the effective sample size n is a multiple of $4k$, so that the block size $m = \frac{n}{4k}$ is integral. By definition (56a), the function g is a function of the sequences $\{X_{1-k}^{1+k}, X_{2-k}^{2+k}, \ldots, X_{n-k}^{n+k}\}$. We begin by dividing these sequences into blocks. Let us define the subsets of indices

$$H_i^j = \{4k(i-1) + k + j \mid 4k(i-1) + 3k + j\}, \quad \text{and}$$
$$R_i^j = \{4k(i-1) - k + j \mid 4k(i-1) + k - 1 + j\}.$$

With this notation, we have the decomposition

$$g(X) = \frac{1}{2}\left(\frac{1}{2k}\sum_{j=1}^{2k}\underbrace{\frac{1}{m}\sum_{i=1}^{m} f(X_{H_i^j})}_{g^{H^j}(X)} + \frac{1}{2k}\sum_{j=1}^{2k}\underbrace{\frac{1}{m}\sum_{i=1}^{m} f(X_{R_i^j})}_{g^{R^j}(X)}\right),$$

from which we find that

$$\begin{aligned}\mathbb{P}\big[\sup_{g\in\mathcal{F}} \|g(X) - \mathbb{E}g(X)\|_2 \leq \epsilon\big] &\geq \mathbb{P}\big(\bigcap_{j=1}^{2k}\{\sup_{g\in\mathcal{F}} \|g^{H^j}(X) - \mathbb{E}g(X)\|_2 \leq \epsilon\} \\ &\qquad \cap \{\sup_{g\in\mathcal{F}} \|g^{R^j}(X) - \mathbb{E}g(X)\|_2 \leq \epsilon\}\big) \\ &\overset{\text{(i)}}{\geq} 1 - 4k\,\mathbb{P}(\sup_{g\in\mathcal{F}} \|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon),\end{aligned}$$

where (i) follows using stationarity of the underlying sequence combined with the union bound.

In order to bound the probability $\mathbb{P}\big[\|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon\big]$, it is convenient to relate it to the probability of the same event under the product measure $\mathbb{P}_0$ on the blocks $\{H_1^1, \ldots, H_m^1\}$. In particular, we have $\mathbb{P}(\|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon) \leq T_1 + T_2$, where

$$\begin{aligned}T_1 &:= \mathbb{P}_0(\|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon), \quad \text{and} \\ T_2 &:= |\mathbb{P}(\|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon) - \mathbb{P}_0(\|g^{H^1}(X) - \mathbb{E}g(X)\|_2 \geq \epsilon)|.\end{aligned}$$

By our assumed concentration (56b), we have $T_1 \leq \frac{\delta}{8k}$, and so it remains to show that $T_2 \leq \frac{\delta}{8k}$.

Now following standard arguments (e.g., see the papers Nobel and Dembo (1993); Yu (1994)), we first define

$$\beta(k) = \sup_{A\in\sigma(\mathcal{S}_{-\infty}^0, \mathcal{S}_k^\infty)} |\mathbb{P}(A) - \mathbb{P}_{-\infty}^0 \times \mathbb{P}_1^\infty(A)|, \tag{58}$$

where $\mathcal{S}_{-\infty}^0$ and $\mathcal{S}_k^\infty$ are the σ-algebras generated by the random vector $X_{-\infty}^0$ and X_k^∞ respectively, and $\mathbb{P}_{-\infty}^0 \times \mathbb{P}_1^\infty$ is the product measure under which the sequences $X_{-\infty}^0$ and X_1^∞ are independent. Define $\mathcal{S}_i$ to be the σ-algebra generated by $X_{H_i^j}$ for $i = \{1, \ldots, m\}$; it then follows by induction that $\sup_{A\in\sigma(\mathcal{S}_1,\ldots,\mathcal{S}_m)} |\mathbb{P}(A) - \mathbb{P}_0(A)| \leq m\beta(k)$. An identical relation holds over the blocks R_i^j.

For our two-state HMM, Lemma 12 implies that

$$\begin{aligned}\beta(k) = |p(x) - p(x_k^\infty)p(x_{-\infty}^0)| &\leq |p(x_{-\infty}^0 \mid x_k^n) - p(x_{-\infty}^0)| \\ &\leq |p(z_0 \mid x_k^n) - p(z_0)| \\ &\overset{\text{(i)}}{\leq} \frac{3}{\overline{\pi}_{\min}^3 \epsilon_{\mathrm{mix}}^3}\rho_{\mathrm{mix}}^k = \frac{3}{\overline{\pi}_{\min}^3 \epsilon_{\mathrm{mix}}^3}\mathrm{e}^{-k\log(1/\rho_{\mathrm{mix}})},\end{aligned} \tag{59}$$

where step (i) follows from inequality (73). From our assumed lower bound on k, we conclude that $m\beta(k) \leq \frac{\delta}{8k}$, which completes the proof. ■

In the following sections we apply it in order to prove the bounds on the approximation and sample error of the M-operators.

C.1 Proof of Lemma 1

We prove each of the two inequalities in equations (47b) and (47c) in turn by using suitable choices of the function f in Lemma 7. Throughout, note that our function class is parameterized and $f \in \mathcal{F}$ is equivalent to $\theta \in \Omega = \mathbb{B}_2(r; \mu^*) \times \Omega_\beta$.

Proof of inequality (47b)**:** We use the notation from the proof of Lemma 7 and furthermore define the weights $w_\theta(X_{i-k}^{i+k-1}) = p(Z_i = 1 \mid X_{i-k}^{i+k-1}, \theta)$, as well as the function $f_0(X_{i-k}^{i+k-1}, \theta') = (2w_{\theta'}(X_{i-k}^{i+k-1}) - 1)X_i$. It is then possible to write the EM operator explicitly as the average

$$M_n^{\mu,k}(\theta') = \arg\max_{\mu \in \widetilde{\Omega}} \frac{1}{n}\Big[\sum_{i=1}^n \mathbb{E}_{Z_i | X_{i-k}^{i+k}, \theta'} \log p(X_i \mid Z_i, \mu)\Big] = \frac{1}{n}\sum_{i=1}^n f_0(X_{i-k}^{i+k-1}, \theta').$$

We are now ready to apply Lemma 7 with the choices $f_1 = f_0$, $g_1(X) = M_n^{\mu,k}(\theta)$. According to Lemma 7, given that the lower bound on the truncation parameter k holds, we now need to show that f_0 is (δ, k)-concentrated, that means finding ϵ_n^μ such that

$$\mathbb{P}_0\left[\sup_{\theta\in\Omega} \big\|\frac{1}{m}\sum_{i=1}^m f_0(\widetilde{X}_{i;2k}, \theta') - \mathbb{E} f_0(\widetilde{X}_{i;2k}, \theta')\big\|_2 \geq \epsilon_n^\mu\right] \leq \frac{\delta}{8k},$$

where $\mathbb{P}_0$ denotes the product measure over the independent blocks and $m := m_1 = \lfloor n/4k \rfloor$.

Let X_i be the middle element of the (i.i.d. drawn) sequence $\widetilde{X}_{i;2k}$ and Z_i, V_i the corresponding latent and noise variable. We can then write $X_i = Z_i + V_i$ where V_i are zero-mean Gaussian random variables with covariance matrix $\sigma^2 I$.

With a minor abuse of notation, let us use $X_{i,\ell}$ to denote ℓ^{th} element in the block $\widetilde{X}_{i;2k} = (X_{i,1}, \ldots, X_{i,2k})^T$, and write $\widetilde{X} = \{\widetilde{X}_{i;2k}\}_{i=1}^n$. In view of Lemma 7, our objective is to find the smallest scalar ϵ_n^μ such that

$$\mathbb{P}\big[\sup_{\theta\in\Omega} \|\frac{1}{m}\sum_{i=1}^m \underbrace{(2w_\theta(\widetilde{X}_{i;2k}) - 1)X_{i,k} - \mathbb{E}(2w_\theta(\widetilde{X}_{i;2k}) - 1)X_{i,k}}_{f_\theta(\widetilde{X}_{i;2k})} \|_2 \geq \epsilon_n^\mu\big] \leq \frac{\delta}{8k} \qquad (60)$$

For each unit norm vector $u \in \mathbb{R}^d$, define the random variable

$$\tilde{V}_m(\widetilde{X}; u) = \sup_{\theta\in\Omega} \frac{1}{m}\sum_{i=1}^m (2w_\theta(\widetilde{X}_{i;2k}) - 1)\langle X_{i,k}, u\rangle - \mathbb{E}(2w_\theta(\widetilde{X}_{i;2k}) - 1)\langle X_{i,k}, u\rangle.$$

Let $\{u^{(1)}, \ldots, u^{(T)}\}$ denote a 1/2-cover of the unit sphere in $\mathbb{R}^d$; by standard arguments, we can find such a set with cardinality $\log T \leq d \log 5$. Using this covering, we have

$$\sup_{\theta\in\Omega} \|\frac{1}{m}\sum_{i=1}^m f_\theta(\widetilde{X}_{i;2k})\|_2 = \sup_{\|u\|_2 \leq 1} \tilde{V}_m(\widetilde{X}; u) \leq 2 \max_{j\in[T]} \tilde{V}_m(\widetilde{X}; u^{(j)}),$$

where the inequality follows by a discretization argument. Consequently, we have

$$\mathbb{P}\big[\sup_{\theta\in\Omega} \|\frac{1}{m}\sum_{i=1}^m f_\theta(\widetilde{X}_{i;2k})\|_2 \geq \epsilon_n^\mu\big] \leq \mathbb{P}\big[\max_{j\in[T]} \tilde{V}_m(\widetilde{X}; u^{(j)}) \geq \frac{\epsilon_n^\mu}{2}\big] \leq T \max_{j\in[T]} \mathbb{P}\big[\tilde{V}_m(\widetilde{X}; u^{(j)}) \geq \frac{\epsilon_n^\mu}{2}\big].$$

The remainder of our analysis focuses on bounding the tail probability for a fixed unit vector u, in particular ensuring an exponent small enough to cancel the $T \leq e^{d \log 5}$ pre-factor. By Lemma 2.3.7 of van der Vaart and Wellner (1996), for any $t > 0$, we have

$$\mathbb{P}_X\big[\tilde{V}_m(\widetilde{X}; u) \geq t\big] \leq c\mathbb{P}_{X,\epsilon}\big[V_m(\widetilde{X}; u) \geq \frac{t}{4}\big],$$

where $V_m(\widetilde{X}; u) = \sup_{\theta\in\Omega} \big|\frac{1}{m}\sum_{i=1}^m \epsilon_i(2w_\theta(\widetilde{X}_{i;2k}) - 1)\langle X_{i,k}, u\rangle\big|$, and $\{\epsilon_i\}_{i=1}^m$ is a sequence of i.i.d. Rademacher variables.

We now require a sequence of technical lemmas; see Section C.3 for their proofs. Our first lemma shows that the variable $V_m(\widetilde{X}; u)$, viewed as a function of the Rademacher sequence, is concentrated:

Lemma 8 *For any fixed $(\widetilde{X}, u)$, we have*

$$\mathbb{P}_\epsilon\big[V_m(\widetilde{X}; u) \geq \mathbb{E}_\epsilon V_m(\widetilde{X}; u) + t\big] \leq 2e^{-\frac{t^2}{16L_m^2(\widetilde{X}; u)}}, \qquad (61)$$

where $L_m(\widetilde{X}; u) = \frac{1}{m}\sqrt{\sum_{i=1}^m \langle X_{i,k}, u\rangle^2}$.

Our next lemma bounds the expectation with respect to the Rademacher random vector:

Lemma 9 *There exists a universal constant c such that for each fixed $(\widetilde{X}; u)$, we have*

$$\mathbb{E}_\epsilon V_m(\widetilde{X}; u) \leq \underbrace{c\frac{\|\mu^*\|_2}{\sigma^2}\sqrt{\log m}\,\Big[\sum_{\ell=1}^{2k} \mathbb{E}_{\tilde{\epsilon}} \|\frac{1}{m}\sum_{i=1}^m \tilde{\epsilon}_{i,\ell} X_{i,\ell}\langle X_{i,k}, u\rangle\|_2\Big]}_{M_m(\widetilde{X}; u)} + \underbrace{\mathbb{E}_g\big|\frac{1}{m}\sum_{i=1}^m g_{i,2k+1}\langle X_{i,k}, u\rangle\big|}_{N_m(\widetilde{X}; u)} \qquad (62)$$

where $\epsilon, \tilde{\epsilon} \in \mathbb{R}^m$ are random vectors with i.i.d. Rademacher components, and g is a random vector with i.i.d. $\mathcal{N}(0,1)$ components.

We now bound the three quantities $L_m(\widetilde{X}; u)$, $M_m(\widetilde{X}; u)$, and $N_m(\widetilde{X}; u)$ appearing in the previous two lemmas. In particular, let us introduce the quantities $L' = cL\|\mu^*\|_2\big(\frac{\|\mu^*\|_2^2}{\sigma^2} + 1\big)$, $L'' = L\sqrt{\|\mu^*\|_2^2 + \sigma^2}$ and $L = \frac{\sqrt{8}}{1-\rho_{\mathrm{mix}}}$.

Lemma 10 *Define the event*

$$\mathcal{E} = \Bigg\{ L_m(\widetilde{X}; u) \leq \tilde{c}\sqrt{\frac{2(\|\mu^*\|_2^2 + \sigma^2)\log\frac{1}{\delta}}{m}}, \quad M_m(\widetilde{X}; u) \leq L'k\sqrt{\frac{d\log m \log\frac{k}{\delta}}{m}} \\ \text{and } N_m(\widetilde{X}; u) \leq cL''\sqrt{\frac{d\log\frac{1}{\delta}}{m}} \Bigg\}.$$

Then we have $\mathbb{P}[\mathcal{E}] \geq 1 - \mathrm{e}^{-c' \, d \log \frac{1}{\delta}}$ *for* $m > d$ *and a universal constant* $c' > 0$ *which increases with the constants* c *in* L', N_m *and* $\tilde{c}$ *in* L_m.

In conjunction, Lemmas 8 and 9 imply that conditionally on the event $\mathcal{E}$, we have

$$\mathbb{E}_\epsilon\big[V_m(\widetilde{X}; u)\big] \leq c\sqrt{\|\mu^*\|_2^2 + \sigma^2}\big(\frac{\|\mu^*\|_2^2}{\sigma^2} + 1\big)k\sqrt{\frac{d \log m \log \frac{k}{\delta}}{m}}.$$

Note that by assumption on n we also have $m \geq d$ so that we can combine this bound with Lemma 10 which yields

$$\begin{aligned} T\,\mathbb{P}_X\big[\tilde{V}_m(\widetilde{X}; u) \geq t\big] &\leq T\,\mathbb{P}_{X,\epsilon}\big[V_m(\widetilde{X}; u) \geq \frac{t}{4} \mid \mathcal{E}\big] + T\,\mathbb{P}\big[\mathcal{E}^c\big] \\ &\leq 2\mathrm{e}^{4d - \left(\frac{c}{\tilde{c}}\right)^2 k^2 d \log m \log \frac{k}{\delta}} + \delta \mathrm{e}^{4d - c' d} \\ &\leq \delta, \end{aligned}$$

where the second inequality follows by setting $t/4 = c\|\mu^*\|_2\big(\frac{\|\mu^*\|_2^2}{\sigma^2} + 1\big)k\log\big(\frac{k}{\delta}\big)\sqrt{\frac{d\log m}{m}}$ and the final inequality holds for c', c and $\tilde{c}$ big enough. After rescaling δ by $8k$ and setting $m = \frac{n}{4k}$, the result follows after an application of Lemma 7.

Proof of inequality (47c)**:** In order to bound $|M_n^{\beta,k}(\theta) - \overline{M}^{\beta,k}(\theta)|$, we need a few extra steps. First, let us define new weights

$$v_\theta(X_{i-k}^{i+k-1}) = p(Z_0 = Z_1 = 1 \mid X_{i-k}^{i+k-1}, \theta) + p(Z_0 = Z_1 = -1 \mid X_{i-k}^{i+k-1}, \theta),$$

and also write the update in the form

$$\begin{aligned} M_n^{\beta,k}(\theta) &= \arg\max_{\zeta \in \Omega_\zeta} \Big\{ \mathbb{E}_{Z_1 | X_{i-k}^{i+k}, \theta} \log p(Z_1 \mid \zeta) + \sum_{i=2}^n \mathbb{E}_{Z_{i-1}^i | X_{i-k}^{i+k}, \theta} \log p(Z_i \mid Z_{i-1}, \zeta) \Big\} \\ &= \arg\max_{\zeta \in \Omega_\zeta} \Big\{ \frac{1}{2} + \sum_{i=2}^n \mathbb{E}_{Z_{i-1}^i | X_{i-k}^{i+k}, \theta} \log p(Z_i \mid Z_{i-1}, \zeta) \Big\} \\ &= \Pi_{\Omega_\zeta}\Big(\frac{1}{n}\sum_{i=2}^n v_\theta(X_{i-k}^{i+k-1})\Big), \end{aligned}$$

where we have reparameterized the transition probabilities with ζ via the equivalences $\beta = h(\zeta) := \frac{1}{2}\log\left(\frac{\zeta}{1-\zeta}\right)$. Note that the original EM operator is obtained via the transformation $M_n^{\beta,k}(\theta') = h(M_n^{\beta,k}(\theta'))$ and we have $\overline{M}^{\beta,k}(\theta) = \Pi_{\Omega_\zeta}\mathbb{E}v_\theta(X_{i-k}^{i+k-1})$ by definition.

Given this set-up, we can now pursue an argument similar to that of inequality (47b). The new weights remain Lipschitz with the same constant—that is, we have the bound $|v_\theta(\widetilde{X}_{i;2k}) - v_{\theta'}(\widetilde{X}_{i;2k})| \leq L\|\tilde{\theta}_i - \tilde{\theta}_i'\|_2$. As a consequence, we can write

$$\mathbb{P}\big[\sup_{\theta \in \Omega} \big| \frac{1}{m}\sum_{i=1}^m v_\theta(\widetilde{X}_{i;2k}) - \mathbb{E}v_\theta(\widetilde{X}_{i;2k})\big| \geq \epsilon_n^\beta\big] \leq \frac{\delta}{8k},$$

with ϵ_n^β defined as in the lemma statement. In this case, it is not necessary to perform the covering step, nor to introduce extra Rademacher variables after the Gaussian comparison step; consequently, the two constants ϵ_n^β and ϵ_n^μ differ by a factor of $\sqrt{d \log n}$ modulo constants.

Applying Lemma 7 then yields a tail bound for the quantity $\big|\frac{1}{n}\sum_{i=1}^n v_\theta(\widetilde{X}_{i;2k}) - \mathbb{E}v_\theta(\widetilde{X}_{i;2k})\big|$ with probability δ. Since projection onto a convex set only decreases the distance, we find that

$$\mathbb{P}\left[|M_n^{\beta,k}(\theta) - \overline{M}^{\beta,k}(\theta)| \geq C\frac{\sqrt{\|\mu^*\|_2^2 + \sigma^2}}{\sigma^2}\sqrt{\frac{k^3 \log(k^2/\delta)}{n}}\right] \leq \delta.$$

In order to prove the result, the last step needed is the fact that

$$\frac{1}{2}\Big|\log\frac{x}{1-x} - \log\frac{y}{1-y}\Big| \leq \frac{1}{\tilde{x}(1-\tilde{x})}|x-y| \leq \frac{2}{1-b^2}|x-y| =: L|x-y|$$

for $x, y, \tilde{x} \in \Omega_\zeta$. Since $M_n^{\beta,k}(\theta) \in \Omega_\zeta$ we finally arrive at

$$\mathbb{P}\Big[|M_n^{\beta,k}(\theta) - \overline{M}^{\beta,k}(\theta)| \geq C(1-b^2)\frac{\sqrt{\|\mu^*\|_2^2 + \sigma^2}}{\sigma^2}\sqrt{\frac{k^3 \log\left(\frac{k^2}{\delta}\right)}{n}}\Big] \leq \delta$$

and the proof is complete.

C.2 Proof of Lemma 2

We need to show that

$$\mathbb{P}\Big[\sup_{\theta \in \Omega} \|M_n(\theta) - M_n^k(\theta)\|_\star^2 \geq c_1\varphi_n^2(\delta, k)\Big] \leq \delta$$

with

$$\varphi_n^2(\delta, k) = \frac{Cs^4}{(1-b^2)\epsilon_{\mathrm{mix}}^{10}\bar{\pi}_{\min}^3}\Big[\frac{1}{\sigma}\frac{d\log^2(C_\epsilon n/\delta)}{n} + \frac{\|\mu^*\|_2}{\sigma}\frac{\log^2(C_\epsilon n/\delta)}{n} + \frac{\|\mu^*\|_2^2}{\sigma^2}\frac{\delta}{n}\Big].$$

We first claim that

$$\sup_{\theta \in \Omega}\|M_n(\theta) - M_n^k(\theta)\|_\star^2 \leq \frac{8\|Q_n - Q_n^k\|_\infty}{\lambda}, \quad \text{where} \quad \lambda \geq \frac{2}{3}(1-b^2). \tag{63}$$

In Section 5.3.1. we showed that population operators are strongly concave with parameter at least λ. We make the added observation that using our parameterization, the sample Q functions $Q_n^k(\cdot \mid \theta'), Q_n(\cdot \mid \theta')$ are also strongly concave. This is because the concavity results for the population operators did not use any property of the covariates in the HMM, in particular not the expectation operator, and the single term $\frac{1}{n}\mathbb{E}\sum_{z_0} p(z_0 \mid X_1^n, \beta')\log p(z_0; \beta) = \frac{1}{n}\log\frac{1}{2}$ is constant for all $\beta \in \Omega_\beta$. From this λ-strong concavity, the bound (63) follows immediately using the same argumentation as in the proof of Theorem 1.

Given the bound (63), the remainder of the proof focuses on bounding the difference $\|Q_n - Q_n^k\|_\infty$. Recalling the shorthand notation

$$h(X_i, z_i, \theta, \theta') = \log p(X_i|z_i, \theta) + \sum_{z_{i-1}} p(z_i|z_{i-1}, \theta') \log p(z_i|z_{i-1}, \theta),$$

we use a similar argumentation as in the Proof of Proposition 1 equation (52) to obtain

$$\begin{aligned}
\|Q_n - Q_n^k\|_\infty &= \Big| \sup_{\theta,\theta' \in \Omega} \frac{1}{n} \sum_{i=1}^{n} \sum_{z_i} (p(z_i|X_1^n, \theta') - p(z_i|X_{i-k}^{i+k}, \theta')) h(X_i, z_i, \theta, \theta') \Big| \qquad (64) \\
&+ \Big| \sup_{\theta,\theta' \in \Omega} \frac{1}{n} \sum_{z_0} p(z_0 \mid x_1^n, \theta') \log p(z_0 \mid \theta) \Big| \\
&\leq \frac{2Cs^3}{\epsilon_{\mathrm{mix}}^8 \overline{\pi}_{\min}} \frac{1}{n} \big[\sum_{i=1}^{k} \widetilde{\rho}_{\mathrm{mix}}^i \max_{z_i \in [s]} \big| h(X_i, z_i, \theta, \theta') \big| + \log \overline{\pi}_{\min}^{-1} \big] \\
&+ \frac{Cs^3 \widetilde{\rho}_{\mathrm{mix}}^k}{\epsilon_{\mathrm{mix}}^8 \overline{\pi}_{\min}} \frac{1}{n-2k} \sum_{i=k}^{n-k} \max_{z_i \in [s]} \big| h(X_i, z_i, \theta, \theta') \big| \\
&\leq \underbrace{\frac{2Cs^3}{\epsilon_{\mathrm{mix}}^8 \overline{\pi}_{\min} n} \big[\max_{z_i \in [s], X_1^k} \big| \log p(X_i \mid z_i, \theta) \big| \sum_{i=1}^{k} \widetilde{\rho}_{\mathrm{mix}}^i + \frac{s \log(\overline{\pi}_{\min} \epsilon_{\mathrm{mix}})^{-1}}{\overline{\pi}_{\min} \epsilon_{\mathrm{mix}}} + \log \overline{\pi}_{\min}^{-1} \big]}_{S_1} \\
&+ \frac{Cs^3 \widetilde{\rho}_{\mathrm{mix}}^k}{\epsilon_{\mathrm{mix}}^8 \overline{\pi}_{\min}} \big[\mathbb{E} \max_{z_i \in [s]} \big| \log p(X_i \mid z_i, \theta') \big| + e_{n-2k}(X) + s \log(\overline{\pi}_{\min} \epsilon_{\mathrm{mix}})^{-1} \big]
\end{aligned}$$

where we use $\max_{z_i \in [s]} \big| h(X_i, z_i, \theta, \theta') \big| \leq \max_{z_i \in [s]} \big| \log p(X_i|z_i, \theta) \big| + s \log(\overline{\pi}_{\min} \epsilon_{\mathrm{mix}})^{-1}$, and

$$e_n(X) := \Big| \frac{1}{n} \sum_{i=1}^{n} \max_{z_i \in [s]} \Big| \log p(X_i \mid z_i, \theta) \Big| - \mathbb{E} \max_{z_i \in [s]} \Big| \log p(X_i \mid z_i, \theta) \Big| \Big|.$$

By assumption, we have that $\mathbb{E} \max_{z_i \in [s]} |\log p(X_i \mid z_i, \theta)|$ is bounded by an appropriately large universal constant. We therefore have with probability one that

$$S_1 \leq \frac{Cs^4}{\epsilon_{\mathrm{mix}}^9 \overline{\pi}_{\min}^2} \frac{k}{n} \log(\epsilon_{\mathrm{mix}} \overline{\pi}_{\min})^{-1}.$$

Putting these together, we find that

$$\sup_{\theta \in \Omega} \|M_n(\theta) - M_n^k(\theta)\|_\star^2 \leq \frac{Cs^4}{\lambda \epsilon_{\mathrm{mix}}^9 \overline{\pi}_{\min}^2} \big[\frac{k}{n} \log(\epsilon_{\mathrm{mix}} \overline{\pi}_{\min})^{-1} + \widetilde{\rho}_{\mathrm{mix}}^k e_{n-2k}(X) \big].$$

Suppose that we can show that

$$\mathbb{P}\Big(e_n(X) \geq c_0 \Big(\frac{1}{\sigma} \sqrt{\frac{d \log^2(C_\epsilon n/\delta)}{n}} + \frac{\|\mu^*\|_2}{\sigma} \sqrt{\frac{\log^2(C_\epsilon n/\delta)}{n}} + \frac{\|\mu^*\|_2^2}{\sigma^2} \Big) \Big) \leq \delta, \qquad (65)$$

where c_0 is a universal constant and $C_\epsilon = \frac{C}{\epsilon_{\mathrm{mix}}^3 \overline{\pi}_{\min}^3}$. By assumption we have $\frac{1}{2} \frac{\log\left(Cn/\delta\right)}{\log(1/\widetilde{\rho}_{\mathrm{mix}})} \leq k \leq C \frac{\log\left(Cn/\delta\right)}{\log(1/\widetilde{\rho}_{\mathrm{mix}})}$ so that we obtain

$$\sup_{\theta \in \Omega} \|M_n(\theta) - M_n^k(\theta)\|_\star^2 \leq \varphi_n^2(\delta, k)$$

with probability at least $1 - \frac{\delta}{3}$ for an appropriate choice of C.

We now move on to prove the bound (65). Observe that we have

$$\begin{aligned}
e_n(X) &= \frac{1}{2n\sigma^2} \sum_{i=1}^{n} \big[\max\{\|X_i + \mu\|_2^2, \|X_i - \mu\|_2^2\} - \mathbb{E} \max\{\|X_i + \mu\|_2^2, \|X_i - \mu\|_2^2\} \big] \\
&= \frac{1}{2n\sigma^2} \sum_{i=1}^{n} \left(\|X_i\|_2^2 - \mathbb{E}\|X_i\|_2^2 \right) + \frac{1}{n\sigma^2} \sum_{i=1}^{n} \left(|X_i^T \mu| - \mathbb{E}|X_i^T \mu| \right).
\end{aligned}$$

Note that we are again dealing with a dependent sequence so that we cannot use usual Hoeffding type bounds. For some $\tilde{k}$ to be chosen later on, and $m = n/\tilde{k}$ using the proof idea of Lemma 7 with $f_2(X_i) = |X_i^T \mu|$ and $f_2(X_i) = \|X_i\|_2^2$, we can write

$$\begin{aligned}
\mathbb{P}(e_n(X) \geq \frac{t}{2\sigma^2}) \leq \tilde{k} \Big(& \underbrace{\mathbb{P}_0 \Big(|\frac{1}{m} \sum_{i=1}^{m} \|X_i\|_2^2 - \mathbb{E}\|X_i\|_2^2| \geq \frac{t}{2} \Big)}_{T_1} \\
& + \underbrace{\mathbb{P}_0 \Big(|\frac{1}{m} \sum_{i=1}^{m} |X_i^T \mu| - \mathbb{E}|X_i^T \mu|| \geq \frac{t}{4} \Big)}_{T_2} + m\beta(\tilde{k}) \Big),
\end{aligned}$$

where $\beta(\tilde{k})$ was previously defined in equation (58). We claim that the choices

$$t := c_1 \Big(\sigma \sqrt{\frac{d \log(\tilde{k}/\delta)}{m}} + \sigma \|\mu^*\|_2 \sqrt{\frac{\log(\tilde{k}/\delta)}{m}} + \|\mu^*\|_2^2 \Big), \quad \text{and} \quad \tilde{k} := \frac{C_2 \log(\frac{3n}{\epsilon_{\mathrm{mix}}^3 \overline{\pi}_{\min}^3 \delta})}{\log 1/\widetilde{\rho}_{\mathrm{mix}}},$$

suffice to ensure that $\mathbb{P}(e_n(X) \geq t/(2\sigma^2)) \leq \delta$. Notice that the bound (59) implies that

$$m\beta(\tilde{k}) \leq \frac{cm\rho_{\mathrm{mix}}^{\tilde{k}}}{\epsilon_{\mathrm{mix}}^3 \overline{\pi}_{\min}^3} \leq \frac{\delta}{3\tilde{k}}.$$

In the sequel we develop bounds on T_1 and T_2. For T_1, observe that since $X_i \sim Z_i \mu^* + \epsilon_i$ where ϵ_i is a Gaussian vector with covariance $\sigma^2 I$ and Z_i independent under $\mathbb{P}_0$, standard χ^2 tail bounds imply that

$$\mathbb{P}_0 \Big[|\frac{1}{m} \sum_{i=1}^{m} \|X_i\|_2^2 - \mathbb{E}\|X_i\|_2^2| \geq \frac{t}{2} \Big] \leq \frac{\delta}{3\tilde{k}}.$$

Finally, we turn our attention to the term T_2. Observe that,

$$X_i^T\mu \sim \frac{1}{2}\mathcal{N}(\mu^T\mu^*, \sigma^2\|\mu\|_2^2) + \frac{1}{2}\mathcal{N}(-\mu^T\mu^*, \sigma^2\|\mu\|_2^2),$$

so that $|\ X_i^T\mu \sim |\mathcal{N}(\mu^T\mu^*, \sigma^2\|\mu\|_2^2)|$. Denote $U_i =|\ X_i^T\mu\ |$. Letting ϵ denote a Rademacher random variable, observe that

$$\mathbb{E}\exp(tU_i) \overset{\text{(i)}}{\leq} \mathbb{E}\exp(2t\epsilon U_i) \overset{\text{(ii)}}{\leq} \exp\left(2t^2\sigma^2\|\mu\|_2^2 + 2t\mu^T\mu^*\right),$$

where (i) follows using symmetrization, and (ii) follows since the random variable ϵU_i is a Gaussian mixture. Observe that

$$\mathbb{E}U_i \overset{\text{(iii)}}{\leq} |\mu^T\mu^*| + \sigma\|\mu\|_2 \overset{\text{(iv)}}{\leq} \underbrace{2(\sigma + \|\mu^*\|_2)\|\mu^*\|_2}_{M},$$

where we have used for (iii) that U_i is a folded normal, and for (iv) that $\|\mu - \mu^*\|_2 \leq \frac{\|\mu^*\|_2}{4}$. Setting $D := 4\sigma\|\mu^*\|_2\sqrt{\frac{\log(6\tilde{k}/\delta)}{m}}$ observe that $\frac{t}{4} \geq 2M + D$ for big enough c_1. Thus, applying the Chernoff bound yields

$$\begin{aligned} T_2 \leq \mathbb{P}_0\Big[|\frac{1}{m}\sum_{i=1}^m U_i - \mathbb{E}U_i| \geq 2M + D\Big] &\leq \mathbb{P}_0\Big(\ |\ \frac{1}{m}\sum_{i=1}^m U_i\ |\geq M + D\Big) \\ &\leq 2\inf_{t\geq 0}\Big\{\mathbb{E}\exp\Big(\frac{t}{m}\sum_{i=1}^m U_i - Mt - Dt\Big)\Big\}, \\ &\leq 2\exp\Big(-\frac{mD^2}{8\sigma^2\|\mu\|_2^2}\Big) \leq \frac{\delta}{3\tilde{k}}. \end{aligned}$$

By combining the bounds on T_1 and T_2, some algebra shows that our choices of $t, \tilde{k}$ yield the claimed bound—namely, that $\mathbb{P}\big[e_n(X) \geq t/(2\sigma^2)\big] \leq \delta$.

C.3 Proofs of technical lemmas

In this section, we collect the proofs of various technical lemmas cited in the previous sections.

C.3.1 Proof of Lemma 8

We use the following concentration theorem (e.g., Ledoux (1997)): suppose that the function $f : \mathbb{R}^n \to \mathbb{R}$ is coordinate-wise convex and L-Lipschitz with respect to the Euclidean norm. Then for any i.i.d. sequence of variables $\{X_i\}_{i=1}^n$ taking values in the interval $[a, b]$, we have

$$\mathbb{P}\big[f(X) \geq \mathbb{E}f(X) + \delta\big] \leq \mathrm{e}^{-\frac{\delta^2}{4L^2(b-a)^2}} \tag{66}$$

We consider the process without absolute values (which introduces the factor of two in the lemma) and see that $\epsilon := (\epsilon_1, \ldots, \epsilon_n)$ is a random vector with bounded entries and that the supremum over affine functions is convex.

It remains to show that the function $\epsilon \mapsto V_m(\widetilde{X}, u)$ is Lipschitz with $L_m(\widetilde{X}; u)$ as follows

$$\begin{aligned} &\big|\sup_\theta \frac{1}{m}\sum_{i=1}^m \epsilon_i f_\theta(\widetilde{X}_{i;2k}) - \sup_\theta \frac{1}{m}\sum_{i=1}^m \epsilon_i' f_\theta(\widetilde{X}_{i;2k})\big| \\ &\leq \frac{1}{m}|\sum_{i=1}^m (\epsilon_i - \epsilon_i') f_\theta(\widetilde{X}_{i;2k})| \\ &\leq \frac{1}{m}\sqrt{\sum_{i=1}^m (2w_{\tilde{\theta}}(\widetilde{X}_{i;2k}) - 1)^2\langle X_{i,k}, u\rangle^2}\|\epsilon - \epsilon'\|_2 \\ &\leq L_m(\widetilde{X}; u)\|\epsilon - \epsilon'\|_2 \end{aligned}$$

where $\tilde{\theta} = \arg\max_{\theta\in\Omega}\sum_i \epsilon_i f_\theta(\widetilde{X}_{i;2k})$ in the last line and we use that $|2w_\theta(\widetilde{X}_{i;2k}) - 1| \leq 1$.

C.3.2 Proof of Lemma 9

The proof consists of three steps. First, we observe that the Rademacher complexity is upper bounded by the Gaussian complexity. Then we use Gaussian comparison inequalities to reduce the process to a simpler one, followed by a final step to convert it back to a Rademacher process.

Relating the Gaussian and Rademacher complexity: Let $g_i \sim \mathcal{N}(0, 1)$. It is easy to see that using Jensen's inequality and the fact that $\epsilon_i|g_i| \overset{d}{=} g_i$

$$\begin{aligned} \mathbb{E}_\epsilon \sup_\theta \frac{1}{m}\sum_{i=1}^m \epsilon_i f_\theta(\widetilde{X}_{i;2k}) &= \sqrt{\frac{2}{\pi}}\mathbb{E}_\epsilon \sup_\theta \frac{1}{m}\sum_{i=1}^m \epsilon_i \mathbb{E}_g[|g_i|] f_\theta(\widetilde{X}_{i;2k}) \\ &\leq \sqrt{\frac{2}{\pi}}\mathbb{E}_g \sup_\theta \frac{1}{m}\sum_{i=1}^m g_i f_\theta(\widetilde{X}_{i;2k}). \end{aligned}$$

Lipschitz continuity: For $\theta = (\mu, \beta)$ define the corresponding effective parameter that is obtained by treating the observed variables X as fixed

$$\tilde{\theta}_i := (\gamma_i, \beta) = (\frac{\langle \mu, X_{i,1}\rangle}{\sigma^2}, \ldots, \frac{\langle \mu, X_{i,2k}\rangle}{\sigma^2}, \beta). \tag{67}$$

Now we can use results in the proof of Corollary 1 to see that $\tilde{\theta}_i \mapsto F(\tilde{\theta}_i; \widetilde{X}_{i;2k}) := f_\theta(\widetilde{X}_{i;2k})$ is Lipschitz in the Euclidean norm, i.e. there exists an L, only dependent on ρ_{mix} such that

$$|F(\tilde{\theta}_i; \widetilde{X}_{i;2k}) - F(\tilde{\theta}_i'; \widetilde{X}_{i;2k})| \leq L\|\tilde{\theta}_i - \tilde{\theta}_i'\|_2|\langle X_{i,k}, u\rangle| \tag{68}$$

For this we directly use results (exponential family representation) that were used to show Corollary 1. We overload notation and write $X_\ell := X_{1,\ell}$ and analyze Lipschitz continuity for the first block. First note that $F(\tilde{\theta}_i, X_{1;2k}) = (2\mathbb{E}_{Z_k|X_1^{2k},\theta}Z_k - 1)X_{i,k}$. By Taylor's theorem, we then have

$$\begin{aligned} |F(\tilde{\theta}_i; \widetilde{X}_{i;2k}) - F(\tilde{\theta}_i'; \widetilde{X}_{i;2k})| &= |\langle X_{i,k}, u\rangle||\mathbb{E}_{Z_k|\widetilde{X}_{i;2k},\theta}Z_k - \mathbb{E}_{Z_k|\widetilde{X}_{i;2k},\theta'}Z_k| \\ &\leq |\langle X_{i,k}, u\rangle||\mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu,\beta)}Z_k - \mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta)}Z_k| \\ &\quad + |\langle X_{i,k}, u\rangle||\mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta)}Z_k - \mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta')}Z_k| \end{aligned}$$

Let us examine each of the summands separately. By the Cauchy-Schwartz inequality and Lemma 6, we have

$$\begin{aligned}|\mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu,\beta)}Z_k - \mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta)}Z_k| &= \frac{1}{\sigma}|\sum_{\ell=1}^{2k}\frac{\partial^2\Phi}{\partial\gamma_\ell\partial\gamma_0}\Big|_{\theta=\tilde{\theta}}(\gamma_\ell-\gamma'_\ell)| \\ &= |\sum_{\ell=1}^{2k}\mathrm{cov}(Z_0, Z_\ell \mid \widetilde{X}_{i;2k},\tilde{\theta})(\langle\mu, X_\ell\rangle - \langle\mu', X_\ell\rangle)| \\ &\leq \sqrt{(\sum_{\ell=1}^{2k}4\rho_{\mathrm{mix}}^{2\ell})\sum_{\ell=1}^{2k}(\gamma_\ell-\gamma'_\ell)^2},\end{aligned}$$

as well as

$$\begin{aligned}|\mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta)}Z_k - \mathbb{E}_{Z_k|\widetilde{X}_{i;2k},(\mu',\beta')}Z_k| &= |\sum_{\ell=1}^{2k}\frac{\partial^2\Phi}{\partial\beta_\ell\partial\gamma_0}\Big|_{\theta=\tilde{\theta}}(\beta-\beta')| \\ &= |\sum_{\ell=1}^{2k}\mathrm{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \widetilde{X}_{i;2k},\tilde{\theta})(\beta-\beta')| \\ &\leq \frac{2}{1-\rho_{\mathrm{mix}}}|\beta-\beta'|.\end{aligned}$$

Combining these two bounds yields

$$\begin{aligned}|F(\tilde{\theta}_i;\widetilde{X}_{i;2k}) - F(\tilde{\theta}'_i;\widetilde{X}_{i;2k})|^2 &\leq \langle X_{i,k},u\rangle^2 L\big(\sum_{\ell=1}^{2k}(\gamma_\ell-\gamma'_\ell)^2 + (\beta-\beta')^2\big) \\ &= \langle X_{i,k},u\rangle^2 L^2\|\tilde{\theta}_i - \tilde{\theta}'_i\|_2^2\end{aligned}$$

with $L^2 = \frac{8}{(1-\rho_{\mathrm{mix}})^2}$.

Applying the Sudakov-Fernique Gaussian comparison: Let us introduce the shorthands $X_\theta = \frac{1}{m}\sum_i g_i f_\theta(\widetilde{X}_{i;2k})$, and

$$Y_\theta = \frac{1}{m}L\sum_i\big(\sum_{\ell=1}^{2k}g_{i\ell}\frac{\langle\mu, X_{i,\ell}\rangle}{\sigma^2} + g_{i,2k+1}\beta\big)\langle X_{i,k},u\rangle.$$

By construction, the random variable $X_\theta - X'_\theta$ is a zero-mean Gaussian variable with variance

$$\begin{aligned}\mathbb{E}_g(X_\theta - X_{\theta'})^2 &= \sum_i(F(\tilde{\theta};\widetilde{X}_{i;2k}) - F(\tilde{\theta}';\widetilde{X}_{i;2k}))^2 \\ &\leq L^2\sum_i\langle X_{i,k},u\rangle^2\big(\sum_{\ell=1}^{2k}(\gamma_{i,\ell}-\gamma'_{i,\ell})^2 + (\beta-\beta')^2\big) \\ &= \mathbb{E}_g(Y_\theta - Y_{\theta'})^2 \qquad (69)\end{aligned}$$

By the Sudakov-Fernique comparison Ledoux and Talagrand (2013),we are then guaranteed that $\mathbb{E}\sup_\theta X_\theta \leq \mathbb{E}\sup_\theta Y_\theta$. Therefore, it is sufficient to bound

$$\mathbb{E}_g\sup_{\theta\in\Omega}Y_\theta = \underbrace{\mathbb{E}_g\sup_\theta\frac{L}{\sigma^2 n}\sum_{i=1}^m\sum_{\ell=1}^{2k}g_{i\ell}\langle\mu, X_{i,\ell}\rangle\langle X_{i,k},u\rangle}_{T_1} + \underbrace{\mathbb{E}_g\sup_\theta\frac{L}{n}\sum_{i=1}^m g_{i,2k+1}\beta\langle X_{i,k},u\rangle}_{T_2}.$$

Converting back to a Rademacher process: We now convert the term T_1 back to a Rademacher process, which allows us to use sub-exponential tail bounds. We do so by re-introducing additional Rademacher variables, and then removing the term $\max_i|g_i|$ via the Ledoux-Talagrand contraction theorem (Ledoux and Talagrand, 2013). Given a Rademacher variable ϵ_{il} independent of g, note the distributional equivalence $\epsilon_{il}g_{il}\stackrel{d}{=}g_{i\ell}$. Then consider the function $\phi_{i\ell}(g_{i\ell}) := g_{i\ell}h_{i\ell}$ with $h_{i\ell} := \langle\mu, X_{i,\ell}\rangle\langle X_{i,k},u\rangle$ for which it is easy to see that

$$|\phi_{i\ell}(g_{i\ell},h_{i\ell}) - \phi_{i\ell}(g_{i\ell},h'_{i\ell})| \leq |g_{i\ell}||h_{i\ell}-h'_{i\ell}| \qquad (70)$$

Applying Theorem 4.12. in Ledoux and Talgrand Ledoux and Talagrand (2013) yields

$$\mathbb{E}\sup_\theta\frac{1}{m}\sum_{i=1}^m\sum_{\ell=1}^{2k}\epsilon_{i\ell}g_{i\ell}\langle\mu, X_{i\ell}\rangle\langle X_{i,k},u\rangle \leq \mathbb{E}_g\|g\|_\infty\mathbb{E}_\epsilon\sup_\theta\frac{1}{m}\sum_{i=1}^m\sum_{\ell=1}^{2k}\epsilon_{i\ell}\langle\mu, X_{i,\ell}\rangle\langle X_{i,k},u\rangle.$$

Putting together the pieces yields the claim (62).

C.3.3 Proof of Lemma 10

We prove that the probability of each of the events corresponding to the inequalities is smaller than $\frac{1}{3}\mathrm{e}^{-\tilde{c}d\log(\frac{k}{\delta})}$.

Bounding L_m: We start by bounding $L_m(\widetilde{X};u)$. Note that

$$\frac{1}{m}\sum_{i=1}^m\langle X_{i,k},u\rangle^2 \leq \|\mu^*\|_2^2 + \frac{1}{m}\sum_{i=1}^m\langle n_{i,k},u\rangle^2 + \frac{1}{m}\sum_{i=1}^m\langle\mu^*,u\rangle\langle n_{i,k},u\rangle$$

where the sum $\sum_{i=1}^m\langle n_{i,k},u\rangle^2$ is sub-exponential random variable with parameters $(2\sqrt{m}\sigma^2,4)$ so that

$$\mathbb{P}(\frac{1}{m}\sum_{i=1}^m\langle n_{i,k},u\rangle^2 - \sigma^2 \geq \tilde{c}^2\sigma^2\log(1/\delta)) \leq \mathrm{e}^{-c'm\log\frac{1}{\delta}} \leq \mathrm{e}^{-c'd\log\frac{1}{\delta}}$$

where the last inequality follows since $m \geq d$ by assumption. Since $\langle n_{i,k},u\rangle$ can be readily bounded by a sub-Gaussian tailbound it then follows directly that $L_m^2(\widetilde{X};u) \leq \tilde{c}^2\frac{2(\|\mu^*\|_2^2+\sigma^2)\log\frac{1}{\delta}}{m}$ with probability at least $1-\frac{1}{3}\mathrm{e}^{-c'd\log(\frac{k}{\delta})}$ for c' large enough.

Bounding N_m: In order to bound $N_m(\widetilde{X};u)$, we first introduce an extra Rademacher random variable into its definition; doing so does not change its value (now defined by an expectation over both g and the Rademacher variables). We now require a result for a product of the form ϵgh where g,h are independent Gaussian random variables.

Lemma 11 *Let (ϵ, g, h) be independent random variables, with ϵ Rademacher, $g \sim \mathcal{N}(0, \sigma_g^2)$, and $h \sim \mathcal{N}(0, \sigma_h^2)$. Then the random variable $Z = \epsilon gh$ is a zero-mean sub-exponential random variable with parameters $(\frac{\sigma_g^2\sigma_h^2}{2}, \frac{1}{4})$.*

Proof Note that $g' = \alpha h$ with $\alpha = \frac{\sigma_g}{\sigma_h}$ is identically distributed as g. Therefore, we have

$$gh = \frac{1}{\alpha} g g' = \frac{1}{4\alpha}[(g - g')^2 + (g + g')^2]$$

The random variables $g - g'$ and $g + g'$ are independent and therefore $(g - g')^2, (g + g')^2$ are sub-exponential with parameters $\nu^2 = 4\sigma_g^4$, $b = \frac{1}{4}$. This directly yields

$$\mathbb{E}\mathrm{e}^{\lambda\epsilon[(g+g')^2 - (g-g')^2]} \leq \mathrm{e}^{4\lambda^2\sigma_g^4}$$

for $|\lambda| \leq \frac{1}{b}$. Therefore $\mathbb{E}\mathrm{e}^{\lambda\epsilon gh} \leq \mathrm{e}^{\frac{\lambda^2\sigma_g^2\sigma_h^2}{4}}$, which shows that ϵgh is sub-exponential with parameters $(\frac{\sigma_g^2\sigma_h^2}{2}, \frac{1}{4})$. ■

Returning to the random variable $N_m(\widetilde{X}; u)$, each term $\epsilon_i g_{i,2k+1}\langle X_{i,k}, u\rangle$ is a sub-exponential random variable with mean zero and parameter $\nu^2 = \|\mu^*\|_2^2 + \frac{\sigma^2}{2}$. Consequently, there are universal constants such that $N_m(\widetilde{X}; u) \leq cL\nu\sqrt{\frac{d\log\frac{k}{\delta}}{m}}$ with probability at least $1 - \frac{1}{3}\mathrm{e}^{-c' d\log(\frac{k}{\delta})}$.

Bounding M_m: Our next claim is that with probability at least $1 - \frac{1}{3}\mathrm{e}^{-c' d\log(\frac{k}{\delta})}$, we have

$$\mathbb{E}_\epsilon\|\frac{1}{m}\sum_{i=1}^m \epsilon_{i\ell} X_{i,\ell}\langle X_{i,k}, u\rangle\|_2 \leq (\|\mu^*\|_2^2 + \sigma^2)\sqrt{\frac{d\log\frac{k}{\delta}}{m}}, \tag{71}$$

which then implies that $M_m(\widetilde{X}; u) \leq c\|\mu^*\|_2\big(\frac{\|\mu^*\|_2}{\sigma^2} + 1\big)k\sqrt{\frac{d\log m\log\frac{k}{\delta}}{m}}$. In order to establish this claim, we first observe that by Lemma 11, the random variable $\epsilon_{i,\ell}\langle X_{i,\ell}, u\rangle\langle X_{i,k}, u\rangle$ is zero mean, sub-exponential with parameter at most $\nu^2 = (\|\mu^*\|_2^2 + \sigma^2)^2$. The bound then follows by the same argument used to bound the quantity N_m.

Appendix D. Mixing related results

In the following we use the shorthand notation $\pi_k^\theta := p(z_k \mid x_0^k, \theta)$ which we refer to the filtering distribution which is tied to some distribution μ on z_0.

Introducing the shorthand notation $p_\mu(x_k) := \sum_{z_k}\sum_{z_{k-1}} p(x_k \mid z_k)p(z_k \mid z_{k-1})\mu(z_{k-1})$, we define the filter operator

$$F_i\nu(z_i) := \frac{\sum_{z_{i-1}} p(x_i \mid z_i)p(z_i \mid z_{i-1})\nu(z_{i-1})}{\sum_{z_i}\sum_{z_{i-1}} p(x_i \mid z_i)p(z_i \mid z_{i-1})\nu(z_{i-1})} = \sum_{z_{i-1}} \frac{p(x_i \mid z_i)p(z_i \mid z_{i-1})}{p_\nu(x_i)}\nu(z_{i-1}).$$

where the observations x are fix. Using this notation, the filtering distribution can then be rewritten in the more compact form $\pi_k^\theta = p(z_k \mid x_0^k, \theta) = F_k \ldots F_1\mu$. Similarly, we define

$$K_{j|i}(z_j \mid z_{j-1}) := \frac{p(z_j \mid z_{j-1})p(x_j \mid z_j)p(x_{j+1}^i \mid z_j)}{\sum_{z_j} p(z_j \mid z_{j-1})p(x_j \mid z_j)p(x_{j+1}^i|z_j)}, \quad \text{and} \quad \nu_{\ell|i} := \frac{p(x_{\ell+1}^i \mid z_\ell)\nu(z_\ell)}{\sum_{z_\ell} p(x_{\ell+1}^i \mid z_\ell)\nu(z_\ell)}$$

Note that $\epsilon_{\mathrm{mix}}C_0 \leq p(x_{\ell+1}^i \mid z_\ell) \leq \epsilon_{\mathrm{mix}}^{-1}C_0$ where

$$C_0 = \sum_{z_i \ldots z_{\ell+1}} p(x_i \mid z_i)p(z_i \mid z_{i-1}) \ldots p(x_{\ell+1} \mid z_{\ell+1})\overline{\pi}(z_{\ell+1})$$

and therefore by definition of ϵ_{mix} (3)

$$\sup_x \frac{\sup_z p(x_{\ell+1}^i \mid z_\ell)}{\inf_z p(x_{\ell+1}^i \mid z_\ell)} \leq \epsilon_{\mathrm{mix}}^{-2}. \tag{72}$$

With these definitions, it can be verified (e.g., see Chapter 5 of van Handel (2008)) that $F_i \ldots F_{\ell+1}\nu = \nu_{\ell+1|i}^T K_{\ell+1|i} \ldots K_{i|i}$, where $\nu^T K := \int \nu(x')K(x|x')\mathrm{d}x'$. In the discrete setting, this relation can be written as the row vector ν being right multiplied by the kernel matrix K.

D.1 Consequences of mixing

In this technical appendix we derive several useful consequences of the geometric mixing condition on the stochastic process Z_i.

Lemma 12 *For any geometrically ρ_{mix}-mixing and time reversible Markov chain $\{Z_i\}$ with s states, there is a universal constant c such that*

$$\sup_{z_0} \big|p(z_0 \mid x_k^n) - p(z_0)\big| < \frac{c(s+1)}{\overline{\pi}_{\min}^3 \epsilon_{\mathrm{mix}}^3}\rho_{\mathrm{mix}}^k. \tag{73}$$

Proof We first prove the following relation

$$\sup_x |p(z_i \mid x_{i+k}) - p(z_i)| \leq c_0 \frac{\rho_{\mathrm{mix}}^k}{\overline{\pi}_{\min}}. \tag{74}$$

Using time reversibility and the definition of mixing (4) we obtain

$$\begin{aligned}
\max_x (p(z_0 \mid x_k) - \overline{\pi}(z_0)) &= \sum_{z_k} (p(z_0 \mid z_k) - \overline{\pi}(z_0))p(z_k \mid x_k) \\
&\leq \max_{z_k} |(p(z_0 \mid z_k) - \overline{\pi}(z_0))| \sum_{z_k} p(z_k \mid x_k) \\
&\leq \max_{z_k} \Big|\frac{p(z_k \mid z_0)\overline{\pi}(z_0)}{\overline{\pi}(z_k)} - \frac{\overline{\pi}(z_0)\overline{\pi}(z_k)}{\overline{\pi}(z_k)}\Big| \\
&\leq \frac{\overline{\pi}(z_0)}{\overline{\pi}(z_k)} \max_{z_k} |p(z_k \mid z_0) - \overline{\pi}(z_0)| \leq \frac{c_0\rho_{\mathrm{mix}}^k}{\overline{\pi}_{\min}}
\end{aligned}$$

where $p(z_k \mid z_0) = P(Z_k = z_k \mid Z_0 = z_0)$ and $p(z_0 \mid z_k) = P(Z_0 = z_0 \mid Z_k = z_k)$.

Using this result we can now prove inequality (73). By definition, we have

$$p(z_0) = \frac{p(x_{k+1}^n \mid x_k)p(x_k)p(z_0)}{p(x_{k+1}^n, x_k)}, \quad \text{and} \quad p(z_0 \mid x_k, x_{k+1}^n) = \frac{p(x_{k+1}^n \mid x_k, z_0)p(x_k \mid z_0)p(z_0)}{p(x_{k+1}^n, x_k)}$$

and therefore

$$|p(z_0) - p(z_0 \mid x_k^n)| \leq \frac{p(x_k)p(z_0)}{p(x_k^n)}|p(x_{k+1}^n \mid x_k) - p(x_{k+1}^n \mid x_k, z_0)| + \frac{p(x_{k+1}^n \mid x_k, z_0)p(z_0)}{p(x_{k+1}^n \mid x_k)}|p(x_k) - p(x_k \mid z_0)| \quad (75)$$

In the following we bound each of the two differences. Note that

$$\begin{aligned}|p(x_{k+1}^n \mid x_k, z_0) - p(x_{k+1}^n \mid x_k)| &= \sum_{z_k}\sum_{z_{k+1}} p(x_{k+1}^n \mid z_{k+1})p(z_{k+1} \mid z_k)|p(z_k \mid x_k, z_0) - p(z_k \mid x_k)| \\ &\leq \sup_{z_k, x_k} |p(z_k \mid x_k, z_0) - p(z_k \mid x_k)| \sum_{z_k} p(x_{k+1}^n \mid z_k) \quad (76)\end{aligned}$$

The last term $\sum_{z_k} p(x_{k+1}^n \mid z_k)$ is bounded by s for s-state models. Using the bound (74), we obtain

$$|p(x_k \mid z_0) - p(x_k)| = \frac{|p(z_0 \mid x_k) - \overline{\pi}(z_0)|p(x_k)}{\overline{\pi}(z_0)} \leq \frac{p(x_k)}{\overline{\pi}_{\min}^2}\rho_{\mathrm{mix}}^k \quad (77)$$

which yields

$$\begin{aligned}|p(z_k \mid x_k, z_0) - p(z_k \mid x_k)| &= p(x_k \mid z_k)\left|\frac{p(z_k \mid z_0)}{p(x_k \mid z_0)} - \frac{\overline{\pi}(z_k)}{p(x_k)}\right| \\ &\leq \frac{p(x_k \mid z_k)}{p(x_k \mid z_0)}\left(|p(z_k \mid z_0) - \overline{\pi}(z_k)| + \frac{\overline{\pi}(z_k)}{p(x_k)}|p(x_k \mid z_0) - p(x_k)|\right) \\ &\leq \frac{p(x_k \mid z_k)}{p(x_k \mid z_0)}\left(\rho_{\mathrm{mix}}^k + \frac{1}{\overline{\pi}_{\min}^2}\rho_{\mathrm{mix}}^k\right) \\ &\leq \frac{2\rho_{\mathrm{mix}}^k}{p(z_k \mid z_0)\overline{\pi}_{\min}^2} \leq \frac{2}{\overline{\pi}_{\min}^3\epsilon_{\mathrm{mix}}}\rho_{\mathrm{mix}}^k. \quad (78)\end{aligned}$$

The last statement is true because one can check that for all $t \in \mathbb{N}$ we have

$$\min_{z_k, z_0} p(z_k \mid z_0) = \min_{ij}(A^t)_{ij} \geq \min_{ij}(A)_{ij} \geq \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$$

for any stochastic matrix A which satisfies the mixing condition (3).

Substituting (76) with (78) and (77) into (75), we obtain

$$\begin{aligned}|p(z_0) - p(z_0 \mid x_k^n)| &\leq \frac{\sum_{z_k} p(x_{k+1}^n \mid z_k)p(z_0)}{\sum_{z_k} p(x_{k+1}^n \mid z_k)p(z_k \mid x_k)}\frac{2\rho_{\mathrm{mix}}^k}{\overline{\pi}_{\min}^3\epsilon_{\mathrm{mix}}} + \frac{p(x_{k+1}^n \mid x_k, z_0)p(z_0)}{p(x_{k+1}^n \mid x_k)}\frac{\rho_{\mathrm{mix}}^k}{\overline{\pi}_{\min}} \\ &\leq \left(\frac{2s}{\overline{\pi}_{\min}^3\epsilon_{\mathrm{mix}}^3} + \frac{1}{\epsilon_{\mathrm{mix}}^2\overline{\pi}_{\min}}\right)\rho_{\mathrm{mix}}^k \leq \frac{2s+1}{\overline{\pi}_{\min}^3\epsilon_{\mathrm{mix}}^3}\rho_{\mathrm{mix}}^k\end{aligned}$$

where we use (72) to see that

$$\frac{\sum_{z_k} p(x_{k+1}^n \mid z_k)p(z_k \mid x_k, z_0)}{\sum_{z_k} p(x_{k+1}^n \mid z_k)p(z_k \mid x_k)} \leq \frac{\max_{z_k} p(x_{k+1}^n \mid z_k)}{\min_{z_k} p(x_{k+1}^n \mid z_k)} \leq \epsilon_{\mathrm{mix}}^{-2}$$

and similarly for the first term. ■

Lemma 13 (Filter stability) *For any mixing Markov chain which fulfills condition* (3)*, the following holds*

$$\|F_i \dots F_1(\nu - \nu')\|_\infty \leq \epsilon_{\mathrm{mix}}^{-2}\widetilde{\rho}_{\mathrm{mix}}^i\|\nu - \nu'\|_1$$

where $\widetilde{\rho}_{\mathrm{mix}} = 1 - \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$*. In particular we have*

$$\sup_{z_i} |p(z_i \mid x_1^i) - p(z_i \mid x_{-n}^i)| \leq 2\epsilon_{\mathrm{mix}}^{-2}\widetilde{\rho}_{\mathrm{mix}}^i. \quad (79)$$

Proof Given the mixing assumption (3) we can show that $K_{j|i}(x|y) \geq \epsilon p_{j|i}(x)$ with $\epsilon = \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$ for some probability distribution $p_{j|i}(\cdot)$. This is because we can lower bound

$$\begin{aligned}K_{j|i}(z_j \mid z_{j-1}) &= \frac{p(z_j \mid z_{j-1})p(x_j \mid z_j)p(x_{j+1}^i \mid z_j)}{\sum_{z_j} p(z_j \mid z_{j-1})p(x_j \mid z_j)p(x_{j+1}^i \mid z_j)} \\ &\geq \underbrace{\frac{\epsilon_{\mathrm{mix}}\overline{\pi}(z_j)p(x_j \mid z_j)p(x_{j+1}^i \mid z_j)}{\sum_{z_j}\frac{\overline{\pi}(z_j)}{\overline{\pi}_{\min}}p(x_j \mid z_j)p(x_{j+1}^i \mid z_j)}}_{=:\epsilon p_{j|i}(z_j)}\end{aligned}$$

with $\epsilon = \epsilon_{\mathrm{mix}}\overline{\pi}_{\min}$. This allows us to define the stochastic matrix

$$Q_{j|i} = \frac{1}{1-\epsilon}(K_{j|i} - \epsilon P_{j|i}) \text{ or } K_{j|i} = \epsilon P_{j|i} + (1-\epsilon)Q_{j|i}.$$

where $(P_{j|i})_{k\ell} = p_{j|i}(\ell)$ and for any two probability distributions ν_1, ν_2 we have $(\nu_1 - \nu_2)^T P_{j|i} = 0$. Using $\widetilde{\rho}_{\mathrm{mix}} = 1 - \epsilon$ we then obtain by induction, Hoelder's inequality and

inequality (72)

$$\begin{aligned}
&\|(\nu_{1|i} - \nu'_{1|i})^T K_{1|i} \dots K_{i|i}\|_\infty \\
&\leq \prod_{j=1}^{i} (1-\epsilon) \|(\nu_{1|i} - \nu'_{1|i})^T \otimes_{j=1}^{i} Q_{j|i}\|_2 \\
&\leq \widetilde{\rho}^i_{\text{mix}} \|\nu_{1|i} - \nu'_{1|i}\|_2 \prod_{j=1}^{i} \|Q^T_{j|i}\|_{op} \leq \widetilde{\rho}^i_{\text{mix}} \|\nu_{1|i} - \nu'_{1|i}\|_2 \\
&\leq \widetilde{\rho}^i_{\text{mix}} \left\| \frac{p(x^i_2 \mid \cdot)\nu(\cdot)}{\sum_{z_1} p(x^i_2 \mid z_1)\nu(z_1)} - \frac{p(x^i_2 \mid \cdot)\nu'(\cdot)}{\sum_{z_1} p(x^i_2 \mid z_1)\nu'(z_1)} \right\|_2 \\
&\leq \widetilde{\rho}^i_{\text{mix}} \Big[\Big\| \frac{p(x^i_2 \mid \cdot)}{\sum_{z_1} p(x^i_2 \mid z_1)\nu(z_1)} (\nu(\cdot) - \nu'(\cdot)) \Big\|_2 \\
&+ \Big| \sup_{z_1} p(x^i_2 \mid z_1) \Big(\frac{1}{\sum_{z_1} p(x^i_2 \mid z_1)\nu(z_1)} - \frac{1}{\sum_{z_1} p(x^i_2 \mid z_1)\nu'(z_1)} \Big) \Big| \|\nu'(\cdot)\|_1 \Big] \\
&\leq \widetilde{\rho}^i_{\text{mix}} \Big(\frac{\sup_{z_1} p(x^i_2 \mid z_1)}{\inf_{z_1} p(x^i_2 \mid z_1)} \Big)^2 \|\nu - \nu'\|_1 \leq \epsilon^{-2}_{\text{mix}} \widetilde{\rho}^i_{\text{mix}} \|\nu - \nu'\|_1,
\end{aligned}$$

since $Q_{j|i}$ are stochastic matrices and $\|\nu\|_2 \leq \|\nu\|_1 \leq 1$ for probability vectors. The second statement is readily derived by substituting $\nu(z_1) = p(z_1)$ and $\nu'(z_1) = p(z_1 \mid x^1_{-n})$. ■

D.2 Proof of Lemma 3

Recall the shorthand $\widetilde{\rho}_{\text{mix}} = 1 - \epsilon_{\text{mix}} \overline{\pi}_{\min}$. First observe that

$$\begin{aligned}
\sup_{z_i} |p(z_i \mid x^n_1) - p(z_i \mid x^{i+k}_{i-k})| &\leq |p(z_i|x^n_{i+1})p(z_i|x^i_1) - p(z_i|x^{i+k}_{i+1})p(z_i|x^i_{i-k+1})| \frac{p(x^n_{i+1})}{p(x^n_{i+1}|x^i_1)p(z_i)} \\
&\quad + |A-1| \frac{p(x^{i+k}_{i+1})}{p(x^{i+k}_{i+1}|x^i_{i-k+1})} \frac{1}{p(z_i)}
\end{aligned}$$

where $A = \frac{p(x^n_{i+1})}{p(x^n_{i+1}|x^i_1)} \left(\frac{p(x^{i+k}_{i+1})}{p(x^{i+k}_{i+1}|x^i_{i-k+1})} \right)^{-1}$. We bound the two terms in the sum separately.

From Lemma 13 we directly obtain the following upper bounds

$$\begin{aligned}
\sup_{z,x} |p(z_i \mid x^i_1) - p(z_i \mid x^i_{i-k+1})| &\leq \epsilon^{-2}_{\text{mix}} \widetilde{\rho}^{\min\{i,k\}}_{\text{mix}} \\
\sup_{z,x} |p(z_i \mid x^n_{i+1}) - p(z_i \mid x^{i+k}_{i+1})| &\leq \epsilon^{-2}_{\text{mix}} \widetilde{\rho}^{\max\{n-i,k\}}_{\text{mix}}
\end{aligned}$$

where the latter follows because of reversibility assumption (2) of the Markov chain. Inequality (72) can also be used to show that $\frac{p(x^n_{i+1})}{p(x^n_{i+1}|x^i_1)}, \frac{p(x^{i+k}_{i+1})}{p(x^{i+k}_{i+1}|x^i_{i-k+1})} \leq \epsilon^{-2}_{\text{mix}}$. A proof for a similar statement is given after inequality (80). The first term of the sum is therefore bounded

above by $2 \frac{\widetilde{\rho}^{\min\{i,n-i,k\}}_{\text{mix}}}{\pi_{\min} \epsilon^4_{\text{mix}}}$.

For the second term, we mainly need to bound $|A-1|$. In order to simplify the notation in the proof, we divide the sequence of values all observed variables in the window $i-k, i+k$ around index i, i.e. $x^{\max\{i+k,n\}}_{\min\{i-k,1\}}$, into four disjoint chunks and call them a, b, c, d in chronological order, explicitly defined as

$$a := x^{\max\{i-k,1\}}_{\min\{i-k,1\}} \quad b := x^{i}_{\max\{i-k,1\}+1} \quad c := x^{\min\{i+k,n\}}_{i+1} \quad d := x^{\max\{i+k,n\}}_{\min\{i+k,n\}+1}.$$

Note that the definition depends on whether $i-k > 1$ or $i+k < n$. Depending on the combination of $i+k < n$ and $i-k > 1$ being true or false,

$$A = \begin{cases} \frac{p(d|c)p(a|b)}{p(d|a,b,c)p(a|b,c)} & \text{if } i-k > 1,\ i+k < n \\ \frac{p(a|b)p(d|a,b,c)}{p(a|b,c,d)p(d|c)} & \text{if } i-k > 1,\ i+k > n \end{cases}.$$

For the other two possible cases, A is an inverse of the above. We demonstrate the main argument by looking into these two cases in more detail. Observe that the following inequality holds for the first case

$$|A-1| \leq \frac{|p(d \mid c) - p(d \mid a,b,c)|}{p(d \mid a,b,c)} \frac{p(a \mid b)}{p(a \mid b,c)} + \frac{|p(a \mid b) - p(a \mid b,c)|}{p(a \mid b,c)}$$

holds for all x. For the second case there is only an additional conditioning on d for the second term on the right hand side. In the inverse case that $i-k < 1, i+k > n$ we have

$$|A-1| \leq \frac{|p(d \mid c) - p(d \mid a,b,c)|}{p(d \mid c)} \frac{p(a \mid b,c)}{p(a \mid b)} + \frac{|p(a \mid b) - p(a \mid b,c)|}{p(a \mid b)}$$

and equivalently with an additional conditioning on d for $i-k < 1, i+k < n$. It is thus sufficient to consider $\sup_x |p(d \mid c) - p(d \mid a,b,c)|$ and $\sup_x |p(a \mid b) - p(a \mid b,c,d)|$. We see later that this is also the critical quantity to bound for the inverses.

First note that

$$\max\Big\{ \frac{p(a \mid b)}{p(a \mid b,c)}, \frac{p(a \mid b,c)}{p(a \mid b)} \Big\} \leq \epsilon^{-2}_{\text{mix}}. \tag{80}$$

For the first term we see that for all x we have

$$\begin{aligned}
\frac{p(a \mid b)}{p(a \mid b,c)} = \frac{p(x^\beta_\alpha \mid x^i_{\beta+1})}{p(x^\beta_\alpha \mid x^i_{\beta+1}, x^\gamma_{i+1})} &= \frac{\sum_{z_{\beta+1}} p(x^\beta_\alpha \mid z_{\beta+1}) p(z_{\beta+1} \mid x^i_{\beta+1})}{\sum_{z_{\beta+1}} p(x^\beta_\alpha \mid z_{\beta+1}) p(z_{\beta+1} \mid x^\gamma_{\beta+1})} \\
&\leq \frac{\sup_z p(x^\beta_\alpha \mid z_{\beta+1})}{\inf_z p(x^\beta_\alpha \mid z_{\beta+1})} \leq \epsilon^{-2}_{\text{mix}}
\end{aligned}$$

where the second inequality holds because of conditional independence of $x^i_{\beta+1}$ and x^β_α given $z_{\beta+1}$ in an HMM, and the last line holds because of inequality (72) and the fact that the Markov chain is invertible. Observe that the same arguments goes through for the inverse as well so that inequality (80) holds.

Let us now look at the rest of the terms involving differences. For the sake of simplification, let us introduce the shorthand notation

$$\alpha := \min\{i-k,1\}, \quad \beta := \max\{i-k,1\}, \quad \gamma := \min\{i+k,n\}, \quad \text{and} \quad \delta := \max\{i+k,n\}.$$

Then we can write $x_\alpha^\beta = a; x_{\beta+1}^i = b; x_{i+1}^\gamma = c; x_{\gamma+1}^\delta = d$ and bound $|p(d \mid c) - p(d \mid a,b,c)|$. Using Lemma 13 and inequality (72), we have the bound

$$\begin{aligned}
\frac{p(d \mid c) - p(d \mid a,b,c)}{p(d \mid a,b,c)} &= \frac{|p(x_{\gamma+1}^\delta | x_{i+1}^\gamma) - p(x_{\gamma+1}^\delta | x_\alpha^i, x_{i+1}^\gamma)|}{p(x_{\gamma+1}^\delta | x_\alpha^i, x_{i+1}^\gamma)} \\
&\leq \frac{\sum_{z_\gamma} p(x_{\gamma+1}^\delta \mid z_\gamma)|p(z_\gamma|x_{i+1}^\gamma) - p(z_\gamma|x_\alpha^i, x_{i+1}^\gamma)|}{\sum_{z_\gamma} p(x_{\gamma+1}^\delta|z_\gamma)p(z_\gamma|x_\alpha^\gamma)} \\
&\leq \frac{\sup_z p(x_{\gamma+1}^\delta|z_\gamma)}{\inf_z p(x_{\gamma+1}^\delta|z_\gamma)} \sum_{z_\gamma} |p(z_\gamma|x_{i+1}^\gamma) - p(z_\gamma|x_\alpha^\gamma)| \\
&\leq Cs\epsilon_{\text{mix}}^{-4}\tilde{\rho}_{\text{mix}}^{\gamma-i} = Cs\epsilon_{\text{mix}}^{-4}\tilde{\rho}_{\text{mix}}^{\min\{n-i,k\}}.
\end{aligned}$$

The same argument applies if the denominator is $p(d \mid c)$. Analogously, we have that

$$\frac{|p(a \mid b) - p(a \mid b,c)|}{p(a \mid b,c)} \leq Cs\epsilon_{\text{mix}}^{-4}\tilde{\rho}_{\text{mix}}^{i-\beta+1} = Cs\epsilon_{\text{mix}}^{-4}\tilde{\rho}_{\text{mix}}^{\min\{k,i\}}$$

and the same holds for the case when the denominator is $p(a \mid b)$ by inequality (80).

Note that the additional conditioning on d, does not change the result. Also, considering the inverses we see that the inequalities still hold.

Putting everything together now yields

$$|A - 1| \leq C's\epsilon_{\text{mix}}^{-6}\tilde{\rho}_{\text{mix}}^{\min\{n-i,i,k\}},$$

where C' is a generic constant and thus

$$\sup_{z_i} |p(z_i \mid x_1^n) - p(z_i \mid x_{i-k}^{i+k})| \leq C\frac{s\tilde{\rho}_{\text{mix}}^{\min\{i,n-i,k\}}}{\bar{\pi}_{\min}\epsilon_{\text{mix}}^8}.$$

D.3 Proof of Lemma 6

The latter inequality is valid in our particular case because

$$\begin{aligned}
|\operatorname{cov}(z_0, z_\ell \mid x_0, \ldots, x_k)| &= |\sum_{z_0,z_\ell} z_0 z_\ell p(z_\ell \mid z_0, x)p(z_0|x) - \sum_{z_0} z_0 p(z_0|x) \sum_{z_\ell} z_\ell p(z_\ell|x)| \\
&= |\sum_{z_0,z_\ell} z_0 z_\ell p(z_0|x)(p(z_\ell|z_0,x) - p(z_\ell \mid x))| \\
&\leq \sup_{z_\ell,z_0} |p(z_\ell|z_0,x) - p(z_\ell \mid x)| \sum_{z_0}\sum_{z_\ell} |z_0 z_\ell| p(z_0 \mid x)
\end{aligned}$$

Let us now show that $\sup_{z_\ell,z_0} \left|p(z_\ell \mid z_0,x) - p(z_\ell \mid x)\right| \leq \rho_{\text{mix}}^\ell$. Introducing the shorthand $\Delta(\ell) = p(z_\ell = 1 \mid z_0 = 1, x) - p(z_\ell = 1 \mid z_0 = -1, x)$, we first claim that

$$|\Delta(1)| \leq \rho_{\text{mix}} \tag{81}$$

To establish this fact, note that

$$\begin{aligned}
\Delta(1) &= \left|\frac{p(x \mid z_\ell = 1)}{p(x \mid z_{\ell-1} = 1)} p(z_\ell = 1 \mid z_{\ell-1} = 1) - \frac{p(x \mid z_\ell = 1)}{p(x \mid z_{\ell-1} = -1)} p(z_\ell = 1 \mid z_{\ell-1} = -1)\right| \\
&= \frac{ap}{ap + b(1-p)} - \frac{a(1-p)}{a(1-p) + bp} \\
&= \frac{ab}{(ap + b(1-p))(a(1-p) + bp)}(2p - 1)
\end{aligned}$$

where we write $a = p(x \mid z_\ell = 1)$ and $b = p(x \mid z_\ell = -1)$. The denominator is minimized at $p = 1$ so that inequality (81) is shown. The same argument shows that $|\Delta(-1)| \leq \rho_{\text{mix}}$.

Induction step: Assume that $\Delta(\ell - 1) \leq \rho_{\text{mix}}^{\ell-1}$. It then follows that

$$\begin{aligned}
&|p(z_\ell = 1 \mid z_0 = 1, x) - p(z_\ell = 1 \mid z_0 = -1, x)| \\
&= |\sum_{z_{\ell-1}} p(z_\ell = 1 \mid z_{\ell-1}, x)p(z_{\ell-1} \mid z_0 = 1, x) - p(z_\ell = 1 \mid z_{\ell-1}, x)p(z_{\ell-1}|z_0 = -1, x)| \\
&= \Delta(1)\Delta(\ell - 1) \leq \rho_{\text{mix}}^\ell
\end{aligned}$$

Since

$$p(z_\ell = 1 \mid z_0 = -1, x) - p(z_\ell = 1 \mid z_0 = 1, x) = -p(z_\ell = -1 \mid z_0 = -1, x) + p(z_\ell = -1 \mid z_0 = 1, x)$$

we use the shorthand $s = p(z_0 = 1 \mid x)$ to obtain

$$\begin{aligned}
&\sup_{z_\ell,z_0} |\, p(z_\ell \mid z_0, x) - p(z_\ell \mid x)| \\
&= \sup_{b_\ell,b_0} p(z_\ell = b_\ell \mid z_0 = b_0, x) - [(p(z_\ell = b_\ell \mid z_0 = 1, x)s + p(z_\ell = b_\ell \mid z_0 = -1, x)(1 - s)] \\
&\leq (1 - s)|\Delta(\ell)| \leq \rho_{\text{mix}}
\end{aligned}$$

which proves the bound for $\operatorname{cov}(Z_0, Z_1 \mid \gamma)$.

For the two state mixing we define $\widetilde{\Delta}(\ell) = p(z_\ell = 1 \mid z_1 z_0 = 1, x) - p(z_\ell = 1 \mid z_1 z_0 = -1, x)$ and can readily see that $|\widetilde{\Delta}(1)| \leq \rho_{\text{mix}}$ and

$$\begin{aligned}
&|p(z_{\ell+1}z_{\ell+2} = 1 \mid z_\ell z_{\ell-1} = 1, x) - p(z_{\ell+1}z_{\ell+2} = 1 \mid z_\ell z_{\ell-1} = -1, x)| \\
&= [p(z_{\ell+2} = 1 \mid z_{\ell+1} = 1, x) - p(z_{\ell+2} = -1 \mid z_{\ell+1} = -1, x)]\tilde{\Delta}(2)
\end{aligned}$$

Using equation (81), we obtain

$$|\widetilde{\Delta}(2)| = |p(z_1 = 1 \mid z_0 = 1, x) - p(z_1 = -1 \mid z_0 = -1, x)|\widetilde{\Delta}(1) \leq \rho_{\text{mix}} \tag{82}$$

from which it directly follows that

$$|p(z_{\ell+1}z_{\ell+2} = 1 \mid z_\ell z_{\ell-1} = 1, x) - p(z_{\ell+1}z_{\ell+2} = 1 \mid z_\ell z_{\ell-1} = -1, x)| \leq \rho_{\text{mix}}$$

The rest follows the same arguments as above and the bound for $\operatorname{cov}(Z_0 Z_1, Z_\ell Z_{\ell+1} \mid \gamma)$ in inequality (55) is shown.

Finally, the bound for $\operatorname{cov}(Z_0, Z_\ell Z_{\ell+1} \mid \gamma)$ in inequality (55) follows in a straightforward way using the relation (82) and induction with equation (81), as above.

Abstract

We study parameter inference in large-scale latent variable models. We first propose a unified treatment of online inference for latent variable models from a non-canonical exponential family, and draw explicit links between several previously proposed frequentist or Bayesian methods. We then propose a novel inference method for the frequentist estimation of parameters, that adapts MCMC methods to online inference of latent variable models with the proper use of local Gibbs sampling. Then, for latent Dirichlet allocation,we provide an extensive set of experiments and comparisons with existing work, where our new approach outperforms all previously proposed methods. In particular, using Gibbs sampling for latent variable inference is superior to variational inference in terms of test log-likelihoods. Moreover, Bayesian inference through variational methods perform poorly, sometimes leading to worse fits with latent variables of higher dimensionality.

Keywords: Latent Variables Models, Online Learning, Gibbs Sampling, Topic Modelling, Latent Dirichlet Allocation

1. Introduction

Probabilistic graphical models provide general modelling tools for complex data, where it is natural to include assumptions on the data generating process by adding latent variables in the model. Such latent variable models are adapted to a wide variety of unsupervised learning tasks (Koller and Friedman, 2009; Murphy, 2012). In this paper, we focus on parameter inference in such latent variable models where the main operation needed for the standard expectation-maximization (EM) algorithm is intractable, namely dealing with conditional distributions over latent variables given the observed variables; latent Dirichlet allocation (LDA) (Blei et al., 2003) is our motivating example, but many hierarchical models exhibit this behavior, e.g., ICA with heavy-tailed priors. For such models, there exist two main classes of methods to deal efficiently with intractable exact inference in large-scale situations: sampling methods or variational methods.

Sampling methods can handle arbitrary distributions and lead to simple inference algorithms while converging to exact inference. However it may be slow to converge and non scalable to big datasets in practice. In particular, although efficient implementations have been developed, for example for LDA (Zhao et al., 2014; Yan et al., 2009), MCMC methods may not deal efficiently yet with continuous streams of data for our general class of models.

On the other hand, *variational inference* builds an approximate model for the posterior distribution over latent variables—called variational—and infer parameters of the true model through this approximation. The fitting of this variational distribution is formulated as an optimization problem where efficient (deterministic) iterative techniques such as gradient or coordinate ascent methods apply. This approach leads to scalable inference schemes (Hoffman et al., 2013), but due to approximations, there always remains a gap between the variational posterior and the true posterior distribution, inherent to algorithm design, and that will not vanish when the number of samples and the number of iterations increase.

Beyond the choice of approximate inference techniques for latent variables, parameter inference may be treated either from the *frequentist* point of view, e.g., using maximum likelihood inference, or a *Bayesian* point of view, where the posterior distribution of the parameter given the observed data is approximated. With massive numbers of observations, this posterior distribution is typically peaked around the maximum likelihood estimate, and the two inference frameworks should not differ much (Van der Vaart, 2000).

In this paper, we focus on methods that make a single pass over the data to estimate parameters. We make the following contributions:

1. We review and compare existing methods for online inference for latent variable models from a non-canonical exponential family in Section 2, and draw explicit links between several previously proposed frequentist or Bayesian methods. Given the large number of existing methods, our unifying framework allows to understand differences and similarities between all of them.

2. We propose in Section 3 a novel inference method for the frequentist estimation of parameters, that adapts MCMC methods to online inference of latent variable models with the proper use of "local" Gibbs sampling. In our online scheme, we apply Gibbs sampling to the current observation, which is "local", as opposed to "global" batch schemes where Gibbs sampling is applied to the entire dataset.

3. After formulating LDA as a non-canonical exponential family in Section 4, we provide an extensive set of experiments in Section 6, where our new approach outperforms all previously proposed methods. In particular, using Gibbs sampling for latent variable inference is superior to variational inference in terms of test log-likelihoods. Moreover, Bayesian inference through variational methods perform poorly, sometimes leading to worse fits with latent variables of higher dimensionality.

2. Online EM

We consider an *exponential family* model on random variables (X, h) with parameter $\eta \in \mathcal{E} \subseteq \mathbb{R}^d$ and with density (Lehmann and Casella, 1998):

$$p(X, h|\eta) = a(X, h) \exp\big[\langle \phi(\eta), S(X, h)\rangle - \psi(\eta)\big]. \tag{1}$$

We assume that h is hidden and X is observed. The vector $\phi(\eta) \in \mathbb{R}^d$ represents the natural parameter, $S(X, h) \in \mathbb{R}^d$ is the vector of sufficient statistics, $\psi(\eta)$ is the log-normalizer, and $a(X, h)$

is the underlying base measure. We consider a *non-canonical* family as in many models (such as LDA), the natural parameter $\phi(\eta)$ does not coincide with the model parameter η, that is, $\phi(\eta) \not\equiv \eta$; we however assume that ϕ is injective.

We consider N *i.i.d.* observations $(X_i)_{i=1,\dots,N}$ from a distribution $t(X)$, which may be of the form $P(X|\eta^*) = \int_h p(X,h|\eta^*)\mathrm{d}h$ for our model above and a certain $\eta^* \in \mathcal{E}$ (well-specified model) or not (misspecified model). Our goal is to obtain a predictive density $r(X)$ built from the data and using the model defined in (1), with the maximal expected log-likelihood $\mathbb{E}_{t(X)} \log r(X)$.

2.1 Maximum Likelihood Estimation

In the frequentist perpective, the predictive distribution $r(X)$ is of the form $p(X|\hat{\eta})$, for a well-defined estimator $\hat{\eta} \in \mathcal{E}$. The most common method is the EM algorithm (Dempster et al., 1977), which is an algorithm that aims at maximizing the likelihood of the observed data, that is,

$$\max_{\eta \in \mathcal{E}} \sum_{i=1}^{N} \log p(X_i|\eta). \tag{2}$$

More precisely, the EM algorithm is an iterative process to find the maximum likelihood (ML) estimate given observations $(X_i)_{i=1,\dots,N}$ associated to hidden variables $(h_i)_{i=1,\dots,N}$. It may be seen as the iterative construction of lower bounds of the log-likelihood function (Bishop, 2006). In the exponential family setting (1), we have, by Jensen's inequality, given the model defined by $\eta' \in \mathcal{E}$ from the previous iteration, and for any parameter $\eta \in \mathcal{E}$:

$$\begin{aligned}
\log p(X_i|\eta) &= \log \int p(X_i,h_i|\eta) dh_i \\
&\geq \int p(h_i|X_i,\eta') \log \frac{p(X_i,h_i|\eta)}{p(h_i|X_i,\eta')} dh_i \\
&= \int p(h_i|X_i,\eta') \left(\langle \phi(\eta), S(X_i,h_i) \rangle - \psi(\eta) \right) dh_i - C_i(\eta') \\
&= \langle \phi(\eta), \mathbb{E}_{p(h_i|X_i,\eta')} \left[S(X_i,h_i) \right] \rangle - \psi(\eta) - C_i(\eta'),
\end{aligned}$$

for a certain constant $C_i(\eta')$, with equality if $\eta' = \eta$. Thus, EM-type algorithms build locally tight lower bounds of the log-likelihood in (2), which are equal to

$$\langle \phi(\eta), \textstyle\sum_{i=1}^{N} s_i \rangle - N\psi(\eta) + \text{cst},$$

for appropriate values of $s_i \in \mathbb{R}^d$ obtained by computing conditional expectations with the distribution of h_i given X_i for the current model defined by η' (E-step), i.e., $s_i = \mathbb{E}_{p(h_i|X_i,\eta')} \left[S(X_i,h_i) \right]$. Then this function of η is maximized to obtain the next iterate (M-step). In standard EM applications, these two steps are assumed tractable. In Section 3, we will only assume that the M-step is tractable while the E-step is intractable.

Standard EM will consider $s_i = \mathbb{E}_{p(h_i|X_i,\eta')} \left[S(X_i,h) \right]$ for the previous value of the parameter η for all i, and hence, at every iteration, all observations X_i, $i = 1, \dots, N$ are considered for latent variable inference, leading to a slow "batch" algorithm for large N.

Incremental EM (Neal and Hinton, 1998) will only update a single element s_i coming from a single observation X_i and update the corresponding part of the sum $\sum_{j=1}^{N} s_j$ without changing

other elements. In the extreme case where a single pass over the data is made, then the M-step at iteration i maximizes

$$\langle \phi(\eta), \sum_{j=1}^{i} \mathbb{E}_{p(h_j|X_j,\eta_{j-1})} \left[S(X_j,h_j) \right] \rangle - i\psi(\eta),$$

with respect to η. In the next section, we provide a (known) other interpretation of this algorithm.

2.2 Stochastic Approximation

Given our frequentist objective $\mathbb{E}_{t(X)} \log p(X|\eta)$ to maximize defined as an expectation, we may consider two forms of stochastic approximation (Kushner and Yin, 2003), where observations X_i sampled from $t(X)$ are processed only once. The first one is stochastic gradient ascent, of the form

$$\eta_i = \eta_{i-1} + \rho_i \frac{\partial \log p(X_i|\eta)}{\partial \eta},$$

or appropriately renormalized version thereof, i.e., $\eta_i = \eta_{i-1} + \rho_i H^{-1} \frac{\partial \log p(X_i|\eta)}{\partial \eta}$, with several possibilities for the $d \times d$ matrix H, such as the negative Hessian of the partial or the full log-likelihood, or the negative covariance matrix of gradients, which can be seen as versions of natural gradient—see Titterington (1984); Delyon et al. (1999); Cappé and Moulines (2009). This either leads to slow convergence (without H) or expensive iterations (with H), with the added difficulty of choosing a proper scale and decay for the step-size ρ_i.

A key insight of Delyon et al. (1999); Cappé and Moulines (2009) is to use a different formulation of stochastic approximation, *not explicitly based on stochastic gradient ascent*. Indeed, they consider the stationary equation $\mathbb{E}_{t(X)} \left[\frac{\partial \log p(X|\eta)}{\partial \eta} \right] = 0$ and expand it using the exponential family model (1) as follows:

$$\begin{aligned}
\frac{\partial \log p(X|\eta)}{\partial \eta} &= \frac{\partial \log \int p(X,h|\eta) dh}{\partial \eta} \\
&= \phi'(\eta) \mathbb{E}_{p(h|X,\eta)} \left[S(X,h) \right] - \psi'(\eta).
\end{aligned}$$

Given standard properties of the exponential family, namely

$$\psi'(\eta) = \phi'(\eta) \mathbb{E}_{p(h,X|\eta)} \left[S(X,h) \right] \text{[1]},$$

and assuming invertibility of $\phi'(\eta)$, this leads to the following stationary equation:

$$\mathbb{E}_{t(X)} \left[\mathbb{E}_{p(h|X,\eta)} \left[S(X,h) \right] \right] = \mathbb{E}_{p(h,X|\eta)} \left[S(X,h) \right].$$

1. Proof: Given (1), $\int_{X,h} p(X,h|\eta) \mathrm{d}(X,h) = 1 \Rightarrow \psi(\eta) = \log \left[\int_{X,h} a(X,h) e^{\langle \phi(\eta), S(X,h) \rangle} \mathrm{d}(X,h) \right]$. We then derive this identity with respect to η, which gives:

$$\begin{aligned}
\psi'(\eta) &= \frac{\int_{X,h} \phi'(\eta) S(X,h) a(X,h) e^{\langle \phi(\eta), S(X,h) \rangle} \mathrm{d}(X,h)}{\int_{X,h} a(X,h) e^{\langle \phi(\eta), S(X,h) \rangle} \mathrm{d}(X,h)} \\
&= \frac{\phi'(\eta) \int_{X,h} S(X,h) a(X,h) e^{\langle \phi(\eta), S(X,h) \rangle} \mathrm{d}(X,h)}{e^{\psi(\eta)}} \\
&= \phi'(\eta) \int_{X,h} S(X,h) p(X,h|\eta) \mathrm{d}(X,h) \\
&= \phi'(\eta) \mathbb{E}_{p(h,X|\eta)} \left[S(X,h) \right].
\end{aligned}$$

This stationary equation states that at optimality the sufficient statitics have the same expectation for the full model $p(h, X|\eta)$ and the joint "model/data" distribution $t(X)p(h|X, \eta)$.

Another important insight of Delyon et al. (1999); Cappé and Moulines (2009) is to consider the change of variable $s(\eta) = \mathbb{E}_{p(h,X|\eta)}\left[S(X, h)\right]$ on sufficient statistics, which is equivalent to

$$\eta = \eta^*(s) \in \arg\max \langle \phi(\eta), s\rangle - \psi(\eta),$$

(which is the usual M-step update). See Cappé and Moulines (2009) for detailed assumptions allowing this inversion. We may then rewrite the equation above as

$$\mathbb{E}_{t(X)}\big(\mathbb{E}_{p(h|X,\eta^*(s))}\left[S(X, h)\right]\big) = s.$$

This is a non-linear equation in $s \in \mathbb{R}^d$, with an expectation with respect to $t(X)$ which is only accessed through i.i.d. samples X_i, and thus a good candidate for the Robbins-Monro algorithm to solve stationary equations (and not to minimize functions) (Kushner and Yin, 2003), which takes the simple form:

$$s_i = s_{i-1} - \rho_i\big(s_{i-1} - \mathbb{E}_{p(h_i|X_i,\eta^*(s_{i-1}))}\left[S(X_i, h_i)\right]\big),$$

with a step-size ρ_i. It may be rewritten as

$$\left\{ \begin{array}{rl} s_i &= (1-\rho_i)s_{i-1} + \rho_i \mathbb{E}_{p(h_i|X_i,\eta_{i-1})}[S(X_i, h_i)] \\ \eta_i &= \eta^*(s_i), \end{array} \right. \tag{3}$$

which has a particularly simple interpretation: instead of computing the expectation for all observations as in full EM, this stochastic version keeps tracks of old sufficient statistics through the variable s_{i-1} which is updated towards the current value $\mathbb{E}_{p(h_i|X_i,\eta_{i-1})}[S(X_i, h_i)]$. The parameter η is then updated to the value $\eta^*(s_i)$. Cappé and Moulines (2009) show that this update is asymptotically equivalent to the natural gradient update with three main improvements: (a) no matrix inversion is needed, (b) the algorithm may be accelerated through Polyak-Ruppert averaging (Polyak and Juditsky, 1992), i.e., using the average $\bar{\eta}_N$ of all η_i instead of the last iterate η_N, and (c) the step-size is particularly simple to set, as we are taking *convex* combinations of sufficient statistics, and hence only the decay rate of ρ_i has to be chosen, i.e., of the form $\rho_i = i^{-\kappa}$, for $\kappa \in (0, 1]$, without any multiplicative constant.

2.2.1 INCREMENTAL VIEW

For the specific stepsize $\rho_i = 1/i$, the online EM algorithm (3) corresponds exactly to the incremental EM presented above (Neal and Hinton, 1998), as then

$$s_i = \frac{1}{i}\sum_{j=1}^{i} \mathbb{E}_{p(h_j|X_j,\eta_{j-1})}[S(X_j, h_j)].$$

See Mairal (2014) for a detailed convergence analysis of incremental algorithms, in particular showing that step-sizes larger than $1/i$ are preferable (we observe this in practice in Section 6).

2.2.2 MONTE CARLO METHODS

There exist alternative methods to the EM algorithm based on Monte Carlo sampling to compute the maximum likelihood. For instance, the Monte Carlo EM method (MCEM) (Wei and Tanner, 1990) is a general Bayesian approach (i.e., η is a random variable) to approximate the maximizer of the posterior distribution $p(\eta|X, h)$ with Monte Carlo sampling. More precisely, in the MCEM method, similarly to EM, a surrogate function of the log-likelihood is used, given by:

$$Q(\eta, \eta_t) = \int_h \log[p(\eta|X, h)]p(h|X, \eta_t)\mathrm{d}h.$$

The function Q is approximated by sampling the latent variables h from the current conditional $p(h|X, \eta_t)$:

$$\hat{Q}(\eta, \eta_t) = \sum_{i=1}^{P} \log p(\eta|X, h^i),$$

where $(h^i)_{i=1,\dots,P}$ are the samples drawn from the conditional $p(h|X, \eta_t)$. The approximation $\hat{Q}$ is then maximize with respect to η. Note that this method is a batch method, namely, samples are drawn over all the dataset.

Other sequential Monte Carlo methods (SMC) use importance sampling to estimate the conditional distributions $p(h|X)$ using an auxiliary density function. This auxiliary distribution is then reweighted at each iteration. In our case where the conditional distribution $p(h|X)$ is intractable to compute, these methods fail to accurately approximate this distribution (Cappé et al., 2005; Kantas et al., 2015) and our Gibbs sampling scheme is more relevant. The SMC methods are also more adapted to models with dependency between observations.

The two Monte Carlo methods mentioned above also consist in sufficient statistics updates for the class of models considered here.

3. Online EM with Intractable Models

The online EM updates in (3) lead to a scalable algorithm for optimization when the local E-step is tractable. However, in many latent variable models—e.g., LDA, hierarchical Dirichlet processes (Teh et al., 2006), or ICA (Hyvärinen et al., 2004)—it is intractable to compute the conditional expectation $\mathbb{E}_{p(h|X,\eta)}[S(X, h)]$.

Following Rohde and Cappé (2011), we propose to leverage the scalability of online EM updates (3) and locally approximate the conditional distribution $p(h|X, \eta)$ in the case this distribution is intractable to compute. We will however consider different approximate methods, namely Gibbs sampling or variational inference. Our method is thus restricted to models where the hidden variable h may naturally be splitted in two or more groups of simple random variables. Our algorithm is described in Algorithm 1 and may be instantiated with two approximate inference schemes which we now describe.

Algorithm 1 Gibbs / Variational online EM

Input: η_0, s_0, $\kappa \in (0, 1]$.
for $i = 1, \dots, N$ **do**
- Collect observation X_i,
- Estimate $p(h_i|X_i, \eta_{i-1})$ with sampling (`G-OEM`) or variational inference (`V-OEM`),
- Apply (3) to sufficient statistics s_i and parameter η_i with $\rho_i = 1/i^\kappa$,

end for
Output: $\bar{\eta}_N = \frac{1}{N}\sum_{i=1}^N \eta_i$ or η_N.

3.1 Variational Inference: `V-OEM`

While variational inference had been considered before for online estimation of latent variable models, in particular for LDA for incremental EM (Sato et al., 2010), using it for online EM (which is empirically faster) had not been proposed and allows to use bigger step-sizes (e.g., $\kappa = 1/2$). These methods are based on maximizing the negative variational "free-energy"

$$\mathbb{E}_{q(h|\eta)}\left[\log \frac{p(X, h|\eta)}{q(h|\eta)}\right], \tag{4}$$

with respect to $q(h|\eta)$ having a certain factorized form adapted to the model at hand, so that efficient coordinate ascent may be used. See, e.g., Hoffman et al. (2013). We now denote online EM with variational approximation of the conditional distribution $p(h|X, \eta)$ as `V-OEM`.

3.2 Sampling Methods: `G-OEM`

MCMC methods to approximate the conditional distribution of latent variables with online EM have been considered by Rohde and Cappé (2011), who apply locally the Metropolis-Hasting (M-H) algorithm (Metropolis et al., 1953; Hastings, 1970), and show results on simple synthetic datasets. While Gibbs sampling is widely used for many models such as LDA due to its simplicity and lack of external parameters, M-H requires a proper proposal distribution with frequent acceptance and fast mixing, which may be hard to find in high dimensions. We provide a different simpler local scheme based on Gibbs sampling (thus adapted to a wide variety of models), and propose a thorough favorable comparison on synthetic and real datasets with existing methods.

The Gibbs sampler is used to estimate posterior distributions by alternatively sampling parts of the variables given the other ones (see Casella and George, 1992, for details), and is standard and easy to use in many common latent variable models. In the following, the online EM method with Gibbs estimation of the conditional distribution $p(h|X, \eta)$ is denoted `G-OEM`.

As mentioned above, the online EM updates correspond to a stochastic approximation algorithm and thus are robust to random noise in the local E-step. As a result, our sampling method is particularly adapted as it is a random estimate of the E-step—see a theoretical analysis by Rohde and Cappé (2011), and thus we only need to compute a few Gibbs samples for the estimation of $p(h|X_i, \eta_{i-1})$. A key contribution of our paper is to reuse sampling techniques that have proved competitive in the batch set-up and to compare them to existing variational approaches.

3.3 "Boosted" Inference

As the variational and MCMC estimations of $p(h|X_i, \eta_{i-1})$ are done with iterative methods, we can boost the inference of Algorithm 1 by applying the update in the parameter η in (3) after each iteration of the estimation of $p(h|X_i, \eta_{i-1})$. In the context of LDA, this was proposed by Sato et al. (2010) for incremental EM and we extend it to all versions of online EM. With this boost, we expect that the global parameters η converge faster, as they are updated more often. In the following, we denote by `G-OEM++` (resp. `V-OEM++`) the method `G-OEM` (resp. `V-OEM`) augmented with this boost.

3.4 Variational Bayesian Estimation

In the Bayesian perspective where η is seen as a random variable, we either consider a distribution based on model averaging, e.g., $r(X) = \int p(X|\eta)q(\eta)d\eta$ where $q(\eta) \propto \prod_{i=1}^N p(X_i|\eta)p(\eta)$ is the posterior distribution, or

$$r(X) = p(X|\bar{\eta}),$$

where $\bar{\eta}$ is the summary (e.g., the mean) of the posterior distribution $q(\eta)$, or of an approximation, which is usually done in practice (see, e.g., Hoffman and Blei, 2015) and is asymptotically equivalent when N tends to infinity.

The main problem is that, *even when the conditional distribution of latent variables is tractable*, it is intractable to manipulate the *joint* posterior distribution over the latent variables $h_1, \dots, h_N$, and the parameter η. Variational inference techniques consider an approximation where hidden variables are independent of the parameter η, i.e., such that

$$p(\eta, h_1, \dots, h_N|X_1, \dots, X_N) \approx q(\eta)\prod_{i=1}^N q(h_i),$$

which corresponds to the maximization of the following lower bound—called Evidence Lower BOund (ELBO)—on the log-likelihood $\log p(X_1, \dots, X_n)$ (Bishop, 2006):

$$\int q(\eta)\prod_{i=1}^N q(h_i)\log\frac{p(\eta)\prod_{i=1}^n p(X_i, h_i|\eta)}{q(\eta)\prod_{i=1}^N q(h_i)}d\eta dh_1\cdots dh_N.$$

The key insight from Hoffman et al. (2010); Broderick et al. (2013) is to consider the variational distribution $q(\eta)$ as the global parameter, and the cost function above as a sum of *local* functions that depend on the data X_i and the variational distribution $q(h_i)$. Once the local variational distribution $q(h_i)$ is maximized out, the sum structure may be leveraged in similar ways than for frequentist estimation, either by direct (natural) stochastic gradient (Hoffman et al., 2010) or incremental techniques that accumulate sufficient statistics (Broderick et al., 2013). A nice feature of these techniques is that they extend directly to models with intractable latent variable inference, by making additional assumptions on $q(h_i)$ (see for example the LDA situation in Section 4).

In terms of actual updates, they are similar to online EM in Section 3.1, with a few changes, but which turn out to lead to significant differences in practice. The similarity comes from the expansion of the ELBO as

$$\mathbb{E}_{q(\eta)}\Big[\sum_{i=1}^N \mathbb{E}_{q(h_i)}\log\frac{p(X_i, h_i|\eta)}{q(h_i)}\Big] + \mathbb{E}_{q(\eta)}\left[\log\frac{p(\eta)}{q(\eta)}\right].$$

The left hand side has the same structure than the variational EM update in (4), thus leading to similar updates, while the right hand side corresponds to the "Bayesian layer", and the maximization with respect to $q(\eta)$ is similar to the M-step of EM (where η is seen as a parameter).

Like online EM techniques presented in Section 3, approximate inference for latent variable is used, but, when using Bayesian stochastic variational inference techniques, there are two additional sources of inefficiencies: (a) extra assumptions regarding the independence of η and $h_1, \dots, h_N$, and (b) the lack of explicit formulation as the minimization of an expectation, which prevents the simple use of the most efficient stochastic approximation techniques (together with their guarantees). While (b) can simply slow down the algorithm, (a) may lead to results which are far away from exact inference, even for large numbers of samples (see examples in Section 6).

Beyond variational inference, Gibbs sampling has been recently considered by Gao et al. (2016): their method consists in sampling hidden variables for the current document given current parameters, but (a) only some of the new parameters are updated by incrementally aggregating the samples of the current document with current parameters, and (b) the method is slower than `G-OEM` (see Section 6).

4. Application to LDA

LDA (Blei et al., 2003) is a probabilistic model that infers hidden topics given a text corpus where each document of the corpus can be represented as topic probabilities. In particular, the assumption behind LDA is that each document is generated from a mixture of topics and the model infers the hidden topics and the topic proportions of each document. In practice, inference is done using Bayesian variational EM (Blei et al., 2003), Gibbs sampling (Griffiths and Steyvers, 2004; Wallach, 2006) or stochastic variational inference (Hoffman et al., 2010; Broderick et al., 2013; Sato et al., 2010).

4.0.1 HIERARCHICAL PROBABILISTIC MODEL.

Let $\mathcal{C} = \{X_1, \dots, X_D\}$ be a corpus of D documents, V the number of words in our vocabulary and K the number of latent topics in the corpus. Each topic β^k corresponds to a discrete distribution on the V words (that is an element of the simplex in V dimensions). A hidden discrete distribution θ_i over the K topics (that is an element of the simplex in K dimensions) is attached to each document X_i. LDA is a generative model applied to a corpus of text documents which assumes that each word of the i^{th} document X_i is generated as follows:

- Choose $\theta_i \sim \text{Dirichlet}(\alpha)$,
- For each word $x_n \in X_i = \left(x_1, \dots, x_{N_{X_i}}\right)$:
  - Choose a topic $z_n \sim \text{Multinomial}(\theta_i)$,
  - Choose a word $x_n \sim \text{Multinomial}(\beta^{z_n})$.

In our settings, an observation is a document $X_i = (x_1, \dots, x_{N_{X_i}})$ where for all $1 \leq n \leq N_{X_i}$, $x_n \in \{0,1\}^V$ and $\sum_{v=1}^V x_{nv} = 1$. Each observation X_i is associated with the hidden variables h_i, with $h_i \equiv (Z_i = (z_1, \dots, z_{N_{X_i}}), \theta_i)$. The vector θ_i represents the topic proportions of document X_i and Z_i is the vector of topic assignments of each word of X_i. The variable h_i is local, i.e., attached

to one observation X_i. The parameters of the model are global, represented by $\eta \equiv (\beta, \alpha)$, where β represents the topic matrix and α represents the Dirichlet prior on topic proportions.

We derive the LDA model in Section 4.1 to find ϕ, S, ψ and a such that the joint probability $p(Z, \theta | X, \alpha, \beta)$ is in a non-canonical exponential family (1).

We may then readily apply all algorithms from Section 3 by estimating the conditional expectation $\mathbb{E}_{Z,\theta|X,\alpha,\beta}[S(X, Z, \theta)]$ with either variational inference (`V-OEM`) or Gibbs sampling (`G-OEM`). See Sections 4.2 and 4.3 for online EM derivations. Note that the key difficulty of LDA is the presence of two interacting hidden variables Z and θ.

4.1 LDA and Exponential Families

An observation X is a document of length N_X, where $X = (x_1, \dots, x_{N_X})$, each word is represented by $x_n \in \{0,1\}^V$ with $\sum_{v=1}^V x_{nv} = 1$. Our corpus $\mathcal{C}$ is a set of D observations $\mathcal{C} = (X^1, \dots, X^D)$. For each document X^i a hidden variable θ^i is associated, corresponding to the topic distribution of document X^i. For each word x_n of document X^i a hidden variable $z_n \in \{0,1\}^K$ is attached, corresponding to the topic assignment of word x_n. We want to find ϕ, S, ψ and a such that, the joint probability is in the exponential family (1):

$$p(X, Z, \theta | \beta, \alpha) = a(X, Z, \theta) \exp\left[\langle \phi(\beta, \alpha), S(X, Z, \theta) \rangle - \psi(\beta, \alpha)\right],$$

given an observation X and hidden variables Z and θ. For the LDA model, we have:

$$p(X, Z, \theta | \beta, \alpha) = \prod_{n=1}^{N_X} p(x_n | z_n, \beta) p(z_n | \theta) p(\theta | \alpha) = \prod_{n=1}^{N_X} \prod_{k=1}^{K} \prod_{v=1}^{V} \left[(\beta_v^k)^{x_{nv}} \theta_k\right]^{z_{nk}} p(\theta | \alpha),$$

which we can expand as:

$$p(X, Z, \theta | \beta, \alpha) = \exp\left[\sum_{n=1}^{N_X} \sum_{k=1}^{K} z_{nk} \log \theta_k\right] \times \exp\left[\sum_{n=1}^{N_X} \sum_{k=1}^{K} \sum_{v=1}^{V} x_{nv} z_{nk} \log \beta_v^k\right] \times \exp\left[\sum_{k=1}^{K} (\alpha_k - 1) \log \theta_k + B(\alpha)\right],$$

with $B(\alpha) = \log\left[\Gamma\left(\sum_{i=1}^K \alpha_i\right)\right] - \sum_{i=1}^K \log[\Gamma(\alpha_i)]$, where Γ is the gamma function. We deduce the non-canonical exponential family setting ϕ, S, ψ a:

$$S(X, Z, \theta) = \begin{pmatrix} S_{kv}^1 \equiv \left[\sum_{n=1}^{N_X} z_{nk} x_{nv}\right]_{kv} \\ S_k^2 \equiv [\log \theta_k]_k \end{pmatrix}, \tag{5}$$

$$\phi(\beta, \alpha) = \begin{pmatrix} \phi_{kv}^1 \equiv \left[\log \beta_v^k\right]_{kv} \\ \phi_k^2 \equiv [\alpha_k]_k \end{pmatrix}, \tag{6}$$

with $S^1, \phi^1 \in \mathbb{R}^{K\times V}$ and $S^2, \phi^2 \in \mathbb{R}^K$,

$$\psi(\beta,\alpha) = \sum_{i=1}^{K} \log[\Gamma(\alpha_i)] - \log\left[\Gamma\left(\sum_{i=1}^{K}\alpha_i\right)\right], \tag{7}$$

and

$$a(X,Z,\theta) = \exp\left[\sum_{k=1}^{K}\left(\sum_{n=1}^{N_X} z_{nk} - 1\right)\log\theta_k\right].$$

The one-to one mapping between the sufficient statistics $s = \binom{s^1}{s^2}$ and (β,α) is defined by:

$$(\beta,\alpha)^*[s] = \begin{cases} \arg\max_{\beta\geq 0,\alpha\geq 0} & \langle\phi(\beta,\alpha), s\rangle - \psi(\beta,\alpha) \\ \text{s.t.} & \beta^\top \mathbf{1} = \mathbf{1}, \end{cases}$$

where $\mathbf{1}$ denotes the vector whose all entries equal 1. The objective $\langle\phi(\beta,\alpha), s\rangle - \psi(\beta,\alpha)$ is concave in β from the concavity of log and concave in any α_k for $\alpha \geq 0$ as the function $B(\alpha)$ is concave as the negative log-partition of the Dirichlet distribution. We use the Lagrangian method for β:

$$L(\beta,\lambda) = \sum_{k=1}^{K}\sum_{v=1}^{V} s^1_{kv}\log\beta_v^k + \lambda^\top(\beta^\top\mathbf{1} - \mathbf{1}),$$

with $\lambda \in \mathbb{R}^K$. The derivative of L is set to zero when:

$$\forall(k,v), \frac{s^1_{kv}}{\beta_v^k} + \lambda_k = 0 \Rightarrow \lambda_k = -\sum_{v=1}^{V} s^1_{kv},$$

as $\sum_{v=1}^{V}\beta_v^k = 1$. We then have $(\beta^*(s))_{kv} = \frac{s^1_{kv}}{\sum_j s^1_{kj}}$. This mapping satisfies the constraint $\beta \geq 0$ because for any observation X and hidden variable Z, we have $S^1(X,Z)_{kv} \geq 0$. This comes from (5) and the fact that $\forall(n,k,v), (x_{nv}, z_{nk}) \in \{0,1\}^2$. We find the condition on α by setting the derivatives to 0, which gives $\forall k \in [\![1,K]\!]$:

$$s_k^2 - \Psi([\alpha^*(s)]_k) + \Psi\left(\sum_{i=1}^{K}[\alpha^*(s)]_i\right) = 0,$$

where $\Psi : x \mapsto \frac{\partial}{\partial x}[\log\Gamma](x)$ is the digamma function. Finally, $(\alpha^*(s), \beta^*(s))$ satisfies $\forall(k,v)$:

$$\begin{cases} (\beta^*(s))_{kv} & \equiv & \left[\frac{s^1_{kv}}{\sum_j s^1_{kj}}\right]_{kv} \\ \Psi([\alpha^*(s)]_k) - \Psi\left(\sum_{i=1}^{K}[\alpha^*(s)]_i\right) & = & s_k^2. \end{cases} \tag{8}$$

The parameter α^* is usually estimated with gradient ascent (Blei et al., 2003; Hoffman et al., 2010). We can also estimate α with the fixed point iteration (Minka, 2000) which consists in repeating the following update until convergence:

$$\alpha_k^{new} = \Psi^{-1}\left(\Psi\left(\sum_{i=1}^{K}\alpha_i^{old}\right) + s_k^2\right).$$

We use the fixed point iteration to estimate α^* as it is more stable in practice. We study different updates for α in Appendix C.

We can now apply Algorithm 1 to LDA. The only missing step is the estimation of the conditional expectation $\mathbb{E}_{Z,\theta|X,\alpha_t,\beta_t}[S(X,Z,\theta)]$, with $X = (x_1,\dots,x_{N_X})$ and $Z = (z_1,\dots,z_{N_X})$. We explain how to approximate this expectation with variational inference and Gibbs sampling.

4.2 Variational Online EM Applied to LDA (V−OEM)

In this section we explain how to approximate $\mathbb{E}_{Z,\theta|X,\alpha_t,\beta_t}[S(X,Z,\theta)]$ with variational inference, in the frequentist setting. See Hoffman et al. (2013) for detailed derivations of variational inference for LDA in the Bayesian setting (from which the updates in the frequentist setting may be easily obtained). The idea behind variational inference is to maximize the Evidence Lower BOund (ELBO), a lower bound on the probability of the observations:

$$p(X) \geq \text{ELBO}(X,p,q),$$

where q represents the variational model. In the case of LDA, the variational model is often set with a Dirichlet(γ) prior on θ and a multinomial prior on Z (Hoffman et al., 2013):

$$q(Z,\theta) = q(\theta|\gamma)\prod_{n=1}^{N_X} q(z_n|\zeta_n). \tag{9}$$

We then maximize the ELBO with respect to γ and ζ, which is equivalent to minimizing the Kullback-Leibler (KL) divergence between the variational posterior and the true posterior:

$$\max_{\gamma,\zeta}\ \text{ELBO}(X,p,q) \Leftrightarrow \min_{\gamma,\zeta}\ \text{KL}[p(Z,\theta|X)||q(\theta,Z)]. \tag{10}$$

We solve this problem with block coordinate descent, which leads to iteratively updating γ and ζ as follows:

$$\zeta_{nk} \propto \prod_{v=1}^{V}\left(\beta_v^k\right)^{x_{nv}}\exp\left[\Psi(\gamma_k)\right], \tag{11}$$

$$\gamma_k = \alpha_k + \textstyle\sum_{n=1}^{N_X}\zeta_{nk}. \tag{12}$$

We then approximate $\mathbb{E}_{Z,\theta|X,\alpha_t,\beta_t}[S(X,Z,\theta)]$ with the variational posterior. Given (5) and (9), we have:

$$\mathbb{E}_{p(Z,\theta|X)}[S(X,Z,\theta)] \approx \mathbb{E}_{q(Z,\theta)}[S(X,Z,\theta)] = \begin{bmatrix} \left(\sum_{n=1}^{N_{X_{t+1}}}\zeta_{nk}x_{nv}\right)_{kv} \\ \left(\Psi(\gamma_k) - \Psi\left(\sum_{j=1}^{K}\gamma_j\right)\right)_k \end{bmatrix}. \tag{13}$$

The variational approximation of $\mathbb{E}_{p(Z,\theta|X)}[S(X,Z,\theta)]$ is then done in two steps:

1. Iteratively update ζ with (11) and γ with (12),
2. $\mathbb{E}_{p(Z,\theta|X)}[S(X,Z,\theta)] \leftarrow \mathbb{E}_{q(Z,\theta|\gamma,\zeta)}[S(X,Z,\theta)]$ with equation (13).

As γ and ζ are set to minimize the distance between the variational posterior and the true posterior (10) we expect that this approximation is close to the true expectation. However, as the variational model is a simplified version of the true model, there always remains a gap between the true posterior and the variational posterior.

4.3 Gibbs Online EM Applied to LDA (G-OEM)

In this section we explain how to approximate $\mathbb{E}_{Z,\theta|X,\alpha_t,\beta_t}[S(X,Z,\theta)]$ with Gibbs sampling.

4.3.1 EXPECTATION OF S^1.

Given (5), we have $\forall k \in [\![1,K]\!]$, $\forall v \in [\![1,V]\!]$:

$$\mathbb{E}_{Z,\theta|X,\alpha,\beta}\left[(S^1(X,Z))_{kv}\right] = \mathbb{E}_{Z,\theta|X,\alpha,\beta}\left[\sum_{n=1}^{N_X} z_{nk}x_{nv}\right]$$
$$= \sum_{n=1}^{N_X}\int_{Z,\theta} z_{nk}x_{nv}p(z_n,\theta|X,\beta,\alpha)\mathrm{d}\theta\mathrm{d}z = \sum_{n=1}^{N_X} x_{nv}p(z_{nk}=1|X,\beta,\alpha).$$

We see that we only need the probability of z, and can thus use collapsed Gibbs sampling (Griffiths and Steyvers, 2004). We have, following Bayes rule:

$$p(z_{nk}=1|z_{-n},X,\beta,\alpha) \propto p(x_n|z_{nk}=1,\beta)p(z_{nk}=1|z_{-n},\alpha),$$

where z_{-n} is the topic assignments except index n. In the LDA model, each word x_n is drawn from a multinomial with parameter β^{z_n}, which gives:

$$p(x_n|z_{nk}=1,\beta) = \sum_{v=1}^{V} x_{nv}\beta_v^k.$$

In the following, we use the notation $\beta_{x_n}^k \equiv \sum_{v=1}^V x_{nv}\beta_v^k$ for the sake of simplicty. We then use the fact that the topic proportions θ has a Dirichlet(α) prior, which implies that $Z|\alpha$ follows a Dirichlet-multinomial distribution (or multivariate Pólya distribution). As a result, the conditional distribution is:

$$p(z_{nk}=1|z_{-n},\alpha) = \frac{N_{-n,k}+\alpha_k}{(N_X-1)+\sum_j \alpha_j},$$

with $N_{-n,k}$ the number of words assigned to topic k in the current document, except index n. Finally, we have the following relation (Griffiths and Steyvers, 2004):

$$p(z_{nk}=1|z_{-n},X,\beta,\alpha) \propto \beta_{x_n}^k \times \frac{N_{-n,k}+\alpha_k}{(N_X-1)+\sum_j \alpha_j}. \tag{14}$$

We estimate $p(z_{nk}=1|X,\beta,\alpha)$ with Gibbs sampling by iteratively sampling topic assignments z_n for each word, as detailed in Algorithm 2. We average over the last quarter of samples to reduce noise in the final output. We then incorporate the output in Algorithm 1.

4.3.2 EXPECTATION OF S^2.

Given (5), we also have $\forall k \in [\![1,K]\!]$, $\forall v \in [\![1,V]\!]$:

$$\mathbb{E}_{Z,\theta|X,\alpha,\beta}[(S^2(X,Z))_k] = \mathbb{E}_{Z,\theta|X,\alpha,\beta}[\log\theta_k].$$

On the one hand, we have:

$$p(Z,\theta|X,\beta,\alpha) = p(Z|\theta,X,\beta,\alpha)p(\theta|X,\beta,\alpha) = C(\alpha)\prod_{k=1}^K \theta_k^{\left(\sum_{n=1}^{N_X} z_{nk}\right)+\alpha_k-1},$$

with $C(\alpha) = \frac{\Gamma\left(\sum_{i=1}^K \alpha_i\right)}{\prod_{i=1}^K \Gamma(\alpha_i)}$. On the other hand:

$$p(Z,\theta|X,\beta,\alpha) \propto p(\theta|Z,\alpha)p(Z|X,\beta).$$

We deduce from the two identities:

$$p(\theta|Z,\alpha) \propto \prod_{k=1}^K \theta_k^{\left(\sum_{n=1}^{N_X} z_{nk}\right)+\alpha_k-1} \Rightarrow \theta|Z,\alpha \sim \text{Dirichlet}\left(\alpha + \textstyle\sum_{n=1}^{N_X} z_n\right).$$

Finally, the expectation is:

$$\begin{aligned}\mathbb{E}_{Z,\theta|X,\alpha,\beta}[(S^2(X,Z))_k] =& \mathbb{E}_{Z,\theta|X,\alpha,\beta}[\log\theta_k]\\ =& \mathbb{E}_{Z|X,\beta,\alpha}\left[\mathbb{E}_{\theta|Z,\alpha}\left[\log\theta_k\right]\right]\\ =& \mathbb{E}_{Z|X,\beta,\alpha}\left[\Psi\left([\alpha(s)]_k + \textstyle\sum_{n=1}^{N_X} z_{nk}\right)\right] - \Psi\left(\sum_{i=1}^K [\alpha(s)]_i + N_X\right),\end{aligned}$$

as the distribution of $\theta|Z,\alpha$ is Dirichlet $\left(\alpha + \sum\limits_{n=1}^{N_X} z_n\right)$. We use the values of z sampled with Algorithm 2 to estimate this expectation. More precisely, keeping notations of Algorithm 2:

$$\mathbb{E}_{Z|X,\beta,\alpha}\left[\Psi\left([\alpha(s)]_k + \textstyle\sum_{n=1}^{N_X} z_{nk}\right)\right] \approx \frac{1}{P}\sum_{t=1}^P \Psi\left([\alpha(s)]_k + \sum_{n=1}^{N_X} z_{nk}^t\right).$$

4.4 Bayesian Approach

In a Bayesian setting, we consider β as a random variable, with $\beta \sim \text{Dirichlet}(b\mathbf{1})$, with $b \in \mathbb{R}$ and $\mathbf{1} \in \mathbb{R}^V$ denotes the vector whose all entries equal 1. The variational distribution of the global parameter β is then set to $q(\beta^k|\lambda^k) = \text{Dirichlet}(\lambda^k)$, with $\lambda^k \in \mathbb{R}^V$ $\forall k = 1,\dots,K$. The main difference with the frequentist methods above (G-OEM and V-OEM) is to optimize the ELBO with respect to the variational parameters $(\lambda^k)_k$. In practice, it is equivalent to replace β_v^k by $\exp\left[\mathbb{E}_q[\log\beta_v^k]\right]$ in all the updates above (i.e., in Equation (11) for V-OEM and in Equation (14) for G-OEM). The variational parmater $\lambda^k \in \mathbb{R}^V$ is updated with stochastic gradient on the ELBO, which gives, at iteration t:

$$\lambda^k(t+1) = \rho_t\lambda^k(t) + (1-\rho_t)\hat{\lambda}^k, \tag{15}$$

with $\hat{\lambda}^k \in \mathbb{R}^V$, $\hat{\lambda}_v^k = b + D\mathbb{E}_q\left[S_{kv}^1\right]$, where D is the total number of documents in the dataset and b is the prior on β^k (Hoffman et al., 2013).

Algorithm 2 Gibbs sampling scheme to approximate $p(z_{nk} = 1|X, \beta, \alpha)$

Input: β, α, X.

Initialization: $Z_n^0 \sim \text{Mult}([\bar{\beta}_{x_n}^k]_{k=1,\dots,K})$, with $\bar{\beta}_{x_n}^k = \frac{\beta_{x_n}^k}{\sum_j \beta_{x_n}^j}$ $\forall n \in [\![1, N_X]\!]$.

for $t = 1, 2, \dots, P$ **do**

Compute random permutation σ^t on $[\![1, N_X]\!]$,

for $n = 0, 1, \dots, N_X$ **do**

- Set $Z_{-n}^t = \left\{ (z_{\sigma^t(i)}^t)_{1 \leq i < n}, (z_{\sigma^t(i)}^{t-1})_{n < i \leq N_X} \right\}$,
- Compute $\forall k$, $p(z_{\sigma^t(n)k} = 1|Z_{-n}^t, X, \beta, \alpha)$ with Equation (14),
- Sample $z_{\sigma^t(n)}^t \sim \text{Mult}\left[p(z_{\sigma^t(n)}|Z_{-n}^t, X, \beta, \alpha)\right]$,

end for

end for

for $n = 0, 1, \dots, N_X$ **do**

Set $Z_{-n}^t = \left\{ (z_i^t)_{1 \leq i < n}, (z_i^t)_{n < i \leq N_X} \right\}$ for $t \geq \frac{3}{4}P$,

$p(z_{nk} = 1|X, \beta, \alpha) \leftarrow \frac{4}{P} \sum_{t=\frac{3}{4}P}^{P} p(z_{nk} = 1|Z_{-n}^t, X, \beta, \alpha)$

end for

Output: $\forall k, \forall n$: $(z_n^t)_{t=1,\dots,P}$, $p(z_{nk} = 1|X, \beta, \alpha)$.

5. Application to Hierarchical Dirichlet Process (HDP) (Teh et al., 2006)

The HDP model is a generative process to model documents from an infinite set of topics β_k, $k = 1, 2, 3, \dots$. Each topic is a discrete distribution of size V, the size of the vocabulary. Each topic is associated to a weight $\pi_k \in [0, 1]$, representing the importance of the topic in the corpus. For each document d, the (infinite) topic proportions ν_d are drawn from $\nu_d \sim \text{Dirichlet}(b\pi)$. We then generate words with a similar scheme to LDA scheme. More formally a corpus is generated as follows:

1. Draw an infinite number of topics $\beta_k \sim \text{Dirichlet}(\eta)$, for $k \in \{1, 2, 3, \dots\}$;
2. Draw corpus breaking proportions $\bar{\pi}_k \sim \text{Beta}(1, \alpha)$, for $k = 1, 2, 3, \dots$; with $\pi_k = \sigma_k(\bar{\pi})$;
3. For each document d:
   (a) Draw document-level topic proportions: $\nu_d \sim \text{Dirichlet}(b\pi)$;
   (b) For each word n in d:
      i. Draw topic assignment $z_{dn} \sim \text{Multinomial}(\nu_d)$;
      ii. Draw word $w_n \sim \text{Multinomial}(\beta_{z_{dn}})$.

In practice, we set the initial number of topics to $T = 2$. We then increase the number of topics used in the corpus using Gibbs sampling and $p(z_{dn} > T|X, \eta) \propto b(1 - \sum_{i=1}^{T} \pi_i)$. See Section 5.2 for details.

5.1 HDP and Exponential Families

We consider an exponential family model on random variables (X, h) with parameter $\eta \in \mathcal{E} \subseteq \mathbb{R}^d$ and with density:

$$p(X, h|\eta) = a(X, h) \exp\left[\langle \phi(\eta), S(X, h) \rangle - \Psi(\eta)\right].$$

In the case of HDP, an observation X is a document of length N_X, where $X = (x_1, \dots, x_{N_X})$, $x_n \in \{0, 1\}^V$ and $\sum_{v=1}^{V} x_{nv} = 1$. In the frequentist approach, the parameters of the model are global, represented by $\eta \equiv (\beta, \pi)$, where β represents the corpus topics, π represents the corpus breaking proportions. Our corpus $\mathcal{C}$ is a set of D observations $\mathcal{C} = (X^1, \dots, X^D)$. For each document X^d, the associated hidden variables are $\nu_d \in [0, 1]^K$ corresponding to document-level topic proportions. For each word x_n of document X^d, a hidden variable $z_n \in \{0, 1\}^T$ is attached, corresponding to the topic assignment of word x_n.

We want to find ϕ, S, ψ and a such that, the joint probability is in the exponential family:

$$p(X, Z, \nu|\beta, \pi) = a(X, Z, \nu) \exp\left[\langle \phi(\beta, \pi), S(X, Z, \nu) \rangle - \psi(\beta, \pi)\right],$$

given an observation X and hidden variables Z and ν. For the HDP model, we have:

$$\begin{aligned}
p(X, Z, \nu|\beta, \pi) =& p(\nu|\pi) \prod_{n=1}^{N_X} p(x_n|z_n, \beta) p(z_n|\nu) \\
=& W(\pi) \prod_{k \in \mathbb{N}^*} (\nu_k)^{b\pi_k - 1} \prod_{n=1}^{N_X} \prod_k (\nu_k)^{z_{nk}} \prod_v (\beta_{k,v})^{x_{nv} z_{nk}} \\
=& \exp\left[-\psi(\pi)\right] \exp\left[\sum_k \log \nu_k \left(\sum_{n=1}^{N_X} z_{nk} - 1 \right)\right] \\
& \times \exp\left[\sum_k (b\pi_k) \log \nu_k\right] \\
& \times \exp\left[\sum_{k,v} \log \beta_{k,v} \sum_{n=1}^{N_X} x_{nv} z_{nk}\right],
\end{aligned}$$

with $\psi(\pi) = \sum_k \log \Gamma(b\pi_k) - \log \Gamma(b)$.We deduce the exponential family setting ϕ, S, a:

$$S(X, Z, \nu) = \begin{pmatrix} S_k^1 \equiv [\log \nu_k]_k \\ S_{kv}^2 \equiv \left[\sum_{n=1}^{N_X} z_{nk} x_{nv} \right]_{kv} \end{pmatrix}, \tag{16}$$

$$\phi(\beta, \pi) = \begin{pmatrix} \phi_k^1 \equiv [b\pi_k]_k \\ \phi_{kv}^2 \equiv [\log \beta_{k,v}]_{kv} \end{pmatrix}, \tag{17}$$

with

$$a(X, Z, \nu) = \exp\left[\sum_k \log \nu_k \left(\sum_{n=1}^{N_X} z_{nk} - 1 \right)\right].$$

The one-to one mapping between the sufficient statistics $s = (s^1, s^2)^\top$ and (β, π) is defined by:

$$(\beta, \pi)^*[s] = \begin{cases} \arg\max_{\beta \geq 0, 1 \geq \pi \geq 0} & \langle \phi(\beta, \pi), s \rangle - \psi(\beta, \pi) \\ \text{s.t.} & \beta^\top \mathbf{1} = \mathbf{1}, \end{cases}$$

where $\mathbf{1}$ denotes the vector whose all entries equal 1.

With the same computation than LDA, $\beta^*(s)_{kv} \equiv \left[\frac{s^2_{kv}}{\sum_j s^2_{kj}}\right]$. We find $\pi^*(s)$ by solving:

$$\pi^*(s) = \arg\max_{1 \geq \pi \geq 0} \sum_{k=1}^{K} \left(b\pi_k s^1_k - \log\Gamma(b\pi_k)\right) + \log\Gamma(b\sum_k \pi_k),$$

which gives:

$$\Psi(b\pi^*(s)_k) - \Psi\left(b\sum_i \pi^*(s)_i\right) = s^1_k.$$

where $\Psi : x \mapsto \frac{\partial}{\partial x}\left[\log\Gamma\right](x)$ is the digamma function. We estimate $(b\pi)^*$ with the fixed point iteration which consists in repeating the following update until convergence:

$$(b\pi)^{new}_k = \Psi^{-1}\left(\Psi\left(\sum_i (b\pi_i)^{old}\right) + s^1_k\right).$$

Finally, $(\beta, \pi)^*[s]$ satisfies $\forall (k, v)$:

$$\boxed{\begin{cases} (\beta^*(s))_{kv} & = & \left[\frac{s^2_{kv}}{\sum_j s^2_{kj}}\right] \\ \Psi(b\pi^*(s)_k) - \Psi\left(b\sum_i \pi^*(s)_i\right) & = & s^1_k. \end{cases}}$$

5.2 Inference with Online EM

In this section, we explain how to approximate $\mathbb{E}_{Z,\nu|X,\eta}[S(X, Z, \nu)]$ with Gibbs sampling from a frequentist and a Bayesian perspective. In particular, as the total number of topics is infinite, we need to keep track of the previously used topics and iteratively extend the number of topics considered.

5.2.1 GIBBS ONLINE EM (G-OEM)

In our frequentist G-OEM approach, η is a parameter. The Gibbs sampling scheme to approximate $\mathbb{E}_{Z,\nu|X,\eta}[S(X, Z, \nu)]$ is different from LDA and a probability of adding a new topic to the current list is computed at each iteration, as explained below.

5.2.2 EXPECTATION OF S^1.

We have:

$$\begin{aligned} \mathbb{E}_{Z,\nu|X,\eta}[S^1(X, Z, \nu)]_k &= \mathbb{E}_{Z,\nu|X,\eta}\left[\log\nu_k\right] \\ &= \mathbb{E}_{Z|X,\eta}\left[\Psi\left(b\pi_k + \sum_{n=1}^{N_X} z_{nk}\right)\right] - \Psi\left(b\sum_i \pi_i + N_X\right), \end{aligned}$$

and we use the values of z sampled with Gibbs sampling to compute:

$$\mathbb{E}_{Z|X,\eta}\left[\Psi\left(b\pi_k + \sum_{n=1}^{N_X} z_{nk}\right)\right] \approx \frac{1}{P}\sum_{t=1}^{P} \Psi\left(b\pi_k + \sum_{n=1}^{N_X} z^t_{nk}\right)$$

5.2.3 EXPECTATION OF S^2.

We have:

$$\mathbb{E}_{Z,\nu|X,\eta}[S^2(X, \nu)]_{kv} = \mathbb{E}_{Z,\nu|X,\eta}\left[\sum_{n=1}^{N_X} z_{nk}x_{nv}\right] = \sum_{n=1}^{N_X} x_{nv}p(z_{nk} = 1|X, \eta)$$

5.2.4 SAMPLING $z|X, \eta$.

If T is the current number of topics, we have:

$$\begin{aligned} \forall k \in \{1, \ldots, T\}, \;\; p(z_{nk} = 1|z^{-n}, X, \eta) &\propto (N^{-n}_k + b\pi_k) \times p(x_n|z_{ni} = 1, c_{ik} = 1, \eta) \\ &\propto (N^{-n}_k + b\pi_k) \times \beta_{k,x_n}, \end{aligned}$$

and the probability of sampling a new topic is given by:

$$p(z_n > T|z^{-n}, X, \eta) \propto b\left(1 - \sum_{t=1}^{T} \pi_k\right)/V.$$

When a new topic is generated, we initialize the probability π_{T+1} with $\bar{\pi}_{T+1} \sim \text{Beta}(1, \alpha)$ and $\pi_{T+1} = \bar{\pi}_{T+1}\prod_{t=1}^{T}(1 - \bar{\pi}_t)$.

5.2.5 BAYESIAN APPROACH: VARGIBBS (WANG AND BLEI, 2012)

In a Bayesian settings where $\beta^k \sim \text{Dirichlet}(\eta)$; $q(\beta^k|\lambda) = \text{Dirichlet}(\lambda^k)$ and $\pi_k \sim \text{Beta}(1, a)$; $q(\pi_k|a_k, b_k) = \text{Beta}(a_k, b_k)$, the sampling scheme is different as we also sample π and an auxiliary variable s_{dk} corresponding to the number of "tables" serving "dish" k in "restaurant" d (in the fomulation of HDP as a Chinese restaurant process; see Wang and Blei (2012) for details).
Sampling z:

$$p(z_{nk} = 1|z^{-n}, \lambda, \pi) \propto (N^{-n}_{dk} + b\pi_k)\frac{N^{-n}_{kx_n} + \lambda_{kx_n}}{N^{-n}_k + \sum_v \lambda_{kv}}.$$

Sampling s:

$$p(s_{dk}|N_{dk}, b\pi_k) = \frac{\Gamma(b\pi_k)}{\Gamma(b\pi_k + N_{dk})}S(N_{dk}, s_{dk})\,(b\pi_k)^{s_{dk}},$$

with $S(n, m)$ are unsigned Stirling number of the first kind.
Sampling π:

$$p(\bar{\pi}_k) \propto \bar{\pi}_k^{a_k - 1 + \sum_{d \in \mathbb{S}} s_{dk}}\,(1 - \bar{\pi}_k)^{b_k - \alpha + \sum_{d \in \mathbb{S}} \sum_{j=k+1}^{\infty} s_{dj}}$$

We then set:

$$\begin{cases} \hat{\lambda}_{kv} = \eta + D \sum_{n=1}^{N_X} z_{nk} x_{nv} \\ \hat{a}_k = 1 + D s_{dk} \\ \hat{b}_k = \alpha + D \sum_{j=k+1}^{\infty} s_{dj} \end{cases} \tag{18}$$

and $\lambda^{t+1} = (1-\rho_t)\lambda^t + \rho_t \hat{\lambda}$; $a^{t+1} = (1-\rho_t)a^t + \rho_t \hat{a}$; $b^{t+1} = (1-\rho_t)b^t + \rho_t \hat{b}$.

In practice, for each document we sample the hidden variables z for each word and compute the topic counts N_{dk} for topic k in document d, then we sample the variable s. Finally, we perform the online EM algorithm by making the approximation $\mathbb{E}_{p(h|X,\eta)}[S(X,h)] \approx \mathbb{E}_{q(h)}[S(X,h)]$, which corresponds to equation (18). Note that in this Bayesian approach, the parameters (λ, a, b) represent the distribution parameters of the random variables β and π.

6. Evaluation

We evaluate our method by computing the likelihood on held-out documents, that is $p(X|\beta,\alpha)$ for any test document X. For LDA, the likelihood is intractable to compute. We approximate $p(X|\beta,\alpha)$ with the "left-to-right" evaluation algorithm (Wallach et al., 2009) applied to each test document. This algorithm is a mix of particle filtering and Gibbs sampling. On any experiments, this leads essentially to the same log-likelihood than Gibbs sampling with sufficiently enough samples—e.g., 200. In the following, we present results in terms of log-perplexity, defined as the opposite of the log-likelihood $-\log p(X|\eta)$. The lower the log-perplexity, the better the corresponding model. In our experiments, we compute the average test log-perplexity on N_t documents. We compare eight different methods:

- `G-OEM` (our main algorithm): Gibbs online EM. Online EM algorithm with Gibbs estimation of the conditional distribution $p(h|X,\eta)$ (Algorithm 2). Frequentist approach and step-size $\rho_i = 1/\sqrt{i}$;
- `V-OEM++`: variational online EM (also a new algorithm). Online EM algorithm with variational estimation of the conditional distribution $p(h|X,\eta)$, augmented with inference boosting from Section 3.3. Frequentist approach and step-size $\rho_i = 1/\sqrt{i}$;
- `OLDA`: online LDA (Hoffman et al., 2010). Bayesian approach which maximizes the ELBO from Section 3.4, with natural stochastic gradient ascent and a step-size $\rho_i = 1/\sqrt{i}$;
- `VarGibbs`: Sparse stochastic inference for LDA (Mimno et al., 2012). This method also maximizes the ELBO but estimates the variational expectations $q(Z,\theta)$ with Gibbs sampling instead of iterative maximization of variational parameters—see Section 4.2;
- `SVB`: streaming variational Bayes (Broderick et al., 2013). A variational Bayesian equivalent of `V-OEM` with step-size $\rho_i = 1/i$;

- `SPLDA`: single pass LDA (Sato et al., 2010). The difference with `V-OEM++` is that $\rho_i = 1/i$ and the updates in α done with a Gamma prior (see Appendix C);
- `SGS`: streaming Gibbs sampling (Gao et al., 2016). This method is related to `G-OEM` with $\rho_i = 1/i$. In this method, α is not optimized and set to a constant C_α. For comparison purposes, for each dataset, we set C_α to be the averaged final parameter $\hat{\alpha}$ obtained with `G-OEM` on the same dataset: $C_\alpha = \frac{1}{K}\sum_k \hat{\alpha}_k$. For each observation, only the last Gibbs sample is considered, leading to extra noise in the output;
- `LDS`: Stochastic gradient Riemannian Langevin dynamics sampler (Patterson and Teh, 2013). The authors use the Langevin Monte Carlo methods on probability simplex and apply their online algorithm to LDA. For this method and only this method, we set to $P = 200$ the number of internal updates.

For existing variational methods—`OLDA`, `SVB`, `SPLDA`—β is a random variable with prior $q(\beta)$. We estimate the likelihood $p(X|\hat{\beta},\alpha)$ with the "left-to-right" algorithm by setting $\hat{\beta} = \mathbb{E}_q[\beta]$ for Bayesian methods. For simplicity, we only present our results obtained with `G-OEM` and `V-OEM++`. Indeed, the inference boost presented in Section 4 is only beneficial for `V-OEM`. A detailed analysis is presented in Appendix A.1.

6.1 Explicit Links for LDA

In this section, we propose to make the links between the methods listed above explicit, using the framework described in Section 4 for the particular LDA model. We present in Table 1 a summary of the compared method.

6.1.1 CATEGORY

In the frequentist approach, β is a parameter and is updated with Equation (8), as the "M-step" in online EM.

In a Bayesian setting, β is a random variable with prior $\beta \sim \text{Dirichlet}(b\mathbf{1})$, with $b \in \mathbb{R}$ and $\mathbf{1} \in \mathbb{R}^V$ denotes the vector whose all entries equal 1. The variational distribution of the global parameter β is then set to $q(\beta^k|\lambda^k) = \text{Dirichlet}(\lambda^k)$, with $\lambda^k \in \mathbb{R}^V \ \forall k = 1,\dots,K$. The variational parameter λ^k is updated by maximizing the ELBO with stochastic gradient ascent (Equation (15)).

	CATEGORY	$\mathbb{E}_{Z\|X,\eta}[S(X,Z)]$	STEP-SIZE ρ_t	UPDATE FOR α
G-OEM	FREQUENTIST	GIBBS SAMPLING	FREE	FIXED POINT
V-OEM	FREQUENTIST	VARIATIONAL	FREE	FIXED POINT
OLDA	BAYESIAN	VARIATIONAL	FREE	GRADIENT ASCENT
VARGIBBS	BAYESIAN	GIBBS SAMPLING	FREE	α FIXED
SVB	BAYESIAN	VARIATIONAL	FIXED: $1/t$	GRADIENT ASCENT
SPLDA	FREQUENTIST	VARIATIONAL	FIXED: $1/t$	GAMMA PRIOR
SGS	FREQUENTIST	GIBBS SAMPLING	FIXED: $1/t$	α FIXED

Table 1: Comparison of existing methods for LDA.

6.1.2 ESTIMATION OF $\mathbb{E}_{Z|X,\eta}[S(X,Z)]$

For LDA, the expectation $\mathbb{E}_{Z|X,\eta}[S(X,Z)]$ can either be estimated with Gibbs sampling—using Equation (14)—or with variational approximation—using Equation (10).

6.1.3 STEP-SIZE

Some of the methods listed above (`SVB`, `SPLDA` and `SGS`) are incremental, which means the sufficient statistics are incrementally aggregated $s_t = s_{t-1} + \mathbb{E}_{Z_t|X_t,\eta}[S(X_t,Z_t)]$. For LDA, it exactly corresponds to a step-size $\rho_t = 1/t$ in the online EM setting, even though the link is not explicit in the corresponding papers.

For the other listed methods, the step-size exponent κ is chosen arbitrarily in $[0.5, 1)$, with $\rho_t = 1/t^\kappa$. However, results are mostly presented with $\kappa = 1/2$ and $\rho_t = 1/\sqrt{t}$.

6.2 General Settings

6.2.1 INITIALIZATION

We initialize randomly $\eta \equiv (\beta, \alpha)$. For a given experiment, we initialize all the methods with the same values of (β, α) for fair comparison, except `SPLDA` that has its own initilization scheme—see Sato et al. (2010) for more details.

6.2.2 MINIBATCH

We consider minibatches of size 100 documents for each update in order to reduce noise (Liang and Klein, 2009). In the case of online EM in Equation (3), we estimate an expectation for each observation of the minibatch. We update the new sufficient statistics s towards the average of the expectations over the minibatch. We do the same averaging for all the presented methods.

6.2.3 NUMBER OF LOCAL UPDATES

For all the presented methods, we set the number of passes through each minibatch to $P = 20$. For `G-OEM`, this means that we perform 20 Gibbs sampling for each word of the minibatch. All other methods access each document 20 times (e.g., 20 iterations of variational inference on each document). For `G-OEM`, inference with larger values for P (e.g., $P = 50$ or $P = 100$) leads to very similar results.

6.2.4 DATASETS

We apply the methods on six differents datasets, summarized in Table 2 ($\overline{N_X}$ is the average length of documents). Following Blei et al. (2003), the synthetic dataset has been generated from 10 topics and the length of each document drawn from a Poisson(60). The 10 topics are inferred with online LDA (Hoffman et al., 2010) from 50,000 reviews of the IMDB dataset with a vocabulary size of 10,000. We only consider the entries of the 1,000 most frequent words of this dataset that we normalize to satisfy the constraint $\sum_v \beta_v^k = 1$.

The words in the datasets IMDB, Wikipedia, New York Times, Pubmed and Amazon movies are filtered by removing the stop-words and we select the most frequent words of the datasets. For the synthetic dataset, IMDB, Pubmed and Amazon movies, the size of the test sets is $N_t = 5{,}000$ documents. For Wikipedia and New York Times, the test sets contain $N_t = 2{,}000$ documents.

DATASET	#DOCUMENTS	$\overline{N_X}$	#WORDS
SYNTHETIC	1,000,000	60	1,000
WIKIPEDIA[1]	1,010,000	162.3	7702
IMDB[2]	614,589	82.2	10,000
AMAZON MOVIES[3]	338,565	75.4	10,000
NEW YORK TIMES[4]	299,877	287.4	44,228
PUBMED[4]	2,100,000	82.0	113,568

Table 2: Datasets.

We run the methods on 11 differents train/test splits of each dataset. For all the presented results, we plot the median from the 11 experiments as a line—solid or dashed. For the sake of readability, we only present the same plots with error bars between the third and the seventh decile in Appendix D and Appendix E.

6.2.5 COMPUTATION TIME

For each presented method and dataset, the computational time is reported in Table 3. Although all methods have the same running-time complexities, coded in Python, sampling methods (`G-OEM`, `VarGibbs` and `SGS`) need an actual loop over all documents while variational methods (`OLDA`, `SVB`, `SPLDA` and `V-OEM++`) may use vector operations, and may thus be up to twice faster. This could be mitigated by using efficient implementations of Gibbs sampling on minibatches (Yan et al., 2009; Zhao et al., 2014; Gao et al., 2016). Note also that to attain a given log-likelihood, our method `G-OEM` is significantly faster and often attains log-likelihoods not attainable by other methods (e.g., for the dataset New York Times).

6.2.6 STEP-SIZE

In the following, we compare the results of our methods `G-OEM` and `V-OEM++` with $\kappa = 1/2$, i.e., the step-size $\rho_t = 1/\sqrt{t}$, without averaging. Detailed analysis of different settings of our method can be found in Appendix A. In particular, we compare different step-sizes and the effect of averaging over all iterates. We also compare the performance of `OLDA` with different step-sizes in Appendix A.2 and observe that results are very similar for all the step-sizes that we try. Note that for incremental methods (`SVB`, `SPLDA`, `SGS`), the step-size is fixed to $\rho_t = 1/t$. For `LDS`, we run the method with parameters as close as possible to our method for fair comparison.

6.3 Results on LDA

Results obtained with the presented methods applied to LDA on different datasets for different values of the number K of topics are presented in Figure 1. Performance through iterations (i.e., as the number of documents increases) is presented in Figure 4. We first observe that for all experiments, our new method `G-OEM` performs better—often significantly—than all existing methods. In particular, it is highly robust to diversity of datasets.

1. Code available from Hoffman et al. (2010)
2. Dataset described in Diao et al. (2014)
3. Data from Leskovec and Krevl (2014)
4. UCI dataset (Lichman, 2013)

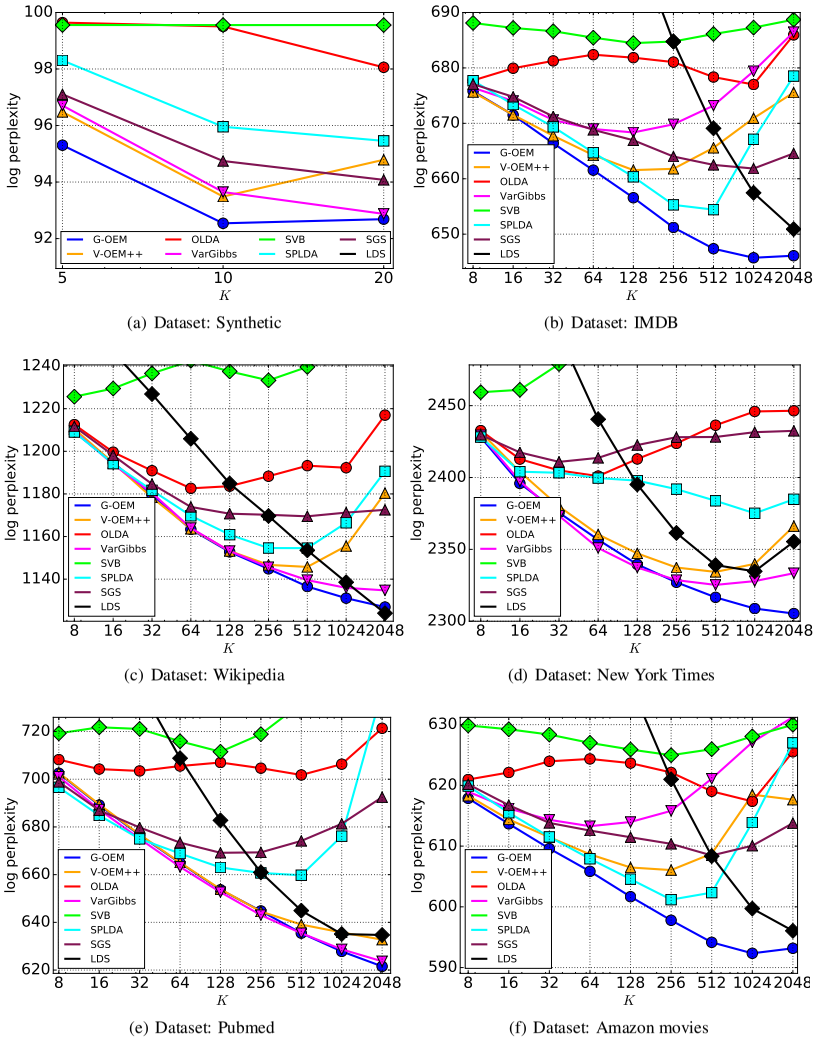
	IMDB	WIKIPEDIA	NYT	PUBMED
G-OEM	13H	55H	30H	58H
V-OEM++	9H	37H	20H	54H
OLDA	7H	33H	8H	30H
VARGIBBS	12H	50H	28H	54H
SVB	7H	34H	9H	30H
SPLDA	9H	37H	20H	54H
SGS	11H	48H	27H	50H
LDS	7H	17H	12H	40H

Table 3: Average computational time (in hours) for each method—$K = 128$.

6.3.1 INFLUENCE OF THE NUMBER OF TOPICS K

As shown in Figure 1, for synthetic data in plot (a), although the true number of topics is $K^* = 10$, SPLDA, OLDA, VarGibbs and SGS perform slightly better with $K = 20$, while G-OEM has the better fit for the correct value of K; moreover, SVB has very similar performances for any value of K, which highlights the fact that this method does not capture more information with a higher value of K. LDS performs very poorly on this dataset—for any value of K the log-perplexity is around 400—and is not displayed in Figure 1 (a) for clarity.

On non-synthetic datasets in plots (b)-(f), while the log-perplexity of frequentist methods—G-OEM, V-OEM++ and SPLDA—decreases with K, the log-perplexity of variational Bayesian methods—OLDA and SVB—does not decrease significantly with K. As explained below, our interpretation is that the actual maximization of the ELBO does not lead to an improvement in log-likelihood. The hybrid Bayesian method VarGibbs—which uses Gibbs sampling for local updates (θ, z) and variational updates for global parameters (β, α)—performs much better than the variational Bayesian methods. Our interpretation is that the objective function maximized with VarGibbs is a much better approximation of the log-likelihood than the ELBO.



In terms of robustness, G-OEM and LDS are the only methods that do not display overfitting on any dataset. However, LDS is only competitive for the highest values of K—$K \geq 500$.

6.3.2 PERFORMANCE THROUGH ITERATIONS

As shown in Figure 4, for synthetic data in plot (a), after only few dozens of iterations—few thousands of documents seen—G-OEM, V-OEM++ and VarGibbs outperform the other presented methods. Variational Bayesian methods again do converge but to a worse parameter value. On real datasets in plots (b)-(f), G-OEM and VarGibbs are significantly faster; we can indeed still observe that after around 100 iterations—10,000 documents seen—G-OEM and VarGibbs perform better than other methods on all the datasets except Pubmed, where the performances of G-OEM, V-OEM++, VarGibbs and SPLDA are similar. Note that

6.3.3 VARIATIONAL VS. SAMPLING

Our method G-OEM directly optimizes the likelihood with a consistent approximation, and performs better than its variational counterparts SPLDA and V-OEM++ in all experiments. The hybrid method VarGibbs is less robust than G-OEM as it performs either similarly to G-OEM—for the datasets

Wikipedia, New York Times and Pubmed—or worse than G-OEM and its variational counterparts SPLDA and V-OEM++—for the datasets IMDB and Amazon.

6.3.4 FREQUENTIST VS. BAYESIAN

In all our experiments we observe that frequentist methods—G-OEM, V-OEM++ and SPLDA—outperform variational Bayesian methods—OLDA and SVB. As described in Section 3.4, variational Bayesian methods maximize the ELBO, which makes additional strong independence assumptions and here leads to poor results. For example, as the number K of topics increases, the log-likelihood goes down for some datasets. In order to investigate if this is an issue of slow convergence, we show on Figure 2 (dotted black line) that running $P = 100$ internal updates in OLDA to get a finer estimate of the ELBO for each document may deteriorate the performance. Moreover, Figure 3 presents the evolution of the ELBO, which does always increase when K increases, showing that the online methods do optimize correctly the ELBO (while not improving the true log-likelihood). See Appendix B for additional results on the convergence of the ELBO. The results are mitigated for the hybrid Bayesian method VarGibbs. The performance of this method is either similar to G-OEM and V-OEM++ or significantly worse than both G-OEM and V-OEM++.

6.3.5 SMALL STEP-SIZES VS. LARGE STEP-SIZES

SPLDA is also a variational method which is equivalent to V-OEM++, but with a step-size $1/t$, which is often slower than bigger step-sizes (Mairal, 2014), which we do observe—see Appendix A.2 for a further analysis on the effect of the choice of step-sizes as $1/i^\kappa$ on G-OEM. Note that we run all the methods on a fixed (finite) number of observations. If we were to extend to infinite datasets, the difference between the step-sizes should be the speed of convergence. However, even if the number of observations is large, the gap between the step-sizes is still significant to justify the use of $1/\sqrt{t}$ for the step-size. Indeed, when considering large datasets, the contribution of each

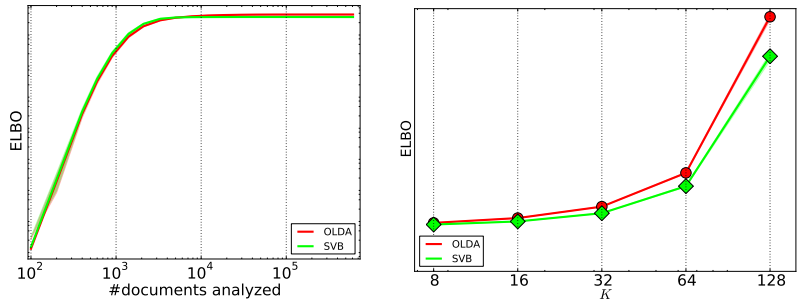

Figure 3: Dataset: IMDB. Evidence Lower BOund (ELBO) computed on test sets (20 internal iterations and 1 pass over the dataset). *Left*: ELBO through iterations with $K = 128$. *Right*: ELBO as a function of the number of topics K.

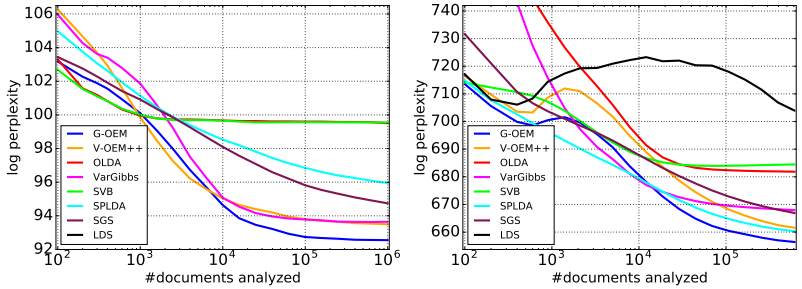
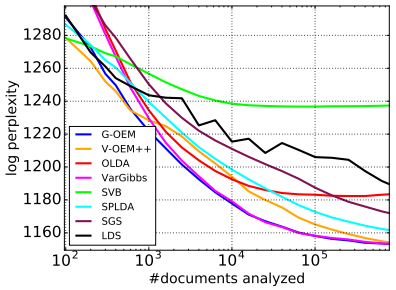


iteration at the end of the pass over the data is squeezed by the step-size in $1/t$. When the number of observations is large enough to prevent the use of batch algorithms but still insufficient for an online algorithm to converge in one pass, a possible solution could be to consider constant step-sizes in order to converge even faster to a local maxima. As proposed, we do not have any guarantee for our methods to converge with constant step-sizes, but previous works have shown the benefits of using constant step-sizes under certain assumptions (e.g., Bach and Moulines (2013))

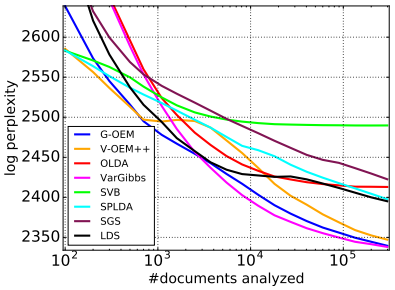
6.4 Empirical Analysis

In this section we provide a qualitative empirical analysis on the topics extracted with the different methods. We note this is clearly a subjective analysis but it stresses the benefits of a "better" inference mechanism in terms of log-likelihood (Chang et al., 2009). Examples of eight topics extracted with G-OEM and OLDA on the IMDB dataset of movie reviews are presented in Table 4 page 30.

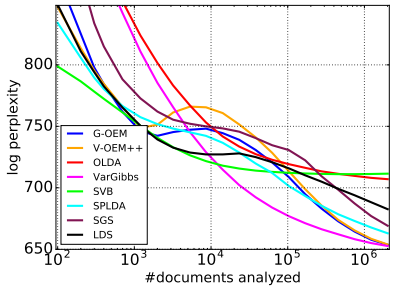


We first compute the KL divergence between the $K = 128$ topics extracted with G-OEM and the $K = 128$ topics extracted with OLDA. We run the Hungarian algorithm on the resulting distance matrix to assign each topic extracted with G-OEM to a single topic of OLDA. We choose manually eight topics extracted with G-OEM that are representative of the usual behavior, and display the eight corresponding topics of OLDA assigned with the above method.

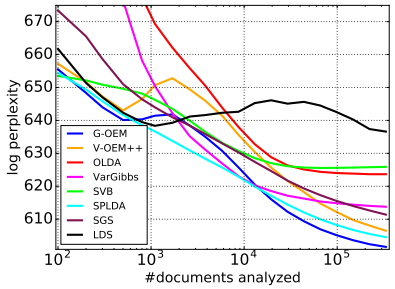
We observe that the topics extracted with G-OEM are more consistent than topics extracted with OLDA: topics of G-OEM precisely describe only one aspect of the reviews while the topics of OLDA tend to mix several aspects in each topic. For instance, the words of topic 1 extracted with G-OEM are related to *horror* movies. The words of the corresponding topic extracted with OLDA mix *horror* movies—e.g., *horror, scary*—and *ghost* movies—e.g., *ghost, haunt*. In this OLDA topic 1, we can also observe less relevant words, like *effective, mysterious*, which are not directly linked with *horror* and *ghost* vocabularies. We can make the same remarks with topic 2 and topic 3, respectively related to *comedy* movies and *romantic comedy* movies. In topic 2 extracted with G-OEM, the least related



(a) Synthetic, $K = 10$



(b) IMDB, $K = 128$



(c) Wikipedia, $K = 128$

(d) New York Times, $K = 128$

(e) Pubmed, $K = 128$

(f) Amazon movies, $K = 128$

Figure 4: Perplexity through iterations on different test sets with the presented methods. Best seen in color.

words to *comedy* are names of characters/actors—i.e., *steve* and *seth*—while the words not related to *comedy* in topic 25 of OLDA are more general, belonging to a different lexical field—e.g., *sport, site, progress, brave, definition*. In topic 3 of G-OEM, all the presented words are related to *romantic comedy* while in topic 3 of OLDA, the words *old, hard* and *review* are not related to this genre.

We also observe that G-OEM extracts strongly "qualitative" topics—topic 4 and topic 5—which is not done with OLDA. Indeed, it is difficult to group the top words of topic 4 or topic 5 of OLDA in the same lexical field. Except *dialogue* and *suppose*, all the top words of topic 4 of G-OEM are negative words. These two words may appear in a lot of negative sentences, leading to a high weight in this topic. In topic 5 of G-OEM, the words *absolutely* and *visual* are non strictly positive words while the thirteen other words in this topic convey a positive opinion. The word *absolutely* is an adverb much more employed in positive sentences than negative or neutral sentences, which can explain its high weight in topic 5.

The topic 6 of both G-OEM and OLDA can be considered as a "junk" topic, as for both method, most of its top words are contractions of modal verbs or frequent words—e.g., *didn't, isn't, wait, bad*. The contractions are not filtered when removing the stop words as they are not included in the list of words removed[1].

For both G-OEM and OLDA, the top words of topic 7 are general words about movies. These words are usually employed to describe a movie as a whole—e.g., *narrative, filmmaker*.

Finally, the top words of topic 8 of G-OEM are related to the situation of the scenes. We could not find such topic in the other presented methods and we can see that the top words of topic 8 of OLDA—supposedly close to topic 8 of G-OEM—are related to *family* movies. Each word of topic 8 of G-OEM—except *group* and *beautiful*—are related to a *spatial location*, and may help answer the question "*where does the scene take place?*".

6.5 Results on HDP

For the HDP model, we compare our G-OEM method to the Bayesian VarGibbs (Wang and Blei, 2012) method. We set the initial number of topics to $T = 2$. We present in Figure 5 results obtained with G-OEM and VarGibbs applied to both LDA and HDP. Results with error bars are presented in Appendix F. For both LDA and HDP, G-OEM outperforms the Bayesian method VarGibbs.

7. Conclusion

We have developed an online inference scheme to handle intractable conditional distributions of latent variables, with a proper use of local Gibbs sampling within online EM, that leads to significant improvements over variational methods and Bayesian estimation procedures. Note that all methods for the same problem are similar (in fact a few characters away from each other); ours is based on a proper stochastic approximation maximum likelihood framework and is empirically the most robust. It would be interesting to explore distributed large-scale settings (Broderick et al., 2013; Yan et al., 2009; Gao et al., 2016) and potentially larger (e.g., constant) step-sizes that have proved efficient in supervised learning (Bach and Moulines, 2013).

1. See NLTK toolbox (Bird et al., 2009) for the exhaustive list of stop words.

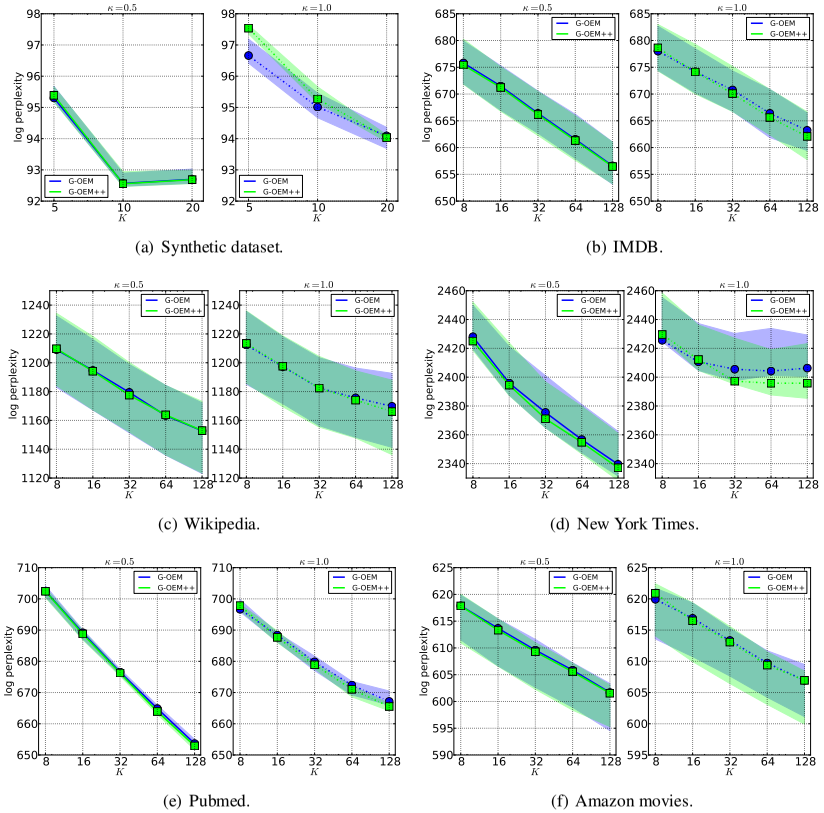
Appendix A. Gibbs/Variational Online EM Analysis

In this section we evaluate the proposed methods G−OEM and V−OEM with different settings in terms of step-sizes, averaging outputs and boosting internal updates.

A.1 Effect of Inference Boosting on G−OEM and V−OEM



The effect of the inference boost as described in Section 3.3 on G−OEM and V−OEM with synthetic and IMDB datasets is presented in Figure 6 and in Figure 7. It leads to a minor improvement for G−OEM++ and a significant one for V−OEM++.

A.2 Step-sizes and Averaging

We apply G−OEM with different stepsizes $\rho_i = \frac{1}{i^\kappa}$. Note that because we average sufficient statistics, there is no needed proportionality constants. We first compare the performance of the last iterate η_N (without averaging) and the average of the iterates $\bar{\eta}_N = \frac{1}{N}\sum_{i=0}^{N} \eta_i$ (with averaging) for different values of κ.

Results are presented in Figure 8 on the synthetic data and in Figure 9 on the IMDB dataset. For $\kappa \in \left[0, \frac{1}{2}\right[$, averaging improves the performance while for $\kappa \in \left]\frac{1}{2}, 1\right]$, averaging deteriorates the performance. For $\kappa = \frac{1}{2}$, averaging is only slightly beneficial on IMDB dataset. For constant stepsizes $\kappa = 0$ the averaging improves significantly the performance, as the iterates do not converge and tend to oscillate around a local optimum (Bach and Moulines, 2013). We can expect the same effect for $\kappa \in \left[0, \frac{1}{2}\right[$ as the function $n \mapsto \frac{1}{n^\kappa}$ deacreases slowly for such values of κ. For $\kappa \in \left]\frac{1}{2}, 1\right]$, the stochastic gradient ascent scheme is guaranteed to converge to a local optimum (Bottou, 1998). The averaging then deteriorates the performance as it incorporates the first iterates, which gets the last iterate away from local optimum. However, the stepsize $1/i$ ($\kappa = 1$) is not competitive. The performance with $\kappa = 0.75$ is only slightly better on IMDB dataset. The setting $\kappa = \frac{1}{2}$ represents a good balance between first and last iterates. For this step-size, performances with or without averaging are similar but results without averaging seem to be more stable, hence our choice for all our other simulations.

We also apply OLDA with different step-sizes $\rho_t = \tau/t^\kappa$ for different values of τ, κ. Results are presented in Figure 10 without error bars and in Figure 11 with error bars. For OLDA, results are very similar for any step-size.

Appendix B. Evolution of the ELBO

Figure 12 presents the evolution of the ELBO for online LDA (OLDA) and SVB on different test sets. We compute the ELBO on test documents as described by Hoffman et al. (2010). This plot helps us to observe that even if the ELBO reaches a local maximum (i.e., it stabilizes), the quality of the model in terms of perplexity is not controllable. We can also see in Figure 12 that the ELBO is much better optimized with $K = 128$ than with other values of K for both SVB and OLDA, that is, as expected, latent variables of higher dimensionality lead to better fits for the cost function which is optimized. However, for several datasets the performance in terms of perplexity is better with low values of K ($K = 8$ or $K = 16$) than with high dimensional variables ($K = 64$ or $K = 128$).

(a) IMDB, $K = 128$ (b) Wikipedia, $K = 128$

(c) IMDB (d) Wikipedia

Figure 12: Evidence Lower BOund (ELBO) computed on different test sets. Top: ELBO through iterations, with 4 passes over each dataset and 200 internal iterations. Bottom: ELBO as a function of the number of topics K, with 20 internal iterations and 1 pass over each dataset. Best seen in color.

In order to check if more internal iterations could help variational Bayesian methods, we present in Table 5 the values of perplexity reached by OLDA when running 4 passes over each dataset with $P = 200$ internal iterations 1 pass over each dataset with $P = 20$ internal iterations. We observe that the ELBO converges quickly to a local optimum and doing ten times more internal iterations does not change significantly the final performance.

	$P = 200$, 4 passes	$P = 20$, 1 pass
OLDA	682.6±3.7	681.9±3.9
SVB	683.8±3.8	684.5±3.8

Table 5: Comparison of log-perplexity levels reached with OLDA and SVB on IMDB dataset.

Appendix C. Updates in α

In this section we compare the different types of updates for α. Figure 13 presents results obtained on synthetic dataset for fixed point iteration algorithm (Minka, 2000) and by putting a gamma prior on α (Sato et al., 2010). We observe that the fixed point method leads to better performance for G-OEM and G-OEM++. For V-OEM, the gamma updates better perform for $\kappa = \frac{1}{2}$. The performances of the gamma updates and the fixed point method are very similar for V-OEM++. Note that the algorithm V-OEM++ with $\kappa = 1$ and gamma updates on α is exactly equivalent to SPLDA (Sato et al., 2010). The performance of this method can be improved by setting $\kappa = \frac{1}{2}$ with any update on α.

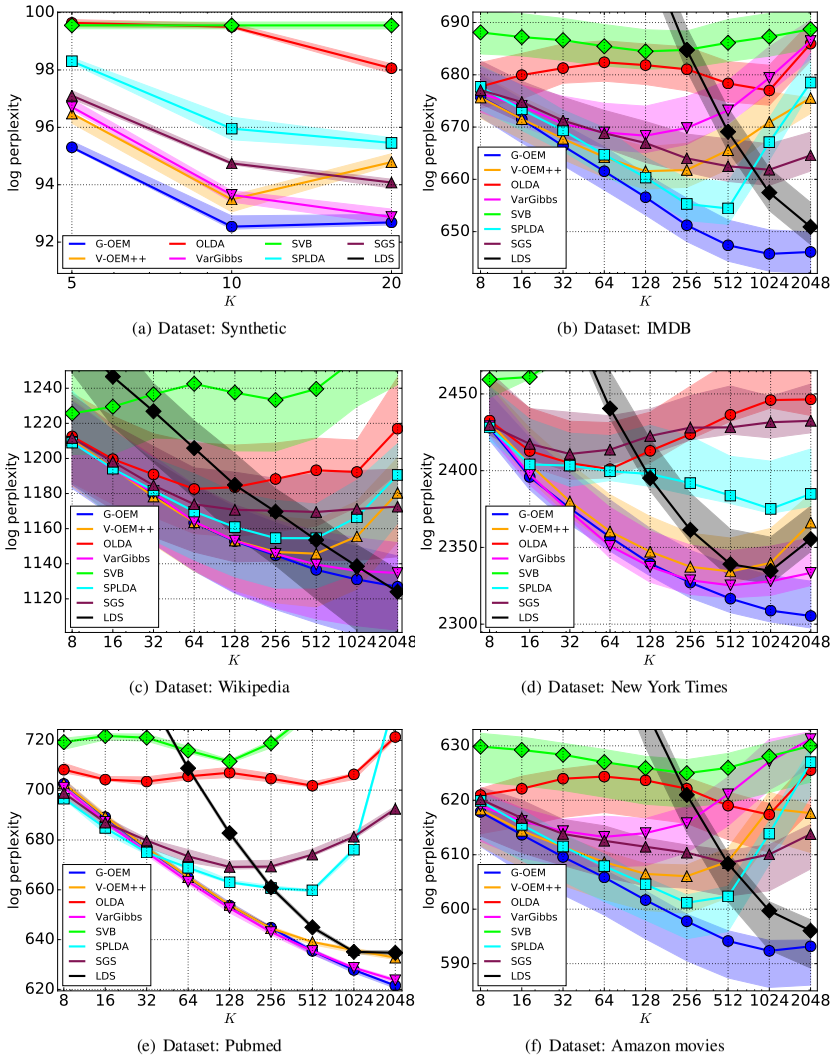
We also observe that fixing α to α_{true} that generated the data does not necessarily lead to better performance.

(a) G-OEM (b) G-OEM++

(c) V-OEM (d) V-OEM++

Figure 13: Dataset: Synthetic, $K = 10$. Perplexity on different test sets for different types of updates for α; for boosted methods, we use the same inference for α for local and global updates. NO: α is fixed and set to α_{true} that generated the data; FP: fixed point iteration; Gam: gamma prior on α (Sato et al., 2010). Best seen in color.

Appendix D. Performance with Different K, with Error Bars



The performance of the presented methods for different values of K on the different datasets is presented in Figure 14. We plot the median from the 11 experiments as a line—solid or dashed—and a shaded region between the third and the seventh decile.

Appendix E. Performance Through Iterations, with Error Bars

The performance through iterations of the presented methods on the different datasets is presented in Figure 15. We plot the median from the 11 experiments as a line—solid or dashed—and a shaded region between the third and the seventh decile.

Appendix F. Results on HDP, with Error Bars

The performance through iterations of the `G-OEM` and `VarGibss` applied to both LDA and HDP is presented in Figure 15. We plot the median from the 11 experiments as a line—solid or dashed—and a shaded region between the third and the seventh decile.

Abstract

We present the *Wright-Fisher Indian buffet process* (WF-IBP), a probabilistic model for time-dependent data assumed to have been generated by an unknown number of latent features. This model is suitable as a prior in Bayesian nonparametric feature allocation models in which the features underlying the observed data exhibit a dependency structure over time. More specifically, we establish a new framework for generating dependent Indian buffet processes, where the Poisson random field model from population genetics is used as a way of constructing dependent beta processes. Inference in the model is complex, and we describe a sophisticated Markov Chain Monte Carlo algorithm for exact posterior simulation. We apply our construction to develop a nonparametric focused topic model for collections of time-stamped text documents and test it on the full corpus of NIPS papers published from 1987 to 2015.

Keywords: Bayesian nonparametrics, Indian buffet process, topic model, Markov chain Monte Carlo, Poisson random field

1. Introduction

The Indian buffet process (IBP) (Griffiths and Ghahramani, 2011) is a distribution for sampling binary matrices with any finite number of rows and an unbounded number of columns, such that rows are exchangeable while columns are independent. It is used as a prior in Bayesian nonparametric models where rows represent objects and columns represent an unbounded array of features. In many settings the prevalence of features exhibits some sort of dependency structure over time and modeling data via a set of independent IBPs may not be appropriate. There has been previous work dedicated to extending the IBP to dependent settings (e.g., Williamson et al., 2010a; Zhou et al., 2011; Miller et al., 2012; Gershman et al., 2015). In this paper we present a novel approach that achieves this by means of a particular time-evolving beta process, which has a number of desirable properties and is better-suited for a different range of applications.

For each discrete time $t_0, \ldots, t_T$ at which the data is observed, denote by Z_t the feature allocation matrix whose entries are binary random variables such that $Z_{ikt} = 1$ if object i possesses feature k at time t and 0 otherwise. Denote by $X_k(t)$ the probability that $Z_{ikt} = 1$, namely the probability that feature k is active at time t, and by $X(t)$ the collection of these probabilities at time t. The idea is to define a prior over the stochastic process $\{X(t)\}_{t\geq 0}$ which governs its evolution in continuous time. In particular, for each feature k, $X_k(t)$ evolves independently, while features are born and die over time. This is a desirable property in several applications such as in topic modeling, where at some point in time a new topic may be discovered (birth) or forsaken (death). Our model benefits from these properties while retaining a very simple prior where sample paths are continuous and Markovian. Finally, we show that our construction defines a time-dependent beta process from which the two-parameter generalization of the IBP is marginally recovered for every fixed time t (Ghahramani et al., 2007).

The stochastic process we use is a modification of the so-called Poisson Random Field (PRF), a model widely used in population genetics (e.g., Sawyer and Hartl, 1992; Hartl et al., 1994; Bustamante et al., 2001, 2003; Williamson et al., 2005; Boyko et al., 2008; Gutenkunst et al., 2009; Amei and Sawyer, 2010, 2012). In this setting, new features can arise over time and each of them evolves via an independent Wright-Fisher (W-F) diffusion. The PRF model describes the evolution of feature probabilities within the interval $[0, 1]$, allows for flexible boundary behaviours and gives access to several off-the-shelf results from population genetics about quantities of interest, such as the expected lifetime of features or the expected time feature probabilities spend in a given subset of $[0, 1]$ (see Ewens, 2004).

We apply the WF-IBP to a topic modeling setting, where a set of time-stamped documents is described using a collection of latent topics whose probabilities evolve over time. The WF-IBP prior allows us to incorporate time dependency into the focused topic model construction described in Williamson et al. (2010b), where the IBP is used as a prior on the topic allocation matrix determining which topics underlie each observed document. As opposed to several existing approaches to topic modeling, which require specifying the total number of topics in the corpus in advance (see for instance Blei et al., 2003), adopting a nonparametric approach saves expensive model selection procedures (such as the one described in Griffiths and Steyvers, 2004). This is also reasonable in view of the fact that the total number of topics in a corpus is expected to grow as new documents accrue. Most existing nonparametric approaches to topic modeling are not designed to capture the evolution of the popularity of topics over time and may thus not be suitable for corpora that span large time periods. On the other hand, existing nonparametric and time-dependent topic models are mostly based on the Hierarchical Dirichlet Process (HDP) (Teh et al., 2006), which implicitly assumes a coupling between the probability of topics and the proportion of words that topics explain within each document. This assumption is undesirable since rare topics may account for a large proportion of words in the few documents in which they appear. Our construction inherits from the static model presented in Williamson et al. (2010b) the advantage of eliminating this coupling. Moreover, it keeps inference straightforward while using an unbounded number of topics and flexibly capturing the evolution of their popularity continuously over time.

Section 2 introduces the beta process construction of the IBP and the PRF, providing the background for Section 3 where we modify the PRF to construct the WF-IBP, our

novel time-varying feature allocation model. Section 4 describes a fixed-K approximation and an intuitive inference scheme that is built upon in Section 5 to develop an exact MCMC algorithm for posterior inference with the WF-IBP. Section 6 combines the model with a linear-Gaussian likelihood and evaluates it on a range of synthetic data sets. Finally, Section 7 illustrates the application of the WF-IBP to topic modeling and presents results obtained on both synthetic data and on the real-world data set consisting of the full text of papers from the NIPS conferences between the years 1987 and 2015.

2. Background

Before introducing our time-varying feature allocation model we first review its two building blocks, namely the IBP and the PRF. We show how the beta process connects these two models, and we adjust the PRF to develop a time-dependent extension of the two-parameter IBP in the next section.

2.1 The beta and Indian buffet processes

A completely random measure B over a measurable space (Ω,Σ) is a random measure that assigns independent masses to disjoint subsets of Ω. Any positive completely random measure is uniquely characterized by a certain Levy measure on $\Omega \times \mathbb{R}^+$ (see Kingman, 1967). Denote by c a positive function over Ω (concentration function) and by B_0 a fixed measure on Ω (base measure), and assume the base measure B_0 is continuous. A beta process B $\sim BP(c, B_0)$ on Ω is a completely random measure uniquely characterized by the Levy measure

$$\nu(d\omega, dx) = B_0(d\omega)c(\omega)x^{-1}(1-x)^{c(\omega)-1}dx,$$

where $x \in [0,1]$ and $\omega \in \Omega$. This completely random measure can be represented via a Poisson process. In order to draw $B \sim BP(c, B_0)$, draw a set of points $(\omega_i, x_i) \in \Omega \times [0,1]$ from a Poisson point process with base measure $\nu(d\omega, dx)$ and let

$$B = \sum_{k=1}^{\infty} x_k \delta_{\omega_k},$$

where $\{\omega_i\}$ are the atoms of the measure B and $\{x_i\}$ their respective weights. Given a realization B of a beta process $BP(c, \alpha B_0)$ with $\alpha > 0$, one can obtain a draw from the IBP (Thibaux and Jordan, 2007). This is done by sampling each row z_i, $i = 1, \dots, N$, of an allocation matrix Z from a Bernoulli process $z_i \mid B \sim BeP(B)$ defined as

$$z_i = \sum_{k=1}^{\infty} p_{ik}\delta_{\omega_k}, \quad p_{ik} \overset{iid}{\sim} \text{Bernoulli}(x_k).$$

Notice that as the location of the atoms is not in fact relevant for constructing the matrix Z, the IBP depends only on the so-called mass parameter $B_0(\Omega) = \alpha$ and on $c(\omega)$. In the standard IBP, $c(\omega)$ is set to be identically 1, so that the Levy measure of the corresponding one-parameter beta process is

$$\nu(d\omega, dx) = B_0(d\omega)x^{-1}dx. \tag{1}$$

If $c(\omega)$ is equal to a constant β we have the two-parameter generalization of the IBP (Thibaux and Jordan, 2007).

2.2 The Wright-Fisher model

The starting point of the PRF is the Wright-Fisher (W-F) model from population genetics (Ewens, 2004), which we briefly summarize here. Consider a finite population of organisms of size G such that $i \in \{0, 1, \dots, G\}$ individuals have the mutant version of a gene at generation k, while the rest has the non-mutant variant. Assume that each individual produces an infinite number of gametes such that the gametes yielded by a non-mutant become mutant with probability μ_G and, conversely, those yielded by a mutant become non-mutant with probability β_G. Finally, assume that the next generation of G individuals is formed by simple random sampling from this infinite pool of gametes. The evolution of the number $Y^G(k)$ of mutant genes at time k is described by a Markov chain on the discrete space $\{0, \dots, G\}$. The transition probability p_{ij} of switching from i mutants (at time k) to j mutants (at time $k+1$) is given by the following binomial sampling formula:

$$p_{ij} = \binom{G}{j} (\Psi_i)^j (1-\Psi_i)^{G-j},$$
$$\Psi_i = \frac{i(1-\beta_G) + (G-i)\mu_G}{G}.$$

Assume the initial state is $Y^G(0) = y_0$ and denote the resulting Markov chain by $Y^G = (Y^G(k))_{k=1,2,\dots} \sim \text{W-F}^G(\mu_G, \beta_G)$. Notice that, if $\mu_G = 0$ and/or $\beta_G = 0$, the states 0 and/or G are absorbing states that respectively correspond to the extinction and fixation of the mutation.

A continuous-time diffusion limit of the W-F model can be obtained, by rescaling time as $t = k/G$, and taking $G \to \infty$. The Markov chain $Y^G(\lfloor Gt \rfloor)/G$ converges to a diffusion process on $[0,1]$ (see Ethier and Kurtz, 1986; Sawyer and Hartl, 1992) which obeys the one-dimensional stochastic differential equation

$$dX(t) = \gamma(X(t))dt + \sigma(X(t))dB(t),$$

where

$$\gamma(x) = \frac{1}{2}[\mu(1-x) - \beta x], \tag{2}$$
$$\sigma(x) = \sqrt{x(1-x)}, \tag{3}$$

with some initial state $X(0) = x_0$, over the time interval $t \in [0, T]$, with rescaled parameters $\mu = \lim_{G\to\infty} 2G\mu_G$, $\beta = \lim_{G\to\infty} 2G\beta_G$, and with $B(t)$ denoting a standard Brownian motion. The terms $\gamma(x)$ and $\sigma(x)$ are respectively referred to as the drift term and the diffusion term. Denote the diffusion process as $X \sim \text{W-F}(\mu, \beta)$.

When $x(t) \to 0$ (respectively $x(t) \to 1$), then the diffusion term tends to 0 while the drift term tends to $\frac{\mu}{2}$ (respectively $-\frac{\beta}{2}$), preventing absorption at 0 or 1 provided that $\mu > 0$ (respectively $\beta > 0$). Otherwise, 0 is an absorbing extinction state (respectively, 1 is an absorbing fixation state). Moreover, if both $\mu, \beta > 0$ then the diffusion is ergodic and has a stationary distribution that is a Beta(μ, β).

As there exists no closed form expression for its transition function, simulating from the W-F diffusion requires non-trivial computational techniques. The method we used is outlined in Dangerfield et al. (2012), a stochastic Taylor scheme tailored to the W-F diffusion. A novel alternative approach that allows for exact simulation has very recently been proposed by Jenkins and Spanò (2017). Finally, note that simulating from the W-F diffusion implies doing so for a given diffusion time unit Δt. While in population genetics diffusion time is related to the population size, in different applications it can be used to regulate the degree of sample path variance, which is linear in time and equal to $\mathrm{Var}(x(1-x)\Delta t)$.

2.3 The Poisson random field

The W-F model describes the evolution of a gene at one particular site. The PRF generalizes it to modeling an infinite collection of sites, each of which evolves independently according to the W-F model. As before, we start with a model with a population of finite size G, before taking the diffusion limit as $G \to \infty$. For a site i at which some individuals carry the mutant gene, denote by $X_i(k)$ the fraction of mutants in generation k. Each site evolves independently according to the W-F$^G(0,0)$ model. Further suppose that at each generation k a number of mutations $M \sim \mathrm{Poisson}(\nu_G)$ arise in new sites with indices $j_1, j_2, \ldots j_M$. ν_G is referred to as the immigration parameter of the PRF. Assume that each of the new mutations occurs at a new site in a single individual, with initial frequency $X_{j_m}(k) = 1/G$. Subsequently, each new process $X_{j_m}(k+1), X_{j_m}(k+2), \ldots$ evolves independently according to the W-F$^G(0,0)$ model as well (Figure 1). As with pre-existing mutant sites, each process eventually hits one of the boundaries $\{0,1\}$ and stays there (we say that the mutation is extinct/has been fixed).

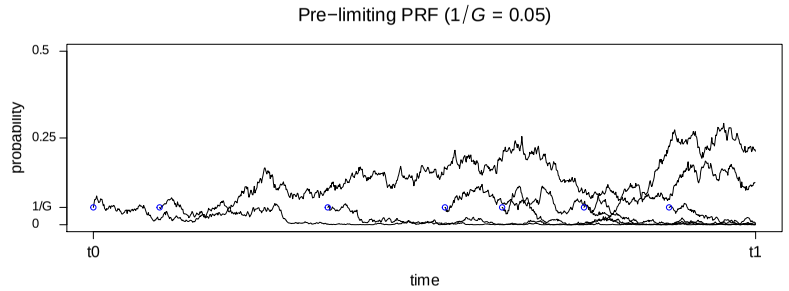

Figure 1: Evolution of mutant sites over time in the pre-limiting PRF model. The blue circles indicate mutations arising at a new site.

Consider the limit $G \to \infty$, so that after the same rescaling $t = k/G$ of time as in Section 2.2 each site evolves as an independent W-F diffusion $X_i \sim \text{W-F}(0,0)$. We also assume that $\nu_G \to \alpha$ as $G \to \infty$. This means that in the diffusion time scale the immigration rate is $G\nu_G \to \infty$, which suggests that the number of sites with mutant genes should explode. However, the initial frequency of each diffusion is $1/G \to 0$ as $G \to \infty$, and moreover 0 is an absorbing state. It can be shown (Sawyer and Hartl, 1992; Amei and Sawyer, 2010) that only

$O(G^{-1})$ of the newborn processes are not almost immediately absorbed. Therefore, there is a balance between the infinite number of newborn mutations and the infinite number of them going extinct in the first few generations, in such a way that the net immigration rate is $O(G\nu_G \times G^{-1}) = O(\alpha)$, and hence the limiting stationary measure is nontrivial. Provided that we remove from the model all sites whose frequency hits either the boundary 1 or 0, Sawyer and Hartl (1992) prove that the limiting distribution of the fractions of mutants in the interval $[0,1]$ is a Poisson random field with mean density

$$\alpha x^{-1} dx. \tag{4}$$

Interestingly, the rate measure of the PRF coincides with the distribution of weights in the one-parameter beta process given in Equation (1). This means that at equilibrium the number of sites whose frequencies $X_i(t)$ are in any given interval $(a,b]$ is Poisson distributed with rate $\alpha \int_a^b x^{-1} dx$, and these are independent for nonoverlapping intervals. Integrating (4) over $[0,1]$ shows that the number of mutations in the population that has not been fixed or gone extinct is infinite. However, most mutations are present in a very small proportion of the population.

3. Time-Varying Feature Allocation Model

The derivation of the PRF in the previous section shows that, as long as sites reaching frequency 1 or 0 are removed from the model, the equilibrium distribution of the PRF is related to the one-parameter beta process. In this section we generalize the PRF so that it is better adapted to applications in feature allocation modeling. Specifically, we identify mutant sites with features, and identify the proportion of the population having the mutant gene with the probability of the feature occurring in a data observation. The PRF can be then used in a time-varying feature allocation model whereby features arise at some unknown time point, change their probability smoothly according to a W-F diffusion process and eventually die when their probability reaches zero.

3.1 The WF-IBP

Recall from the previous section that mutant sites whose frequency hits 1 are removed from the PRF model. This means that features with high probability of occurrence can be removed from the model instantaneously, which does not make modeling sense. Instead, one expects a feature probability to change smoothly and to be removed from the model only once its probability of occurrence is *small*. A simple solution to this conundrum is to prevent 1 from being an absorbing state by using instead a W-F$(0,\beta)$ diffusion with $\beta > 0$. This is a departure from Sawyer and Hartl (1992), due to the differing modeling requirements of genetics versus feature allocation modeling. At the same time, both models let features disappear once their probability gets to 0, which is suitable from a feature allocation perspective and, as we now see, allows for a nontrival equilibrium mean density.

We shall denote the modified stochastic process as PRF(α,β). The following theorem derives the equilibrium mean density of PRF(α,β), with proof given in Appendix A:

Theorem 1 *The equilibrium mean density of the* PRF(α,β) *is*

$$l(x) = \alpha x^{-1}(1-x)^{\beta-1} dx. \tag{5}$$

In other words, the mean density of the PRF(α, β) is the Lévy measure of the two-parameter beta process, with the immigration rate α identified with the mass parameter, and β identified with the concentration parameter of the beta process. When $\beta = 1$ the one-parameter beta process is recovered. We assume that the initial distribution of PRF(α, β) is its equilibrium distribution, that is, a Poisson random field with mean density (5), so that the marginal distribution of the PRF at any point in time is the same.

We will now make the connection more precise by specifying how a PRF can be used in a time-varying feature allocation model. Denote by $X_k(t)$ the probability of feature k being active at time t and define our PRF as the stochastic process $X := \{X_k(t)\}$. Assume that at a finite number of time points $t = t_0, \ldots, t_T$ there are N_t objects whose observable properties depend on a potentially infinite number of latent features. Let D_{it} be the observation associated with object $i = 1, \ldots, N_t$ at time $t = t_0, \ldots, t_T$. Consider a set of random feature allocation matrices Z_t such that entry Z_{ikt} is equal to 1 if object i at time t possesses feature k, and 0 otherwise. Let $Z := \{Z_{ikt}\}$. Finally, let ρ_k be some latent parameters of feature k and $\rho = \{\rho_k\}$ be the set of all feature parameters. Our complete WF-IBP model is given as follows.

$$\begin{aligned} X &\sim \text{PRF}(\alpha, \beta), \\ Z_{ikt} \mid X &\overset{ind}{\sim} \text{Bernoulli}(X_k(t)), \\ \rho_k &\overset{iid}{\sim} H, \\ D_{it} \mid \rho, Z_{it} &\overset{ind}{\sim} F(\{\rho_k : Z_{ikt} = 1\}), \end{aligned} \tag{6}$$

where $i = 1, \ldots, N_t$, $t = t_0, \ldots, t_T$ and $k = 1, 2, \ldots, H$ is the prior distribution for feature parameters, and where $F(\rho)$ is the observation model for an object with a set of features with parameters ρ.

Since the feature probabilities X have marginal density (5), at each time t the feature allocation matrix Z_t has marginal distribution given by the two-parameter Indian buffet process (Thibaux and Jordan, 2007). Further, since X varies over time, the complete model is a time-varying Indian buffet process feature allocation model. The corresponding De Finetti measure would then be a time-varying beta process. More precisely, this is the measure-valued stochastic process $G = \{G(t)\}$ where

$$G(t) = \sum_{k=1}^{\infty} X_k(t) \delta_{\rho_k},$$

which has marginal distribution given by a beta process with parameters α, β and base distribution H. We denote the distribution of G as WFBP(α, β, H). We can also express the feature allocations using random measures as well. In particular, let

$$B_{it} = \sum_{k=1}^{\infty} Z_{ikt} \delta_{\rho_k}$$

be a Bernoulli process BeP$(G(t))$ with mean measure given by the beta process $G(t)$ at time t. An equivalent way to express our model (6) using the introduced random measures

is then

$$\begin{aligned} G &\sim \text{WFBP}(\alpha, \beta, H), \\ B_{it} \mid G &\sim \text{BeP}(G(t)), \\ D_{it} \mid B_{it} &\sim F(B_{it}), \end{aligned}$$

where WFBP denotes our time-varying beta process, and we have used $F(B)$ to denote the same observation model as before, but with B being a random measure with an atom for each feature, and whose location is the corresponding feature parameter. In the following, we use the notation introduced in (6) instead of in terms of beta and Bernoulli processes for simplicity.

As in the two-parameter IBP, α and β separately control the distribution of the number of features per object and the total number of features. In addition, the discrete time points $t_0, \ldots, t_T$ at which the observations are given influence the number of time units for which the W-F diffusions should be simulated. This introduces a parameter that regulates the strength of the time-dependency or accounts for gaps of varying sizes between successive observations. The time parameter can also be chosen according to the expected life time of features (see Chapter 15 of Karlin and Taylor, 1981). A detailed description of how to simulate from the model is given in Appendix B.

3.2 Related models

The WF-IBP fits a line of research that aims at introducing dependency structures into the IBP. A number of these extensions are designed to drop the exchangeability assumption from the IBP by coupling the rows and columns of the feature allocation matrix, and are thus orthogonal to our work (see Zhou et al., 2011; Miller et al., 2012; Gershman et al., 2015). What we are rather interested in achieving is partial exchangeabilty, whereby objects can be permuted independently at each time point without changing the probability of the process. This is necessary for time-dependent topic models where each time has a different set of documents and there is no correspondence between documents at different times.

One example that is more closely related to our model is the dependent Indian buffet process (dIBP) (Williamson et al., 2010a), which can also be applied to the partially exchangeable case. The dIBP uses a hierarchical Gaussian process to introduce couplings between features and items in such a way that, for an appropriate choice of the kernel, items can be permuted independently at each time. Although both the dIBP and the WF-IBP try to achieve the same goal, their methodologies are substantially different: while the former introduces dependencies at the feature-matrix level, the latter does so at the beta-process level. The construction of a dependent beta process represents a significantly different research direction, and is indeed anticipated as future work in Williamson et al. (2010a). First, an important consequence is that the WF-IBP prior describes the evolution of feature probabilities explicitly, whereas the dIBP fixes them and effectively describes a time-evolving Bernoulli process. The WF-IBP is then preferable in all settings where one is interested in a direct interpretation of the evolution of features. Second, the dIBP suffers from a less flexible boundary behaviour as it does not allow features to be born and die over time. Third, the dIBP is based on the stick-breaking construction of the IBP, which is only available for the one-parameter IBP; instead, our approach extends the two-parameter

IBP and models the dimensionality of the feature allocation matrix and its sparsity independently.

4. Fixed-K approximation

In order to give more intuition on the exact inference with the WF-IBP that is developed in Section 5, we first describe a finite-dimensional approximation where the number of features is a finite number K, and show that this marginally converges to the WF-IBP as $K \to \infty$.

Assume that the random feature allocation matrix Z_t has a fixed number of features, say K. First, let $\alpha, \beta > 0$ and consider the beta-binomial model

$$Z_{ikt} \mid \{X_k(t) = x_k(t)\} \overset{iid}{\sim} \text{Bernoulli}(x_k(t)),$$
$$X_k(t) \overset{iid}{\sim} \text{Beta}\left(\frac{\alpha\beta}{K}, \beta\right),$$

$\forall k = 1, \dots, K, \forall i = 1, \dots, N_t$. This coincides with the pre-limiting model of the two-parameter IBP presented in Ghahramani et al. (2007). Then, for each feature, think of the $\text{Beta}\left(\frac{\alpha\beta}{K}, \beta\right)$ distribution as the stationary distribution of a W-F diffusion with parameters $\frac{\alpha\beta}{K} > 0$ and $\beta > 0$. This suggests making the model time-dependent by letting each feature evolve, starting at stationarity, as an independent W-F diffusion with these parameters. Generate for all times $t = t_0, \dots, t_T$ the binary variables z_{ikt} as

$$Z_{ikt} \mid \{X_k(t) = x_k(t)\} \overset{iid}{\sim} \text{Bernoulli}(x_k(t)),$$
$$X_k \sim \text{WF}\left(\frac{\alpha\beta}{K}, \beta\right),$$

$\forall k = 1, \dots, K, \forall i = 1, \dots, N_t$. In this way, the closer two time points, the stronger the dependency between the probabilities of a given feature (Figure 2). Moreover, as we assume the W-F diffusion to start at stationarity, this construction coincides marginally with the beta-binomial model. The parameters of the W-F diffusion are positive, so that neither fixation nor absorption ever occurs and the number K of features remains constant.

4.1 Fixed-K MCMC inference

Given a set of observations D, a natural inference problem would be to recover the latent feature allocation matrices $Z = \{Z_t\}_{t=t_0}^{t_T}$ responsible for generating the observed data, the underlying feature probabilities X and their parameters ρ. Inference is straightforward; we propose the following updates.

- $Z \mid X, D, \rho$ via Gibbs sampling.
- $\rho \mid D, Z$ according to the likelihood model.
- $X \mid Z$ via Particle Gibbs.

Consider first the Gibbs sampling step to perform posterior inference over the matrices Z. Denote by $Z_{-(ik)t}$ all the components of the matrix Z_t excluding Z_{ikt}, and by Z_{i-kt} all

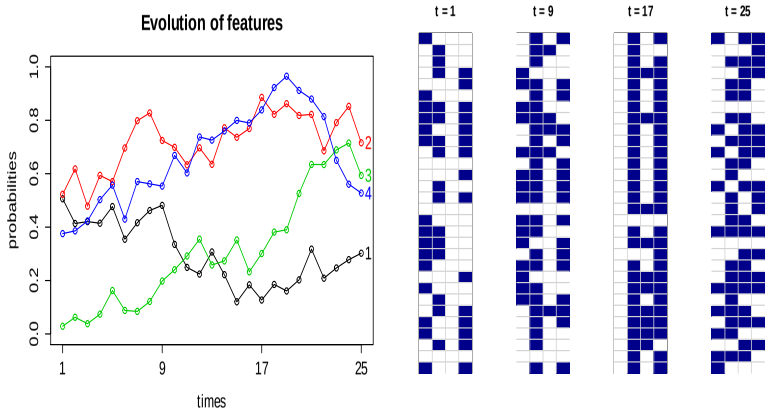

Figure 2: Left: underlying feature probabilities over time. Right: corresponding feature allocation matrices. Rows represent objects and columns features, which can be active (blue) or inactive (white).

the components in row i excluding k. We can easily derive for all t the distribution of a given component Z_{ikt} conditioning on the state of all other components $Z_{-(ik)t}$, on data D_{it}, on the parameters ρ and on the prior probability $X_k(t)$ of feature k. The full conditional probability of the entry Z_{ikt} being active is equal to

$$P(Z_{ikt} = 1 \mid Z_{-(ik)t}, X_k(t), D_{it}, \rho) \propto x_k(t) P(D_{it} \mid Z_{i-kt}, Z_{ikt} = 1, \rho). \tag{7}$$

By the same token, the full conditional probability of the entry Z_{ikt} being inactive is

$$P(Z_{ikt} = 0 \mid Z_{-(ik)t}, X_k(t), D_{it}, \rho) \propto (1 - x_k(t)) P(D_{it} \mid Z_{i-kt}, Z_{ikt} = 0, \rho). \tag{8}$$

As the matrices Z are conditionally independent given the feature probabilities X, equations (7) and (8) can be used to sample the matrices Z independently given the respective feature probabilities at each time. Note that the likelihood $P(D_{it} \mid Z_t, \rho)$ needs to be specified according to the problem at hand. A typical choice, detailed in Section 6, is the linear-Gaussian likelihood model, whose parameters can easily be integrated out (Griffiths and Ghahramani, 2011). The update $\rho \mid D, Z$ over the feature parameters is also specific to the likelihood model and, as we will illustrate, can easily be derived in conjugate models such as the linear-Gaussian one.

Consider now the Particle Gibbs (PG) step (Andrieu et al., 2010) to perform Bayesian inference on the feature trajectories continuously over the interval $[t_0, t_T]$. As the prior probability of each feature is a Beta $\left(\frac{\alpha\beta}{K}, \beta\right)$ and the column-wise sums of Z_{t_0} are realizations from binomial distributions, by conjugacy we have

$$X_k(t_0) \mid \{Z_{t_0} = z_{t_0}\} \sim \text{Beta}\left(\frac{\alpha\beta}{K} + n_{kt_0}, \beta + N_{t_0} - n_{kt_0}\right),$$

where $k = 1, \ldots, K$, and $n_{kt} := \sum_{i=1}^{N_t} z_{ikt}$ denotes the number of objects in matrix Z_t possessing feature k. This posterior distribution can be therefore used to draw the whole set of features at time t_0 and the trajectories in the interval $[t_0, t_T]$ can be obtained via PG.

More precisely, start with an initial reference trajectory $x^{r,k}_{t_0:t_T} := (x^{r,k}_{t_0}, \ldots, x^{r,k}_{t_T})$ for $k = 1, \ldots, K$ and, independently for each feature, iterate the following procedure. Draw a given number of particles from the posterior beta distribution at time t_0 and propagate them forward to time t_1 according to $\mathrm{WF}(\frac{\alpha\beta}{K}, \beta)$. At time t_1, assign each of these particles and the reference feature a weight given by the binomial likelihood of seeing that feature active in $n(t)$ objects out of $N(t)$ in $Z(t)$, i.e., $x_k(t)^{n_{kt}}(1 - x_k(t))^{N_t - n_{kt}}$. Sample the weighted particles with replacement and propagate the off-springs forward. This corresponds to using a bootstrap filter with multinomial resampling, but other choices to improve on the performance of the sampler can be made (see Andrieu et al., 2010). Repeat this procedure up to time t_T and sample only one particle at that time. Reject all the others and keep the trajectory that led to the sampled particle as the reference trajectory for the next iteration. Notice that the reference feature is kept intact throughout each iteration of the algorithm.

This procedure is illustrated more precisely by Algorithm 1, which needs to be iterated independently for each feature to provide posterior samples from their trajectories. To simplify the notation, we drop the index k and write $x^i_t | x^i_{t_0} \sim \mathrm{WF}(\frac{\alpha\beta}{K}, \beta)$ for $t \in [t_0, t_1]$ to denote the following: simulate from a W-F diffusion with initial value $x(t_0)$ and set $X(t_1) = x(t_1)$, the value of the diffusion at time t_1.

4.2 Approximation for large K

As already noted, the marginal distribution with the fixed-K approximation corresponds to the beta-binomial model, which is the pre-limiting model of the two-parameter IBP. As a consequence, at any fixed time t and as $K \to \infty$, the fixed-K approximation converges to the two-parameter generalization of the IBP, which in turns coincides with the marginal distribution of the WF-IBP. An aspect of interest is then whether the whole dynamics of the fixed-K approximation can be used as a finite approximation of the infinite model in such a way that, the larger K, the better the approximation. Two caveats need to be noted. First, only in the infinite model can features be born. For large K, however, the number of particles in the fixed-K approximation whose mass is close to zero becomes so large that, with a sufficient amount of time, some of them gain enough mass to become 'visible'. The behavior of these particles resembles the behavior of the newborn features of the infinite model. Second, as the fixed-K approximation has an upwards drift equal to $\alpha\beta/K$, only the infinite model allows for features to be absorbed at 0. This discrepancy is however overcome by the fact that, when K goes to infinity, 0 behaves like an absorbing boundary, in that features get trapped at probabilities close to 0. For these reasons, a comparison of the two models requires relabeling the particles in the finite model in such a way that, whenever a particle goes below a certain threshold $\epsilon \approx 0$, it is considered to have gone extinct, while if its probability is below ϵ and later exceeds ϵ the particle is labeled as newborn. We choose this threshold to be $\epsilon = 1/K$, as then $\lim_{K\to\infty} \epsilon = 0$.

Taking these caveats into account, we performed an empirical comparison of the fixed-K approximation with the infinite model. Consider the joint distribution at two given time points $t_0 = 0$ and $t_1 = 1$ of the feature probabilities, first in the fixed-K and then in the

Algorithm 1: Particle Gibbs

Input: Reference trajectory $x^r_{t_0:t_T}$; M.
Set $x^M_{t_0} = x^r_{t_0}$;
Draw $x^i_{t_0} \sim \mathrm{Beta}(\frac{\alpha\beta}{K} + n_{t_0},\ \beta + N_{t_0} - n_{t_0})$ for $i = 1, \ldots, M-1$;
Simulate $x^i_t | x^i_{t_0} \sim \mathrm{WF}(\frac{\alpha\beta}{K}, \beta)$ for $t \in [t_0, t_1]$ for $i = 1, \ldots, M-1$;
Set $x^M_{t_1} = x^r_{t_1}$;
Compute $w^i_{t_1} = (x^i_{t_1})^{n_{t_1}}(1 - x^i_{t_1})^{N_{t_1} - n_{t_1}}$ for $i = 1, \ldots, M$;
Sample $\bar{x}^i_{t_1}$ with $P(\bar{x}^i_{t_1} = x^i_{t_1}) \propto w^i_{t_1}$ for $i = 1, \ldots, M-1$;
Set $\bar{x}^M_{t_1} = x^r_{t_1}$;
Simulate $x^i_t | x^i_{t_1} \sim \mathrm{WF}(\frac{\alpha\beta}{K}, \beta)$ for $t \in [t_1, t_2]$ for $i = 1, \ldots, M-1$;
Set $j \leftarrow 2$;
while $t_j < t_T$ **do**
  Set $x^M_{t_j} = x^r_{t_j}$;
  Compute $w^i_{t_j} = (x^i_{t_j})^{n_{t_j}}(1 - x^i_{t_j})^{N_{t_j} - n_{t_j}} w^i_{t_{j-1}}$ for $i = 1, \ldots, M$;
  Sample $\bar{x}^i_{t_j}$ with $P(\bar{x}^i_{t_j} = x^i_{t_j}) \propto w^i_{t_j}$ for $i = 1, \ldots, M-1$;
  Set $\bar{x}^M_{t_j} = x^r_{t_j}$;
  Simulate $x^i_t | \bar{x}^i_{t_j} \sim \mathrm{WF}(\frac{\alpha\beta}{K}, \beta)$ for $t \in [t_j, t_{j+1}]$ for $i = 1, \ldots, M-1$;
  Set $j \leftarrow j + 1$;
end
Compute $w^i_{t_T} = (x^i_{t_T})^{n_{t_T}}(1 - x^i_{t_T})^{N_{t_T} - n_{t_T}} w^i_{t_{T-1}}$ for $i = 1, \ldots, M$;
Sample r_{new} with $P(r_{new} = i) \propto w^i_{t_T}$, where $i = 1, \ldots, M$;
Output: New reference trajectory $x^{r_{new}}_{t_0:t_T}$.

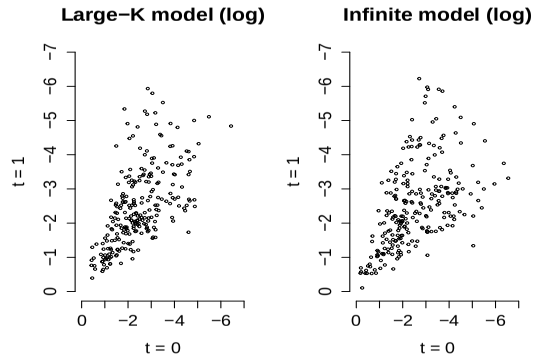

Figure 3: Scatterplot of the log feature probabilities greater than $1/K$ at time $t_0 = 0$ and at time $t_1 = 1$ to compare the fixed-K ($K = 1000$) and infinite model.

infinite model. Separately for each model, we took 1000 samples of the feature probabilities at time 0 and at time 1, excluding the ones below $1/K$. Figure 3 shows the logarithm of these values for the two models, suggesting a remarkable similarity between the two underlying joint distributions. The validity of this comparison is supported by the maximum mean discrepancy (mmd) test (Gretton et al., 2006), which does not reject the null hypothesis of the two joint distributions being the same. Although this suggests a strong similarity between the dynamics of the fixed-K approximation and the infinite model, we leave a proof of the convergence of these joint distributions as $K \to \infty$ for future work.

5. Exact MCMC inference

Building on the fixed-K approximation, we now develop a sophisticated MCMC algorithm for exact inference with the WF-IBP. The first point to notice is that, while in the fixed-K approximation the total number of features is constant over time and equal to K, in the WF-IBP model this is not a finite number. In order to use the WF-IBP for inference it is necessary to augment the state space with the features that are not seen in the feature allocation matrices, but simulating the dynamics of the PRF would require generating an infinite number of features, which is clearly unfeasible. One way to deal with this could be to resort to some sort of truncation, considering only features whose probability is greater than a given threshold and are likely to be seen in the data. We rather choose this truncation level adaptively by introducing a collection of slice variables $\{S_t\}_{t=1}^{T_t}$ and adopting conditional slice sampling (Walker, 2007; Teh et al., 2007). This scheme, which is detailed in Section 5.1, has the advantage of making inference tractable without introducing approximations.

Partition the set of features into two subsets, one containing the features that have been seen at least once among times $t = t_0, \dots, t_T$, and the other containing the features that have never been seen for all $t = t_0, \dots, t_T$, so that $X = X_{\text{seen}} \cup X_{\text{unseen}}$. Since the unseen

features cannot be identified individually based on the matrices Z, and as all features are conditionally independent given Z, we consider seen and unseen features separately. As for the seen features, we use the same Particle Gibbs scheme as in the fixed-K approximation. As for the unseen features, we simulate them via a thinning scheme. The exact MCMC inference scheme can be then summarized by the following updates.

- $Z \mid X, S, D, \rho$ via Gibbs sampling.
- $S \mid Z, X$ via slice sampling.
- $\rho \mid D, Z$ according to the likelihood model.
- $X_{\text{seen}} \mid Z$ via Particle Gibbs.
- $X_{\text{unseen}} \mid S$ via thinning.

We present each of these steps in Sections 5.1 and 5.2, which build on the simpler inference scheme developed in Section 4.

5.1 Gibbs and slice sampling
